Heparin administration should be started as soon as the diagnosis of ALI is entertained. Numerous studies have shown that this measure decreases the morbidity and mortality associated with ALI and increases the limb salvage rate. Heparin impedes the propagation of clots and, in the instance of embolism, may help prevent additional events.

Heparin acts at multiple sites in the normal coagulation system, inhibiting reactions that lead to the clotting of blood and the formation of fibrin clots both *in vitro* and *in vivo*. Small amounts of heparin, in combination with antithrombin (heparin cofactor), can inhibit thrombosis by inactivating activated factor X and inhibiting the conversion of prothrombin to thrombin.¹² Once active thrombosis has developed, larger amounts of heparin can inhibit further coagulation by inactivating thrombin and preventing the conversion of fibrinogen to fibrin. Heparin also prevents the formation of a stable fibrin clot by inhibiting the activation of fibrin-stabilizing factor.¹²⁻¹⁴

Heparin does not have fibrinolytic activity and therefore does not lyse existing clots. Heparin therapy can be complicated by thrombocytopenia, which has a reported incidence of 0% to 30%.¹⁵ If the thrombocyte count falls below 100,000/mm³ or if recurrent thrombosis develops, heparin should be discontinued.^{16,17} Patients receiving heparin may experience new thrombus formation, either early or late, in association with this thrombocytopenic phenomenon as a consequence of irreversible heparin-induced platelet aggregation (the so-called white clot syndrome). This process may lead to severe thromboembolic complications, including skin necrosis, gangrene of the extremities, MI, pulmonary embolism, stroke, and, possibly, death.^{16,18,19} Accordingly, if new thrombosis develops in association with thrombocytopenia, heparin should be promptly discontinued.

Periodic platelet counts, hematocrits, and tests for fecal occult blood are recommended during the entire course of heparin therapy, regardless of the route of administration.

Bleeding time is usually unaffected by heparin. Clotting time is prolonged by full therapeutic doses of heparin, but in most cases, it is not measurably affected by low doses.

Thrombolysis

The use of thrombolysis to treat chronic and acute arterial insufficiency dates back to the 1970s, when it was popularized by Dotter.²⁰ Systemic fibrinolytic therapy has not proved effective and consequently has been supplanted by intra-arterial (catheter-directed) thrombolysis, which yields significantly better results. Still, the role of thrombolytic therapy for ALI is somewhat controversial. In addition, such therapy requires a skilled team with considerable clinical expertise, typically including a vascular surgeon, an interventional radiologist, and a well-trained ancillary staff. The benefits of pharmacologic clot lysis must always be weighed against those of surgical intervention and the risk of bleeding associated with fibrinolysis.

Despite the use of fibrin-specific agents and catheter-directed infusion, thrombolytic agents still exert systemic effects, most of which are dose related. About 10% of patients receiving throm-

bolytic therapy experience significant bleeding, including bleeding from both puncture and remote sites. Absolute contraindications to the use of lytic agents include recent surgery, recent stroke or brain tumor, pregnancy, a bleeding diathesis, recent trauma, and active bleeding [see Table 4].

Thrombolysis versus surgical treatment Three prospective, randomized trials—the University of Rochester trial,²¹ the Surgery versus Thrombolysis for Ischemia of the Lower Extremity (STILE) trial,²² and Thrombolysis Or Peripheral Arterial Surgery (TOPAS) trial^{23,24}—addressed the differences between thrombolytic therapy and traditional surgery.

Rochester trial. This randomized, controlled single-center trial compared urokinase (UK) with surgery in patients with ischemia of less than 7 days' duration.²¹ At the end of 1 year, overall mortality was lower in the thrombolysis group (25%) than in the surgery group (48%). The amputation rates were similar in the two groups. Total hospital charges were comparable as well, which suggests that at initial treatment, thrombolytic therapy is as costly as surgery. Major bleeding was encountered in 11% of patients.

STILE trial. This randomized, controlled multicenter trial compared surgery with recombinant tissue plasminogen activator (rt-PA) and with UK.²² It was stopped early because of an increase in the number of patients with ongoing ischemia in the thrombolysis groups. An ad hoc committee later determined that the reason for this increase was the inclusion of chronically symptomatic patients in the study. In any case, the study clearly demonstrated that patients with less than 14 days of ischemia had a lower amputation rate when treated with thrombolysis (11% versus 30%; $P = 0.02$) but that patients with more than 14 days of ischemia had a lower amputation rate when treated with surgery.

TOPAS trial. This randomized, controlled multicenter trial compared surgery with recombinant urokinase (r-UK) thrombolysis in patients with ischemic symptoms of less than 14 days' duration.^{23,24} At the end of 1 year, the amputation rates in the two groups were similar. Bleeding complications were seen only in patients undergoing thrombolysis, four of whom had intracranial

Table 4 Contraindications to Thrombolytic Therapy⁹⁸

Absolute contraindications

- Established cerebrovascular event (including TIAs) within past 2 mo
- Active bleeding diathesis
- GI bleeding within past 10 days
- Neurosurgery (intracranial, spinal) within past 3 mo
- Intracranial trauma within past 3 mo

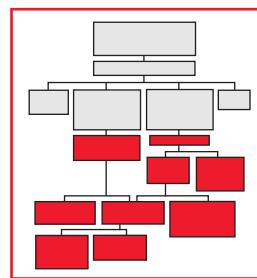

Major relative contraindications

- Cardiopulmonary resuscitation within past 10 days
- Major nonvascular surgery or trauma within past 10 days
- Uncontrolled hypertension: systolic BP > 180 mm Hg, diastolic BP > 110 mm Hg
- Puncture of noncompressible vessel
- Intracranial tumor
- Recent eye surgery

Minor relative contraindications

- Hepatic failure, particularly in patients with coagulopathy
- Bacterial endocarditis
- Pregnancy
- Diabetic hemorrhagic retinopathy

TIA—transient ischemic attack

hemorrhage. When additional end points were considered, the thrombolysis group was found to require significantly fewer major interventions at the time of discharge and at 12 months.

A prospective, randomized multicenter trial evaluated local thrombolysis with either rt-PA or urokinase in 234 patients with thrombotic occlusions (223 native femoral or popliteal arteries, 11 bypass grafts).²⁵ Complete reperfusion occurred in 62% of the patients treated with rt-PA and in 50% of the patients treated with urokinase ($P = 0.18$). However, bleeding was observed in 12.8% of rt-PA-treated patients (including one instance of cerebral hemorrhage) and in 9.1% of UK-treated patients (none of whom experienced cerebral bleeding).

Current data suggest, but do not prove, that thromolytic therapy is effective as initial therapy for patients with acute arterial and graft occlusions and no sensorimotor deficits. Such an approach, however, is not suitable for patients with common femoral artery emboli, which should be treated surgically, and there are certain patients with sensorimotor deficits (e.g., those without any runoff) for whom the potential benefits of thrombolysis outweigh the risks of delay.

At present, acute thrombotic arterial occlusion in an occluded bypass graft is the area where intra-arterial fibrinolysis may be most useful, permitting better planning of the subsequent operation and resulting in a less extensive procedure. Such therapy, however, does not necessarily yield improvements in major long-term end points. It is important to remember that thrombosis of femoropopliteal or similar bypasses is related to early or late surgical stenosis and atherosclerosis and that restoring flow usually does not suffice to ensure continued patency.

Logistics of thrombolysis In patients with mild or no sensory deficits, angiography is performed first. Depending on the location of the obstruction, the type of clot present, and the level of patient risk, the patient may be offered thrombolysis as initial therapy.

In our practice, the patient is taken from the emergency department to the angiography suite. Informed consent is obtained for diagnostic and therapeutic angiography, including the use of stents, balloon angioplasty, stent grafts and thrombolysis, and finally the requirement for an emergency surgical procedure. A discussion is undertaken with the patient to outline the course of treatment and to explain that indwelling catheters may have to be placed and that a stay in the ICU may be required.

Access to the arterial system is gained via a single-wall puncture technique; the risk of posterior-wall bleeding associated with a double-wall technique is thereby avoided. Access should be obtained from a site as remote from the intervention site as possible. Generally, this is accomplished by starting from the contralateral counterpart of the target artery and going up and over the aortic bifurcation, then back to the ipsilateral artery. By removing the puncture site from the site of catheter-directed thrombolysis, the incidence of bleeding and formation of hematomas or pseudoaneurysms is reduced.

After completion of the angiogram and delineation of the pathology, a guide wire is passed into the occluded area. We use a 0.035 in. hydrophilic guide wire, which has a slippery, wet coating that enables it to cross nonhydrophilic lesions. Once in place, the wire is guided through the clot. A multiple-sidehole catheter is placed through the clot, and a hand-injection angiogram is performed to confirm that the catheter tip is in the true lumen. The guide wire is then left within the catheter to occlude the tip, so that the lytic agent is infused through the sideholes preferentially. This graded "coaxial" infusion technique allows the agent to reach the greatest possible surface area, maximizes the length of infusion, and enables the surgeon to treat some of the longest bypass grafts.

In many cases, mechanical thrombus removal, with or without pulse spray, is employed initially, followed by continuous infusion of a thrombolytic agent. In addition to lytic therapy, administration of heparin is started (200 to 400 units I.V. or via sheath) to prevent pericatheter thrombosis. Serial laboratory evaluation is carried out to verify that the patient is not bleeding and that the fibrinogen level is higher than 100 mg/dl. Serial follow-up arteriograms are performed to monitor progress. It is critically important that successful thrombolysis be followed by treatment, whether endovascular or open, of any lesions uncovered during thrombolysis; if it is not, reocclusion is inevitable. At the conclusion of thrombolysis and before intervention, the patient must be kept on a heparin drip to prevent the formation of a new thrombus. The rate of successful reperfusion is approximately 90% to 95% in most studies.

An important advantage of this selective approach is that it allows simultaneous angiographic definition of the nature of the occlusion (i.e., embolic versus thrombotic) and of any vessel wall abnormalities that would lead to rethrombosis if not corrected by surgery or balloon angioplasty. A major drawback to this approach is that arterial catheterization is required for prolonged periods (20 hours, on average), leading to major bleeding and thromboembolic complications in 6% to 20% of patients. Therefore, the end points of thromolytic therapy are (1) resolution and reconstitution of flow through the obstruction, (2) absence of change in the occlusion of the vessel on angiography, and (3) bleeding complications. If it is determined that thrombolysis is not progressing, it should be abandoned and surgical intervention undertaken.

Thrombectomy

Percutaneous aspiration thrombectomy This technique uses a large, thin-walled catheter and a large syringe to remove an embolus or thrombus from a vascular conduit, whether native vessel or graft. The catheter is placed as previously described [see Logistics of Thrombolysis, above] and is parked immediately by the clot. Aspiration of the clot with the syringe is then attempted. If the clot is new, success is likely, but an old clot that is organized will not be as amenable to removal. Percutaneous aspiration thrombectomy is most effective as an adjunct to catheter-directed thrombolysis.^{26,27}

Percutaneous mechanical thrombectomy Percutaneous mechanical thrombectomy (PMT) functions on the basis of a hydrodynamic circulation. The basic concept is that a hydrodynamic vortex is created around the tip of the PMT catheter. Thrombectomy is accomplished with the introduction of a pressurized saline jet stream through the directed orifices in the distal tip of the catheter. The jets generate a localized low-pressure zone via the Bernoulli effect, which entrains and macerates thrombus. The saline and the fragmented thrombus are then sucked back into the exhaust lumen of the catheter and out of the body for disposal.

This technique has proved beneficial when used in appropriate settings and properly selected patients. Its efficiency relies on the age of the clot. Fresh thrombus is readily treated with PMT, but older clots are much less amenable to this technique and may have to be treated with an adjunctive catheter-based modality (e.g., angioplasty, intra-arterial thrombolysis, or atherectomy).²⁸⁻³¹

Surgical Embolectomy and Revascularization

When a patient has significant sensory and motor deficits related to a profoundly ischemic limb, immediate surgical revascularization is indicated. The decision whether to accomplish this percutaneously or surgically should be made expeditiously. OR availability should be determined, the method of anesthesia should be chosen, and the technical details of the procedure should be planned [see 6:18

Infrainguinal Arterial Procedures]. Heparin administration should be started before the patient enters the OR. General anesthesia is the preferred method of anesthesia.

For lower-extremity emboli, access to the femoral vessels should be obtained rapidly. The common, deep, and superficial femoral arteries are controlled proximally and distally with tape, and the common femoral artery is opened transversely. Catheter embolectomy of the superficial femoral, deep femoral, common femoral, and external iliac arteries is then performed. Differently sized embolectomy catheters are used, depending on the size of each artery. In our experience, a No. 3 catheter is usually suitable for the deep femoral artery, a No. 4 for the superficial femoral artery, and a No. 5 for the common femoral and external iliac arteries. The extracted clot is sent for pathologic evaluation. When the clot is believed to be in the distal vessels of the lower extremity, control of the popliteal artery and its trifurcation is obtained via a popliteal incision. A No. 3 catheter should be adequate at this site.

For upper-extremity emboli, a curvilinear incision is made that starts on the medial aspect of the upper arm, extends transversely across the antecubital fossa, and ends halfway down the middle of the lower arm. This incision allows control of the brachial, radial, and ulnar arteries. A No. 3 embolectomy catheter is typically used here.

Several passes are done in each vessel until no more clot can be seen and there is brisk back-bleeding from the vessel. When no further clot can be retrieved, a completion angiogram is done to visualize the distal vessels and elucidate any anatomic pathology in the native vessels. If distal clot is still present after the completion angiogram, intraoperative thrombolysis can be employed for a brief period to soften the clot. The multiple-sidehole catheter is advanced distally to the location of the clot, the guide wire is passed through the lesion, and the catheter is passed over the wire into the substance of the clot. Infusion of the lytic agent is then started.

Repeat angiograms indicate whether the clot has dissolved or is still present. If the clot is still apparent, repeat embolectomy is attempted. If thrombosis rather than embolism is suspected, an underlying lesion must be sought. In performing the embolectomy, attention should be paid to the tactile sensations felt as the balloon is withdrawn. Such sensations give the operator a sense of the disease process. When several deflations are needed and the withdrawal path of the balloon feels rough, a long-standing process (e.g., an atherosclerotic calcified vessel with anatomic discrepancies) is likely.

If there appears to be no residual clot after embolectomy, then a completion angiogram is sufficient and the artery can be closed primarily. Heparin is continued, and the patient is eventually switched to warfarin, which is continued for at least 6 months postoperatively. Finally, the location from which the embolus originated is sought and appropriately treated. When an underlying lesion is identified, a decision must be made as to whether it can be treated with angioplasty or stenting or whether a formal bypass is required to correct the problem and salvage the limb.

Key to the final management of these patients is assessment of the lower extremities, especially the calves, for compartment syndrome. To minimize the chances that an otherwise successful surgical operation may fail as a consequence of this syndrome, we typically perform intraoperative fasciotomies on the extremity if profound ischemia has been present for several hours.

Cost Considerations

A retrospective study published in 1995 compared thrombolysis with surgical thrombectomy as first-line therapy for ALI.³² Only the costs of the initial admission were documented. The average charge for the two treatments ranged from \$20,000 to \$26,000. Economic analysis confirmed that the total economic impact of thrombolysis

approximated that of initial operative therapy. The conclusion of the study was that there was no difference between an endovascular approach and an operative approach with respect to cost. Thus, when acute treatment of ALI is being considered, cost should not be factored into the decision-making process.^{32,33}

Atheroembolism

Atheroembolism is a condition in which microscopic cholesterol-laden debris travels from proximal arteries until it reaches the most distal arterial segments, typically in the skin of the lower extremities and in the end-organs.³⁴⁻³⁷ This debris usually originates from unstable plaque found at inflection points in the arterial tree, especially in the aorta.^{38,39} It may also originate from aneurysmal sacs either in the aorta or in the peripheral arteries.

CLINICAL EVALUATION

Patients with atheroembolism usually present with focal toe ischemia—the so-called blue-toe syndrome—in conjunction with palpable pulses in the distal extremity [see Figure 1]. Acute pain of sudden onset is typically noted in the affected area. This pain can often establish the exact timing of embolization. Cyanosis is present either on the toe or over a more extensive area if the atheroemboli were circulated throughout the extremity.^{40,41} When both lower extremities are involved, an aortic source of the microemboli is commonly found.

A complete vascular examination should be performed and pulses documented. Although a patent arterial tree is the rule, emboli that are sufficiently small may travel through collateral channels. Palpation should be done to detect any aneurysmal disease. A massive proximal atheroembolic event may affect the entire abdominal wall and both extremities, giving the appearance of livedo reticularis. As the source of the atheroemboli ascends in the arterial tree, more vital organs (e.g., the kidneys and the GI tract) may be damaged.

Manipulation of an intra-arterial catheter or clamping or surgical manipulation of the arterial tree can also result in plaque disruption. In these cases, the adverse effects are usually apparent immediately after the procedure.

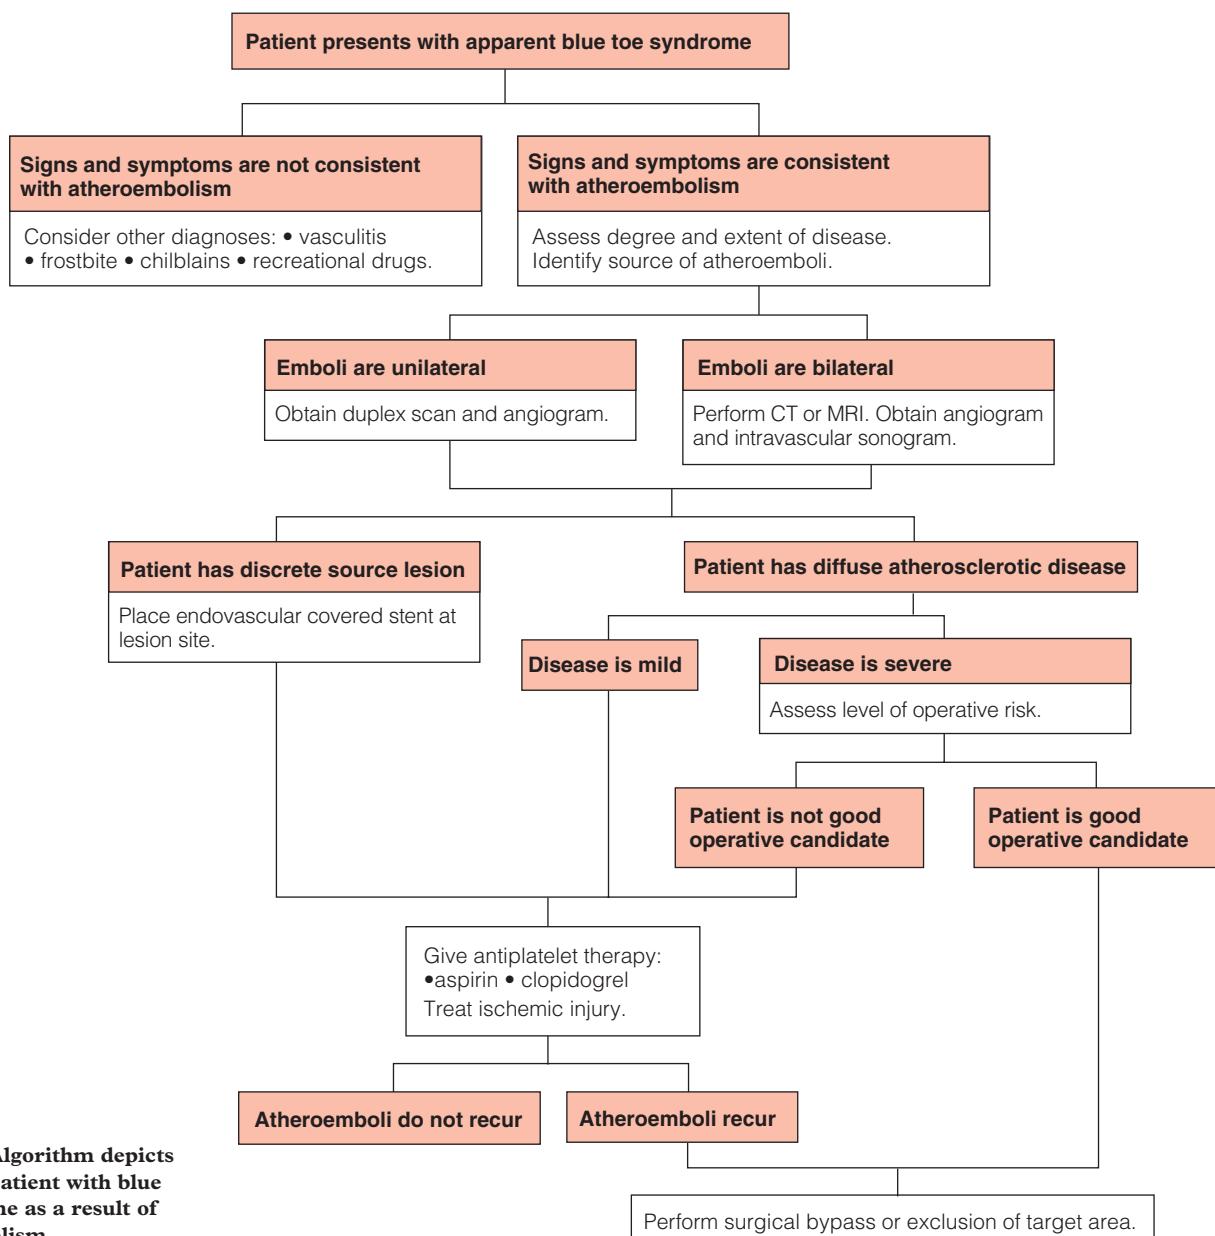

INVESTIGATIVE STUDIES

Doppler examination may visualize unstable ulcerated plaques or aneurysmal disease. Doppler segmental pressures may be used to identify the responsible lesion by localizing a significant drop in pressure and determining where the plaque is. Duplex imaging with noncolor flow can also provide clues to the morphology of a plaque. This is only true, however, in the extremity arteries. When the aorta is the suspected source of the emboli, computed tomography, magnetic resonance imaging, or magnetic resonance angiography is performed; these modalities provide better visualization of intraluminal disease. Arteriography also plays a useful role in identifying intraluminal pathology along the entire vascular tree. In addition, intravascular ultrasonography may be performed with the guide wire in place and may help delineate the extent of the underlying disease.

TREATMENT

If the atheroembolic events are minor and solitary, conservative medical management is recommended. If, however, the emboli are recurrent or massive, a thorough evaluation should be initiated, followed by urgent treatment.

Medical management of atheroembolism consists primarily of antiplatelet therapy. Given that most patients with atheroemboli are already receiving aspirin, addition of clopidogrel or ticlopidine

is appropriate. The optimal agents for preventing recurrence of atheroembolism may prove to be lipid-lowering drugs, particularly statins. At present, direct evidence from randomized trials supporting the use of statins to prevent atheroembolism is lacking, but the hypothesis remains under investigation.

The role of warfarin therapy in treating atheroembolic disease has not been established with certainty. Such therapy may even aggravate the disease process by causing intraplaque hemorrhage and increased embolization. The Warfarin Aspirin Recurrent Stroke Study (WARSS), a randomized multicenter study that included 2,206 patients who had recently experienced an ischemic stroke, found no evidence that warfarin is superior to aspirin for preventing recurrent ischemic stroke or death within 2 years.⁴² Nor was there a significant difference in bleeding risk between warfarin-treated patients and aspirin-treated patients.

For patients with diffuse atherosclerotic disease, the mainstay of therapy is an antiplatelet regimen. Traditionally, an atheroembolic source has been treated by surgical excision or by exclusion of the disease process with a bypass graft, either of which provides a good

degree of safety from further embolization.⁴³ With the advent of endovascular surgery, however, the use of covered stents, placed securely and precisely at the site of the offending lesion, appears to be an increasingly effective and popular option [see Table 5].^{44,45}

Table 5 Surgical Management of Atheroembolism

Source of Emboli	Treatment
Upper extremity	Bypass of subclavian or axillary artery First rib or cervical rib resection
Aorta	Focal disease: covered aortic stent Diffuse disease: aortobifemoral bypass
Iliac artery	Covered iliac stent
Popliteal artery	Ligation and bypass of popliteal artery

Our current approach to treating atheroembolism may be summarized as follows. The source lesion is first identified by means of the modalities already discussed. If embolization is minor, aspirin and clopidogrel are started. If embolization is recurrent or massive, an endovascular approach is attempted, involving the placement of a covered stent over the lesion. This approach is indicated for segments of the arterial tree where there are no collaterals, so that vital blood flow to organs is not hindered. If aneurysmal disease is present, either conventional or

endovascular therapeutic approaches may be applied to exclude any source of emboli. In the case of thoracic aortic disease, covered stents may be placed to push the plaque against the wall and prevent further embolization. If suprarenal plaque cannot be treated with a stented graft, aortic ligation with an axillofemoral bypass may be performed [see 6:12 *Aortoiliac Reconstruction*]. Such treatment does not, however, protect the renal and visceral vessels, and these patients require lifelong strict antiplatelet therapy.

Discussion

Pathophysiology of ALI

The course of ALI usually begins with occlusion of a peripheral artery or bypass graft. It can then develop either slowly, over an extended period, or quickly, over a few hours. A protracted course leading to thrombosis allows collateral vessels to form, and the onset of symptoms is gradual. When occlusion is acute, however, as in embolization or acute thrombosis of a vessel or a bypass graft, signs and symptoms of acute ischemia may become rapidly apparent, including excruciating pain, mottling, cyanosis, and, commonly, sensorimotor changes. Patients typically are seen in an emergency setting within hours after the onset of such symptoms.

With the advent of aggressive surgical management of peripheral vascular disease, more and more patients are being treated with bypass grafts. As a result, graft occlusions now outnumber thromboses of native arteries by a ratio of 1.3 to 1. Thrombotic occlusions outnumber embolic events by a ratio of 6 to 1.

The pathophysiology of limb ischemia is related to the progression of tissue infarction and irreversible cell death. The lower extremity comprises different tissues with different metabolic rates. The extent to which each cell type can tolerate ischemia depends on its metabolic rate. Bone and skin are the most resistant to ischemia, nervous tissue is the least resistant, and muscle is somewhere in between. For muscle and nerve cells, 6 hours is the approximate upper limit of ischemic tolerance; nervous tissue is affected well before this point.⁴⁶ Knowledge of the varying degrees of ischemic tolerance helps in determining the viability of the limb.

HYPOPERFUSION-REPERFUSION STATE

Hypoperfusion leads to ischemic infarcts via various mechanisms. During the hypoperfusion state, three major physiologic events occur. First, movement of blood through the vessels is slowed. As a result, the thrombus is able to grow and propagate, occluding collateral vessels and further decreasing blood flow. Second, ischemic cells swell and accumulate water. The resulting increase in pressure within a fixed space between fascial structures creates a compartment syndrome that further decreases flow and exacerbates the injury. Third, the precapillary arteriolar cells swell, narrowing the lumina of distal arterioles, capillaries, and venules and again reducing blood flow.

The reperfusion state that results when flow is restored can be as detrimental to the ischemic extremity as the hypoperfusion state was. During reperfusion, highly active oxygen metabolites are produced by neutrophils.⁴⁷ These free radicals destroy cells by attacking the unsaturated bonds of fatty acids within the phospholipid membrane, thereby disrupting the cell membrane, allowing water to enter the cell, and eventually causing cell lysis. Free radical scavengers (e.g., mannitol and superoxide dismutase) have a slight protective effect against reperfusion injury when given

before large-scale release of these radicals.^{48,49} In addition, myoglobin from injured muscle cells is released into the circulation and is cleared via the renal system. Myoglobin may cause renal failure through its direct toxic effect on the renal tubules and through the accumulation of casts in the tubules.

Creatinine phosphokinase levels may also increase to dramatic levels once perfusion is reestablished. High concentrations of lactic acid, potassium, thromboxane, and cellular enzymes are secreted as a consequence of the rhabdomyolysis; these substances accumulate in the ischemic limb and are released into the systemic circulation upon reperfusion.⁵⁰ In one study that measured the venous effluent from a series of patients with limb ischemia, the pH was 7.07 and the mean potassium level 5.7 mEq/L 5 minutes after surgical embolectomy.⁵¹

Detrimental physiologic changes are seen when toxic oxygen metabolites are released systemically. Depression of myocardial function, an increase in cardiac dysrhythmias, and loss of vascular tone may induce shock and even death.⁵²

Etiology of ALI

The etiology of ALI can be divided into two distinct categories: thrombosis and embolism. A thorough evaluation must be performed to elucidate the precise cause of ischemia in each individual patient.

The two categories are each associated with specific symptoms and signs [see Table 6]. Knowledge of these associations helps direct the clinician toward the most appropriate means of accomplishing limb salvage in a given situation.

Thrombosis of a native vessel or bypass graft almost always develops in conjunction with an underlying lesion in the vessel or graft. The lesion usually has been present for some time, and the throm-

Table 6 Differentiation of Embolism from Thrombosis

Variable	Embolism	Thrombosis
Identifiable source	Frequently detected	None
Claudication	Rare	Frequent
Physical findings	Proximal and contralateral pulses normal	Evidence of ipsilateral and contralateral peripheral vascular disease
Angiographic findings	Minimal atherosclerosis; sharp cutoff; few collaterals; multiple occlusions	Diffuse atherosclerotic disease; tapered and irregular cutoff; well-developed collateral circulation

bosis occurs as a result of it. In contrast, embolic events occur in nondiseased vessels that become resting places for emboli.

THROMBOSIS

Native Artery Thrombosis

Native artery thrombosis is usually the end stage of a long-standing disease process of atherosomatous plaque formation at specific sites in the arterial tree. Atherosclerotic plaque begins with the slow deposition of lipids in the intima of the vessel and continues with the deposition of calcium, resulting in an atherosclerotic core.⁵³ This core is a highly thrombogenic surface that encourages platelet aggregation, which results in disturbances of blood flow.⁵⁴ The flow disturbances create a zone of separation, stagnation, turbulence, and distorted velocity vectors. These factors cause low shear rates at inflection points in the arterial tree, and endothelial damage ensues. The endothelial damage activates a repair process that results in intimal hyperplasia, which causes further attraction of platelets and eventual thrombus formation. The process by which occlusion develops from an atherosomatous plaque may be more important than the degree of stenosis within the lumen. This would explain why acute occlusion occurs in vessels with minimal (< 50%) stenosis: the contact between the atherosclerotic core and the bloodstream leads to platelet aggregation and hence to eventual thrombosis.

Occasionally, thrombosis of a native artery occurs without any obvious underlying pathologic condition. In such cases, a thorough investigation should be initiated into other causes of thrombosis (e.g., hypovolemia, malignancy, hypercoagulable states, and blood dyscrasias).

Bypass Graft Thrombosis

Aggressive management of patients with peripheral vascular disease has led to an increase in bypass graft procedures. As a result, graft thrombosis has become the leading cause of acute lower-extremity ischemia. In patients with native conduits, intimal hyperplasia and valvular hyperplasia are the two leading causes of graft failure.⁵⁵ The situation is different in the prosthetic graft population, where the inherent thrombogenicity of the graft material and kinking of the graft from crossing joints are the leading causes. These patients often have graft occlusions without any definable underlying lesion.

EMBOLISM

Peripheral arterial embolization results in the sudden onset of extreme ischemia as the absence of collateral vessels compounds the reduction in flow to the extremity. The heart is by far the predominant source of spontaneous arterial emboli. As the population ages, the number of patients with significant cardiac disease increases and the incidence of embolic phenomena increases. Over the past 20 years or so, the incidence of embolization has doubled, from 23 to 51 per 100,000 admissions. Atherosclerotic heart disease currently accounts for as many as 60% to 70% of all cases of arterial embolism,^{56,57} and atrial fibrillation and rheumatic valvular disease account for the remaining 30% to 40%.^{56,58}

With respect to peripheral emboli in particular, atrial fibrillation is currently associated with two thirds to three quarters of cases. Transthoracic echocardiography is notoriously insensitive in visualizing atrial clots, especially in the left atrial appendage, which is the most common cardiac source of emboli.^{59,60} Transesophageal echocardiography, however, offers significantly better imaging of all four chambers and hence is considered the superior diagnostic test for suspected cardiac embolic sources.⁶¹⁻⁶⁴

MI is the next most important cause of peripheral emboli. A 1986 study of 400 patients found that MI was a causative factor in 20%.⁵⁸

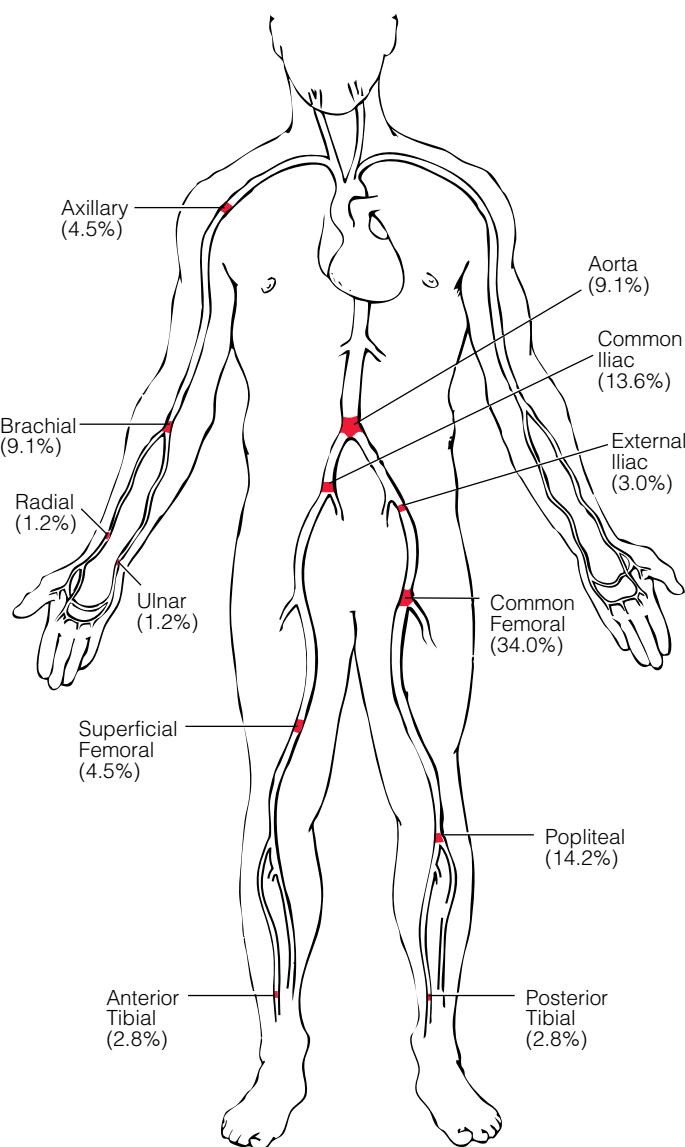

Figure 2 Depicted are the most common sites of arterial embolic occlusions.

After an MI, a left ventricular wall thrombus is often seen, with⁶⁵ or without⁶⁶⁻⁶⁸ a left ventricular wall aneurysm; however, only 5% of such thrombi embolize and cause a problem.⁶⁶⁻⁶⁸ Other studies suggest that the period in which the risk of embolization is highest for an intracardiac thrombus is that between day 3 and day 28.⁶⁹

The ring portions of prosthetic cardiac valves are major intracardiac embolic sources before anticoagulation,⁷⁰ as are biologic xenovalves, which do not require anticoagulation.⁷¹ Finally, tumors (e.g., atrial myxomas) are occasional sources of peripheral emboli.⁶⁹ Cardiac vegetations from bacterial or fungal endocarditis should be considered as possible sources of peripheral emboli when I.V. drug abuse is suspected in a patient with no previous history of cardiac disease.^{72,73}

Noncardiac sources account for 5% to 10% of peripheral emboli. The majority of these involve downstream atherosclerotic arterial disease (e.g., aneurysms or unstable plaques).⁷⁴⁻⁷⁷ Foreign objects (e.g., missiles^{78,79}) and tumors (e.g., melanoma^{80,81}) can also embolize if they gain access to the arterial tree. So-called paradoxical embolization occurs when a venous thrombus crosses from right to left via an atrial or ventricular route, gains access to

the arterial side, and becomes an arterial embolus.⁸²⁻⁸⁴ About 5% to 10% of emboli remain unidentified despite a thorough diagnostic evaluation^{85,86}; some of these are now being attributed to hypercoagulable states.⁸⁷

Incidence

As a consequence of the ongoing growth in the number of endovascular interventions being performed, overall incidence patterns for embolism are shifting yet again, with a greater number of emboli now arising from intravascular handling. A 1996 study found that 45% of all atheroemboli were iatrogenic and that the majority of these originated during manipulation of the abdominal aorta, the iliac artery, or the femoropopliteal artery, with the remainder originating during surgery.⁸⁸ Emboli usually lodge at arterial bifurcations and consequently impair blood flow to more than one vessel. Axial limb vessels account for 60% to 80% of clinically significant embolic events,^{58,69,89} with the remainder divided between cerebral vessels (20%) and upper-extremity vessels (10% to 20%). The most common site for embolic lodgment is the common femoral bifurcation [see Figure 2]. The aortoiliac region is the next most common site, followed closely by the popliteal artery.^{52,57,58,69,90,91}

The presence of normal pulses in the contralateral leg in a patient with an ischemic leg should elicit an aggressive workup to rule out cardiac sources for the emboli and may be a clue that the occlusive event is more likely to be embolic than thrombotic.

Upper-Extremity Emboli

Acute ischemia of the upper extremity is usually caused by embolism, usually deriving from an intracardiac source. Subclavian aneurysms, arteriovenous fistulae, upper-extremity arterial bypasses, and iatrogenic manipulation of the arteries are rare causes.⁹² As noted (see above), emboli lodge at inflection points of the arterial tree. In the upper extremity, the bifurcation of the brachial artery into the radial and ulnar arteries is the most common lodgment site, followed by the takeoff of the deep brachial artery. Adequate exposure of all three arteries can be obtained via an elongated S-shaped incision that runs medially to laterally across the elbow joint.

Other Causes

Sepsis and cardiogenic shock bring about a low-flow state that places patients at high risk for thrombosis. Certain vasoconstrictors and recreational drugs are also associated with lower-extremity thrombosis.^{93,94} Patients with these conditions usually present with bilateral extremity ischemia. Vasculitides (e.g., Takayasu) may also cause extremity ischemia.⁹⁵

The hypercoagulable states (e.g., antithrombin deficiency, antiphospholipid syndrome, protein C and S deficiencies, factor V Leiden mutation, and hyperprothrombinemia) are the most common disorders associated with acute arterial thrombosis.⁹⁶ The consequences are usually devastating.

6 VENOUS THROMBOEMBOLISM

John T. Owings, M.D., F.A.C.S.

Deep vein thrombosis (DVT) (deep thrombophlebitis) occurs in approximately 2.5 million people in the United States each year.¹ The incidence of DVT in surgical patients varies widely depending on the method of study: in eight series, the incidence of DVT verified by venography or autopsy ranged from 18% to 90% (average, 42%).²

Reviews suggest that pulmonary embolism (PE) occurs in approximately 700,000 people in the United States each year, of whom about 200,000 will die as a result.^{3,4} In the absence of prophylaxis, fatal PE occurs in 4% to 7% of hip surgery patients and in 0.1% to 0.8% of general surgery patients.^{3,5} In 40% to 60% of patients who die of PE, the diagnosis is not made clinically. PE may be responsible for as many as 5% of postoperative deaths, and it may occur in as many as 25% of patients admitted to the hospital.^{6,7} Pulmonary infarction occurs in about 10% of PE patients.⁸

Significant PE is believed, as a rule, to arise from thrombosis of the deep veins of the thigh and the pelvis. Most studies of thromboembolism use DVT as a surrogate end point for PE. The only major study of thromboembolism prophylaxis to date that successfully used death from PE as an end point required more than 5,000 patients to reach statistical significance.⁹ Accordingly, the National Institutes of Health has concluded that using DVT as a surrogate for PE is a valid approach.¹⁰

The optimal treatment of thromboembolism is prevention, particularly in persons at high risk [see Table 1].^{11,12} Risk factors for venous thromboembolism include increased age (≥ 30 years in some studies),¹³ major trauma (Injury Severity Score of 15 or greater or the presence of a pelvic or lower-extremity long bone fracture), morbid obesity, major operation, prolonged immobility, thrombophilia, and previous thromboembolism.

Prophylaxis against Thromboembolism

In evaluating the effectiveness of the methods used to prevent thromboembolic complications, it is important to consider the specific population of patients studied. Within the surgical patient population, there is one reasonable division: between (1) patients who have an ongoing pathologic process that affects coagulation when first encountered and (2) elective patients for whom the surgical insult is the inciting risk factor. For the first group, the typical patient is the polytrauma patient; for the second, the patient undergoing elective hip or knee replacement.

The key distinction between these two groups lies in whether prophylaxis can be given before the inciting insult. Several techniques for prophylaxis of thromboembolism that are effective when employed before the inciting event are completely ineffective if employed afterward. This point can be illustrated by comparing elective colorectal surgery patients with trauma patients. In a 2001 study, elective colorectal surgery patients who were given their first dose of unfractionated heparin before operation and then were given additional doses of unfractionated heparin (5,000 units subcutaneously three times daily) after operation were as well protected against DVT as comparable patients receiving low-molecular-weight heparin (LMWH) and were at lower risk for bleeding.¹⁴ In a 1996 study, however, trauma patients who were given unfrac-

tionated heparin subcutaneously as prophylaxis against DVT fared no better than those treated with placebo.¹⁵ Subsequent work has shown that effective DVT prophylaxis can be achieved in this population by using the LMWH enoxaparin.

COMPRESSION TECHNIQUES

Elastic stockings have long been used as prophylaxis for thromboembolism. Most commercial stockings, however, do not fit adequately or provide adequate compression and thus probably offer little or no benefit.⁴ Low-molecular-weight dextran, which lowers blood viscosity and inhibits platelet aggregation, may be helpful in certain instances, but data showing greater efficacy as compared with current techniques are lacking.¹²

Pneumatic devices that compress the venous plexuses of the lower extremities are popular because they do not require anticoagulation and thus are not associated with increased bleeding risk. Intermittent pneumatic compression is capable of intermittently increasing venous flow velocities in the femoral and pelvic veins.¹⁶ It has been argued that some of the benefit might derive from the known tourniquet effect of enhancing fibrinolytic activity, attributed both to an increase in tissue plasminogen activator (t-PA) and to a decrease in plasminogen activator inhibitor (PAI). This argument seems to be valid for up to 24 hours of continuous use,¹⁷ but after that point, the effect is exhausted.¹⁶ Intermittent pneumatic compression is a safe, albeit somewhat uncomfortable, method of preventing clots in patients immobilized for prolonged periods. It is particularly useful in critical care units, where other forms of prophylaxis are inapplicable or contraindicated.¹¹

Several different pneumatic compression devices have been developed. The first to gain widespread acceptance was the full-length (calf and thigh) sequential compression stocking, which proved effective in a number of settings, including trauma.¹⁸

Table 1 Risk Factors for the Development of Venous Thromboembolism

Hypercoagulability
Congenital hypercoagulability
Malignancy
Oral contraceptives
Polycythemia
Thrombocytosis
Venous stasis
Immobilization
Varicose veins
Advanced age
Congestive heart failure
Obesity
Endothelial injury
Trauma
Recent surgery
Severe infection

Because some injured patients were unable to wear the device, various modified compression devices were developed, including a calf-only device and a foot pump designed to compress the plantar venous plexus. Several studies have demonstrated that the various compression devices are not all equally effective in preventing thromboembolism. This is an important point because many of the devices are marketed solely on the basis of compliance data rather than efficacy data; those that are marketed without published evidence of efficacy often use cost advantages to gain market share.

The effectiveness of pneumatic compression devices is based on their ability to increase peak venous flow velocity in the large vessels of the thigh and the pelvis. Because some units create higher peak flow velocities, it would be logical to assume that these units would be more effective in reducing DVT. Support was lent to this assumption by a 2000 study in which more than 300 patients undergoing elective knee surgery were treated with different compression devices.¹⁹ Devices applying asymmetrical compression (which results in higher peak venous flow velocity) were compared with traditional compression devices, and calf-only devices were compared with calf-and-thigh devices. The two calf-and-thigh units studied proved superior to the calf-only unit, and the calf-and-thigh asymmetrical sequential compression device that generated higher peak flow velocities was superior to the traditional calf-and-thigh device. Similar results were obtained in a 2004 study that compared knee-high compression devices.²⁰

It is therefore important to recognize that although compliance is a critical component of compression devices, differences in efficacy must be taken into account. Given the absence of efficacy data for many of the compression devices now in use, great caution should be exercised in considering whether these products should be adopted, regardless of anticipated cost savings.

PROPHYLACTIC ANTICOAGULATION

A major study of thromboembolic prophylaxis in hip surgery patients found that subcutaneous administration of 5,000 units of

heparin two or three times daily before, during, and after the operation substantially reduced thromboembolic complications without increasing bleeding.⁵ This low-dose protocol has been criticized as being insufficiently individualized for specific high-risk patients. Low-dose heparin acts by markedly augmenting the antithrombotic effect of antithrombin²¹; therefore, it may be ineffective if antithrombin levels are reduced, and higher doses may be more appropriate in such settings.

Because of these pitfalls, an adjusted-dose technique was devised in the mid-1980s.²² In this method, heparin is given (either subcutaneously or I.V.) in sufficient doses to elevate the activated partial thromboplastin time (aPTT) by 2 to 5 seconds, thereby compensating for depleted antithrombin levels in high-risk patients. This technique is superior to the low-dose method for preventing venous thromboembolism,²² and for practical purposes, it should replace the latter as the standard prophylactic dosing technique for unfractionated heparin.^{22,23}

LMWH possesses the same antithrombin-potentiating pentasaccharide chain that unfractionated heparin does. Consequently, it is similarly ineffective if antithrombin levels are depleted. The main advantage of LMWH over unfractionated heparin is that it has a more dependable half-life and bioavailability. Thus, it can be given without monitoring of drug effect or plasma heparin level.

Most of the clinical trials documenting the efficacy of LMWH evaluated patients undergoing elective hip^{24,25} or knee operations. A few, however, addressed other patient populations (e.g., trauma patients).¹⁵ In these studies, the incidence of DVT in patients receiving unmonitored LMWH therapy was generally lower than that in patients receiving placebo²⁴ or low-dose heparin.^{15,25} LMWH therapy and adjusted-dose heparin therapy were of roughly equal efficacy.

In the light of these data, it appears that LMWH can be recommended over low-dose unfractionated heparin in elective, emergency, and trauma patients. Whether it is superior to adjusted-dose unfractionated heparin therapy remains uncertain, though it is clearly simpler to manage. Where compliance with monitoring and

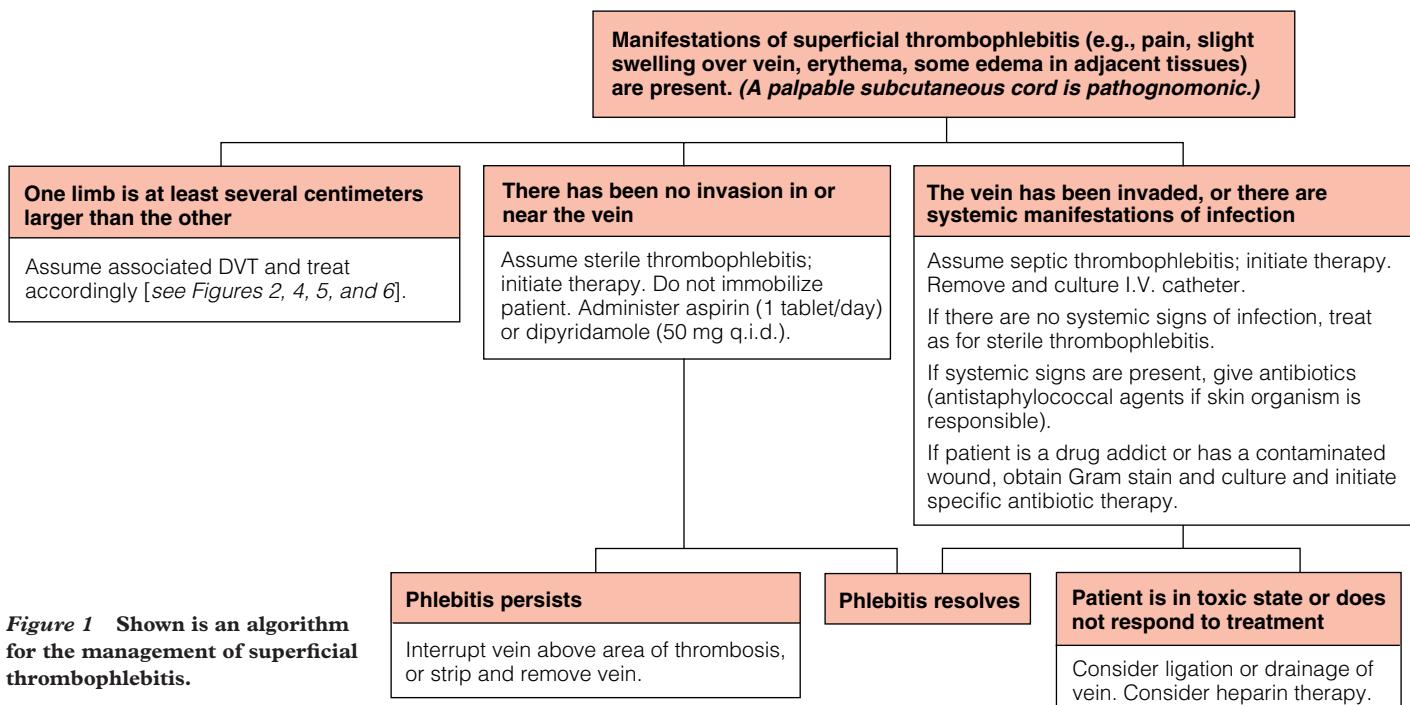

Figure 1 Shown is an algorithm for the management of superficial thrombophlebitis.

dose-adjusting protocols is an issue, unmonitored LMWH therapy may well be preferable.

Fondaparinux, a synthetic form of the specific pentasaccharide that interacts with antithrombin to potentiate its effect, has been approved by the Food and Drug Administration. This agent is smaller than the LMWHs and seems to have the same advantages over these substances that they have over unfractionated heparin—namely, increased bioavailability, longer half-life, and a more consistent effect. As the molecular weight of the antithrombin potentiator decreases, the antithrombotic effect focuses more sharply on inhibiting factor X (as opposed to factors II, IX, XII, etc.).

Before fondaparinux is uniformly adopted for thromboembolism prophylaxis, the supporting evidence should be carefully considered. The initial findings are quite promising. In a prospective, randomized trial that included approximately 1,700 hip fracture patients, fondaparinux was superior to enoxaparin with respect to the incidence of venographically identified DVT²⁶; however, the enoxaparin dosage (40 mg once daily) was lower than the dosage shown to be effective in trauma patients by previous investigators (30 mg twice daily).¹⁵ No significant difference in bleeding rates was observed. In another trial, which included approximately 700 patients undergoing elective knee surgery, fondaparinux, 2.5 mg once daily, proved superior to enoxaparin, 30 mg twice daily.²⁷ In this study, the bleeding rate was significantly higher with fondaparinux.

Ultimately, with regard to prophylactic anticoagulation, simple logic applies. The more potent the anticoagulant used, the lower the risk of PE and the higher the risk of serious bleeding. It is therefore appropriate to base one's selection of an anticoagulant regimen on a careful weighing of the expected benefits against the anticipated bleeding risk.

In some patients (e.g., those undergoing major gynecologic procedures), warfarin may be used instead of heparin.^{12,28} A low-dose regimen (as little as 1 mg/day) may offer some prophylactic benefit.²⁸ Warfarin anticoagulation must be started 3 or 4 days before the surgical procedure. The international normalized ratio (INR) [see General Principles of Anticoagulation and Lytic Therapy, below] should be kept below 3.0 to prevent excessive bleeding. Warfarin is not as easy to regulate as heparin is. In addition, the therapeutic effect takes several days to be realized and several more days to wear off. Frequently, postoperative patients are unable to resume a normal stable diet. Because warfarin interferes with the clotting factors in the vitamin K pathway, dosage management in the immediate postoperative period is challenging. Because the risk of intracranial bleeding is greater with warfarin than with heparin, great care should be taken in using warfarin for immediate perioperative prophylaxis.

PROPHYLACTIC VENA CAVAL INTERRUPTION

Prophylactic vena caval interruption or filter placement provides prophylaxis only against PE, not against DVT, and thus is discussed elsewhere [see Pulmonary Embolism, Minor, Vena Cava Filters, below]. There is evidence that placement of a vena cava filter in fact increases the likelihood of DVT.²⁹

Superficial Thrombophlebitis

Characteristic clinical manifestations of superficial thrombophlebitis [see Figure 1] include pain and slight swelling of the extremity, with most of the edema over the course of the involved vein. Unless the patient is obese, a palpable, tender subcutaneous cord is usually found (a pathognomonic finding). Erythema may be present in the overlying skin. The differential diagnosis includes

cellulitis and streptococcal lymphangitis. For both conditions, there should be a proximal source (e.g., an open wound). If there is overt limb swelling in a patient who appears to have superficial phlebitis, DVT should be assumed and appropriate treatment [see Deep Vein Thrombosis, below] initiated.

Superficial thrombophlebitis is largely benign but is often over-treated out of fear that infection may be contributing to phlebitis. It is therefore important to differentiate between sterile and septic superficial thrombophlebitis.

STERILE

If there is no invasion in or near the superficial vein involved, sterile thrombophlebitis can be assumed with minimal risk of misdiagnosis. It is best treated simply by giving aspirin (one tablet daily) or dipyridamole (50 mg four times daily).

If superficial phlebitis of the saphenous vein extends to the saphenofemoral junction, interruption of the vein may be appropriate. The choice of treatment is between interrupting the vein above the area of palpable thrombosis and stripping the vein. The second alternative carries a higher morbidity but can be effective when there are associated varicosities. Stripping of the channels above and below the phlebitic process as well as the phlebitic area itself removes the risk of extension and subsequent recurrence. Several authors have explored medical management of patients with above-the-knee superficial thrombophlebitis, using an approach similar to that used for DVT. Therapeutic-dose heparin (unfractionated heparin or LMWH) is given initially, followed by long-term oral anticoagulation. The incidence of extension may be higher than with surgical management, but the operative risks are avoided.³⁰

SEPTIC

If there are systemic manifestations of severe infection, septic thrombophlebitis is likely. In addition, the induration, tenderness, and redness over and along the course of the vein are usually more extensive than with sterile thrombophlebitis.

Septic thrombophlebitis associated with an I.V. catheter can be detected by removing the device and culturing the tip. Antibiotics should be administered. In most cases, antistaphylococcal drugs are appropriate. If the patient is a drug addict or phlebitis is associated with a contaminated wound, blood samples for culture and Gram staining should be obtained by aspirating the vein. Specific antibiotic therapy directed toward the organisms identified should then be instituted.

If the patient is in a toxic state from presumed septic thrombophlebitis in a subcutaneous vein or is not responding to treatment, it may be appropriate to ligate the vein, to drain it by cutting down on the phlebitic process with the patient under local or general anesthesia and laying the vein open, or to combine ligation with drainage. Moist compresses are then applied, the area is immobilized, and antibiotics are administered. Heparin may occasionally be of value, particularly when the process appears to be extending into the deep venous system.

Deep Vein Thrombosis

DVT can involve either obstructive clots, which affect drainage of venous blood from an extremity, or nonobstructive clots, which are relatively asymptomatic. The latter may be more dangerous because such clots are not circumferentially attached to the vein wall and thus are more likely to embolize. DVT may be divided into three main forms: nonocclusive, occlusive, and phlegmasia cerulea dolens (massive, limb-threatening DVT).

NONOCCLUSIVE

Nonocclusive DVT is common in postoperative and trauma patients but all too often is not suspected until an embolic complication occurs.³¹ There may be absolutely no manifestations of clot on clinical examination, or there may be nonspecific swelling in an extremity; rarely is there sufficient pain or tenderness to suggest DVT. Consequently, it is essential to be aware of the major risk factors [see Table 1].

When DVT develops in an outpatient, every effort should be made to determine the cause [see Figure 2]. Apparent spontaneous onset is often the manifestation of an underlying malignancy or even a congenital clotting tendency that will necessitate lifelong treatment [see Hypercoagulability States, below]. Conversely, when risk factors for DVT are identified in a hospitalized patient, it can be assumed that the cause is acquired and that the clotting tendency will be reversed upon recovery.

Before therapy is begun, the diagnosis should be verified. The differential diagnosis includes muscle contusion, plantar or gastrocnemius muscle rupture, ruptured Baker's cyst, popliteal artery aneurysm, arthritis of the knee or the ankle, cellulitis, and myositis. The gold standard for diagnosis of DVT is ascending venography. However, study of the entire lower-extremity venous system

often involves injection of dye not only at the foot or ankle level [see Figure 3] but also at the groin level for visualization of the iliac and femoral veins. This approach is uncomfortable and is associated with morbidity; in critically ill ICU patients, it may not be feasible. Accordingly, noninvasive evaluation techniques are favored.

The presence of intravascular clot can be confirmed by detecting D-dimer, a product formed when cross-linked fibrin is broken down by the fibrinolytic system. Both qualitative and quantitative assays are in current use. The various quantitative assays available have differing negative predictive values. The gold standard is the enzyme-linked immunosorbent assay (ELISA) method. Generally, 500 µg/L (in fibrin-equivalent units) or 250 µg/L (in standard units) is an acceptable threshold for a positive result. The latex agglutination test, though inexpensive, has an unacceptably low sensitivity and is the one quantitative method that should not be used. Because some amount of physiologic intravascular clot (e.g., at a wound site) is to be expected in many, if not most, patients at risk for DVT, a positive D-dimer assay is of little diagnostic value. D-dimer assay is therefore unsuitable for screening. In patients suspected of having DVT or PE, however, a negative D-dimer assay can, for the most part, rule out DVT and, by extension, PE.³²⁻³⁴

Various forms of plethysmography (e.g., impedance plethysmography) have been used to identify nonocclusive DVT.^{35,36} These techniques are accurate only when there is at least 50% obstruction of the lumen of a deep vein. The presence of large collateral vessels may result in a false-negative test result as well. Doppler ultrasonography can be performed quickly and easily, though interpretation of the results requires considerable experience. It has essentially the same drawbacks as plethysmography.³⁵

Real-time B-mode (duplex) ultrasonography can be valuable in this setting.^{35,37,38} It can actually visualize thrombus within a vessel. Inability to obliterate the vein with probe compression is additional evidence of thrombus. Often, experienced users can even differentiate between new and old thrombi on the basis of echogenicity. Duplex ultrasonography is quite sensitive and specific in patients with suspected DVT, and its diagnostic qualities can be further enhanced by the addition of color flow imaging. It has in fact become the noninvasive procedure of choice for assessment of clot in the neck and the extremity vessels. Unfortunately, it is less specific proximal to the axilla and the inguinal ligament, where compression of the vessels is difficult or impossible. Duplex ultrasonography is particularly valuable for detecting associated conditions that may confuse the diagnosis (e.g., muscle hematomas or a Baker's cyst).³⁸

Ultimately, ascending venography is the most accurate method of diagnosing DVT.^{39,40} If a good contrast study fails to demonstrate the presence of clot, DVT is conclusively ruled out.

Once nonocclusive DVT is diagnosed, the treatment of choice is initial therapeutic-dose heparin therapy followed by warfarin therapy. If the patient is responsible and reasonably well educated, initial heparin anticoagulation can be done on an outpatient basis with subcutaneous LMWH.^{41,42} If this approach is not appropriate, inpatient therapeutic-dose I.V. heparin anticoagulation is employed. After 3 or 4 days, depending on the response, heparin is replaced with warfarin.

OCCLUSIVE

Lower Extremity

Lower-extremity occlusive DVT [see Figure 4] is usually associated with swelling; however, if good collateral circulation or duplicate veins are present, especially in the thigh, only local inflammation may be apparent. Typical findings include pain and tenderness

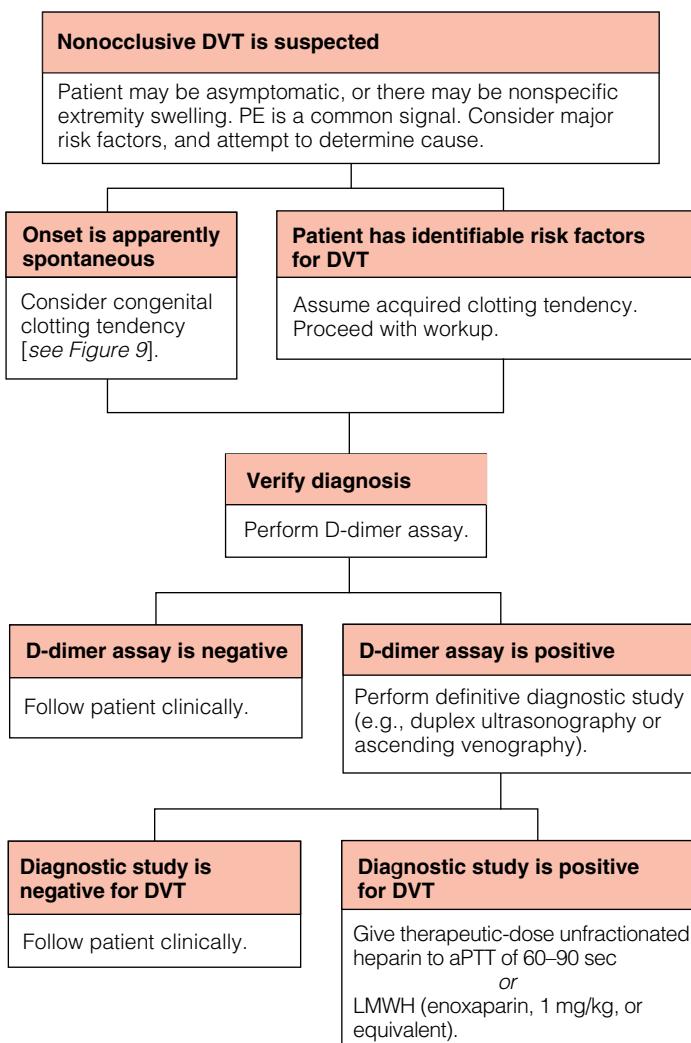

Figure 2 Shown is an algorithm for the management of nonocclusive DVT.

Figure 3 Injection of dye into dorsal foot veins demonstrates occlusion of iliac veins with excellent pelvic collateral circulation.

over the involved veins as well as swelling in the distal limb (which may be minimal with the patient supine). The differential diagnosis is essentially the same as for nonocclusive DVT. In addition, lower-extremity DVT can be associated with PE: free-floating clot may occur in conjunction with occlusive clot.

If both legs are swollen, the proximal extent of the thrombus is likely in the vena cava. If one entire leg is swollen, the proximal extent must be in the iliac veins. If the swelling is limited to the lower leg below the knee, the thrombus is probably in the superficial femoral vein. If the only manifestations are minimal swelling and calf tenderness, the thrombus is probably limited to the sural vein, the gastrocnemius vein, or both.

If the patient has a history of DVT, is hospitalized, and is at risk for recurrence, heparin therapy may be started before test results are available (provided that there is no contraindication to anticoagulation). If the patient is an outpatient, is hospitalized but lacks risk factors for DVT, or has a contraindication to anticoagulation, a D-dimer assay should be performed. If the assay is negative, an alternative diagnosis should be sought. If it is positive, the diagnostic workup of DVT should proceed. If diagnostic studies yield equivocal results and venography is difficult or impossible, treatment should proceed as if the diagnosis had been confirmed.

The treatment of choice is immobilization in bed, elevation of the limb (with or without elastic compression), and therapeutic-dose heparin (unfractionated heparin or LMWH), followed by 3 to 6 months of warfarin therapy. If the episode is mild, recovery is usually prompt. If pain and swelling do not respond promptly to anticoagulation, either the diagnosis is wrong or anticoagulation is

inadequate. Lytic therapy combined with heparin anticoagulation may be superior to heparin anticoagulation alone, leading to better clearance of clot from the valves with improved function and less risk of postphlebitic syndrome.⁴³

Upper Extremity

For all practical purposes, upper-extremity DVT [see *Figure 5*] involves only the axillary, the subclavian, or the innominate vein (or a combination thereof). Involvement of the superior vena cava is rare, mainly occurring in chronic conditions (e.g., long-term venous catheterization). Arm thrombophlebitis is characterized by pain and swelling with tenderness over the involved vein. Often, it is relatively asymptomatic: because of the excellent collateral circulation in the arm, thrombosis must be extensive to produce marked swelling.

Spontaneous onset of axillary or subclavian vein thrombosis can occur in association with thoracic compression syndromes (effort thrombosis) or as a complication of so-called Saturday night palsy, in which an alcoholic sleeps with the axilla compressed by the arm of a chair. If a potential mechanical cause is not apparent, other possible causes must be explored. The onset of swelling, tenderness, or fever in a patient with a central venous catheter is an indication for removal of the catheter. If there is no bacteremia or fever, if there has been a catheter in the vein, and if the problem developed spontaneously, sterile thrombophlebitis may be assumed. In these cases, once the catheter is removed, anticoagulation is unnecessary.⁴⁴

Subclinical nonocclusive clot is probably of little significance because documented PE from the upper extremity is quite rare.

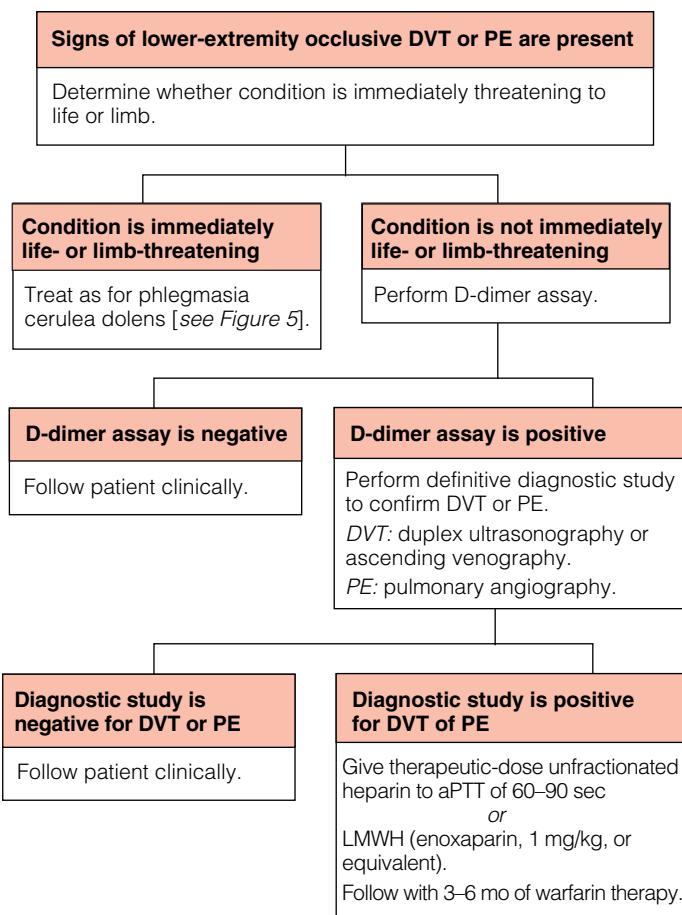

Figure 4 Shown is an algorithm for the management of lower-extremity occlusive DVT.

Noninvasive tests [*see Nonocclusive, above*] typically yield positive results when the upper extremity is involved.³⁹ Moreover, distal vein catheterization is easy, and phlebography is relatively uncomplicated. These techniques should be used whenever the diagnosis is in doubt.

The morbidity of occlusive upper-extremity DVT can be substantial. Thus, if the patient presents with massive swelling of the upper limb, therapeutic-dose heparin anticoagulation should be initiated immediately, and consideration should be given to lytic therapy.⁴³ If phlebography shows compression of arm veins at the thoracic inlet after lytic therapy or spontaneous recovery from the thrombotic process, resection of rib 1 may be indicated, particularly if positional morbidity is present.^{45,46}

Septic DVT is more common in the upper extremity than in the lower, primarily because upper-extremity veins are more frequently catheterized and more often used for injection of illicit drugs. If phlebitis occurs in a catheterized vein with fever and sepsis, the catheter should be removed immediately, the tip cultured, and Gram staining done on any clot present. Broad-spectrum antibiotics should be administered until more specific antibiotic therapy can be instituted. Heparin anticoagulation is the primary treatment unless contraindicated.

Ligation and drainage are not as practical for deep veins as for superficial veins, but either may be indicated on rare occasions if the process does not respond to conventional therapy within 3 or 4 days and marked swelling and fever persist. Drainage is done on the most accessible portion of the phlebitic process. For ligation, the proximal end of the process should be identified via surgery or phlebography and the vein then ligated proximally.

MASSIVE (PHLEGMASIA CERULEA DOLENS)

Phlegmasia cerulea dolens [see Figure 6] is most apt to occur in dehydrated, cachectic patients and is usually superimposed on another critical illness. It can involve either the upper or the lower extremity but more commonly affects the lower. In the lower

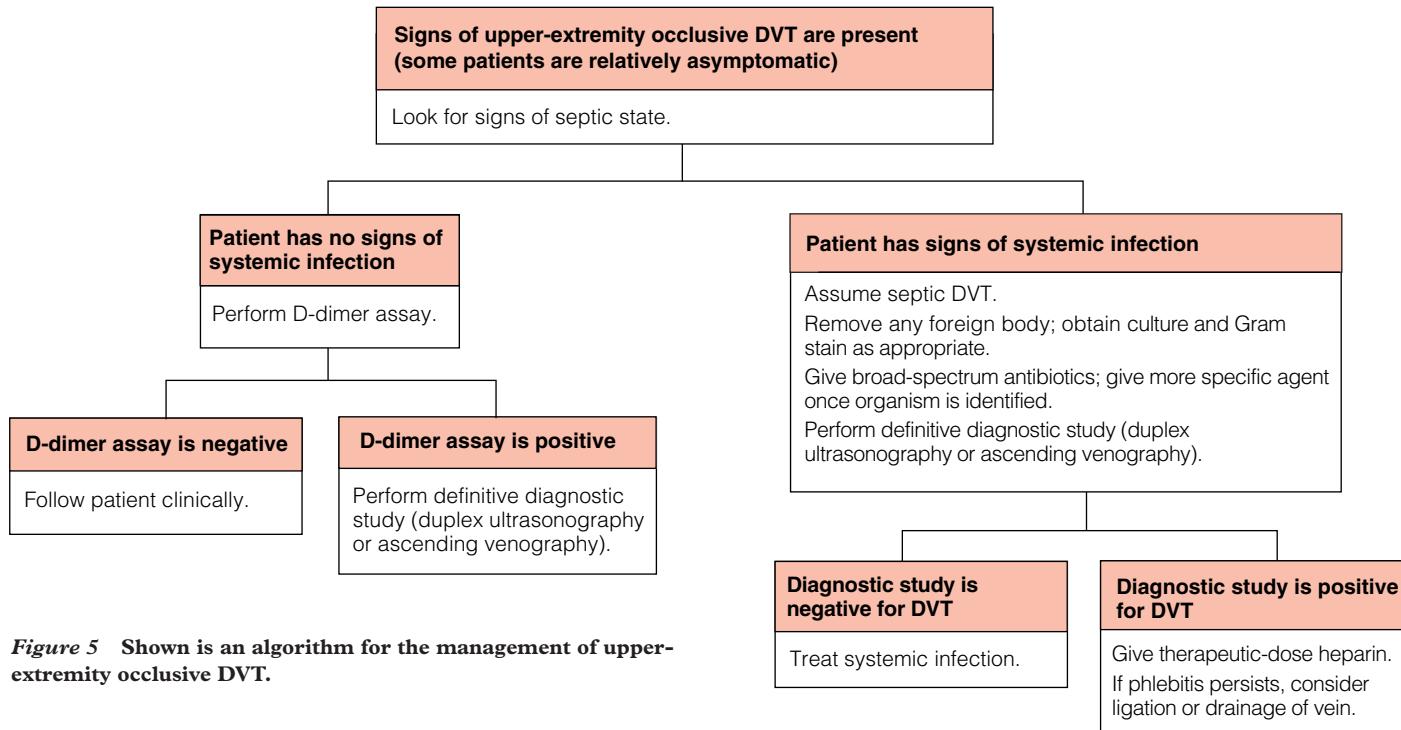

Figure 5 Shown is an algorithm for the management of upper-extremity occlusive DVT.

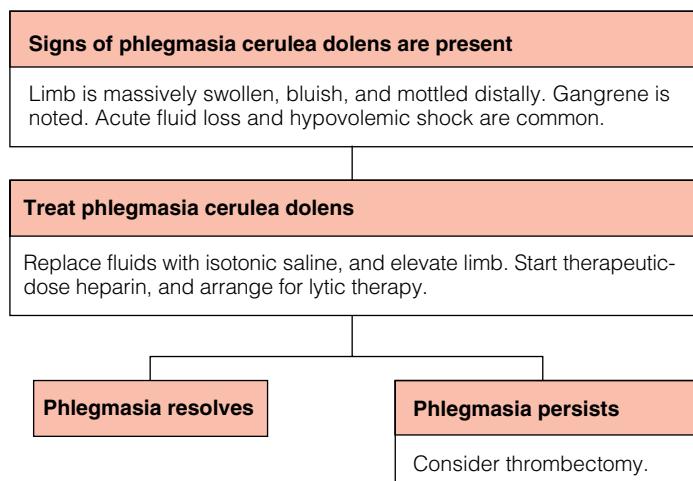

Figure 6 Shown is an algorithm for the management of massive DVT (phlegmasia cerulea dolens).

extremity, there is usually simultaneous thrombosis of the iliac, femoral, common femoral, and superficial femoral veins. The limb is massively swollen, bluish, and mottled. Eventually, it becomes nonviable as arterial flow stops because of arterial spasm associated with venous outflow obstruction. The problem is compounded by acute massive fluid loss into the limb, which can result in hypovolemic shock.

Treatment involves rapid and aggressive fluid replacement, elevation of the limb, and aggressive heparin anticoagulation or catheter-directed lytic therapy.^{47,48} If the patient does not respond, thrombectomy may be considered, provided that the associated disease does not carry a fatal prognosis.⁴⁹ The procedure is best done transfemorally with a limited incision so that anticoagulation can be continued postoperatively. If anticoagulation cannot be continued, thrombophlebitis will recur immediately.

Pulmonary Embolism

It is widely agreed that PE is grossly underdiagnosed.^{3,4,50,51} Most episodes (up to 90%) are unsuspected,^{52,53} and only a minority (10% to 25%) of fatal episodes are diagnosed before death. Clinical manifestations include dyspnea, hemoptysis, pleurisy, heart failure, and cardiovascular collapse; however, each of these is also associated with other conditions [see Table 2]. Risk factors for PE are similar to those for DVT [see Table 1].

PE should be distinguished from pulmonary infarction. Of the approximately 10% of all pulmonary emboli that are recognized clinically, only 10% are associated with pulmonary infarction.⁸ Because the lung has excellent collateral circulation, obstruction of the larger pulmonary arteries rarely leads to death of lung tissue. When pulmonary infarction does occur, the diagnosis is usually obvious; hemoptysis, pleuritic chest pain, and a wedge-shaped density on chest x-ray are the classic manifestations. In most PE patients (i.e., those without pulmonary infarction), these findings are absent, and the chest x-ray may even be normal.

For the purposes of clinical diagnosis and treatment, PE is best classified as minor (or suspected), moderate, or catastrophic [see Figure 7].

MINOR

Manifestations of minor PE [see Figure 7a] may include transient tachypnea (with perhaps a slight change in blood gas values)

and cardiac irritability (with frequent premature beats or tachyarrhythmias).⁵⁴⁻⁵⁶ These changes may resolve in moments, and the patient may then appear perfectly normal. In these circumstances, the embolus probably either is small or is composed of relatively fresh clot that produces only transient obstruction when it enters the pulmonary vascular tree.

It was long believed that after operation, hospitalization, or injury, the earliest PE might occur was 4 to 7 days after the insult. A 1997 study of previously healthy trauma patients, however, found that approximately 25% of the PE episodes occurred in the first 4 days after injury.⁵⁷ Accordingly, the presence of clinical signs and symptoms consistent with PE in a patient with risk factors calls for appropriate workup, regardless of how soon after the insult they appear.

The differential diagnosis includes acute respiratory distress syndrome (ARDS), aspiration, atelectasis, heart failure, pneumonia, and systemic infection. If the diagnosis is not obvious but the risk of PE is substantial and there is no contraindication to anticoagulation, heparin therapy (therapeutic-dose unfractionated heparin or LMWH) may be instituted while diagnostic tests are being selected and performed.

If PE is unlikely, the risk from anticoagulation is high, or other serious diagnostic possibilities cannot be ruled out, specific studies (e.g., intravascular coagulation, spiral computed tomography, or pulmonary angiography) should be ordered before anticoagulation.

In a stable patient with suspected PE, a blood D-dimer level should be obtained. If the result is negative, PE can be excluded and further diagnostic studies canceled. As with DVT, a positive

Table 2 Clinical Features of Pulmonary Embolism: Differential Diagnosis

Clinical Feature	Other Conditions Associated with Feature
Dyspnea	Aspiration Atelectasis Pneumonia Pneumothorax Pulmonary edema Systemic infection
Heart failure	Cardiac tamponade Intracardiac injury Myocardial contusion Myocardial infarction
Hemoptysis	Bronchial injury Pulmonary contusion Tracheal erosion Unsuspected neoplasm
Pleurisy	Chest wall injury Pneumonia Pneumothorax Subphrenic inflammation
Cardiovascular collapse	Air embolism Cardiac tamponade Hypovolemia Myocardial infarction Severe hypoxemia Systemic infection Tension pneumothorax

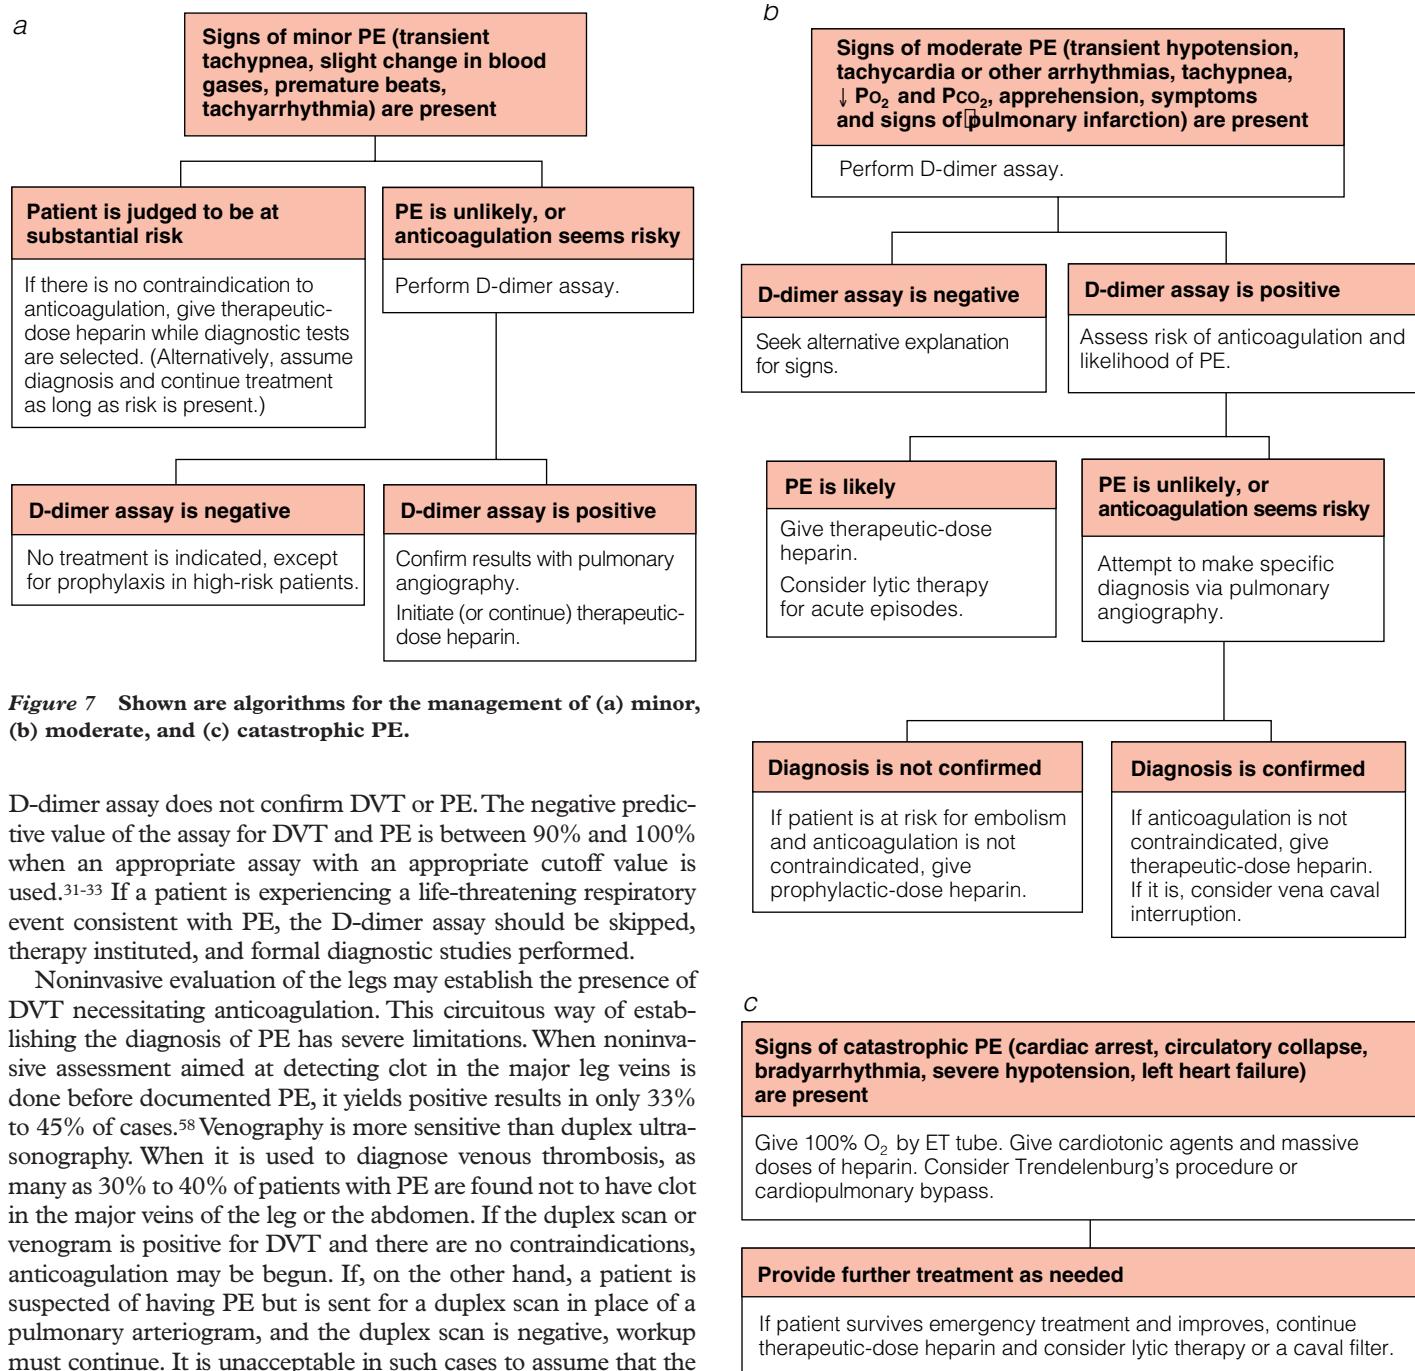

Figure 7 Shown are algorithms for the management of (a) minor, (b) moderate, and (c) catastrophic PE.

D-dimer assay does not confirm DVT or PE. The negative predictive value of the assay for DVT and PE is between 90% and 100% when an appropriate assay with an appropriate cutoff value is used.³¹⁻³³ If a patient is experiencing a life-threatening respiratory event consistent with PE, the D-dimer assay should be skipped, therapy instituted, and formal diagnostic studies performed.

Noninvasive evaluation of the legs may establish the presence of DVT necessitating anticoagulation. This circuitous way of establishing the diagnosis of PE has severe limitations. When noninvasive assessment aimed at detecting clot in the major leg veins is done before documented PE, it yields positive results in only 33% to 45% of cases.⁵⁸ Venography is more sensitive than duplex ultrasonography. When it is used to diagnose venous thrombosis, as many as 30% to 40% of patients with PE are found not to have clot in the major veins of the leg or the abdomen. If the duplex scan or venogram is positive for DVT and there are no contraindications, anticoagulation may be begun. If, on the other hand, a patient is suspected of having PE but is sent for a duplex scan in place of a pulmonary arteriogram, and the duplex scan is negative, workup must continue. It is unacceptable in such cases to assume that the negative result excludes PE.

The initial enthusiasm for the use of lung scans to diagnose or screen for PE has diminished.^{59,60} Current thinking about the use of scans for this purpose may be summarized as follows. If a scan is read as high probability, there is roughly an 85% chance that the diagnosis is correct. If a scan is read as normal, there is roughly a 5% chance that the patient had PE. If a scan is read as low or intermediate probability (the most likely scenario), the likelihood that the diagnosis is correct is little better than random chance.

As a result of the dramatic improvements in CT imaging, many proposed replacing pulmonary angiography with CT. There were several good arguments for this proposal. First, CT scanning is less invasive than pulmonary angiography. Second, it does not require the immediate presence of a radiologist. Third, it is less costly at most institutions. Finally, CT scanning is usually more easily obtained than pulmonary angiography. The initial results

from CT scanning for PE were quite promising.⁶¹

In the past few years, CT has undergone rapid increases in sophistication. Specifically, as CT technology has moved from single-detector to multiple-detector (light-speed) scanners, the sensitivity achievable with this modality has skyrocketed. As a result, the negative predictive value of CT in this setting—that is, the degree to which a negative CT pulmonary angiogram can be relied on to rule out PE—has risen dramatically.⁶² For most institutions, the result of this technologic improvement is that CT angiography is now the primary radiologic diagnostic study for excluding PE. It has been argued that CT angiography cannot yet replace pulmonary angiography altogether, because thrombolytic therapy (if required) may be provided during pulmonary angiography, whereas it typically cannot be provided during CT angiography. This

argument probably applies only to the sickest PE patients, who are the ones most likely to benefit from thrombolytic therapy and least likely to be able to tolerate a second load of dye (as when pulmonary angiography is done for treatment purposes after CT angiography).

For critically ill patients, who tolerate diagnostic testing poorly, pulmonary angiography is a more appropriate initial study [see Figure 8].^{3,50,63} If the angiogram is obtained immediately after the clinical episode, particularly if the patient is still symptomatic, a negative result rules out PE. However, if the patient improves or recovers before angiography, the angiogram may be falsely negative, implying that the clot was minimal or was disposed of by natural lytic processes. Thus, a negative angiogram in such a patient does not unequivocally rule out PE.⁶⁴ The pulmonary angiogram does, however, establish the degree of patency of the pulmonary vasculature, which affects prognosis.

PE can occur even immediately after injury in previously healthy persons.⁵⁷ These early emboli are generated from fresh clot and thus are more easily fragmented and broken down. They are much more likely to be found in the periphery.⁶⁵ For these reasons, CT is less sensitive in detecting them.⁶⁵ Accordingly, patients with suspected PE shortly after injury or operation should undergo pulmonary arteriography.

If all diagnostic tests for PE yield negative results, therapeutic anticoagulation is not indicated; however, if risk factors are present, prophylaxis is indicated. If test results are suggestive or indicative of PE, therapeutic heparin anticoagulation should be continued.

Figure 8 Pulmonary angiogram shows unequivocal filling defects in multiple arteries.

MODERATE

Manifestations of moderate PE [see Figure 7b] include transient hypotension, tachycardia or other cardiac dysrhythmias, tachypnea with a significant fall in arterial oxygen and carbon dioxide tension, apprehension, and symptoms or signs of pulmonary infarction^{54,56}; there may be signs of right heart failure as well. Electrocardiography is rarely helpful in the differential diagnosis. Acute right axis deviation, new incomplete right bundle branch block, and changes in S₁, Q₃, or T₃ are thought to characterize this disorder but are found in only a small percentage of patients with proven PE.

If the diagnosis is probable and there are no likely alternatives, heparin therapy should be initiated. Lytic therapy is of debatable utility in these patients: compared with standard heparin therapy, it appears not to reduce mortality or pulmonary dysfunction significantly, yet it carries a higher risk of bleeding.^{3,66} Moreover, lytic therapy is often contraindicated because of recent surgery, injury, or vascular punctures.

If there is a relative contraindication to anticoagulation (e.g., an acute surgical wound, a previous bleeding episode, or an allergic reaction to heparin) or alternative diagnoses are likely, specific diagnosis is required, ideally via pulmonary angiography. Peripheral noninvasive venous studies may be helpful because if they show significant venous obstruction, the likelihood of PE increases and the need for therapy is documented. Ventilation-perfusion scanning, again, is valuable only if strongly positive.

If there is no contraindication to heparin therapy and the diagnosis is strongly suspected but not confirmed, therapeutic-dose heparin anticoagulation should be started.^{67,68} Treatment is continued if the diagnosis is verified and stopped if the diagnosis is excluded.⁶⁹⁻⁷²

Vena Caval Filters

Vena caval interruption has often been recommended for patients with documented PE despite apparently adequate systemic anticoagulation, but many authorities now advocate vena caval filter placement even in patients who do not have documented thromboembolism but are at high risk and in whom anticoagulation is contraindicated.⁷³⁻⁷⁵ Supporting data come largely from studies with historical controls. In the one prospective, randomized, controlled trial involving patients with thromboembolic disease, there was no reduction in mortality at any time, nor was there even a reduction in PE at 2 years; however, there was an increased incidence in DVT over that period.²⁹ These findings suggest that vena cava filters should be reserved for patients with documented DVT, a contraindication to anticoagulation, and a high risk of subsequent PE.

In 2005, an 8-year follow-up analysis of the patients enrolled in the aforementioned prospective, randomized trial²⁹ was published.⁷⁶ Over the 8-year period, the incidence of PE was lower in the group that received inferior vena cava filters than in the group that did not; however, there was an increased rate of recurrent DVT in the filter group. Overall, there was no significant difference in mortality between the two groups. The authors reiterated their recommendation that vena cava filters be used with restraint.

If vena caval interruption is considered necessary, it should be done percutaneously via either the jugular or the femoral route. If it is done by the latter route, phlebography (from the insertion site through the vena cava) should be performed first to document the absence of clot along the planned route. A number of different vena caval filters are currently on the market. Each is slightly different from the others, but none has demonstrated clear superiority in preventing PE or reducing caval thrombosis. Surgeons

should be aware of the advantages and disadvantages of the types available at their institutions.

Removable filters are now widely available. Several have been approved by the FDA and are in clinical use. Because these devices were approved comparatively recently, data on long-term efficacy and complication rates are not yet available.

One of the most critical questions that remains unanswered is, what will be the long-term consequences when the damage caused by the venotomy required for filter removal is superimposed on the endothelial damage caused by the filter? This question should be kept in mind, as should the reservations expressed by the authors of the only prospective, randomized trial of inferior vena caval filters published to date.^{29,76} Still, it appears that removable vena caval filters are likely to have a role to play in this setting. They should be considered in patients who are at extremely high risk for PE, who have an absolute contraindication to anticoagulation for a finite period, and in whom anticoagulation can be instituted upon removal of the filter.

CATASTROPHIC

Catastrophic PE [see *Figure 7c*] is most apt to be superimposed on a critical illness or a major operation. The peak incidence is 7 to 10 days after the procedure or the onset of clinical illness, though emboli may occur at any time.⁵⁴ The reason for this apparent delay is that for the clot to remain intact after embolization to the pulmonary vasculature, it must mature in the vascular system, a process that takes several days. Fresh clot breaks up readily and dissipates promptly, whereas older clot is resistant to lysis. The manifestation of early embolization of fresh clot to the pulmonary vasculature is ARDS. Embolization of older clot can produce acute pulmonary obstruction and acute right heart failure, making radiologic diagnosis of PE relatively easy.⁵⁴ Occlusion of large portions of the vasculature is associated with hemodynamic catastrophe.

Typically, the clinical onset of catastrophic PE comes when a patient, having just been mobilized, performs a vigorous Valsalva maneuver in the course of his or her first postoperative bowel movement. The great abdominal veins distend, and any clot present tends to be stripped loose. If a large clot embolizes, immediate collapse and cardiac arrest may result; in some cases, bradycardia or severe hypotension precedes the actual arrest. Immediate emergency treatment comprises intubation and administration of 100% oxygen, heparin anticoagulation, and, if cardiac arrest occurs, cardiopulmonary resuscitation. A Swan-Ganz catheter should be inserted as soon as possible so that the effects of therapy can be monitored. Cardiotonic agents (e.g., dopamine, 2.0 to 5.0 µg/min, or dobutamine, 2.5 to 10.0 µg/kg/min) should be administered to strengthen myocardial function. If sudden arrest occurs in circumstances that permit emergency thoracotomy, Trendelenburg's procedure can be performed; however, it is rarely indicated and even more rarely successful. If the patient survives initial emergency treatment and improves, high-dose heparin therapy should be continued and lytic therapy considered.^{71,77}

General Principles of Anticoagulation and Lytic Therapy

HEPARIN ANTICOAGULATION

Therapeutic Dose

Heparin therapy may be instituted with either unfractionated heparin or LMWH. In either case, the key is to give enough heparin soon enough to have a beneficial effect. Both types of heparin exert their effect by potentiating antithrombin; thus, if a patient's anti-

thrombin stores are depleted, progressively higher heparin doses will be required to achieve the same degree of anticoagulation.

Unfractionated heparin therapy is also frequently referred to as conventional anticoagulation.⁷⁸⁻⁸⁰ Before therapy is begun, a clotting battery should be performed, consisting of the aPTT, the INR, the platelet count, and levels of fibrinogen, antithrombin, and D-dimer. High fibrinogen levels and platelet counts are seen in patients with chronic clotting syndromes,⁸¹ probably representing overcompensation for increased utilization. Elevated D-dimer levels suggest intravascular clotting with activation of the fibrinolytic system.

In the average patient, therapeutic-dose heparin anticoagulation begins with administration of 5,000 to 10,000 units, followed by continuous I.V. infusion at a rate sufficient to double or triple the aPTT—typically, 1,000 to 2,000 units/hr. When dosages higher than 2,000 units/hr are required, antithrombin depletion is highly probable.

Tight control of the aPTT change as a result of heparin therapy is not as important as monitoring for evidence of bleeding and platelet depletion. Clinical evidence of bleeding is not necessarily a contraindication to anticoagulation. Minimal amounts of blood may be lost in the urine or through the GI tract; if the patient has a clearly identifiable need for anticoagulation, such minor blood loss should be accepted. Only when transfusion is indicated to maintain the hematocrit should discontinuance of heparin be considered. At that point, if the risks of bleeding seem to outweigh the benefits of anticoagulation, heparin infusion can be stopped or reduced to prophylactic levels. It is important to watch for falls in the hematocrit indicative of significant bleeding. The most common sites for hemorrhagic complications are surgical wounds and the retroperitoneum. Retroperitoneal bleeding is generally asymptomatic until the patient progresses to hemorrhagic hypovolemic shock.

As a rule, the therapeutic dose of LMWH is twice the prophylactic dose. The various LMWHs currently on the market all have slightly different activities and half-lives. Enoxaparin may be taken as prototypical. The accepted prophylactic dose for enoxaparin is 30 mg twice daily, and the therapeutic dose is 60 mg (or 1 mg/kg) twice daily.

A major benefit of using LMWHs to treat DVT and PE is that therapeutic doses can be given subcutaneously.^{41,42} As a result, patients may be treated as outpatients both in the acute phase of the disease and in the subacute phase, during the transition to oral anticoagulants. This approach requires that patients be clinically stable and able to follow dosing instructions. Because there are no validated methods of monitoring LMWH therapy, an initial assessment of antithrombin activity is appropriate. If this is low, unfractionated heparin therapy in conjunction with aPTT monitoring is probably preferable.

High Dose

High-dose heparin therapy is reserved for patients who are dying of PE or are at risk for immediate limb loss from phlegmasia cerulea dolens. Such therapy consists of administering a large enough dose of heparin to elevate the aPTT off the scale. The maximum aPTT that can be measured by our laboratory is 150 seconds; high-dose heparin treatment should therefore yield an aPTT higher than this value. Theoretically, given that a fully anticoagulated patient should not form clot at all, the aPTT should be infinite. This method of treatment may be used in patients with immediately life-threatening PE or phlegmasia cerulea dolens when the more conventional technique, catheter-directed thrombolytic therapy, is unavailable.

In most patients, high-dose therapy begins with a 20,000 unit I.V. bolus, followed by infusion of 5,000 units/hr I.V.⁸²⁻⁸⁶ The end point of therapy is clinical evidence of improvement. In patients being treated for PE, pulmonary function should improve.

Because complete anticoagulation is the essential principle of high-dose heparin therapy, there is no need to be concerned about an upper limit for the dosage: if the patient cannot clot, doubling or even tripling the dosage should not increase the risk of bleeding. Moreover, because the incidence of bleeding is very low in the first 2 or 3 days of therapy, regardless of the dosage,^{85,86} high initial dosages do not carry an unacceptable bleeding risk. After heparin has been observed to have an effect and a prolonged aPTT documented, the high dosage should be continued for at least 24 hours, then decreased by 500 to 1,000 units/hr over the next 24 hours. If the clinical effect is maintained and improvement continues, the dosage can be decreased by another 500 to 1,000 units/hr over the following 24 hours. In theory, once all clotting stops, natural antithrombin levels should recover, allowing lower dosages of heparin to be effective. After 3 or 4 days of therapy, the dosage may be reduced to more conventional levels [see Therapeutic Dose, *above*].

If the initial improvement is lost, the dosage should be restored to its previous high level and maintained there for several days before any attempt is made to reduce it again. The platelet count and the hematocrit should be carefully monitored, the latter at least four times a day. Heparin should be discontinued or the dosage reduced only when the risks of bleeding and transfusion exceed the benefits of anticoagulation. In a monitored environment, patients very rarely die of hemorrhage; rather, they die of the consequences of clotting.

Complications

The most devastating hemorrhagic risk of heparin therapy—fortunately, a rare one—is intracranial bleeding. The risk of major hemorrhage ranges from 4% to 9% and is directly affected by how tightly the INR is controlled.⁸⁷ The risk is greatest in elderly patients, particularly women,⁷⁹ but it is still small in comparison with the obvious risks posed by the clotting episode. Nevertheless, the existence of this risk makes it appropriate to use high-dose heparin primarily in life-threatening conditions.

A more common complication of full heparin anticoagulation is retroperitoneal bleeding. This problem is accentuated in elderly patients. Because aging is associated with loss of connective tissue elasticity, bleeding into retroperitoneal connective tissue that would normally be insignificant can become life-threatening. Usually, this is not a serious problem if the hematocrit is followed, heparin dosing adjusted, and lost blood replaced. When the perceived risk of bleeding outweighs the thrombotic risk, heparin should be discontinued.

Two forms of acute heparin-induced thrombocytopenia (HIT) have been reported.⁸⁸⁻⁹¹ Mild HIT occurs in 2% to 5% of patients 2 to 15 days after the initiation of therapy. The platelet count usually remains at about 100,000/mm³, and treatment can be continued without undue risk of bleeding or thrombosis. Severe HIT is much less frequent. It usually occurs about 7 to 14 days after the initiation of heparin therapy and is reversible once the drug is discontinued. It is not dependent on the heparin dose given. Clinical manifestations include a substantial (at least 50%) drop in the platelet count followed by a thrombotic episode (frequently both arterial and venous). An ELISA directed at the platelet factor 4-heparin complex is generally accepted for laboratory confirmation of the diagnosis. Treatment consists of discontinuation of heparin. If the patient still requires anticoagulation, a different

anticoagulant must be used. The most widely accepted agent for this purpose is lepirudin (a direct thrombin inhibitor).⁹² Other direct thrombin inhibitors (e.g., argatroban) and heparinoids (e.g., danaparoid) have also been successfully used to provide anticoagulation in patients with HIT. None of the LMWHs are acceptable in this setting, and at present, the FDA does not allow use of the pentasaccharide in severe HIT.

Unlike warfarin, heparin does not cross the placenta and has not been associated with fetal malformations; thus, it is preferred for thrombotic complications of pregnancy. Heparin can be administered subcutaneously in an outpatient setting for 3 to 6 months. Long-term administration can lead to osteoporosis and spontaneous vertebral fractures.⁹³

Very rarely, heparin therapy can lead to adrenal hemorrhage and consequent adrenal insufficiency.⁷⁹ If acute adrenal insufficiency is suspected, anticoagulant therapy should be discontinued and high-dose steroid therapy (preferably with hydrocortisone) initiated. Treatment should not await laboratory confirmation. CT scanning may be useful. Heparin may suppress aldosterone synthesis, especially with prolonged use.⁷⁹

Reversal of Heparin Effect

The anticoagulant effect of heparin disappears within hours after discontinuance. If the effect must be reversed quickly, the patient should receive protamine sulfate I.V. This agent binds the heparin and prevents it from activating antithrombin. Protamine sulfate should be given in the smallest dosages that still evoke the desired result—typically, about 1 mg for every 100 units of heparin remaining in the patient. It should be administered slowly over 5 to 10 minutes; rapid infusion can cause shortness of breath, flushing, bradycardia, hypotension, or anaphylaxis. On rare occasions, patients previously sensitized to protamine may experience massive platelet aggregation, as manifested by catastrophic arterial thrombosis. Patients particularly likely to manifest this adverse reaction include diabetics and persons with fish allergies. Protamine has little or no capacity for reversing either LMWH or fondaparinux. Research aimed at developing specific protamines to inactivate the LMWHs is now being carried out, but at present, no such agents are available in the United States.

ORAL ANTICOAGULATION

Warfarin is the prototypical oral anticoagulant; the agents in this class have much the same effects, differing primarily with respect to potency and duration of action.^{79,80} Warfarin is also available in an I.V. form; however, in view of its mechanism of action, caution should be exercised when it is given parenterally.

Dosage

Historically, warfarin dosage has been regulated by monitoring the prothrombin time (PT), with a PT 1.5 to 2.5 times normal (11 or 12 seconds) generally considered to represent the optimal level. In response to the wide variations in PT reported by different laboratories, the World Health Organization (WHO) has recommended substituting the INR for the PT ratio so that all laboratory assessments will be comparable.⁹⁴ An INR of 2.0 to 3.0 corresponds to a PT that is 1.3 to 1.5 times normal (moderate dose); an INR of 3.0 to 4.5 corresponds to a PT that is 1.5 to 2.0 times normal (high dose). Lower INRs are recommended for all but extremely high-risk patients (e.g., those with mechanical heart valves) [see Table 3].⁹⁴

Initially, the daily dose of warfarin required to increase the INR to between 2.0 and 3.0 is estimated and administered. The INR is then checked every morning. If it suddenly overshoots the target

Table 3 Recommendations for Use of Varying Dosages of Warfarin

The dosage of warfarin is regulated by monitoring the INR. A less intense therapeutic range (INR = 2.0 to 3.0, corresponding to a PT 1.3 to 1.5 times normal with a WHO-designated thromboplastin) is appropriate for the following applications:

1. The prevention of venous thromboembolism in high-risk patients.
2. The treatment of venous thrombosis and PE after an initial course of heparin.
3. The prevention of systemic embolism (a) in patients with tissue heart valves, (b) in selected patients with atrial fibrillation, (c) in patients with acute anterior wall myocardial infarction, and (d) in patients with valvular heart disease.

A more intense therapeutic range (INR = 3.0 to 4.5, corresponding to a PT 1.5 to 2.0 times normal with a WHO-designated thromboplastin) is appropriate for patients with mechanical prosthetic valves and patients with recurrent systemic embolism.

INR—international normalized ratio PT—prothrombin time WHO—World Health Organization

range, the warfarin dosage is reduced. If the INR has not reached or surpassed 1.5 after the third dose, the dosage is increased. The maintenance dosage averages about 5 mg/day but may range from 1 to 10 mg/day.

While the maintenance dosage is being determined, the INR should be checked daily. Once the patient stabilizes, the INR can be checked less often: twice weekly for the first few weeks, once weekly for the next several months, and once monthly thereafter if the patient is stable. The patient should be cautioned about drug interactions. If the dosages of other medications are changed, the impact on the INR should be investigated and the warfarin dosage adjusted as appropriate.

Duration

There is no general agreement on how long oral anticoagulant therapy should be continued after a thromboembolic event. Current data suggest that the duration of therapy should be based on the level of underlying risk rather than on the severity of the event. For patients with a limited risk period (e.g., a young patient with a femur fracture and no other risk factors), an 8- to 12-week course is as efficacious as a longer course.⁹⁵ For patients with a lifelong risk (e.g., a patient with a congenital hypercoagulability syndrome or cancer), a therapeutic dosage for 3 to 6 months, followed by a low dosage for the remainder of the patient's life, is indicated.⁸⁷ Lengthening the duration of full anticoagulant therapy in patients with long-term risk factors appears only to delay the recurrence of thromboembolism, not to prevent it.

Drug Interactions

Response to warfarin is affected not only by various bodily factors but also by drug interactions [see Table 4]. Such interactions are most dangerous when drugs administered in parallel are taken intermittently.^{79,80} Increased metabolic clearance of the drug can result from administration of barbiturates, rifampin, or phenytoin; long-term use of alcohol; ingestion of large amounts of vitamin K; and rich foods. Elevated levels of coagulation factors during pregnancy also decrease warfarin's effectiveness.

Decreased metabolism or displacement from protein-binding sites caused by phenylbutazone, sulfinpyrazone, metronidazole, disulfiram, allopurinol, cimetidine, amiodarone, or acute intake of ethanol can elevate the INR and increase the risk of hemorrhage. Relative vitamin K deficiency, resulting from inadequate diet or the

elimination of the intestinal flora by antimicrobial agents, may have similar effects. For these reasons, warfarin should be used with great caution in patients who are receiving antibiotics or who cannot tolerate a regular diet.

There are some serious interactions that increase the risk of bleeding without altering the INR. These include inhibition of platelet function by drugs such as aspirin and gastritis or gastric ulceration induced by anti-inflammatory drugs. Obviously, when placing a patient on more than one anticoagulant simultaneously, great care must be taken.

Complications

Bleeding is the major complication of oral anticoagulation. Tight control of warfarin therapy is essential for minimizing this complication.⁸⁷ Bleeding is rare when the INR is kept below 3.0. When bleeding does occur, a preexisting lesion is likely. If the bleeding is minor, the warfarin dosage should be adjusted; if it is major, the drug may have to be discontinued. The risk of intracerebral or subdural hematoma is greater with warfarin than with heparin, particularly in patients older than 50 years. If there is any sign of hemorrhage, the next anticoagulant dose should be withheld and the INR measured. For continued or serious bleeding, 5 to 10 mg of vitamin K₁ oxide (phytonadione) I.V. is effective. Several hours may pass before hemostasis improves significantly, and 24 hours or longer may be needed for maximal effect. If immediate restoration of hemostatic competence is necessary, levels of vitamin K-dependent coagulation factors can be raised by giving fresh frozen plasma, 10 to 20 ml/kg body weight, or prothrombin complex concentrate.⁹⁶

Administration of warfarin during pregnancy can cause birth defects and abortion and therefore is contraindicated. Warfarin-induced skin necrosis is a rare complication of oral anticoagulant therapy.⁹⁰ This syndrome, characterized by the appearance of skin lesions shortly after initiation of treatment, may be the result of a

transient hypercoagulable state caused by depletion of the natural anticoagulants (proteins C and S) before the onset of warfarin's effect. To mitigate the initial hypercoagulable state, some advocate starting warfarin therapy only after initial heparinization.

Investigational Oral Anticoagulant

A newer oral anticoagulant, the direct thrombin inhibitor ximelagatran, has been approved for use in Europe and has been widely studied; however, it has not been approved by the FDA for use in the United States. Initial studies of this agent yielded promising results, raising hopes that there might be an effective oral anticoagulant that is safer and easier to administer than warfarin.

In a prospective, double-blind study from 2003, more than 1,800 patients undergoing knee surgery were randomly assigned to receive either ximelagatran or warfarin.⁹⁷ Venography was performed on day 7. Warfarin was given in standard dosages, with a target INR of 2.0 to 3.0. Ximelagatran was given in two different doses (as a dosing trial), without monitoring. The authors observed a significantly lower incidence of DVT in the ximelagatran group, with no significant difference in bleeding. After the publication of this study, several reports of adverse reactions (specifically, liver failure) were reported to the FDA.

In a subsequent study, almost 4,000 patients with atrial fibrilla-

tion were randomly assigned to receive either warfarin or ximelagatran for stroke prophylaxis.⁹⁸ The authors found no significant differences in the rates of stroke, embolism, or death but did note a significantly higher incidence of bleeding in the warfarin group. They also found that a significant percentage of the patients in the ximelagatran group had increases in their hepatic enzymes that were correlated with administration of the drug. In addition, there were cases of fatal hepatic failure that could have been associated with the drug.

Thus, ximelagatran appears to hold great promise, but it is unclear whether it will be approved for the American market.

LYTIC THERAPY

A number of different lytic agents have been studied [see Table 5]. At present, however, lytic therapy is generally understood to refer to administration of streptokinase, urokinase, or t-PA,^{79,80,99–102} all of which act on the endogenous fibrinolytic system to convert plasminogen to plasmin. Streptokinase combines with plasminogen to form streptokinase-plasminogen complexes that are converted to streptokinase-plasmin complexes, which then convert residual plasminogen to plasmin.^{79,102} Urokinase directly cleaves a peptide bond in the plasminogen molecule to form plasmin. t-PA binds to fibrin via lysine binding sites at the N-terminal.

Lytic therapy is most effective when it can be initiated within hours. It is worth attempting when the clot has been present for less than 1 week, particularly if it has been present for less than 3 days. When lytic therapy is begun, heparin therapy usually is temporarily discontinued because of the theoretical possibility of increased bleeding risk; it may be resumed immediately upon completion of lytic therapy. If, however, the problem is immediately life-threatening (e.g., myocardial infarction or massive PE), anticoagulation should probably be done in parallel with lytic therapy to prevent rethrombosis.

Indications and Contraindications

The indications for lytic therapy are being extended.⁹⁶ Urokinase, t-PA, and, to a much lesser degree, streptokinase are being used for venous thrombotic conditions, such as symptomatic obstruction of major upper-extremity veins. The morbidity of axillary vein thrombosis can be considerable; clearance of clot may not only help restore patency but also help identify the underlying cause. In the lower extremities, more thorough clearance of clot should, in theory, help restore valve function and prevent so-called post-phlebitic syndrome.^{101,103}

Contraindications to lytic therapy include surgery in the previous 10 days, serious GI bleeding in the previous 3 months, a history of hypertension, an active bleeding or hemorrhagic disorder, a previous cerebrovascular accident, and an active intracranial process. As with heparin, the risk of intracranial bleeding is increased in older patients; the risk appears to be higher with t-PA than with streptokinase or urokinase.

Agents

Streptokinase Streptokinase is a 47 kd protein produced by β -hemolytic streptococci. Because it is not endogenous, circulating antibodies to it (from previous streptococcal infections) often are already present in plasma. When streptokinase is infused, a loading dose must be given to overcome these antibodies. Once the antibodies are depleted, the half-life of streptokinase is about 80 minutes. Achievement of the desired therapeutic effects is confirmed by documenting a rise in the thrombin time (TT), a fall in the fibrinogen level, or an abrupt rise in the D-dimer level. Because streptokinase may deplete circulating plasminogen after a few hours, the optimal approach may be to administer it for 6 hours by continuous infusion every 24 hours for 2 or 3 days, then to administer heparin in the intervals between infusions.

Urokinase Urokinase is a 34 kd globulin originally found in human urine and now isolated from cultured human cells. It has a half-life of 15 minutes and is metabolized by the liver. It was removed from the U.S. market for several years as a result of concerns expressed by the FDA, but it subsequently was reintroduced after these concerns were satisfactorily addressed. For catheter clearance, a solution containing 5,000 units/ml should be infused into the obstructed tubing. Urokinase is not fibrin-specific and therefore produces a systemic lytic state. Its primary disadvantage is that it costs far more than streptokinase.

t-PA Tissue plasminogen activator is an enzymatic glycoprotein composed of 527 amino acids that is produced from a human melanoma cell line by means of recombinant DNA technology. Its half-life is approximately 4 minutes; it is metabolized by the liver, and approximately 80% of the dose is excreted in the urine within 18 hours. It is not antigenic and does not promote antibody formation. Theoretically, t-PA should be somewhat more specific for fibrin clot than urokinase or streptokinase. In practice, however, its

effects are clinically indistinguishable from those of urokinase. Like urokinase, t-PA is extremely expensive.

Technique of Administration

The traditional method of administering lytic therapy, venous infusion, is widely used to treat coronary artery thrombosis¹⁰⁴; however, it is only modestly effective against peripheral arterial occlusion and is associated with a high rate of hemorrhagic complications.¹⁰⁵ Current methods focus more closely on the site of occlusion, particularly with the development of intra-arterial infusion techniques.

Lytic therapy for acute PE has attractive theoretical benefits; however, the FDA currently approves this approach only for patients with so-called massive PE (i.e., PE resulting in both shock and heart failure). Clinical trials demonstrated that in patients who were hemodynamically unstable as a result of PE, thrombolysis achieved greater improvements in intermediate end points (e.g., right ventricular function) than heparin alone did, though survival was not improved.¹⁰⁶ Subsequent studies evaluated recombinant t-PA in patients with so-called submassive PE, with similar results.⁶⁶

Monitoring

Although monitoring of lytic therapy is less standardized than monitoring of anticoagulant therapy, several principles should be followed. The effects must be monitored from both a clinical and a laboratory perspective. Clinical monitoring involves following improvements on the angiograms. Laboratory monitoring has three components. First, D-dimer levels should be measured; a marked increase signals that cross-linked fibrin is undergoing breakdown. Second, adequate stores of plasminogen should be documented; without plasminogen, none of the thrombolytic drugs are effective. Third, fibrinogen levels should be followed to prevent exhaustion of native clotting; most authorities recommend that lytic therapy be discontinued once fibrinogen levels fall below 50 mg/dl. Previously, the TT was used for monitoring thrombolysis; today, however, given the recommendation for concurrent use of heparin,¹⁰⁴ the TT is considered to be of little value in this setting.

Complications

The major toxicity of all three major lytic agents is hemorrhage, resulting from (1) lysis of physiologic thrombi occurring at vascular injury sites and (2) a systemic lytic state caused by the systemic formation of plasmin. The incidence of bleeding is many times higher after lytic therapy than after anticoagulant therapy and is dependent on both the dosage and the duration of lytic therapy. Careful administration of lytic agents can keep the incidence of major hemorrhage below 5% and the incidence of intracranial hemorrhage below 1%.¹⁰²

A potential major complication is distal embolism of partially lysed clot. In theory, this possibility should rule out lytic therapy for treating thrombus in the heart or in the cerebrovascular system.¹⁰² Surprisingly, however, dislodgment of intracardiac clot as a result of lytic therapy is rare.

Streptokinase causes several adverse reactions that urokinase and t-PA do not. When first produced, streptokinase was associated with a very high incidence of antigenicity and severe pyrogenic reactions. The current purified formulation is relatively free of pyrogens and has a reduced incidence of allergic side effects, but it is still antigenic and may still cause allergic reactions or, in rare instances, anaphylaxis. Streptokinase may also induce the formation of additional antibodies that make re-treatment impossible. In contrast, retreatment with urokinase may be carried out as often as necessary with minimal risk of allergic reactions.

Hypercoagulability States

Certain patients seem to have a tendency to clot spontaneously. So-called hypercoagulability states were long thought to exist, but they were difficult to document except on clinical grounds. Currently, however, these clotting tendencies are better understood,¹⁰⁷ thanks in large part to recognition of the role of antithrombins. If an antithrombin deficiency exists and clotting goes unchecked, activation of a clotting cascade could theoretically progress to clotting throughout the entire vasculature. Another important development was the recognition that deficiencies of certain natural clot-removing substances in the blood may lead to a clinical thrombotic tendency. Both types of deficiency can be either acquired or congenital.

SCREENING

When the etiology of a clotting episode is unclear, the family history should be reviewed for evidence of a congenital disorder. Even if the history is negative, the patient should be screened for both acquired and congenital disorders [see Figure 9].

Acquired Clotting Conditions

Screening for acquired clotting conditions [see Table 6] is based on the history, physical examination, and laboratory assessment. The history should include medications, diseases, and surgical procedures or other injuries.¹⁰⁸⁻¹¹⁰ Examination may disclose causes of hypercoagulability.¹¹¹ Soft tissue injury, for example, is a potent activator of the coagulation system. If the injury is severe enough, it may be capable of causing a severe acquired coagulopathy. The problem is usually obvious, but on occasion, detailed study may be necessary to identify tissue damage or ischemic injury to bowel or extremities. Hypovolemia—especially hypovolemic shock—markedly reduces clotting time: blood from a patient in profound shock may clot instantaneously in the syringe as it is being drawn. The breakdown of red cells in a hemolytic transfusion reaction can cause clotting. Severe infection, especially from gram-negative organisms, is a potent activator of coagulation.¹¹²

Of the acquired hypercoagulability syndromes, Trousseau syndrome is a particularly important condition for surgeons to recognize because it occurs in the surgical population (cancer patients) and must be treated with heparin (it is unresponsive to warfarin). It occurs when an adenocarcinoma secretes a protein recognized by the body as tissue factor, resulting in multiple episodes of venous thromboembolism over time (migratory thrombophlebitis). Simple depletion of vitamin K-dependent factors is ineffective. Patients should receive therapeutic-dose heparin indefinitely or until the cancer is brought into remission.¹¹³

Laboratory screening may facilitate diagnosis. A complete blood count may document the presence of polycythemia or leukemia. Thrombocytopenia may be a manifestation of a hypercoagulable disorder, and thrombocytopenia after the administration of heparin raises the possibility of intravascular platelet aggregation. A prolonged aPTT is suggestive of lupuslike anticoagulant. Increased levels of D-dimers, fibrin degradation products (FDPs), or fibrin monomers in the plasma may reflect low-grade intravascular coagulation.

Congenital Clotting Conditions

Congenital clotting tendencies can result from deficiencies in inhibitors of thrombosis (antithrombin, proteins C and S, and possibly heparin cofactor II), dysfibrinogenemias, or dysfibrinolysis [see Table 7]. Most congenital clotting defects are transmitted as an autosomal dominant trait. A negative family history does not pre-

clude inherited thrombophilia, because the defects have a low penetrance, and fresh mutations may have occurred.

INITIAL LABORATORY ASSESSMENT

Initial evaluation of a patient with an unexplained thrombotic episode should be directed at the most common causes of hypercoagulability. Acquired causes of clotting are more commonly seen by surgeons than congenital causes and therefore must be excluded first. If a clotting disorder is determined to be congenital, a laboratory workup should be undertaken. Several of the relevant assays (see below)—specifically, the functional assays—should be performed after the acute phase of the disorder has passed. If they are performed during the acute phase, levels of several antithrombotics (e.g., antithrombin and proteins C and S) will be misleadingly low—not because deficiencies of these substances caused the underlying thrombotic process but because they were consumed in that process.

SPECIFIC CAUSES OF THROMBOTIC TENDENCY

The most common congenital causes of accelerated clotting are mutations of prothrombin (prothrombin G20210A mutation) and factor V (Leiden mutation, or activated protein C resistance).¹¹⁴⁻¹¹⁶ The prevalence of each of these ranges from 1% to 5% in the general population and may be much higher in specific ethnic subpopulations.¹¹⁷ Each mutation may be identified conclusively by means of polymerase chain reaction (PCR) techniques. Detection of these mutations, unlike assays for antithrombin and proteins C and S, is not dependent on the patient's current inflammatory state. It must be remembered that the presence of one of these mutations, especially in the heterozygous form, does not imply that it is the sole cause of thrombosis. In many patients, a second precipitating factor must be present for the pathologic genetic thrombotic potential to be manifested.

Prothrombin G20210A Mutation

The prothrombin G20210A mutation is known to involve a single amino acid substitution in the prothrombin gene, but precisely how this increases the risk of venous thromboembolism is unclear. The one apparent manifestation of the mutation is a 15% to 40% increase in circulating prothrombin. Regardless of the mechanism at work, patients who are at least heterozygous for the trait are at two- to sixfold greater risk for venous thromboembolism than those without the mutation.¹¹⁸

Resistance to Activated Protein C (Factor V Leiden)

Resistance of human clotting factors to inactivation by activated protein C is believed to be the most common inherited procoagulant disorder.¹¹⁴ Normally, activated factor V is degraded by activated protein C in the presence of membrane surface as part of normal regulation of thrombosis. Activated protein C resistance is caused by a single substitution mutation in the factor V gene, which is passed in an autosomal dominant fashion. The mutant factor V that results, termed factor V Leiden, is resistant to inactivation by activated protein C and thus has a greater ability to activate thrombin and accelerate clotting.

Two techniques are commonly used to diagnose this disorder. The first is a functional assay that compares a standard aPTT to one performed in the presence of exogenous activated protein C. If the latter aPTT does not exhibit significant prolongation, the patient is probably resistant to activated protein C. The results of this assay must be interpreted with caution if the patient is still in the acute phase of the illness. The second technique, which is more reliable, involves direct detection of the mutation via PCR analysis of DNA.

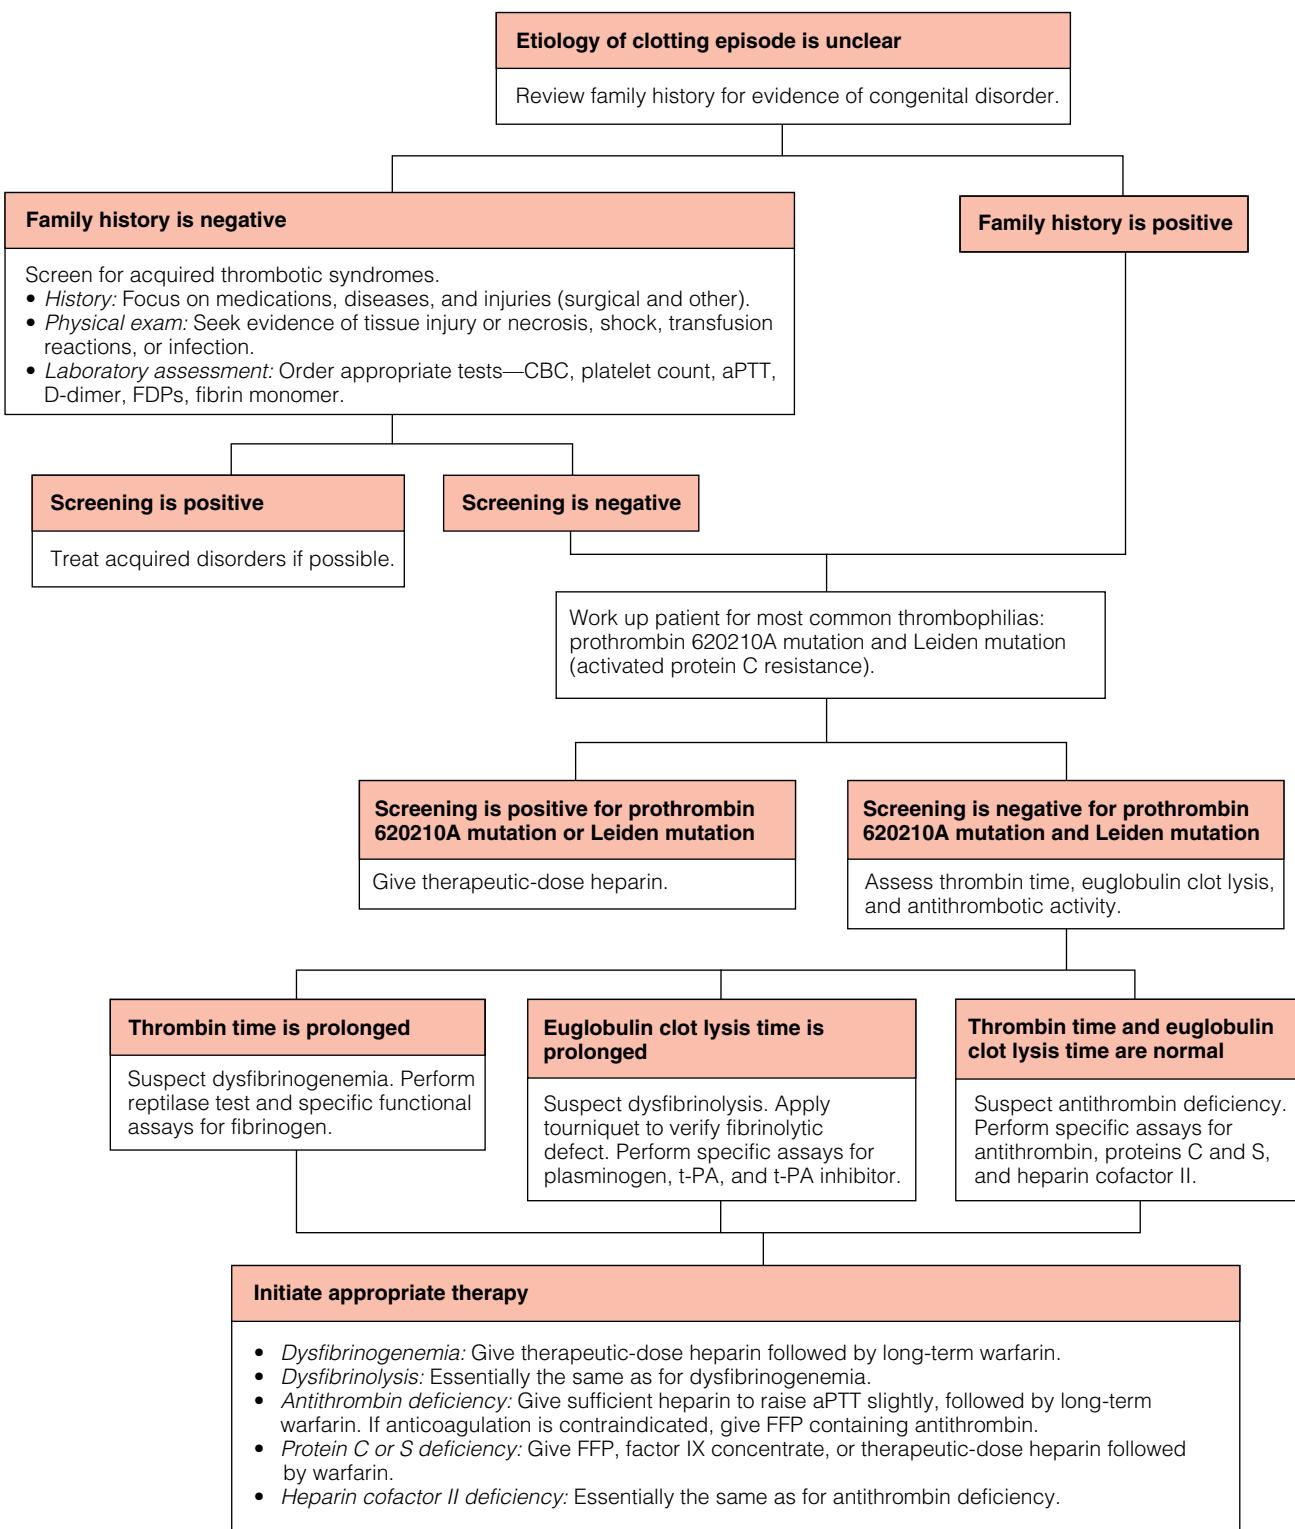

Figure 9 Shown is an algorithm for screening for acquired and congenital thrombotic syndromes.

Antithrombin Deficiency

Antithrombin (once termed antithrombin III) is a 65 kd protein that decelerates the coagulation system by inactivating activated factors—primarily factor Xa and thrombin but also factors XII, XI, and IX.^{119,120} Antithrombin therefore acts as a scavenger of activated clotting factors. Its activity is enhanced 100-fold by the presence of heparans on the endothelial surface

and 1,000-fold by administration of exogenous heparin.

Congenital antithrombin deficiency occurs in approximately 0.01% to 0.05% of the general population and 2% to 4% of patients with venous thrombosis.¹¹⁹ The trait is passed on as an autosomal dominant trait, with the heterozygous genotype being incompatible with life. Antithrombin-deficient patients are at increased risk for thromboembolism when their antithrombin activi-

Warfarin	

ity falls below 70% of normal.¹²¹

Patients with congenital antithrombin deficiency frequently present after a stressful event. They usually have DVT but sometimes have PE. If anticoagulation is not contraindicated, the treatment of choice is heparin at a dosage sufficient to raise the aPTT to the desired level, followed by warfarin. If anticoagulation is contraindicated (as it is during the peripartum period), antithrombin concentrate should be given to raise the antithrombin activity to 80% to 120% of normal during the period when anticoagulants cannot be given.

Acquired antithrombin deficiency is a well-recognized entity. In most patients undergoing severe systemic stress, antithrombin levels fall below normal.¹²² Patients with classic risk factors for venous thromboembolism tend to have the lowest levels.

Protein C and Protein S Deficiency

Protein C is a 62 kd glycoprotein with a half-life of 6 hours. Because it is vitamin K dependent, a deficiency will develop in the absence of vitamin K. Acquired protein C deficiency is seen in liver disease, malignancy, infection, the postoperative state, and disseminated intravascular coagulation.⁴⁹ Protein C deficiency occurs in approximately 4% to 5% of patients younger than 40 to 45 years who present with unexplained venous thrombosis.¹²³ It is transmitted as an autosomal dominant trait, and the family history is usually positive for a clotting tendency. Protein C levels range from 70% to 164% of normal in patients without a clotting tendency; levels below 70% of normal are associated with a thrombotic tendency. The most appropriate tests for screening are functional assays; there are cases of dysfunctional protein C deficiency in

which protein C antigen levels are normal but protein C activity is low, and these would not be detected by the usual immunoassays.

Protein S is a vitamin K-dependent protein that acts as a cofactor for activated protein C by enhancing protein C-induced inactivation of activated factor V. The incidence of protein S deficiency is similar to that of protein C deficiency.¹²³ It is transmitted as a dominant trait, and the family history is often positive for a thrombotic tendency.

Hyperhomocysteinemia

Although hyperhomocysteinemia is more commonly associated with cardiac disease and arterial thrombosis, it may also be associated with an increased incidence of venous thromboembolism.¹²⁴ This association is not as strong as those already discussed (see above). Accordingly, anticoagulation of asymptomatic patients with elevated homocysteine levels is not currently recommended.

Dysfibrinogenemia

More than 100 qualitative abnormalities of fibrinogen (dysfibrinogenemias) have been reported.¹²⁵ Dysfibrinogenemias are inherited in an autosomal dominant manner, with most patients being heterozygous. Most patients with dysfibrinogenemia have either no clinical symptoms or symptoms of a bleeding disorder; a minority (about 11%) have clinical features of a recurrent thromboembolic disorder.^{126,127} Congenital dysfibrinogenemias associated with thrombosis account for about 1% of cases of unexplained venous thrombosis occurring in young people. The most commonly observed functional defect in such dysfibrinogenemias is abnormal fibrin monomer polymerization combined with resistance to fibrinolysis. Decreased binding of plasminogen and increased resistance to lysis by plasmin have been noted.

In addition to a prolonged TT, patients who have dysfibrinogenemia associated with thromboembolism may have a prolonged INR. The diagnosis is confirmed if the reptilase time is also prolonged. Measured with clotting techniques, fibrinogen levels may be slightly or moderately low; measured immunologically, levels may be normal or even increased.

Dysfibrinolysis

Fibrinolysis can be impaired by inherited deficiencies of plasminogen, defective release of t-PA from the vascular endothelium, and high plasma levels of regulatory proteins (e.g., t-PA inhibitors).^{127,128} In addition, factor XII (contact factor) deficiency may induce failure of fibrinolysis activation.

Inherited plasminogen deficiency is probably only rarely responsible for unexplained DVT in young patients. It is transmitted as an autosomal dominant trait. In heterozygous persons with a thrombotic tendency, plasminogen activity is about one half normal (3.9 to 8.4 μ mol/ml). The euglobulin clot lysis time is prolonged. Functional assays should be carried out, and there should be full transformation of plasminogen into plasmin activators.

The important role of t-PA inhibitors I and II in the regulation of fibrinolysis is well defined.^{128,129} In normal plasma, t-PA inhibitor I is the primary inhibitor for both t-PA and urokinase. Release of t-PA inhibitor I by platelets results in locally increased concentrations where platelets accumulate. The ensuing local inhibition of fibrinolysis may help stabilize the hemostatic plug. t-PA inhibitor II is present in and secreted by monocytes and macrophages.

Factor XII deficiency is a rare cause of impaired fibrinolysis. Initial contact activation of factor XII not only results in activation of the clotting cascade and of the inflammatory response but also leads to plasmin generation. This intrinsic activation of fibrinolysis requires factor XII, prekallikrein, and high-molecular-weight ki-

Table 7 Congenital Clotting Disorders

Prothrombin G20210A mutation
Activated protein C resistance (Leiden V mutation)
Antithrombin deficiency
Proteins C and S deficiency
Dysfibrinogenemias
Dysfibrinolysis
Hypoplasminogenemia
Impaired release of t-PA
High levels of t-PA inhibitor
Factor XII deficiency

ninogen. Patients with factor XII deficiencies can be identified by a prolonged aPTT in the absence of clinical bleeding.^{107,130}

TREATMENT

Treatment of a clinical hypercoagulable state involves both prophylaxis [see Prophylaxis against Thromboembolism, *above*] and specific treatment.¹³¹ Prophylaxis in postoperative patients consists primarily of maintaining good hydration, ensuring normal cardiac output, and early mobilization. Low-dose heparin, intermittent pneumatic compression, low-molecular-weight dextran, or some combination of these may also be appropriate.

Patients with activated protein C resistance who present with venous thrombosis should be treated with heparin in the standard fashion. They also should receive genetic counseling and refrain from using oral contraceptives.

Treatment of antithrombin deficiency associated with active clotting involves initiating heparin anticoagulation at a dosage sufficient to ensure a significant rise in the aPTT. Warfarin is the drug

of choice for long-term prophylaxis and should be given at a dosage sufficient to maintain an INR of 2.0 to 3.0. When anticoagulation is contraindicated, a purified form of antithrombin may be administered directly. Patients with acquired antithrombin deficiency should receive prophylaxis in the form of heparin at a dosage sufficient to raise the aPTT 5 seconds above the upper limit of the normal laboratory value.

Treatment of clotting states related to protein C or protein S deficiency involves administering fresh frozen plasma or factor IX concentrate. Therapeutic-dose heparin followed by warfarin may be appropriate for long-term treatment.

Treatment of thromboembolism associated with dysfibrinogenemia involves therapeutic-dose heparin followed by long-term warfarin. Treatment of thromboembolic disorders associated with dysfibrinolysis is essentially the same as that of dysfibrinogenemia. Some patients with these qualitative plasminogen defects and acute massive thrombotic events may not respond to fibrinolytic treatment with urokinase or streptokinase.

7 DIABETIC FOOT

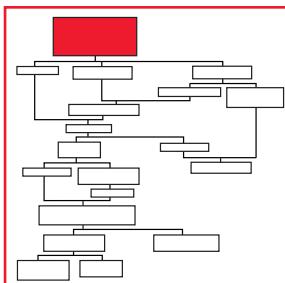

Cameron M. Akbari, M.D., F.A.C.S., and Frank W. LoGerfo, M.D., F.A.C.S.

Evaluation and Management of the Diabetic Foot

Surgeons caring for diabetic patients are faced with a diverse spectrum of foot disease.^{1,2} The clinical presentation may range from the asymptomatic patient who requires nothing more than preventive foot care to the unstable and critically ill patient in whom both loss of limb and death are imminent threats. This wide range of disease severity, coupled with inappropriate and untimely use of diagnostic testing, contributes to the clinical confusion that often leads to delays in diagnosis and treatment and, ultimately, to limb loss. It is important, therefore, that surgeons caring for diabetic patients develop a simple but comprehensive and orderly approach to diabetic foot problems that (1) can be implemented for any such problem, (2) recognizes the pathogenic roles of neuropathy, ischemia, and infection, and (3) emphasizes the initial clinical assessment at the bedside.³

Clinical Evaluation

Evaluation of any diabetic foot problem begins with a complete history and a careful physical examination. Broadly speaking, such evaluation should address the healing potential of the foot, the details of the foot problem (e.g., ulcer, gangrene, infection, or osteomyelitis), the systemic consequences of diabetes, and any immediate threats to life or limb. With this information in hand, the surgeon can usually make an accurate diagnosis and start a comprehensive treatment plan without having to order further diagnostic tests, which are liable to be both costly and time-consuming.

HISTORY

The history of the foot problem can yield valuable insights into the potential for healing, the presence of coexisting infection or arterial occlusive disease, and the need for further treatment. Whenever a patient presents with a foot ulceration or gangrene, possible underlying arterial insufficiency should immediately be suspected, even if neuropathy or infection is present. It is helpful to be aware of the event that incited the foot problem. In a patient with diabetes and arterial insufficiency, the inciting event for a foot ulcer may be a seemingly benign action, such as cutting a toenail, soaking the foot in a warm bath, or applying a heating pad. Unfortunately, because of the broad microneurovascular and macrovascular abnormalities associated with diabetes, these relatively innocuous actions can progress to a nonhealing ulcer and gangrene. Similarly, failure to heal after any podiatric procedure is strongly suggestive of underlying unrecognized arterial insufficiency.

The duration of the ulcer also provides important clues, in that a long-standing, nonhealing ulcer is strongly suggestive of ischemia. Certainly, an ulcer or gangrenous area that has been present for several months is unlikely to heal without some further treatment, whether it be offloading of weight-bearing areas, treat-

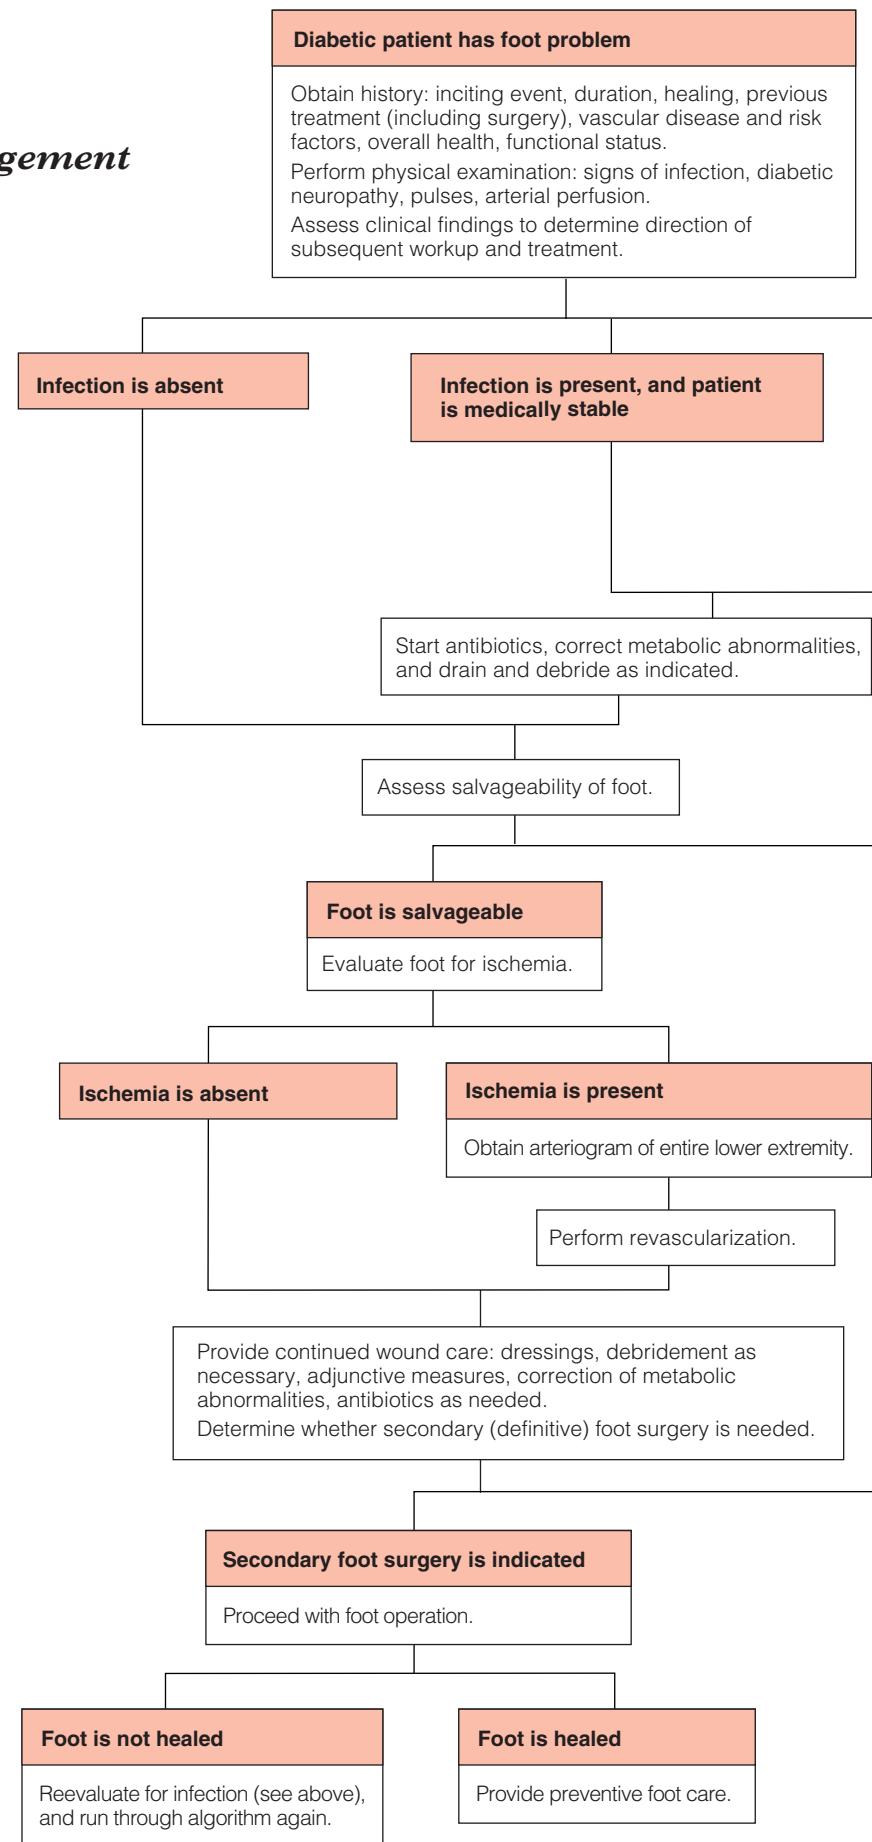

ment of infection, or, most commonly, correction of arterial insufficiency. In some cases, the present ulcer has already healed at least once, and the current episode represents a relapse. A history of intermittent healing followed by relapse raises the possibility of underlying untreated infection (e.g., recurrent osteomyelitis) or an uncorrected architectural abnormality (e.g., a bony pressure point or a varus deformity).

In view of the many vague and unsupported therapies advocated for the diabetic foot, it is helpful to know the type and duration of any treatments the patient has already undergone for the current problem. For example, a patient with an ischemic ulceration may have completed several different courses of antibiotics without success. Thus, if antibiotic therapy is contemplated for a current infection, possible antibiotic resistance must be taken into account in choosing the appropriate agent. It is also helpful to know which treatments were not previously offered to the patient and to look critically at why they were not offered. For example, many diabetic patients with correctable foot ulceration and limb ischemia are told that their only option is limb amputation, usually because of the physician's inherited pessimism or his or her inadequate knowledge of the advances made in limb and foot salvage. No patient should be denied an opportunity for limb salvage on the basis of a previous medical or surgical opinion without a new comprehensive evaluation being performed.

Inquiries should be made about any previous foot and limb problems—for instance, whether the patient had other ulcers on the same foot that healed spontaneously, how long such healing took, and whether foot surgery was ever performed on that side. A history of recent ipsilateral ulceration or foot surgery that healed in a timely and uncomplicated manner suggests, but does not prove, that the arterial supply is adequate. Problems and procedures more remote in time, however, are less useful indicators. A history of previous leg revascularization (including percutaneous therapies) is also an important clue to possible underlying arterial insufficiency. Because of the predilection for mirror image-type atherosclerotic occlusive disease, the contralateral leg must be considered as well: previous revascularization in the opposite leg is often associated with arterial insufficiency on the affected side. Other cardiovascular risk factors, such as cigarette smoking and hyperlipidemia, must also be taken into account: their presence increases the likelihood that ischemia is contributing to the current foot problem.

Although claudication and rest pain have traditionally been associated with vascular disease, they may be obscured by diabetic neuropathy; hence, their absence in the diabetic patient certainly does not rule out ischemia. Because even moderate ischemia precludes healing in the diabetic foot, the absence of rest pain is not a reliable indicator of an adequate arterial blood supply; moreover, many patients may not be walking long enough distances for vasculogenic claudication to develop. Conversely, some patients with true ischemic rest pain are dismissed for years as having “painful neuropathy.”

Evaluation and Management of the Diabetic Foot

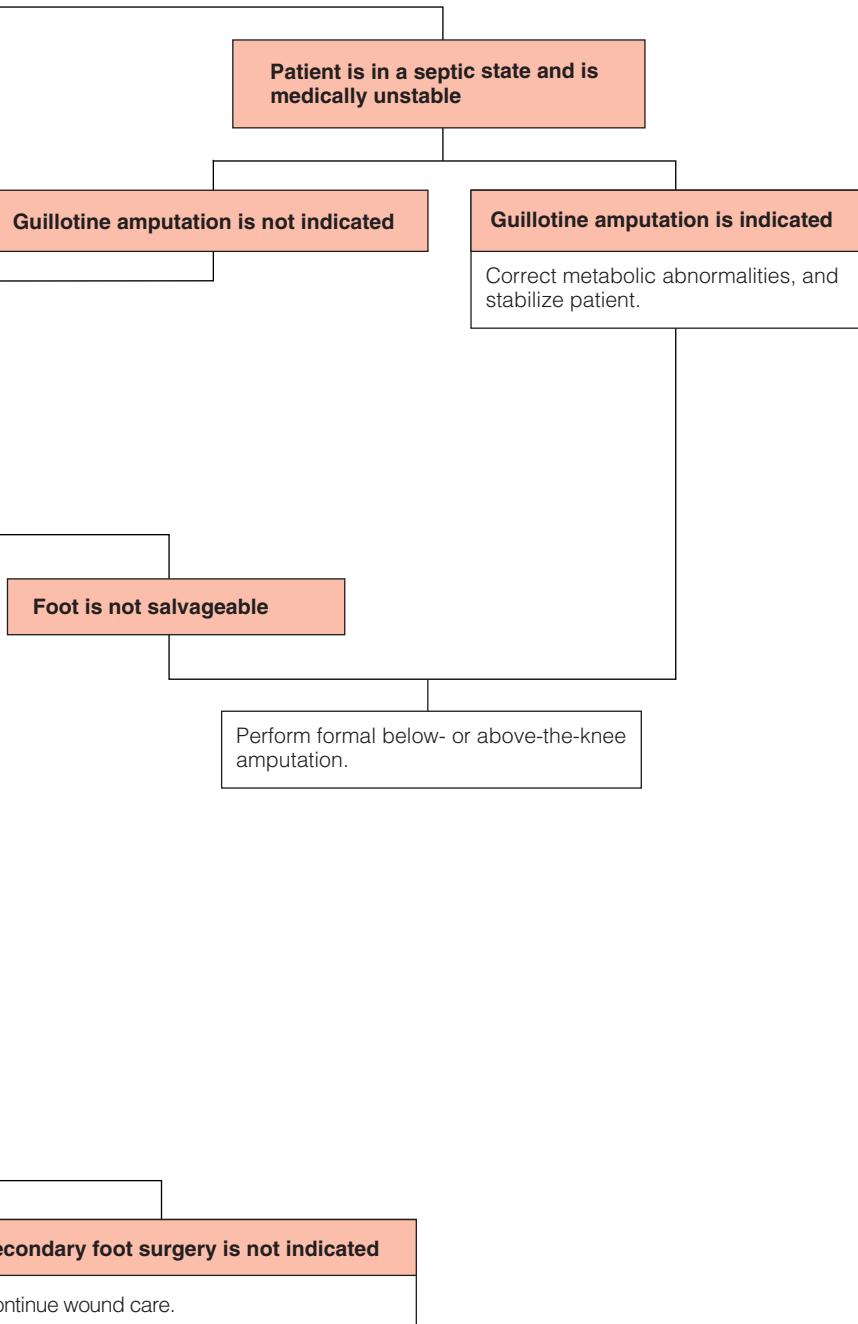

Figure 1 Shown is a benign-appearing gangrenous eschar (a) on the foot of a diabetic patient. Plain x-ray (b) reveals extensive subcutaneous air in soft tissue, consistent with severe necrotizing fasciitis.

Both the systemic effects of the foot problem and the systemic consequences of diabetes itself should be assessed. Because unrecognized infection in the diabetic patient may rapidly progress to a life-threatening condition, attention should be directed toward detecting the subtle manifestations of an infected foot ulcer. The patient should be asked about worsening hyperglycemia, recent erratic blood glucose control, and higher insulin requirements. As a consequence of the microvascular and neuropathic abnormalities in the diabetic foot, classic symptoms of infection (e.g., chills and pain) are often absent, and hyperglycemia is often the sole presenting symptom of undrained infection. Faced with ongoing infection and hyperglycemia, the surgeon should strongly suspect impending ketoacidosis or nonketotic hyperglycemic hyperosmolar coma, with the attendant symptoms of weakness, confusion, and altered mental status.

Because a patient with a diabetic foot problem often needs some type of operative intervention, the history should also include a comprehensive assessment of overall health status to help stratify perioperative risk [see ECP:4 Risk Stratification, Preoperative Testing, and Operative Planning]. For example, knowledge of previous cardiac events (e.g., myocardial infarction or revascularization) and current cardiac status (e.g., New York Heart Association [NYHA] class or anginal severity) can help determine whether perioperative cardiac monitoring or preoperative cardiac testing is indicated and what form such monitoring or testing should take. Similarly, in a patient with suspected infection and ischemia, a history of worsening renal function or impending need for hemodialysis can help determine the choice and dosage of antibiotics and may alter plans for standard contrast arteriography. The essential point is that diabetes may affect virtually every organ system, often in an indolent pattern; thus, in the evaluation of any diabetic patient with foot disease, attention must be paid to all of these systems.

Functional status also becomes an important consideration at this point, and the history should carefully determine the patient's

ambulatory and rehabilitative potential. Many different methods of quantifying functional status have been suggested. One simple approach is to classify functional status as a point on a continuum. One end of the continuum might be a fully ambulatory patient; almost all surgeons would recognize that such a patient should be offered every attempt at limb salvage. The other end might be a completely bedridden patient with multiple comorbid conditions; most surgeons would adopt a far less aggressive approach to such a patient. In practice, many patients fall somewhere between these two extremes, in which case a more thorough evaluation of functional and social status becomes imperative before any firm decisions can be made regarding limb salvage.

PHYSICAL EXAMINATION

Fever and tachycardia are strongly suggestive of deep or undrained infection, with hypotension being a late manifestation of ongoing sepsis. It is important to remember, however, that these signs may be absent in diabetic patients with impending or progressive infection. A focused cardiopulmonary examination helps confirm the presence or absence of congestive heart failure, valvular abnormalities, or rhythm disturbances, which must be recognized in diabetic patients with poor underlying medical reserve.

Evaluation of the diabetic foot ulcer should include a strong suspicion of infection and a thorough search for it. In a patient with cellulitis, the entire foot, including the web spaces and the nail beds, should be examined for any potential portals of entry, such as a puncture wound or an interdigital ("kissing") ulcer. Encrusted and heavily calloused areas over the ulceration should be unroofed and the wound thoroughly inspected to determine the extent of involvement. A benign-appearing dry gangrenous eschar often hides an undrained infectious collection [see Figure 1]. Cultures should be taken from the base of the ulcer; superficial swabs may yield only colonizing organisms.

Findings consistent with infection include purulent drainage, crepitus, tenderness, mild erythema, and sinus formation [see Figure 2], though these findings may be entirely absent in the neuropathic foot. With more advanced and deep infection, edema may be present as a result of elevated pressures within one or more of the plantar compartments [see Figure 3]. If left untreated, this process may spread proximally along tendon sheaths to involve the ankle or even the calf. Close inspection of the ulcer and the use of a sterile probe may also confirm the presence of osteomyelitis, which occurs commonly even in conjunction with benign-appearing ulcers. If bone is detected with gentle probing, osteomyelitis is presumed present.

Because of its prevalence and its causative role in diabetic foot ulceration and limb loss, neuropathy should be assessed in every diabetic patient, and appropriate preventive measures should be taken to guard against foot ulceration in the high-risk neuropathic foot. Protective sensation may be evaluated by pressing a Semmes-Weinstein 5.07 monofilament against the skin; inability to feel the monofilament correlates well with an increased risk of foot ulceration. Advanced sensorimotor neuropathy will lead to the presence of a so-called claw foot (from gradual atrophy of the intrinsic muscles) or to Charcot degeneration with bone and joint destruction at the midfoot. Both of these conditions give rise to abnormal pressure points on the plantar prominences and the potential for foot ulceration.

Assessment of the arterial perfusion in the diabetic foot is a fundamental consideration, in that the diabetic foot needs maximal perfusion to heal. In the presence of ischemia, all efforts at limb salvage will fail. Therefore, the physical examination must include a systematic approach to the assessment of arterial insufficiency. Simple inspection of the leg and foot, including the ulcer, often provides suggestive clues. For example, distal ulceration (on the

tip of a digit), ulceration unassociated with an exostosis or a weight-bearing area, and gangrene are all strongly consistent with underlying ischemia [see Figure 4]. The presence of multiple ulcerations or gangrenous areas on the foot, the absence of granulation tissue, and the lack of bleeding with debridement of the ulcer should immediately be taken as signals of possible underlying arterial insufficiency. Other signs suggestive of ischemia are pallor with elevation, fissures (particularly at the heel), and the absence of hair growth. Poor skin condition and hyperkeratosis, though not always good indicators of arterial disease, should be noted because they may help confirm initial clinical impressions.

The pulse examination, including the status of the foot pulses, is the single most important component of the physical examination. In the absence of a palpable pulse, ischemia is always presumed to be present. Although an accurate pulse examination of the lower extremities is not difficult, it is an acquired skill, and time should be devoted to practicing and perfecting the technique.

The femoral pulse is palpated midway between the superior iliac spine and the pubic tubercle, just below the inguinal ligament. The popliteal pulse is palpated with both hands and with the knee flexed no more than 15°. Palpation of the foot pulses is somewhat more demanding, requiring close attention and a good knowledge of the usual locations of the native arteries. The dorsalis pedis is located between the first and second metatarsal bones, just lateral to the extensor hallucis longus tendon, and its pulse is palpated with the pads of the fingers as the hand is partially wrapped around the foot [see Figure 5]. If the pulse cannot be palpated, the fingers may be moved a few millimeters in each direction; the dorsalis pedis occasionally follows a slightly aberrant course. A common mistake is to place a single finger at one location on the dorsum of the foot. The posterior tibial artery is typically located in the hollow curve just behind the medial malleolus,

Figure 2 Purulent drainage is seen from a sub-metatarsal ulcer on the plantar surface of the foot of a diabetic patient.

Figure 3 Shown is wet gangrene with edema and undrained severe infection in the foot of a diabetic patient presenting with hyperglycemia and ketoacidosis.

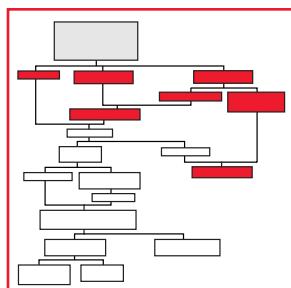

Figure 4 Shown is dry gangrene of several toes in a diabetic patient with femoropopliteal and tibial arterial occlusive disease.

approximately halfway between the malleolus and the Achilles tendon. The examiner's hand should be contralateral to the examined foot (i.e., the right hand should be used to palpate the left foot, and vice versa), so that the curvature of the hand naturally follows the contours of the ankle [see Figure 6].

Assessment of Clinical Findings

Once the clinical evaluation is complete, the next step is to assess the findings from the history and the physical examination so as to determine the course and urgency of the subsequent workup and treatment. This assessment is made at the bedside, focusing on three main concerns: (1) the presence and severity of infection, (2) the salvageability of the limb, and (3) the presence of ischemia.

PRESENCE OF INFECTION

Evaluation for and treatment of infection is the first priority in the management of any diabetic foot problem.^{4,5} Although radiographic tests may confirm initial clinical suspicions, the determination of the severity of infection is almost always made on the basis of clinical findings. Infection in the diabetic foot may range from a minimal superficial infection to fulminant sepsis with extensive necrosis and destruction of foot tissue. Accordingly, the treatment plan should address the choice of antibiotic (which requires knowledge of the microbiology), the need for drainage, the option of local or even guillotine amputation, and the patient's overall medical condition.

The microbiology of the diabetic foot varies according to the depth and severity of the infection and the nature of the patient's

environment (e.g., hospitalized or outpatient). Certain general assumptions can be made about likely causative organisms. Mild localized and superficial ulcerations, particularly in outpatients, are usually caused by aerobic gram-positive cocci (e.g., *Staphylococcus aureus* and streptococci). In contrast, deeper ulcers and generalized limb-threatening infections are usually polymicrobial. In addition to gram-positive cocci, potential causative organisms include gram-negative bacilli (e.g., *Escherichia coli*, *Klebsiella*, *Enterobacter aerogenes*, *Proteus mirabilis*, and *Pseudomonas aeruginosa*) and anaerobes (e.g., *Bacteroides fragilis* and peptostreptococci). Enterococci may also be isolated from the wound, notably in hospitalized patients; in the absence of other cultured virulent organisms, they should probably be considered pathogenic.

Currently, it is clear that resistant organisms, particularly methicillin-resistant *S. aureus* (MRSA), are playing a growing role in the development of skin and soft tissue infections. Traditionally arising in patients who had previously been hospitalized and those who had previously received antibiotic therapy, MRSA-associated infections are now frequently encountered in outpatient settings. Indeed, in many U.S. cities, these so-called community-acquired MRSA infections are the most common skin and soft tissue infections seen in patients presenting to the emergency department.⁶ Accordingly, in both outpatient and inpatient settings, it is advisable to assume that MRSA is present in a patient with a diabetic foot infection until the culture data suggest otherwise. Awareness of the increasing prevalence of resistant organisms is critical for current management of diabetic foot infections, especially with respect to the initiation of antibiotic coverage.

Initially, the choice of antibiotics is made empirically on basis of these general assumptions. When the results of the initial cultures become available, antibiotic coverage may be broadened or narrowed as appropriate. In a compliant patient with a small ulcer and no evidence of deep space involvement or systemic infection, treatment may be delivered on an outpatient basis. A dual-antibiotic regimen (pending culture results) is instituted, typically consisting of a cephalosporin or a β-lactam antibiotic (for activity against staphylococci and streptococci) and trimethoprim-sulfamethoxazole or a tetracycline (for activity against MRSA). A dual regimen consisting of fluoroquinolone and linezolid is an acceptable alternative that also provides adequate coverage. In addition, the patient is instructed to offload weight from the

Figure 5 Illustrated is the correct technique for palpation of the dorsalis pedis pulse.

Figure 6 Illustrated is the correct technique for finding the posterior tibial pulse.

involved extremity and is taught appropriate methods for changing wound dressings. Frequent follow-up is vital, and guidelines should be imparted by which improvement or worsening of the lesion can be determined.

A more common presentation, unfortunately, is a patient with ulceration or gangrene who has a deep infection affecting tendon or bone and possible systemic involvement. For such patients, immediate hospitalization is indicated, including bed rest with elevation of the infected foot, correction of any systemic abnormalities, and broad-spectrum I.V. antibiotic therapy (which may be focused more tightly once culture results are complete). Because the clinical findings of impending sepsis may be subtle, these patients should undergo a complete laboratory workup aimed at detecting and correcting electrolyte and acid-base imbalances.

The choice of antibiotic agent and the duration of therapy are dependent on the extent of the infection. For patients with deep or chronic recurrent ulcers, which are typically polymicrobial, or

those with limb-threatening or life-threatening infections, appropriate empirical antibiotic options include (1) vancomycin plus a β -lactam antibiotic with a β -lactamase inhibitor (e.g., piperacillintazobactam) and (2) vancomycin plus metronidazole plus a quinolone (in cases of penicillin allergy). Subsequent culture results then dictate further antibiotic coverage, if any. In the absence of osteomyelitis, antibiotics should be continued until the wound appears clean and all surrounding cellulitis has resolved (typically, 10 to 14 days). If osteomyelitis is present, treatment should include both surgical debridement and a prolonged (4- to 6-week) course of antibiotic therapy (though the course may be abbreviated if the entire infected bone has been removed, as with digital or transmetatarsal amputation). Heel lesions often present with some degree of calcaneal destruction, and determination of osteomyelitis may be made by clinical examination either alone or in conjunction with other radiographic tests (e.g., magnetic resonance imaging) [see Figure 7].

In the presence of an abscess or deep space infection, immediate incision and drainage of all infected tissue planes is mandatory. Incisions should be chosen with an eye to the normal anatomy of the foot (including the various compartments) and the need for subsequent secondary (foot salvage) procedures [see Figure 8]. Drainage should be complete, with incisions placed to allow for dependent drainage, and all necrotic tissue must be debrided. Repeat cultures (including both aerobes and anaerobes) should be obtained from the deep tissues. Drainage incisions on the dorsum of the foot should be avoided. Abscesses in the medial, central, or lateral compartment should be drained via longitudinal incisions made in the direction of the neurovascular bundle and extending the entire length of the abscess. The medial and central compartments are drained through a medial incision, and the lateral compartment is drained through a lateral incision; both of these incisions are made just above the plantar surface of the forefoot [see Figure 9]. Web space infections may be drained similarly through the plantar aspect of the foot. In some instances, open amputation of the foot (e.g., an open toe or transmetatarsal amputation) may be necessary to allow complete drainage and resection of necrotic tissue. Strict adherence to textbook amputations may lead to unnecessary soft tissue removal and possibly to a higher amputa-

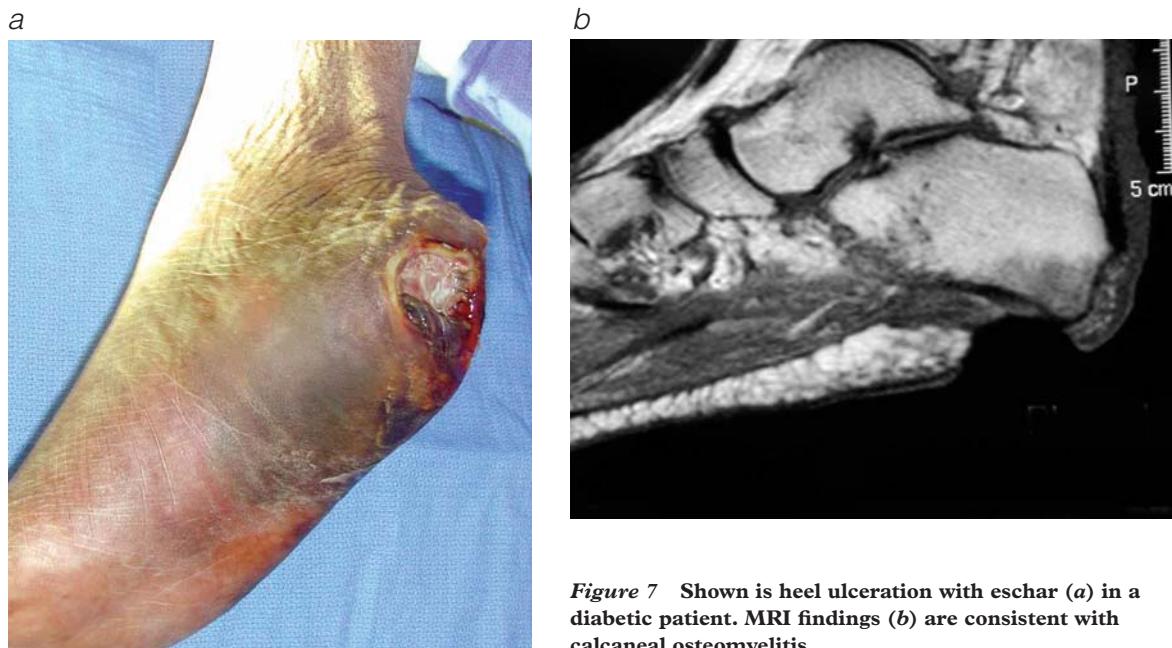

Figure 7 Shown is heel ulceration with eschar (a) in a diabetic patient. MRI findings (b) are consistent with calcaneal osteomyelitis.

tion during future closure; therefore, all viable tissue should be conserved.

A patient with an ongoing undrained infection may present with an unsalvageable foot and fulminant sepsis, manifested by hemodynamic instability, bacteremia, and severe acid-base and electrolyte abnormalities. Such patients should undergo prompt open (guillotine) below-the-knee amputation [see 6:19 Lower-Extremity Amputation for Ischemia]. This type of amputation is usually performed at the ankle level, with the aim of removing the septic source while allowing for revision and closure at a later date. Administration of I.V. antibiotics, correction of dehydration and electrolyte abnormalities, and continuous cardiac monitoring are absolutely essential throughout treatment.

Once the infection has been drained and tissues debrided, continued wound inspection and management are essential. Ongoing necrosis should raise the possibility of undrained infection or untreated ischemia, in which case further debridement and treatment may be necessary. Avoidance of weight-bearing should be continued. Neither whirlpool therapy nor soaks are beneficial.

Medical Stabilization

Concomitant with the measures outlined above to control infection, medical stabilization of the diabetic patient must be carried out, and the surgeon must be directly involved in this process. Hyperglycemia is almost always seen when infection is present; it should be gradually corrected. More advanced hyperglycemia leads to ketotic or nonketotic hyperosmolar states, which carry a 10% to 25% mortality. Serum concentrations of electrolytes, magnesium, and creatinine should be obtained and osmolality determined at frequent intervals; any abnormalities should be corrected [see 8:7 Disorders of Water and Sodium Balance and 8:8 Acid-Base Disorders]. Dehydration is common in hyperglycemic patients and should be corrected. A urinary catheter is mandatory to help guide the response to fluid therapy; in unstable patients, a central venous pressure catheter or a pulmonary arterial catheter may be needed [see 8:26 Cardiovascular Monitoring]. Continuous cardiac monitoring is essential in patients with the hyperglycemic hyperosmolar syndrome or ketoacidosis.

SALVAGEABILITY OF LIMB

While the infection is being treated and controlled, the surgeon should determine whether limb salvage is feasible. This determination is based largely on the patient's functional status and the degree of foot destruction. For example, primary limb amputation may be considered in a nonambulatory, bedridden patient or in a patient with severe Charcot destruction and degeneration, for whom no further reconstructive foot surgery is possible. Poor medical condition, by itself, is not necessarily an indication for primary limb amputation, given the high perioperative morbidity associated with amputation. Moreover, it is often possible to improve the patient's overall medical status while he or she is being treated for infection and evaluated for ischemia.

Assessment of limb salvageability should be carried out simultaneously with treatment of infection because appropriate drainage and antibiotics can dramatically change the appearance and viability of the foot. If limb salvage is not deemed possible, the patient should undergo formal below-the-knee or above-the-knee amputation [see 6:19 Lower-Extremity Amputation for Ischemia].

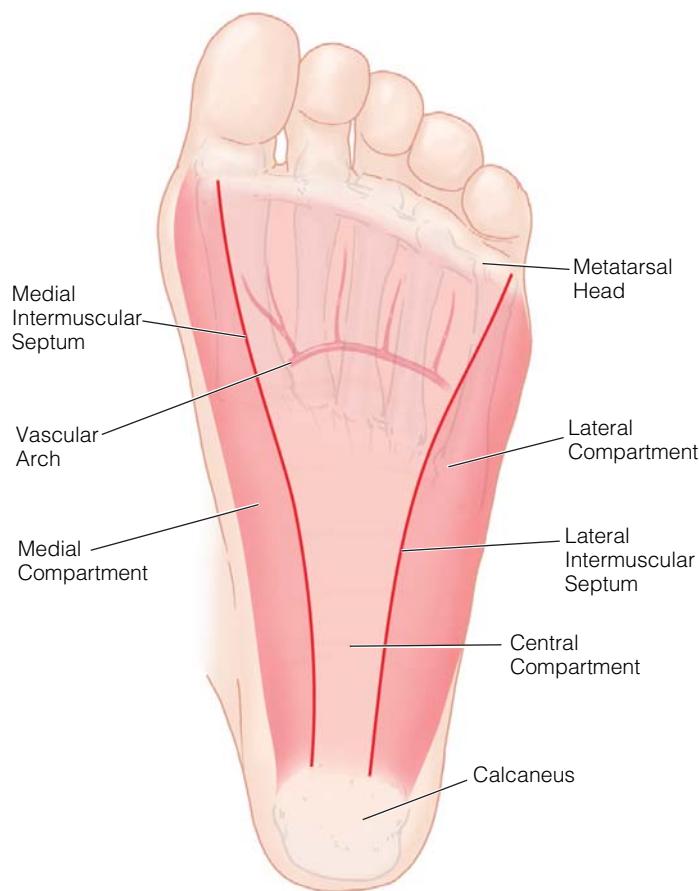

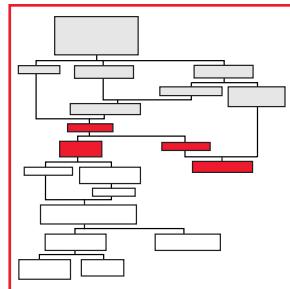

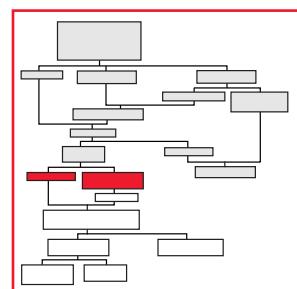

Figure 8 The foot has three plantar compartments: medial, central, and lateral. The intrinsic muscles of the great toe are in the medial compartment, and those of the fifth toe are in the lateral compartment. The central compartment contains the intrinsic muscles of the second through fourth toes, the extensor flexor tendons of the toes, the plantar nerves, and the plantar vascular structures. The floor of each compartment is the rigid plantar fascia; the roof is composed of the metatarsal bones and interosseous fascia. The medial and central compartments are separated by the medial intermuscular septum, which extends from the medial calcaneal tuberosity to the head of the first metatarsal. The lateral and central compartments are separated by the lateral intermuscular septum, which extends from the calcaneus to the head of the fifth metatarsal.

PRESENCE OF ISCHEMIA

Evaluation of the diabetic foot for ischemia begins with the history and the physical examination. By the conclusion of the clinical evaluation, the surgeon can usually make an accurate assessment of the adequacy of the arterial circulation to the foot. As noted [see Clinical Evaluation, Physical Examination, above], the absence of a palpable foot pulse strongly suggests ischemia unless proved otherwise.

Noninvasive arterial testing plays only a limited role in the assessment of diabetic patients with foot ulceration and should not be employed in place of the bedside evaluation. Certainly, for patients with poor healing or gangrene and absent foot pulses, noninvasive testing adds little additional useful information to the initial clinical

evaluation and typically serves only to further delay vascular reconstruction. For selected patients, however, noninvasive testing, in conjunction with the clinical findings, may be useful. Patients who might benefit from such testing include those with absent foot pulses who have a superficial ulcer with evidence of healing or a previous history of a healed foot ulcer and those without any foot lesions who are scheduled to undergo elective foot surgery.

The presence of diabetes imposes limitations on all of the noninvasive arterial tests currently available. Medial arterial calcinosis occurs frequently and unpredictably in patients with diabetes and can result in noncompressible arteries and artificially elevated segmental systolic pressures and ankle-brachial indices. Because calcification levels tend to be lower in the toe vessels, toe systolic pressures are sometimes obtained, but their value is often limited by the proximity of the foot ulcer to the cuff site. Segmental Doppler waveforms and pulsed volume recordings are unaffected by medial calcification, but evaluation of these waveforms is primarily qualitative rather than quantitative. In addition, the quality of the waveforms is affected by peripheral edema, and cuff placement is commonly affected by the presence of ulceration. Regional transcutaneous oximetry measurements are also unaffected by medial calcinosis, and this modality appears to be reliable for predicting ulcer healing and amputation levels. However, transcutaneous oximetry measurements are actually higher in patients with diabetes and foot ulcers than in nondiabetic patients, possibly because of the effects of arteriovenous shunting. Other limitations, including lack of equipment standardization, user variability, and a large gray area in the interpretation of the measurements, further limit the ability of this test to predict ischemia. Therefore, although these measurements have been used to predict healing in patients without diabetes, high values may not correlate with healing potential in the presence of diabetes.

When a patient presents with absent foot pulses in conjunction with gangrene, nonhealing ulceration, or significant tissue loss, it can be assumed that ischemia is present and must be corrected if the limb is to be salvaged. In such patients, arteriography of the entire lower extremity should be performed. The decision to perform arteriography and vascular reconstruction should be made as

soon as infection has started to resolve and signs of systemic toxicity have disappeared; prolonged delays in making this decision may result in further tissue loss and make salvage impossible. For a complete assessment, the arteriogram should include the foot vessels in both lateral and anterior views.

Concern over possible contrast-induced renal failure should not be considered a contraindication to high-quality angiography of the entire lower extremity. The incidence of contrast nephropathy is not higher in diabetic patients without preexisting renal disease, even when ionic contrast agents are employed. Selective use of magnetic resonance angiography (MRA), carbon dioxide angiography, and duplex scanning may help minimize the contrast dye load.

In patients with preexisting renal disease, use of a nonionic contrast agent, in conjunction with appropriate hydration and judicious administration of kidney-protecting agents, should minimize the risk of contrast-induced nephrotoxicity. *N*-acetylcysteine, 600 mg twice daily, should be started on the day before the arteriogram and continued for 48 hours, and 0.45 N saline should be given I.V. at a rate of 1 mg/kg/hr, beginning 12 hours before the scheduled arteriogram.⁷

Management

REVASCULARIZATION

The goals of arterial reconstruction are to restore maximal perfusion to the foot and, ideally, to restore a palpable foot pulse. Possible approaches include endovascular techniques (angioplasty and stenting) [see 6:23 *Endovascular Procedures for Lower-Extremity Disease*], bypass grafting (with autogenous or prosthetic grafts), and some combination of the two. Ultimately, the choice of procedure in any given case is based on the individual patient's anatomy, the comorbid conditions present, and the results of the preoperative assessment, with the aim being to provide the

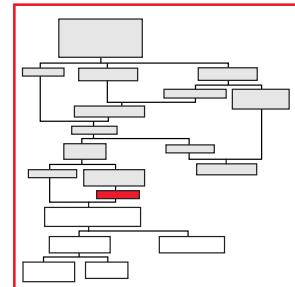

Figure 9 Shown is an infection in the central compartment of the foot from a submetatarsal ulcer that has extended proximally to include the medial compartment (a). A plantar incision through the ulcer and both compartments (including the septum) allows complete dependent drainage (b).

most durable procedure with the least risk. For example, in rare patients with isolated iliac artery stenoses, angioplasty may be effective by itself, but in patients with multilevel disease, it may have to be combined with an infrainguinal bypass [see 6:18 *Infrainguinal Arterial Procedures*]. In patients who have previously undergone surgical revascularization, careful consideration should be given to the availability of an autogenous conduit (e.g., an arm vein or the lesser saphenous vein), given the superiority of autogenous vein over prosthetic grafts.

As a rule, arterial bypass grafting is required for restoration of the foot pulse.⁸ Proximal bypass to either the popliteal artery or the tibial and peroneal arteries may restore foot pulses, and preference should be given to these vessels if they are in continuity with the foot. Often, however, because of the presence of more distal obstructive disease, bypass grafting to the popliteal or even the tibial artery will not restore the foot pulse. In such cases, restoration of pulsatile flow to the foot may be accomplished with autogenous vein bypass grafts to the paramalleolar or inframalleolar arteries (e.g., the dorsalis pedis). The vein graft can be prepared as an in situ graft, a reversed graft, or a nonreversed graft, without any significant difference in outcome; the choice of approach should be based on the patient's particular vascular anatomy.

As noted (see above), the absence of an ipsilateral greater saphenous vein is not a contraindication to pedal bypass: comparable results may be obtained by using arm vein or lesser saphenous vein grafts. Prosthetic material should seldom, if ever, be used for dorsalis pedis or other extreme distal (inframalleolar) bypass grafts. Active infection in the foot is not a contraindication to pedal bypass, provided that the proximal dorsum of the foot is free of infection and that incisions can be placed in clean tissue planes. The foot should be free of cellulitis, lymphangiitis, and edema before any inframalleolar bypass.

Current advances in endovascular therapy are allowing this approach to be used more frequently and successfully in the peripheral vasculature. Lesions determined to be favorable on the basis of arteriography (e.g., short-segment stenoses) may be treated with angioplasty and, possibly, stenting. Similarly, endovascular therapy may be preferred to surgical bypass grafting in high-risk patients and patients who have no suitable autogenous conduit. Ultimately, the goal of endovascular intervention should be the same as that of bypass grafting: to restore the foot pulse and maximal blood flow to the foot.

CONTINUED WOUND CARE

Once the foot is fully revascularized—or once it is clear that the foot was adequately perfused to begin with—care of the foot wound should be continued. Revascularization of a severely ischemic foot ulcer may result in an immediate paradoxical worsening of the infection, and frequent inspection is mandatory postoperatively. New-onset cellulitis, hyperglycemia, or fever should prompt concern regarding potential worsening of the foot infection. Frequent debridement to healthy, bleeding tissue is required more often than not.

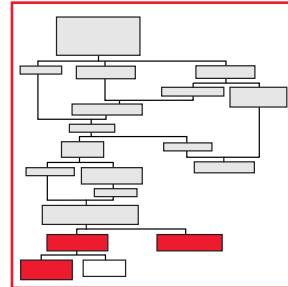

Wounds should be kept moist, with wet-to-dry dressings avoided in favor of normal saline wet-to-wet dressings. Various adjunctive wound treatments are available, including chemical enzymatic debriding agents, growth factors, and hyperbaric oxygen therapy. Some of these may offer a slight additional benefit in terms of improved healing, but they are expensive; blanket use of these costly modalities is therefore discouraged. Failure of wound healing in

the diabetic foot is usually attributable to unrecognized ischemia, ongoing infection, or poor conventional wound care—not, as a rule, to the absence of more sophisticated wound therapy.

Hyperglycemia and malnutrition are common in hospitalized diabetic patients with foot ulceration, and both adversely affect wound healing. Correction of these abnormalities should begin early and continue throughout the wound-healing period. Attention should also be directed toward preventing new foot lesions (e.g., decubitus ulcers on the heel from prolonged bed rest). Heel splints, air mattresses, and leg pillows are all valuable in this regard.

SECONDARY FOOT PROCEDURES

After successful revascularization, secondary procedures on the foot may be performed for maximal foot salvage, with the aim of addressing both the acute problem and the underlying cause. The basic goals of such procedures are (1) to remove infected bone (if present), (2) to restore functional stability, and (3) to reduce the risk of subsequent ulceration.

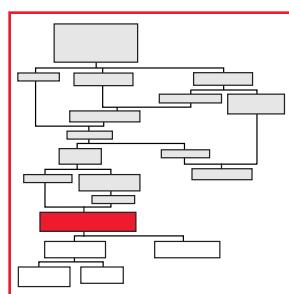

In the forefoot, digital, single metatarsal (ray), or transmetatarsal amputation [see 6:19 *Lower-Extremity Amputation for Ischemia*] may be performed, depending on the location of the ulcer. Tissue should be handled gently, forceps should not be used, and incisions should be carefully placed. Care must be taken to prevent dead spaces along tendon sheaths, bone splintering, and areas of residual necrosis, all of which can lead to failure of the procedure. If there is persistent infection or an abscess, the wound should be left open. Every effort, however, should be made to perform a closed amputation so as to avoid the time and cost associated with open wound care. This is a particularly important consideration in the occasional diabetic patient with unreconstructible foot ischemia, because open amputations rarely heal in the presence of ischemia.

Underlying bony structural abnormalities in the diabetic foot are often the cause of ulceration. Such abnormalities may be corrected with hallux arthroplasty, metatarsal head resection, metatarsal osteotomy, or sesamoideectomy; if ulceration is present, these procedures may be combined with ulcer excision. Similarly, ulceration on a previous transmetatarsal amputation may be the result of an equinovarus deformity (from disrupted tendons and a decrease in calcaneal inclination). This problem should be treated with revision of the transmetatarsal amputation (perhaps in conjunction with ulcer excision) and biomechanical correction (e.g., Achilles tendon lengthening or, in more severe cases, posterior tibial tendon release).

Heel lesions are particularly formidable, and there is considerable confusion regarding how best to manage them. Generally, dry eschars with no evidence of deep infection or abscess may be treated with offloading alone so as to allow healing beneath the eschar in the fully revascularized foot. In patients with chronic ulceration or osteomyelitis, partial calcaneectomy may be considered. The presence of calcaneal osteomyelitis may be determined by means of probing or adjunctive studies such as MRI [see Figure 7]. Primary closure is occasionally possible, but given the relatively fixed nature of the heel, either secondary healing or some type of flap coverage is usually indicated. Both local and free flaps may be used in the fully revascularized foot.

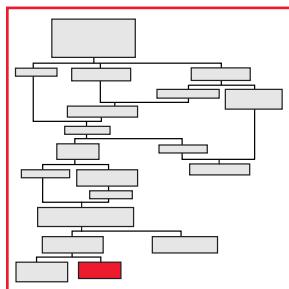

After any type of surgery of the diabetic foot, frequent postoperative observation of the wound is mandatory. Delays in

healing or wound breakdown should immediately raise the possibility of infection or unrecognized ischemia and should trigger the appropriate workup.

PREVENTIVE FOOT CARE

Once the foot has healed, preventive measures should be initiated to prevent future ulceration. Foremost among these measures is patient education, focusing on general hygiene (e.g., daily washing and moisturizer use) and daily inspection of the feet. Walking barefoot, employing heat pads, wearing thong

sandals, and using caustic over-the-counter foot medications should all be strongly discouraged.

Neuropathy continues to be the most common cause of diabetic foot ulceration, and its presence is a strong predictor of the likelihood of future ulceration. As noted (see above), inability to feel a Semmes-Weinstein 5.07 monofilament when it is pressed to the skin correlates well with an increased risk of foot ulceration. In addition, abnormal pressure points (secondary to mechanical deformity of the foot and motor neuropathy) can be identified by means of pedobarography, a procedure in which plantar pressure is measured on specialized contour plots as the patient walks on a pressure-sensitive platform. Identification of any high-pressure areas can facilitate the construction of specific, custom-molded orthotics and insoles to help in offloading.

8 FUNDAMENTALS OF ENDOVASCULAR SURGERY

Jon Matsumura, M.D., F.A.C.S., and Joseph Vijungco, M.D.

Endovascular techniques are now an important part of vascular surgery. Ongoing technological advances have made it possible to treat the majority of vascular diseases by minimally invasive means. To perform these new therapeutic techniques, it is necessary to possess certain basic endovascular skills. In this chapter, we describe some of the fundamental techniques that a skilled vascular interventionalist must master.

Choice of Vascular Access Site

The initial step in endovascular surgery is selection of the vascular access site. Several choices are available. The ideal access vessel is large, close to the treatment site, free of disease, and only minimally tortuous. Such a vessel is least likely to be associated with complications.¹ For most endovascular interventions, the femoral artery is the preferred choice, though the axillary, brachial, subclavian, common carotid, and iliac arteries may also be used. Occasionally, the aorta is accessed via direct puncture, laparotomy, or thoracotomy.

Before puncture, the vessel undergoes evaluation, including palpation to assess the strength of the pulse in comparison with the opposite side. A weak pulse suggests disease at or proximal to the area, and the vessel should therefore be used with caution. Pre-operative assessment may include noninvasive imaging (e.g., duplex ultrasonography, computed tomography, or magnetic resonance angiography) to visualize significant lesions. Finally, with any endovascular procedure, it is helpful to assess and document the peripheral pulses and the ankle-brachial index (ABI) beforehand to provide reference points for possible subsequent complications.

Puncture of Artery

GENERAL TECHNICAL PRINCIPLES

Once the skin site has been prepared and draped, 1% lidocaine is infiltrated into the skin and the perivascular tissue. Besides providing anesthesia to the area, lidocaine helps prevent vasospasm.² The pain and discomfort from intradermal injection of lidocaine is caused by the low pH of commercially available preparations and can be reduced by adding sodium bicarbonate (1 ml of a 1 mEq/ml NaHCO₃ solution in 10 ml of 1% lidocaine).³ A small nick should be made in the skin about 1 to 2 cm beyond the intended site of arterial entry, and the subcutaneous tissue should be gently dissected with a clamp; this measure allows smoother entry of the needle, the guide wire, the sheath, and the catheter. Access needles are available in different sizes, of which the two most common are the 18-gauge thin-walled needle, which accepts a 0.035-in. guide wire, and the 21-gauge needle, which accepts an 0.018-in. guide wire. The latter is used for micropuncture techniques and is favored for brachial approaches. Longer needles are used for translumbar puncture.

There are two main methods of cannulating the artery with the needle [see Figure 1]: double-wall entry and single-wall entry.

Certain principles apply to both methods. The needle is advanced at an angle of 45° to 60°. When it is within the subcutaneous tissue, it should proceed in a straight line: the needle tip is sharp, and side-to-side movement may cause inadvertent laceration of a neurovascular structure. When a needle must be repositioned, it should be withdrawn into the subcutaneous tissue superficial to the intended target and redirected along another course. If the needle becomes dulled as a result of contact with bone or other hard surfaces, it should be discarded and a new one used.

The double-wall entry method involves a through-and-through puncture of both the anterior wall and the posterior wall of the vessel. A multipart needle with an inner trochar may be helpful. After the needle is advanced through both walls of the artery, the inner trocar is removed. The needle is then slowly withdrawn until arterial pulsation is noted. The needle is stabilized, and a guide wire is advanced through it into the artery. Once the guide wire is in place, the needle is removed.

In the single-wall entry method, the needle is slowly moved toward the anterior wall of the vessel. The arterial pulsation can be felt through the shaft of the needle. Gentle pressure is applied, and the needle is advanced through the anterior wall only. It may be helpful to think of the arterial pulse wave as pushing the anterior arterial wall onto the needle. The appearance of pulsatile flow confirms entry into the arterial lumen. The needle may be rotated or deflected slightly to optimize pulsatile back-bleeding. A guide wire is then passed into the needle, and the needle is removed.

Pulsations should be transmitted through the needle shaft in an anterior-to-posterior manner. If the needle is either medial or lateral to the artery, the pulsations may deflect the needle from side to side.² Once the needle is in the vessel, the flow pattern should be observed. A forceful but irregular spraying flow may indicate arterial stenosis in the vicinity of the needle. A barely pulsatile flow may signal occlusive disease, a subintimal location of the needle, or a venous puncture.² If the guide wire cannot be passed with minimal resistance after access is obtained, the needle tip may be against the wall or against plaque, or (if the needle tip has already entered the wall) a dissection may have been started. Often, the situation can be remedied by making a small change in the needle's insertion angle or by withdrawing the needle slightly.

FEMORAL ARTERY PUNCTURE

As noted, the common femoral artery (CFA) is the vessel most commonly used for arterial access. It is generally quite well suited to this purpose, being readily accessible, fairly large, and easily compressible. CFA puncture facilitates study and treatment of a number of key structures, including the lower-extremity arteries, the abdominal aorta and its branches, the thoracic aorta, the brachiocephalic vessels, the coronary arteries, and the left ventricle. In addition, it is associated with a lower complication rate than puncture of other arteries.¹ The CFA should, however, be avoided when the patient is known to have severe iliofemoral occlusive disease, a local infection, a femoral artery aneurysm, or marked tortuosity of the iliac arteries that would preclude catheter placement or manipulation.

The CFA runs lateral to the common femoral vein (CFV) and beneath the inguinal ligament. It may be localized by palpation just proximal to its bifurcation into the superficial femoral artery (SFA) and the profunda femoris (PF). The inguinal ligament, which runs from the anterior superior iliac spine to the pubic tubercle, is a convenient landmark for localization of the CFA, but these bony landmarks provide only a rough approximation of the location of the inguinal ligament. The CFA typically lies about two fingerbreadths lateral to the pubic tubercle along the line of the inguinal ligament. The artery should be punctured over the middle of the medial third of the femoral head in the posterior-anterior projection [see *Figure 2*]. The window available for safe CFA puncture is small—only 3 to 5 cm.

There are several methods that can be used to localize the CFA in patients with difficult anatomy (e.g., those who have previously undergone groin surgery, those who are obese, and those who have a pulseless artery). The bony landmarks are even less reliable guides to the location of the inguinal ligament in these patients. According to a 1993 anatomic study, in the majority of cases, the position of the inguinal ligament is about 1 to 2 cm below where palpation would suggest it to be, and the average position of the ligament is approximately 1.5 cm superior to the midfemoral head.⁴

Fluoroscopy may help localize the CFA over the medial third of the femoral head. The chances of hitting the artery are maximized by aiming for the middle (craniocaudal) portion of the medial third of the femoral head. To minimize parallax errors, the femoral head should be centered in the image intensifier. The

anatomic relations of the arteries in this area vary little with body habitus, gender, or age. A 1999 anatomic study showed that the CFA bifurcates into the SFA and the PF approximately 2 cm below the femoral head.⁵ Occasionally, calcifications in the arteries may serve as landmarks for locating the CFA.

Another localization approach involves palpation of anatomic landmarks; this approach may be especially useful when the artery is pulseless.⁶ With a finger placed immediately lateral to the pubic tubercle and inferior to the inguinal ligament, palpation is carried out to locate the point allowing the greatest degree of posterior depression. Anatomically, this point of maximal depression lies between the iliopsoas muscle laterally and the pectenous muscle medially. The CFV lies in the floor of this depression, and the CFA lies 1.5 cm lateral to the depression.⁶

Ultrasonography has also proved useful for finding the CFA. The projection of choice with real-time ultrasonography is the transverse plane. The nonpalpable CFA is identified lateral to the compressible CFV. Occasionally, the artery can be identified on the basis of sonographic shadowing from calcified atheromatous plaques.⁷ A second ultrasonographic technique involves the use of a so-called smart needle, which has an ultrasound probe at its tip. The needle emits a signal as it approaches the artery, thereby giving notice of proximity to the vessel.

Another method of localizing and puncturing a pulseless CFA involves performing a contralateral femoral artery puncture, obtaining a diagnostic angiogram, and roadmapping. A similar method that is useful in patients who may be moving or who cannot receive additional contrast material is to pass a guide wire over the aortic

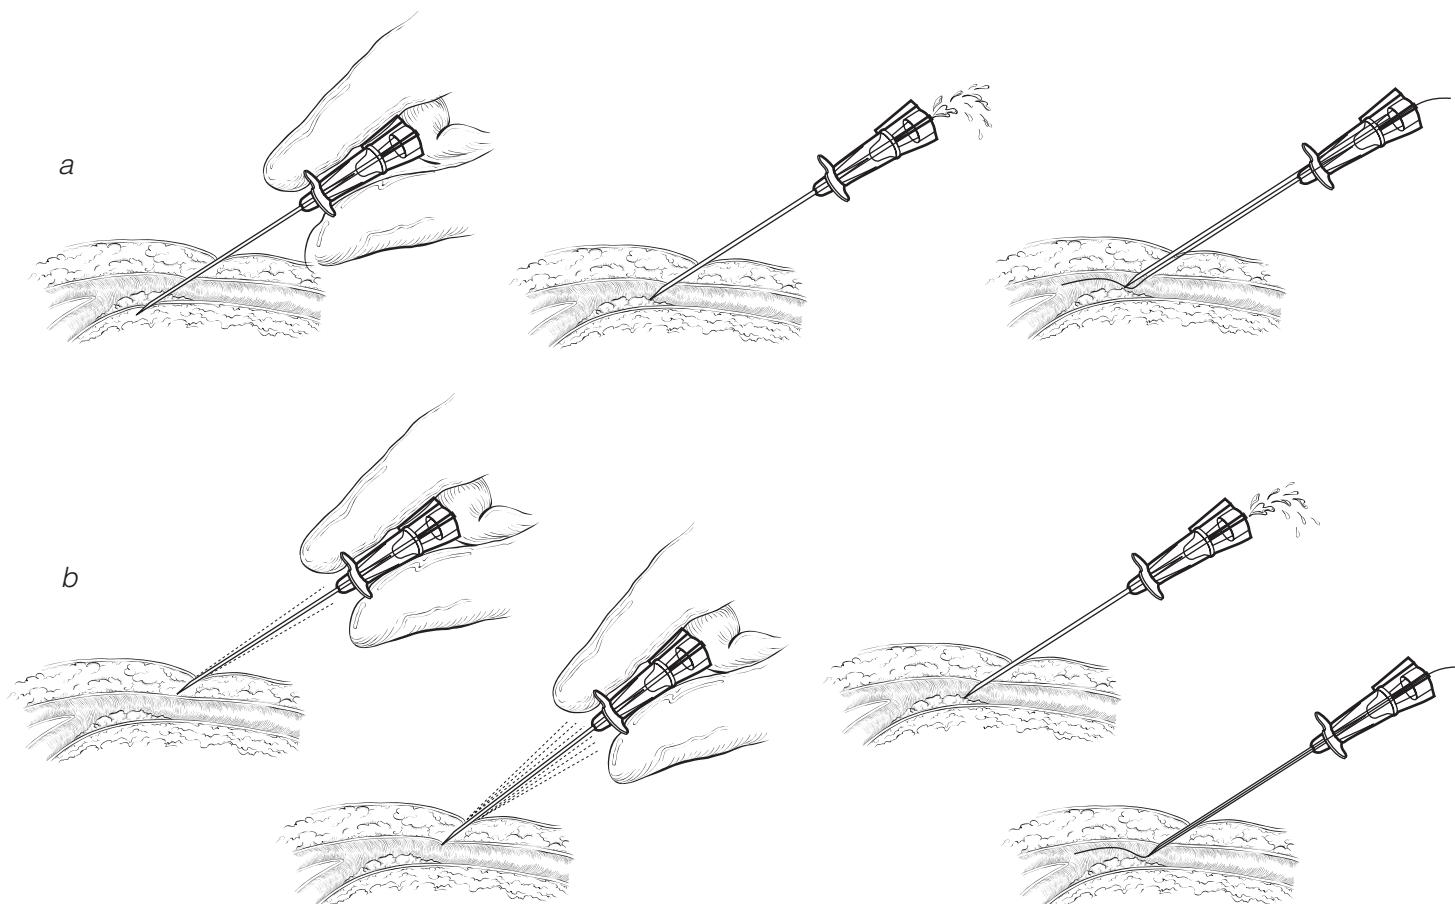

Figure 1 Shown are the two methods of entry into an artery: (a) through-and-through puncture of both walls and (b) puncture of the anterior wall only.

bifurcation and then antegrade through the iliac artery into the target femoral artery.⁸ Under fluoroscopy, the guide wire becomes a visible target for introduction of the needle into the CFA.

Troubleshooting

The CFA is typically described as lateral to the CFV; however, one study showed that attempts to puncture the CFA frequently result in puncture of the CFV, signaled by the appearance of dark, nonpulsatile venous blood. If this occurs, one should note the position of the original puncture, move the needle 1 to 1.5 cm laterally, and reinsert the needle. At times, especially in emergency procedures, arterial blood may be dark and may resemble venous blood. If it is unclear whether the blood is coming from an artery or a vein, a small amount of a contrast agent should be gently injected into the needle by hand; the source of the blood should then be easily identifiable. When contrast is injected in the femoral sheath outside the artery, the resulting tubular “filling defect” can be used to identify the femoral artery.

If the puncture is done too high (in the external iliac artery), the inguinal ligament and the deeper location of the external iliac artery may make adequate compression of the vessel impossible. Many closure systems will not work in the external iliac artery. High puncture is associated with retroperitoneal bleeding, which should be suspected in any patient with an unexplained drop in the hematocrit, hypotension, or flank pain. To minimize this problem, the artery should be entered caudal to the inguinal ligament at a site where it can be compressed against the femoral head.⁹

If the puncture is done too low (in the SFA or the PF), there is a greater incidence of hematoma, pseudoaneurysm, arteriovenous fistula, and catheter-related thrombosis.^{4,10} The reason for this increased incidence may be that it is harder to compress the SFA and the PF adequately than it is to compress the CFA, which lies over bone for most of its length. The CFA is larger in diameter than either the SFA or the PF and thus is better suited for the passage of large catheters and sheaths.

Experience is critical for achieving easy and complication-free femoral artery access. Although standard learning points are helpful in the accumulation of this experience, veteran interventionalists typically develop their own individual procedural algorithms, based on what is most familiar to and works best for them. Routine use of femoral arteriography and ultrasonography can shorten the learning period by visually demonstrating the nuances of the anatomy in tandem with the tactile learning. Thoughtful study of failed or complicated access cases, including observing the vascular anatomy when surgical repair becomes necessary, can also help develop experience more rapidly. In such cases, exploration often reveals altered femoral anatomy, side-wall punctures, low and high punctures, and posterior wall dissection. For even the most masterful interventionalist, femoral puncture complications are an ever-present risk, despite his or her best efforts.

BRACHIAL ARTERY PUNCTURE

The brachial artery is typically the second choice for arterial access after the femoral artery. This vessel is located in the lower third of the upper arm, anteromedial to the humerus. The median nerve lies just medial to the brachial artery at this level, and the radial nerve lies posterior to the artery. Even though the brachial artery is best palpated in the lower middle third of the arm, some clinicians prefer to puncture it in the high brachial position because complications may be less frequent with this approach.

The patient's arm is extended and supinated. The upper portion of the brachial artery is entered several fingerbreadths distal to the axillary crease, over the proximal humeral shaft. The middle por-

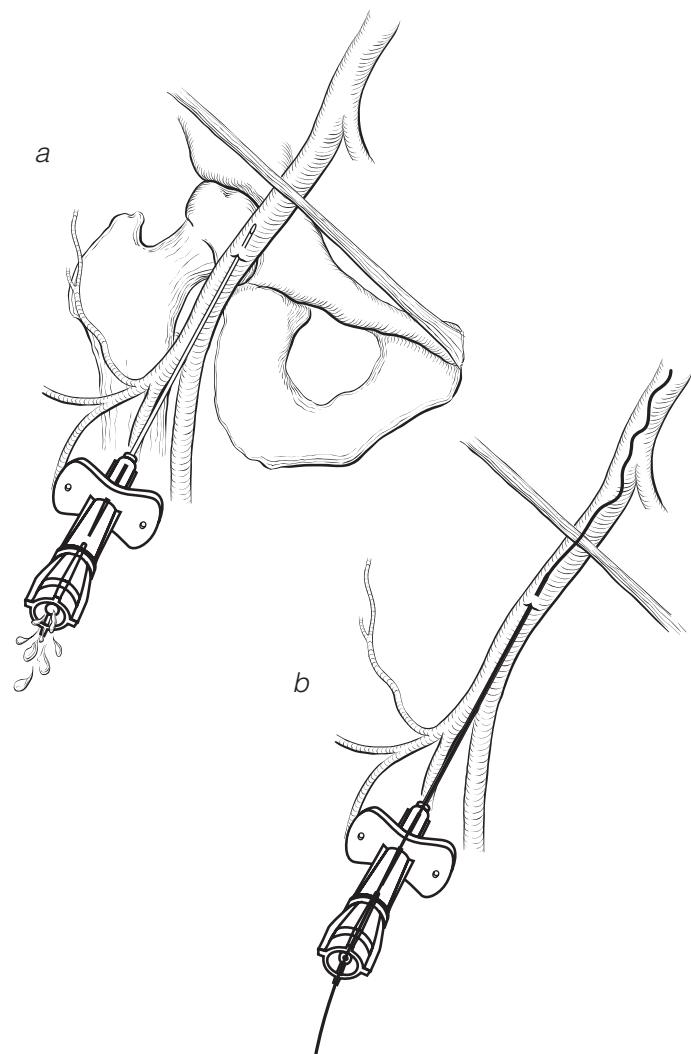

Figure 2 Puncture of common femoral artery. (a) The needle enters the CFA. (b) The guide wire is passed through the needle.

tion of the brachial artery is entered just above the antecubital fossa. Because this vessel is very mobile, it may be advisable to fix it between the surgeon's middle and index fingers before puncture.

Troubleshooting

The brachial artery is typically smaller than the CFA and more prone to thrombosis. Accordingly, the needles, guide wires, catheters, and sheaths used for brachial artery puncture must be smaller as well. Occasionally, the median nerve or the radial nerve may be damaged by the puncture. Any distal neurologic symptoms (e.g., median nerve distribution paresthesias or pain or weakness of the opponens muscle) that arise are evaluated on an urgent basis; on occasion, emergency exploration proves necessary. Frequently, there is no palpable hematoma, and the symptoms are attributable to a very small hematoma adjacent to the nerve. Not uncommonly, the brachial artery goes into spasm after puncture. Intra-arterial injection of papaverine, tolazoline, or nitroglycerin may reduce the risk of spasm.

AXILLARY ARTERY PUNCTURE

The axillary artery is divided into three parts on the basis of its relation to the overlying pectoralis minor. The third portion of the artery lies lateral to the pectoralis minor, and its most distal por-

tion extends beyond the pectoralis major, at which location it is very superficial.² The axillary artery is typically used for vascular access when neither the femoral nor the brachial artery is available. The use of this approach may be restricted in patients who have subclavian artery occlusive disease or aneurysmal disease. A physical examination should be performed before the procedure to look for a blood pressure differential between the two arms, as well as to auscultate for the presence of a supraclavicular bruit. A blood pressure differential greater than 20 mm Hg suggests the presence of hemodynamically significant arterial stenosis in the arm with the lower pressure.

Axillary artery puncture is useful in patients with a steeply downward-coursing (caudal) mesenteric or renal artery, patients with infrarenal aortic or bilateral iliac occlusion, and patients with a history of embolization from infrarenal aortic catheterization.³ However, access at this site poses an added risk, in that the artery is located near the brachial plexus, which may be damaged by direct trauma or compression from a hematoma. In addition, access via the axillary artery is relatively uncomfortable for both patient and physician. Generally, for access to the descending thoracic aorta, the abdominal aorta, and the lower-extremity vessels, the left axillary artery may be preferred, whereas for access to the ascending aorta and the coronary vessels, the right axillary artery may be preferred.

The arm can be placed in either of two positions: (1) abducted 90° or (2) maximally abducted with the patient's hand placed under the head. The second position stretches the artery and fixes it in place. The artery is palpated along the lateral axillary fold over the proximal humerus at the neck so that the underlying bone provides support during compression.¹¹ The vessel is then entered over the proximal humeral shaft just distal to the axillary fold. Like the brachial artery, the axillary artery is relatively mobile. It may be compressed along its length between the index and middle fingers to fix it in place for subsequent puncture.

Troubleshooting

Thrombosis and pseudoaneurysm formation are more common with the axillary artery approach.³ In addition, the median and ulnar nerves run along with the axillary and proximal brachial arteries in a fascial sheath, so that a small hematoma can cause nerve compression. If a sensory or motor deficit develops, surgical decompression may be required. Cerebral embolization occurs in as many as 4% of cases of axillary artery puncture.³

TRANSLUMBAR PUNCTURE

Translumbar puncture of the aorta is indicated when femoral, axillary, and brachial methods are all relatively unsuitable. It is frequently used in patients who have abdominal aneurysms after endovascular repair.

An upper translumbar approach is indicated if visualization of the visceral and renal arteries is required. The patient is placed in a prone position. The 12th thoracic vertebra is located either by palpating the 12th rib or, more accurately, by means of fluoroscopy. The skin is entered 1 to 2 cm below the level of the 12th rib and 8 to 10 cm to the left, lateral to the posterior spinous process of the 12th vertebra. The needle is aimed ventrally and cephalad toward the level of the middle to lower portion of the body of T12 until the needle strikes the vertebra. Care must be taken to keep the needle below the diaphragm so that it does not hit the lung and the pleura. Particular care must also be taken to avoid the renal arteries inferiorly. After striking T12, the needle is withdrawn several centimeters and aimed laterally and ventrally until the pulsations of the aorta are felt. When the needle hits the aorta, slight resistance

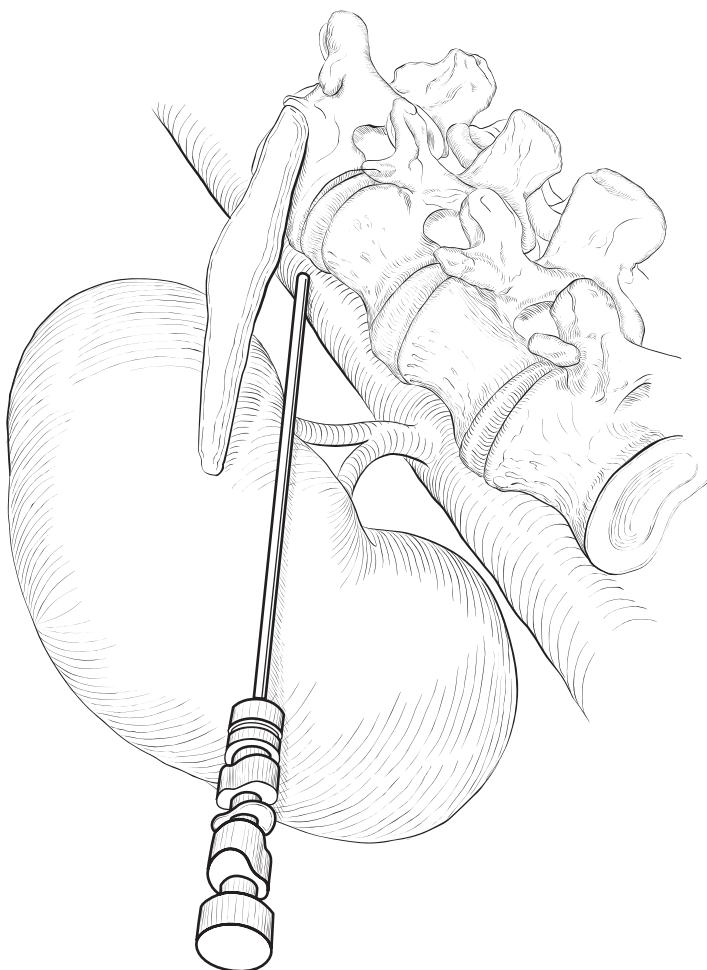

Figure 3 Translumbar puncture of aorta. The vessel is approached at the level of T12.

will be felt, followed by release of tension and a very slight give or “pop” when the needle enters the aorta. Only the proximal wall should be punctured. The needle is then advanced about 3 to 5 mm to the middle of the lumen [see Figure 3].

A lower translumbar approach may be used to access an aortic aneurysm sac after endovascular repair. The puncture site is located via fluoroscopy of radiopaque markers on the device already in place. With the patient in the prone position, the needle is introduced 8 to 10 cm lateral to the spinous process of L2 and directed anterior to the lumbar spine. Often, careful review of the CT images suggests a specific target and tract. As with an upper translumbar puncture, a “pop” can be felt when the needle enters the aneurysm sac; alternatively, the needle can be visualized entering a calcified wall.

Troubleshooting

The high translumbar technique is limited by its inability to deliver the contrast material at the bifurcation of the aorta or to perform selective catheterization of vessels. Too high a puncture (e.g., at T11) can lead to inadvertent puncture of the lung and cause a hemothorax or a pneumothorax. If the needle moves with the respiratory diaphragmatic movements of the patient, it may be in the thoracic cavity. If the initial needle stick is too medial, only the lateral wall of the aorta is reached. If the needle stick is too lateral, the needle passes between the vertebral body and the aorta. If the needle is advanced at too shallow an angle, it may enter the spinal canal.² If resistance is felt when the guide wire is placed, the

wire may have entered the renal, celiac, or superior mesenteric artery. Small retroperitoneal hematomas develop in most patients who undergo translumbar puncture, but the incidence of major complications is only 3%.

Placement of Guide Wires

Once vascular access has been obtained through arterial puncture, it is maintained through placement of a guide wire. Most guide wires consist of a soft tip and a stiffer main body. The flexibility of the soft tip allows the surgeon to manipulate the guide wire past stenoses while minimizing the risk of perforation or dissection. For best results, the guide wire must be suitable for the intended procedure in terms of (1) tip configuration, (2) diameter, and (3) length. Sometimes, multiple wires are used at different stages of the procedure.

Guide wires come in several different tip configurations, including straight, angled, and J-shaped. Straight-tipped wires are used in vessels that are relatively straight and free of disease. J-tipped guide wires are sometimes preferred for atherosclerotic vessels because the shape of the tip reduces the likelihood that the wire will pass subintimally and cause unintentional dissection. Many specialty wires are available for specific uses (e.g., crossing chronic total occlusions).

Guide wires also come in a variety of diameters, typically ranging from 0.014 to 0.052 in. The diameters most commonly used for endovascular procedures are 0.035 and 0.014 in. Larger guide wires are typically stiffer, which makes it easier to deliver sheaths and catheters over them. Smaller wires are typically used for endovascular work involving the carotid, renal, or infragenicular vessels. In choosing the diameter of the wire, the interventionalist must keep in mind the gauge of the needle that was used to access the vessel. The guide wire should fit the needle yet be large enough to allow delivery of interventional devices.

The length of the guide wire is an important concern because choosing an appropriate length facilitates exchange of catheters or interventional devices without loss of access across a remote lesion. A general rule for determining optimal guide wire length is as follows¹²:

$$\text{Optimal guide wire length} = \text{Length from outer edge of sheath or insertion site to lesion} + \text{length of longest catheter or interventional device} + \text{at least } 10 \text{ cm}$$

In an average adult, the wire used for selective angiography is typically about 145 to 180 cm long. Longer wires (260 to 300 cm) are used for exchanging long over-the-wire vascular devices. Occasionally, a 450 cm long wire is needed for combined brachial-femoral access.

Once arterial access is obtained, several safety measures should be undertaken. The needle should have its bevel facing upward to optimize conditions for wire advancement; a downward-facing bevel may cause the sharp edge of the needle to damage or even sever the wire. The floppy end of the wire should be used for initial introduction into the needle and the vessel; the stiff end may damage the vessel if used for initial entry. Caution should be exercised in introducing the guide wire if there is unexpected poor flow from the needle.

After entry into the lumen, the guide wire is advanced about 15 to 20 cm. The needle is then removed, and a catheter or an introducer sheath is placed over the wire. Further advancement of the wire is done under fluoroscopic guidance. Once placed, the guide wire should be carefully monitored and kept in place (pinned)

whenever any other devices are manipulated. As a general rule, the guide wire is not removed until the very end of the procedure. After removal, guide wires are rinsed and loosely coiled for storage (in case they are needed later).

TROUBLESHOOTING

The guide wire should never be forcefully introduced into the vessel. If significant resistance is encountered, the end of the needle may be against the vessel wall or partially within the wall. In this situation, the needle should be repositioned slightly and another attempt made to pass the wire. Occasionally, the guide wire may pass easily for several centimeters before encountering resistance to further advancement. Such resistance may be secondary to stenosis or tortuosity of the vessel. Placement of a different wire with a different tip configuration or insertion of a guide catheter may be necessary to advance the wire further.

Wiping the guide wire with heparinized saline minimizes thrombus formation on the wire. If thrombus is allowed to build up, friction will increase during catheter exchange, making the exchange more difficult. Some hydrophilic-coated guide wires require constant wetting to maintain their characteristics. Other guide wire coatings swell after prolonged wetting and thus may inhibit catheter exchanges. Hydrophilic wires should not be used for initial cannulation through the access needle, because they may be sheared off by the needle tip when withdrawn. Damaged or kinked guide wires should be exchanged for new undamaged wires when this can be done safely.

Placement of Sheaths

Once guide wire access is achieved, a sheath or guide is typically placed over the guide wire to maintain a stable pathway for catheter exchange or for placement of a device. Before the sheath is placed, dilators are first passed over the guide wire to create a smooth tract through the soft tissue into the vessel. Whereas sheaths are measured according to their inner circumference (1 mm circumference = 1 French), guides are measured according to their outer circumference; thus, a 6 French guide fits inside a 6 French sheath. Dilators are also measured according to their outer circumference. Therefore, when a 5 French sheath is to be placed in scarred fibrous tissue, a 6 French dilator must be placed to create a similarly sized tract. Most commonly, a dilator and a sheath of the same size are pinned and placed together.

Most introducer sheaths have hemostatic valves and side ports. Guide catheters can be effectively converted to sheaths by adding a Touhy-Borst valve apparatus. These valves seal around a smaller catheter and reduce back-bleeding. The side port can be used for continuous infusion of heparinized saline to reduce the risk of thrombus formation. The sheath can also be used to straighten tortuous arteries (e.g., the iliac arteries). For example, when a guide wire has been passed through the iliac artery and into the abdominal aorta, the sheath can be advanced over the wire into the abdominal aorta. Passage of a sheath through the tortuous iliac vessel facilitates subsequent passage of catheters and devices.

Once properly placed, sheaths should be secured in position (i.e., pinned or sutured) so that they are not inadvertently advanced without the introducer or accidentally withdrawn.

Insertion of Catheters

There are many differentiating characteristics by which various types of catheters can be distinguished from one other, including size, shape, stiffness, coating, radiopacity, and side-hole configura-

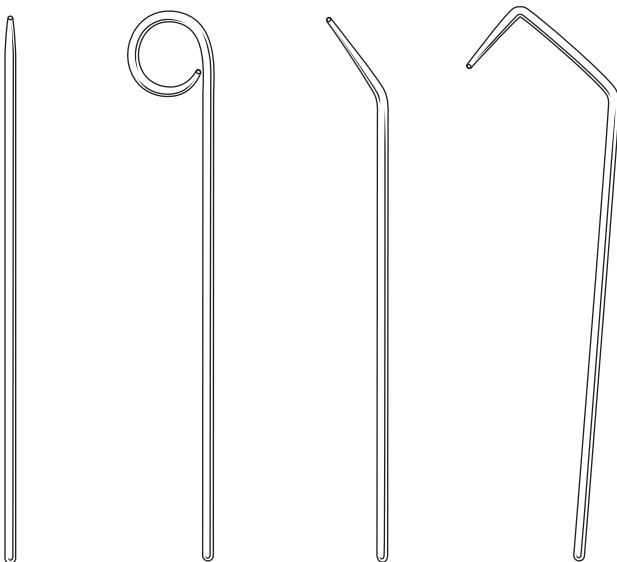

Figure 4 Catheters come with various tip configurations. Shown are straight, pigtail, angled, and double-angled tips (left to right).

tion. As a rule, catheters are sized according to their outer diameter (French) and their length (cm). Numerous tip shapes are available [see Figure 4] (e.g., straight, cobra, headhunter, angled, shepherd's hook, reverse curve, pigtail, and racquet). The initial catheter shape is selected on the basis of the specific requirements of the procedure and the individual patient anatomy. Generally, within the abdominal aorta, the angle of the primary curve of the catheter tip should be similar to that of the vessel takeoff. In some cases, multiple catheters may be needed, used either in sequence or coaxially to perform superselective catheterizations. A variety of complex catheter shapes may be used to select vessels that have steep angles of origin. The use of coatings (e.g., hydrophilic surfaces and Teflon) can facilitate advancement of the catheter in tortuous vessels. Specialty catheters may come with radiopaque tips or with multiple radiopaque markers placed at 1 cm intervals for reference during vessel sizing. Multi-side-hole catheters have a spiraling set of holes that allow more even distribution of a large volume of contrast or other infusate; they are typically used to opacify large vessels with high flows. Generally, opacification of smaller vessels requires a smaller dose of contrast material administered at a slower rate; for this purpose, an end-hole catheter suffices.

Before contrast is injected, the catheter should be aspirated to remove any air bubbles and to verify intraluminal location by means of free-flowing back-bleeding. A small test injection is useful for checking the catheter's position. Depending on the clinical circumstances, the patient may undergo anticoagulation to reduce the risk of thrombus formation on the outside of the catheter. Periodically, the catheter may be flushed with heparinized saline to prevent thrombus formation within it. When a stiffer catheter is advanced forward, it is usually advanced over a guide wire; however, a softer catheter can be used in the same way as a guide wire. Some complex curved catheters may have to be removed over a wire to reduce the risk that the catheter will scrape the vessel wall.

TROUBLESHOOTING

There are several areas in the handling of catheters where attention to detail and good technique can help optimize results. Two common errors of selective catheterization are (1) looking for a specific artery in the wrong location (e.g., as a consequence of

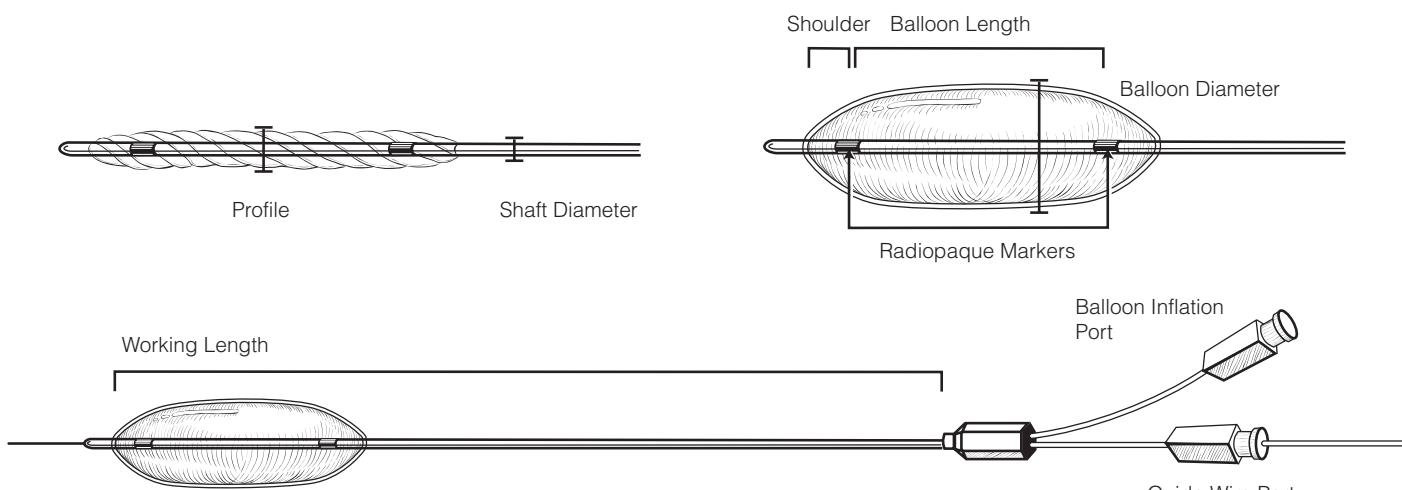

misidentification of bone landmarks) and (2) failing to recognize when the appropriate vessel has been entered (particularly in patients with anomalous vessels or postoperative changes).¹³ These errors can be prevented by first performing roadmapping with nonselective catheterization and angiography; often, repeated roadmapping in multiple projections is required. Another potential problem is accidental loss of guide wire access, which may be more common with inexperienced operators who are not pinning the guide wire in place while a catheter is being pulled out. There are many advanced techniques for handling catheters and guide wires, but these are outside the scope of this discussion.

Use of Balloon Catheters

The purpose of a balloon catheter is to exert a radial force on the luminal surface of a blood vessel to dilate a stenotic lesion. As the balloon inflates, the media and adventitia of the artery stretch, causing a longitudinal fracture of the plaque. Minor arterial dissection is expected with this technique. Thus, the compression of the plaque is not the principal means of increasing the cross-sectional area of the vessel.

Several features are considered in selecting a balloon catheter for a specific intervention, including balloon diameter and length, catheter size and length, trackability, balloon type (e.g., compliant, noncompliant, cutting, or trilobed), and catheter profile [see Figure 5]. Typically, balloons range from 1.5 to 40 mm in diameter and from 1.5 to 10 cm in length. The vessel should be slightly overdistended when the balloon is inflated. Thus, measuring the diameter of the normal vessel distal to the lesion will help determine an appropriate balloon diameter. If the operator is unsure of the proper balloon diameter, it is best to choose a smaller-diameter balloon and then move to a larger balloon if necessary. The shortest balloon length that spans the entire lesion with a slight extension into the normal artery should be chosen, so that the shoulder of the balloon dilates as little as possible of the normal portion of the vessel. If the balloon is too short and is not centered, it may be squeezed away from the stenosis during inflation (the so-called watermelon seed effect). Balloon catheters typically range from 70 to 150 cm in length. The shortest catheter length that reaches the lesion from the access site is preferred because a shorter catheter is easier to manipulate. The diameter (or profile) of the catheter depends on the type and size of the balloon and typically ranges from 3 to 14 French. Sometimes, a smaller-profile balloon may be used if a smaller-diameter guide wire provides enough support for treatment of the lesion. If the balloon catheter is smaller than the sheath, contrast injection is possible when the balloon is in position; this allows the balloon's position to be fine-tuned immediately before inflation.

The balloon catheter is advanced over the guide wire through the sheath to the lesion, and the balloon is centered over the lesion. The balloon is inflated with a dilute contrast solution so that its expansion can be monitored fluoroscopically. Guidelines for inflation and deflation techniques vary with respect to speed and duration of inflation, number of dilatations, and balloon pressure. Typically, the balloon is inflated to a pressure that results in a smooth parallel profile of the balloon walls, held for 20 to 60 seconds, and then deflated. In most clinical circumstances, the inflation pressure should not exceed rated burst pressures. After dilatation, the balloon catheter is removed, with the guide wire left in place across the lesion (in case stenting proves necessary). Completion angiography is performed for evaluation of the results, including assessment of distal vascular beds.

**Figure 5** Shown is a balloon angioplasty catheter.

Dilatation may be considered successful if (1) flow-limiting dissection is absent, (2) residual luminal diameter stenosis is less than 30%, and (3) the systolic pressure gradient is less than 5 to 10 mm Hg. Vasodilators can unmask a significant gradient.

TROUBLESHOOTING

Complications associated with the use of balloon catheters include thrombosis, vessel rupture, embolization, and dissection. The incidence of these complications is influenced by patient selection and by the nature of the lesion being treated. For example, complications may be more likely with treatment of stenoses adjacent to aneurysms, long segments of occlusion, tandem lesions, lesions near major branches, and calcified eccentric plaques. Even though some degree of dissection is expected after balloon angioplasty, larger flow-limiting dissections may call for further management. This problem can often be solved by placing a stent over the dissection.

Most patients feel discomfort and mild pain during balloon inflation. If a patient experiences severe pain that persists after deflation of the balloon, the possibility of vessel rupture must be considered. If the vessel ruptures, the balloon may be reinflated over the injury to tamponade it. Prolonged balloon inflation often closes the leak, but at the risk of causing thrombosis. If the vessel continues to leak, a covered stent may be placed over the injury, or open vascular repair may be necessary.

If inflation of the balloon fails to dilate the vessel completely, it may be helpful to use a larger-diameter balloon or a higher inflation pressure. Higher inflation pressures may be cautiously attempted, but the vessel may simply recoil after dilatation.¹⁴ A stent is often useful in this scenario.

If the balloon crosses the lesions only partially, it should not be inflated. The position of the guide wire should be checked: the wire may be in a subintimal location. If the stenosis is very tight, the lesion may be predilated with a smaller-profile balloon catheter.

Placement of Vascular Stents

Intravascular stents are commonly used in endovascular surgery, particularly after failed percutaneous transluminal angioplasty. Placement of an iliac artery stent is indicated when there is significant residual stenosis, flow-limiting dissection, or a persistent pressure gradient. Although angioplasty is often successful, it may fail when there is elastic recoil of the arterial wall or when the lesion is resistant to dilatation because of heavy calcification.

Stenting can often remedy these situations by providing physical support to keep the vessel open. Many physicians now regard primary stenting (i.e., routine use of stents) as a preferred approach for many vascular lesions.

CHOICE OF STENT TYPE

Stents are divided into two categories: balloon-expandable stents and self-expanding stents. They may also be described as being covered (with a graft material), coated (with a therapeutic compound), absorbable, or radioactive. Stent types differ with respect to hoop strength (for resisting arterial recoil), cell size, cell structure, shape (e.g., tapered or nontapered), radiopacity, longitudinal flexibility (for crossing tortuous vessels), radial elasticity (for resisting repeated external compression), and profile. Stents come in many different lengths and expanded diameters on a wide variety of deployment catheters.

Balloon-Expandable Stents

Balloon-expandable stents come either premounted on balloon catheters or unmounted; unmounted stents must be manually crimped onto a balloon to be delivered. With unmounted stents, a smaller inventory can be maintained, and a wider range of stent-balloon combinations is available. Pre-mounted stents, however, tend to be more solidly mounted and less likely to be lost during delivery. Once the stent is at the desired lesion, the balloon is inflated and the stent expanded.

The main advantage balloon-expandable stents have over self-expanding stents is that they have greater hoop strength, which means that they can better resist the recoil of the vessel after full expansion of the stent. In addition, many interventionalists feel that balloon-expandable stents can be more precisely placed than self-expanding stents and thus are preferable when accuracy is of high clinical importance. However, older balloon-expandable stents are less flexible than current models, and navigating such older devices in a tortuous vessel can be difficult.

Self-Expanding Stents

Self-expanding stents are placed within a delivery catheter and rely on a self-expansion mechanism for full deployment. A common deployment mechanism involves the use of an outer jacket and a plunger: the jacket is withdrawn while the stent is held in position by the plunger, and the stent then expands to its predetermined diameter. Commonly, a balloon is employed to ensure that the stent is fully expanded and impacted into the plaque.

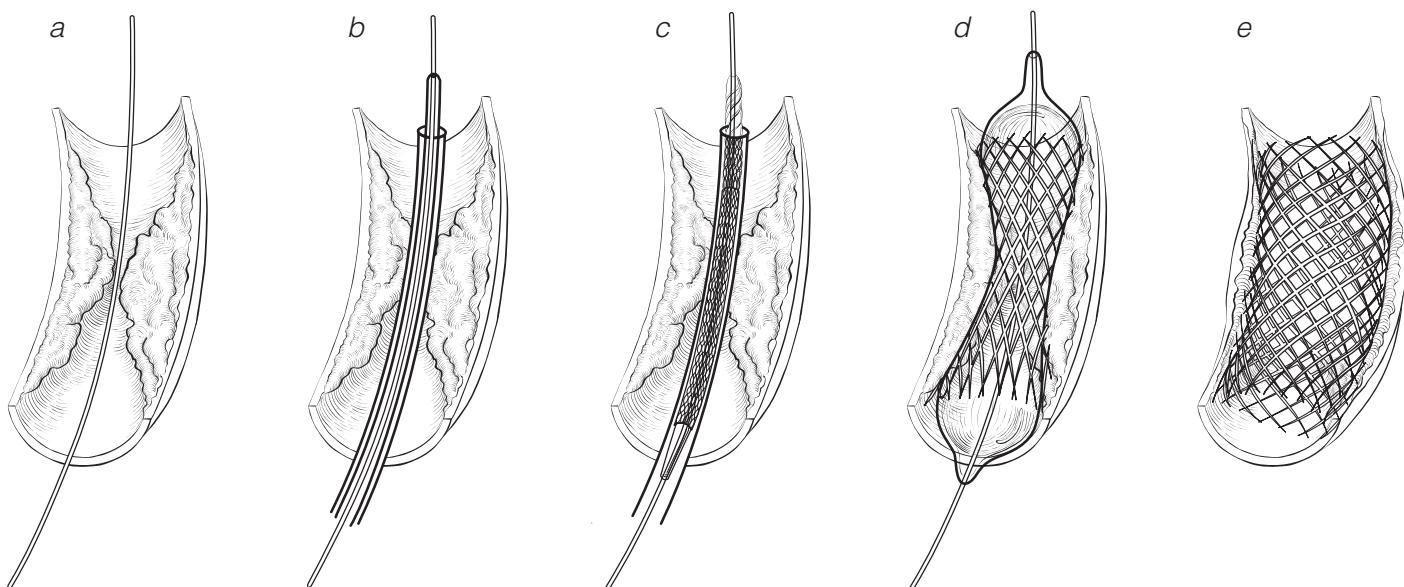

Figure 6 Deployment of a balloon-expandable stent. (a) The guide wire is passed across the lesion. (b) The sheath-dilator combination is passed over the guide wire across the lesion. (c) The dilator is removed, and the balloon-expandable stent is advanced. (d) The sheath is retracted and the balloon inflated. (e) The balloon is deflated and withdrawn, leaving the stent fully deployed.

An advantage self-expanding stents have over balloon-expandable stents is that they offer a greater degree of longitudinal flexibility and thus are more easily tracked into position. Self-expanding stents come in lengths of up to 20 cm, which means that fewer overlap zones and fewer stents are required in the treatment of long lesions. In addition, they may be delivered by catheters with smaller profiles, which may reduce arterial-access complications. Self-expanding stents may also be placed in regions of the body where they are subject to crushing forces (e.g., the carotid artery) because they are capable of recovering from the deformation and maintaining the arterial lumen.¹⁵ As noted, however, self-expanding stents have less hoop strength than the balloon-expandable stents.

Covered Stents

Stents may be covered with polyester, polytetrafluoroethylene, or other materials. Currently, covered stents are being used more frequently for treating occlusive lesions, but they are more commonly employed for treating aneurysms, arterial rupture, and arteriovenous fistulas.^{15,16}

GENERAL TECHNICAL PRINCIPLES

Conceptually, stent placement is very similar to balloon angioplasty [see Figure 6]. Preoperatively, the patient is often given an antiplatelet agent, which may be continued for 4 weeks or longer postoperatively to reduce the risk of thrombosis. In general, the diameter of the fully deployed stent should slightly exceed that of the vessel, though many interventionalists do not fully dilate stents in the aorta and the carotid bifurcation.¹¹ If occlusion makes the exact diameter of the artery difficult to measure, the vessel's contralateral counterpart can be used as a guide.¹⁶ The stent should also be slightly longer than the lesion to ensure that the entire lesion is covered. In this way, good wall apposition can be achieved and stent migration prevented.

The classic approach is to advance a guide (or a long sheath) across the stenosis over the previously placed guide wire; the vascular stent is then passed through the guide and positioned at the lesion, the guide is withdrawn, and the stent is deployed. With newer stent delivery systems, the leading tip often allows the stent

to be delivered without precrossing the lesion with a guide or sheath. Multiple stents are sometimes required to complete the procedure.

TROUBLESHOOTING

It is often helpful to place the leading end of a self-expanding stent slightly beyond the lesion, then draw it back. This measure removes loaded tension from the system; it also allows the stent to be pulled back slightly after the initiation of deployment, at which point various forces sometimes cause the stent to move forward. However, the partially deployed struts of the stent can injure the vessel wall if moved too much or advanced forward. It is also important to keep in mind the potential for foreshortening of the stent during deployment. Failure to cover the entire lesion with the stent results in residual disease after the procedure, which can cause subsequent thrombosis and necessitate the placement of an additional stent. To prevent restenosis, multiple stents should generally be placed so as to overlap one another, but doing so may increase the risk of fatigue fractures. Clearly, the nuances of stent deployment vary according to the system being used; frequent use of a particular system will enhance the interventionalist's familiarity with the behavior of the device and improve the subsequent clinical results.

Postprocedural Management of Arterial Access Site

After any endovascular procedure, the arterial access site must be addressed. Manual compression is still the most common method of hemostasis and is effective in most instances. The artery often must be compressed for longer than 20 minutes to prevent bleeding complications. If the patient is receiving anticoagulant therapy, it may be necessary to wait until the coagulation parameters have normalized before pulling out the sheath. This can be done when the patient is out of the OR or the interventional suite and in the recovery room or when the patient has been moved onto the hospital floor. After hemostasis has been achieved at the access site, the patient should refrain from walking for about 6 hours, after which period the puncture site generally is sufficient-

ly stable. After therapeutic procedures involving relatively large devices, use of an arterial closure device may be advantageous. Several such closure devices are now commercially available. These devices are improving in quality and are certain to be used more frequently in the future.

Summary: Basic Steps in Endovascular Procedures

1. Before operation, assess the patient with respect to renal function, allergies, active infections, anticoagulant management, and skin condition (in cases of planned access). Consider prescribing antiplatelet agents.
2. Monitor and sedate the patient as necessary.
3. Prepare and drape the selected arterial access site or sites.
4. Infiltrate a local anesthetic at the selected site.
5. Use a scalpel to nick the skin at the planned needle entry site, a few centimeters distal to the intended arterial puncture site.
6. Cannulate the artery with the entry needle.
7. Pass the guide wire into the needle for at least 20 to 25 cm. Use fluoroscopy to follow the guide wire as indicated.
8. Remove the needle while pinning the guide wire in place.
9. Apply manual compression during exchanges to prevent hematoma formation around the artery.
10. Use dilators to create an appropriate tract while pinning the guide wire.
11. Pass a sheath over the pinned guide wire. Often, with small sheaths and minimal scarring, the dilator and the sheath

- are placed simultaneously. Remove the dilator.
12. Administer anticoagulation as indicated.
 13. Manipulate the guide wire to the appropriate position past the lesion (in cases of nonselective catheterization).
 14. Pass the catheter over the guide wire and through the sheath. Manipulate the catheter to select the branches for guide wire cannulation.
 15. Perform angiography through the catheter or the sheath to clarify the anatomy.
 16. Remove the catheter while pinning the guide wire.
 17. Pass the balloon catheter over the guide wire. Advance the balloon across and center it over the lesion. If indicated, primary stenting may be performed.
 18. Inflate the balloon.
 19. Deflate the balloon.
 20. Remove the balloon catheter while pinning the guide wire.
 21. Perform angiography.
 22. If necessary, pass the vascular stent over the guide wire and advance it across the lesion.
 23. Deploy the stent.
 24. Perform completion angiography.
 25. If the angiogram is satisfactory, remove the guide wire, the catheter, and the sheath.
 26. Apply manual compression to the access site, or use a closure device.

9 SURGICAL TREATMENT OF CAROTID ARTERY DISEASE

Wesley S. Moore, M.D., F.A.C.S.

The rationale for operating on patients with carotid artery disease is to prevent stroke. It has been estimated that in 50% to 80% of patients who experience an ischemic stroke, the underlying cause is a lesion in the distribution of the carotid artery, usually in the vicinity of the carotid bifurcation. It would follow, then, that appropriate identification and intervention could significantly reduce the incidence of ischemic stroke.

Carotid endarterectomy (CEA) for both symptomatic and asymptomatic carotid artery stenosis has been extensively evaluated in prospective, randomized trials. Symptomatic patients have been studied in the North American Symptomatic Carotid Endarterectomy Trial (NASCET),¹ the European Carotid Stenosis Trial (ECST),² and the symptomatic carotid stenosis trial from the Veterans Affairs (VA) Cooperative Studies Program.³ The results of all three trials conclusively demonstrate that symptomatic patients with greater than 50% stenosis on arteriography are at substantially lower risk for stroke after CEA than control subjects receiving medical management alone. Asymptomatic patients with hemodynamically significant stenosis also benefit from surgical treatment: the Asymptomatic Carotid Atherosclerosis Study (ACAS)⁴ and the asymptomatic carotid stenosis trial from the VA Cooperative Studies Program⁵ show that the risk of both transient ischemic attacks (TIAs) and stroke is markedly lower in patients treated with CEA and best medical management than in control subjects treated with best medical management alone. The Medical Research Council study of the Asymptomatic Carotid Stenosis Trial (ACST) confirmed the findings of these two studies, citing results virtually identical to those originally reported by ACAS.⁶

Surgical reconstruction of the carotid artery yields the greatest benefits when done by surgeons who can keep complication rates to an absolute minimum. The majority of complications associated with carotid arterial procedures are either technical or judgmental; accordingly, in what follows, I emphasize the procedural details that I consider particularly important for deriving the best short- and long-term results from surgical intervention.

Preoperative Evaluation

PATIENT SELECTION

Indications for carotid artery surgery can be divided into two major categories: (1) asymptomatic critical stenosis and (2) symptomatic hemodynamically significant stenosis.⁷

Asymptomatic Critical Stenosis

The VA asymptomatic carotid stenosis study, ACAS, and ACST all found that in patients with diameter-reducing stenosis of 60% or greater on angiography, CEA resulted in fewer fatal and nonfatal strokes over a 5-year period than nonoperative treatment with best medical management alone. It is important to keep in mind that there are several different ways of measuring stenosis [see 6:2 *Asymptomatic Carotid Bruit*]. The 60% figure cited by ACAS and the VA study was determined according to the North American

method rather than the European method. Moreover, it was determined by means of contrast angiography rather than duplex ultrasonography (DUS) or magnetic resonance imaging. If the decision for CEA is to be based on DUS, some conversion of values is required. A patient who has an 80% to 99% stenosis on DUS can generally be assumed to have a diameter-reducing stenosis of at least 60% on angiography; a stenosis that is less than 80% on DUS may fall short of a 60% diameter-reducing stenosis on angiography.

Symptomatic Hemodynamically Significant Carotid Stenosis

Both NASCET and ECST found that symptomatic patients with hemodynamically significant stenoses experienced fewer fatal and nonfatal strokes after CEA combined with best medical management than after best medical management alone, provided that the perioperative morbidity and mortality from stroke was 6.0% or less. Thus, patients with monocular or hemispheric TIAs are good candidates for CEA. Global ischemic attacks have also been used as an indication for CEA. This practice has not been evaluated in clinical trials; it is usually justified on the basis of the ACAS data alone.

Patients who have previously experienced a hemispheric stroke but who are not disabled and have made a reasonable recovery are also good candidates for CEA if they have a hemodynamically significant stenosis.

IMAGING

Identification of a carotid lesion that can be treated with endarterectomy usually begins with a carotid duplex scan. Indications for carotid duplex scanning fall into three main categories: symptoms, signs, and risk factors. Symptoms include classic TIAs and strokes that give rise to clinical suspicion of carotid bifurcation disease. The primary sign is the presence of a carotid bruit on auscultation. Risk factors include cigarette smoking, hypertension, diabetes mellitus, hypercholesterolemia, peripheral vascular disease, and coronary artery disease. As the number of risk factors present increases, the likelihood of associated carotid bifurcation disease increases exponentially.

Patients who present with focal ischemic symptoms are likely to have associated carotid bifurcation disease; however, other pathologic conditions (e.g., emboli of cardiac origin, aortic arch disease, intracranial vascular disease, coagulopathy, and brain tumors) can also be responsible for focal symptoms. Accordingly, a complete workup of a symptomatic patient should include cardiac evaluation as well as intracranial imaging.

The accuracy of carotid duplex scanning is highly dependent on the technician performing it and on the laboratory where it is done. A carefully performed carotid duplex scan is often the most accurate indicator of carotid bifurcation disease; however, a hastily or carelessly performed scan can result in overestimation of the extent of the carotid bifurcation disease. For this reason, additional imaging studies (e.g., magnetic resonance angiography, computed tomographic angiography, and, when there is serious doubt, contrast angiography) may be indicated.

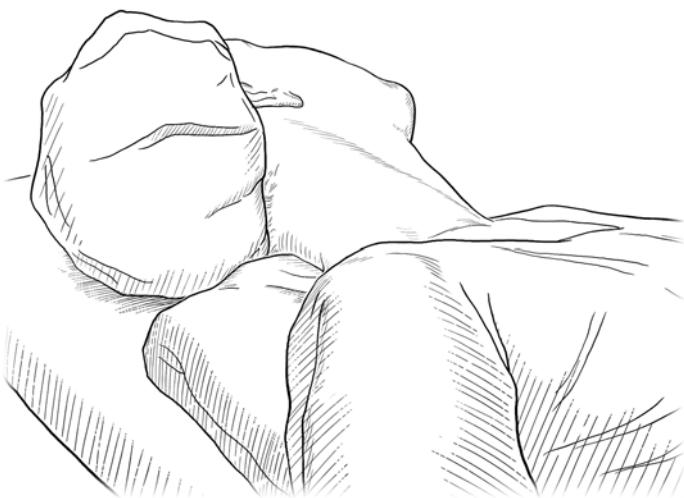

Figure 1 Carotid arterial procedures. Shown is the recommended patient positioning.

Operative Planning

Before operation is scheduled, the general health of the patient must be assessed, with particular attention paid to cardiac and pulmonary status. Given that many patients with carotid artery disease are hypertensive or diabetic, good preoperative control of diabetes mellitus and blood pressure is mandatory. In addition, to reduce the risk of thromboembolic complications, patients should receive antiplatelet drugs (e.g., aspirin) up to and on the day of operation. Finally, it is well documented that the risk of perioperative cardiac complications can be materially reduced by placing patients on a combination regimen that includes a statin and a beta blocker.

ANESTHESIA

Surgery on the cervical portion of the carotid artery may be performed with the patient under either general or cervical block anesthesia. Both techniques have their advocates, their advantages, and their disadvantages.

The advantages of general anesthesia include a quiet operative field, maximal patient comfort, and good airway control. In addition, general anesthesia may lead to improved cerebral blood flow and give better protection against reduced blood flow during carotid clamping. The disadvantages of general anesthesia include blood pressure swings during induction and the inability to monitor the patient's conscious response to carotid clamping. Some reports also suggest that the incidence of cardiac complications is higher during general anesthesia than during cervical block anesthesia.

The main advantage of cervical block anesthesia is the ability to monitor cerebral function during carotid clamping: an awake patient can be engaged in conversation and can be asked to carry out motor activities of the extremities. The disadvantages of cervical block anesthesia include possible patient discomfort, restlessness, and intolerance of the longer operations that are sometimes necessary for technical reasons. Another disadvantage is that on occasion, a patient cannot tolerate carotid clamping and demonstrates an immediate neurologic deficit with clamp application. Such an occurrence heightens the anxiety level of the surgical team, thereby increasing the risk that they will commit technical errors in the rush to place an internal shunt.

Besides considering the inherent advantages and disadvantages of these two anesthetic techniques with respect to the patient, it is important to consider their advantages and disadvantages with respect to individual surgical practice. A given

surgeon may well work better and achieve better results with one technique or the other.

Whichever anesthetic approach is used, all patients should have a radial arterial line in place to allow continuous blood pressure monitoring and to provide access for determining blood gas levels. As a rule, there is no need to place a central venous line or a right heart catheter, except in patients with marginal cardiac function.

PATIENT POSITIONING

Proper positioning of the patient is necessary to provide optimal exposure of the neck from the clavicle up to the mastoid process on the side of the proposed operation [see Figure 1]. The patient is placed in the supine position with a folded sheet under the shoulders to induce a mild degree of neck extension. Excessive neck extension should be avoided, however, because it places tension on the artery and actually hinders rather than facilitates exposure. This potential problem can be addressed by placing one or more towels under the head to adjust the neck to the optimal degree of extension. The patient's head is then turned away from the side of the operation to improve cervical exposure further. Finally, the table top may be rotated slightly away from the side of the operation so as to provide a flat surgical field. The head of the table may be elevated slightly if the patient's blood pressure is adequate; this step helps lower venous pressure and reduce venous bleeding during the operation [see Figure 1].

Operative Technique

STEP 1: INITIAL INCISION

Either of two incisions may be used for exposure of the cervical carotid artery. The more common choice is a vertical incision placed along an imaginary line that extends from the sternoclavicular junction to the mastoid process, paralleling the anterior margin of the sternocleidomastoid muscle as well as the course of the carotid artery and the contents of the carotid sheath [see Figure 2]. The incision is centered over the presumed location of the carotid bifurcation. The advantage of this incision is that it pro-

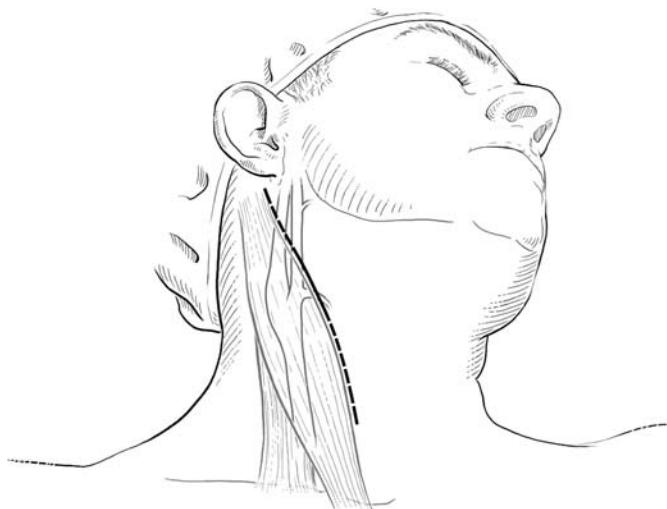

Figure 2 Carotid arterial procedures. The incision most commonly used to expose the cervical carotid artery is a vertical one placed along the anterior margin of the sternocleidomastoid muscle and centered over the presumed location of the carotid bifurcation. It may be extended proximally or distally, depending on where the carotid bifurcation turns out to be.

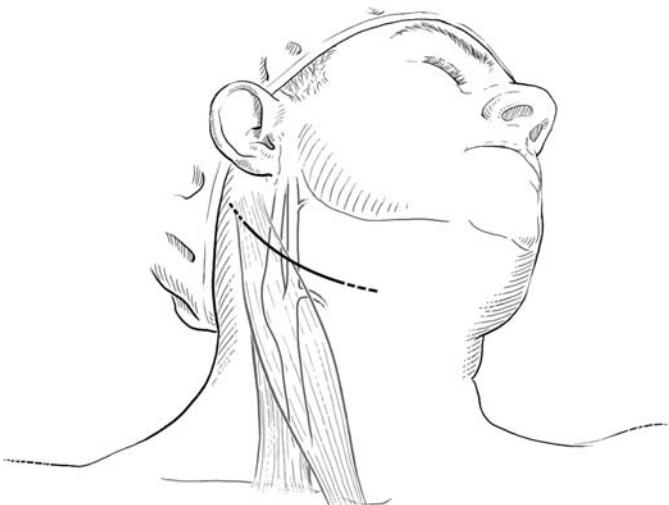

Figure 3 Carotid arterial procedures. An alternative incision to the vertical incision is a transverse incision along a skin crease in the vicinity of the carotid bifurcation.

vides optimal exposure of the cervical carotid artery and can readily be extended either proximally or distally along the aforementioned imaginary line to give additional exposure when needed (e.g., when the carotid bifurcation is unusually high). The disadvantage of this incision is that it runs against Langer's lines; thus, if a keloid occurs, it is likely to be in an unsightly position. In most patients, the incision heals to a fine line, and it usually is not noticeable once healing is complete.

The alternative to the vertical incision is a transverse incision that is placed in a skin crease on the anterior portion of the neck and then curved toward the mastoid process posteriorly [see Figure 3].

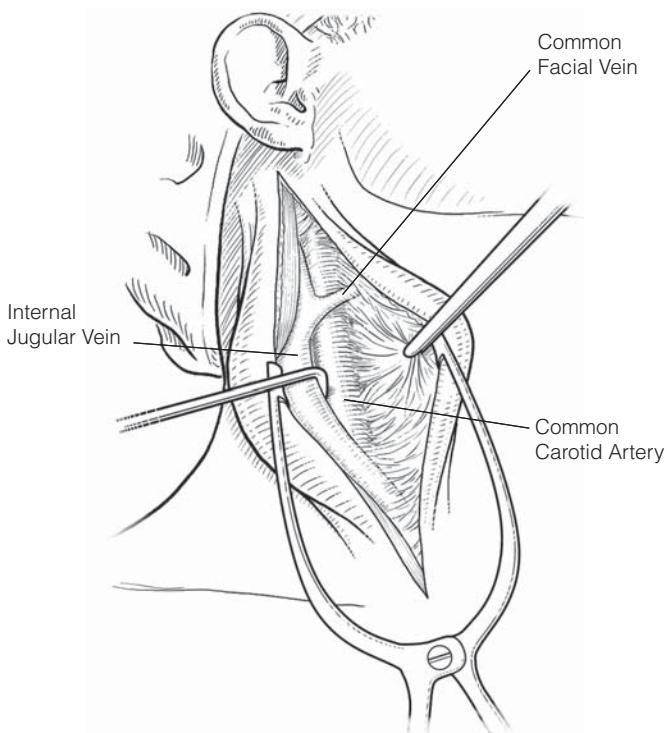

Figure 4 Carotid arterial procedures. After the sternocleidomastoid muscle is mobilized off the carotid sheath, the jugular vein is identified. The perivascular plane along the jugular vein is opened until the common facial vein is exposed.

Skin flaps are raised in a subplatysmal layer, and the incision is deepened along the anterior border of the sternocleidomastoid muscle. The advantage of this alternative incision is that it may be more cosmetically acceptable; however, its inferior portion frequently crosses the neck anteriorly, which may make it more visible than an incision confined to the line of the sternocleidomastoid muscle would be. The disadvantage of this incision is that it requires the raising of skin flaps, which takes additional time and may limit the extent of any proximal exposure that may be required.

STEP 2: EXPOSURE OF CAROTID ARTERY

Once the incision through the platysmal layer has been completed, an avascular areolar plane is developed along the anterior border of the sternocleidomastoid muscle for the full length of the incision so as to expose the carotid sheath. The internal jugular vein is usually the most visible vessel, and the carotid sheath is opened along this vessel's anterior border. The common facial vein, which drains into the internal jugular vein, is a relatively constant landmark. Because the common facial vein is the venous analogue of the external carotid artery, it can generally be used as a guide to the position of the carotid bifurcation [see Figure 4]. On occasion, a patient has several accessory facial veins instead of a single common facial vein. The common facial vein or the accessory facial veins are then divided between ligatures so that the jugular vein can be retracted laterally. The common carotid artery and the carotid bifurcation lie immediately beneath the divided facial veins.

At this point, care must be taken to look for the vagus nerve. This nerve is usually located posterior to the common carotid artery, but it is sometimes rotated into a more superficial position. Another important neurologic structure in this area is the ansa cervicalis, which is formed by the junction of fibers from the hypoglossal (12th cranial) nerve and fibers from the first cervical nerve and which continues inferiorly as a single trunk, providing innervation to the strap muscles. This nerve should be spared if possible, but it can be divided without significant sequelae if it interferes with optimal exposure of the carotid bifurcation. One convenient method of separating the nerve from the artery is to divide the fibers running from the first cervical nerve to the ansa cervicalis; when this is done, the nerve is readily mobilized and retracted anteriorly away from the carotid artery.

The perivascular plane of the common carotid artery is then entered, and the common carotid artery is circumferentially mobilized. The common carotid artery is palpated against a right-angle clamp to determine the proximal extent of the atherosclerotic plaque. If possible, the common carotid artery should be mobilized proximal to the plaque until a circumferentially soft portion of that vessel is reached. During mobilization, the vagus nerve should be identified in its usual location posterior to the vessel and carefully protected; this nerve sometimes spirals anterior to the carotid artery as the vessel is dissected distally.

Dissection is then extended distally toward the carotid bifurcation and continued along both the internal and external carotid arteries. Excessive manipulation of the area around the carotid bifurcation must be avoided. In particular, it is important to be careful around the bulb of the internal carotid artery: this is where the majority of the plaque will be located, and manipulation can easily dislodge plaque or thromboembolic material. With exposure of the carotid bifurcation, the hypoglossal nerve may come into view. Care should be taken not to injure this nerve, though it may have to be mobilized to permit sufficient distal exposure of the internal carotid artery.

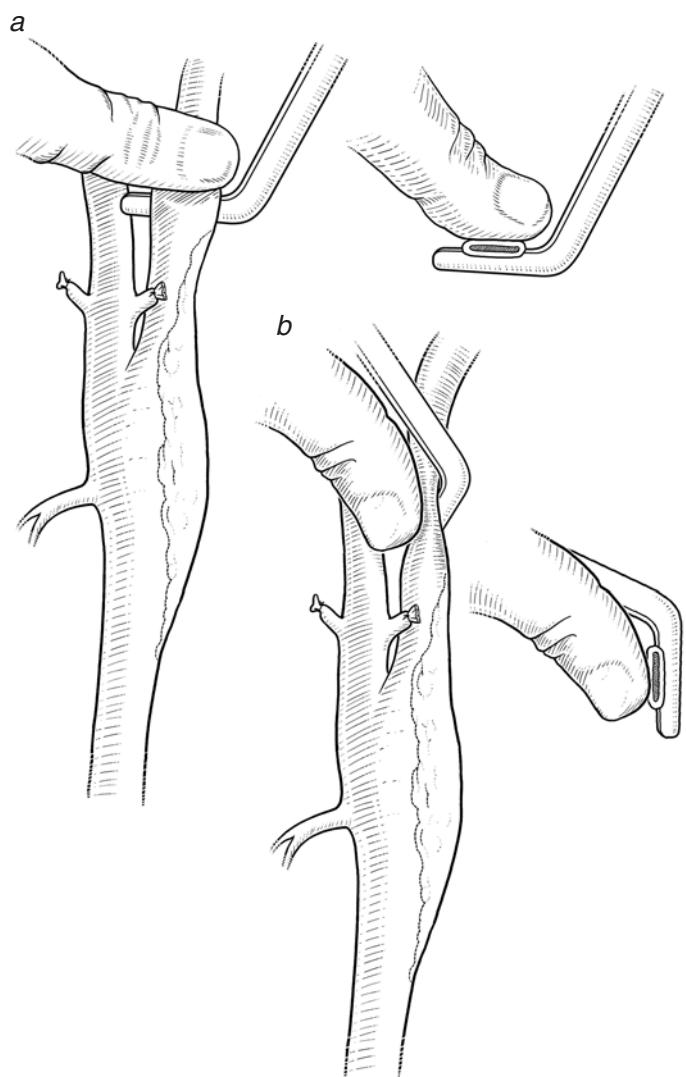

Figure 5 Carotid arterial procedures. After the common carotid artery and the internal and external carotid arteries have been mobilized, the internal carotid artery is palpated against a right-angle clamp in at least two planes (*a, b*) to confirm that the artery has been freed beyond the end point of the plaque.

Next, dissection is continued distally beyond the bulb of the internal carotid artery to a point where the internal carotid artery is normal. At this point, the relevant portion of the vessel is circumferentially mobilized and palpated against a right-angle clamp in at least two planes to confirm that the atheromatous plaque does not reach up to the level of the proposed clamping [see Figure 5]. Once this is accomplished, the external carotid artery is mobilized beyond the end point of plaque extension in a similar manner.

If the patient has a high carotid bifurcation or if the plaque in the internal carotid artery extends further distally than usual, a more extensive exposure of the carotid bifurcation, the internal carotid artery, or both is required. To provide such exposure, the skin incision is extended all the way to the mastoid process. The sternocleidomastoid muscle is fully mobilized up to the mastoid process, with care taken to look for the spinal portion of the accessory (11th cranial) nerve as it enters the sternocleidomastoid muscle on the medial surface. With the sternocleidomastoid muscle fully mobilized and retractors in place, the internal carotid artery can then be further exposed.

The jugular vein is mobilized up toward the base of the skull, with care taken to look for additional accessory facial branches, which must be divided between ligatures so that the jugular vein can be fully mobilized and moved posteriorly. The perivascular plane of the internal carotid artery is carefully defined, and the artery is gently mobilized; the more distal portion of the internal carotid artery can then be mobilized downward. If the vessel is still insufficiently mobile, then the nerve to the carotid body and the ascending pharyngeal artery within the crotch between the internal and external carotid arteries are mobilized and divided between ligatures. These two structures often serve as a de facto suspensory ligament for the carotid bulb; dividing them allows the carotid bifurcation to drop down and permits further downward traction of the internal carotid artery as the vessel is gently mobilized distally [see Figure 6].

Once the internal carotid artery is further exposed distally and the hypoglossal nerve is mobilized along its vertical portion and moved anteriorly, the posterior belly of the digastric muscle is encountered. An areolar plane is developed posteriorly and superiorly along the inferior margin of the posterior belly of the digastric muscle, allowing the muscle to be mobilized anteriorly to yield additional exposure of the internal carotid artery. If the

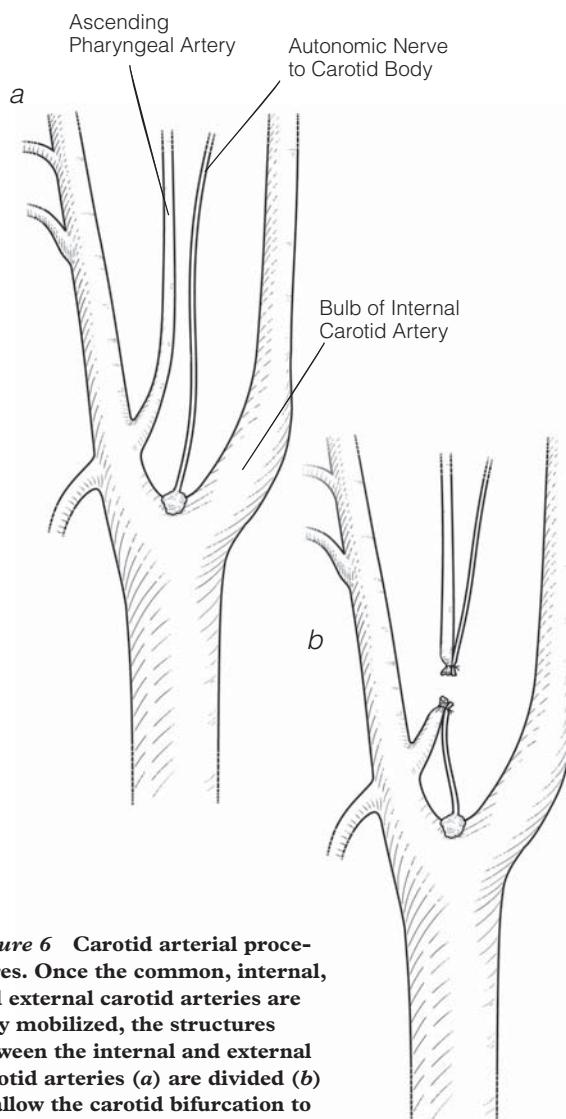

Figure 6 Carotid arterial procedures. Once the common, internal, and external carotid arteries are fully mobilized, the structures between the internal and external carotid arteries (*a*) are divided (*b*) to allow the carotid bifurcation to drop down.

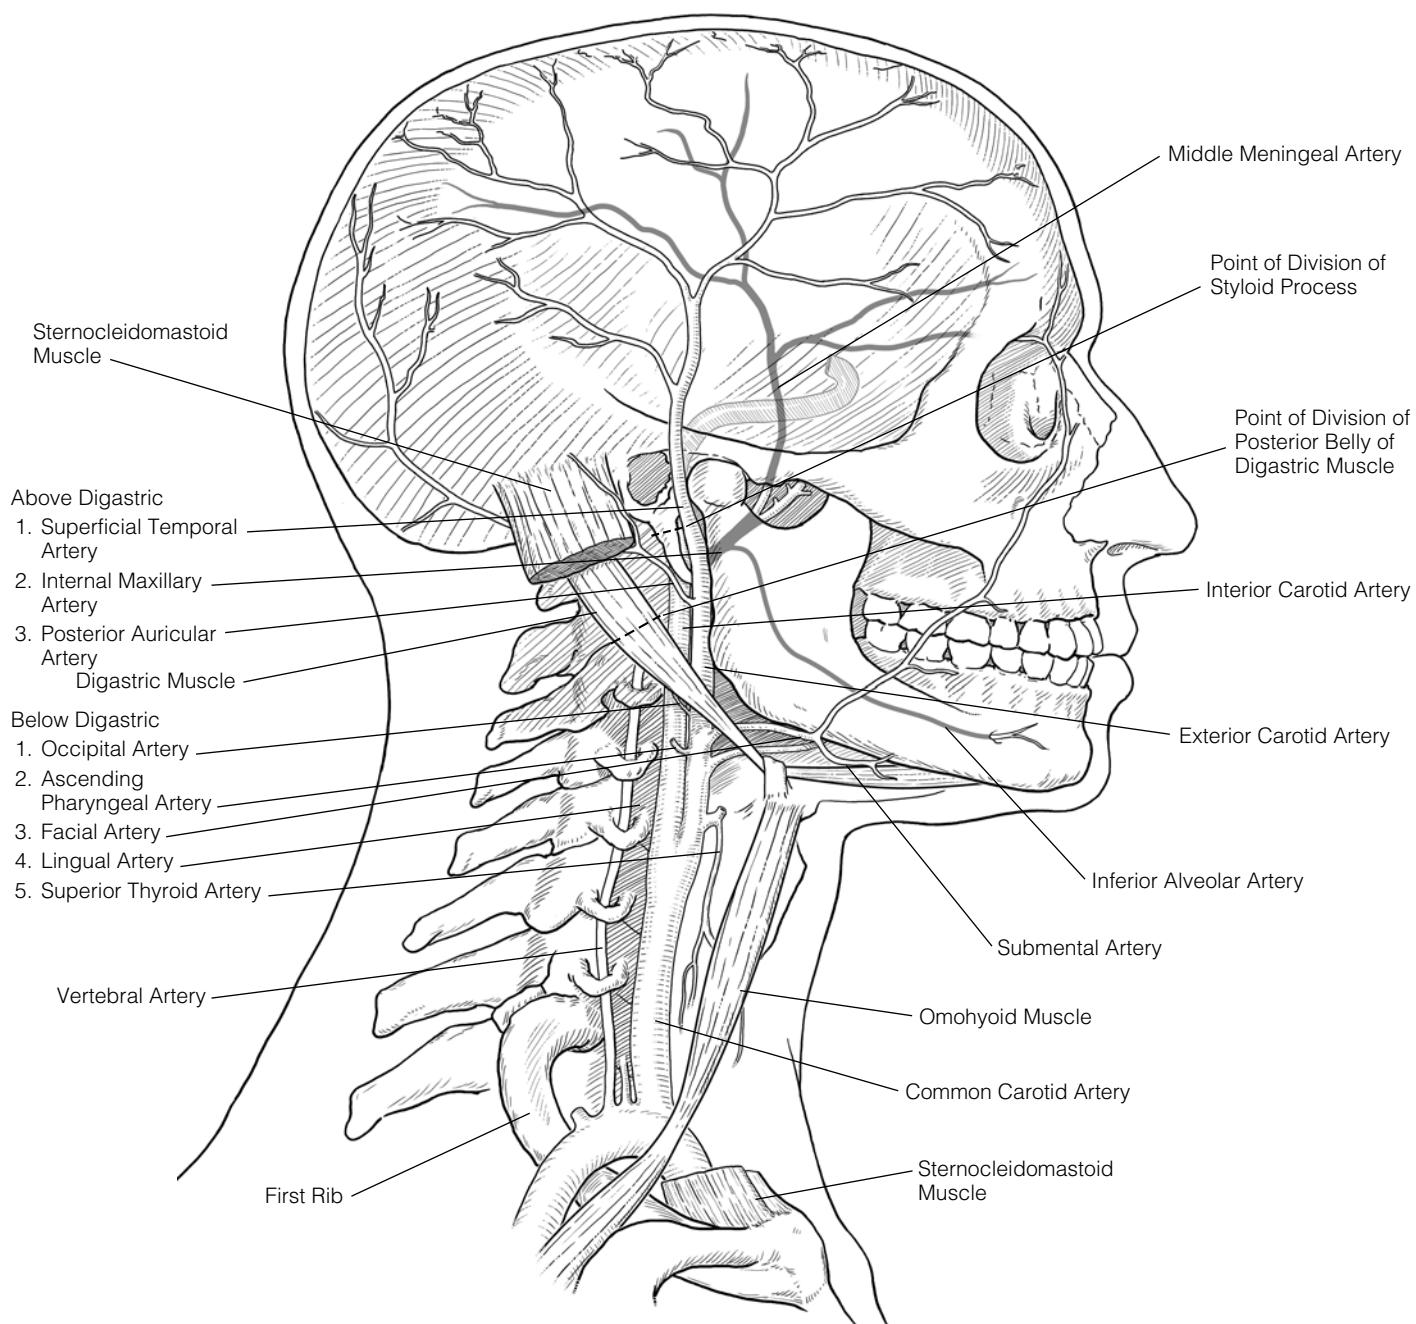

Figure 7 Carotid arterial procedures. Division of the posterior belly of the digastric muscle yields additional exposure of the internal carotid artery. If the internal carotid artery must be mobilized all the way to the base of the skull, further distal exposure is obtained by separating the attachments of the ligaments to the styloid process and dividing the styloid process.

resulting exposure is not sufficient, the muscle may be carefully encircled with a right-angle clamp and divided [see Figure 7]. In those relatively uncommon cases in which even further distal exposure is required, the styloid process is palpated and the muscular and ligamentous attachments to the styloid process divided, so that the styloid process can be exposed with a periosteal elevator. Once the styloid process has been completely freed of its muscular and ligamentous attachments and the cranial nerves in the vicinity have been identified and carefully protected, the styloid process is cut close to the base of the skull [see Figure 7]. This step yields optimal exposure of the internal carotid artery all the way to the base of the skull.

Additional adjunctive measures for more extensive exposure of the internal carotid artery have been described. These include subluxation or dislocation of the mandible,⁸ wiring of the mandible into a subluxed position, and division of the ramus of the mandible with rotation of the mandible away from the base of the skull. In my view, these measures are unnecessary, provided that the sternocleidomastoid muscle and the jugular vein have been adequately mobilized, the plane around the internal carotid artery has been developed, and the carotid bifurcation has been released.

A significant risk associated with extended exposure of the internal carotid artery is possible injury to the vagus nerve, the accessory nerve, or the hypoglossal nerve. Retraction of the vagus

nerve may produce either temporary or permanent vocal cord palsy, and extensive retraction of or injury to the hypoglossal nerve causes denervation of the ipsilateral side of the tongue, manifested by tongue deviation to the ipsilateral side on protrusion or difficulty with mastication or swallowing. In addition, posterior exposure of a high carotid bifurcation may result in injury to branches of the glossopharyngeal (ninth cranial) nerve.

A common error in carotid artery mobilization is failure to recognize that the plaque in the internal carotid artery extends beyond the upper limit of the arterial exposure. It is far better to anticipate this problem before clamping and opening the artery than to discover it afterward and be forced to mobilize the vessel after it has been clamped. Once the common carotid and internal carotid arteries have been mobilized sufficiently, they are encircled with umbilical tapes; Rumel tourniquets are used if an internal shunt is required or desired.

STEP 3: CEREBRAL CIRCULATORY SUPPORT

Clamping of the carotid artery necessarily results in interruption of blood flow through the vessel. Patients who have good collateral circulation via the contralateral carotid artery or the vertebral arteries generally (though not always) tolerate the temporary interruption of flow through the clamped artery well.⁹ Patients who have inadequate collateral blood flow require cerebral circulatory support, usually in the form of placement of an internal shunt. There are three basic approaches to shunt use: (1) routine use of an internal shunt, (2) selective use of an internal shunt, and (3) routine avoidance of shunting in an attempt to minimize clamp time.

Shunting Options

Routine shunting In approximately 10% of patients undergoing carotid artery surgery, collateral blood flow is inadequate and temporary use of an indwelling shunt is necessary to prevent brain damage. In the remaining 90%, collateral blood flow is adequate and clamping generally well tolerated, and shunting is therefore unnecessary. Clearly, routine use of an internal shunt takes care of the 10% of patients who require shunts. Its disadvantage is that it is an additional procedure that carries its own complications, to which not only the 10% of patients who require shunting but also the 90% who do not are subjected. The potential complications associated with placement of a shunt include intimal injury (including the raising of an intimal flap), atheroma embolization (if atherosomatous material is scooped up during shunt placement), and air embolization (if air bubbles are trapped within the shunt and not recognized).

Selective shunting Selective placement of a shunt has an advantage over routine placement in that the procedure and its potential complications are limited to the 10% of patients who actually require a shunt. Its main disadvantage is that the methods used to identify patients who require shunting may not be entirely reliable.

Selective identification of patients who require shunting can be accomplished in several ways. The most direct—and perhaps safest—method is to employ local or cervical block anesthesia so that the effect of temporary carotid clamping can be assessed in a conscious patient; if clamping leads to a neurologic deficit, then the patient clearly requires an internal shunt. Other methods of identifying patients who require a shunt make use of techniques such as continuous electroencephalographic monitoring, measurement of somatosensory evoked potential, and monitoring of middle cerebral blood flow with transcranial Doppler ultrasonography.

A useful method of determining the adequacy of collateral cere-

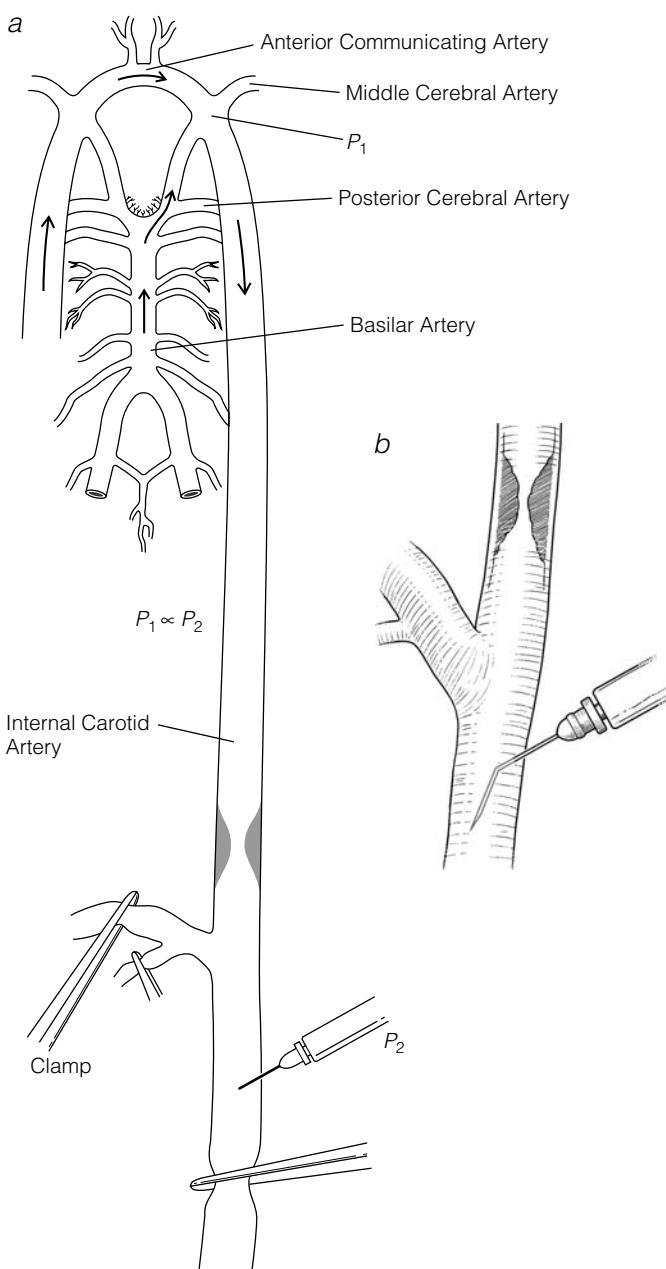

Figure 8 Carotid arterial procedures. (a) Shown is a graphic representation of the measurement of internal carotid artery back-pressure. (b) The needle is bent at a 45° angle before being inserted into the common carotid artery.

bral blood flow is measurement of back-pressure in the internal carotid artery.¹⁰ Back-pressure has been shown to be a good index of the adequacy of collateral blood flow, and it correlates well with the safety of temporary clamping and thus with the necessity of placing an internal shunt. Back-pressure is measured by placing into the common carotid artery a needle that is connected to pressure tubing and a pressure transducer. The tip of the needle is bent at a 45° angle. Systemic blood pressure is measured, and clamps are placed on the common carotid artery proximal to the needle and on the external carotid artery. The residual pressure in the common carotid artery, which is in continuity with the internal carotid artery, is then allowed to equilibrate; the resulting pressure reading represents internal carotid artery back-pressure [see Figure 8]. It has been determined that patients with back-pressures high-

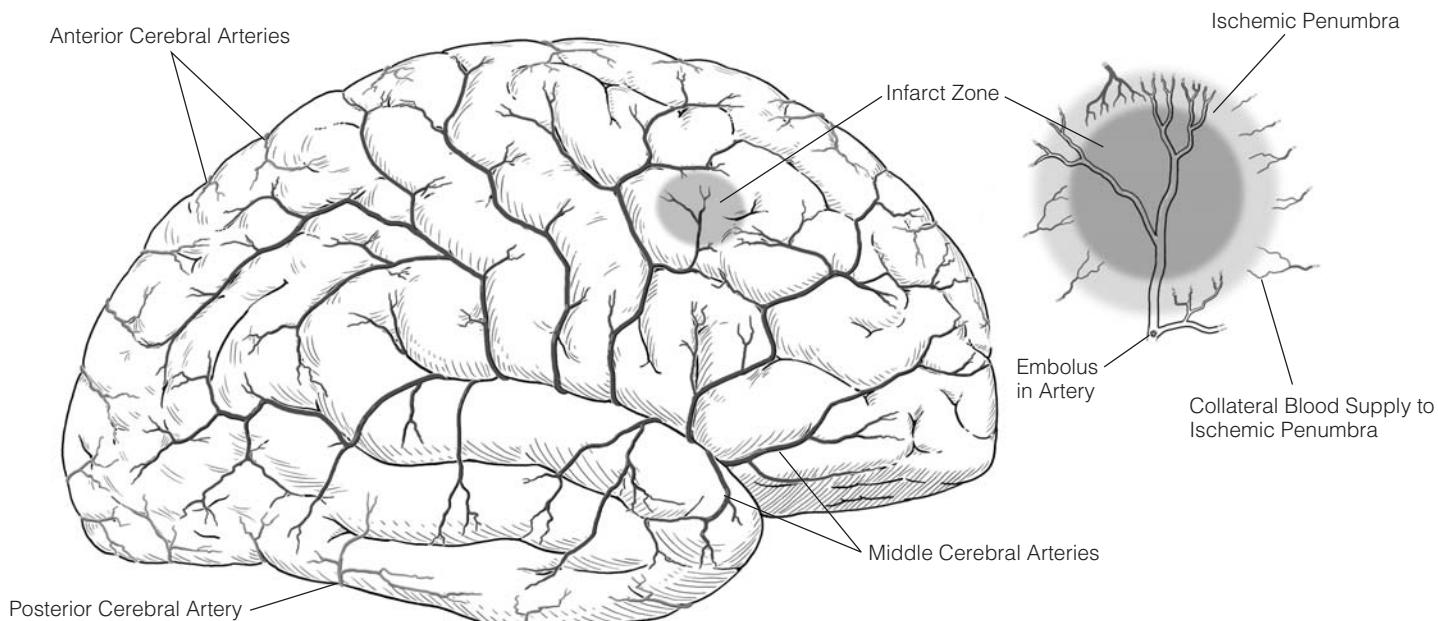

Figure 9 Carotid arterial procedures. When a thromboembolic fragment occludes a cortical arterial branch, a central infarct zone develops, surrounded by an ischemic zone that derives some residual blood supply from collateral vessels. In this zone, known as the ischemic penumbra, the residual blood supply is sufficient to maintain viability.

er than 25 mm Hg can tolerate temporary clamping without incurring brain damage.

The utility of selective shunting in appropriate settings notwithstanding, routine shunting is recommended for patients who have previously had a stroke, regardless of the degree of neurologic recovery. In these patients, a central area of cerebral infarction is surrounded by a zone of relatively ischemic tissue—the so-called ischemic penumbra. The ischemic penumbra is made up of live and potentially functional brain tissue, but its viability is highly dependent on maximization of cerebral perfusion pressure through collateral channels. Accordingly, any interruption of carotid circulation, regardless of the degree of collateral circulation present, may threaten the ischemic penumbra and extend the infarct [see Figure 9]. In my opinion, all CEA patients with prior strokes should receive shunts on a routine basis.

Routine avoidance of shunting The advantage of routinely avoiding the use of shunts is that the technical issues and potential complications associated with the additional procedure are avoided entirely. The disadvantage is that unshunted patients with poor collateral blood flow may sustain ischemic brain damage, particularly if the clamp time turns out to be longer than was anticipated.

Technique of Shunt Placement

Internal shunts must be placed with great care if shunt-associated complications are to be avoided. Of the various shunts currently available, I prefer the Javid shunt, which is tapered, has smooth leading edges, and possesses external bulbous circumferential extensions that permit it to be held in place with a circumferential Rumel tourniquet, thereby minimizing the chances of inadvertent dislodgment. Optimal placement of an internal shunt may be achieved by means of the following steps [see Figure 10].

After the patient has been adequately heparinized and the artery clamped and opened, the distal portion of the internal shunt is placed into the internal carotid artery. A clamp is placed

on the shunt and briefly opened to allow back-bleeding; good back-bleeding confirms that the shunt is lying free in the lumen of the internal carotid artery. The shunt is then secured by tightening a Rumel tourniquet, and the bulbous portion of the shunt is engaged to prevent dislodgment.

Next, the proximal portion of the shunt is placed into the common carotid artery. As this is done, the clamp is removed from the shunt so that backflow from the shunt will dislodge any loose material and air within the common carotid artery. The shunt is then reclamped, and the clamp is removed from the common carotid artery as the proximal portion of the shunt is passed into that vessel.

When the proximal portion of the shunt is in the proper position in the common carotid artery, it is secured by tightening a Rumel tourniquet on the vessel. The clamp on the shunt is then slowly opened so that the surgeon can observe flow through the translucent device and thus verify that no solid particles or air bubbles are passing through it. Because the shunt is relatively long, the surgeon has a reasonable amount of time in which to observe flow. If any particles or air bubbles are identified, the shunt can be quickly clamped, removed from the common carotid artery, and back-bled, and the procedure can then be repeated.

Once the shunt is secured in place and open, its length and redundancy allow it to be easily manipulated medially and laterally; endarterectomy can then be performed without the encumbrance of an inlying shunt.

STEP 4: RECONSTRUCTION OPTIONS

There are four principal reconstructions involving the common carotid artery and the carotid bifurcation: (1) conventional open CEA with either patch angioplasty or primary closure, (2) eversion endarterectomy, (3) reconstruction for proximal lesions of the common carotid artery, and (4) reconstruction for recurrent stenosis with resection of the carotid bifurcation and grafting.

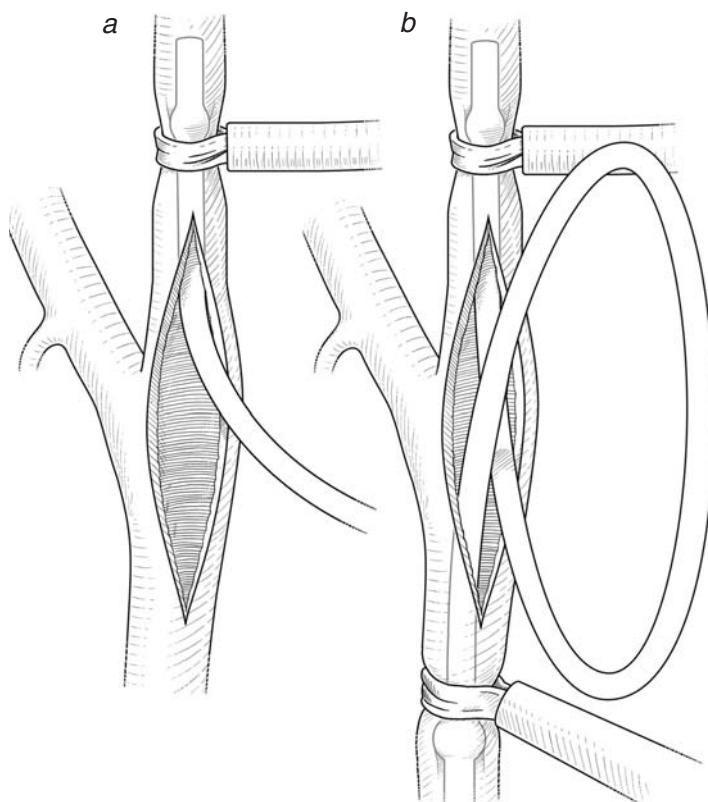

Figure 10 Carotid arterial procedures. Shown is the technique of shunt placement, first distally (a) and then proximally (b).

Open Carotid Endarterectomy

Once the carotid bifurcation has been fully mobilized both proximal and distal to the lesion, systemic anticoagulation with heparin is initiated. I generally give 5,000 units, an amount that is sufficient to produce adequate anticoagulation for the duration of carotid clamping but is not large enough to necessitate heparin reversal on completion of the operation. If the patient has been receiving clopidogrel—particularly if clopidogrel was given in combination with aspirin—the heparin dose must be reduced to allow adequate hemostasis to be achieved after reconstruction. In these cases, I usually limit the heparin dose to 3,000 units. If internal carotid artery back-pressure is to be used to determine whether the patient requires an internal shunt, then it is measured at this time. If cerebral electrical activity is to be the determinant, then the internal, external, and common carotid arteries are clamped and electrical activity is monitored (e.g., via EEG) with the clamps in place. If electrical changes are noted with clamping, an internal shunt is required.

Arteriotomy The common carotid artery and the carotid bifurcation are rotated so as to be positioned for an arteriotomy that begins on the common carotid artery and extends through the bulb of the internal carotid artery to a point 180° opposite the flow divider [see Figure 11]. This incision effectively bivalves the carotid bulb, thus making possible a more accurate primary or patch closure. The arteriotomy continues through the plaque and extends well up into the internal carotid artery, beyond the visible end point of the atherosclerotic plaque.

Plaque removal A dissection plane separating the atherosclerotic intima from the media and the adventitia is then developed with a sharp-bladed dissector. As a rule, it is easiest to begin

the endarterectomy at the point where the plaque is bulkiest. At this point, the medial fibers are usually gone, but as the dissection continues both proximally and distally, more normal medial tissue may be seen. It is important to develop the dissection plane between the intima and the media if possible because doing so permits the creation of a feathered end point distally as dissection proceeds into a relatively normal portion of the internal carotid artery [see Figure 12]. If the dissection plane is between the media and the adventitia, a feathered end point is much harder to achieve. Failure to achieve a feathered end point often results in a sharp shelf at the internal carotid artery level, which increases the risk of subsequent intimal dissection when blood flow is restored.

Once the dissection plane is complete on one side of the arteriotomy at the level of the common carotid artery, a right-angle clamp is gently inserted into the plane and advanced through it to the opposite side of the arteriotomy, thereby separating the plaque from the arterial wall around the entire circumference of the vessel. The clamp is then gently spread and brought downward to complete the circumferential dissection of the plaque proximally. The proximal end point of plaque dissection is obtained by cutting the intima with a No. 15 blade.

With the same depth of dissection now existing on both sides of the open common carotid artery, dissection then continues distally up to the carotid bifurcation. At this point, the plaque within the external carotid artery is carefully separated in a circumferential fashion. This is usually done by using a sharp mosquito clamp until all of the plaque has been separated from the vessel wall and dissection has reached normal intima. The freed plaque is gently grasped with the opened mosquito clamp, traction is applied, and

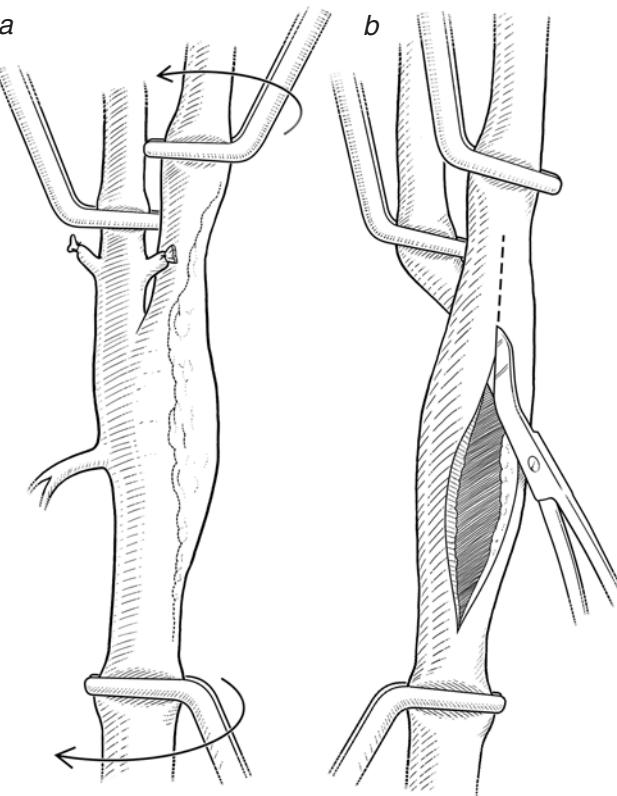

Figure 11 Carotid arterial procedures: open endarterectomy. Clamps are applied to the common, internal, and external carotid arteries, and the structures are rotated (a) so that an arteriotomy can be made in the common carotid artery 180° opposite the flow divider (b).

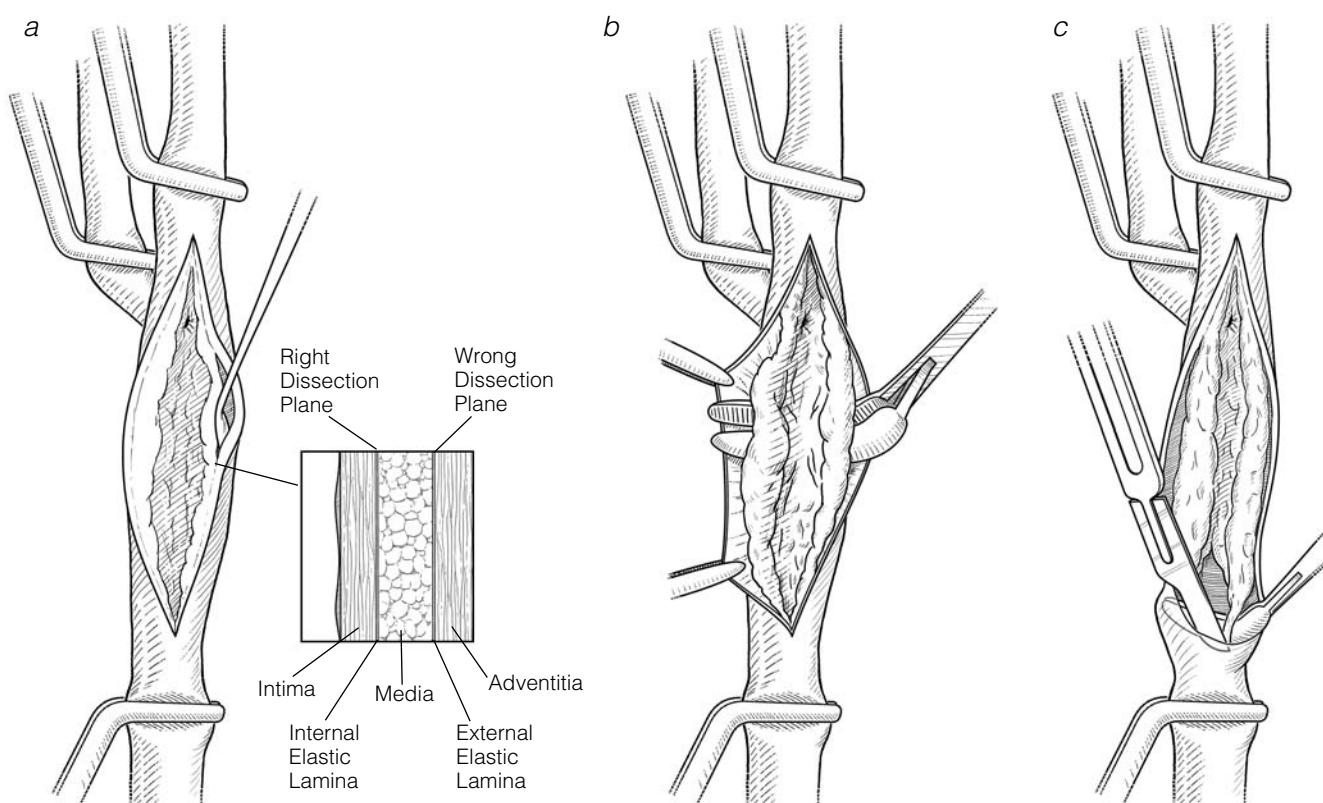

Figure 12 Carotid arterial procedures: open endarterectomy. (a) Dissection is started where plaque is thickest. Often, medial fibers are completely gone here. Dissection proceeds both proximally and distally along one side, and more normal medial tissue may be found. Development of a plane between intima and media, if possible, is valuable for creating a feathered end point distally. (b) Once dissection is complete on one side, the same plane is established on the opposite side. (c) The end point of proximal dissection is established by sharp division of plaque against the clamp.

the distal end point of plaque dissection in the external carotid artery is obtained.

Dissection then continues up the internal carotid artery, with care taken to leave normal intima behind. Often, the plaque becomes a relatively narrow tongue of atheroma on the posterior wall of the internal carotid artery. If the edge of the atheromatous plaque is followed to its end, a tapered, feathered end point can be achieved.

Irrigation and clearing of debris After removal of the specimen, the intimectomized surface is vigorously irrigated with heparinized saline. Any medial debris present is carefully removed. The distal end point is irrigated to determine whether there is a residual flap that might lead to subsequent intimal dissection; if there is a flap, it is carefully removed. If there is a sharp shelf at the distal end point, it is usually an indication that the endarterectomy has not been carried far enough distally. When this is the case, the arteriotomy should be lengthened so that the endarterectomy can be extended to a point where the intima is completely normal. If the patient has a very high carotid bifurcation, very distal plaque, or both and further dissection is impeded by the base of the skull, it may be necessary to secure the distal end point with tacking sutures. Tacking sutures should be used only in exceptional circumstances because their use may lead to healing abnormalities or to the presence of platelet aggregate material that can cause thromboembolic or occlusive complications.

Once the intimectomized surface is completely clear of debris, the lumen of the external carotid artery should be visually inspect-

ed to confirm that all overlying dissected intima has been cleared. Any residual dissected intima can be gently teased out with a mosquito clamp. Once the vessel is completely clear, preparation is made for closure of the arteriotomy.

Closure of arteriotomy If the arteriotomy is relatively short and extends only up to the central portion of the bulb of the internal carotid artery, it can usually be closed primarily with a continuous 6-0 polypropylene suture. Placing very small stitches close together in the internal carotid artery should minimize the risk of vessel narrowing.

If the vessel is relatively small or the arteriotomy was extended well up on the internal carotid artery to ensure a complete endarterectomy, the arteriotomy should be closed with a patch angioplasty. Of the several patch options available, the basic choice is between a prosthetic patch and an autogenous patch composed of a segment of saphenous vein obtained from an extremity. The relative merits of autogenous and prosthetic patches have been extensively debated in the literature, but no definitive conclusions have been reached. One of the disadvantages of an autogenous patch is that surgeons tend to use the entire open portion of the saphenous vein, which then dilates further under arterial pressure, leading to an artery of aneurysmal proportions. Another disadvantage is the potential for patch blowout, which, though rare, has been reported in several series. The main disadvantage of a prosthetic patch is the risk of infection, but this is extremely low.

At present, it would appear that a prosthetic patch is at least as acceptable as an autogenous patch, and the prosthetic patch has

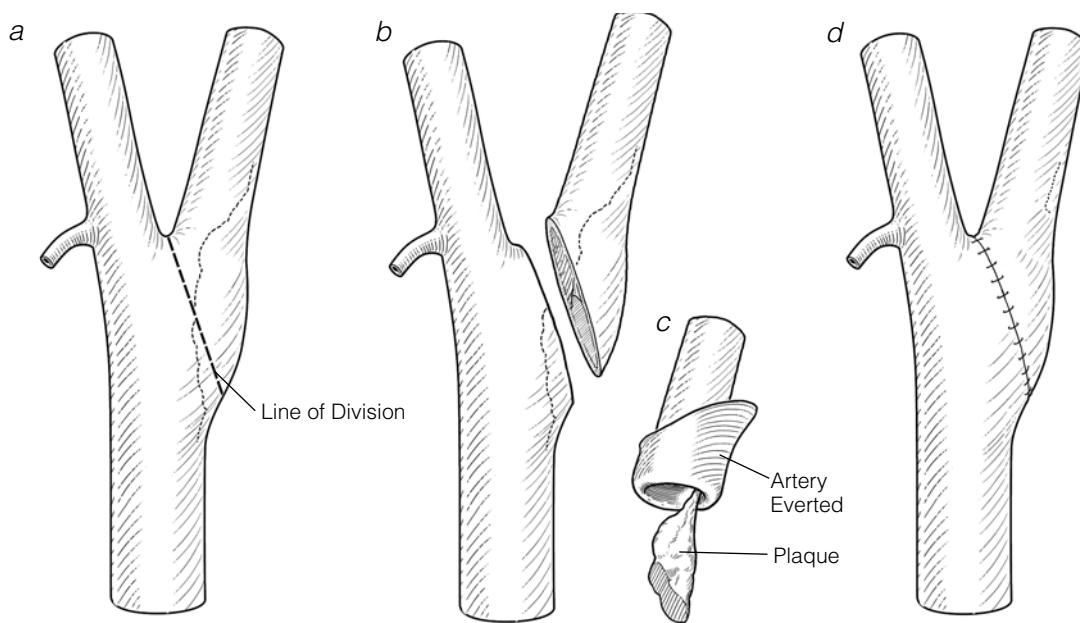

Figure 13 Carotid arterial procedures: eversion endarterectomy. (a, b) The internal carotid artery is divided from the common carotid artery in an oblique line. (c) The divided internal carotid artery is everted on itself so that it can be separated from the underlying plaque. Eversion proceeds distally until the plaque end point is encountered, and the plaque is removed from the internal carotid artery. Proximal endarterectomy of the common carotid artery and endarterectomy of the external carotid artery are then carried out. (d) Once all of the plaque has been removed, the internal carotid artery is reverted and an end-to-side anastomosis is fashioned between the common carotid artery opening and the internal carotid artery.

an additional advantage in that there is no need to remove a normal saphenous vein segment from an extremity. Prosthetic patches can be composed of either fabric or polytetrafluoroethylene (PTFE). Fabric patches now come impregnated with either collagen or gelatin to make them leakproof; PTFE patches do not leak on the surface, but they are prone to leakage at suture needle puncture sites.

Patch size is a crucial consideration: it is important that the patch be neither too wide nor too narrow. If the patch is too narrow, it will not provide the additional material needed to restore the carotid bifurcation to a normal diameter. If the patch is too wide, it will provide too much additional material and create what virtually amounts to a carotid aneurysm; this would represent a significant disadvantage to the patient in terms of flow dynamics and the risk of producing laminated thrombus in the most dilated portion of the carotid bulb. My preference is to use a 6.0 mm wide collagen-impregnated fabric patch for patch angioplasty.

Whichever patch is selected is cut to length, beveled at each end, and sewn in place with a continuous 6-0 polypropylene suture.

Before completion of the closure, the internal carotid artery and the external carotid artery are back-bled and the common carotid artery flushed. The arteriotomy is then completely closed. Removing the clamp on the internal carotid artery allows blood flow to fill the carotid bulb and permits one last internal flush. The origin of the internal carotid artery is then occluded with a vascular forceps, and the clamps are removed first from the external carotid artery and then from the common carotid artery to allow resumption of blood flow. After several heartbeats, the forceps on the origin of the internal carotid artery is removed, and blood flow through the internal carotid artery is restored. There may be some leakage of blood along the suture line, which can usually be controlled with the placement of thrombin-soaked absorbable gelatin

sponge. If any obvious defect is noted between sutures, an additional stitch should be placed.

Eversion Endarterectomy

Eversion endarterectomy was designed and developed to eliminate the need for a suture line on the internal carotid artery, in the hope that doing so would reduce the incidence of myointimal hyperplasia and consequent restenosis. There is evidence to suggest that the use of eversion endarterectomy has led to some reduction in the incidence of myointimal hyperplasia, but the data are controversial and certainly are not conclusive. Nonetheless, the technique may well have merit, and it should be a part of the vascular surgeon's armamentarium.

Besides the avoidance of a suture line on the internal carotid artery, the advantages of eversion endarterectomy include the simple end-to-side anastomotic closure and the possibility of managing a redundant internal carotid artery by moving it down the common carotid artery. One disadvantage is the potential difficulty of achieving an end point in cases in which the bifurcation is high or plaque extends well up the internal carotid artery toward the base of the skull. Another disadvantage arises with patients who require an internal shunt, in that it is not possible to keep an internal shunt in place for the entire duration of an eversion endarterectomy. Yet another disadvantage is that the distal end point cannot be viewed as clearly as it can in open endarterectomy. A fourth disadvantage is that eversion endarterectomy is poorly suited to cases in which the internal carotid artery is relatively small and contracted and thus better treated with patch angioplasty.

Eversion and plaque dissection After the carotid bifurcation is fully mobilized, the internal, external, and common carotid arteries are clamped. A circumferential incision is placed in an

oblique fashion at the junction of the common carotid artery and the bulb of the internal carotid artery to permit division of the bulbous portion of the internal carotid artery from the common carotid [see *Figure 13*]. The edges of the adventitia of the bulb of the internal carotid artery are grasped, and the outer layers of the vessel wall are gradually everted away from the plaque within the artery. Eversion continues cephalad until it reaches the distal end point of the atherosclerotic lesion, which is marked by the presence of a thin, filmy intima that clearly separates with the specimen, leaving normal vessel behind. The plaque in the common carotid artery and the external carotid artery is then removed in the traditional manner; the opening in the common carotid artery may be extended proximally to facilitate this portion of the endarterectomy.

Reversion and reanastomosis The internal carotid artery is then reverted to its normal anatomic position, and an anastomosis between the end of the divided bulb of the internal carotid artery and the common carotid artery is fashioned with a continuous 6-0 polypropylene suture. If the internal carotid artery is redundant [see Special Considerations, below], the arteriotomy on the common carotid artery is extended proximally and the arteriotomy on the medial aspect of the bulb of the internal carotid artery is extended distally so that the carotid bifurcation may be advanced between the internal and common carotid arteries to eliminate the redundancy.

Reconstruction for Proximal Lesions of Common Carotid Artery

Lesions at the origin of the common carotid artery, either at the level of the aortic arch (in the case of the left common carotid artery) or at the innominate bifurcation (in the case of the right common carotid artery), are relatively rare but do occur. Such lesions may arise either in isolation or in combination with carotid bifurcation disease. They can be managed by dividing the common carotid artery and transposing it to the adjacent subclavian artery, provided that there is no occlusive disease in the ipsilateral subclavian artery.

Exposure and mobilization If the lesion at the origin of the common carotid artery is the only one being treated, both the common carotid artery and the subclavian artery should be exposed through a supraclavicular incision that parallels the clavicle. If a carotid bifurcation lesion is present in conjunction with the lesion at the origin of the common carotid artery, the supraclavicular incision is supplemented with a vertical incision along the sternocleidomastoid muscle to permit exposure of the carotid bifurcation. Exposure of the bifurcation has already been addressed (see above); accordingly, I focus here on exposure of the subclavian artery and the proximal common carotid artery.

A supraclavicular incision is placed approximately 1.5 fingerbreadths above the clavicle and centered over the lateral head of the sternocleidomastoid muscle. The lateral head of the sternocleidomastoid muscle is divided, and the scalene triangle is defined. The scalene fat pad is mobilized off the anterior scalene muscle. The phrenic nerve is identified, mobilized off the scalene muscle, and gently retracted. A plane is developed with gentle dissection between the posterior portion of the anterior scalene muscle and the underlying subclavian artery, and the anterior scalene muscle is divided. Division of the muscle exposes the underlying subclavian artery, a sufficient length of which can then be mobilized in the perivascular plane to permit an anastomosis.

The jugular vein is identified at the medial aspect of the incision and mobilized anteriorly and medially to expose the common

carotid artery. The vagus nerve is identified and carefully protected. The common carotid artery is then mobilized both proximally and distally; proximal mobilization should extend as far behind the sternoclavicular junction as the surgeon can comfortably manage.

Transection and anastomosis The common carotid artery is clamped proximally and distally, then divided; the proximal portion of the vessel is oversewn. The transected common carotid artery is brought posterior to the jugular vein in the vicinity of the subclavian artery. The subclavian artery is clamped proximally and distally, a longitudinal arteriotomy is made, and a small ellipse of subclavian arterial tissue is removed. The end of the common carotid artery is then sewn to the side of the subclavian artery with a continuous 6-0 polypropylene suture.

Before completion, the vessels are back-bled and flushed. Once the anastomosis is complete, blood flow is restored, first to the distal subclavian artery and then to the common carotid artery.

Reconstruction for Recurrent Carotid Stenosis

For an initial recurrence of carotid stenosis that primarily results from myointimal hyperplasia, conversion to a patch angioplasty is generally the best treatment. For second or third recurrences or for recurrences that develop in spite of patch angioplasty, resection of the carotid bifurcation with interposition grafting between the common carotid artery and the normal distal internal carotid artery is the best treatment.

Exposure and mobilization Exposure of a carotid bifurcation for treatment of recurrent carotid stenosis can be challenging. The initial skin incision is reopened, and dissection is carried down through the scar tissue to the common carotid artery. The common carotid artery is sharply dissected from the surrounding scar tissue, with the dissection plane kept close to the adventitia to minimize the risk of injury to the vagus nerve and the hypoglossal nerve. Once the common carotid artery has been adequately mobilized, dissection is carried distally to include the carotid bifurcation and the internal carotid artery. In the course of distal dissection, care must be taken to watch for the hypoglossal nerve, which may be incorporated into the scar tissue; this structure must be carefully dissected away from the artery and protected.

Distal dissection continues beyond the end point of the previous closure of the internal carotid artery. Beyond this end point, it is usually possible to enter a previously undissected plane of the internal carotid artery; from here onward, the artery typically is soft around its circumference and is not involved in the recurrent stenosis. The external carotid artery is then mobilized sufficiently to allow the surgeon to control back-bleeding.

Conversion to patch angioplasty If the artery was originally closed primarily, an arteriotomy is made through the old suture line and carried distally through the area of stenosis and onto a relatively normal area of the internal carotid artery. Exploration of the luminal surface usually reveals a smooth, glistening neointima, and observation of the cut section of the artery reveals an area where a whitish, firm thickening of the intimal wall has occurred as a result of myointimal hyperplasia. No attempt should be made to reendarterectomize the stenotic area, because the intimal lesion is not, in fact, plaque but scar tissue. If the intima is removed, the cascade of events that led to the myointimal hyperplasia will simply be reinitiated. Accordingly, the healed intimal surface should be carefully protected. A patch angioplasty across the stenotic area, extending from the common carotid

artery proximally to a relatively normal portion of the internal carotid artery distally, is usually sufficient to treat the lesion.

Resection of carotid bifurcation with interposition grafting If the stenosis is recurring for the second or third time or the artery was originally closed with a patch, the surgeon should proceed with resection and interposition grafting. In most cases, it is necessary to sacrifice the external carotid artery and oversew its origin. The internal carotid artery is divided distal to the intimal hyperplastic lesion, the common carotid artery is divided proximally, and the diseased specimen is removed.

I prefer to use 6.0 mm thin-walled PTFE for the interposition graft. The internal carotid artery distally and the common carotid artery proximally are spatulated by making vertical incisions approximately 6.0 mm in length. The PTFE graft is appropriately beveled both proximally and distally, and beveled or spatulated end-to-end anastomoses are performed, first to the internal carotid artery and then to the common carotid artery.

Before completion, the vessels are back-bled and flushed; once the anastomoses are complete, blood flow is reestablished.

Some surgeons may be tempted to use autogenous saphenous vein for the interposition graft. To use such grafts would appear, on the face of it, to be a good idea; in fact, it is a mistake. For reasons not clearly understood, the use of autogenous saphenous vein in the neck has an extremely poor track record, yielding unacceptably high rates of recurrent stenosis and occlusion in comparison with the use of prosthetic grafts.

Special Considerations

Fibromuscular dysplasia of internal carotid artery

Fibromuscular dysplasia of the internal carotid artery is a congenital or acquired lesion that has been subdivided into four pathologic varieties, of which the most common is medial fibroplasia. On contrast angiography, medial fibroplasia has a characteristic appearance, resembling a string of beads in the extracranial portion of the internal carotid artery [see Figure 14]. A common initial manifestation is a relatively loud bruit in the neck of a young woman. Fibromuscular dysplasia can cause symptoms of monocular or hemispheric TIAs, or it may go on to cause a stroke, usually as a consequence of a dissection resulting in thrombotic occlusion. If symptoms develop, they can generally be controlled by means of antiplatelet drugs. Currently, the only indication for surgical intervention is the persistence of symptoms despite antiplatelet therapy.

Treatment of fibromuscular dysplasia has evolved over the years. The first attempts at surgical repair involved a total resection of the internal carotid artery coupled with interposition of a graft (usually composed of saphenous vein). This technique has largely been abandoned because of the extensive surgical dissection required and the substantial risk of cranial nerve injury; its only remaining application is in cases where there is associated aneurysmal dilatation in the dysplastic segment that calls for resection and graft interposition. At present, the two most popular modes of therapy both involve intraluminal dilatation with disruption of the small septa within the artery. One mode achieves intraluminal dilatation via an open approach, and the other achieves the same end via a percutaneous approach that includes balloon angioplasty. Dilatation and fracturing of the intraluminal septa often result in the release of particles of septal tissue, which in turn can lead to cerebral embolization and infarction. Consequently, an open approach, which enables the surgeon to flush out the disrupted segments, or balloon angioplasty with cerebral embolic protection is usually favored.

Figure 14 Carotid arterial procedures: repair of fibromuscular dysplasia. Depicted is the so-called string of beads deformity of the cervical portion of the internal carotid artery, which is characteristic of medial fibroplasia.

In symptomatic patients with fibromuscular dysplasia, the carotid bifurcation may be exposed in the usual manner. If there is significant redundancy of the internal carotid artery, as documented by preoperative imaging, the artery should be mobilized relatively extensively so that it can be straightened by downward traction before intraluminal dilatation is begun. If, on the other hand, the artery is relatively straight, only minimal mobilization is required. It should be kept in mind that approximately 25% of patients with fibromuscular dysplasia have associated atherosclerotic disease of the carotid bifurcation that must be dealt with at the time of operation. In addition, about the same number of

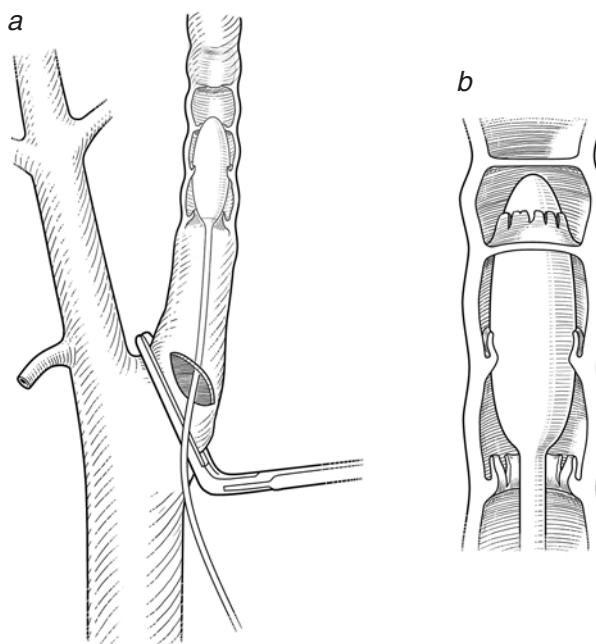

Figure 15 Carotid arterial procedures: repair of fibromuscular dysplasia. (a) The proximal portion of the internal carotid bulb is clamped, a transverse arteriotomy is made, and a coronary dilator is passed into the internal carotid artery and advanced up the vessel to the base of the skull. (b) The small septa in the internal carotid artery are disrupted by the advancing probe.

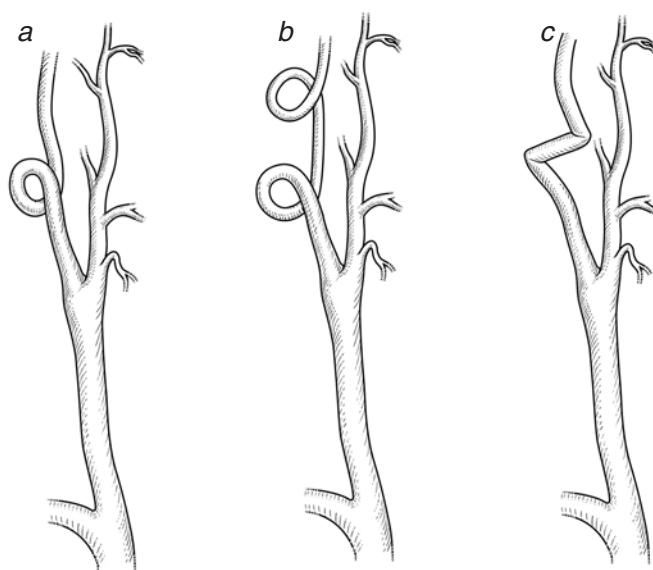

Figure 16 Carotid arterial procedures: repair of coiling or kinking of the internal carotid artery. (a, b) Redundancy of the internal carotid artery can result in one or more 360° coils in the vessel. (c) Degenerative atheromatous changes of the internal carotid artery can cause elongation with associated kinking or buckling.

patients have associated intracranial aneurysms that should be checked for by means of intracranial imaging studies.

Once the carotid bifurcation has been suitably mobilized and it has been established that no associated atheromatous plaque is present, a small transverse incision is made on the bulb of the internal carotid artery, with flow being maintained between the common and external carotid arteries. Serial intraluminal dilatations are then performed with coronary artery dilators of progressively increasing diameter [see Figure 15]. The first dilator (usually 2.5 mm in diameter) is passed up the carotid artery to the base of the skull under digital control. The dilator is then withdrawn, and the artery is back-bled to flush out any fractured segments. The next larger dilator (3.0 mm in diameter) is passed in a similar fashion. Dilatation is repeated with progressively larger dilators (3.5, 4.0, and possibly 4.5 mm in diameter) to complete the procedure.

The transverse arteriotomy is closed with 6-0 polypropylene suture material and flow is reestablished. A completion angiogram verifies that the dysplastic segment is fully restored.

Coiling or kinking of internal carotid artery Redundancy of the internal carotid artery, often resulting in a 360° coil of the high cervical portion of the internal carotid artery, is usually thought to be developmental in origin [see Figure 16a]. Elongation of the internal carotid artery, which often results in kinking of the vessel, is believed to be related to the degenerative changes that occur with aging and atherosclerosis [see Figure 16b]. Both of these phenomena, in and of themselves, are usually asymptomatic; exceptions occur when an atheromatous plaque develops at the apex of the coil or when kinking of the internal carotid artery is accentuated with changes in head position in a patient who depends on relatively normal blood flow through that vessel. Redundancy of the internal carotid artery often becomes a technical consideration during standard surgical treatment of a carotid bifurcation atheroma. When redundancy occurs, it must be appropriately dealt with to prevent postoperative complications.

Anticipated redundancy of the internal carotid artery at the time of carotid bifurcation endarterectomy can usually be managed with

a patch angioplasty. Provided that the arteriotomy extends beyond the apex of the kink, the patch should smooth out the curvature of the redundant vessel and eliminate the kink. If it appears that internal carotid artery redundancy is greater than can be corrected by an elongated patch, then detachment of the internal carotid artery followed by eversion endarterectomy and reimplantation is indicated.

If the arteriotomy has already been closed when it becomes apparent that a kink is present, the problem may be dealt with by mobilizing the external carotid artery sufficiently and then resecting a segment of the common carotid artery and pulling down on the carotid bifurcation with a new end-to-end anastomosis to straighten the redundant internal carotid artery [see Figure 17]. Segmental resection of the internal carotid artery itself combined with end-to-end repair has also been described; this approach is less desirable, being more technically demanding and hence more subject to technical error.

Patients with coiling of the internal carotid artery may present a more difficult problem. If the atheromatous plaque involves only the first portion of the internal carotid artery and the vessel beyond that first portion is relatively normal up to the point where coiling begins, the surgeon can simply avoid the problem by leaving the smooth coil in place and not carrying out an extensive distal dissection. If, on the other hand, it appears that there may be plaque in the coil, then the entire coil must be dissected free, and the patient is left with a very redundant internal carotid artery that must be dealt with. Once again, the best method of managing the problem is to resect the redundant segment of the internal carotid artery, with or without eversion endarterectomy, and to reimplant the internal carotid artery onto the distal common carotid artery at the point of transection.

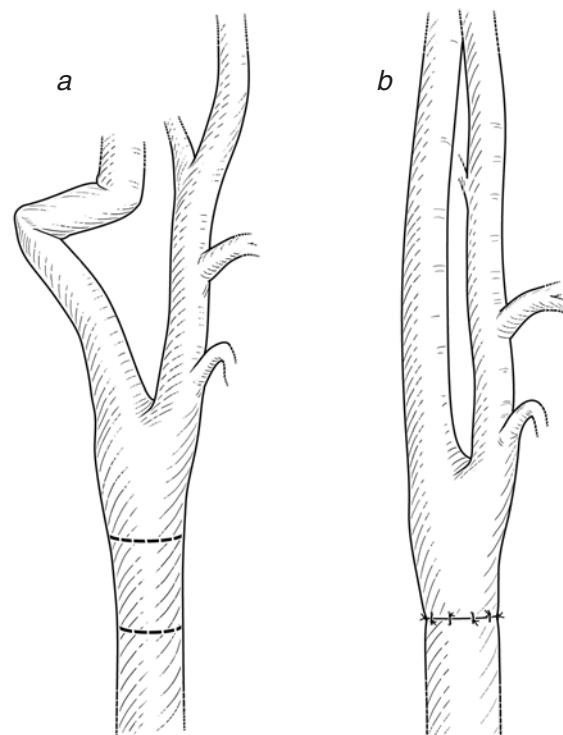

Figure 17 Carotid arterial procedures: repair of coiling or kinking of the internal carotid artery. Kinking or redundancy of the internal carotid artery can be managed by mobilizing the external carotid artery, then resecting a segment of the common carotid artery (a). The surgeon can then draw down the carotid bifurcation for a new primary anastomosis (b).

Upon completion of the reconstruction, a completion angiogram should be obtained to verify that the coiling or kinking has been adequately treated.

STEP 5: COMPLETION IMAGING

Given that the majority of neurologic complications after carotid artery surgery are attributable to technical error, it is imperative that the technical accuracy of the reconstruction be confirmed before the incision is closed and the patient is sent to the recovery room. There are two principal methods of determining the technical quality of the reconstruction: on-table angiography and direct-contact duplex scanning of the carotid artery. To perform either of these techniques routinely in all patients adds relatively little time to the surgical procedure and offers significant advantages to both the patient and the surgeon.^{11,12}

My preferred method of confirming the quality of the reconstruction is completion angiography using a C-arm with digital imaging. For this reason, the operation is done on a table that has angiographic capability, and the radiology technician and the equipment are called for at the beginning of the arteriotomy closure. A 10 ml syringe is connected to flexible tubing, and a 20-gauge needle is attached to the end of the tubing and bent at a 45° angle. Air bubbles are carefully evacuated from the tubing and the needle. Placing the needle into the artery or, in the case of a patched artery, into the midportion of the patch in a retrograde fashion will provide good stability for the needle, which lies in the lumen of the artery in an axial position. Once the C-arm is in place and the fluoroscopy unit turned on, the contrast material is injected by hand. The resulting image of the carotid bifurcation can be continuously replayed until maximal radiographic opacity of the carotid bifurcation and the intracranial circulation has been attained. The image is then carefully inspected for defects at the end points in the internal and external carotid arteries.

Intimal defects in the internal carotid artery are unusual, though not rare. Defects in the external carotid artery are more common because the endarterectomy is essentially done in a blind or closed manner. Defects in the external carotid artery are matters of concern because they may lead to thrombus formation in this vessel; if the thrombus propagates proximally, it may embolize up the internal carotid artery and cause a stroke.¹³ For this reason, if a defect is found in the external carotid artery, it is repaired at the time of the operation. To accomplish the repair, clamps are placed on the external carotid artery proximally at its origin and distally beyond the intimal flap. A transverse arteriotomy is made in the external carotid artery to permit identification and removal of the intimal flap. Once the flap has been carefully removed, the transverse arteriotomy is closed with two or three interrupted 6-0 polypropylene sutures and flow is restored.

Completion angiography also has the advantage of permitting the surgeon to image the intracranial circulation. Now that many operations are being performed on the basis of preoperative carotid duplex scanning, intracranial imaging is typically unavailable beforehand, which means that the status of the intracranial circulation with respect to atherosclerotic lesions in the area of the siphon or the middle cerebral artery or with respect to intracranial aneurysms is usually unknown at the start of the procedure. A completion angiogram gives the surgeon the opportunity to rule out these lesions by looking not only at the area around the reconstruction but also at the intracranial circulation.

An alternative to completion angiography is intraoperative DUS. DUS can be a highly satisfactory way of examining the area of reconstruction, provided that the operating room has duplex scanning capability and that a technologist is available to operate

the equipment. Standard B-mode imaging, in conjunction with Doppler ultrasonography, can accurately identify patent or compromised internal and external carotid arteries.

Once the surgeon has confirmed that a good technical reconstruction has been achieved, preparations can be made for closure.

STEP 6: CLOSURE

The dissected area around the reconstructed carotid artery is carefully irrigated with an antibiotic solution, and the wound is meticulously inspected for hemostasis. Even when good hemostasis has been achieved, it is my practice to place a drain overnight—specifically, a 7.0 mm Jackson-Pratt drain brought out through a small separate stab wound. The platysmal layer is closed with a continuous 3-0 absorbable suture, and the skin is closed with a continuous 4-0 subcuticular absorbable suture. A clear adhesive plastic dressing is applied to the skin, and the patient is sent to the recovery room.

Postoperative Care

The main patient variables to be evaluated in the postoperative period are neurologic status, blood pressure, and wound stability.

On awakening from anesthesia, the patient is carefully observed with a view to determining gross cerebral function on the basis of response to commands and movement of extremities. When the patient is fully awake, vagus nerve and hypoglossal nerve function can be tested.

Blood pressure monitoring is of critical importance after CEA. It is essential first to decide on an acceptable blood pressure range for the patient and then to ensure that this pressure is maintained: neither hypertension nor hypotension is acceptable. Patients with severe carotid bifurcation disease who have undergone CEA temporarily lose autoregulation on the side of the operation; therefore, hypertension can result in reperfusion injury to that side of the brain, ranging all the way from simple headache to fatal intracerebral hemorrhage.

The surgical site should be carefully observed for possible wound expansion resulting from hematoma formation. Even when good hemostasis is achieved and a drain is in place, there is still the possibility of delayed bleeding leading to hematoma and airway compromise. If an expanding hematoma is noted, the safest response is to return the patient to the OR so that the hematoma can be evacuated and a bleeding site sought. The earlier this is done, the better.

If the patient is neurologically intact, blood pressure is well controlled, and there is no evidence of an expanding hematoma, then the remaining postoperative care can be provided in a regular hospital room. It is seldom necessary to observe the patient in the intensive care unit, as was once standard practice.

Follow-up

Periodic follow-up examination is essential. There are two major areas of concern: (1) the possibility of recurrent stenosis on the side that was operated on and (2) the possibility of disease developing or progressing in the contralateral carotid artery. It is my practice to see the patient approximately 3 weeks after CEA. In that visit, the patient is examined for quality of wound healing and the presence or absence of a carotid bruit on both the operated side and the contralateral side, and a carotid duplex scan is performed. If at this time there are no grounds for concern about the contralateral side, scanning is done only on the side of the operation. The scan serves to establish the new baseline and confirms that the carotid reconstruc-

tion is satisfactory. The new baseline is then used as the basis for assessing patient status during subsequent follow-up.

The next patient visit takes place 6 months after operation, at which time a bilateral carotid duplex scan is performed. If the operated side continues to be normal and there are no major problems on the contralateral side, the patient is seen again at the 1-year anniversary of the procedure. If examinations yield satisfactory results at this time, the patient may thereafter be seen at 1-year intervals, with bilateral carotid duplex scanning done at each visit.

Alternatives to Direct Carotid Reconstruction

Carotid angioplasty with stenting (CAS) has been investigated as a therapeutic alternative to CEA for carotid artery stenosis [see 6:10 *Carotid Angioplasty and Stenting*]. In the Wallstent trial (an industry-supported prospective, randomized study), patients with stenosis of 60% to 99%, which was angiographically confirmed according to the North American method of measurement, were randomly assigned to undergo either CAS or CEA.¹⁴ Initially, it was proposed that the study would include 700 patients with symptomatic lesions; however, the trial was stopped by the safety-monitoring committee after 219 patients were randomized. The results were reported at the 26th International Stroke Conference in February 2001.

Of the 219 patients, 107 were entered into the CAS arm and 112 into the CEA arm. Patients were well matched with respect to age, gender, symptoms, degree of stenosis, and median follow-up. The primary end point was ipsilateral stroke, procedure-related death, or vascular death within 1 year. At approximately 1 year, the primary end-point rate was 12.1% in the CAS group and 3.6% in the CEA group. The 30-day stroke morbidity and mortality was 12.1% in the CAS group and 4.5% in the CEA group. Upon cessation of the study, the investigators concluded that CAS was not equivalent to CEA for treatment of symptomatic carotid stenosis.

In the SAPPHIRE (Stenting and Angioplasty with Protection in Patients at High-Risk for Endarterectomy) trial, which was also an industry-sponsored study, CAS with the use of a cerebral antiembolism device was compared with CEA.¹⁵ Nonrandomized patients were entered into either a stent registry or a surgical reg-

istry, but the important part of the study was a randomized, multicenter trial involving 307 patients at 29 investigational sites. Of these 307 patients, 156 were entered into the CAS–cerebral protection arm and 151 into the CEA arm. The primary end points were (1) death, any stroke, or nonfatal myocardial infarction (MI) within 30 days after the procedure and (2) 30-day major morbidity plus death and ipsilateral stroke between 31 days and 12 months after the procedure. Secondary end points included (1) patency (defined by restenosis < 50%), (2) disabling stroke between 30 days and 6 months, and (3) a composite of major adverse clinical events at 6 months, 1 year, 2 years, and 3 years.

At 30 days, there were no statistically significant differences between the two study arms when the individual parameters—death, stroke, and nonfatal MI—were considered separately. When these events were viewed in the aggregate, their composite incidence was 5.8% in the CAS–cerebral protection group and 12.6% in the CEA group. When death and stroke were considered together, however, the incidence was 4.5% in the CAS–cerebral protection group and 6.6% in the CEA group. Thus, it is apparent that the major benefit of CAS over CEA lies in reducing the incidence of nonfatal MI.

In November 2006, the results of a large French trial that compared CAS with CEA in good-risk symptomatic patients were published.¹⁶ The study design called for the prospective randomization of 872 patients so as to yield a statistical power of 80%, the aim being to determine whether CAS was not inferior to CEA. After the inclusion of 527 patients, the trial was stopped prematurely for reasons of unsafety and futility. The 30-day incidence of any stroke or death was 3.9% after CEA and 9.6% after CAS. At 6 months, the incidence of stroke or death was 6.1% after CEA and 11.7% after CAS.¹⁶

On the basis of the evidence accumulated to date, the Medicare guidelines are still appropriate. CAS is indicated only for (1) symptomatic patients in whom CEA, in the opinion of a vascular surgeon, poses unacceptable risks or (2) patients who are willing to participate in an approved clinical trial (e.g., CREST [Carotid Revascularization Endarterectomy versus Stenting Trial]). CEA remains the treatment of choice for patients with suitable lesions of the carotid bifurcation.

10 CAROTID ANGIOPLASTY AND STENTING

Timothy M. Sullivan, M.D., F.A.C.S.

Choice between Carotid Endarterectomy and Carotid Angioplasty and Stenting

OPERATIVE RISK AND PATIENT SELECTION

For most patients with high-grade carotid lesions, whether symptomatic or asymptomatic, surgical endarterectomy [see 6:9 *Carotid Arterial Procedures*], rather than best medical therapy (i.e., risk factor reduction and antiplatelet agents), is the treatment of choice for stroke prophylaxis, as the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the Asymptomatic Carotid Atherosclerosis Study (ACAS) have shown.^{1,2} In NASCET, the risk of disabling stroke or death after carotid endarterectomy (CEA) was 1.9%, and the risk of minor stroke was 3.9%. In ACAS, the risk of major stroke or death was 0.6% when the 1.2% risk of stroke caused by diagnostic arteriography was excluded. These findings have led to the performance of CEA in increasing numbers of patients.

In the past few years, however, despite the proven efficacy of CEA in preventing ischemic stroke, great interest has been generated in carotid angioplasty and stenting (CAS) as an alternative to surgical therapy, and CEA has again come under attack.³ Proponents of CAS have suggested that the results of NASCET and ACAS are not achievable in general practice outside selected centers of excellence. Both ACAS and NASCET included patients

who were determined to be good operative risks on the basis of reasonable life expectancy (so that they would be available for follow-up) and the absence of other potential causes of stroke (e.g., atrial fibrillation) [see Table 1].

A number of investigators have examined the results of CEA in high-risk subsets, albeit using several different ways of defining high risk [see Tables 2 and 3].⁴⁻⁸ In one study, involving 776 consecutive CEAs performed at the Mayo Clinic in Rochester, Minnesota, procedures were categorized as high risk according to the patient inclusion and exclusion criteria employed by the Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) trial of CAS with cerebral embolic protection.⁴ Of the 776 CEAs, 323 (42%) were considered high risk. The clinical presentation was similar in the high-risk and low-risk groups. The overall postoperative stroke rate was 1.4% (symptomatic, 2.9%; asymptomatic, 0.9%), and there was no statistical difference in stroke rate between the high-risk group and the low-risk group. Patients at significantly increased stroke risk were those who underwent cervical radiation therapy, those who had class III or IV angina, those who were symptomatic at presentation, and those who were 60 years of age or younger. Overall mortality was 0.3% (symptomatic, 0.5%; asymptomatic, 0.2%), and there was no significant difference between the high-risk group (0.6%) and the low-risk group (0.0%). Myocardial

infarction (MI) was more frequent in the high-risk group (3.1%) than in the low-risk group (0.9%); notably, all of the MIs reported in this series were nontransmural (non-Q). A composite cluster of adverse clinical events (death, stroke, and MI) was more frequent in the symptomatic high-risk group (9.3% versus 1.6%), but not in the asymptomatic cohort. There was a trend toward a higher incidence of major cranial nerve injuries in patients with local risk factors (e.g., high carotid bifurcation, reoperation, and cervical radiation therapy) (4.6% versus 1.7%). In 121 patients who were excluded on the basis of synchronous or immediate subsequent operations (and who would also have been excluded from SAPPHIRE), the overall rates of stroke (1.65%), death (1.65%), and MI (0.83%) were not significantly different from those in the study population. The authors concluded that SAPPHIRE-eligible high-risk patients could undergo CEA with stroke and death rates that were well within accepted standards and that patients with local risk factors were at higher risk for cranial nerve injuries but not necessarily for stroke. These conclusions call into question the application of CAS as an alternative to CEA, even in high-risk patients.

Although these studies do not support the premise that operative risk is higher in patients who would be excluded by NASCET and ACAS criteria, there may in fact be categories of patients for whom CEA is not optimal therapy. A 2001 study from the Cleveland Clinic attempted to identify a subgroup of patients who, on retrospective analysis, were at increased risk for CEA and therefore might be better served by CAS.⁵ A total of 3,061 carotid endarterectomies were examined from a prospective database covering a 10-year period. A high-risk cohort was identified on the basis of the presence of severe coronary artery disease, a history of congestive heart failure (CHF), the presence of severe chronic obstruc-

tive pulmonary disease (COPD), or the development of renal insufficiency [see Table 2]. For the composite end point of stroke, death, and MI, the rate was 3.8% in the group as a whole (stroke, 2.1%; MI, 1.2%; death, 1.1%); however, the rate was 7.4% in high-risk patients, compared with only 2.9% in low-risk patients. High-risk patients were further subdivided into those who underwent CEA alone and those who underwent CEA combined with coronary artery bypass grafting (CABG). Not surprisingly, the incidence of the composite end point was greater in the latter subgroup than in the former. Among patients who underwent CEA

Contralateral vocal cord paralysis
Surgically inaccessible lesions
Lesion at or above C2
Lesion inferior to clavicle
Radiation-induced carotid stenosis
Previous ipsilateral radical neck dissection

alone, the risk of death was significantly greater in the high-risk group. Notably, although the risk of the combined end point was greater in the high-risk group, the difference was not statistically significant. In addition, the rates of the individual end points of MI and stroke did not differ statistically between the high-risk group and the low-risk group.

These data appear to support the notion that the patients enrolled in the multicenter trials of CEA (i.e., NASCET and ACAS) were probably similar to the Cleveland Clinic's low-risk group and that the patients in the Clinic's high-risk group might not have had such stellar outcomes if they had been included in those multicenter endarterectomy trials. Subsequent clinical investigations have therefore focused on medically compromised, high-risk patients who may benefit from alternatives to CEA (e.g., CAS).

INDICATIONS FOR CAROTID ANGIOPLASTY AND STENTING

The basic indications for CAS are essentially the same as those for standard open CEA:

- Asymptomatic lesions that fall within the high-grade stenosis (typically, 80% to 99%) range on duplex ultrasonography, which correlates with a stenosis of at least 60% on angiography [see **6:2 Asymptomatic Carotid Bruit**]. Most clinical trials of CAS in asymptomatic patients require an angiographic stenosis of at least 80% for study inclusion.
- Symptomatic lesions (e.g., hemispheric transient ischemic attack [TIA], amaurosis fugax, or stroke with minimal residua) with a stenosis of at least 70% on angiography [see **6:1 Stroke and Transient Ischemic Attack**]. Symptomatic patients who have greater than 50% stenoses with ulceration may benefit from endarterectomy; however, this finding has not yet been extrapolated to carotid intervention.

At present, there is a paucity of data on the safety and efficacy of CAS from well-controlled studies. Accordingly, my use of CAS to date has been limited to treatment of patients judged to be at high risk for CEA. Such patients account for 10% to 20% of all patients undergoing intervention (open or endovascular) for carotid disease in the Division of Vascular Surgery at the Mayo Clinic. Symptomatic patients with greater than 50% angiographic stenosis and asymptomatic patients with greater than 80% angiographic stenosis are considered for intervention, either surgical or percutaneous.

Reasonable criteria for patients at increased risk for CEA have been developed, and these criteria may serve as a general guide for those embarking on a program of carotid stenting [see **Table 4**]. Relative contraindications to CAS have also been determined [see **Table 5**]. CAS should be performed by physicians with a thorough knowledge of the pathophysiology and natural history of carotid disease and by those with current expertise in peripheral, cardiac, or neurointerventional procedures. If a physician is unable to participate in FDA-approved trials, the procedure should be performed as part of a local Institutional Review Board (IRB)-approved protocol with dispassionate oversight, independent preprocedural and postprocedural neurologic examination, and prospective case review. In addition, development of a carotid stenting program may facilitate cooperation among the various specialists who may desire to participate in this high-profile arena. A team of experienced personnel should be assembled (including one or two physicians and a technician) to ensure patient safety, maximize exposure within a small cadre of operators, and avoid duplication of effort. All patients considered for CAS should have provided informed consent, should receive counseling regarding the risks and benefits vis-à-vis CEA and best medical therapy, and should possess a clear understanding of the investigational nature of the procedure. In addition, patients must agree to regular and careful follow-up examinations.

Anatomic Considerations

A solid grasp of the anatomy of the cerebral circulation is crucial for the planning of CAS. Several anatomic considerations are particularly germane. The first important anatomic issue to address is the configuration of the aortic arch. With advancing age, the apex of the arch tends to become displaced further distally. This displacement makes selective catheterization of the brachiocephalic vessels more challenging and influences the choice of a catheter. The interventionalist should become familiar with a variety of selective catheters; I prefer the Simmons II catheter, which allows deep cannulation of the common carotid artery (CCA) and thus facilitates eventual passage of a guide wire for delivery of a sheath. As the level of the vessel's origin becomes farther from the dome of the arch, the task of obtaining guide-wire and sheath access becomes more difficult. Cannulation of a left CCA arising from a common brachiocephalic trunk (bovine arch) may be particularly

Table 5 Limitations of and Contraindications to Carotid Angioplasty and Stenting

Inability to obtain femoral artery access
Unfavorable aortic arch anatomy
Severe tortuosity of CCA or ICA
Severely calcified or undilatable stenoses
Lesions containing fresh thrombus
Large amount of laminated thrombus at site of patch angioplasty (previous CEA) on duplex ultrasonography
Extensive stenoses (> 2 cm)
Critical (\geq 99%) stenoses
Lesions adjacent to carotid artery aneurysms
Contrast-related issues
Chronic renal insufficiency
Previous life-threatening contrast reaction
Preload-dependent states (e.g., severe aortic valvular stenosis)

difficult to accomplish. Problematic arch configurations should be identified on preprocedural contrast studies or magnetic resonance angiography (MRA) of the aorta. Especially at the beginning of an operator's experience with these interventions, a complete study that includes the aortic arch and the origins of the brachiocephalic trunks is essential.

Another important issue is the presence of any tandem lesions along the course of the cerebral circulation. If a proximal CCA lesion is present, intervention may be required before revascularization of the internal carotid artery (ICA) to provide safe access to the ICA. A third concern is the tortuosity of the ICA. Fortunately, most ICAs are relatively straight; however, some patients do have extremely tortuous ICAs, which may preclude safe passage of a guide wire or protection device and thus render safe intervention impossible. The anatomic configuration of the external carotid artery (ECA) typically is not an important consideration in carotid intervention, even when this vessel is affected by stenosis of iatrogenic origin or is covered with a bare stent.

Finally, the collateral circulation (or lack thereof) through the circle of Willis is an important consideration that may profoundly influence procedural strategy. The status of the contralateral ICA, the vertebral-basilar system, and the intracranial collaterals may affect the type of embolic protection to be used. Anatomic variations in the circle of Willis are actually the rule rather than the exception: a complete circle is present in fewer than 50% of all cases. Common variations include a hypoplastic (10%) or absent A1 segment of the anterior cerebral artery and a plexiform (10% to 33%) or duplicated (18%) anterior communicating artery. Anomalies of the posterior portion of the circle of Willis, including a hypoplastic (33%) or absent posterior communicating artery, occur in about 50% of all cases. During preprocedural angiography or intracranial MRA, careful attention should be paid to the anterior and posterior communicating arteries. Patients with limited collateral circulation may exhibit reversible neurologic symptoms during inflation of a protective balloon or angioplasty of the target lesion. They may also be at higher risk for permanent neurologic deficits because their limited collateral blood supply is less likely to be able to compensate for any iatrogenic arterial occlusions that may complicate the procedure.

Preoperative Evaluation

For those with limited experience in carotid intervention, diagnostic angiography of the arch, the carotid arteries, and the cerebral arteries (done well in advance of the proposed intervention) is suggested; high-quality MRA that includes the aortic arch is an acceptable substitute. This measure allows the interventionalist to make a careful, unhurried evaluation of the aortic arch and the brachiocephalic origins, which is essential for determining the ease or difficulty of sheath or guide access to the CCAs—an issue that has a direct bearing on the success of the procedure. If the brachiocephalic trunk (i.e., the innominate artery) or the left CCA originates in a location more than two CCA diameters (approximately 2 cm) below the dome of the aortic arch, some difficulty with access should be anticipated. In addition, the length of the lesion, the maximum degree of stenosis, and the diameters of the CCA and the ICA can be determined by placing a radiopaque marker of known diameter in the field of view; ball bearings of progressively increasing diameter (2 through 7 mm) are ideal for this purpose. These measurements facilitate preprocedural selection of appropriately sized balloons and stents and make performance of the procedure smoother

and more efficient, thereby serving the main goals of therapy—patient safety and exemplary results.

In all cases, a thorough history should be taken and a careful physical examination performed, with close attention paid to comorbid medical conditions and femoral pulses. A complete neurologic examination should be performed by a certified neurologist. In addition to preprocedural arteriography or MRA, duplex ultrasonography should be performed in an accredited vascular laboratory—ideally, the same laboratory where the follow-up examinations will be performed. In my practice, patients receive aspirin, 325 mg daily for at least 1 week before the procedure, and clopidogrel, 75 mg daily for at least 3 days beforehand. All patients receive antibiotics (typically cefazolin, 1 g I.V.) immediately before the procedure.

Operative Planning

Regardless of the exact physical location at which the procedure is performed, access to high-quality imaging equipment is mandatory; portable C-arms are less than ideal for this purpose. I perform CAS in a neuroradiology suite, which has the advantage of offering biplane imaging. With this arrangement, duplication of effort and equipment is avoided, and the room is staffed by knowledgeable personnel, including a certified registered nurse anesthetist (CRNA), who monitors the patient with continuous electrocardiography, blood pressure, and pulse oximetry readings. Patients are placed in a supine position, and both groins are prepared. The head is placed in a cradle and gently secured to minimize patient motion during critical portions of the procedure. The procedure is generally performed with the patient awake, though minimal sedation is acceptable if the patient is particularly anxious.

Operative Technique

The technique of CAS has evolved over time. In its current iteration, the procedure is performed in the following steps, with few exceptions. Although it is, of course, essential to be able to adjust the technical approach to deal with unanticipated situations, it is nonetheless desirable to standardize the procedure as much as possible.

Basic principles of endovascular surgery are discussed more fully elsewhere [see **6:8 Fundamentals of Endovascular Surgery**]; the following steps focus primarily on the procedural elements specific to CAS.

STEP 1: SECURING OF ARTERIAL ACCESS

Retrograde femoral access is obtained, and a 5 French sheath is inserted. Full heparin anticoagulation (typically 100 mg/kg body mass) is instituted after arterial access is secured and before manipulation of catheters in the aortic arch and the brachiocephalic vessels.

STEP 2: SELECTIVE CAROTID CATHETERIZATION AND ARTERIOGRAPHY

After selective catheterization of the midportion of the ipsilateral CCA (typically with a Simmons II catheter), a selective arteriogram of the carotid bifurcation is obtained, with care taken to choose a view that yields minimal overlapping of the ICA and the ECA and maximal visualization of the target lesion. A complete cerebral arteriogram, if not previously obtained, is obtained at this point to serve as a baseline and to identify any intracranial pathologic conditions (e.g., aneurysms and arteriovenous communications) that may be present.

STEP 3: ADVANCEMENT OF SHEATH AND DILATOR INTO COMMON CAROTID ARTERY

Two techniques have been employed to advance a sheath into the CCA. The first technique—which I prefer—is to place an exchange-length guide wire into the terminal branches of the ECA. I generally use a stiff, angled glide wire (keeping in mind that sheath exchange over this highly slippery wire can be tricky). The diagnostic catheter and the 5 French sheath are removed (with constant visualization of the guide wire in the ECA maintained all the while). A long (70 to 90 cm, depending on patient body habitus) 6 French sheath is then advanced, along with its dilator, into the CCA. If larger (> 8 mm in diameter) stents are required, a 7 French sheath may be necessary to allow contrast injection around the stent delivery system. Care must be taken to identify the tip of the dilator (which is not radiopaque) because it may extend a significant distance from the end of the sheath, depending on the brand of sheath used. Obviously, inadvertently advancing the dilator into the carotid bulb may have disastrous consequences. In patients with short CCAs or low bifurcations, the sheath can be advanced over the dilator once the sheath edge (a radiopaque marker) is past the origin of the CCA.

The second technique is to advance the long sheath into the transverse arch over a guide wire. The dilator is removed, and an appropriate selective diagnostic catheter is advanced into the CCA. This catheter must be substantially longer than the sheath, typically more than 100 cm long. A stiff guide wire is then advanced into the ECA. Both the wire and the catheter are pinned at the groin to provide support, and the sheath (without the dilator) is advanced into the CCA. This technique may be advantageous in so-called hostile arches, in that the catheter and the wire provide more support than a wire alone would; however, without the protection of the sheath/dilator, there is a risk of “snowplowing” the edge of the sheath at the junction of the aortic arch and the innominate artery or the left CCA, which can cause dissection or distal embolization.

The importance of gaining and maintaining sheath access to the distal CCA should not be underestimated: once the 0.035 in. guide wire is removed (and, eventually, exchanged for a 0.014 in. wire), support for angioplasty and stent placement is provided solely by the sheath. If the sheath backs up into the aortic arch during the interventional procedure, it is virtually impossible to advance it into the CCA over a 0.014 in. guide wire or protection device. Appropriate patient selection and accurate recognition of which arches to avoid are essential for success. In particularly difficult arches, deep inspiration or expiration may facilitate sheath advancement by subtly changing the configuration of the brachiocephalic origins once guide-wire access has been obtained. Alternatively, when a sheath cannot be advanced into the CCA, a pre-shaped guide catheter can be seated in the proximal CCA. Although this maneuver may facilitate an otherwise impossible intervention, it should be kept in mind that guide catheters provide a less stable support platform than sheaths do and should be used only if there is no other reasonable alternative.

Troubleshooting

In patients with an occluded ECA, sheath access to the CCA may be difficult to obtain. Two techniques may be employed to overcome this difficulty. The first is to place a stiff 0.035 in. wire with a preshaped J into the distal CCA, taking care to avoid the bulb and the bifurcation. The J configuration keeps the guide wire from crossing the lesion. A stiff wire with a shapable tip can be used to the same end.

The second technique is to use a variable-diameter wire (0.018 in. at the tip, enlarging to 0.035 in. more proximally) to cross the internal carotid lesion, providing additional guide-wire support to facilitate sheath advancement. This approach is a reasonable option, but it ultimately necessitates crossing the target lesion twice.

STEP 4: REMOVAL OF GUIDE WIRE AND DILATOR AND SELECTIVE ARTERIOGRAPHY OF CAROTID BIFURCATION

Once the sheath is in place, the guide wire and the dilator are removed. The sheath sidearm may be attached to a slow, continuous infusion of heparin-saline solution to keep blood from stagnating in the sheath. Selective angiography of the carotid bifurcation is then performed through the sheath, again demonstrating the area of maximal stenosis, the extent of the lesion, and the normal ICA and CCA above and below the lesion. Roadmapping, if available, is helpful in crossing the lesion with an embolic protection device or guide wire [see Step 6, below]. The overwhelming majority of procedures are now performed with the aid of an embolic protection device, typically a filter [see Figure 1].

STEP 5: MEASUREMENT OF ACTIVATED CLOTTING TIME

It is advisable to measure the activated clotting time (ACT) before crossing the lesion and performing CAS. If balloon occlusion of the ICA is being used for embolic protection, an ACT longer than 300 seconds is desirable. If a filter-type device or a standard guide wire is being used, an ACT longer than 250 seconds is probably sufficient. The interventional team should discuss, in detail, all the subsequent steps to be performed so that all members are on the same page. Balloons are flushed and prepared, and special care should be taken to remove all air from the system as a protective measure against the unlikely event of balloon rupture. The stent is opened and placed on the table, and the crossing guide wire or embolic protection device is prepared. For de novo lesions, I typically administer atropine (0.5 to 1.0 mg I.V.) as prophylaxis against bradycardia during balloon inflation in the carotid bulb; for restenoses after CEA, this measure may not be necessary. The monitoring nurse or CRNA should be alerted that balloon inflation may cause significant hemodynamic instability.

STEP 6: ADVANCEMENT OF GUIDE WIRE ACROSS LESION

The guide wire or embolic protection device (0.014 in.) is advanced across the lesion with the aid of roadmapping (if available). Care should be taken when the device is inserted through the sheath valve because the tip can be damaged at this juncture. If a protection device is being used, it should be deployed into the distal extracranial ICA, just before the horizontal petrous segment. For balloon-occlusion devices, absence of flow in the ICA must be demonstrated. For filter devices, apposition of the device to the ICA must be documented, along with flow in the ICA through the device; these should also be documented after each subsequent step of the intervention to detect possible occlusion of the filter by debris.

STEP 7: PREDILATION OF LESION

The lesion is predilated with a 5.0 mm angioplasty balloon, typically on a monorail or rapid-exchange platform. To save time, the balloon can be advanced into the distal CCA before the lesion is crossed with the guide wire or protection device. In most cases, the desired balloon profile can be achieved with relatively low inflation pressures (4 to 6 mm Hg). After the predilation balloon is removed, another bifurcation angiogram is performed through the sheath (unless distal balloon occlusion is employed, in which case

Figure 1 Carotid angioplasty and stenting. In this example, a filter device is used for cerebral protection. (a) MRA shows aortic arch and cervical carotid and vertebral arteries. (b) MRA shows recurrent (postendarterectomy) high-grade stenosis of right ICA. (c) Selective angiogram shows right carotid bifurcation. (d) FilterWire EX (Boston Scientific, Natick, Massachusetts) is deployed within ICA; angiographic assessment is performed in two planes (left, right) to confirm adequate apposition of filter to vessel wall (arrows). (e) Shown is vessel after angioplasty and placement of self-expanding nitinol stent. Sheath is properly positioned in distal CCA (star). Spasm may be seen at site of filter (arrow).

the ICA will not be visualized and the distal stent must be placed according to predetermined bony landmarks and the location of the CCA bifurcation).

STEP 8: DEPLOYMENT OF STENT

Once correct positioning has been confirmed, the stent is deployed. Currently, I prefer to use nitinol stents, most commonly extending an 8 to 10 mm \times 30 mm stent from the ICA into the CCA and covering the origin of the ECA. Nitinol stents exhibit a tendency to “jump” distally when deployed rapidly (despite manufacturers’ claims to the contrary), and this jump may cause the

operator to miss the target lesion. To counter this tendency, I typically expose and deploy two or three stent rings, then wait for 5 to 7 seconds, allowing the distal stent to become fully expanded, well apposed to the ICA, and attached to the vessel wall above the lesion. I can then deploy the remainder of the stent more rapidly, with little worry that it will migrate.

The diameter of the stent is determined by the diameter of the largest portion of the vessel, which is typically the distal CCA (not the ICA). It is important that there be no unapposed stent in the CCA: any part of the stent that is not apposed to the vessel wall may become a nidus for thrombus formation. The diameter of the

unconstrained stent should be at least 10% (approximately 1 to 2 mm) larger than the maximum diameter of the CCA. On occasion, the lesion is limited to the ICA well above the carotid bifurcation; in such cases, a shorter stent confined to the ICA may be used.

STEP 9: POSTDILATION OF LESION

If necessary, the lesion is postdilated with a 5 or 5.5 mm balloon; larger balloons are rarely necessary. As noted [see Step 7, above], I currently prefer to use a relatively large balloon (5 mm) for predilation so as to obviate postdilation if possible. A residual stenosis of 10% or so is completely acceptable; the goal of the intervention is protection from embolic stroke, not necessarily a perfect angiographic result.

STEP 10: COMPLETION ARTERIOGRAPHY

A completion angiogram of the carotid bulb and bifurcation and the distal extracranial ICA is obtained before wire removal to verify that no dissection or occlusion has occurred. Severe vasospasm may be encountered (sometimes mimicking dissection); watchful waiting, coupled on occasion with administration of vasodilators through the sheath (e.g., nitroglycerin in 100 µg aliquots), usually resolves this problem. Sometimes, the wire must be removed before vasospasm will resolve completely, but this should be done only after dissection is excluded. After the wire is removed, completion angiography of the carotid and intracranial circulation is performed in two views.

STEP 11: ACCESS-SITE HEMOSTASIS

Heparin anticoagulation typically is not reversed. Access-site hemostasis is achieved with a percutaneous closure device.

Postoperative Care

After the procedure, the patient is monitored in the recovery area for approximately 30 minutes, then transferred to a monitored floor; admission to an intensive care unit generally is not necessary. In 2 to 3 hours, patients are allowed to ambulate if a closure device was used and are allowed to resume a regular diet. Some patients experience prolonged hypotension from carotid sinus stimulation; this problem can be managed with judicious fluid administration, pharmacologic treatment of bradycardia, and, occasionally, I.V. infusion of a vasopressor (e.g., dopamine). Rarely, a patient experiences prolonged hypotension that must be treated with an oral agent (e.g., phenylephrine or midodrine).

A duplex ultrasonogram is obtained before hospital discharge as a baseline study; the criteria for stenosis and restenosis change after placement of a metal stent in the carotid artery. Subsequent ultrasound examinations are performed at 6 weeks, 6 months, and 1 year, then yearly thereafter. Neurologic evaluation is performed according to the same schedule as the duplex studies. Patients are treated with aspirin for life and with clopidogrel for 4 to 6 weeks.

As with carotid endarterectomy, proper patient selection, procedural standardization, and meticulous attention to detail are mandatory for a successful procedure, regardless of the exact technique used for CAS.

Special Considerations

CEREBRAL PROTECTION

Ischemic stroke remains the most devastating complication of procedures directed at the extracranial carotid artery, whether open or endovascular. A number of different causes of stroke have

been described, but the majority of strokes are attributable to cerebral embolization of atheromatous debris or thrombus. Even when cerebral emboli do not produce a major stroke, they may cause substantial cognitive impairment. A prospective study of 100 patients monitored with transcranial Doppler ultrasonography (TCD) during CEA found that microemboli were detected during 92% of procedures.⁹ Although most of the emboli were air emboli (and were not associated with adverse clinical events), there were more than 10 particulate emboli whose presence was correlated with significant deterioration of postoperative cognitive function.

A subsequent study evaluated 70 patients who underwent cardiac surgery with cardiopulmonary bypass, measuring cognitive function at 1 week, 2 months, and 6 months after operation; elderly patients who underwent urologic surgery served as the control group.¹⁰ TCD detected more than 200 emboli in 40 patients, principally during aortic clamping and release, when bypass was initiated, and during defibrillation. Emboli were associated with significant memory loss. In addition, cognitive function deteriorated more in the study group than in the control group, though it recovered by 2 months after operation.

A study using a rat model examined the effect of atheroemboli of varying sizes on neuronal cell death.¹¹ The animals exposed to particles less than 200 µm in diameter showed no evidence of brain injury at 1 and 3 days, whereas those exposed to particles between 200 and 500 µm showed a scattered pattern of neuronal cell death at necropsy. At 7 days after embolization, however, both groups showed evidence of cell death. These findings suggest that whereas the brain may have a substantial tolerance for small emboli in the acute setting, even particles smaller than 200 µm may cause neuronal ischemia at a later point.

Angioplasty and Carotid Embolization

Various studies have assessed the embolic potential of carotid plaques in ex vivo models. One such study, which used specimens of human atherosclerotic plaque in a flow chamber to model CAS, found that substantial numbers of particles were released from the lesions during angioplasty and that most of these particles were captured by an experimental filter device.¹² The filter device itself produced very few particles, thanks to its low crossing profile.

A subsequent study also addressed the embolic potential of human carotid plaques during experimental angioplasty.¹³ An average of 133 emboli per angioplasty were measured, and there was a positive correlation between lesion severity and the maximum size of the embolic particles. A notable finding was that patients who had been placed on statin therapy more than 4 weeks before operation had significantly fewer and smaller emboli.

A clinical study that employed a distal balloon-occlusion system during CAS found that the median number of particles, their maximum diameter, and their maximum area were all significantly higher in patients with periprocedural neurologic complications.¹⁴ Three procedural steps are associated with an increased risk of embolization: predilation, stent deployment, and postdilation [see Operative Technique, Steps 7, 8, and 9, above].¹⁵

Devices for Cerebral Embolic Protection

The use of embolic protection in large numbers of patients has been described with respect to the coronary vascular bed, where interventional procedures performed on diseased aortocoronary saphenous vein grafts carry a 20% risk of periprocedural complications, largely related to distal embolization of atheromatous debris. The Saphenous vein graft Angioplasty Free of Emboli Randomized (SAFER) trial was the first multicenter randomized

Figure 2 Carotid angioplasty and stenting. In this example, a balloon occlusion device is used for cerebral protection. (a) MRA shows aortic arch and cervical carotid and vertebral arteries. (b) MRA shows de novo atherosclerotic stenosis of right ICA. (c) Diagnostic arteriogram of right carotid bifurcation in a symptomatic patient shows tandem ulcerated stenoses. (d) Right ICA is occluded with PercuSurge GuardWire device. (e) Shown is vessel after angioplasty and placement of nitinol stent.

study to evaluate the use of distal embolic protection during saphenous vein graft interventions.¹⁶ Of the 801 eligible patients, 406 were randomly assigned to angioplasty and stenting with distal balloon protection and 395 to angioplasty and stenting over a conventional guide wire. The composite primary end point (death, MI, emergency coronary bypass, target lesion revascularization) was reached in 16.5% of the control group and 9.6% of the study group; the differences between the two groups were largely driven by decreases in MI and distal embolization. These dramatic results suggest that patients with lesions of high embolic potential (e.g., those at the carotid bifurcation) may benefit from some type of embolic protection. A 2000 study using an ex vivo model of angioplasty confirmed the findings of other investigators that emboli occur at several stages of carotid intervention and stressed that cerebral protection techniques should be effective from the earliest stages of the procedure.¹⁷

Three types of embolic protection—distal balloon occlusion, distal filter protection, and reversal of ICA flow—are currently available for use in the carotid artery, either as part of an FDA-approved clinical trial or as an “off-label” application of a device approved for noncarotid use. A 1987 study was the first to report on the use of an angioplasty technique involving temporary occlusion of the internal carotid artery during manipulation of ulcerated plaques.¹⁸ The same investigators subsequently reported on the use of a triple-coaxial catheter system for angioplasty with cerebral protection in 13 patients¹⁹; cholesterol crystals ranging in size from 600 to 1,200 µm were aspirated at the time of intervention. The PercuSurge GuardWire (Medtronic AVE, Santa Rosa, California), which is approved for aortocoronary saphenous vein graft intervention, has been used in the MAVERIC trial of carotid intervention and has been employed extensively for off-label carotid intervention outside FDA-approved clinical trials [see Figure 2]. The

advantages of this device include its low profile (which allows it to cross the target lesion easily), its procedural simplicity, and its ability to aspirate large debris particles after intervention. The disadvantages include the potential for incomplete occlusion of the ICA in patients with particularly large arteries (because the device can be inflated only from 3 mm to 6 mm in diameter) and the device's inability to aspirate exceptionally large particles into the suction catheter after intervention.¹⁴ In addition, as flow is diverted into the ECA, emboli may travel by this route and into the ipsilateral middle cerebral artery via periorbital and ophthalmic artery collaterals.²⁰ Finally, a small percentage of patients with an incomplete circle of Willis and an isolated cerebral hemisphere may be intolerant of even temporary ICA occlusion. A 2002 study that evaluated the PercuSurge device in 75 CAS procedures found that four patients (5%) experienced transient neurologic symptoms during balloon occlusion that resolved with deflation and restoration of internal carotid flow.²¹ Embolic material was aspirated from the ICA in all patients; no patients had suffered major or minor stroke at 30 days after the intervention.

Filter protection devices have been the object of a great deal of interest in the past few years. Such devices are designed to be able to trap large particulate debris while maintaining flow in the ICA, thereby not only providing continued cerebral perfusion during intervention but also allowing angiography of the target vessel during various phases of the procedure. All of the currently available filters have pores larger than 100 µm, which means that they allow passage of smaller particles that may not cause clinically significant neurologic events but may nonetheless cause silent neuronal injury. These filters also have higher physical profiles than balloon occlusion devices and thus may be difficult to pass across particularly severe stenoses. Filters that are not completely apposed to the vessel wall may allow emboli to pass around the device and into the distal cerebral circulation. A 2001 study described CAS performed in 86 lesions with three different filter devices.²² In three cases, the filter could not be advanced across the lesion. However, more than half of the successfully deployed filters contained macroscopic embolic material, and only one patient (1.2%) experienced a neurologic complication (a minor stroke).

Finally, a device has been developed that induces reversal of flow in the ICA through balloon occlusion of the CCA and the ECA and creation of a temporary arteriovenous shunt between the ICA and the femoral vein.²³ This device, though potentially more cumbersome than other protection devices, may produce virtually complete protection by preventing any emboli from traveling to the intracranial circulation.

A 2004 report summarized one group of operators' experience with 1,202 CAS procedures between 1994 and 2002.²⁴ In 33% of the patients studied, a cerebral protection device was used during the procedure. The overall stroke rate was 4.4%; the risk of stroke reached its height (9.1%) during the period extending from September 1996 to September 1997 and reached its nadir (0.6%) during the final year of the study. The authors concluded that improvements in technique, equipment, and pharmacotherapy, as well as the use of neuroprotection, contributed significantly to improvements in results. In an earlier series, 46 patients were treated with CAS, of whom 25 received cerebral protection.²⁵ Two neurologic events (9.5%) occurred in the unprotected cohort; no events occurred in the protected group. Although the small numbers of patients prevented meaningful statistical analysis, the authors concluded that cerebral protection was technically feasible and effective in preventing neurologic complications during CAS.

The evidence accumulated to date suggests that most, if not all, CAS procedures should be performed with a cerebral embolic protection device. In time, more such devices will be approved by the FDA and will be available outside the setting of clinical trials.

Outcome Evaluation

The short-term results of CAS depend largely on the presence or absence of cerebral embolization. It is therefore not surprising that the addition of cerebral protection to CAS appears to have reduced the stroke risk associated with the procedure. Admittedly, however, ongoing technological developments have created something of a moving target, making evaluation of the results of CAS difficult at best. Nevertheless, the available literature is sufficient

to provide a reasonably accurate picture of the current status of the procedure [see Table 6].^{8,21,22,26-62}

In a study from the University of Alabama at Birmingham and Lenox Hill Hospital in New York,²⁶ a total of 604 arteries were treated in 528 consecutive patients over a 5-year period. CAS was performed both with balloon-expandable stents and with self-expanding stents and both with and without cerebral protection devices. The overall 30-day combined stroke-death rate was 8.1% (minor stroke, 5.5%; major stroke, 1.6%; nonneurologic death, 1%). On a year-by-year basis, the risk of stroke and death reached its maximum (12.5%) in the period ending in September 1997 and fell to its minimum (3.2%) the following year. This rather dramatic change in results from one year to the next probably is attributable to technical advances (e.g., in protection devices, stents, and guide wires), as well as to improvements in the investigators' ability to select appropriate patients for intervention.

A subsequent report describes the authors' experience with CAS in a vascular surgery practice.²⁷ During a 40-month period from 1997 to 2001, 135 procedures were performed in 132 patients, most (60%) of whom were asymptomatic. The rate of complications was acceptable (2%), and only one patient had a significant restenosis at follow-up (mean follow-up interval, 16 months). Perhaps more important, these 132 patients represented 41% of all patients being treated for carotid disease in this practice. This percentage seems extraordinarily high, but it may simply be a bellwether of things to come in the practice of vascular surgery, and it underscores the importance of multispecialty involvement in this new technology.

The results of the SAPPHIRE trial of CAS in high-risk patients were published in 2004.⁸ To date, this trial, which included 334 patients randomly assigned to either CAS ($N = 167$) or CEA ($N = 167$), is the only industry-sponsored FDA-approved trial that was actually randomized. A separate registry of nonrandomized patients was compiled that included those who were felt to be at unacceptably high risk for CEA and therefore underwent CAS ($N = 406$), as well as those who were not suitable candidates for CAS and therefore underwent CEA ($N = 7$). The goal of the SAPPHIRE trial was to evaluate the combined end point of major

adverse events (stroke, death, and MI). Inclusion and exclusion criteria for the study are listed more fully elsewhere [see Tables 2 and 3]. Patients were independently evaluated by a certified neurologist before and after the procedure. The majority of the randomized patients were asymptomatic: in the CAS group, only 30% were symptomatic, and in the CEA group, only 28% were symptomatic. A key point to keep in mind is that this trial was designed to test the idea that CAS was not inferior to CEA, not to establish that CAS was superior to CEA or CEA to CAS. At 30 days, the risk of stroke was not significantly different in the two groups (CAS, 3.6%; CEA 3.1%). Two patients in the CAS group (1.2%) and four patients in the CEA group (2.5%) died within 30 days; this difference did not reach statistical significance ($P = 0.39$). More patients experienced periprocedural MI in the CEA group (6.1%) than in the CAS group (2.4%), a difference that did not reach statistical significance on the basis of intent to treat. Notably, most of the MIs were non-Q MIs, identified by routine postprocedural laboratory studies. The incidence of the combined end point (stroke-death-MI) was higher in the CEA group (9.8%) than in the CAS group (4.8%), but this difference was statistically insignificant as well. These results have been used to support FDA approval of the stent and filter protection device used in this important study.

Lesions of the proximal CCA are relatively uncommon in comparison with lesions of the carotid bifurcation, but they can also be effectively treated with CAS. In my experience, most are treated with common carotid cutdown, retrograde angioplasty, and placement of a balloon-expandable stent. Of 14 consecutive CCA interventions performed at the Cleveland Clinic,⁶³ one was converted to carotid-subclavian transposition after iatrogenic dissection, and two resulted in stroke secondary to ICA thrombosis. In both of the interventions resulting in stroke, which were performed in conjunction with redo bifurcation endarterectomies, the CCA was patent at the time of surgical reexploration and ICA thrombectomy. Although the carotid stent procedure is unlikely to have played a role in causing these strokes, it is nonetheless advisable to exercise caution when performing these combined procedures.

11 REPAIR OF INFRARENAL ABDOMINAL AORTIC ANEURYSMS

Frank R. Arko, M.D., Stephen T. Smith, M.D., and Christopher K. Zarins, M.D., F.A.C.S.

An arterial aneurysm is defined as a permanent localized enlargement of an artery to a diameter more than 1.5 times its expected diameter. Aneurysms are classified according to morphology, etiology, and anatomic site. The most common morphology is a fusiform, symmetrical, circumferential enlargement that involves all layers of the arterial wall. A saccular morphology is also seen, in which aneurysmal degeneration affects only part of the arterial circumference.

The most common cause of an arterial aneurysm is atherosclerotic degeneration of the arterial wall. The pathogenesis is a multi-factorial process involving genetic predisposition, aging, atherosclerosis, inflammation, and localized activation of proteolytic enzymes. Most aneurysms occur in elderly persons, and the prevalence rises with increasing age. Aneurysms also occur in genetically susceptible individuals with Ehlers-Danlos syndrome or Marfan syndrome. Other causes include tertiary syphilis and localized infection resulting in a mycotic aneurysm.

Aneurysms of the infrarenal aorta are by far the most common arterial aneurysms encountered in clinical practice today: they are three to seven times more common than thoracic aneurysms and affect four times as many men as women.¹ Abdominal aortic aneurysms (AAAs) have a tendency to enlarge and rupture, causing death. In the United States, AAAs result in approximately 15,000 deaths each year and are thus the 13th leading cause of death.^{2,3} The only way to reduce the death rate is to identify and treat aortic aneurysms before they rupture [see 6:3 *Pulsatile Abdominal Mass*].

The relationship between aneurysm size and risk of rupture is well known. The annual risk of rupture is 1% to 2% for aneurysms less than 5 cm in diameter, 10% for aneurysms 5 to 6 cm in diameter, and 25% or higher for aneurysms larger than 6 cm.⁴ Although large aneurysms are much more likely to rupture than small aneurysms, small aneurysms can and do rupture on occasion.

The exact size at which an asymptomatic small AAA should be treated remains unsettled. This issue was the subject of two prospective, randomized clinical trials: the United Kingdom Small Aneurysm Trial⁵ and the Aneurysm Detection And Management (ADAM) Veterans Affairs (VA) Cooperative Study.⁶ Both trials randomly assigned low-risk patients with small (4.0 to 5.4 cm) AAAs to either open surgical repair or ultrasound surveillance. Patients in the surveillance groups were closely monitored with serial ultrasound examinations and underwent open surgical repair if the aneurysm enlarged, became tender to palpation, or became symptomatic. With respect to the primary end point—overall survival—the two trials came to similar conclusions: there was no difference in overall survival between the surgery group and the surveillance group.^{5,6} There was, however, a late survival benefit in the surgery group in the U.K. Small Aneurysm Trial.⁷

Aneurysm rupture rates were low (1%) in both trials, leading many clinicians to conclude that aneurysms smaller than 5.5 cm need not be treated, because the risk of rupture is so low. Closer examination of the data, however, reveals that more than 60% of the patients in the surveillance groups underwent open surgical

repair during the two trials: 81% of patients with 5.0 to 5.4 cm aneurysms in the ADAM trial underwent surgery, and almost all patients in the U.K. trial ultimately required surgical management. Thus, it is likely that the reason for the low rupture risk in these trials was that surgical treatment of the aneurysm was provided when clinically indicated. This conclusion is supported by data from a prospective study of patients from the VA hospitals involved in the ADAM trial who were not eligible for randomization and did not undergo operative repair. In these patients, the 1-year risk of rupture for slightly larger (5.5 to 5.9 cm) aneurysms was 9.4%.⁸ Furthermore, very close surveillance with ultrasound examinations every 3 to 6 months did not prevent aneurysm rupture in 1% of patients. Thus, the decision whether to treat an aneurysm is based on assessment of the risk of aneurysm rupture relative to the risk associated with treatment rather than on an absolute size criterion or a surveillance protocol.

Open Repair

PREOPERATIVE EVALUATION

Identification of Risk Factors

For successful surgical reconstruction of AAAs, any significant comorbidities that would increase the risk of operative repair must be identified and managed at an early stage. Patients undergoing the procedure usually are elderly and often have coexisting cardiac, pulmonary, cerebrovascular, renal, or peripheral vascular disease. The major anesthetic risk factors for elective resection of AAAs are similar to those for other major intra-abdominal operations; in particular, they include inadequate cardiopulmonary and renal function. Patients with unstable angina or angina at rest, a cardiac ejection fraction of less than 25%, a serum creatinine concentration higher than 3 mg/dl, or pulmonary disease (manifested by arterial oxygen tension < 50 mm Hg, elevated arterial carbon dioxide tension, or both on room air) are considered to be at high risk.^{9,10}

Myocardial ischemia is the most common cause of perioperative morbidity and mortality after arterial reconstruction of the aorta. Optimization of preoperative medical management, perioperative invasive monitoring, and long-term risk-factor modification are all facilitated by an accurate preoperative cardiac evaluation. Such evaluation may include transthoracic echocardiography, exercise stress testing, myocardial scintigraphy, stress echocardiography, and coronary angiography; each test has its own merits and limitations with regard to clinical risk assessment.

There has been considerable controversy over the potential benefit of preoperative coronary revascularization in this setting. This issue was addressed by a clinical trial in which patients requiring AAA or peripheral vascular surgery who had high-risk cardiac disease were randomly assigned to undergo either vascular surgery without preoperative coronary revascularization or coronary revascularization followed by vascular surgery.¹¹ There was no differ-

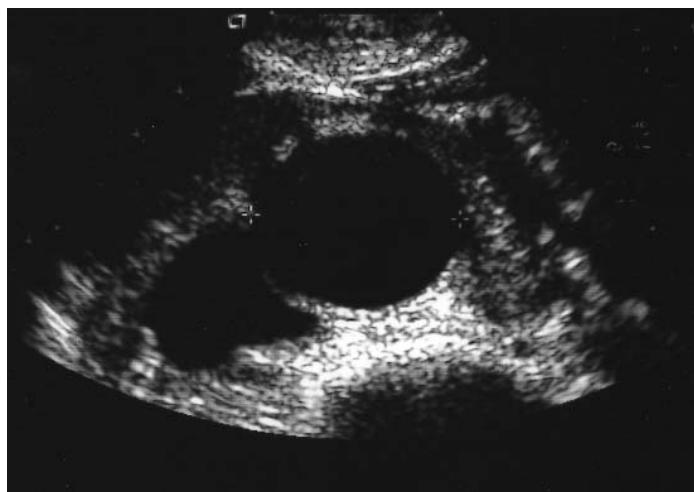

Figure 1 Duplex ultrasonography may be used as a screening test and to determine the actual size of the aneurysm.

ence between the two groups with respect to the incidence of postoperative MI or overall mortality. The investigators concluded that patients with stable coronary disease do not benefit from preoperative coronary revascularization. Patients with unstable severe coronary disease may benefit from invasive cardiac evaluation and preliminary coronary intervention.

To reduce the mortality associated with resection of AAAs, it is necessary not only to identify high-risk groups but also to institute appropriate preoperative, intraoperative, and postoperative alterations in patient care. With intensive perioperative monitoring and support in place, resection of AAAs has been successfully performed even in high-risk patients, with operative mortalities of less than 6%.¹²⁻¹⁴

Confirmation of Diagnosis and Determination of Aneurysm Size

Physical examination suffices for detection of most large aneurysms. To determine the exact size of the aneurysm and to identify smaller aneurysms, however, more objective methods are available and should be used. Determination of the size of the aneurysm is extremely important because size is the most important determinant of the likelihood of rupture and plays a crucial role in subsequent management decisions. Imaging modalities commonly employed to diagnose and measure aneurysms include duplex ultrasonography (DUS), aortography, computed tomography, and magnetic resonance imaging.

The main advantages of DUS are its ready availability in both inpatient and outpatient settings, its low cost, its safety, and its good performance; many studies have documented the ability of DUS to establish the diagnosis and accurately determine the size of AAAs [see Figure 1].¹⁵⁻¹⁷ The primary limitations of DUS are that imaging of the thoracic and suprarenal aorta is poor, that the quality of the images is considerably lower in the presence of obesity or large amounts of intestinal gas, and that it must be performed by a skilled imaging technician.

Aortography yields excellent images of the contours of the aortic lumen, but it is not a reliable method for determining the diameter of an aneurysm or even for establishing its presence, because the mural thrombus within the aneurysm tends to reduce the lumen to near-normal size. Nonetheless, aortography can be helpful in determining the extent of an aneurysm (especially when there is iliac or suprarenal involvement), defining associated arterial lesions involving the renal and visceral arteries, and detecting

lower-extremity occlusive disease. There are risks associated with aortography that place some restrictions on its use. Among these risks are the potential renal toxicity resulting from the use of contrast agents. In addition, manipulation of catheters through the laminated mural thrombus increases the risk of distal embolization. Finally, local arterial complications may arise at the arterial puncture site.

CT provides reliable information about the size of the entire aorta, thereby allowing accurate determination of both the size and the extent of the AAA [see Figure 2]. Spiral CT scanning permits identification of the visceral and renal arteries and their relationship to the aneurysm. The administration of I.V. contrast material allows assessment of the aortic lumen, the amount and location of mural thrombus, and the presence or absence of retroperitoneal hematoma [see Figure 3]. Overall, spiral CT is currently the most useful imaging method for evaluation of the abdominal aorta.

MRI is also useful in the preoperative evaluation of aortic aneurysms.^{18,19} It employs radiofrequency energy and a magnetic field to produce images in longitudinal, transverse, and coronal planes. The advantages of MRI over CT are that no ionizing radiation is administered, multiplane images can be obtained, and no nephrotoxic contrast agents are used.

Classification of Patients for Elective or Urgent Repair

Patients may usefully be classified into three categories according to how they present for repair: (1) elective patients, (2) symptomatic patients, and (3) patients with ruptured aneurysms.

Figure 2 Shown is a CT angiogram providing a three-dimensional reconstruction of an infrarenal AAA after endovascular repair. Of particular interest is the relation of the graft to the renal arteries and the hypogastric arteries distally.

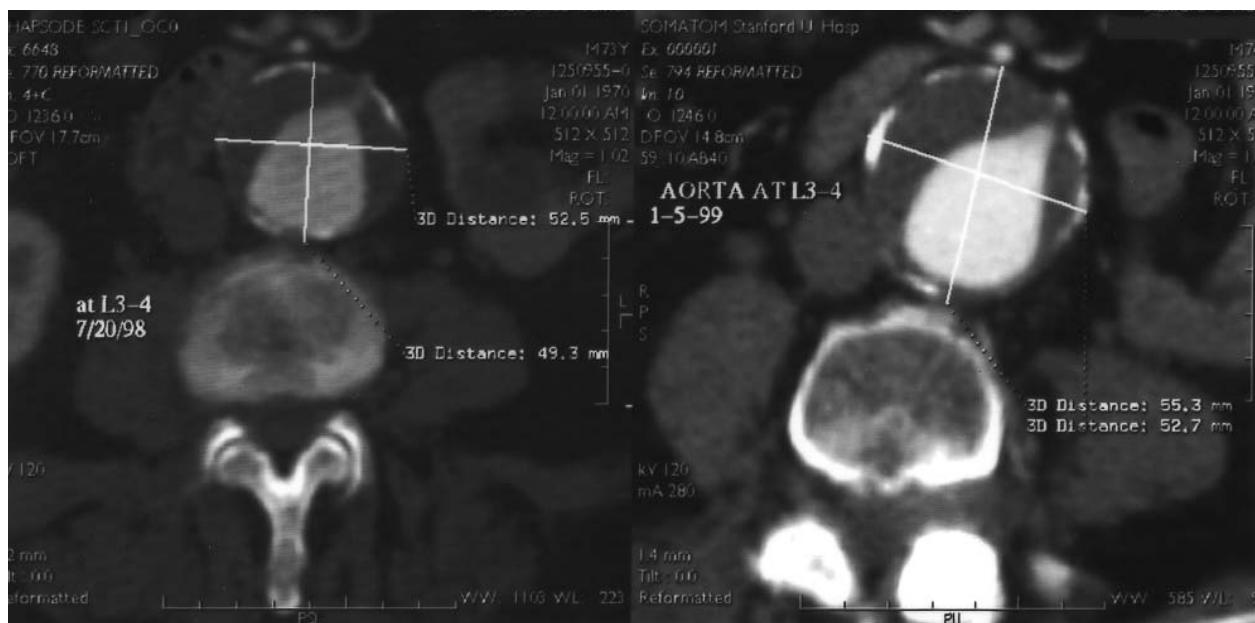

Figure 3 CT scanning assesses the size of the aneurysm, the amount of mural thrombus present, and the relation of other intra-abdominal structures to the aneurysm.

Elective aneurysm repair is recommended for asymptomatic patients who have aneurysms 5.0 cm in diameter or larger, who have an acceptable level of operative risk, and who have a life expectancy of 1 year or more. Furthermore, elective operation should be considered for patients with aneurysms smaller than 5.0 cm who are not at high operative risk if they are hypertensive or live in a remote area where proper medical care is not readily available. Repair is also appropriate for aneurysms that are between 4.0 and 5.0 cm in diameter and have shown growth of more than 0.5 cm on serial images in less than 6 to 12 months. Peripheral embolization originating from the aneurysm is an indication for repair, regardless of the size of the aneurysm.

Urgent operation is indicated for patients with symptomatic aneurysms, regardless of the size of the aneurysm. Such patients typically present with abdominal or back pain. Sometimes, the back pain radiates to the groin, much as in ureteral colic; this pain may be elicited by palpating the aneurysm. In most cases, DUS, CT, and MRI will reliably detect the presence of periaortic blood; however, the absence of this finding should not delay operation, because actual rupture of the aneurysm can occur at any time.

Emergency operation is indicated for almost all patients with known or suspected rupture of an aneurysm.

OPERATIVE PLANNING

Preoperative planning is essential for a successful outcome after repair of an infrarenal AAA. Like the choice between elective and urgent or emergency repair, operative planning is governed by the presentation of the patient. In patients with ruptured aneurysms, diagnosis is immediately followed by operative repair. In patients with symptomatic aneurysms, the amount of preoperative imaging done is balanced against the risk of impending rupture. In patients presenting for elective repair, it is generally possible to perform extensive imaging to determine whether the repair is best done via an endovascular approach [see Endovascular Repair, below] or a standard open approach. Current preoperative imaging methods utilizing CT angiography (CTA) obviate several common pitfalls. The availability of endovascular techniques for excluding an aneurysm should not alter the patient selection criteria for

aneurysm repair. Consideration of endovascular aneurysm repair (EVAR) does introduce certain morphologic criteria into the process of patient selection, in that stent grafting is appropriate only for patients in whom the infrarenal neck and the iliac arteries are suitable.

Given that the long-term outcome of endovascular grafting is currently unknown, younger patients who are at low operative risk and are expected to survive into the long term are typically better served with open surgical repair. In addition, patients who require additional abdominal or pelvic revascularization procedures, who have small or diseased access vessels, or who have short (< 10 mm) or tortuous infrarenal necks are not candidates for endovascular grafting and should undergo open surgical repair instead.

Preoperative preparation to optimize cardiopulmonary function, administration of preoperative antibiotics, and intraoperative hemodynamic monitoring with appropriate fluid management can significantly reduce the risks associated with AAA repair. Before aortic cross-clamping, appropriate volume loading, combined with vaso-dilatation, is carried out to help prevent declamping hypotension.

OPERATIVE TECHNIQUE

Step 1: Initial Incision and Choice of Approach

Open surgical repair of infrarenal AAAs is performed through a transperitoneal or retroperitoneal exposure of the aorta with the patient under general endotracheal anesthesia. The aneurysm may be exposed through either a long midline incision (for the transperitoneal approach) or an oblique flank incision (for the retroperitoneal approach) [see Figure 4a]. An upper abdominal transverse incision may also be used for either retroperitoneal or transperitoneal exposure. The results with the two exposures are equivalent. The transperitoneal approach is preferred when exposure of the right renal artery is required and when access to the distal right iliac system or to intra-abdominal organs is necessary. The retroperitoneal exposure offers advantages when extensive peritoneal adhesions, an intestinal stoma, or severe pulmonary disease is present and when there is a need for suprarenal exposure. Use of the retroperitoneal approach has been associated with a shorter

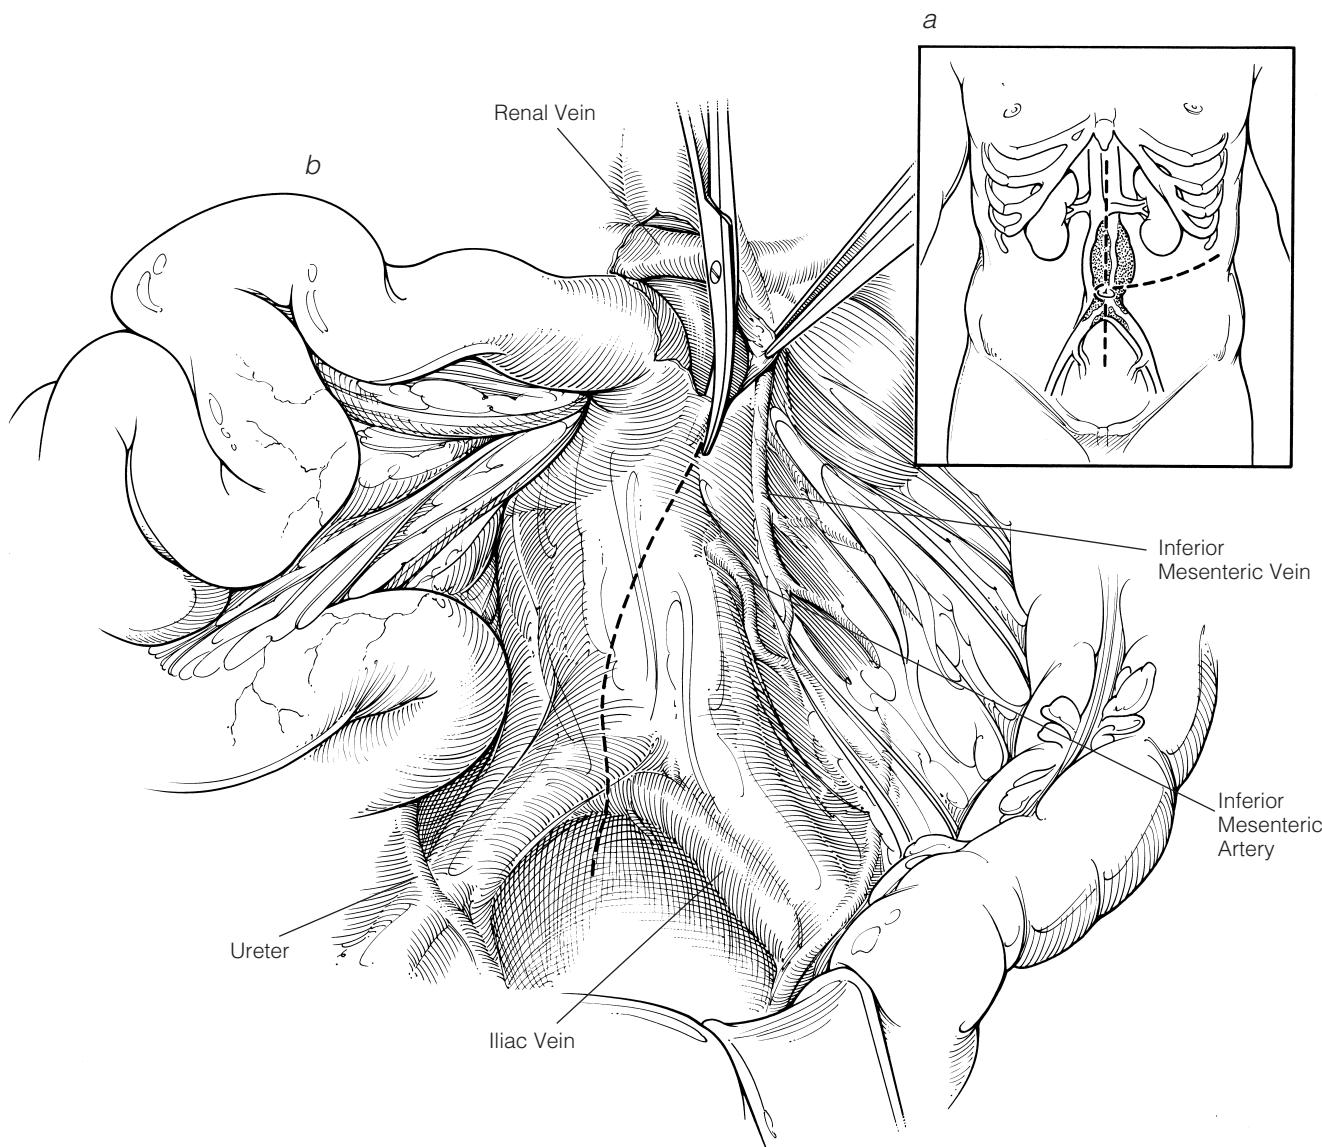

Figure 4 Open repair of infrarenal AAAs. (a) For the transabdominal approach to the abdominal aorta, a midline or transverse incision is appropriate. For the retroperitoneal approach, an oblique flank incision may be used. (b) The small intestine (including the duodenum) is retracted laterally after the ligament of Treitz is mobilized, and the retroperitoneum is incised in the midline. The left renal vein is the landmark for the infrarenal neck.

duration of postoperative ileus, a lower incidence of pulmonary complications, and a reduction in length of stay in the ICU.

Step 2 (Transperitoneal Approach): Exposure and Control of Aorta and Iliac Arteries

When the transperitoneal approach is taken, the small bowel (including the duodenum) is retracted to the right, and the retroperitoneum overlying the aneurysm is divided to the left of the midline [see Figure 4b]. The duodenum is completely mobilized, and the left renal vein is identified and exposed. The normal infrarenal neck, which is just below the left renal vein, is then exposed and encircled for proximal control. Both common iliac arteries are mobilized and controlled, with care taken to avoid the underlying iliac veins and ureters that cross over at the iliac bifurcation [see Figure 5]. If the common iliac arteries are aneurysmal, then both the internal and the external iliac arteries are controlled. The inferior mesenteric artery is then dissected out and controlled for possible reimplantation into the graft after the aneurysm has been repaired.

Step 2 (Retroperitoneal Approach): Exposure and Control of Aorta and Iliac Arteries

When the retroperitoneal approach is taken, a transverse left abdominal or flank incision is made, and the peritoneum is reflected anteriorly. The left kidney usually is left in place but may be mobilized anteriorly to expose the posterolateral aorta. Exposure of the right iliac system can be achieved by dividing the inferior mesenteric artery early in the course of dissection. The aorta and the iliac arteries are controlled in essentially the same fashion regardless of the type of incision used.

Step 3: Opening of Aneurysm and Creation of Proximal Anastomosis

Systemic anticoagulation with I.V. heparin is then performed. After sufficient time (3 to 5 minutes) has elapsed to permit adequate circulation, the infrarenal neck and the iliac arteries are clamped. To prevent distal embolization, the distal clamps should be applied before the proximal aortic clamp. The aneurysm is then

opened longitudinally, the mural thrombus is removed, and back-bleeding lumbar arteries are oversewn. Depending on its degree of backflow and on the patency of the hypogastric arteries, the inferior mesenteric artery may be either ligated or clamped and left with a rim of aortic wall for subsequent reimplantation [see Troubleshooting, below].

The aortic neck is then partially or completely transected, and an appropriately sized tubular or bifurcated graft is sutured to the aorta with a continuous nonabsorbable monofilament suture [see Figure 6]. When the proximal aortic neck is very short, suprarenal aortic

clamping may be required for performance of the proximal anastomosis. If suprarenal clamping is necessary, the security of the proximal anastomosis should be verified, and the clamp should then be moved onto the graft below the renal arteries as soon as possible to minimize renal ischemia. If the aorta is especially weak or friable, the anastomosis may be supported with Teflon-felt pledges.

Step 4: Creation of Distal Anastomosis

When the aneurysm is confined to the aorta, the distal anastomosis is performed by suturing a straight tube graft to the aortic

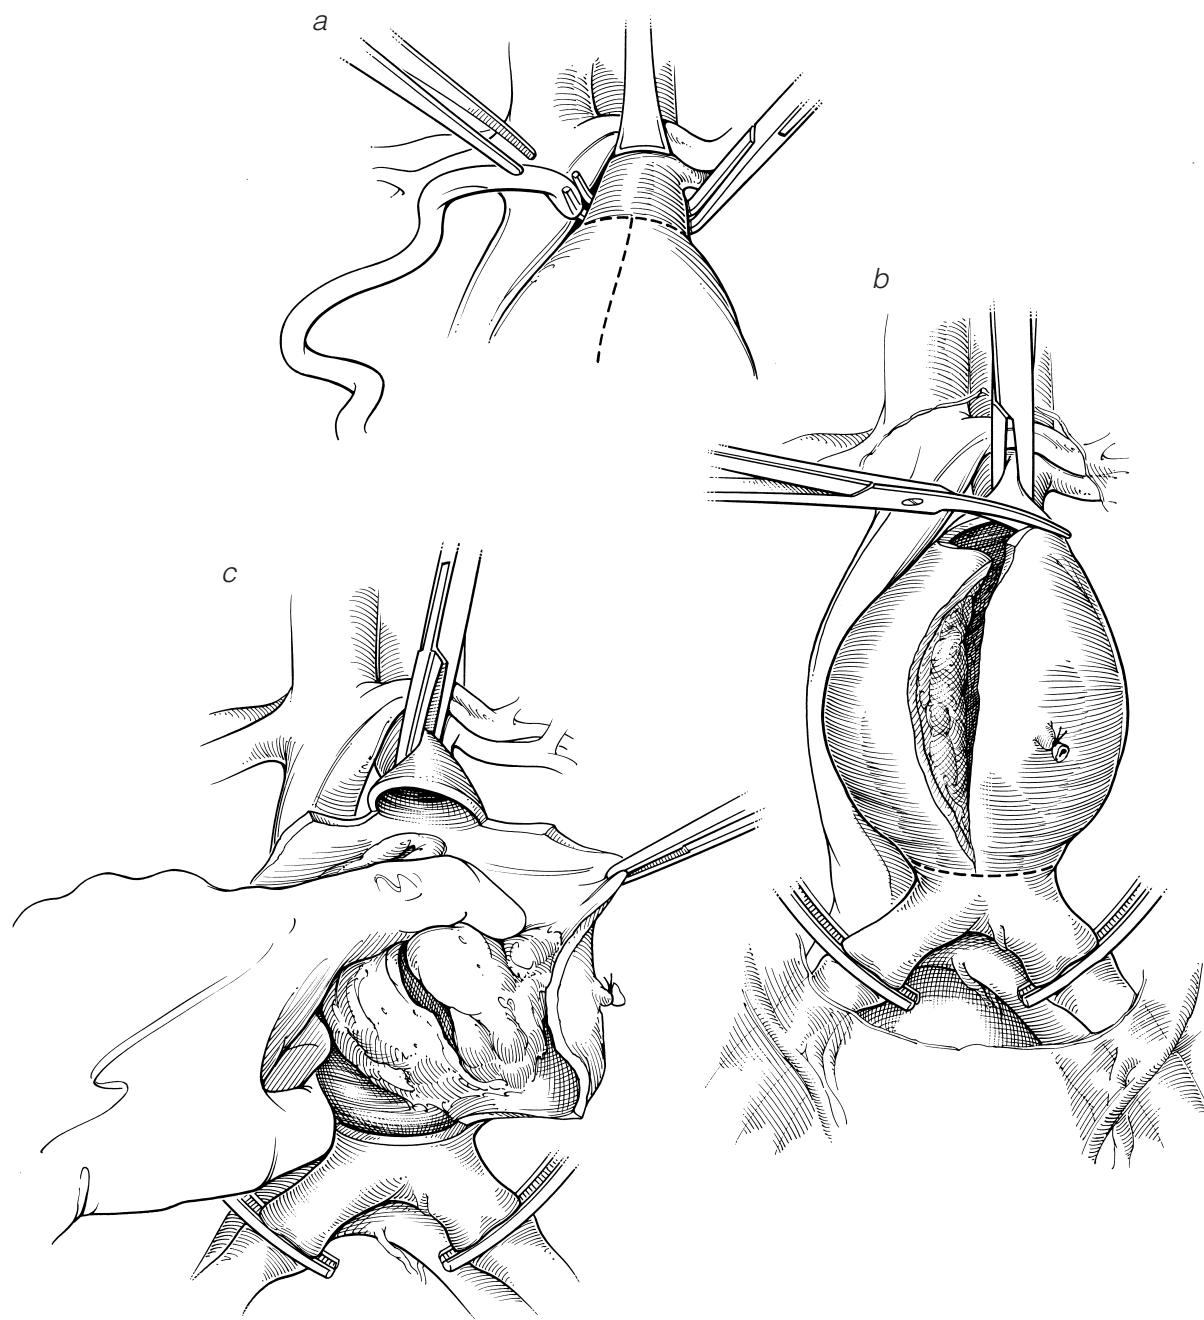

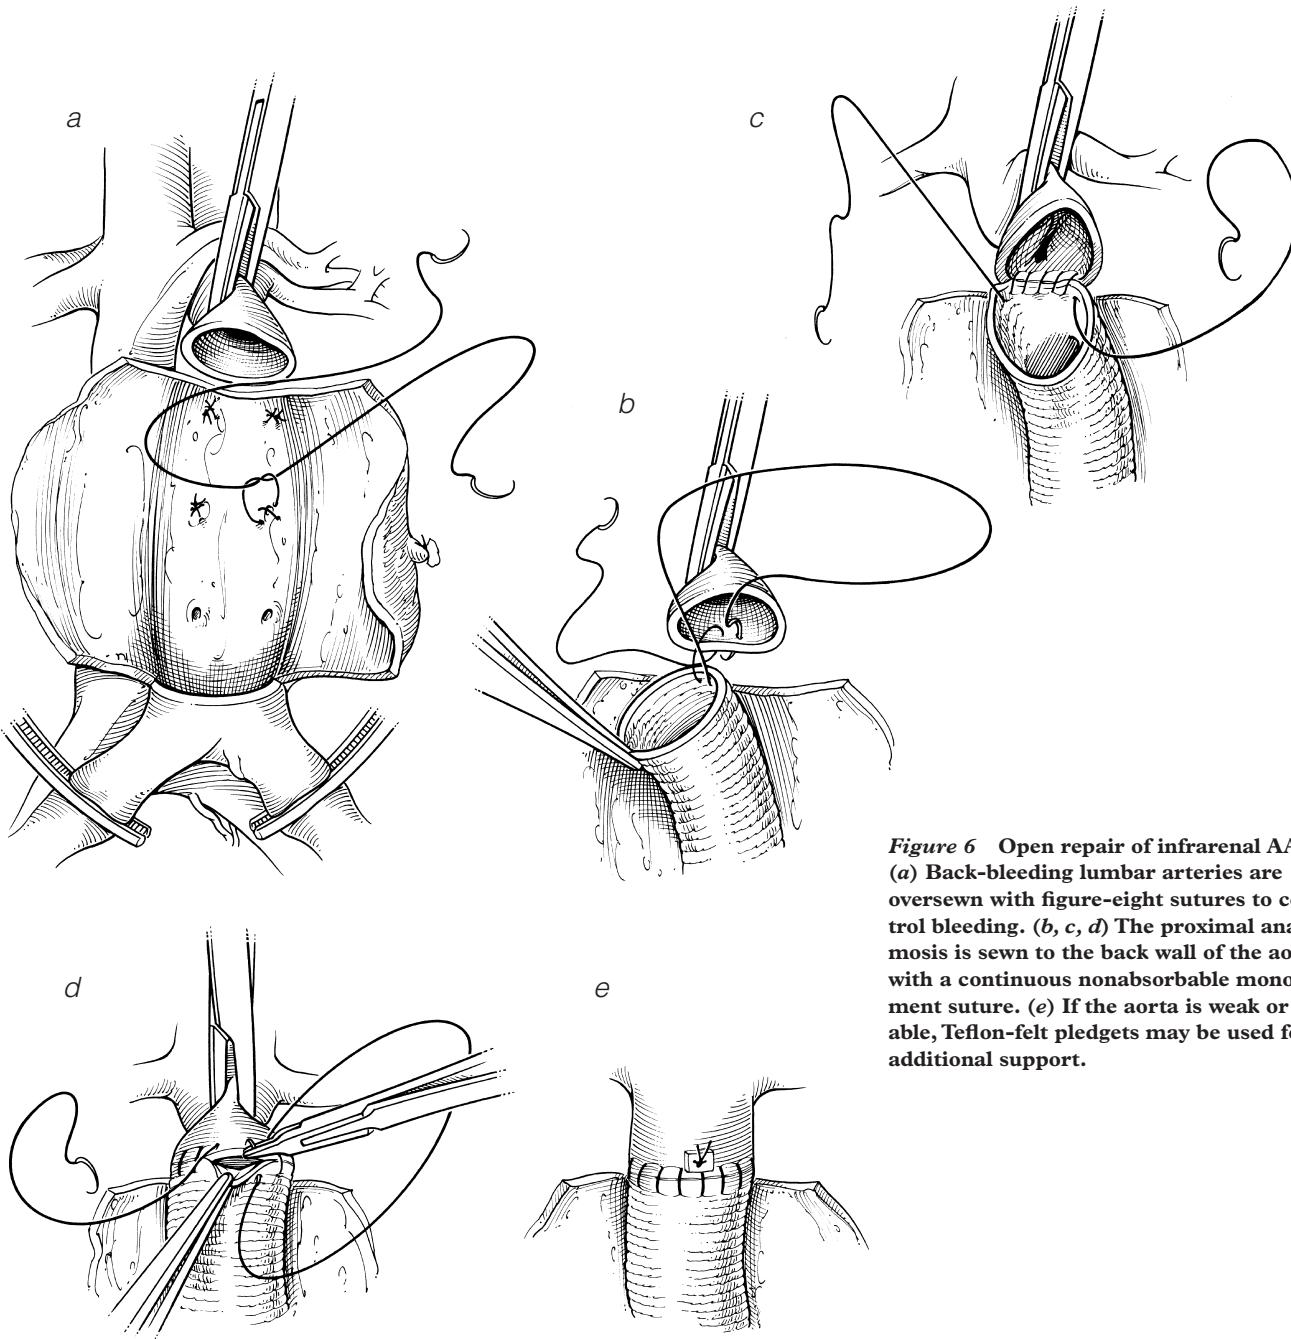

Figure 5 Open repair of infrarenal AAAs. (a) Once the aneurysm is exposed, proximal control is obtained by encircling the proximal neck with an umbilical tape or heavy Silastic. The inferior mesenteric artery is identified and then either clamped or ligated for possible reimplantation at the end of the procedure. (b) The iliac arteries are dissected free, systemic heparin anticoagulation is instituted, and distal control is obtained, followed by proximal control to prevent distal embolization. The aneurysm sac is then opened longitudinally. (c) All mural thrombus is removed, and the proximal and distal necks of the aorta are incised.

**Figure 6** Open repair of infrarenal AAAs.

(a) Back-bleeding lumbar arteries are oversewn with figure-eight sutures to control bleeding. (b, c, d) The proximal anastomosis is sewn to the back wall of the aorta with a continuous nonabsorbable monofilament suture. (e) If the aorta is weak or friable, Teflon-felt pledgets may be used for additional support.

bifurcation [see *Figure 7*]; straight tube graft reconstructions are used about 30% of the time. Distally, the dissection should avoid the fibroareolar tissue overlying the left common iliac artery because this tissue contains branches of the inferior mesenteric artery and the autonomic nerves that control sexual function in men.

When the aneurysm extends into the common iliac arteries, the distal anastomosis is accomplished by suturing a bifurcated graft to the distal common iliac arteries or, in the case of significant occlusive disease, to the common femoral arteries. In these situations, control of the iliac arteries is best achieved by mobilizing the external and internal arteries and clamping them individually [see *Figure 8*]. It is sometimes easier to control iliac artery back-bleeding by using intraluminal balloon catheters and oversewing the common iliac arteries from within the opened aortic or iliac aneurysms. Care must be taken not to injure the accompanying venous structures or the ureters, which cross anterior to the iliac bifurcation.

Every effort should be made to ensure perfusion of at least one hypogastric artery to help minimize the risk of postoperative left colon ischemia.

Declamping hypotension may occur after reperfusion of the lower extremities. It is essential to maintain communication with the anesthesiologist so that blood and fluid replacement can be adjusted in anticipation of lower-extremity reperfusion. Even though the graft and vessels are flushed and back-bled before distal flow is reestablished, it is preferable first to establish flow into one of the hypogastric arteries so as to minimize the chances of distal embolization to the legs.

Before the abdomen is closed, adequate perfusion of the lower extremities and the left colon should be ensured via either direct inspection or noninvasive monitoring. The open aneurysm sac is then sutured closed over the aortic graft to separate the graft from the duodenum and the viscera [see *Figure 9*]. This step reduces the risk of aortoenteric fistula.

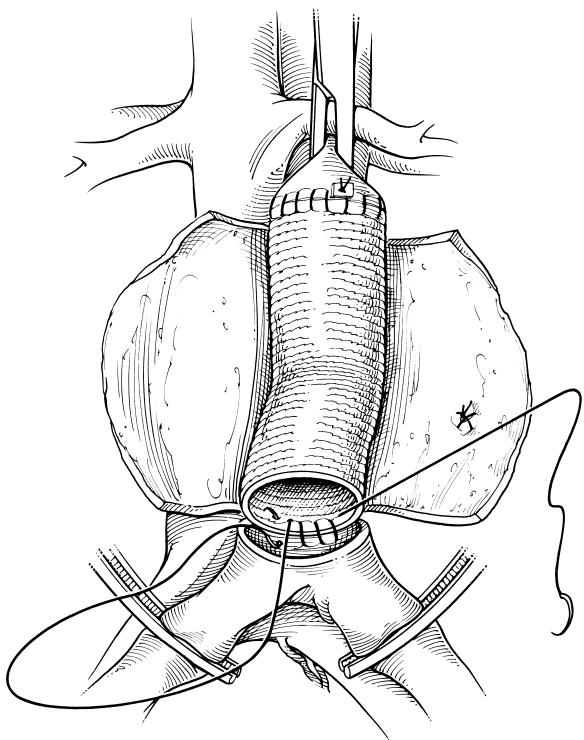

Figure 7 Open repair of infrarenal AAAs. When the aneurysm does not extend into the iliac arteries, a straight tube graft is used. The distal anastomosis is completed with a continuous suture. Before completion of the anastomosis, the graft is flushed by back-bleeding the iliac arteries and flushing the proximal anastomosis.

Troubleshooting

If the inferior mesenteric artery is small and back-bleeding is adequate, it may be ligated [see Figure 10a]; however, if the vessel is large or back-bleeding is meager, it should be reimplanted. Reimplantation of the inferior mesenteric artery can be accomplished with relative ease by using the Carrel patch technique. After the graft has been completely sewn to the aorta, a partial occluding clamp is placed on the main body of the graft or on one of the limbs. An opening in the graft is then created, and an end-to-side anastomosis [see Figure 10b]—with an interposition graft added if necessary [see Figure 10c]—is used to reconstruct the inferior mesenteric artery. This anastomosis is created with a continuous monofilament suture.

SPECIAL CONSIDERATIONS

Concurrent Disease Processes

At times, a concurrent disease process complicates repair of an AAA. The most common problems encountered are hepatobiliary, pancreatic, gastrointestinal, gynecologic, and genitourinary disorders. Careful evaluation of the situation is necessary to determine whether to treat the two disease entities concurrently. As a rule, the more life-threatening disorder is treated first.

There are three key points that should be remembered in the management of patients with AAAs and concurrent diseases. First, a careful preoperative diagnostic workup usually detects any concomitant disease processes. Second, in emergency situations such as ruptured or symptomatic aneurysms, the aneurysm always takes priority unless the other condition is life-threatening and the aneurysm clearly is not the cause of the critical symptoms. Finally, many concomitant intra-abdominal problems can be avoided by taking an endovascular approach.

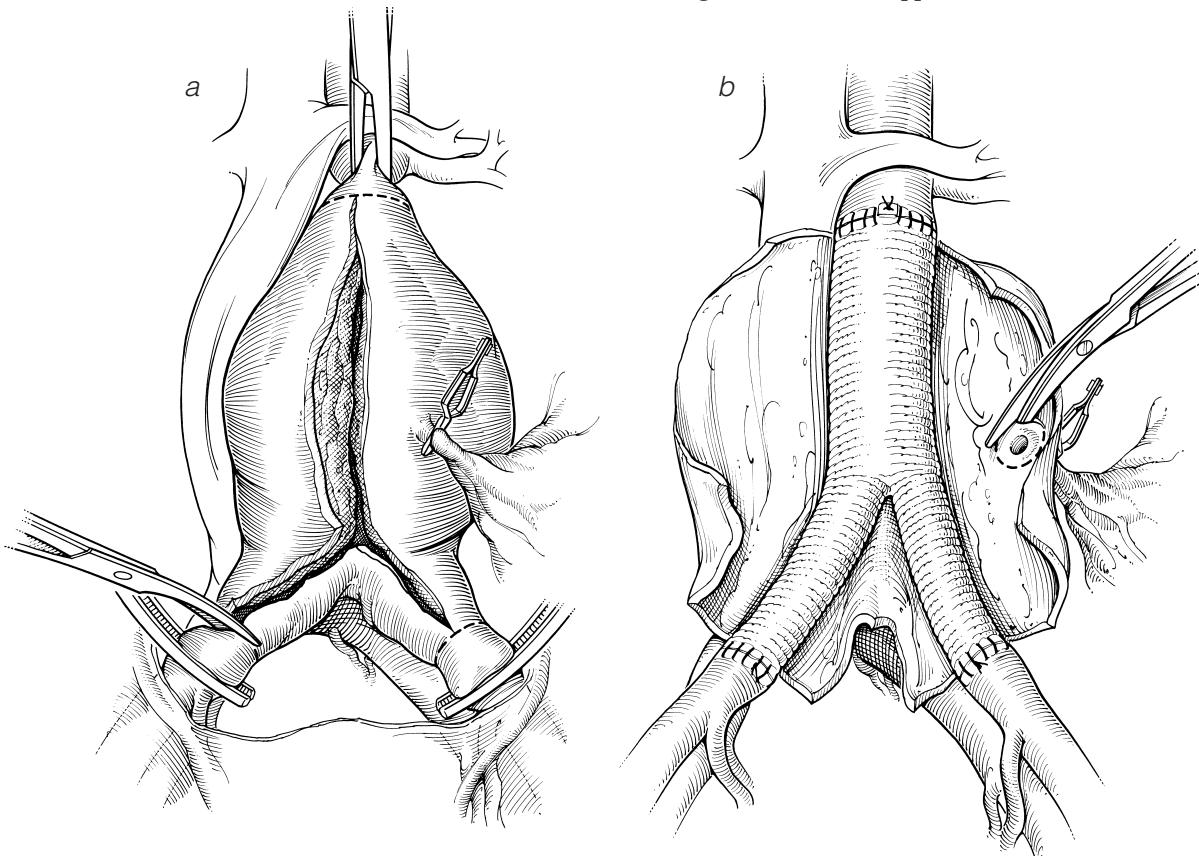

Figure 8 Open repair of infrarenal AAAs. When the common iliac arteries are aneurysmal, both the internal and the external iliac arteries must be clamped individually (a), and a bifurcated graft is sewn to the iliac arteries bilaterally (b).

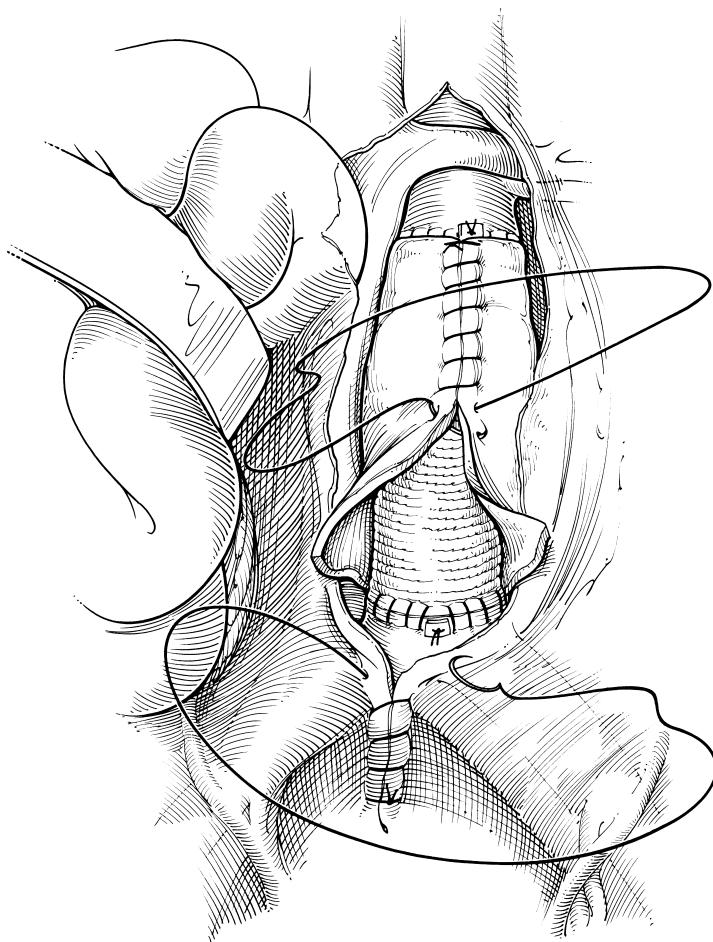

Figure 9 Open repair of infrarenal AAAs. Once the anastomoses have been completed and adequate flow to the lower extremities and the left colon has been confirmed, the open aneurysm sac is sutured closed over the aortic graft.

Anatomic Variants

Several anatomic variants may be encountered during repair of AAAs, including horseshoe kidney, accessory renal arteries, and venous anomalies.

Horseshoe kidney The incidence of horseshoe kidney in the general population is less than 3%. Most patients with horseshoe kidneys have between three and five renal arteries.²⁰ To preserve renal function, renal arteries arising from the aneurysm should be reimplanted. In patients with horseshoe kidneys who have more than five renal arteries, there often are multiple small accessory arteries, some of which originate from the aneurysm, the iliac arteries, or both.

The presence of a horseshoe kidney may complicate—but does not preclude—an anterior approach to repair of an infrarenal AAA.²¹ In such cases, the left retroperitoneal approach provides excellent exposure of the infrarenal aorta. This approach requires that the surgeon dissect the space between the aneurysm and the left portion and isthmus of the kidney; the kidney can then be reflected to the right and the aneurysm fully exposed. The left ureter crosses the iliac arteries from the right in this position, and duplication of ureters may be noted.

Venous anomalies A number of different venous anomalies may be observed in the course of AAA repair; however, the overall

incidence is quite low. Left renal vein variants, such as retroaortic left renal veins and circumaortic venous rings, are the most commonly seen venous anomalies.²² Azygous continuation of the inferior vena cava and bilateral inferior vena cava have also been noted. Unnecessary bleeding can be prevented by means of careful dissection and meticulous technique.

Inflammatory Aneurysm

Approximately 5% of infrarenal AAAs are inflammatory.²³ These AAAs have a dense fibroinflammatory rind that typically adheres to the fourth portion of the duodenum; they may also involve the inferior vena cava, the left renal vein, or the ureters. Patients with inflammatory AAAs typically experience abdominal or flank pain and may present with weight loss. The erythrocyte sedimentation rate is usually elevated as well. Inflammatory aneurysms rarely rupture, because most are symptomatic and consequently are treated before rupture can occur. Repair of inflammatory aneurysms poses technical problems because of the involvement of adjacent structures. A retroperitoneal approach is usually advocated for these aneurysms.

Ruptured Aneurysm

Infrarenal AAAs can rupture freely into the peritoneal cavity or into the retroperitoneum. Free rupture into the peritoneal cavity is usually anterior and is typically accompanied by immediate hemodynamic collapse and a very high mortality. Retroperitoneal ruptures are usually posterior and may be contained by the psoas muscle and adjacent periaortic and perivertebral tissue. This type of rupture may occur without significant blood loss initially, and the patient may be hemodynamically stable.

When an aortic aneurysm ruptures, immediate surgical repair is indicated. If the patient is unstable and either an abdominal aortic aneurysm was previously diagnosed or a palpable abdominal mass is present, no further evaluation is necessary and the patient should be taken directly to the OR. If the patient is stable and the diagnosis is questionable, CT scanning may be performed to confirm the presence of an aneurysm and determine its extent, the site of the rupture, and the degree of iliac involvement. Bedside ultrasonography may also be used for quick confirmation of the presence of an AAA.

Surgical repair of ruptured aneurysms is performed via a transperitoneal approach. In cases of contained rupture, supraceliac control should be achieved before infrarenal dissection; once the neck of the aneurysm has been dissected free, the aortic clamp may be moved to the infrarenal level. In cases of free rupture, efforts to obtain vascular control may include compression of the aorta at the hiatus and infrarenal control with a clamp or an intraluminal balloon. Once proximal and distal control have been achieved, the operation is conducted in much the same way as an elective repair.

OUTCOME EVALUATION

The mortality associated with repair of AAAs has been greatly reduced by improvements in preoperative evaluation and perioperative care: leading centers currently report death rates ranging from 0% to 5%.²⁴ Mortality after repair of inflammatory aneurysms and after emergency repair of symptomatic nonruptured aneurysms continues to be somewhat higher (5% to 10%), primarily as a consequence of less thorough preoperative evaluation.

Overall morbidity after elective aneurysm repair ranges from 10% to 30%. The most common complication is myocardial ischemia, and MI is the most common cause of postoperative death. Mild renal insufficiency is the second most frequent com-

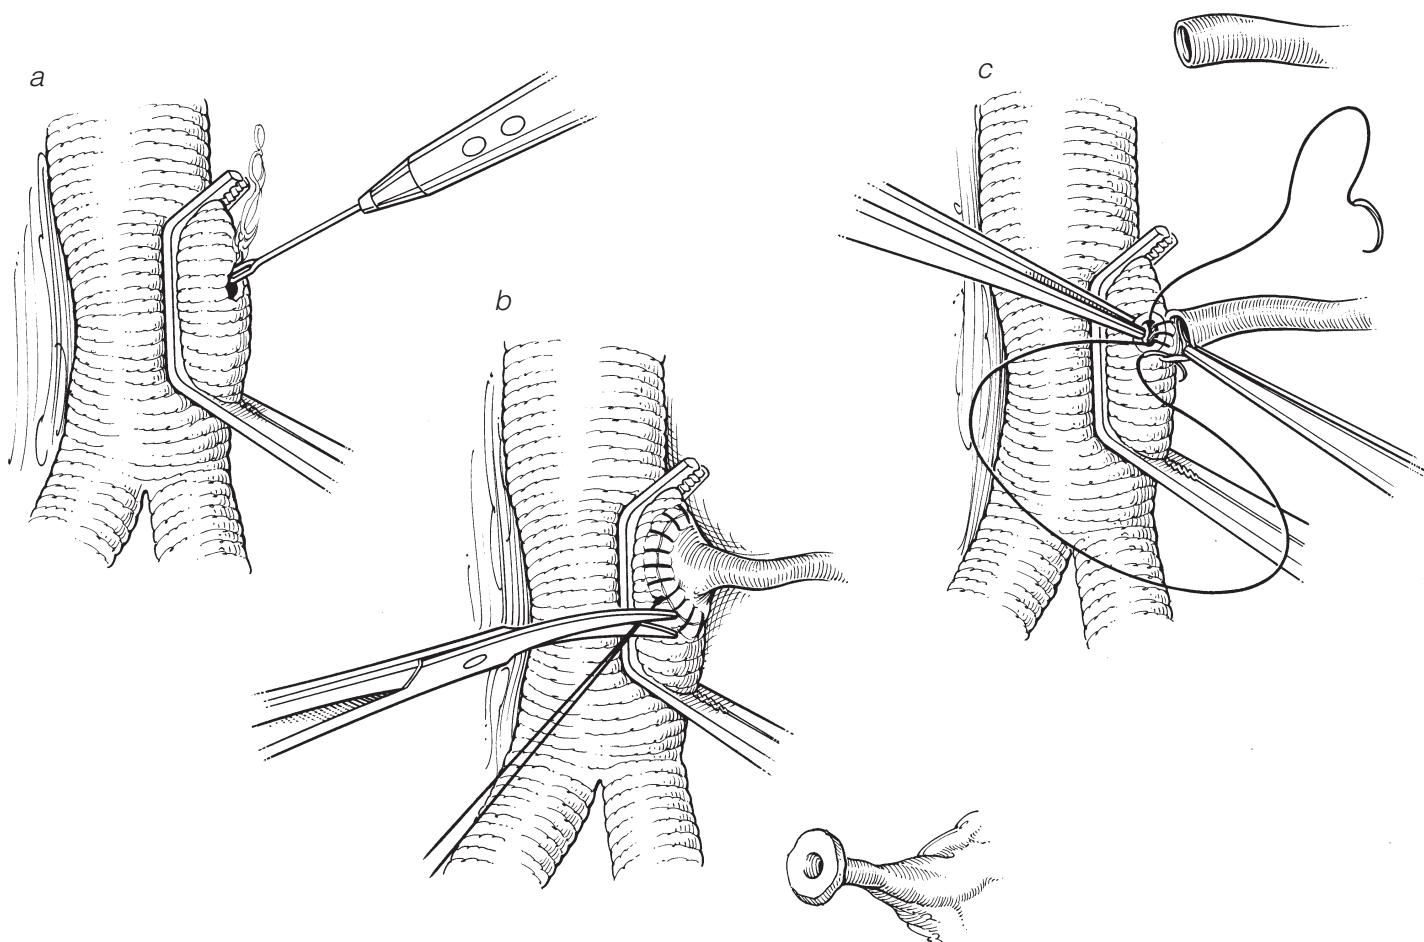

Figure 10 Open repair of infrarenal AAAs. (a) A small, adequately back-bleeding inferior mesenteric artery may be ligated. (b) A large or meagerly back-bleeding inferior mesenteric artery should be reimplanted. A side-biting clamp is applied to the graft, and an end-to-side anastomosis is created with a fine monofilament suture. (c) If the inferior mesenteric artery is not long enough for a direct anastomosis, an interposition graft—either a segment of a vein or a prosthetic graft—may be used for added length.

plication, occurring after 6% of elective aneurysm repairs; however, severe renal failure necessitating dialysis is rare in this setting. The third most common complication is pulmonary disease; the incidence of postoperative pneumonia is approximately 5%.

Postoperative bleeding may occur as well. Common sources of such bleeding include the anastomotic suture lines, inadequately recognized venous injuries, and coagulopathies resulting from intraoperative hypothermia or excessive blood loss. Any evidence of ongoing bleeding is an indication for early exploration.

Lower-extremity ischemia may occur as a result of either emboli or thrombosis of the graft and may necessitate reoperation and thrombectomy. So-called trash foot may also develop when diffuse microemboli are carried into the distal circulation.

Colon ischemia develops after 1% of elective aneurysm repairs. Patients usually present with bloody diarrhea, abdominal pain, a distended abdomen, and leukocytosis. The diagnosis is confirmed by sigmoidoscopy, which reveals mucosal sloughing. In cases of transmural colonic necrosis, colon resection and exteriorization of stomas are warranted.

Paraplegia is rare after repair of infrarenal AAAs: the incidence is only 0.2%. Most instances of paraplegia occur after repair of a ruptured aneurysm or when the pelvis has been devascularized. The majority of patients recover at least some degree of neurologic function.

Late complications (e.g., pseudoaneurysms at the suture lines,

graft or graft limb thrombosis, and graft infection) may occur but are extremely rare. Graft infection may be associated with graft-enteric fistula and is notoriously difficult to diagnose and treat.

Long-term survival in patients who have undergone successful AAA repair is reduced in comparison with that in the general population. The 5-year survival rate after AAA repair is 67% (range, 49% to 84%), compared with 80% to 85% in age-matched control subjects, and the mean duration of survival after AAA repair is 7.4 years. Part of the difference in survival can be attributed to associated coronary disease in patients with aneurysms. Late deaths result primarily from cardiac causes.

Endovascular Repair

Endovascular repair was introduced during the 1990s as a less invasive approach to treating infrarenal AAAs. In this approach, a stent-graft is placed endoluminally via bilateral groin incisions; thus, there is no need for a major abdominal incision and aortic clamping. The results to date have been promising: blood loss is decreased, hospital stay is shortened, and earlier return to function is achieved. Not all patients are candidates for endovascular repair, however. In September 1999, the Food and Drug Administration approved two stent-graft devices for use in surgical management of AAAs: the Ancure device (Guidant, Indianapolis, Indiana), which is a balloon-expandable one-piece bifurcated stent-graft, and the

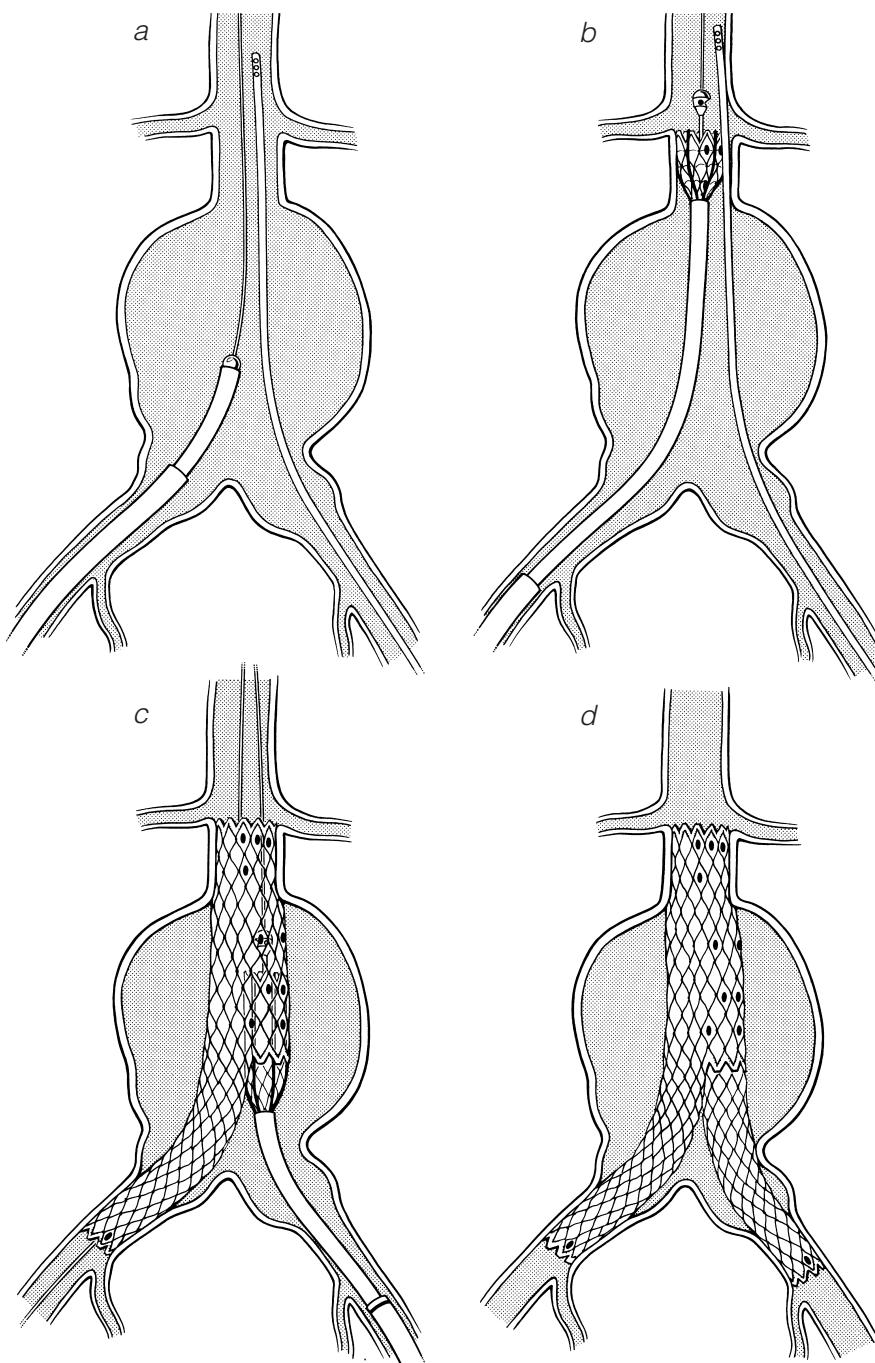

Figure 11 Endovascular repair of infrarenal AAAs. (a) The main bifurcated stent-graft is advanced through the aortoiliac system under fluoroscopic guidance. (b) The sheath over the stent-graft is retracted under fluoroscopic guidance. Controlled deployment allows the graft to be gradually positioned directly below the renal arteries. (c) With the main body of the stent-graft deployed, the contralateral limb is cannulated. Once this is done, the contralateral limb is positioned within the junction gate and the common iliac artery. (d) Shown is proper deployment of the stent-graft within the aortoiliac system, with good proximal and distal fixation of the stent to the arterial wall.

AneuRx device (Medtronic AVE, Santa Rosa, California), which is a self-expanding bifurcated modular device that is fully supported externally by a nitinol stent. Subsequently, the FDA approved three more devices for endovascular repair of AAAs: the Excluder Bifurcated Endoprostheses (W. L. Gore and Associates, Flagstaff, Arizona), in November 2002, the Zenith AAA Endovascular Graft (Cook Incorporated, Bloomington, Indiana), in May 2003, and

the Endologix Powerlink System (Endologix Incorporated, Irvine, California), in November 2004. The Ancure device is no longer available.

PREOPERATIVE PREPARATION

Precise preoperative evaluation that yields accurate measurements will result in proper planning and effective prevention of

problems. Both CTA and contrast biplane angiography are used for this purpose. Of the two, spiral CTA is currently preferred. This imaging modality is capable of obtaining high-quality images of the vascular anatomy and reconfiguring them into detailed three-dimensional images. For optimal evaluation, images should be obtained at 1.5 to 3 mm intervals from the celiac artery to the femoral arteries. Spiral CTA accurately defines the proximal and distal characteristics of the AAA, as well as detects any significant renal, visceral, or iliac occlusive disease. It is particularly helpful in defining the infrarenal neck between the renal arteries and the proximal portion of the aneurysm.

Angiography is employed as a complement to spiral CTA in this setting. An arteriogram is useful in that it helps define renal, mesenteric, and distal arterial anatomy; helps characterize tortuosity, calcification, and stenoses in access arteries; and helps determine the angles between the aorta, the proximal neck, and the aneurysm.

Intravascular ultrasonography (IVUS) is a useful intraoperative imaging adjunct in the process of sizing and selecting endograft components. It can be used to measure vessel diameters and landing zone lengths, as well as to determine the amount of mural thrombus in the aneurysm neck. In patients with severe renal insufficiency, IVUS is used primarily to identify the renal and hypogastric arteries, allowing the endograft to be deployed with minimal or no resort to angiography.

Proper patient selection is mandatory for successful outcome. The common femoral arteries must be large enough to accept a delivery system larger than 21 French. The proximal infrarenal aortic neck must be suitable for device implantation—that is, its diameter must be between 16 and 28 mm, and its length should be at least 15 mm. The common iliac artery implantation should be carried out as close to the iliac bifurcation as possible to increase the columnar strength of the implanted device. The iliac artery diameter must be between 8 and 20 mm. In patients with iliac artery aneurysms, it is possible to land the end of the stent in the external iliac artery and thereby exclude one internal iliac artery. Exclusion of both internal iliac arteries should be avoided so as to prevent ischemic sequelae (e.g., buttock claudication, colon ischemia, and erectile dysfunction). Coil embolization may be performed in conjunction with EVAR to treat internal iliac aneurysms. However, a waiting period of several weeks between coil embolization of a hypogastric artery on one side and the same procedure on the other side should be considered to allow recruitment of collateral vessels and reduce the incidence of pelvic ischemia.

TECHNIQUE

The methods and technical principles we briefly describe here derive from the personal experience of two surgeons (F.R.A and C.K.Z) with more than 1,000 modular implants. The ensuing technical description is not intended to be exhaustive, nor is it meant as a substitute for the instructions provided by any of the manufacturers.

The patient is placed under epidural or general anesthesia. Bilateral femoral artery cutdowns are performed through transverse groin incisions to allow exposure of the common femoral artery from the inguinal ligament to the femoral bifurcation. Proximal control of the femoral arteries is obtained with umbilical tapes. Systemic anticoagulation with I.V. heparin is instituted to prolong the activated clotting time (ACT) to greater than 250 seconds. The ACT is monitored and maintained at this level throughout the procedure, and additional heparin is given as needed.

The femoral arteries are cannulated with an 18-gauge needle,

and 0.035-in. guide wires are placed bilaterally under fluoroscopic guidance; 10 French sheaths are then placed over the two guide wires and advanced into the aneurysm under fluoroscopic guidance. A superstiff 0.035-in. guide wire 260 cm in length is inserted into the thoracic aorta, usually from the right limb. In the contralateral iliac artery, a pigtail catheter is placed just above the level of the renal arteries, and an initial roadmapping aortogram is obtained. The 10 French sheath in the right femoral artery is then exchanged for the device, which is placed over the superstiff guide wire and carefully advanced into the proximal infrarenal aorta under fluoroscopic guidance, then into the perirenal aorta [see *Figure 11a*]. A second aortogram is performed to verify the position of the renal arteries. Under fluoroscopic guidance, the stent-graft is then gradually deployed by retracting the outer sheath and allowing the graft to expand, and it is positioned directly below the level of the renal arteries [see *Figure 11b*].

Once the main bifurcation module has been deployed, the 10 French sheath in the contralateral iliac artery is pulled back, and a 0.035-in. angled hydrophilic wire and a guide catheter are inserted into the contralateral limb of the bifurcation module. The hydrophilic wire is then exchanged for a superstiff guide wire, over which the contralateral limb is then advanced through the sheath into the contralateral vessel and deployed [see *Figure 11c*]. A final aortogram is then performed to confirm that a satisfactory technical result has been achieved [see *Figure 11d*]. Proximal and distal extender cuffs may be placed if necessary. The femoral arteriotomies are repaired, and lower-extremity perfusion is reestablished.

OUTCOME EVALUATION

EVAR is significantly less invasive than open surgical repair and consequently is associated with a significant reduction in major procedure-related morbidity. Prospective clinical trials comparing open AAA repair with EVAR have consistently found that patients undergoing the latter experience less intraoperative blood loss, need less postoperative ICU care, have shorter lengths of stay, and regain normal function earlier.^{25,26} Procedure-related mortality after EVAR is 1% to 2%, which is essentially equivalent to that reported after open repair in prospective clinical trials but lower than the 5% mortality reported after open repair in most multicenter studies.^{27,28}

In the past few years, two randomized, controlled trials comparing EVAR with open AAA repair have been published. The Dutch Randomized Endovascular Aneurysm Management (DREAM) trial found EVAR to have a significant advantage in the first 30 days, with reduced mortality and a lower incidence of severe complications.²⁹ This survival advantage was not sustained, however, and at 1 year, there was no difference between EVAR and open AAA repair. The EVAR 1 trial, carried out in the United Kingdom, found EVAR to yield a similar reduction in 30-day mortality.³⁰ Again, this survival advantage was not sustained, and at 4 years, there was no difference between EVAR and open repair in terms of overall mortality or health-related quality of life. EVAR did, however, have a significant advantage over open AAA repair with regard to 4-year aneurysm-related mortality. The impact of this advantage will continue to be assessed as this trial's follow-up period lengthens.

On occasion, EVAR fails to exclude blood flow from the aneurysm sac completely. This condition, known as endoleak, may arise from an incomplete seal at the site where the endograft is affixed to the aortic neck or the iliac arteries (type I endoleak), from retrograde flow into the aneurysm from the inferior mesenteric artery or the lumbar arteries (type II endoleak), or from the graft or modular junction site (type III endoleak). Type I and type

III endoleaks call for secondary treatment to prevent possible aneurysm rupture. The significance of type II endoleaks is less certain. There is no clear evidence that type II endoleaks lead to aneurysm rupture; however, most such endoleaks are treated if they are associated with aneurysm enlargement.

Although numerous studies have shown that endovascular AAA repair results in less morbidity and perioperative mortality than open repair,³¹⁻³⁴ reports describing endograft migration over time, aneurysm enlargement, and occasional aneurysm rupture have raised questions about the long-term durability of the procedure.^{35,36} These adverse events, though uncommon, serve as reminders that EVAR is still a new technology, one whose long-term outcome is unknown. Accordingly, close patient monitoring and follow-up surveillance are warranted, and secondary treatments may be required (e.g., additional endovascular procedures

or, possibly, open surgical repair). New endovascular devices are currently being designed and evaluated in clinical trials, and endovascular treatment strategies continue to evolve and improve.

Clinical follow-up of patients treated during the initial prospective clinical trials now extends to more than 7 years, and EVAR continues to show favorable results. The largest multicenter endovascular clinical trial to date, involving 1,193 patients who were followed for as long as 6 years, found that prevention of aneurysm rupture (the primary objective) was achieved in 99% of patients, whereas procedure-, aneurysm-, or graft-related death was avoided in 97%.^{37,38} These results are consistent with the favorable overall outcomes reported from a European registry of EVAR using a variety of endovascular devices.³⁹ Thus, the midterm results of EVAR are favorable and support the consideration of this approach for most patients who are candidates for the procedure.

12 AORTOILIAC RECONSTRUCTION

Mark K. Eskandari, M.D.

Symptomatic aortoiliac occlusive disease is the consequence of a diffuse atherosclerotic process that is exacerbated by smoking, hypertension, hypercholesterolemia, and diabetes.¹⁻⁴ The resultant narrowing of the aorta and the iliac vessels impairs circulation into the pelvis and the lower extremities, thereby causing myriad patient complaints. Manifestations range from impotence, claudication (in the buttock, the thigh, or the calf), and rest pain (in the forefoot) to ulceration or gangrene.

Hemodynamically significant obstruction of blood flow arising from aortoiliac occlusion may be either segmental or diffuse. Fortunately, there are a number of different vascular reconstructions that can be performed to reestablish sufficient flow to the lower body. The choice of a surgical revascularization approach is based on two factors: (1) anatomic constraints and (2) comorbid conditions. Regardless of which technique is selected, preoperative workup and planning are essentially the same.

Preoperative Evaluation

Once it has been established that a patient's symptoms (e.g., claudication, rest pain, or a nonhealing wound) are attributable to hemodynamically significant aortoiliac occlusive disease, a thorough preoperative evaluation is initiated. Such evaluation typically includes obtaining objective physiologic documentation of the extent of occlusive disease by measuring lower-extremity blood flow with arterial waveforms and ankle-brachial indices. An imaging study is also required to guide revascularization. Percutaneous diagnostic angiography is widely used for this purpose; however, technological advancements may allow magnetic resonance angiography (MRA) to supplant traditional contrast arteriography.⁵⁻⁷ If an extra-anatomic bypass is anticipated, ancillary tests, including bilateral arm blood pressure measurements and computed tomography scans of the chest, abdomen, or pelvis, may be necessary. A standard cardiac risk assessment is mandatory before any form of revascularization, and the extent of testing is tailored to the level of cardiac risk.

Operative Technique

AORTOILIAC ENDARTERECTOMY

Although localized aortoiliac endarterectomy is less commonly performed today than it once was, it remains useful for a subgroup of patients with focal aortic bifurcation disease. The classic candidate for this procedure has minimal disease of the infrarenal abdominal aorta and the external iliac arteries but a severely diseased and narrowed aortic bifurcation.

Step 1: Incision and Approach

A standard lower midline transperitoneal incision allows rapid, direct access. Usually, the incision can be made below the umbilicus and extended to the pubis.

Step 2: Exposure and Control of Aorta and Iliac Arteries

Upon entry into the abdominal cavity, exposure of the aortic bifurcation is achieved by retracting the small bowel cephalad. A self-retaining retractor, such as an Omni (Omni-Tract Surgical,

Minneapolis, Minnesota) or a Bookwalter (Cardinal Health, V. Mueller, McGaw Park, Illinois), is often helpful. The retroperitoneum overlying the aortic bifurcation is then incised in the midline, and the aorta is exposed to the level of the inferior mesenteric artery [see 6:11 *Repair of Infrarenal Abdominal Aortic Aneurysms*]. Both common iliac arteries are exposed, with care taken not to damage the underlying iliac veins and the overlying ureters, which normally cross at the iliac bifurcation.

Given that this procedure is best suited for treatment of localized disease, exposure beyond the iliac bifurcation is rarely necessary. If it appears that the disease process extends into the external iliac arteries or more proximally in the infrarenal aorta, another form of treatment, such as aortobifemoral bypass (see below), may be indicated.

Step 3: Aortoiliac Endarterectomy

Once the aorta and the iliac vessels are exposed, I.V. heparin is given for systemic anticoagulation. The vessels are then controlled with vascular clamps. As a rule, the iliac vessels should be clamped first to reduce the risk of distal embolization during placement of the aortic cross-clamp. These vessels should be clamped only enough to prevent retrograde bleeding. They must not be repeatedly clamped and unclamped, because they are prone to the development of flow-limiting intimal flaps or fractured atherosclerotic plaques.

Next, the aorta is incised longitudinally from a point just above the bifurcation (where the aorta is soft) down into the common iliac artery in which the disease process extends further. Sometimes, the middle sacral or lower lumbar arteries must be oversewn to control back-bleeding. A dissection plane is developed between the media and the adventitia, and a standard endarterectomy of the infrarenal aorta and the more diseased iliac artery is performed. The endarterectomy of the contralateral iliac artery is performed by means of eversion through the aortotomy [see Figure 1]. If the distal termination points in the iliac vessels are irregular or have a significant step-off, the plaque should be tacked down with two or three 6-0 polypropylene sutures, with the knots tied on the outside of the vessel wall.

Troubleshooting Occasionally, endarterectomy results in a very thin residual wall, or the distal termination points are too steep to fix with tacking sutures alone. In such cases, the best recourse is to replace this section of the aorta and the common iliac vessels with a short standard bifurcated prosthetic interposition graft. Proximally, the graft is sewn to the infrarenal aorta in an end-to-end fashion. Distally, the two limbs are sewn to the two common iliac arteries in the same manner.

Step 4: Repair of Arteriotomy

The arteriotomy can be closed either primarily or with a patch, depending on the size of the aorta and the iliac vessels. Primary closure is preferred, but if it appears that such closure will significantly narrow the aorta or the iliac artery, a patch (either prosthetic or autogenous) should be used instead. Before closure is completed, the vessels should be flushed and back-bled to diminish the risk of distal embolization to the legs upon reestablishment of inline flow. The adequacy of the repair is confirmed pri-

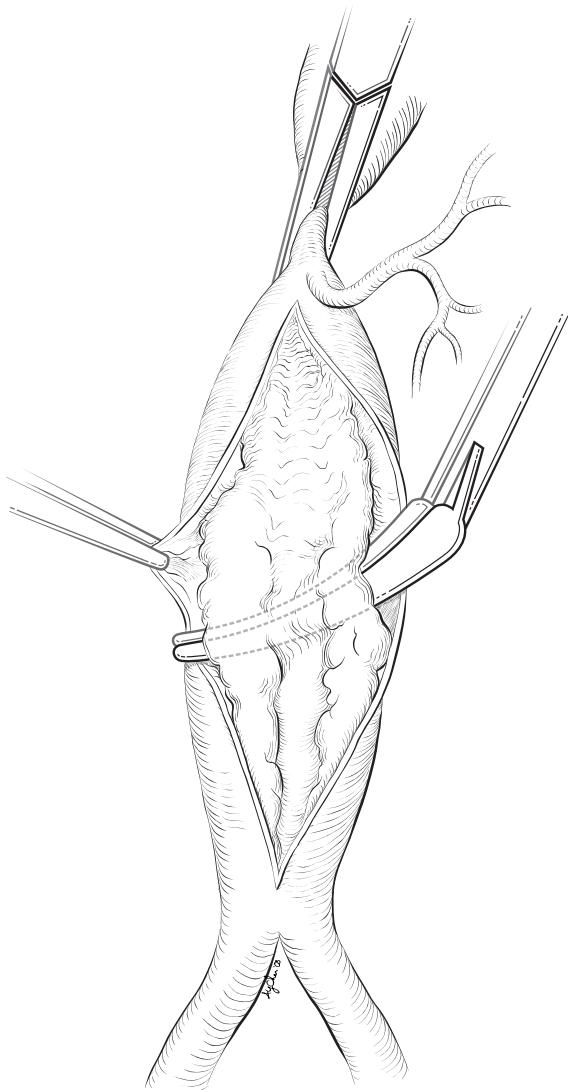

Figure 1 Aortoiliac endarterectomy. Plaque is removed through a longitudinal aortotomy.

marily by the palpation of normal femoral pulses in the groins.

Step 5: Closure of Retroperitoneum

Before abdominal closure, the retroperitoneum is closed with an absorbable suture so as to isolate the repair from the GI tract. This step reduces the risk of an aortoenteric fistula.

ILIOFEMORAL BYPASS

Iliofemoral bypass, already an uncommon procedure, has now largely been supplanted by advances in percutaneous endoluminal techniques. Nevertheless, it is still used on occasion and thus is worth knowing. One limitation on the application of iliofemoral bypass is that aortoiliac occlusive disease typically causes diffuse aortic and bilateral iliac artery narrowing. For this operation to be successful, there must be a relatively disease-free common iliac artery that can provide unimpeded inflow. Accordingly, iliofemoral bypass is most suitable for those rare patients who have isolated unilateral external iliac artery disease.

Step 1: Incision and Approach

The patient is placed in the supine position, and two incisions are made [see Figure 2]. The common iliac artery is approached

through a lower-quadrant retroperitoneal incision positioned medial to the lateral border of the rectus muscle. The femoral artery is approached through a standard vertical groin incision.

Step 2: Exposure of Iliac and Femoral Arteries

Once the retroperitoneum is entered, the visceral contents and the ureter are bluntly dissected away from the psoas muscle medially. This dissection, which takes place through a mostly bloodless field, yields full exposure of the targeted common iliac artery and its bifurcation into the external and internal iliac arteries. It should proceed far enough to allow control of the arteries with vascular clamps. Care must be taken not to damage the underlying iliac veins. In particular, no attempt should be made to isolate these vessels circumferentially, which can lead to troublesome bleeding.

The vertical incision in the groin permits full exposure of the common femoral artery and its bifurcation into the superficial femoral artery and the profunda femoris. Unlike the iliac arteries, the femoral artery and its branches may be circumferentially dissected.

Step 3: Tunneling of Bypass Graft

Once the inflow and outflow vessels are adequately exposed, the bypass graft is tunneled from the retroperitoneum to the groin, passing beneath the ureter and the inguinal ligament. During tunneling, care must be taken not to avulse the bridging epigastric vein found just cephalad and posterior to the inguinal ligament. Typically, a prosthetic graft 6 to 8 mm in diameter is used; however, autogenous material (e.g., a segment of the greater saphenous vein) may be used if desired.

Step 4: Proximal Anastomosis to Iliac Artery

With the bypass graft in position, the patient undergoes systemic anticoagulation with I.V. heparin. The common, external, and internal iliac arteries are controlled with vascular clamps. The proximal anastomosis is then performed to the selected common iliac artery. If practicable, the anastomosis should be an end-to-side one so as to preserve antegrade flow into the internal iliac artery.

Troubleshooting Occasionally, the common iliac artery is too diseased to clamp or to use as an inflow source. In such cases, the infrarenal aorta may be clamped instead or used as the site of the proximal anastomosis.

Step 5: Distal Anastomosis to Femoral Artery

Vascular clamps are placed on the common femoral artery and its branches, and the distal anastomosis is performed in an end-to-side manner. The configuration of the longitudinal arteriotomy depends on the presence and extent of disease in the femoral arteries. If both the superficial femoral artery and the profunda femoris are relatively free of disease, the arteriotomy should extend from the common femoral artery into the superficial femoral artery. If, however, the superficial femoral artery is occluded or heavily diseased, the arteriotomy should extend down into the profunda femoris [see Figure 3]. In either case, an end-to-side anastomosis is fashioned. Before completion of the bypass, the inflow vessel is flushed and the outflow vessel backbled to reduce the risk of distal embolization to the legs.

AORTOFEMORAL BYPASS

Before the application of percutaneous balloon angioplasty and stenting, aortofemoral bypass grafting was the revascular-

ization operation of choice for patients with diffuse aortoiliac occlusive disease. This operation is still favored by many, and it yields excellent long-term patency.

Step 1: Incision and Approach

Typically, the patient is placed in the supine position, and the operation is performed through a midline laparotomy and two longitudinal groin incisions. A self-retaining retractor is recommended to facilitate exposure of the infrarenal aorta.

Alternatively, the infrarenal aorta may be exposed via a left retroperitoneal incision extending obliquely from the lateral border of the rectus muscle, at the level of the umbilicus, to the tip of the 11th rib. For this approach, the patient is placed in a right semilateral decubitus position with the assistance of an inflatable beanbag. The hips are rotated so that they are flat on the bed, providing easy access to the groins.

Step 2: Exposure of Aorta

Upon entry into the abdominal cavity, the fourth portion of the duodenum is dissected free of its retroperitoneal attachments, and the small bowel is retracted to the right of the aorta. The self-retaining retractor may then be placed to facilitate exposure. Next, the retroperitoneum overlying the infrarenal aorta is incised in the midline to expose the vessel, ideally in a location that is not heavily diseased or calcified. Unlike the dissection required in a localized endarterectomy [see Aortoiliac

Endarterectomy, *above*], this dissection is primarily between the renal arteries and the inferior mesenteric artery. In most cases, the dissection need not be extended downward below the aortic bifurcation into the iliac arteries.

When this operation is performed through a left retroperitoneal incision, the external and internal oblique muscles and the transversus abdominis are divided, and the retroperitoneum is entered. Complete exposure of the infrarenal aorta is obtained by mobilizing the abdominal contents, the left kidney, and the left ureter medially after blunt dissection along the anterior border of the psoas muscle.

Troubleshooting In those cases in which aortofemoral bypass is being done for a patient with complete infrarenal aortic occlusion, the operative approach is modified to allow placement of a vascular clamp above the renal arteries. The dissection is carried cephalad by retracting the small bowel mesentery and the superior mesenteric artery to the right. The left renal vein is found anterior to the aorta at the level of the renal arteries. Generally, this vein need not be divided to expose the suprarenal aorta. Rather, it should be thoroughly dissected and encircled with a vessel loop so that it can be retracted cephalad and caudad. Sometimes, an adrenal or gonadal vein draining into the left renal vein must be ligated and divided to give the renal vein added mobility. With the left renal vein retracted caudad, the suprarenal aorta is dissected.

Step 3: Exposure of Femoral Artery

A vertical groin incision provides full exposure of the common femoral artery and its bifurcation into the superficial femoral artery and the profunda femoris. The femoral artery and its branches should be circumferentially dissected to give the surgeon an unobstructed view for placement of the vascular clamps.

Step 4: Tunneling of Bypass Graft

Once the inflow and outflow vessels are adequately exposed, the bypass graft—typically, a bifurcated prosthetic graft measuring 14×7 mm or 16×8 mm—is tunneled from the abdomen to the groins. Its course should pass beneath the ureter and the inguinal ligament. To create the tunnel, one index finger, oriented so that its dorsum faces the vessel wall, is inserted in the midline incision and advanced caudad down to the groin. Simultaneously, the other index finger, oriented so that its volar aspect faces the common femoral artery, is inserted into a groin incision and advanced cephalad until the two fingers meet. As with an iliofemoral bypass graft, care must be taken not to avulse the bridging epigastric vein found just cephalad and posterior to the inguinal ligament. With one of the two fingers held in place, a Silastic tube or vessel loop is passed through the tunnel. The limbs of the graft are attached to the tube or loop and passed through the tunnel down to the groins.

Step 5: Proximal Anastomosis to Aorta

The proximal aortic anastomosis can be done in either an end-to-end or an end-to-side configuration. An end-to-side beveled anastomosis is preferable for (1) patients with a small (< 1.5 cm) infrarenal aorta and (2) patients with severe occlusive disease of both external iliac arteries in whom it is desirable to preserve flow into the pelvic circulation via the internal iliac arteries. An end-to-end anastomosis is preferable for (1) patients with occlusive iliac disease and a concomitant aortic aneurysm and (2) patients undergoing revascularization for chronic total aortic occlusion. The latter configuration is also less bulky and easier to cover and

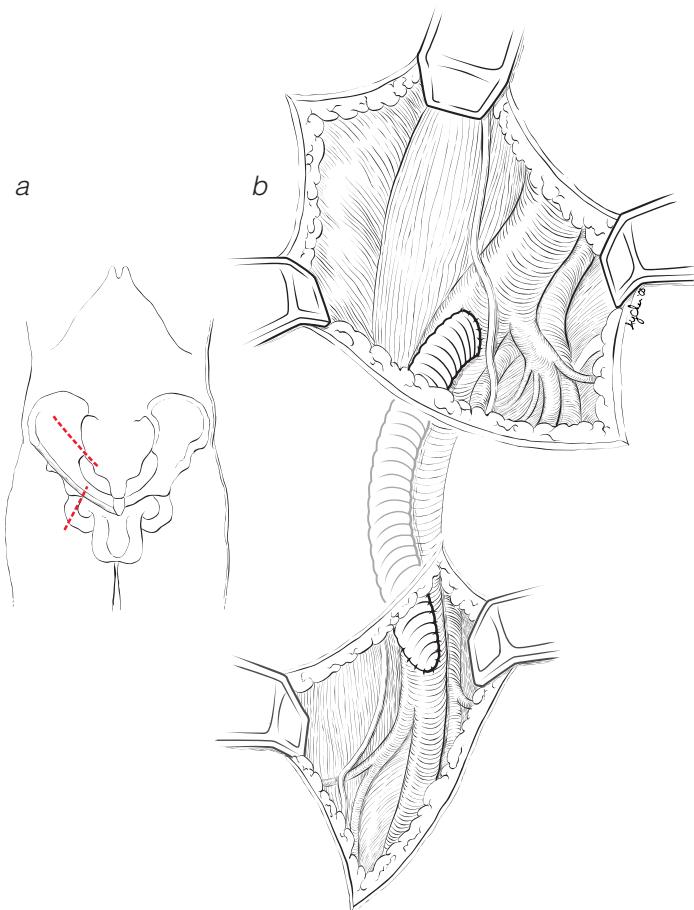

Figure 2 Iliofemoral bypass. (a) A low retroperitoneal incision and an ipsilateral groin incision are made for exposure of the inflow and outflow bypass vessels. (b) The graft is tunneled beneath the ureter and the inguinal ligament.

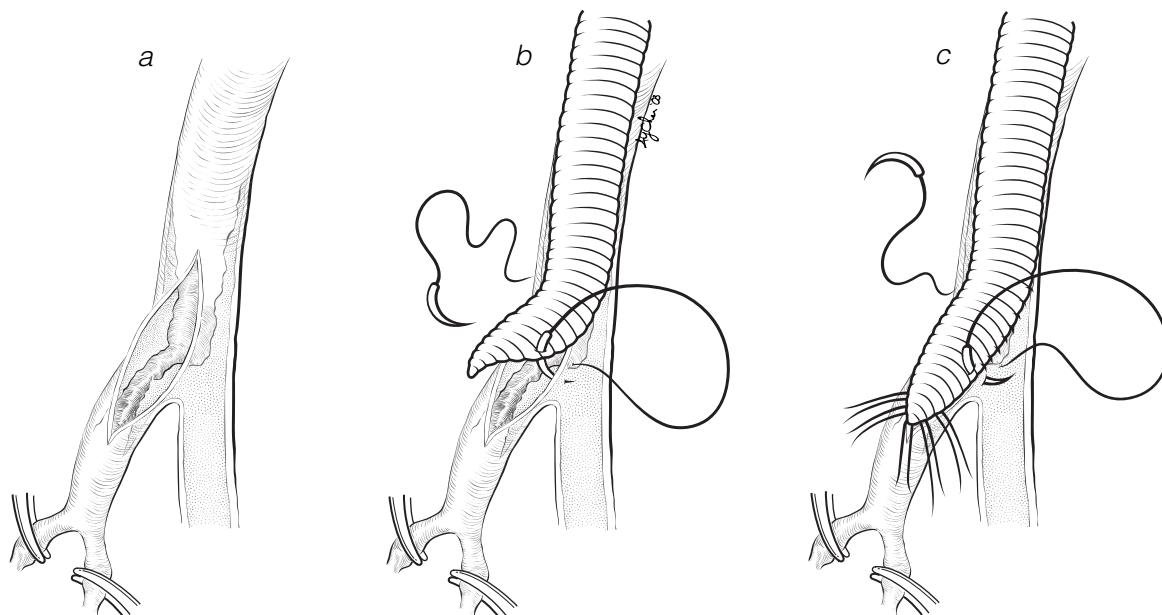

Figure 3 Iliofemoral bypass. (a) When concomitant superficial femoral artery disease is present, the distal anastomosis is performed to a longitudinal arteriotomy that extends onto the proximal profunda femoris. (b) The heel of the hood of the graft is anastomosed to the common femoral artery. (c) The tip of the graft is extended down the profunda femoris.

isolate from the GI tract at the conclusion of the operation.

Once a configuration for the anastomosis has been chosen, I.V. heparin is given for systemic anticoagulation. The graft is trimmed so that its bifurcation lies close to the proximal anastomosis. The infrarenal aorta is controlled, most commonly with vascular clamps above and below the site of the intended anastomosis. Control of the aorta with a partially occluding vascular clamp may be attempted, but the size of the vessel and the coexistence of aortic disease typically make this difficult or impossible to accomplish.

If an end-to-side anastomosis is to be performed, a longitudinal aortotomy is made and the graft sewn in place in a spatulated fashion. The toe of the graft is oriented cephalad [see Figure 4]. The anastomosis should be spatulated steeply so that it is not too bulky in the retroperitoneum and can be covered at the end of the procedure. Before completion of the anastomosis, the graft is flushed and back-bled.

If an end-to-end anastomosis is to be performed, a small portion of the aorta is resected to allow the graft to fit neatly into the retroperitoneum. In some cases, back-bleeding lumbar arteries in the region of the resected aorta must be oversewn. The distal stump is oversewn with 2-0 or 3-0 polypropylene in two rows; the first row is done with a continuous suture in a horizontal mattress stitch, the second with a continuous suture in a baseball stitch [see Figure 5].

Troubleshooting Vascular control of the aorta is achieved differently when chronic infrarenal aortic occlusion is present. In this setting, placement of a vascular clamp just below the renal arteries may squeeze atherosclerotic debris up into the renal arteries. To prevent this, the vascular clamp should be placed between the superior mesenteric artery and the renal arteries. Once the distal clamp is in place, the aorta is opened below the renal arteries and the atherosclerotic plug removed. The suprarenal clamp can then be moved to just below the renal arteries, and the proximal anastomosis can be fashioned as already described (see above).

A heavily calcified infrarenal aorta encountered at the time of

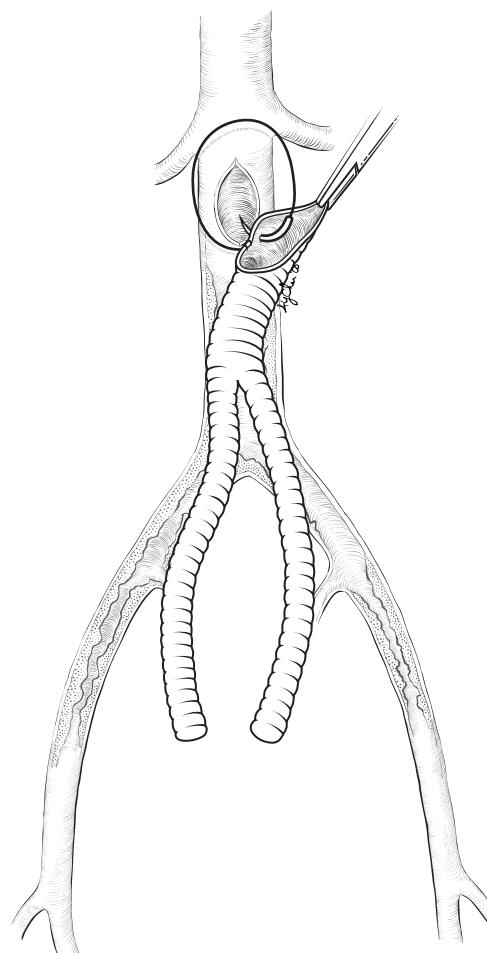

Figure 4 Aortofemoral bypass. Shown is an end-to-side proximal anastomosis.

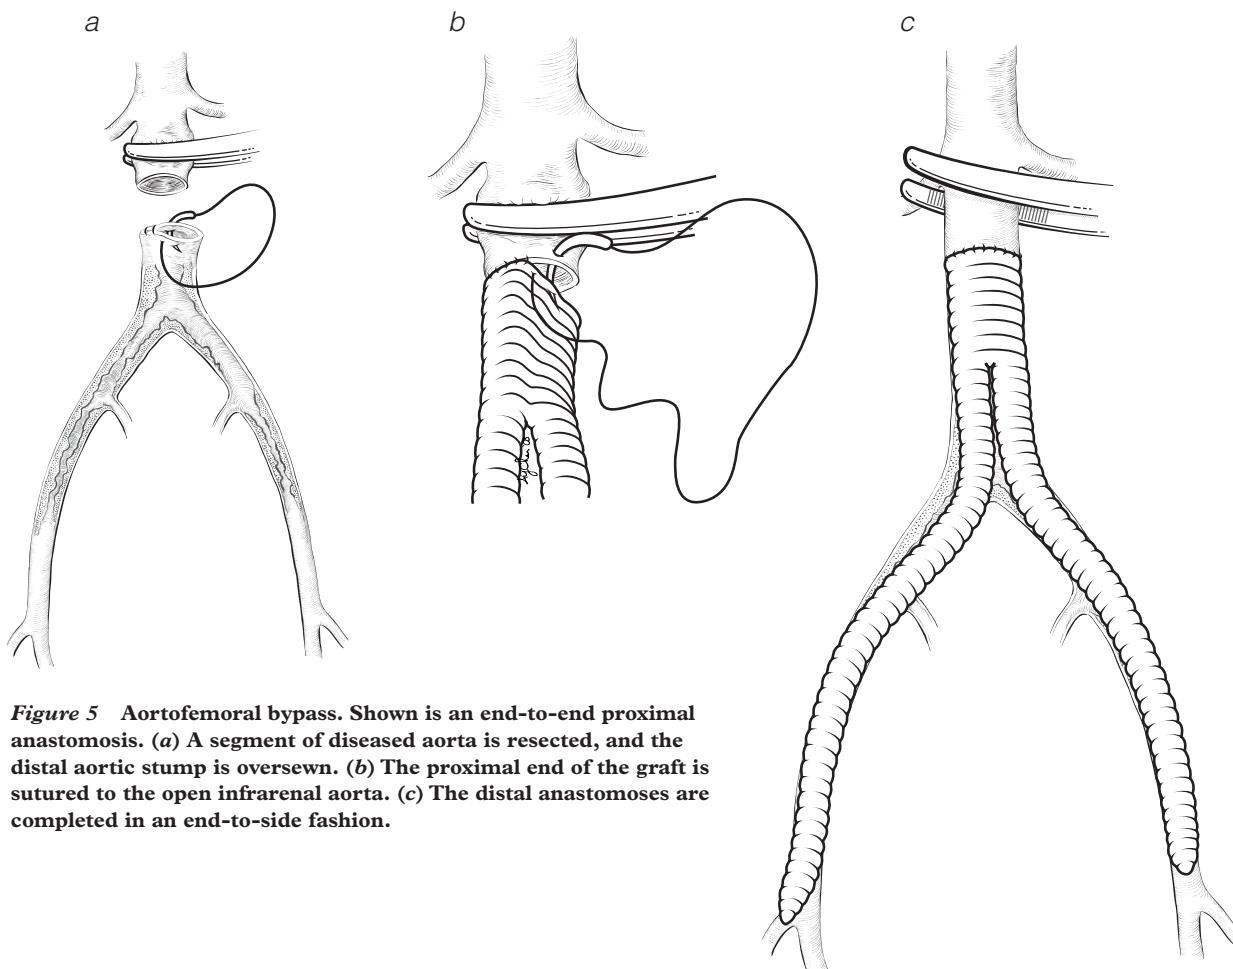

Figure 5 Aortofemoral bypass. Shown is an end-to-end proximal anastomosis. (a) A segment of diseased aorta is resected, and the distal aortic stump is oversewn. (b) The proximal end of the graft is sutured to the open infrarenal aorta. (c) The distal anastomoses are completed in an end-to-side fashion.

operation presents a difficult problem. In most cases, the infrarenal aorta can still be used, but the proximal anastomosis should be performed in an end-to-end configuration. Even in the most calcified aortas, the region 1 to 2 cm below the renal arteries is often soft enough to allow an anastomosis to be fashioned. If this is not the case, there are two alternatives: (1) suprarenal aortic control and endarterectomy of the infrarenal aorta just below the renal ostia before the proximal anastomosis and (2) conversion to a thoracofemoral bypass graft [see Thoracofemoral Bypass, below].

Step 6: Distal Anastomosis to Femoral Artery

Vascular clamps are placed on the common femoral artery and its branches, and the distal anastomosis is performed. As with an iliofemoral bypass, the configuration of the longitudinal arteriotomy depends on the existence of disease in the femoral arteries. If both the superficial femoral artery and the profunda femoris are relatively free of disease, the arteriotomy should extend from the common femoral artery into the superficial femoral artery. If, however, the superficial femoral artery is occluded or heavily diseased, the arteriotomy should extend downward into the profunda femoris. In either case, an end-to-side anastomosis is indicated. Before completion of the bypass, the inflow vessel is flushed and the outflow vessel back-bled to diminish the risk of distal embolization to the legs.

Step 7: Closure of Retroperitoneum

Before abdominal closure, the retroperitoneum is closed with an absorbable suture to isolate the repair from the GI tract and reduce the risk of an aortoenteric fistula. The ureters should be

visualized and preserved. Careless closure of the retroperitoneum can lead to laceration or entrapment of the ureter, particularly the right ureter. Every attempt should be made to cover the graft. If the retroperitoneum is too thin or the graft too bulky, an omental pedicle flap may be used.

THORACOFEMORAL BYPASS

A thoracofemoral bypass is ideal for a small subgroup of patients, comprising (1) those with an occluded old aortofemoral bypass graft, (2) those with a so-called lead-pipe calcified infrarenal aorta that is unusable as an inflow source, and (3) those with a so-called hostile abdomen (i.e., those with an ileal conduit, an ileostomy or colostomy, or a previous aortic graft infection). Candidates for this procedure must have adequate pulmonary reserve and be able to tolerate a thoracotomy. They must also be informed of and accept the low but real risk of paralysis.

The patient is placed in a right semilateral decubitus position so that the hips are nearly flat on the table and the torso is slightly rotated to the patient's right [see Figure 6]. An axillary roll and an inflatable beanbag will help maintain this position. Because single-lung ventilation will be necessary when the proximal anastomosis is done, either a double-lumen endotracheal tube or a bronchial blocker must be used. Placement of an orogastric tube to decompress the stomach helps keep the diaphragm down during exposure of the descending thoracic aorta.

Step 1: Incision and Exposure of Descending Thoracic Aorta

The descending thoracic aorta is approached through a left posterior lateral thoracotomy at the level of the 7th or 8th inter-

space. Additional exposure can be gained by resecting part of the rib and using a self-retaining table-mounted retractor. With the left lung decompressed, the parietal pleura overlying the descending thoracic aorta is incised. The aorta is cleanly dissected, with care taken not to damage the esophagus, which lies medial to it. Having an orogastric tube in place is advantageous in this regard: the esophagus can easily be located by palpating the tube. Any intercostal vessels in the region of the anticipated aortotomy can be preserved and controlled at the time of the anastomosis.

Step 2: Exposure of Femoral Artery

Full exposure of the common femoral artery and its bifurcation into the superficial femoral artery and the profunda femoris is obtained via a standard groin incision.

Step 3: Tunneling of Bypass Graft

The tunnel for the prosthetic graft has two components: (1) a left retroperitoneal tunnel and (2) a subcutaneous tunnel over the pubis. Usually, a tube prosthetic graft is sutured to a bifurcated graft before being tunneled through the retroperitoneum. The retroperitoneal tunnel is started in the chest by making a 1 cm hole in the posterior lateral aspect of the left diaphragm. An index finger is inserted through this hole and advanced caudad into the retroperitoneum as far as it can go. The other index finger is inserted through the left groin incision, oriented directly over the external iliac artery, and advanced cephalad into the retroperitoneum [see Figure 7]. Care is taken not to avulse the bridging epigastric vein found posterior and inferior to the inguinal ligament. In most cases, the left retroperitoneal tunnel must then be completed by using a long, hollow metal tunneling device such as the Gore Tunneler (W. L. Gore & Associates, Inc., Tempe, Ariz.). Once this tunnel is completed, the graft is passed through it in such a way that the bifurcated limbs are brought caudad down into the left groin wound.

Next, the subcutaneous tunnel from the left groin to the right groin is bluntly fashioned anterior to the pubis. It should not be oriented superior to the pubis because of the risk of injury to an overdistended bladder. To minimize this risk, an indwelling urinary catheter is advocated. The subcutaneous tunnel is used to pass the right limb of the graft over to the right groin. It is not uncommon for the bifurcation of the prosthetic graft to lie just cephalad to the left groin wound.

Step 4: Proximal Anastomosis to Descending Thoracic Aorta

Once the graft has been tunneled, the patient undergoes systemic anticoagulation with I.V. heparin. The descending thoracic aorta is controlled either with a side-biting clamp or with two completely occluding aortic clamps placed in close proximity to each other. In the latter case, one or two intercostal arteries may have to be temporarily controlled as well. A longitudinal aortotomy is then made along the left lateral aspect of the thoracic aorta, and a beveled end-to-side anastomosis is fashioned. Exposure can be enhanced by ventilating the right lung and attaching the orogastric tube to suction to decompress the stomach. Before completion of the anastomosis, the aorta is flushed and back-bled.

Troubleshooting Partial aortic control with a side-biting vascular clamp is successful in most cases, but it is not recommended when the descending thoracic aorta is heavily diseased and calcified or when preoperative imaging studies show thrombus in this location. If an intercostal artery cannot be temporarily controlled with clamps, it can be oversewn from the inside of the aorta to prevent nuisance back-bleeding.

Step 5: Distal Anastomosis to Femoral Artery

Vascular clamps are placed on the common femoral artery and its branches, and an end-to-side anastomosis is fashioned distally. Again, the configuration of the longitudinal arteriotomy depends on the existence of disease in the femoral arteries. If both the superficial femoral artery and the profunda femoris are relatively free of disease, the arteriotomy should extend from the common femoral artery into the superficial femoral artery. If, however, the superficial femoral artery is occluded or heavily diseased, the arteriotomy should extend downward into the profunda femoris. Before completion of the bypass, the inflow vessel is flushed and the outflow vessel back-bled.

Step 6: Closure of Chest

Once the proximal anastomosis is complete, the left lung is reinflated. At the conclusion of the operation, the chest is closed in a standard fashion over two chest tubes. The proximal anastomosis should be covered with either a prosthetic patch or bovine pericardium to diminish the risk of an aortopulmonary fistula.

AXILLOFEMORAL BYPASS

Axillofemoral bypass is ideally suited to elderly patients who cannot tolerate an aortic operation. The hemodynamic changes occurring during the operation are minimal, and recovery from the three small incisions used is substantially quicker than that from a laparotomy or a thoracotomy.

Because hemodynamically significant occlusive disease is less common in the right innominate artery than in the left subclavian artery, the right axillary is more often used as the inflow vessel than the left axillary artery is. Such occlusion can easily be identified preoperatively by measuring blood pressure in both arms. The sterile field includes both groins, the appropriate side of the chest (usually the right) up to the neck, and the appropriate flank (again, usually the right). It need not include the entire inflow arm; however, the arm should be abducted 90° and positioned on an arm board.

Step 1: Incision and Exposure of Axillary Artery

The patient is placed in the supine position. The axillary artery is approached through a horizontal 6 cm infraclavicular incision placed approximately 2 cm below the inferior border of the clavicle. Dissection is carried through the subcutaneous tissue, the fascia overlying the pectoralis major is incised, and the muscle is bluntly dissected along the length of its fibers. The dissection plane should remain medial to the pectoralis minor.

Next, the axillary vein is encountered and retracted caudad, and the underlying axillary artery is visualized. The axillary artery is cleanly dissected, with care taken not to retract or damage the brachial plexus lying deep and superior to the artery. For full exposure of the axillary artery, the thoracoacromial artery may have to be ligated at its origin. For easier retraction, the axillary artery may be encircled with vessel loops.

Step 2: Exposure of Femoral Artery

The femoral artery and its bifurcation into the superficial femoral and profunda femoris arteries are approached through a standard groin incision.

Step 3: Tunneling of Bypass Graft

Once the inflow and outflow vessels are adequately exposed, a prosthetic graft 80 to 100 cm long and 8 or 10 mm in diameter is tunneled from the axillary incision, beneath the pectoralis

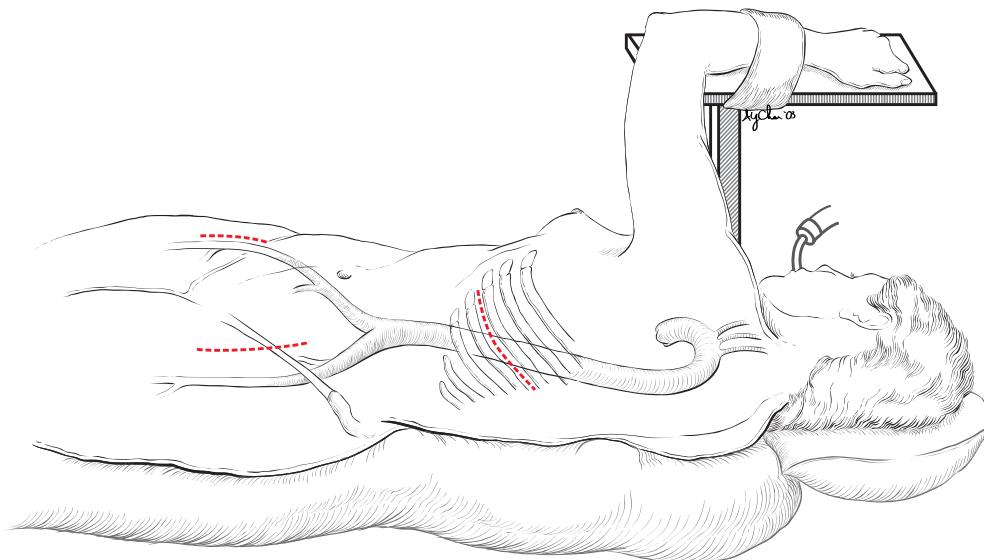

Figure 6 Thoracofemoral bypass. The patient is positioned so that the hips are flat but the torso is slightly rotated to the patient's right. Three incisions are made: a left posterolateral thoracotomy and two groin incisions.

minor, and down to the flank. The use of a long, hollow metal tunneler is recommended at this point. To facilitate tunneling, a single counterincision is made in the midaxillary line over the sixth or seventh intercostal space. From this counterincision, the graft is tunneled along the flank, over the iliac crest, anterior to the anterior superior iliac process, and into the ipsilateral groin wound. Except for the portions in the axilla and the groin, the entire graft should lie in a subcutaneous plane.

Next, a subcutaneous tunnel from the ipsilateral groin to the contralateral groin is bluntly fashioned anterior to the pubis to allow passage of a second prosthetic graft (a short crossover graft 8 mm in diameter). This tunnel should not be oriented superior to the pubis because of the risk of injury to an overdistended bladder.

Step 4: Proximal Anastomosis to Axillary Artery

With the long graft in place, I.V. heparin is given for systemic anticoagulation. The pectoralis minor may be retracted laterally

to provide additional exposure. The axillary artery is controlled with vascular clamps, with care taken not to include any part of the brachial plexus lying nearby. A longitudinal arteriotomy is made along the length of the axillary artery. The proximal anastomosis is then fashioned in an end-to-side configuration. The anastomosis must lie medial to the pectoralis minor. This is critical for preventing avulsion of the graft from the axillary artery when the patient fully abducts the arm. Before the anastomosis is completed, it is flushed and back-bled. Once blood flow to the arm is reestablished, the graft should be positioned so that it lies parallel to the axillary artery for a length of 2 to 3 cm before diving deep and caudad.

Step 5: Distal Anastomosis to Femoral Artery

The distal anastomosis to the femoral arteries is performed as described earlier [see Thoracofemoral Bypass, above]. There remains some controversy over the formation of the short crossover

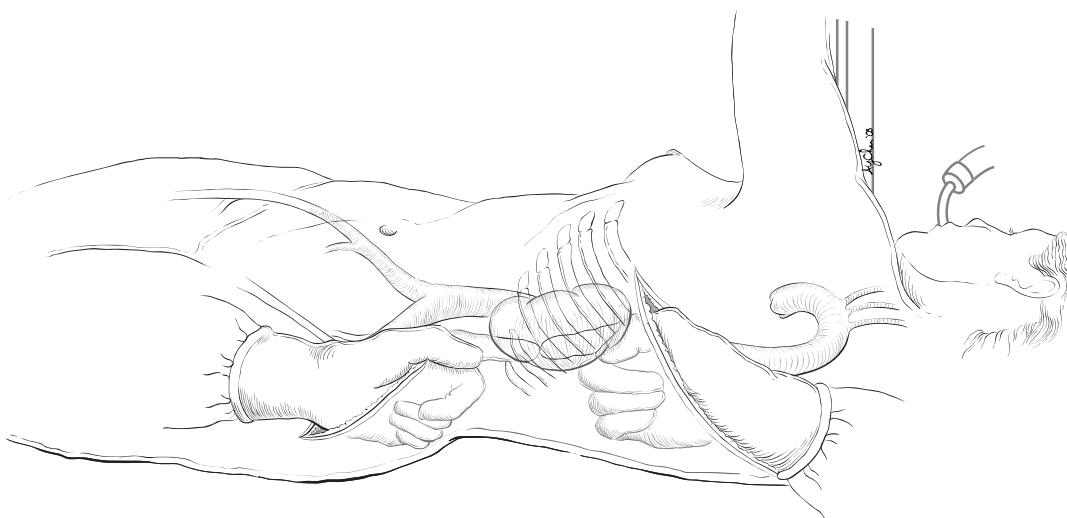

Figure 7 Thoracofemoral bypass. A left retroperitoneal tunnel is fashioned for passage of the prosthetic graft downward to the groin. (The right arm of the graft is subsequently passed to the right groin via a subcutaneous tunnel anterior to the pubis.)

graft from the axillary bypass graft to the contralateral femoral artery. My practice is to place the proximal anastomosis of the crossover femorofemoral anastomosis on the hood (or distal anastomosis) of the axillofemoral bypass graft [see Figure 8]. Others prefer to use a commercially available bifurcated axillofemoral prosthetic graft or to place the crossover graft more proximally along the length of the axillofemoral graft.

FEMOROFEMORAL BYPASS

A femorofemoral crossover bypass is well suited to patients who have unilateral complete occlusion or a diffusely diseased iliac system but have a relatively normal contralateral iliac system. It is performed with the patient supine and is conducted in essentially the same fashion as an axillofemoral bypass, but without the axillary anastomosis.

ENDOVASCULAR THERAPY

The use of percutaneous balloon angioplasty and stenting for the treatment of peripheral vascular disease has grown exponentially since its introduction in the 1990s. As regards short-term results, patients clearly experience less pain, recover more quickly, and regain function earlier. Initially, there was some question about the durability of stenting; however, data from longer follow-up periods indicate that this approach is an acceptable alternative for patients with focal aortoiliac occlusive disease.⁸⁻¹⁰

Complications

Certain complications are associated with all of the revascularization procedures discussed, such as bleeding, distal embolization, graft thrombosis, and graft infection. Late graft infection, recurrent disease, and pseudoaneurysm formation are known long-term complications as well. In addition, the following complications are unique to one or more of the procedures but do not arise with the others.

1. Injury to the ureters, resulting from their position overlying the iliac vessels (aortoiliac endarterectomy, iliofemoral bypass, axillofemoral bypass).
2. Impotence, resulting from damage to the autonomic nerve fibers around the origin of the left common iliac artery (aortoiliac endarterectomy, iliofemoral bypass, axillofemoral bypass).
3. Bleeding or deep venous thrombosis, related to trauma to the underlying iliac venous structures (all).
4. Paraplegia, resulting from the sacrifice of intercostal vessels supplying the anterior spinal artery (thoracofemoral bypass).
5. Colonic ischemia or infarction, resulting from hindered primary flow via the inferior mesenteric artery or collateral vessels from the hypogastric arteries (axillofemoral bypass).
6. Buttock claudication, resulting from disruption of inline flow to the pelvic circulation (axillofemoral bypass).
7. Aortoduodenal fistula, resulting from incomplete coverage of an aortic graft (axillofemoral bypass).
8. Renal failure, resulting from acute tubular necrosis or embolization when a suprarenal aortic clamp is used (thoracofemoral bypass, axillofemoral bypass).
9. Arm paralysis, resulting from injury to the deep and superiorly oriented brachial plexus (axillofemoral bypass).
10. Respiratory failure resulting from effusion or hemothorax after a left thoracotomy or from inadvertent pneumothorax

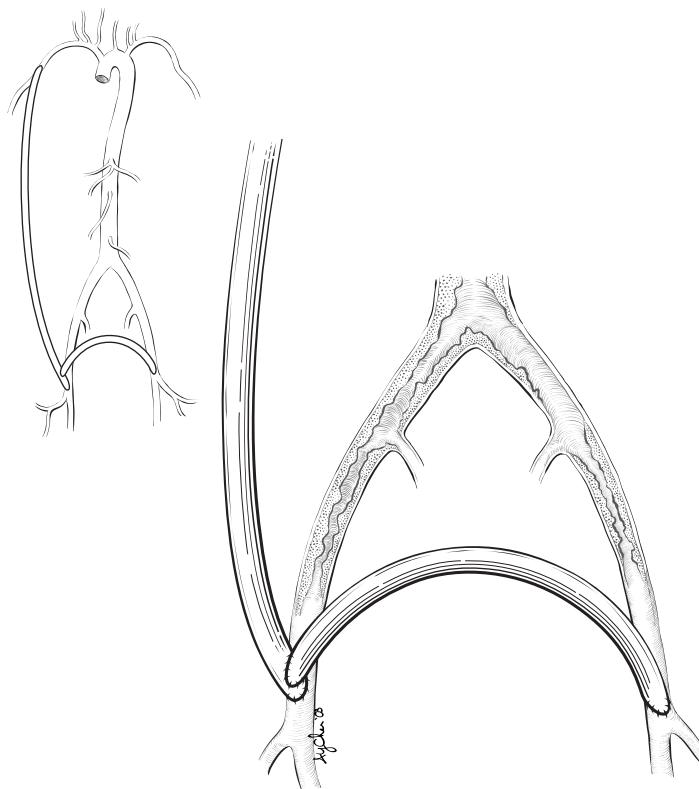

Figure 8 Axillofemoral bypass. Shown is the recommended configuration for the short femorofemoral crossover graft originating from the long axillofemoral graft. The femorofemoral graft originated from the hood of the axillofemoral graft.

during exposure of the axillary artery (thoracofemoral bypass, axillofemoral bypass).

Outcome Evaluation

Regardless of which operation is performed to treat aortoiliac occlusive disease, the subsequent outcome should be immediate relief of presenting symptoms—for example, reduced claudication, resolution of rest pain, or improved distal wound healing. Unfortunately, overall long-term survival in patients with symptomatic aortoiliac occlusive disease is not improved by operative management and is typically 10 to 15 years less than that in a normal age-matched group. Not surprisingly, by far the most significant long-term cause of death in these patients is atherosclerotic cardiac disease, which underscores the importance of a thorough preoperative cardiac evaluation.

In general, direct aortoiliac reconstructions (i.e., endarterectomy, aortofemoral bypass, and thoracofemoral bypass) have an expected patency rate of 85% to 90% at 5 years and 70% to 75% at 10 years.¹¹⁻¹³ When these operations are performed at experienced centers on patients who are considered to be good risk candidates, mortality is typically less than 3%.^{14,15} Femorofemoral bypass and axillobifemoral bypass have expected 5-year patency rates of 70% to 75% and 60% to 85%, respectively.¹⁶⁻¹⁹ Coexistent superficial femoral artery disease in the recipient vessels has a detrimental effect on the long-term patency of these bypasses.²⁰ Long-term anticoagulation may improve the patency for an axillobifemoral bypass graft.

13 SURGICAL TREATMENT OF THE INFECTED AORTIC GRAFT

Victor J. D'Addio, M.D., F.A.C.S., and G. Patrick Clagett, M.D., F.A.C.S.

In dealing with an infected aortic graft, the primary goal of treatment is to save life and limb. This goal is best accomplished by eradicating all infected graft material and maintaining adequate circulation with appropriate vascular reconstruction. Secondary goals are to minimize morbidity, to restore normal function, and to maintain long-term function without the need for repeated intervention or amputation.

Before definitive reconstruction, all infected graft material must be debrided, along with any grossly infected vascular tissue and surrounding soft tissue. Once debridement is complete, there are several options for reconstruction, including (1) extra-anatomic bypass, (2) use of an arterial allograft, (3) placement of vascular prostheses treated with or soaked in antibiotic solutions, and (4) *in situ* replacement with a femoral-popliteal vein (FPV) graft. The choice among these options is made on the basis of the specific clinical situation present. The primary focus of the technical description in this chapter, however, will be on the fourth option [*see Operative Technique, below*].

Choice of Procedure

EXTRA-ANATOMIC BYPASS

Extra-anatomic bypass, usually performed as an axillofemoral bypass [*see Figure 1 and 6:12 Aortoiliac Reconstruction*], is a good option for treatment of an infected aortic graft when groin infection is absent and lower-extremity runoff is good. The primary advantages of extra-anatomic bypass are that it minimizes lower-extremity ischemic time and that it is less of a physiologic insult than an aorta-based bypass procedure (mainly because it is typically done in a staged fashion). The primary disadvantages are that long-term patency is poor and that there is a significant risk of reinfection. In addition, if groin infection is present, the bypass is compromised even further by the need to use vessels such as the profunda femoris artery or the popliteal artery for distal targets. Bilateral axillofemoral bypasses are often required in this situation. Because of these factors, the durability of an extra-anatomic bypass may be limited despite aggressive antithrombotic treatment.

Extra-anatomic bypasses are plagued by sudden thrombotic occlusion, and amputation rates are high. In one large series, one third of patients required a major amputation during long-term follow-up.¹ Reinfection also is a major concern when prosthetic grafts are employed in patients with ongoing infection: it occurs in 10% to 20% of such patients and often proves lethal. A final major concern in patients who undergo excision of an infected aortic graft and extra-anatomic bypass is the possibility of blowout of the aortic stump. This is an infrequent occurrence (incidence < 10%) but one that is typically fatal.

AORTIC ALLOGRAFT

In situ aortic allografting has been employed to treat aortic graft infections, with somewhat mixed results. In one report, a 20%

mortality was associated with this method of treatment.² In addition, many survivors experience significant problems, including early or late allograft rupture and late aortic graft dilation.³ Reinfection of allografts may also occur and usually proves fatal when it does. Complications may be reduced by using cryopreserved allografts instead of fresh ones, but at present, the data are insufficient to determine whether one type of allograft is clearly superior to the other overall. Currently, aortic allografts are available in the United States only on a limited basis; accordingly, this technique is not a useful option in emergency situations.

ANTIBIOTIC-TREATED PROSTHETIC GRAFT

Use of antibiotic-treated prosthetic graft material for reconstruction has the advantage of permitting an expeditious reconstruction that leaves no aortic stump.^{2,4-8} However, the reinfection rate is high and unpredictable, and patients must undergo lifelong antibiotic therapy. Typically, the new prosthetic graft is soaked in rifampin, 60 mg/ml, for 15 minutes before implantation.^{6,7}

IN SITU AUTOGENOUS RECONSTRUCTION

Dissatisfaction with the long-term patency of extra-anatomic bypass led to the development of *in situ* autogenous venous reconstruction.⁹⁻¹¹ Early reconstructive attempts that made use of greater saphenous vein grafts proved unsuccessful because the small caliber of the venous conduit resulted in low patency rates. Subsequent attempts that made use of larger-caliber FPV grafts, however, proved highly successful.

FPV grafts have excellent long-term patency and are resistant to reinfection. In addition, they are ideal conduits for patients with extensive multilevel occlusive disease, in whom venous grafts theoretically would have better patency than prosthetic grafts. (An analogy would be the superior durability of venous grafts for femoropopliteal bypass in comparison with prosthetic grafts.) The 5-year patency rates for aortoiliac/aortofemoral reconstructions using FPV grafts range from 85% to 100%.^{11,12} Long-term amputation rates are correspondingly low.

The primary disadvantage of reconstruction with FPV grafts is that the procedure is time consuming and technically demanding. In our experience, the mean operating time is about 8 hours. The lower-extremity ischemic time is longer than that in patients undergoing extra-anatomic bypass, but it can be minimized by sequencing the operation so as to shorten cross-clamp time and by using a two-team approach. An additional disadvantage of using FPV grafts is the associated short-term venous morbidity. Approximately 20% of patients who undergo FPV harvesting will require fasciotomy, typically performed at the time of the harvest. The fasciotomy rate is highest in patients who undergo concurrent greater saphenous vein harvesting and in those who have severe lower-extremity ischemia (ankle-brachial index [ABI] < 0.4).¹³ Long-term venous morbidity appears to be low, with no known cases of venous ulceration or venous claudication.¹⁴ Mild to moderate chronic edema develops in approximately 30% of

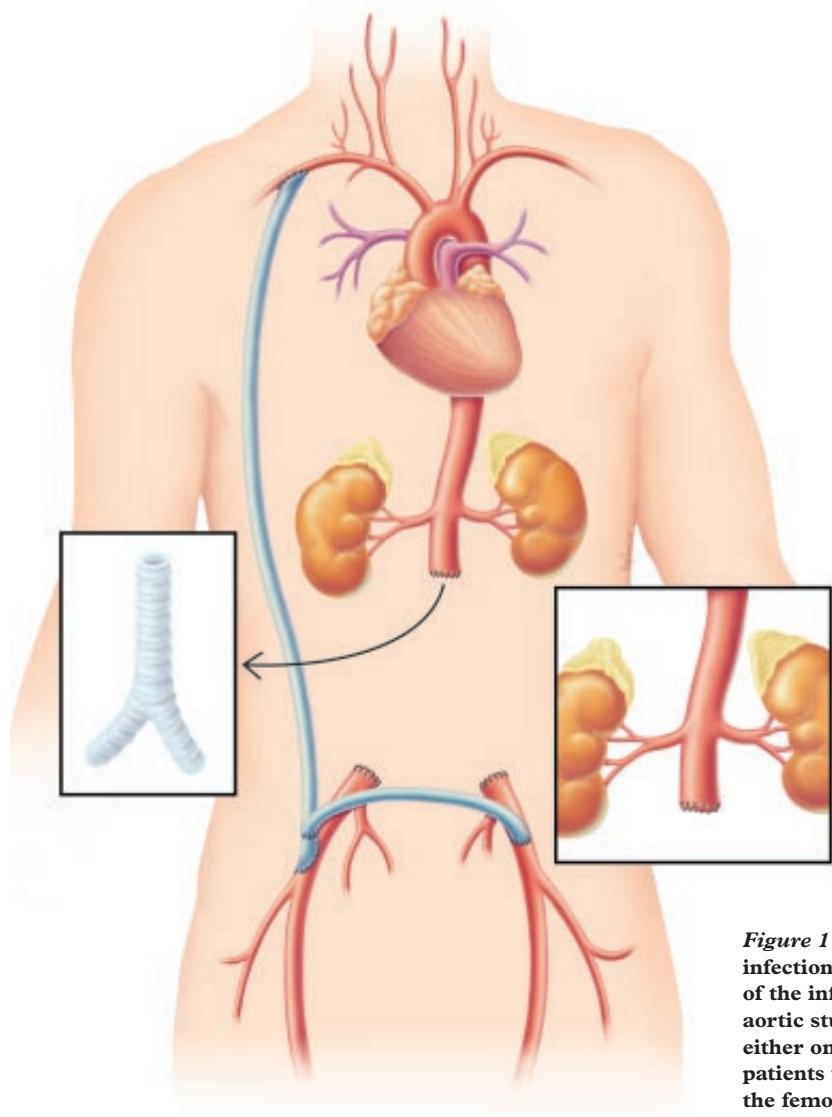

Figure 1 Standard treatment of aortic graft infection involves axillofemoral bypass, removal of the infected prosthesis, and oversewing of the aortic stump. This procedure can be performed in either one or two stages. It is most useful in patients who do not have infection extending into the femoral area.

patients. Aneurysmal degeneration of the vein grafts is a theoretical risk, but in practice, it is rare.

Preoperative Evaluation

The preoperative workup should assess the extent of infection, look for concomitant occlusive disease (indicating a possible need for infrainguinal, visceral, or renal reconstruction), and determine whether there are other associated infectious complications that must be treated surgically (e.g., a psoas abscess, an entrapped ureter with hydronephrosis, or duodenal erosion necessitating duodenal repair). In patients who have previously undergone prosthetic aortofemoral bypass, infection may be limited to one limb of the graft, and it may be treatable by replacing only that limb. In patients who have previously undergone prosthetic infrainguinal bypass, the prosthetic graft may have to be removed and replaced with an autogenous graft.

Traditionally, the mainstay of the preoperative workup was arteriography complemented by computed tomography, but currently, the workup is increasingly being performed with CT angiography alone. CT angiography is often capable of evaluating the extent of infection, visualizing the sites of previous prosthetic anastomoses, and delineating the arterial anatomy. Magnetic reso-

nance angiography can also be a helpful adjunct, particularly in patients with renal insufficiency.

When autogenous reconstruction with deep vein grafts is being considered, preoperative assessment of the adequacy of the vein segments must also be performed. This is accomplished by means of venous duplex ultrasonography. Duplex examination of the lower-extremity venous system establishes the diameter and the available length of the deep veins. In addition, the duplex scan can evaluate acute or chronic thrombosis of the deep veins, any recanalization changes, the congenital absence or duplication of venous segments, and unusually small deep veins. When the FPV is small (< 5 mm), absent, or incomplete, a dominant profunda femoris vein is usually present. This vein courses posteriorly through the thigh to connect with the popliteal vein and can also be used as a venous autograft. Duplex vein mapping of the greater saphenous system is also routinely performed and may provide useful information in the event that concomitant infrainguinal reconstruction is planned or may have to be performed unexpectedly.

Operative Planning

Removal of an infected aortic graft and autogenous reconstruction require prolonged exposure of large portions of the body sur-

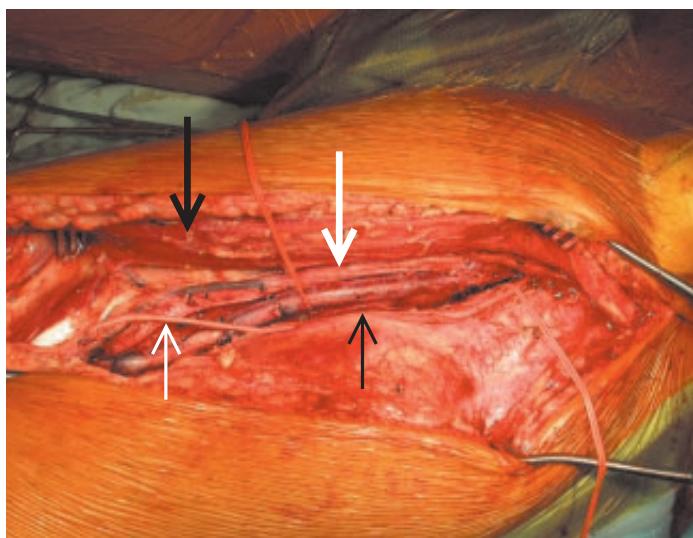

Figure 2 The FPV (thin black arrow), the superficial femoral artery (thick white arrow), and the saphenous nerve (thin white arrow) lie deep to the sartorius (thick black arrow) in the subsartorial canal. The sartorius is reflected medially to expose these structures. The adductor magnus tendon is divided to expose these structures as they traverse Hunter's canal.

face. Significant drops in core body temperature, combined with blood loss and resuscitation, may lead to metabolic acidosis, coagulopathy, cardiac dysrhythmia, and immune compromise. Accordingly, core body temperature should be kept above 36° C (96.8° F) by applying heated-air warming blankets to the upper body, using warmed fluid for resuscitation, and maintaining a warm ambient temperature in the operating room.

To minimize ischemic time with cross-clamping, the major tasks involved in excision of an infected aortic graft and in situ autogenous reconstruction should be sequenced as follows: (1) dissection of FPVs, which are left in situ until needed; (2) isolation and control of the femoral vessels; (3) entry into the abdomen and control of the aorta; (4) removal of the infected prosthesis; and (5) reconstruction with the deep vein grafts.¹⁵

Operative Technique

STEP 1: THIGH INCISION AND EXPOSURE OF FEMORAL VESSELS

The patient is placed in the supine position with the legs “frog-legged” and supported under the thighs. An incision is made on the thigh along the lateral border of the sartorius muscle. This lateral incision not only facilitates vein harvesting but also allows the surgeon to expose the femoral vessels while avoiding the infected femoral incision medially in the groins.

The sartorius is reflected medially so as to preserve the medial segmental blood supply. The subsartorial canal is entered, and the femoral vessels are exposed. The femoral vein is usually located posterior to and slightly medial or lateral to the artery at this level. The deep venous system is then exposed from the distal common femoral vein downward, including the proximal profunda femoris vein through Hunter’s canal to the midpopliteal level [see Figure 2]. The saphenous nerve is located in this canal and is intimately associated with the femoral vessels. Care must be taken not to injure this nerve either directly or through excessive traction; such injury will cause irritating post-operative saphenous neuralgia.

Care must also be taken to preserve major branches of the superficial femoral artery when this vessel is occluded or severely diseased. Interruption of these branches, which may supply collateral circulation to distal beds, may result in unexpected critical ischemia of the lower extremity after completion of the proximal reconstruction, and further infrainguinal arterial reconstruction may be necessary.

STEP 2: DISSECTION OF FPV

The FPV has many large and small side branches. Careful, meticulous and unhurried ligation of these branches is critical. Most are doubly ligated, with suture ligation reserved for the larger ones. Failure to ligate a branch adequately will result in exsanguinating hemorrhage if a tie loosens and pops off when exposed to aortic pressure. Although as a rule, the FPV is larger and sturdier than the typical greater saphenous vein, it is thin-walled in some areas where branches are present. If a branch is avulsed during dissection, suture repair with 6-0 or 7-0 polypropylene is necessary. Branch ligation during FPV harvesting differs from the typical branch ligation during saphenous vein harvesting. The branches of the FPV are ligated close to their bases because this is where the vein wall tends to be thin; the larger caliber of the FPV makes this technique possible. In contrast, the branches of the greater saphenous vein, which is of smaller caliber, are ligated slightly away from the vessel wall to ensure that the lumen of the vein is not encroached on.

The extent of the harvest depends on the length of venous conduit required for reconstruction. Proximally, dissection extends to the level of the junction of the femoral and profunda femoris veins. These veins join to form the common femoral vein, which is also exposed in the dissection. The profunda femoris vein is easily recognizable as a large posteriorly penetrating vein in the proximal thigh. Distally, dissection is carried through the adductor hiatus by dividing the tendon of the adductor magnus; this measure allows easy access to the proximal portion of the popliteal vein. The popliteal segment of the vein has multiple large branches, which must be carefully ligated. The dissection can easily be taken down to the level of the knee joint. The veins are left in situ until the required length of conduit can be determined.

STEP 3: DISSECTION AND CONTROL OF FEMORAL VESSELS

The femoral vessels can usually be dissected by extending the vein harvest incision cephalad along the lateral border of the sartorius to

Figure 3 Use of a valvulotome typically results in incomplete valve lysis. It is preferable to evert the entire venous graft and excise the valves (which usually number 3 or 4) completely with scissors.

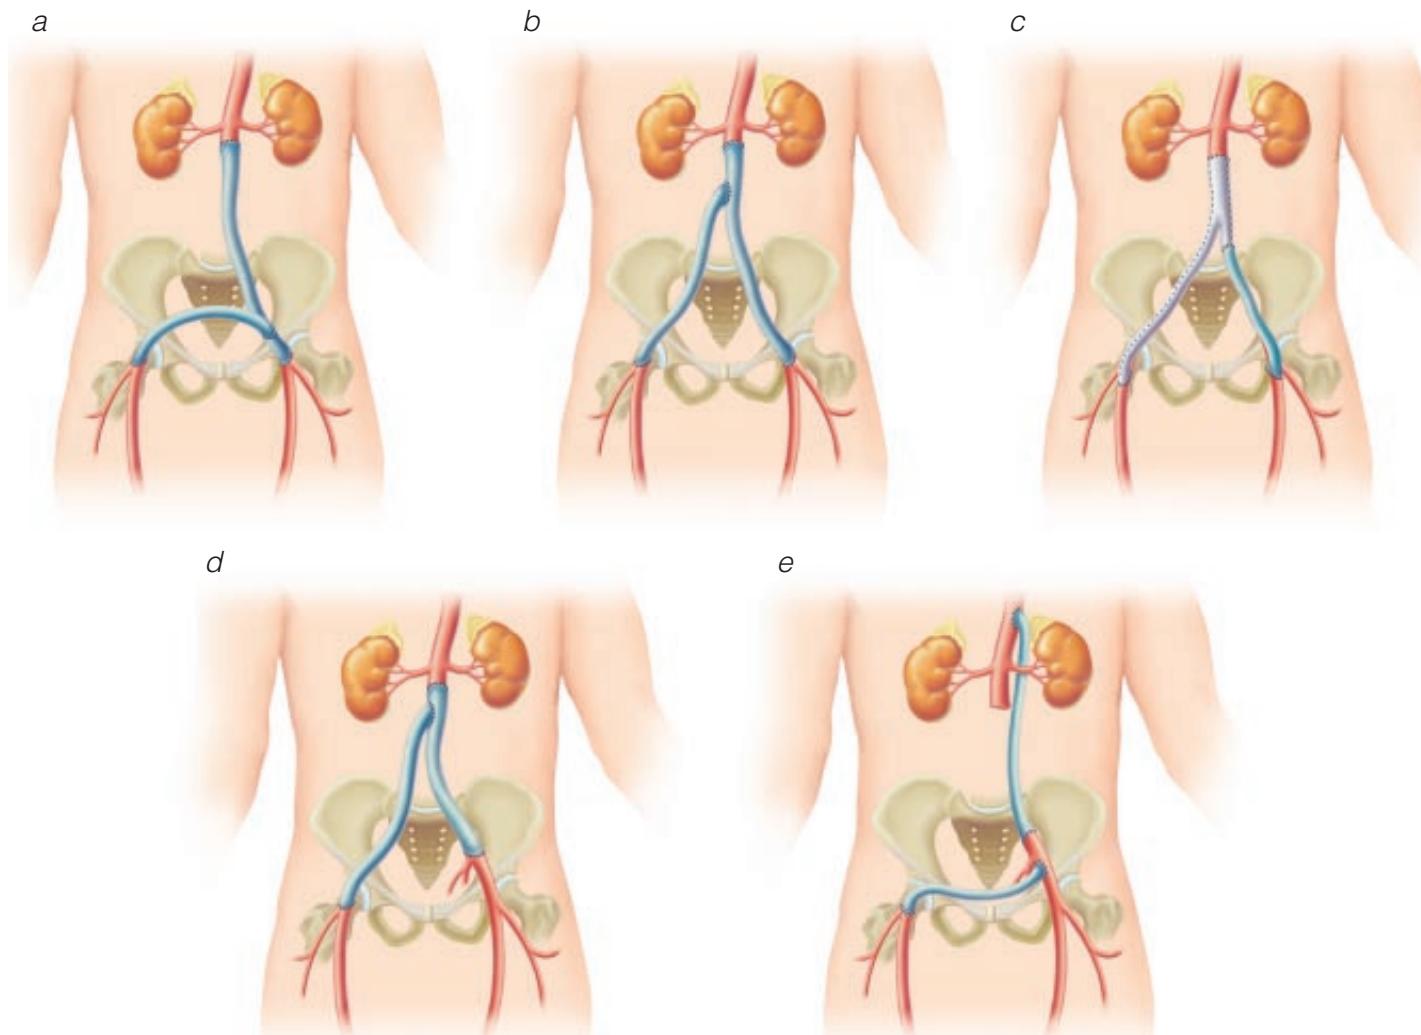

Figure 4 Multiple anatomic reconstructions have been used to recreate the aorto-iliac-femoral anatomy. (a) Shown is an aortounifemoral bypass with a femorofemoral crossover. (b) Instead of a femorofemoral bypass, the second limb may be brought off the midportion of the first limb in an end-to-side manner. (c) If infection is limited to one limb of an aortofemoral bypass, an FPV graft may be used to replace only the infected portion. (d) One segment of vein may be used to replace both segments of an aortoiliac or aortofemoral graft. (e) In some instances, it may be easier to approach the paraceliac aorta via a retroperitoneal approach for the proximal anastomosis.

the level of the anterior superior iliac spine. Through this incision, control of the superficial femoral, profunda femoris, and common femoral vessels is gained. In addition, the distal limbs of the existing aortofemoral graft can be controlled. Occasionally, control is difficult to obtain from a position lateral to the sartorius, in which case the medial aspect of the muscle may be dissected from the subcutaneous tissue to afford improved exposure. Only rarely is a more medial incision required. As noted [see Step 1, above], the lateral approach allows the surgeon to avoid entering the previous incision, where there may be a draining sinus or cellulitis.

STEP 4: ABDOMINAL INCISION AND DISSECTION OF AORTA

The abdomen is then entered either through a midline abdominal incision or via a retroperitoneal approach; the latter is particularly helpful in avoiding tedious abdominal adhesions. Dissection for control of the aorta above the aortic anastomosis is performed. The anastomosis may be near the level of the renal arteries, in which case suprarenal or supraceliac aortic control may be required.

STEP 5: REMOVAL AND PREPARATION OF VENOUS GRAFTS

Before cross-clamping, the vein grafts are removed and prepared. The length of the grafts is determined by measuring from the aortic anastomosis to the femoral anastomoses on both sides. The femoral vein is divided flush with the profunda femoris vein and oversewn with a 5-0 polypropylene suture. This creates a smooth transition point from the profunda femoris vein to the common femoral vein and leaves no stump in which blood can stagnate and create thrombus. The grafts are then distended in a 4° C solution containing lactated Ringer solution (1 L), heparin (5,000 U), albumin (25 g), and papaverine (60 mg). Any leaks are repaired either with additional silk ties or with figure-eight fine polypropylene sutures. Any adventitial bands that distort the lumen are lysed.

Next, the valves in the grafts must be lysed. This is a critical step because the grafts are placed in a nonreversed fashion to optimize size matching with the aorta for the proximal anastomosis. Valvulotomes have been used for valve lysis in these large-caliber

veins, but the results have been unsatisfactory: lysis is often incomplete, and the remnants of the valves may become sites of graft stenosis. Our current practice is to evert venous grafts completely and to excise all valves under direct vision [see Figure 3].

STEP 6: REMOVAL OF BODY OF PREVIOUS GRAFT AND PROXIMAL ANASTOMOSIS OF NEW GRAFT TO AORTA

The patient is heparinized, and the aorta above the anastomosis and both limbs of the graft are cross-clamped. The body of the graft is then excised, with the limbs left in place. All prosthetic material, including sutures, is removed. The previous aortic anastomosis may have been done in either an end-to-end or an end-to-side fashion. If it was an end-to-side anastomosis, the distal end of the aorta will have to be oversewn with a large suture (e.g., 0 or No. 1 polypropylene). Balloon occlusion of the distal lumen is a helpful adjunctive measure before ligation. Regardless of how the previous aortic anastomosis was done, the new anastomosis is typically constructed in an end-to-end fashion. The distal limbs of the existing graft are left in place while the aortic anastomosis is per-

formed so as to cut down on the blood loss that typically occurs when the limbs are removed from their tunnels.

Multiple configurations have been successfully employed to reconstruct the distal aortic and iliac-femoral vasculature [see Figure 4]. The proximal anastomosis is performed with a continuous 4-0 polypropylene suture. The diameter of the FPV graft is typically about 1.5 cm or a little greater, and the mismatch in diameter between the graft and the aorta is dealt with by taking slightly more advancement (i.e., placing sutures slightly farther apart) on the aortic wall than on the graft wall [see Figure 5a]. If the caliber discrepancy between the two structures is too large, another technique must be employed, such as plication of the aorta, joining of the venous grafts in a pantaloons configuration, or placement of a triangular patch at the proximal aspect of the graft [see Figures 5b through 5d].

After the proximal anastomosis is complete, the venous graft is distended under aortic pressure, and the side branches are carefully examined to confirm that all ligatures are securely placed. Any questionable areas are repaired. Anastomotic leakage is also repaired with the aorta clamped to ensure that the venous graft is not torn during repair.

STEP 7: REMOVAL OF LIMBS OF PREVIOUS GRAFT AND DISTAL ANASTOMOSES OF NEW GRAFTS TO FEMORAL ARTERIES

The femoral limbs of the prosthetic aortobifemoral grafts are then removed by pulling them through the groin incisions. When the FPV grafts are tunneled to the groins, care must be taken to ensure that ligated side branches are not torn or dislodged. Because it may be difficult to create new tunnels through the scarred retroperitoneum, the vein grafts may be tunneled through the existing tunnels. In many cases, the existing tunnels are smaller in caliber than the new vein grafts, and careful digital dilation of the tunnels is required.

The femoral anastomoses are fashioned in a standard manner. Once again, all prosthetic material and all surrounding infected tissue must be debrided from the groins. On occasion, profundaplasty or reimplantation of the profunda femoris may be required. If possible, the femoral anastomoses should be done in an end-to-side manner to preserve retrograde pelvic perfusion.

Perfusion of the extremities must be assessed before the leg wounds are closed. If Doppler arterial signals are absent at the level of the ankle, a femoropopliteal or distal bypass may be necessary [see 6:18 *Infrainguinal Arterial Procedures*]. Because the popliteal artery is exposed during FPV harvesting, adjunctive femoropopliteal bypass is easily accomplished in this setting.

STEP 8: CLOSURE

After reversal of heparinization, the thigh wounds are copiously irrigated and closed over closed suction drains. Placement of drains prevents postoperative seromas and subsequent wound complications. Even though these wounds are contaminated as a consequence of the proximity of the infected graft in the groin wound, infection is rare. Often, there are draining sinuses medial to the vein harvest incisions, which are debrided and left open.

Postoperative Care

Parenteral antibiotics are continued for 5 to 7 days, and antibiotic coverage is modified on the basis of intraoperative cultures of the graft material and wound swabs. Intermittent pneumatic compression and low-dose subcutaneous heparin (5,000 U every 8 to 12 hours) are employed for prevention of deep vein thrombosis. Thrombosis of the residual popliteal vein is common, and agi-

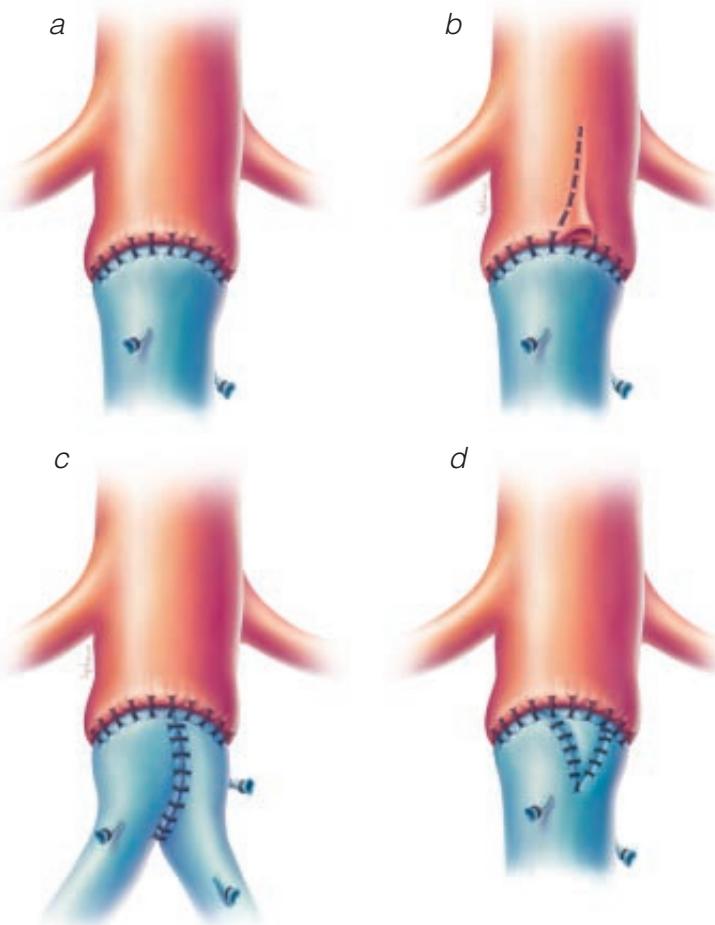

Figure 5 (a) An end-to-end proximal anastomosis is usually possible if the diameter of the FPV graft is large enough and the aorta is of normal size. (b) If the end of the aorta is significantly larger in diameter than the venous graft, plication of the aorta can be performed. (c) A pantaloons technique may also be used to deal with a size mismatch between the aorta and the FPV graft. This technique effectively doubles the circumference of the vein. (d) The proximal anastomosis can also be facilitated by incorporating a wedge-shaped portion of vein into the proximal end of the graft.

gressive prophylaxis may prevent extension of the thrombus into the calf veins. With the FPV absent, the risk of pulmonary embolism is low.

Complications

The incidence of chronic venous morbidity after FPV harvesting is low, but the fasciotomy rate is approximately 20%. In our practice, the decision to perform a fasciotomy is based primarily on clin-

ical examination of the legs. We specifically assess progressive compartment swelling and firmness on serial examination after reperfusion of the lower extremities. We also consider risk factors in making this decision. Two specific risk factors for fasciotomy are (1) a low preoperative ABI (< 0.4) and (2) concurrent greater saphenous vein harvesting.¹³ Other factors may also help determine the need for fasciotomy, including the indication for operation, the length of vein harvested, the duration of arterial cross-clamping, and the amount of fluid administered intraoperatively.

14 OPEN PROCEDURES FOR RENOVASCULAR DISEASE

Matthew S. Edwards, M.D., Juan Ayerdi, M.D., and Kimberley J. Hansen, M.D., F.A.C.S.

Until comparatively recently, intervention for renovascular disease focused entirely on hypertension. However, the introduction of potent new antihypertensive agents and percutaneous endovascular methods of management has led to substantial changes in attitudes to and indications for management of renovascular disease. Today, open surgical repair is commonly reserved for (1) patients who have severe hypertension despite optimal medical therapy, (2) patients in whom percutaneous transluminal renal artery angioplasty (PTRA) fails or who have disease patterns that are not amenable to PTRA, and (3) patients who have renovascular disease associated with excretory renal insufficiency (i.e., ischemic nephropathy).¹

The experience of our center (Wake Forest University School of Medicine) in the management of more than 850 patients over a 16-year period indicates that atherosclerotic renovascular disease frequently exists in combination with diffuse extrarenal atherosclerosis and renal insufficiency. In one study, bilateral atherosclerotic renal artery lesions were present in two thirds of patients, and complete renal artery occlusion was present in more than one third.² Although practitioners frequently cite selected data to support a particular management scheme in this setting, the question of what constitutes optimal management of atherosclerotic renovascular disease responsible for either hypertension or renal insufficiency is still unanswered. To date, there have been no prospective, randomized trials that compare the best medical management with PTRA and with open surgical repair.

Preoperative Evaluation

Evaluation and diagnosis of renovascular hypertension and renovascular renal insufficiency (i.e., ischemic nephropathy) are discussed in more detail elsewhere, as are general issues related to the question of medical versus surgical therapy.

INDICATIONS FOR INTERVENTION

The recognition of both the progressive nature of the atherosclerotic renovascular lesions seen in combination with severe hypertension and the deterioration of renal function seen in selected patients who are managed medically lends support to the idea that renal artery intervention is indicated when either renovascular hypertension or ischemic nephropathy is present. In our view, renal artery intervention is appropriate in patients with severe hypertension and, specifically, in all patients who have severe hypertension in combination with excretory renal insufficiency (i.e., ischemic nephropathy). Open operative management is preferred for children and young adults and for patients with bilateral renovascular disease, especially if renal artery occlusion is present.²

PTRA [see 6:16 Endovascular Procedures for Renovascular

Disease] is liberally used as an alternative to open renal artery revascularization, but the data currently available suggest that it should be employed selectively. The best results with PTRA alone have been achieved with nonostial atherosclerotic renal artery lesions and medial fibroplasia of the main renal artery. Suboptimal results have been achieved with hypoplastic (i.e., developmental) lesions, fibrodysplasia of the intimal and perimedial variety, ostial atherosclerotic renal artery lesions, and renal artery occlusions. For ostial renal artery atherosclerosis, some surgeons have advocated PTRA with primary endoluminal stenting in an effort to improve results; however, the results of PTRA and primary stenting in this setting have been inferior to those of open operative repair. Consequently, in the majority of cases of ostial atherosclerosis in combination with renal insufficiency, we advise operative intervention for good-risk patients.

These recommendations are not absolute. Decisions regarding therapy for renovascular disease must be individualized. Factors contributing to the choice of treatment include the expected morbidity and mortality of operative repair and the presence of predictors of death and dialysis dependence at follow-up. In this regard, severe left ventricular dysfunction with clinical congestive heart failure, diabetes mellitus, and uncorrectable azotemia have all been shown to be significant and independent predictors of reduced dialysis-free survival.^{2,3}

Operative Planning

SURGICAL STRATEGY

Our use of open surgical methods to treat atherosclerotic renovascular disease is based on several guiding principles [see Table 1]. We consider severe hypertension a prerequisite for open operative management and do not perform prophylactic renal artery repair

Table 1 Recommended Principles for Contemporary Surgical Management of Renovascular Disease¹⁰

- Renal artery repair is done on an empirical, but not prophylactic, basis
- Complete renal artery repair is done in one operation when feasible; bilateral ex vivo reconstruction may be staged
- Direct aortorenal methods of reconstruction are preferred
- Nephrectomy is reserved for nonreconstructable disease in a nonfunctioning kidney
- Combined aortic reconstruction is limited to clinically significant disease
- Intraoperative duplex sonography is performed to assess technical success

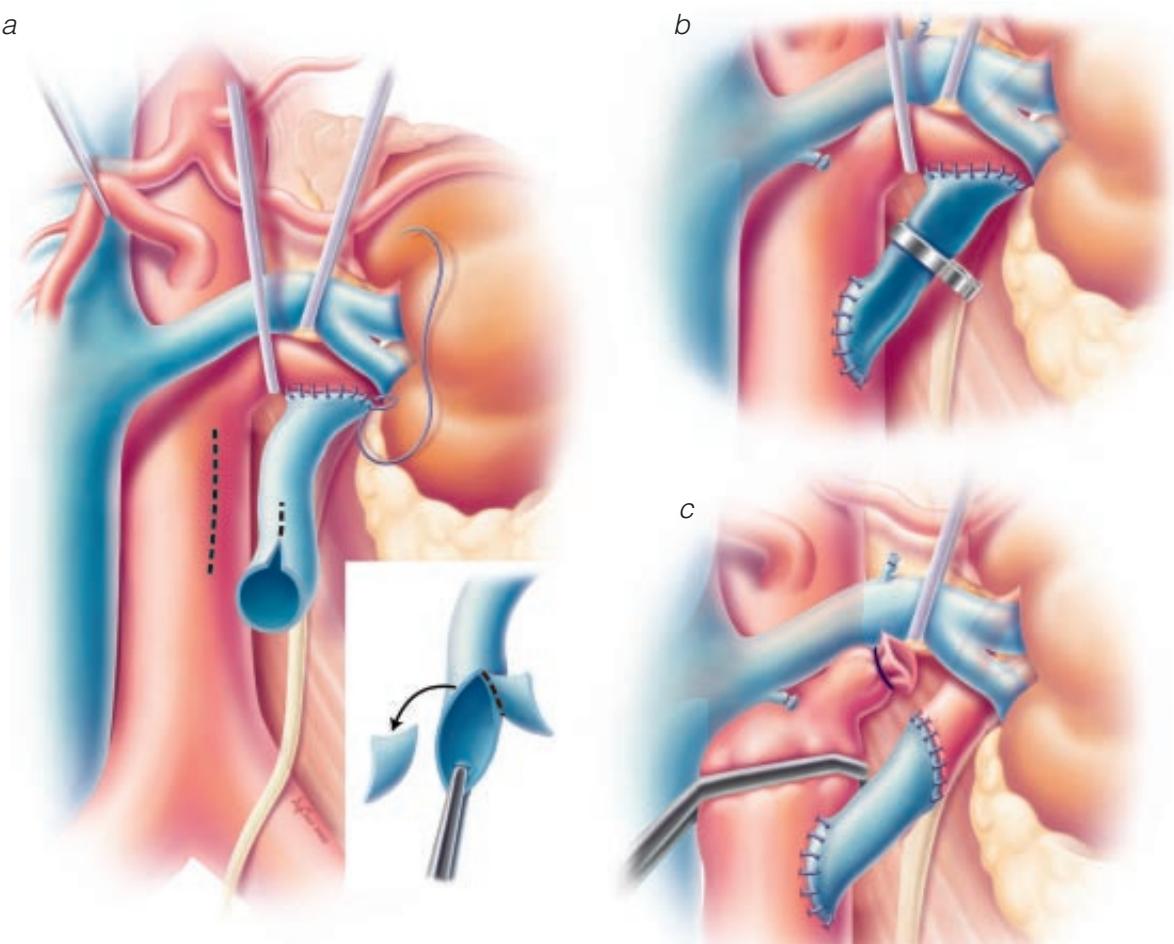

Figure 1 Aortorenal bypass.⁸ Technique for end-to-side (*a, b*) and end-to-end (*c*) aortorenal bypass grafting. The length of arteriotomy is at least three times the diameter of the artery to prevent recurrent anastomotic stenosis. For the anastomosis, 6-0 or 7-0 monofilament polypropylene sutures are used in continuous fashion, under loupe magnification. If the apex sutures are placed too deeply or with excess advancement, stenosis can be created, posing a risk of late graft thrombosis.

in patients who are not hypertensive. Although we employ renal vein renin assays to guide management of unilateral lesions in many cases, we typically perform empirical renal artery repair without functional studies when the hypertension is severe or uncontrolled and when renal artery disease is bilateral or involves a solitary kidney. We attempt to correct all hemodynamically significant renovascular disease in a single operation; we perform staged repair only in cases in which the disease necessitates bilateral *ex vivo* reconstruction. Because the lower limit of renal function retrieval is not known but improved renal function is known to be the strongest predictor of dialysis-free survival, we reserve nephrectomy for patients who have an unreconstructable lesion in a renal artery supplying a nonfunctioning kidney (i.e., a kidney providing less than 10% glomerular filtration on renography).⁴ In the majority of open operative repairs, we employ direct aortorenal reconstruction methods; we seldom use indirect (splanchnorenal) methods, because celiac axis stenosis is present in 40% to 50% of patients and bilateral repair is required in more than 50%.² Regardless of the method of reconstruction employed, we perform intraoperative renal duplex sonography as a completion study to look for any technical errors in the repair that might lead to restenosis or occlusion. Failed renal artery repair has been associated with a significant and independent risk of eventual dependence on dialysis.⁵

Operative Technique

Various open surgical techniques are used to correct atherosclerotic renovascular disease; however, no single repair technique is optimal for all renovascular lesions. The best approach to renal artery reconstruction in any given case depends on patient characteristics, the pattern of renal artery disease, and the presence or absence of associated aortic lesions that may have to be corrected simultaneously. The open procedures most commonly performed to treat renovascular disease are (1) aortorenal bypass, (2) renal artery thromboendarterectomy, and (3) renal artery reimplantation. In general, aortorenal bypass is the most versatile of these procedures. Transaortic thromboendarterectomy may be especially useful when ostial atherosclerosis ends within 1 cm of the origin of the renal artery and involves multiple renal arteries. Renal artery reimplantation is often particularly appropriate for the correction of renovascular disease in children and adolescents, in that concerns regarding graft material are eliminated.

With all of these reconstruction techniques, multiple small doses of mannitol are administered intravenously during perirenal aortic and renal artery dissection. Mannitol is given both before and after periods of warm renal ischemia up to a total dose of 1 g/kg. During cross-clamping of the aorta and the renal artery, the patient is given heparin, 100 U/kg, to establish systemic anticoag-

ulation. When a purely autogenous reconstruction is performed, antibiotics are unnecessary; however, when a prosthetic graft is employed, administration of a first-generation cephalosporin is begun 2 hours before operation and continued for 24 hours.

AORTORENAL BYPASS

Aortorenal bypass [see *Figure 1*] may be performed with either an autogenous conduit or a prosthetic graft. If an entirely autogenous repair is possible, we prefer to use a reversed segment of the greater saphenous vein as the conduit. If the saphenous vein is too narrow (i.e., < 4 mm in diameter) or of inadequate quality, a 6 mm thin-walled polytetrafluoroethylene (PTFE) graft is used instead. In either case, the infrarenal aorta is dissected and clamped proximally and distally, and a longitudinal elliptical opening is created anterolaterally in the aortic wall (e.g., with two or three applications of a 5.2 mm aortic punch). If required, a local endarterectomy at the site of the anastomosis may be performed through this opening.

The proximal and distal anastomoses are then created. Although end-to-side distal renal artery anastomoses were commonly performed at one time, current aortorenal bypass techniques typically employ end-to-end distal renal artery anastomoses. For both the proximal and the distal anastomosis, the length of the arteriotomy should be at least three times the diameter of the smallest conduit, and the ends of the conduit should be widely spatulated to guard against late suture line stenosis. The proximal anastomosis is usually made with a continuous 6-0 monofilament polypropylene suture, and the distal anastomosis is created with a continuous 7-0 or 8-0 monofilament polypropylene suture.

Thromboendarterectomy of the renal arteries and the perirenal aorta may be performed via either a transrenal or a transaortic approach. When the renal artery atheroma extends 1 cm or less from the ostium and involves both or multiple renal arteries, the transaortic technique [see *Figure 2*] is especially useful. With both endarterectomy techniques, extensive aortic exposure is required. The aorta proximal to the origin of the superior mesenteric artery (SMA) is exposed and controlled. This exposure is facilitated by partially dividing the aortic crura and controlling the SMA with a Silastic loop.

THROMBOENDARTERECTOMY

Currently, the majority of aortorenal endarterectomies are performed through a longitudinal aortotomy extending from a point 2 to 3 cm below the renal arteries to the base of the SMA. A sleeve of aortic atheroma is created, then divided sharply at the base of the SMA proximally and well below the most inferior renal artery distally. After the aortic endarterectomy is completed, an eversion-

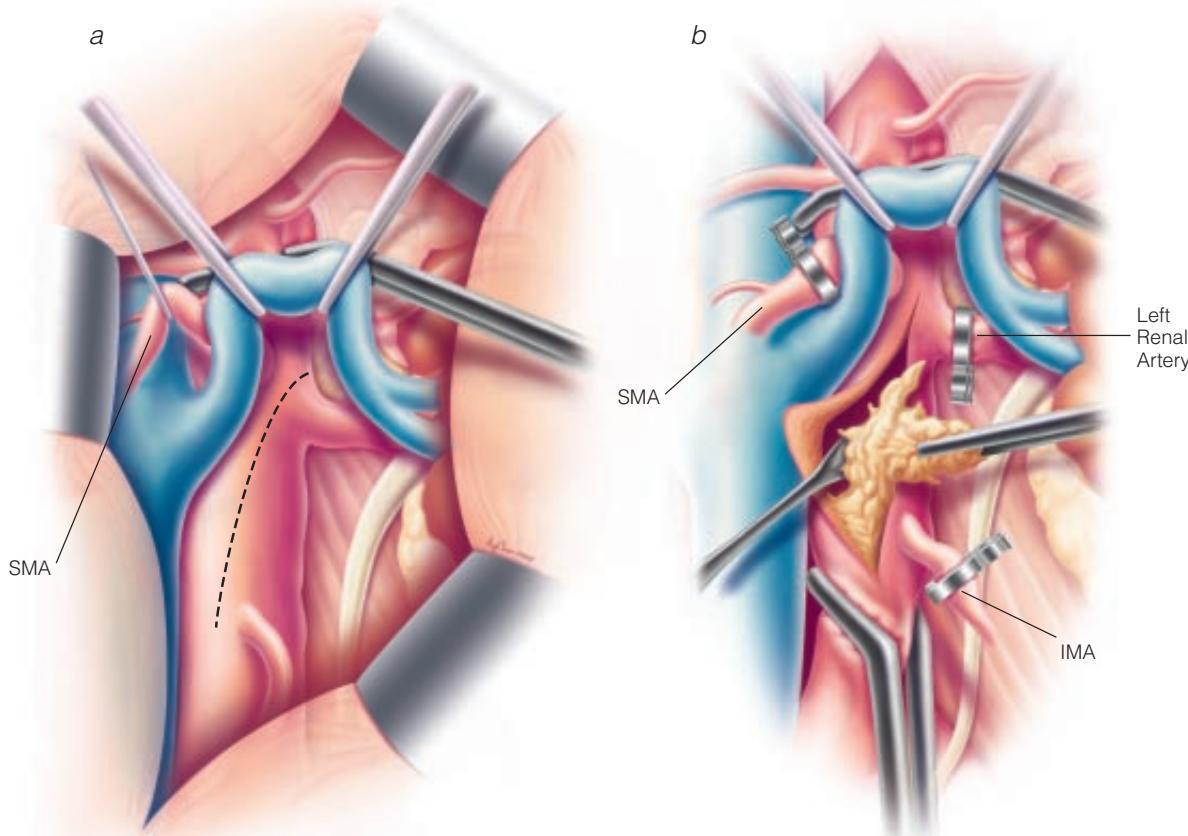

Figure 2 Thromboendarterectomy.⁸ Exposure for a longitudinal transaortic endarterectomy is obtained via the standard transperitoneal approach. The duodenum is mobilized from the aorta laterally in the standard fashion; alternatively, for more complete exposure, the ascending colon and the small bowel are mobilized. (a) Dotted line shows the location of the aortotomy. (b) The plaque is transected proximally and distally, the renal arteries are everted, and the atherosclerotic plaque is removed from each renal ostium. The aortotomy is typically closed with a continuous 4-0 or 5-0 polypropylene suture. (IMA—inferior mesenteric artery)

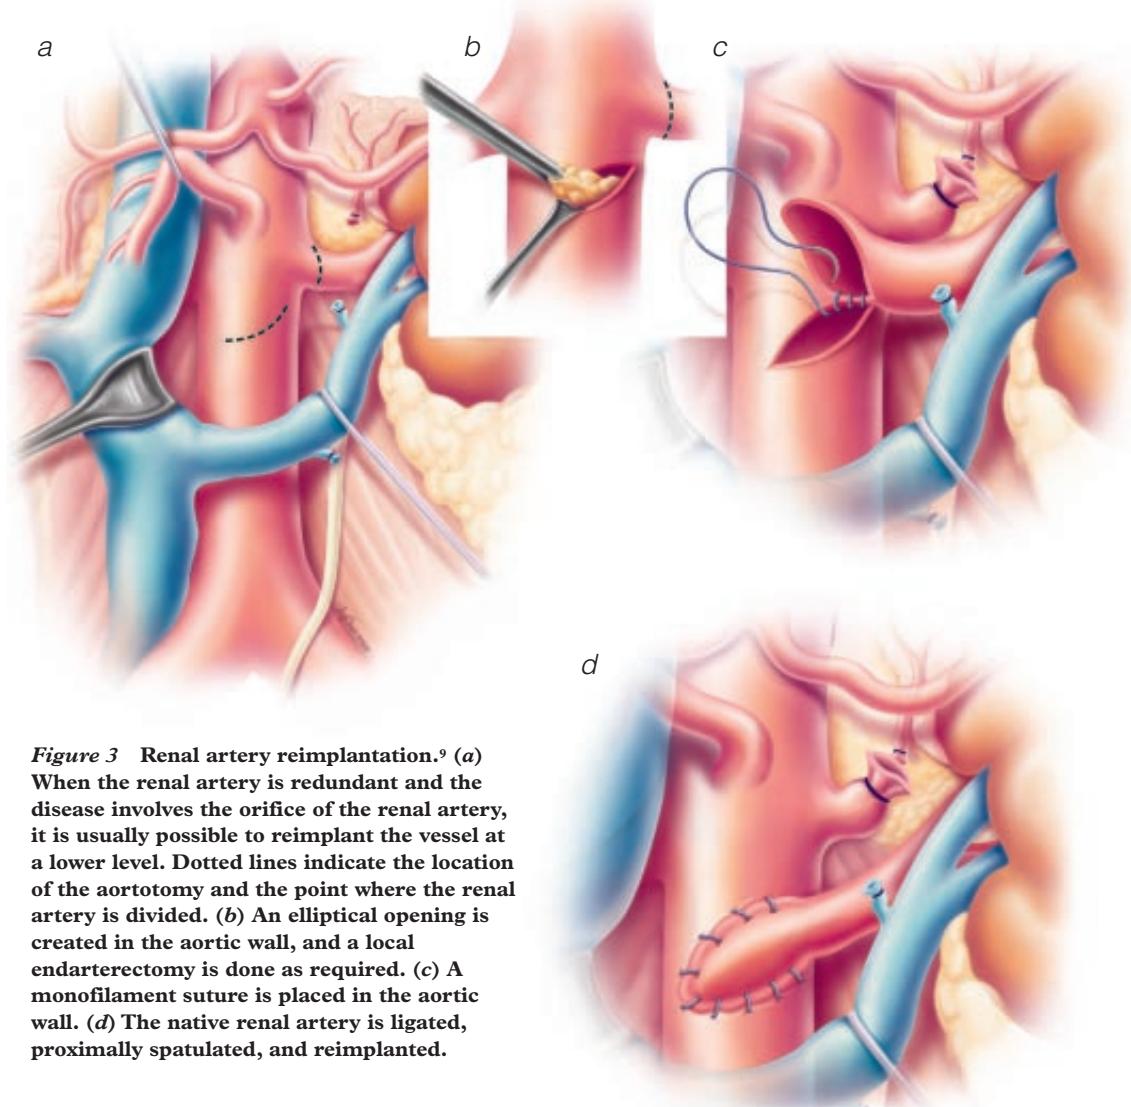

Figure 3 Renal artery reimplantation.⁹ (a) When the renal artery is redundant and the disease involves the orifice of the renal artery, it is usually possible to reimplant the vessel at a lower level. Dotted lines indicate the location of the aortotomy and the point where the renal artery is divided. (b) An elliptical opening is created in the aortic wall, and a local endarterectomy is done as required. (c) A monofilament suture is placed in the aortic wall. (d) The native renal artery is ligated, proximally spatulated, and reimplanted.

type endarterectomy is performed for each of the renal arteries. The surgical assistant retracts the anterior lip of the aortic wall and inverts the renal artery into the aorta, and the operating surgeon retracts the renal artery atheroma while gently pushing the remaining renal artery away with a dissector. In this manner, the end point of the endarterectomy can easily be visualized to confirm that the endarterectomy is complete. The endarterectomy site is then irrigated with heparinized saline, and the longitudinal aortotomy is closed with a continuous 4-0 or 5-0 monofilament polypropylene suture.

Both transrenal and transaortic thromboendarterectomy are contraindicated if aneurysmal degeneration of the perirenal aorta is present or if there is transmural calcification at the site of endarterectomy.

RENAL ARTERY REIMPLANTATION

In the course of renal artery exposure, the vessel is dissected from its aortic origin to its primary bifurcation. On occasion, after complete dissection, the vessel is found to have sufficient redundancy to allow tension-free reimplantation into the infrarenal aorta [see Figure 3]. As in a renal artery bypass [see Aortorenal Bypass, above], an elliptical section of the aortic wall is resected, and a widely spatulated aortorenal anastomosis is fashioned.

Although this technique has only limited applicability to the treatment of atherosclerotic renovascular disease in adults, it may be particularly useful for this purpose in children and young adolescents, who often have congenital or developmental lesions that involve the renal artery orifice. The main advantage of reimplantation is that it obviates concerns regarding the durability of the renal artery conduit.

SPLANCHNORENAL BYPASS

Indirect, or splanchnorenal, bypass [see Figure 4] is an uncommon procedure at our center. In large part, its relative rarity is a reflection of the frequent presence of simultaneous disease of the celiac axis and the frequent need for bilateral renal artery reconstruction in combination with aortic repair. In addition, we believe that this approach does not yield long-term patency equivalent to that provided by direct aortorenal reconstruction. Consequently, these indirect bypass techniques are reserved for a selected subgroup of high-risk patients.

Hepatorenal bypass is most frequently performed through a right subcostal incision, splenorenal bypass through a left subcostal incision. In either procedure, the patient is positioned with a roll beneath the ipsilateral flank, with the operating table flexed and the ipsilateral arm padded and tucked to the side. The incision

may be extended to the contralateral semilunar line and into the ipsilateral flank as necessary for exposure. In a hepatorenal bypass, a greater saphenous vein graft is usually employed, originating from the common hepatic artery and coursing posterior to the portal triad and anterior to the vena cava before the end-to-end renal artery anastomosis [see *Figure 4*]. A splenorenal bypass may be created either in a similar fashion (i.e., with a greater saphenous vein graft) or by anastomosing the transected splenic artery directly to the left renal artery [see *Figure 5*]. If the latter approach is taken, the collateral circulation to the spleen is sufficient to maintain splenic viability.

NEPHRECTOMY

In patients with renovascular renal insufficiency or ischemic nephropathy, an incremental increase in excretory renal function after operation is the dominant determinant of dialysis-free survival. As noted [*see Operative Planning, Surgical Strategy, above*], we reserve nephrectomy for patients in whom an unreconstructable renal artery is supplying a nonfunctioning kidney. When the renal artery is occluded, reconstruction is performed if the distal renal artery is normal at the time of surgical exploration. Past recommendations regarding the management of renal artery occlusion have emphasized kidney length, distal renal artery reconstitution, and the appearance of a nephrogram during angiography as criteria for determining whether reconstruction is indicated. Our practice, however, has been to perform renal artery reconstruction whenever a normal distal renal artery is demonstrated. In a study employing this strategy, we reported retrieval of renal

function in 60% of occluded renal arteries that underwent operative repair.⁴

INTRAOPERATIVE RENAL DUPLEX ULTRASONOGRAPHY

The surgeon's technique plays a dominant role in determining patency after renal artery reconstruction. To look for technical errors at the time of operation, we employ intraoperative renal duplex ultrasonography. A 10.0/5.0 mHz compact linear array probe with Doppler color-flow capability is placed within a sterile sheath that has a latex tip containing sterile gel. The operative field is flooded with warm saline solution, and B-scan images are obtained from the sites of aortic control and of renal artery repair. All defects noted on the B-scan images are then examined in both longitudinal and transverse projections. Doppler samples are obtained proximal and distal to the lesions to determine their hemodynamic significance.⁶ In 249 consecutive renal artery repairs with anatomic follow-up, 10% had a focal increase in peak systolic velocities consistent with residual stenosis.² Each defect was revised immediately, and in each case, a significant defect was found. At 12 months after operation, primary patency of the renal reconstruction was observed in 97% of repairs. This product-limit estimate of patency is stable up to 8 years after operation.

Outcome Evaluation

Surgical repair of atherosclerotic renovascular disease can be accomplished with a high rate of success and sustained long-term patency. With proper patient selection, the majority of patients

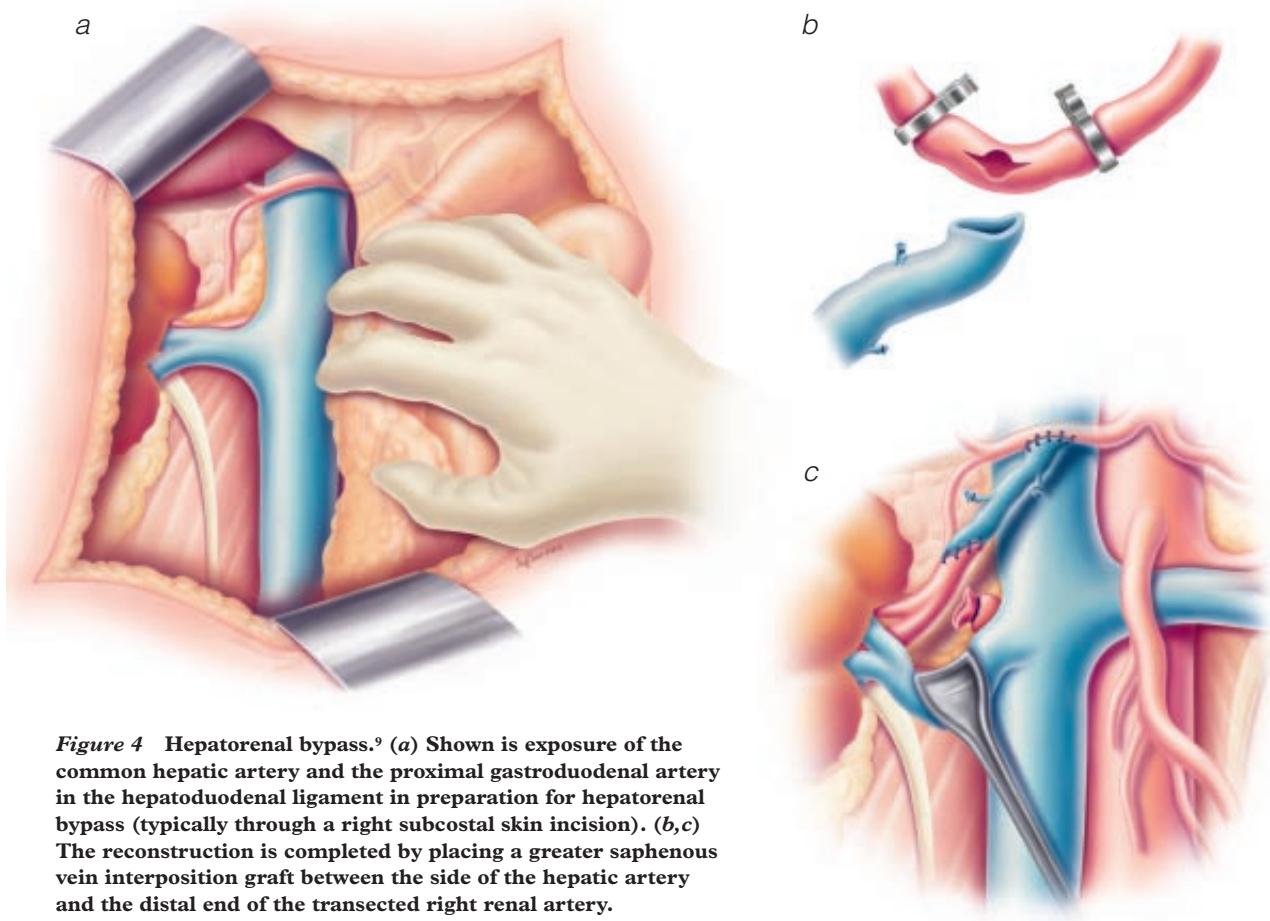

Figure 4 Hepatorenal bypass.⁹ (a) Shown is exposure of the common hepatic artery and the proximal gastroduodenal artery in the hepatoduodenal ligament in preparation for hepatorenal bypass (typically through a right subcostal skin incision). (b,c) The reconstruction is completed by placing a greater saphenous vein interposition graft between the side of the hepatic artery and the distal end of the transected right renal artery.

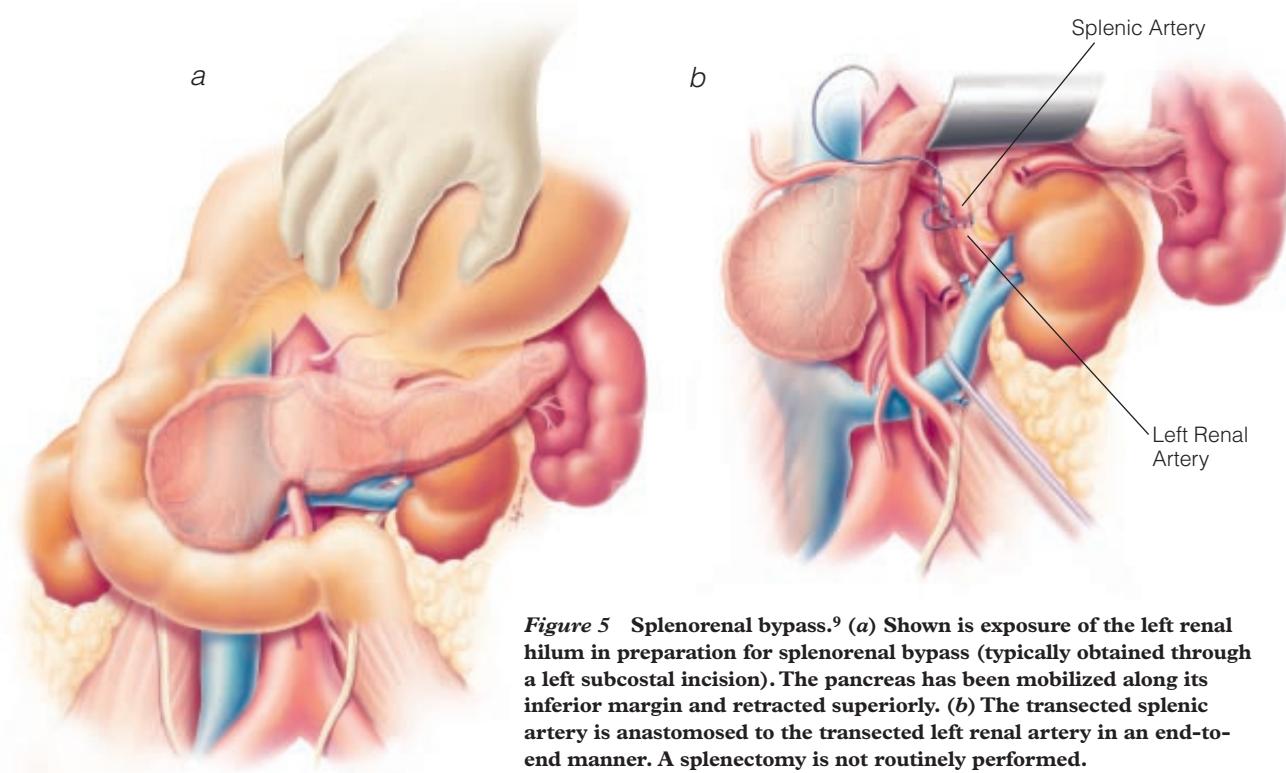

Figure 5 Splenorenal bypass.⁹ (a) Shown is exposure of the left renal hilum in preparation for splenorenal bypass (typically obtained through a left subcostal incision). The pancreas has been mobilized along its inferior margin and retracted superiorly. (b) The transected splenic artery is anastomosed to the transected left renal artery in an end-to-end manner. A splenectomy is not routinely performed.

demonstrate beneficial blood pressure response and renal function response, albeit with perioperative mortality and morbidity that vary according to the complexity of the procedure.

In a 2002 report, we reviewed our center's experience with 500 consecutive patients who underwent open surgical repair for treatment of atherosclerotic renovascular disease between January 1987 and December 1999.² These patients included 254 women and 246 men, with a mean age of 65 ± 9 years. Each patient had severe hypertension. The mean preoperative blood pressure for the group was $200 \pm 35/104 \pm 21$ mm Hg. Most of the patients had diffuse extrarenal atherosclerosis. A total of 81% had at least one manifestation of cardiac disease; 34% had a history of significant cerebrovascular disease; and 78% were considered to have at least mild renal insufficiency, as evidenced by a serum creatinine concentration of 1.3 mg/dl or greater. Ischemic nephropathy was seen in 244 patients (49%), including 40 patients who were dependent on dialysis before operation.

Angiographic evaluation demonstrated the presence of bilateral renal artery disease in 60% of these atherosclerotic patients. The renal artery lesion was considered ostial in 97% of cases, and 16% of renal arteries were completely occluded. A total of 720 renal artery reconstructions were performed [see Table 2]. Aortorenal bypass was performed in two thirds of the repairs, and two thirds of these bypasses were done with venous grafts. Thromboendarterectomy was performed in almost one third of the cases. Renal artery reimplantation was performed in 56 instances, splanchnorenal bypass in only 13 instances. Although there were 124 renal artery occlusions, only 56 of these were treated by means of nephrectomy.

Twenty-three patients (4.6%) died in the hospital or within 30 days of renal reconstruction. Mortality varied significantly with the magnitude of procedure. Mortality after isolated renal artery repair was substantially lower than mortality after combined aortic and bilateral renal artery repair (0.8% versus 6.9%). Moreover,

perioperative mortality demonstrated significant and independent associations with advanced age and clinical congestive heart failure. The estimated primary patency rate for all 720 renal artery reconstructions was 97% at 8 years' follow-up.

HYPERTENSION RESPONSE

Early blood pressure response was estimated on the basis of ambulatory blood pressure values and medication requirements determined at least 1 month after operative repair. Among surgical survivors, 12% were considered cured, 73% were considered improved, and 15% were considered failed [see Table 3].

RENAL FUNCTION RESPONSE

A significant change in excretory renal function was defined as a change of at least 20% in the estimated glomerular filtration rate (eGFR), measured at least 3 weeks after repair. Of patients

with preoperative ischemic nephropathy, 58% showed improvements in renal function, including 30 patients removed from dialysis dependence [see Table 3]. In contrast to previous reports that suggested the existence of a lower limit of renal dysfunction beyond which recovery could not be observed, the percentage of patients who showed improvement rose with increasing preoperative serum creatinine concentration. Overall, 75% of dialysis-dependent patients were permanently removed from dialysis after renal artery repair. In addition, the site of disease and the extent of repair were found to influence increases in the EGFR.

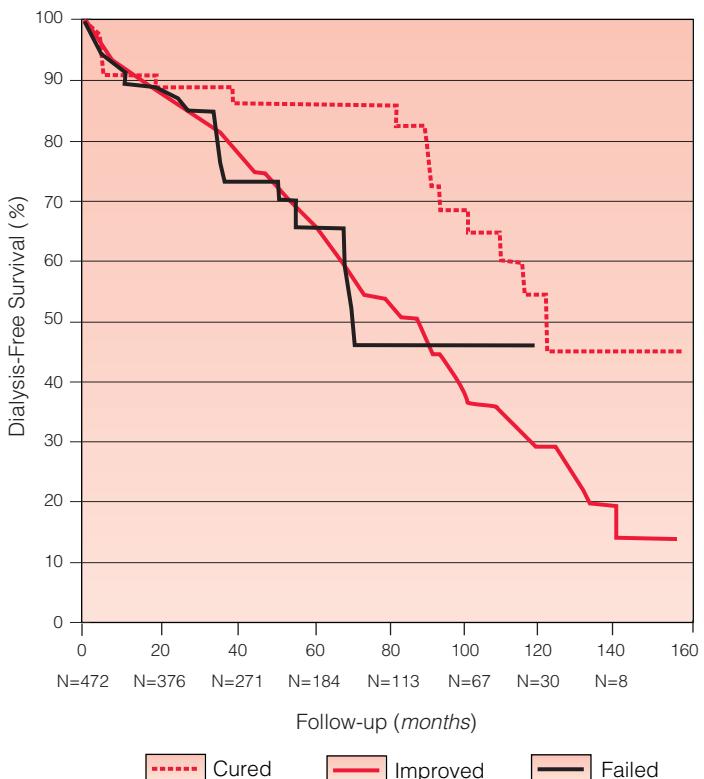

Figure 6 Illustrated are product-limit estimates of time to death or dialysis, stratified according to blood pressure response to operation for atherosclerotic renovascular disease.²

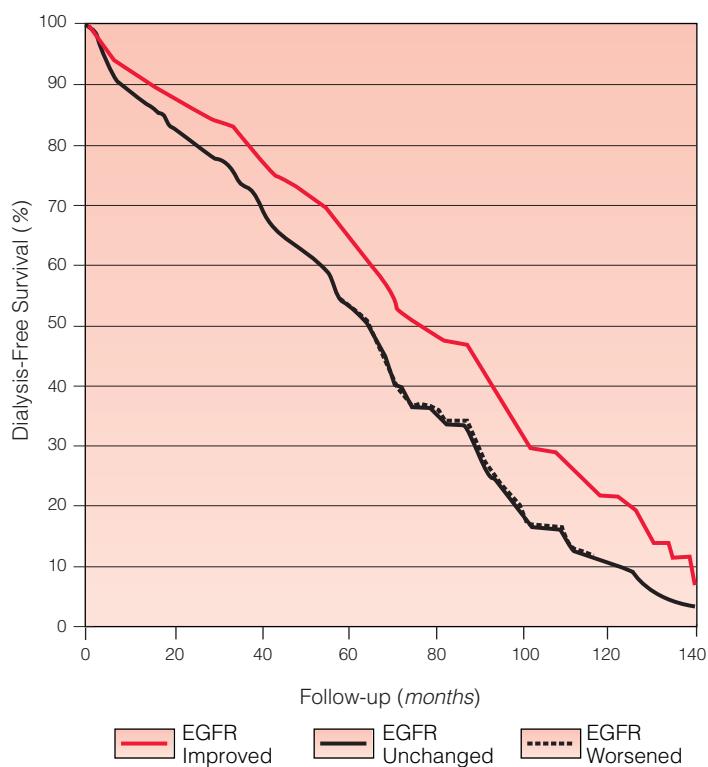

Figure 7 Illustrated are product-limit estimates of time to death or dialysis, stratified according to postoperative renal function response for patients with a preoperative EGFR of 25 ml/min/m^2 . The interaction between preoperative EGFR and renal function response for dialysis-free survival was significant and independent.²

Although each subgroup of patients who underwent operation demonstrated some improvement in renal function, the greatest incremental increase in the EGFR was observed in those who underwent bilateral renal reconstruction for significant bilateral disease.^{3,7}

RELATIONSHIP OF HYPERTENSION RESPONSE AND RENAL FUNCTION RESPONSE TO DIALYSIS-FREE SURVIVAL

At a mean follow-up of 56 months, 171 patient deaths had occurred. When outcomes were considered in terms of the blood pressure response to operative intervention, only hypertension cured was found to be significantly and independently associated with survival or dialysis dependence: patients whose hypertension was cured experienced improved dialysis-free survival [see Figure 6]. In contrast, all outcome categories for the renal function response influenced both survival and eventual dialysis dependence. Patients with improved renal function experienced a significant increase in dialysis-free survival [see Figure 7].² For patients whose renal function remained unchanged after operation, however, the risk of eventual dialysis dependence and death was equivalent to that of patients whose renal function worsened after surgery. Whereas renal function that is unchanged after intervention is frequently described as “stabilized” or “preserved,” our experience suggests that patients with ischemic nephropathy and atherosclerotic renovascular disease whose renal function is unchanged postoperatively remain at increased risk for eventual dialysis dependence and death. Whether similar associations exist for patients treated by means of catheter-based methods is unknown, but the question certainly merits future study.

15 ENDOVASCULAR PROCEDURES FOR RENOVASCULAR DISEASE

Juan Ayerdi, M.D., Matthew S. Edwards, M.D., and Kimberley J. Hansen, M.D., F.A.C.S.

The treatment of renovascular disease is currently in a state of evolution. Open surgical revascularization [see 6:14 *Open Procedures for Renovascular Disease*] remains the gold standard, having demonstrated its durability and efficacy in treating renovascular hypertension and ischemic nephropathy; however, it is associated with substantial morbidity and mortality, even when performed in centers with extensive experience.¹⁻⁴ As a result, endovascular techniques for renal revascularization, including percutaneous transluminal angioplasty with or without endoluminal stent placement (PTAS), have emerged as another option for the revascularization of occlusive renal artery lesions. Compared with conventional open surgical revascularization, these endovascular techniques offer a number of potential benefits (e.g., decreased morbidity, lower mortality, shorter recovery times, and reduced hospital resource utilization); however, they also possess certain potential drawbacks (e.g., reduced effectiveness and decreased durability).

Predictably, controversy persists regarding the appropriate application of surgical and endovascular therapies to the treatment of renovascular disease, with proponents of each modality citing selected literature to support their position. In what follows, we review key technical aspects of endovascular renal revascularization and summarize the current data on technical results, clinical outcomes, and associated complications. There is reason to believe that improvements in our ability to select patients most likely to benefit from treatment,⁵⁻¹⁰ as well as the emergence of technical developments aimed at preventing procedure-related embolization¹¹⁻¹³ and long-term restenosis,¹⁴ may be on the horizon. Such advances, if realized, may further narrow the gap between the clinical results of surgical renal revascularization and those of its endovascular counterpart and may improve the marginal benefit and safety of renal artery PTAS.

Preoperative Evaluation

The general principles of preoperative evaluation and patient selection for persons being considered for renal revascularization, whether open or endovascular, will not be described in detail in this chapter. As a rule, our group reserves renal artery PTAS for patients in whom open surgical repair is considered high risk or who refuse such repair.

CONTRAST ARTERIOGRAPHY

Despite advances in diagnostic imaging and functional testing that allow noninvasive identification of patients with renovascular disease,¹⁵⁻¹⁹ the formulation of an open surgical or endovascular therapeutic plan continues to depend on visualization of the renal artery anatomy by means of angiography. Accordingly, contrast arteriography of the renal arteries should be considered an integral component of the therapeutic armamentarium for clinically significant renal artery lesions.

Contrast-Related Considerations

Patients with known renovascular disease typically have a high prevalence of associated medical comorbidities (e.g., diabetes mellitus, congestive heart failure, chronic renal insufficiency, and diuretic-induced intravascular volume depletion). These conditions may necessitate alterations in the usual routines for patient preparation and use of iodinated contrast agents. Such agents are known to be capable of impairing excretory renal function,²⁰ sometimes permanently. The risk of this complication is highest in persons with preexisting dehydration,²¹ renal insufficiency,²²⁻²⁴ or diabetes mellitus.²⁵⁻²⁷ Administration of higher volumes of iodinated contrast material^{28,29} and use of high-osmolarity agents²⁵⁻²⁷ may also increase the risk of postprocedural renal function impairment. Several reports, however, have demonstrated that periprocedural administration of acetylcysteine^{30,31} and sodium bicarbonate hydration³² can lower the risk of renal function impairment after angiography.

In accordance with the available evidence, our current policy is to prepare all patients for aortorenal arteriography with saline hydration (limited in patients with significant heart failure) and periprocedural administration of acetylcysteine, along with limited use of sodium bicarbonate in patients who have preexisting renal insufficiency. Furthermore, we routinely select low-osmolarity iodinated contrast agents in these patients and pay special attention to limiting the volumes infused. In patients with moderate to severe preexisting renal insufficiency, carbon dioxide^{33,34} or gadopentate dimeglumine³⁵ may also be employed as an intra-arterial contrast agent to reduce or eliminate the use of iodinated contrast material. Our practice with such patients is to use carbon dioxide or gadopentate dimeglumine for initial localization [see Figure 1a] and selective cannulation [see Figure 1b] of the renal artery, then to employ an iodinated contrast agent in small volumes for definitive planning and performance of the required intervention.

Technical Considerations

Choice of arterial access route Femoral artery access, when feasible, is the most versatile and low-risk option. For non-selective renal arteriography, either femoral artery provides adequate access. For selective renal cannulation, however, it is generally better to use the femoral artery contralateral to the renal artery being addressed; this approach takes advantage of the tendency of the catheter to track preferentially toward the contralateral aortic wall and facilitates cannulation of the renal ostia.

If the patient has downsloping renal arteries or if femoral access is not advisable, brachial artery access is a useful alternative. It is preferable to access the left brachial artery so as not to cross the origin of the right common carotid artery. Access may be established by means of either percutaneous or open techniques. The risk of complications is higher with percutaneous brachial artery access, and the maximum permissible sheath and catheter sizes are smaller.³⁶ Accordingly, we generally use an open approach for

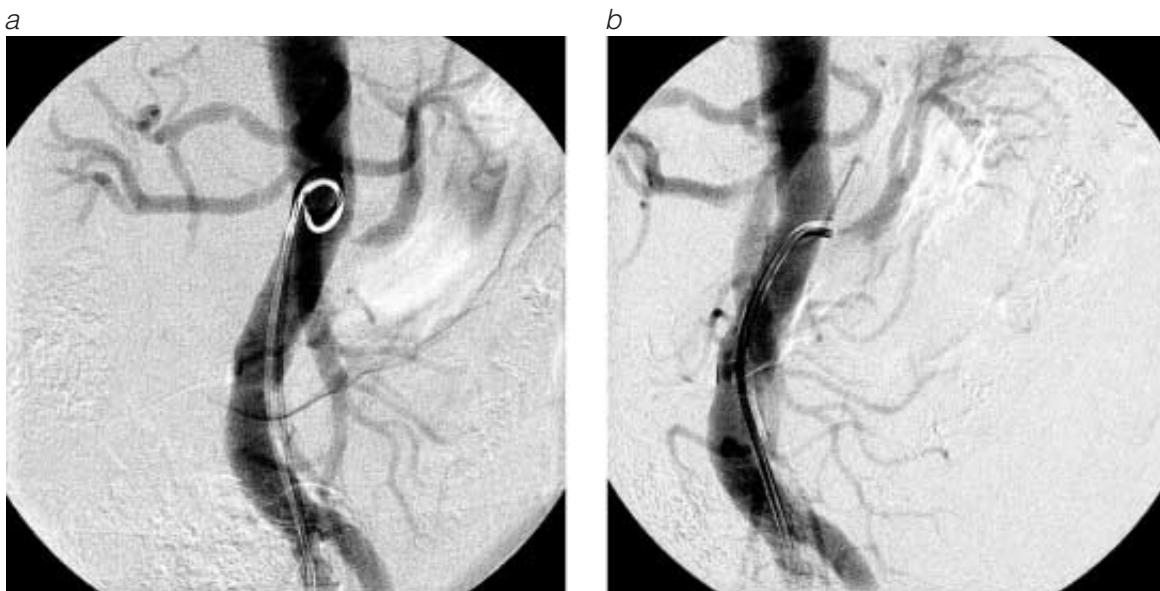

Figure 1 (a) Shown is bilateral high-grade renal artery stenosis visualized by using carbon dioxide angiography to localize the renal ostia. (b) Shown is selective right renal artery cannulation, with placement of a 6 French left internal mammary artery (LIMA) guide catheter and selective renal arteriography using hand-injected half-strength iso-osmolar contrast material.

brachial artery access, with puncture, cannulation, and closure carried out under direct vision.

Choice of imaging views Aortography and selective renal arteriography with multiple projections are necessary for full radiographic evaluation of the renal arteries and the juxtarenal aorta. Initial anteroposterior (AP) images of the visceral aorta are obtained by delivering power contrast injections through a flush catheter with multiple side holes positioned just beneath the diaphragm at the level of the first lumbar vertebra. These initial AP views provide an overview of the renal artery and the perivisceral aortic anatomy [see Figure 2]. All further nonselective images of the renal arteries should be obtained by moving the catheter to a location below the origin of the superior mesenteric artery to prevent contrast opacification of the visceral vessels, which could obscure the anatomic details of the renal arteries.

The renal arteries usually arise from the anterolateral or the posterolateral aspect of the aorta. As a result, lesions within the renal ostia often are not seen or appear insignificant on AP aortograms. Oblique aortography or oblique selective renal arteriography projects these portions of the vessel in profile and thus are often better at identifying any renal ostial lesions present. As a rule, the most useful projection for visualizing the renal ostia is a 15° to 30° left anterior oblique view, though other oblique views may also be necessary.^{37,38} Previously obtained axial images of the renal origins (i.e., computed tomographic scans) may allow better estimation of the necessary degree of obliquity and permit the use of smaller amounts of iodinated contrast material and lower doses of ionizing radiation [see Figure 3].

For full delineation of lesions within the body of the renal artery, selective arteriographic views may be required. Selective cannulation is usually performed with an angled catheter (e.g., a cobra catheter, a Sos catheter, or a renal double-curve catheter) in combination with a steerable guide wire; the varying configurations of the available catheters offer specific advantages in particular anatomic situations. Before selective renal artery cannulation, we typically administer heparin intravenously. Once the guide wire and the cath-

eter have been gently advanced into the renal artery ostia, contrast material is injected by hand to confirm intraluminal placement. Selective images are then obtained with low-volume power injection or hand injection (our preference) of contrast material [see Figure 4]. The proximal third of the left renal artery usually courses anteriorly, the middle third transversely, and the distal third posteriorly; the

Figure 2 Anteroposterior (AP) aortogram is obtained by delivering a power injection of iso-osmolar iodinated contrast material through a 5 French pigtail catheter positioned at the L1-2 interspace.

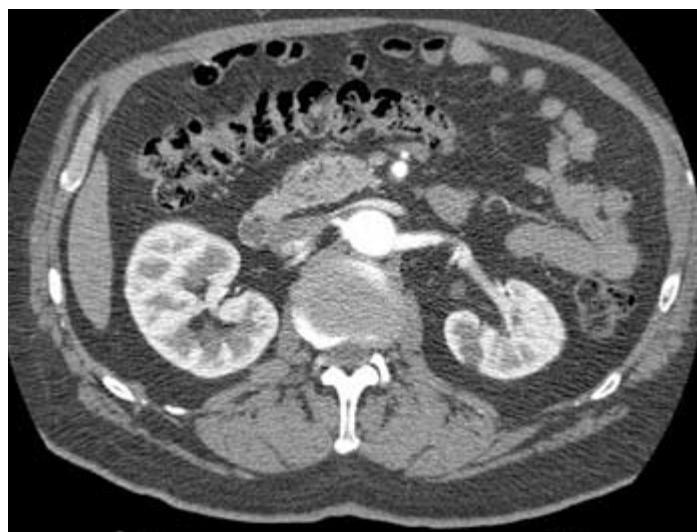

Figure 3 Axial CT scan image of the renal artery origins allows estimation of the degree of obliquity required for optimal imaging of the renal ostia.

Figure 4 Shown is selective arteriography of the right renal artery using hand-injected iso-osmolar contrast material through a complexly curved Simmons catheter.

right renal artery generally pursues a more consistent posterior course. For full delineation of lesions in the various segments, oblique and cranial-caudad rotated images may be necessary.

Adjunctive measures The performance of arteriographic imaging of the renal arteries also affords the surgeon the opportunity to employ other measures to characterize a renal artery lesion. For example, the hemodynamic effects of angiographically detected stenosis or the treatment thereof can be assessed by making direct pressure measurements proximal and distal to the lesion. In general, we consider any pressure gradient greater than 10 mm Hg to be indicative of hemodynamically significant renovascular disease. Additional anatomic information can be obtained by means of intravascular ultrasonography of the renal artery, which can provide detailed information on plaque morphology, vessel size, and potential dissection flaps to complement the data obtained through arteriography.^{39,40}

Arteriographic Findings

As noted (see above), the primary role for contrast arteriography in the treatment of renovascular disease is concerned with therapy rather than diagnosis. Angiography is most frequently performed to assess a renal artery lesion previously identified by means of renal duplex ultrasonography, CT arteriography, or magnetic resonance arteriography either before or as part of a therapeutic intervention. Most clinically significant renal artery lesions are caused by atherosclerotic disease or fibromuscular dysplasia (FMD), with a small minority occurring secondary to other pathologic states. Each of these two major pathologic entities is associated with specific imaging characteristics and specific treatment considerations.

Atherosclerotic renovascular disease Atherosclerosis of the renal artery accounts for roughly two thirds of all renovascular lesions. Elderly persons with multiple comorbid medical conditions and manifestations of atherosclerosis are most frequently affected.⁴¹⁻⁴⁴ Atherosclerotic renal lesions generally represent a continuation of a process that begins in the aorta and spills over into the origin of the renal vessels [see Figure 5]. These lesions are characterized by an eccentric, irregular narrowing of the ostium and the proximal portion of the renal artery [see Figure 6]. In the majority of cases, the lesions are limited to the ostia and the proximal renal artery, and the two sides are affected equally.⁴⁵ The aortic origin of the lesion has important implications for treatment. Placement of an endovascular stent into the proximal renal artery, without the aortic origin of the plaque being taken into account, may result in residual or recurrent disease. Occlusions of the renal artery are also common in patients with clinically significant lesions [see Figure 7] and frequently occur in the setting of contralateral renal artery stenosis.^{2,3}

Fibromuscular dysplasia FMD is a term used to describe a group of histologically distinct pathologic conditions of the arterial wall that most commonly affect the main renal artery and its branches. FMD of the renal artery, with resultant renal artery stenosis, is responsible for approximately 25% to 30% of treated cases of renovascular hypertension.⁴⁵ The lesions are usually categorized according to the layer of the arterial wall predominantly

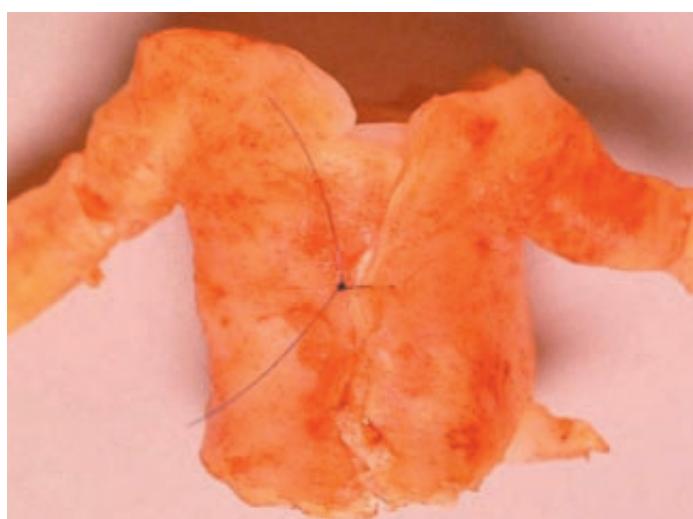

Figure 5 Aortic endarterectomy specimen demonstrates the pathologic basis of atherosclerotic renovascular disease.

Figure 6 Magnified preintervention aortogram demonstrates ostial right renal artery atherosclerotic stenosis.

involved—hence the terms medial fibroplasia, perimedial dysplasia, and intimal fibroplasia. Medial fibroplasia is the most common variant, representing 85% of recognized cases. It is encountered almost exclusively in women, most commonly in the third or fourth decade of life.^{45,46} The arteriographic pattern most frequently associated with medial fibroplasia resembles a string of

Figure 7 Aortogram demonstrates right renal artery stenosis and left renal artery occlusion with distal renal artery reconstitution.

beads [see *Figure 8*], an appearance created by weblike stenotic areas with intervening areas of poststenotic dilatation. These lesions are frequently unilateral, and they can also produce a renal artery aneurysm or dissection.⁴⁷ Stenotic medial fibroplasia of the main renal artery is among the lesions most amenable to endovascular treatment. In our view, however, the presence of branch vessel disease or aneurysms precludes such treatment.

Perimedial dysplasia accounts for approximately 15% of cases of FMD and is most commonly manifested by the appearance of multiple irregular stenoses without microaneurysms.⁴⁶ Intimal fibroplasia is the least common variant of FMD, representing fewer than 5% of recognized cases, and the typical lesions are smooth concentric stenoses.^{45,46} In general, perimedial dysplasia and intimal fibroplasia tend to respond less well to endovascular treatment than medial fibroplasia does.

Operative Planning

PATIENT PREPARATION

Patient preparation for renal artery PTAS is similar to that routinely carried out for diagnostic arteriography. Oral intake of food and liquid is stopped at midnight the evening before the procedure. Warfarin is discontinued at least 4 days beforehand; aspirin and clopidogrel are continued. Intravenous fluids and acetylcysteine are administered the evening before the procedure, with care taken to avoid fluid overload in patients with impaired cardiac function. Routine medications, with the exception of angiotensin-converting enzyme inhibitors and angiotensin receptor antagonists, are taken on the morning of the procedure with a sip of water. A first-generation cephalosporin is administered intravenously 30 minutes before the procedure unless the patient is allergic.

After the intervention, the patient is observed in the hospital overnight to check for access-site problems and severe alterations in blood pressure. Acetylcysteine is continued throughout the hospital stay, and oral administration of clopidogrel is initiated the evening after the procedure. The patient continues to take clopidogrel for at least 30 days after revascularization and remains on aspirin therapy indefinitely.

CORRELATION OF DIAGNOSTIC IMAGES WITH CLINICAL FINDINGS

Once the diagnostic portion of the procedure is completed, the images obtained are closely examined and correlated with the patient's clinical presentation. Intra-arterial pressure measurements are occasionally misleading in renal vessels. Because most renal arteries are approximately 5 to 6 mm in diameter, a stenotic lesion that causes a greater than 60% reduction in the luminal diameter leaves only 2.0 to 2.5 mm of patent lumen. A 4 or 5 French diagnostic catheter may completely occlude this narrowed lumen, thus resulting in an inaccurately low pressure measurement distal to the stenosis. Accordingly, it is our practice to assess the anatomic arteriographic information in the light of the functional significance of the lesion as determined by either renal vein renin assays or duplex ultrasonography.

MATERIALS AND INSTRUMENTS

The materials commonly used for renal artery PTAS at our center include various guide wires, catheters, sheaths, balloons, and stents [see *Table 1*]. The basic principles underlying the use of these devices are outlined more fully elsewhere [see **6:8 Fundamentals of Endovascular Surgery**].

Figure 8 Selective right renal arteriogram demonstrates findings indicative of medial fibroplasia.

Operative Technique

STEP 1: SECURING OF ACCESS TO RENAL ARTERY FOR THERAPEUTIC INTERVENTION

Once the decision for endovascular intervention is made, the patient is systemically heparinized, and the 5 French diagnostic cathe-

ter and the introducer sheath are exchanged over a 0.035 in. guide wire so that an access platform can be established that will provide secure renal artery access for the therapeutic intervention.

Most angioplasty and stenting devices in current use will pass through a 6 French lumen. Access options include guide sheaths and guide catheters. Common to both of these options is the provision of a long mechanical support segment for guide-wire placement that affords direct access to the renal artery for easy passage of therapeutic devices to the target lesion [see *Figure 9*]. Such systems vary in shape and diameter and come in multiple configurations to facilitate renal artery access in different situations.

After the tip of the guide catheter is positioned at or within the renal artery orifice, guide-wire access across the lesion is obtained. For all subsequent manipulations, the sheath or the guide catheter should not be advanced beyond the orifice, because the non-tapered tip may injure the vessel. Depending on the type, severity, and location of the lesion, a 0.35, 0.18, or 0.14 in. guide wire with a floppy radiopaque tip is chosen. The smaller guide-wire systems appear to have inherent advantages, in terms of ability to cross tighter stenoses, limitation of renal artery trauma, and liberation of emboli, but whether these apparent advantages are real remains to be proved. Once the guide wire is in place, the access platform is secured and remains in place until the intervention and any postintervention imaging are complete.

STEP 2: TRANSLUMINAL ANGIOPLASTY

With the guide wire secured distal to the lesion, therapeutic intervention may proceed. Both coaxial systems (in which the entire catheter is exchanged over the wire, so that an assistant is

required to control the wire during intervention and catheter exchange) and monorail or rapid-exchange systems (in which only the distal portion of the catheter is over the wire, so that a single operator can control the wire during intervention and catheter exchange) are available for renal artery intervention.

Regardless of the system chosen, the principles of intervention remain the same. Transluminal angioplasty of the renal artery may be performed either as the sole therapy for a renal artery lesion or as a means of predilating a lesion so that an endoluminal stent can be placed. Angioplasty may also be employed to treat recurrent renal artery stenoses after surgical or endovascular therapy. Angioplasty is an effective stand-alone therapy in most cases of main renal artery disease (FMD and nonostial atherosclerosis) but is frequently ineffective for atherosclerotic ostial and proximal renal artery disease.

The angioplasty balloon size is chosen on the basis of quantitative angiographic images. Direct cut-film images with ball-bearing or marker-catheter reference points may be used, as may the quantitative software packages available on most contemporary digital angiographic systems. In general, the angioplasty balloon should be slightly larger than the adjacent normal artery for primary treatment and somewhat smaller for predilation of a stenotic lesion. For predilation before endoluminal stent placement, we usually employ a 3 × 20 mm low-profile angioplasty balloon. This choice tends to make stent passage less traumatic and helps in estimating the stent diameter and length required.

During inflation of the angioplasty balloon, the aortic origin of most ostial plaques is indicated by the appearance of a visible "waist," and the image can be centered over a bony landmark to facilitate subsequent stent placement. It is not unusual for the patient to experience some discomfort during balloon inflation. This discomfort should resolve quickly when the balloon is deflated; if it does not, renal artery trauma should be suspected. It is our practice to inflate the balloon slowly to its fully inflated profile at the rated nominal pressure, then maintain inflation for 30 to 45 seconds before deflation.

Once the balloon has been completely deflated, it is removed, and selective angiography is repeated to assess the response of the lesion to angioplasty and check for complications. Guide-wire access must be maintained until the end of the procedure so that complications or unsatisfactory results (e.g., dissection or residual stenosis) can be addressed.

STEP 3: ENDOLUMINAL STENTING

Endovascular stent placement may be performed either as a primary procedure or as a secondary procedure in response to suboptimal results from angioplasty. Most FMD lesions and nonostial atherosclerotic lesions respond well to angioplasty alone. Secondary stent placement should, however, be considered for nonostial lesions that do not respond appropriately to angioplasty. Secondary stent placement is typically performed to address elastic recoil, residual stenosis (> 30%), pressure gradients (> 10 mm Hg), and myointimal flaps or dissections. Either balloon-expandable or, less commonly, self-expanding stents may be employed in the renal artery. Typically, balloon-expandable stents have greater radial strength and can be placed more precisely, whereas self-expanding stents are more flexible and conform more readily to the shape of the lumen. We employ balloon-expandable stents primarily in the treatment of ostial atherosclerotic lesions, where their advantages are particularly useful.

In general, the technical aspects of stent placement parallel those of transluminal angioplasty. Frequent hand injections of small amounts of contrast material through the guide sheath or catheter are employed to guide the stent into position across the lesion before deployment [see Figure 10]. After the stent has been deployed, a completion angiogram is performed while guide-wire access to the renal artery is maintained. This is accomplished by hand injection of contrast through the guide sheath or catheter. For the treatment of ostial or proximal renal artery lesions, it is preferable to position the stent with 1 to 2 mm extension into the aorta. Frequent hand injection of contrast material through the guide sheath allows precise placement of the stent and helps prevent misdeployment. If the stent is placed too far into the artery, the true renal orifice is not supported, and there is a greater chance of residual or recurrent disease.⁴⁸⁻⁵² Such recurrent disease often does not respond to further endovascular attempts; accordingly, it is advisable to use the shortest possible stent that will adequately support the lesion. In addition, a stent that extends well out into the distal renal artery can make later surgical options more difficult⁵³ and typically carries a higher failure rate.

A balloon-expandable stent is deployed by inflating the angioplasty balloon on which it is mounted. In the past, these stents had to be crimped and hand-mounted on the angioplasty balloon, which made their delivery somewhat insecure. Currently available stents, however, come securely premounted on low-profile deliv-

ery systems capable of passing across most lesions with minimal or no predilation. We deploy these stents with 1 to 2 mm extension into the aorta, guided by anatomic information provided by previous positioning over bony landmarks. Self-expanding stents, though not commonly applied to the treatment of renovascular disease, can also be employed in this setting. These devices are deployed by retracting an outer membrane of the delivery device to expose the stent. Care must be taken during deployment to ensure that foreshortening of the stent does not compromise coverage of the lesion.

After a stent is deployed, there may be residual narrow areas within the stent that necessitate balloon dilatation. These areas may be visible on fluoroscopic evaluation of the stent, or they may be detected during postdeployment selective renal angiography.

After all therapeutic measures have been completed, the technical result is assessed and undetected defects sought by means of repeat pressure-gradient measurements, intravascular ultrasonography, or both. When a satisfactory result is obtained, the guide wire and the sheath are removed and hemostasis is secured. Although it is possible to perform bilateral renal interventions in a single procedure, we prefer, when possible, to stage these interventions so as to minimize contrast loads.

Postoperative Care

Longitudinal follow-up of all patients undergoing renal revascularization is mandatory to check for recurrent disease, contralateral disease, and deterioration of clinical benefit, as well as other preventable cardiovascular and peripheral vascular conditions. Our current approach to follow-up entails clinical visits at 1, 3, 6, 9, 12, 18, and 24 months after renal artery PTAS, with renal duplex ultrasonography, blood pressure measurement, and serum creatinine measurement at each visit. After 24 months, this intensive early follow-up is relaxed to a yearly visit schedule if no conditions necessitating shorter visit intervals have been identified.

Recurrent disease after renal stenting is a significant concern, and disease that recurs within the stent itself can be a particularly challenging problem [see Figure 11a]. Because most such recurrences are related to intimal hyperplasia, repeat balloon angioplasty generally does little to improve the situation. Initial dilatation with a Cutting Balloon (Boston Scientific, Natick, Massachusetts) is extremely useful for releasing the fibrous scar tissue of the restenotic lesion and allowing subsequent dilatation to a larger diameter with a conventional angioplasty balloon. The Cutting Balloon consists of a noncompliant balloon with three or four atherotomes (microsurgical blades) mount-

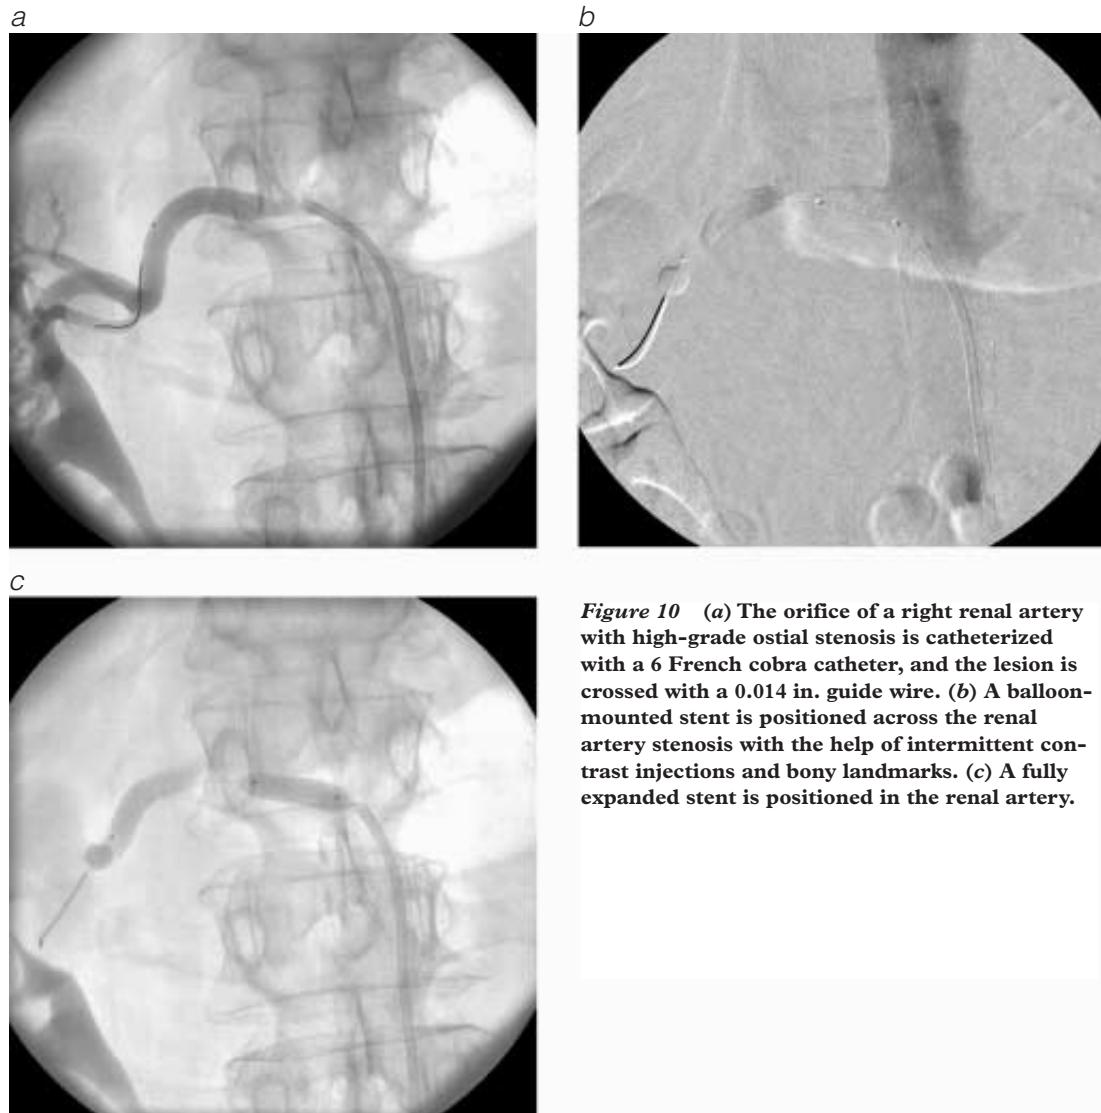

Figure 10 (a) The orifice of a right renal artery with high-grade ostial stenosis is catheterized with a 6 French cobra catheter, and the lesion is crossed with a 0.014 in. guide wire. (b) A balloon-mounted stent is positioned across the renal artery stenosis with the help of intermittent contrast injections and bony landmarks. (c) A fully expanded stent is positioned in the renal artery.

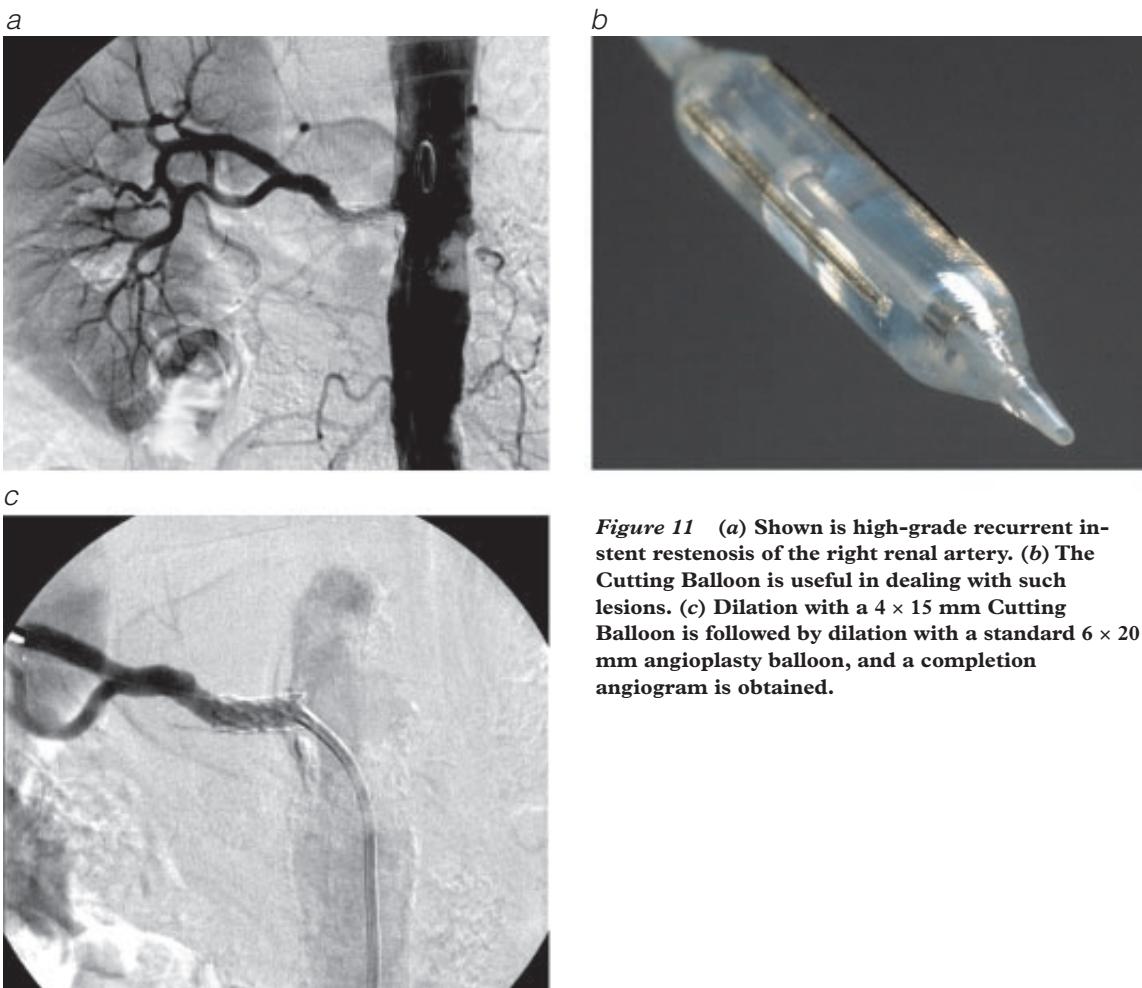

Figure 11 (a) Shown is high-grade recurrent in-stent restenosis of the right renal artery. (b) The Cutting Balloon is useful in dealing with such lesions. (c) Dilation with a 4×15 mm Cutting Balloon is followed by dilation with a standard 6×20 mm angioplasty balloon, and a completion angiogram is obtained.

ed longitudinally on its outer surface [see Figure 11b]. When the device is inflated, the atherotomes score the intimal hyperplasia within the stent; the balloon is then rotated and reinflated to score the lesion in multiple planes. To date, this technique has been used primarily in coronary arteries, but it has also been applied to the treatment of renal artery in-stent restenosis.⁵⁴ After the lesion has been scored, a larger balloon is inserted and inflated to redilate the lesion [see Figure 11c].

Complications

Complications can arise at any point during renal artery PTAS or during the early postoperative period. Potential complications include access-site complications (e.g., hematoma, pseudoaneurysm, retroperitoneal hemorrhage, arteriovenous fistula, and closure-device infection), contrast-mediated allergic reactions or nephrotoxicity, atheroembolism, and direct renovascular trauma. In a meta-analysis published in 2000, the reported complication rate after renal PTAS ranged from 0% to 40% (mean rate, 11%).⁵⁵ The most frequently reported complications were hematomas at arterial access sites. Severe complications occurred in 9% of patients and included renal failure, segmental renal infarction, perinephric hematoma, and renal artery thrombosis. The mean mortality was 1%.

A large single-center retrospective review of complications after endovascular treatment with renal artery stenting reported similar results.⁵⁶ Major complications occurred after 15 of 179 procedures (8.4%) and included renal infarction, permanently increased serum creatinine concentration, dialysis dependence, blood trans-

fusion, surgical intervention, and deep vein thrombosis. There was no apparent association between pretreatment patient characteristics and the subsequent incidence of major complications. Two patients (1.1%) died within 30 days after the procedure.

Outcome Evaluation

To be considered successful, renal artery revascularization should (1) improve quality of life, (2) reduce the incidence of adverse cardiovascular disease events, (3) slow or halt the progression of chronic renal insufficiency, (4) lower the incidence of dialysis-dependent renal failure, and (5) improve overall survival. Unfortunately, few studies addressing these clinical outcome measures have been performed or reported. Thus, the outcome of renal revascularization is currently assessed on the basis of (1) the extent to which the procedure is anatomically or technically successful and (2) the degree to which the procedure alleviates or cures associated hypertension and ischemic nephropathy. Technical success and the response of hypertension or renal dysfunction to therapy are assumed to be the mechanisms by which the five important clinical outcomes listed are achieved.

Interpretation of the results of renal artery PTAS as reported in the current literature is challenging. Despite the publication of hundreds of reports on this procedure, it remains unclear how renal artery PTAS compares with surgical renal revascularization and whether renal artery PTAS conveys any meaningful benefit to patients beyond what can be achieved with medical therapy alone.

These shortcomings in our understanding of renal artery PTAS (and of surgical renal revascularization, for that matter) stem largely from the lack of well-designed clinical trials investigating these questions. Such trials will ultimately be necessary to establish the utility and safety of renal artery PTAS in the treatment of renovascular disease. Until such trials are performed, interpretation of the existing literature is the only available guide to the prudent application of renal artery PTAS.

TECHNICAL SUCCESS

Technical success is defined on the basis of angiographic findings at the completion of renal artery PTAS. Criteria include complete stent coverage of the targeted lesion (if a stent was used) and residual diameter-reducing stenosis of less than 30%.⁵⁷ Angioplasty as stand-alone treatment of renovascular disease is of limited applicability, especially in cases of atherosclerotic disease of the renal ostia (the most commonly encountered lesion). The reason is that ostial renovascular disease usually represents the extension of aortic-based plaque, which possesses substantial inherent recoil and thus is resistant to dilatation unless mechanical support is added to help maintain the enlarged lumen.

A review of the literature on renal artery angioplasty for atherosclerotic renovascular disease determined that immediate technical success was reported in 86% of cases [see Table 2].⁵⁸⁻⁷⁰ The immediate technical success rate was higher when a stent was employed, especially in cases of ostial disease. A review of the literature on primary stenting for atherosclerotic renovascular disease determined that primary use of stents yielded an immediate technical success rate of 98% [see Table 3].^{5,48,50,51,65,70-89} The superiority of primary stenting for ostial lesions was confirmed in a prospective clinical trial.⁶⁵

HYPERTENSION RESPONSE

Three randomized, controlled studies have compared endovascular surgery with medical treatment of renovascular hypertension. These studies provide the best available data on the efficacy of endovascular therapy for managing hypertension, but they are limited in that they all investigated the use of renal artery angioplasty without primary stent placement. The first study involved 49 patients with unilateral renal artery stenosis who were randomly assigned to either angioplasty or best medical hypertension treatment.⁹⁰ The angioplasty group demonstrated no statistically significant decrease in blood pressure; however, it did demonstrate improvement in hypertension control, as evidenced by a significant reduction in the amount of antihypertensive medications required. The second study, reported by the Scottish and Newcastle Renal Artery Stenosis Collaborative Group, involved 55 patients who were randomly assigned to either angioplasty or best medical antihypertensive therapy.⁹¹ Patients with both unilateral and bilateral renal artery stenosis were included in this study. There was a modest improvement in blood pressure control in the angioplasty group, but this benefit was confined to those patients who had bilateral disease. None of the patients were cured of their hypertension. The third study—the largest prospective, randomized trial reported to date in this area—was performed by the Dutch Renal Artery Stenosis Intervention Cooperative Study Group.⁶⁶ A total of 106 patients were randomly assigned to either renal artery angioplasty or best medical therapy for renovascular hypertension. At 12 months, there was no significant reduction in either systolic or diastolic blood pressure, though multiple treatment crossovers occurred that might have skewed the results toward the best medical therapy arm. The authors concluded that

angioplasty had little advantage over antihypertensive therapy in the treatment of renovascular hypertension.

A 2000 meta-analysis examined data from retrospective reports describing a total of 1,322 patients who were treated with renal artery angioplasty or stenting.⁵⁵ The overall hypertension cure rate was 20%, and 49% of the patients had improved blood pressure control. In a similar review of data from 36 reports on primary renal angioplasty or stent placement for the treatment of atherosclerotic renal artery stenosis [see Tables 2 and 3], the reported treatment indications included hypertension, renal insufficiency, and a combination of the two. The percentage of patients cured of hypertension ranged from 0% to 32% (mean, 10%), and the percentage of patients experiencing improved blood pressure control ranged from 5% to 93% (mean, 53%).

To date, only one prospective, randomized, controlled study has compared endovascular treatment with surgical revascularization for the treatment of renovascular hypertension.⁶⁷ In this report, 58 patients with renovascular hypertension were randomly assigned to either surgical revascularization or angioplasty. In both groups, hypertension was cured or improved in approximately 90% of patients. However, more than half of the patients in whom angioplasty failed were switched to the surgical arm for revascularization. On the basis of these results, the authors recommended angioplasty as the treatment of choice for selected renovascular lesions contributing to renovascular hypertension, with aggressive follow-up and repeat intervention (endovascular and surgical) carried out as needed.

Another group of investigators, however, reported that the beneficial blood pressure response seen after open surgical repair for

failed angioplasty may be less than that seen in patients who undergo primary surgical repair without previous endovascular treatment.⁵³ Moreover, a previous endovascular procedure may make open surgical repair technically more demanding, especially if an endoluminal stent is present.

At present, there are no level I data demonstrating any association between improved hypertension control after renal artery PTAS and either increased survival or reduced morbidity and mortality from adverse cardiovascular events. In fact, very few reports contain any data on these important clinical outcomes, and those that do have not documented any significant differences between medical management and renal artery PTAS.^{66,90,91} There is some evidence in the surgical literature of associations between hypertension response and a decrease in adverse cardiovascular events; notably, however, these associations appear to exist only for persons whose renovascular hypertension is cured.²

RENAL FUNCTION RESPONSE

Several factors hinder accurate assessment of the effect of renal artery PTAS on renal function. To date, no prospective, controlled studies have compared renal function responses after medical, surgical, and endovascular treatment of renal artery stenosis. Most observational series report results from a diverse group of patients whose baseline renal function and subsequent responses to treatment vary widely. Interpretation of the existing renal function response data is further complicated by the insensitivity of serum creatinine measurement (the most commonly employed indicator of renal function in these studies) to changes in renal function, especially in patients with serum creatinine levels lower than 1.2 mg/dl.

These limitations notwithstanding, a number of reports published between 1989 and 2004 provided useful data on renal function response after renal artery PTAS, expressed in terms of change (or lack of change) in serum creatinine concentration [*see Tables 2 and 3*]. With improvement defined as a 20% or greater decrease in serum creatinine concentration, response rates ranging from 0% to 55% were observed (mean, 22%). These results are very similar to those reported in the 2000 meta-analysis cited earlier (range, 0% to 50%; mean response rate, 30%).⁵⁵ A number of authorities also make use of the concept of “stabilized” renal function, defined as a less than 20% change in serum creatinine concentration. By this definition, renal function was stabilized in the majority of patients included in the studies published between 1989 and 2004 (range, 23% to 100%; mean response rate, 53%) [*see Tables 2 and 3*]. Again, these results are very similar to those reported in the meta-analysis (range, 0% to 64%; mean response rate, 38%).⁵⁵ A significant percentage of treated patients (range, 0% to 48%; mean, 21%) also experienced post-PTAS worsening of renal function.

Although all investigators agree that worsened post-PTAS renal function represents a treatment failure, it is less clear whether an unchanged serum creatinine concentration should be considered beneficial to the patient. In one study, 88% of patients treated for renal dysfunction exhibited improved or stabilized serum creatinine levels after angioplasty, stenting, or both.⁹² Only 25% of patients, however, showed sustained responses over a 5-year follow-up period; the remainder demonstrated continuing deterioration of renal function. These results contrast sharply with those of reports addressing open surgical treatment of renal dysfunction, which documented durable improvement or stabilization rates of 85% to 93% and 5-year dialysis-free survival rates of 50% to

55%.²⁻⁴ Furthermore, patients with ischemic nephropathy whose renal function did not change after surgical revascularization had increased rates of death and dialysis dependence during follow-up that were similar to those noted in patients with poorer renal function after revascularization.^{2,3} These findings raise serious questions about the concept of stabilized renal function and suggest that improved postprocedural renal function may be the most pertinent surrogate outcome marker for predicting improved survival and dialysis independence.

LONG-TERM COMPLICATIONS

Complications and suboptimal outcomes may also develop in a delayed manner. The principal long-term complications include restenosis of the renal artery and inadequate durability of clinical benefit. Restenosis is a common occurrence with all catheter-based methods of revascularization. According to the meta-analysis cited earlier,⁵⁵ restenosis complicates 11% to 42% (mean, 26%) of renal artery angioplasties and 12% to 23% (mean, 17%) of renal artery stent procedures. Other studies have yielded very similar results [*see Tables 2 and 3*]. Restenosis may or may not be clinically significant. Accordingly, the decision whether to treat restenotic lesions should be made on the basis of the specific physiologic or clinical findings, not simply because restenosis is present.

The beneficial clinical responses noted after renal artery PTAS frequently are not durable. In two studies that reported on a total of 222 individuals undergoing renal artery PTAS, the investigators found that the clinical response, especially the renal function response, was transient.^{92,93} Overall, at 5 years, 50% to 70% of patients exhibiting a positive hypertension response and fewer than 50% of those exhibiting a positive renal function response (defined as improvement or stabilization) retained any benefit. This deterioration of clinical benefit occurred even though a patent renal artery was maintained in all cases. Such results stand in stark contrast to the documented durability of the clinical response after surgical revascularization and underscore the need for close lifelong follow-up of all patients undergoing renal revascularization.¹⁻⁴

OUTCOMES AFTER RENAL ARTERY PTAS FOR FMD

Patients with FMD respond to renal artery PTAS much differently from those with renal artery atherosclerosis. FMD is most commonly manifested as medial fibroplasia in a young woman. In general, balloon angioplasty appears to be an acceptable treatment for adult patients with such lesions, and this approach yields excellent technical success rates, good clinical benefit, and low morbidity. In a study addressing 85 renal artery stenoses in 66 FMD patients, hypertension was cured or improved in 98% of patients after renal angioplasty, and all patients with elevated creatinine levels exhibited improved or stabilized renal function.⁹⁴ Another study, involving a series of older FMD patients (mean age, 59 years) with longstanding hypertension (mean duration, 13 years), reported somewhat different blood pressure response results.⁹⁵ At follow-up more than 3 years later, hypertension was cured in 14% of patients and alleviated in 74%. Both studies supported the general consensus that medial fibroplasia of the main renal artery can be adequately treated by means of primary angioplasty, with stent placement reserved for technical failures. Furthermore, it appeared that a beneficial clinical response was seen after endovascular intervention and that this response was more pronounced in younger patients with a shorter duration of hypertension.

16 MESENTERIC REVASCULARIZATION PROCEDURES

Scott E. Musicant, M.D., Gregory L. Moneta, M.D., F.A.C.S., and Lloyd M. Taylor, Jr., M.D., F.A.C.S.

Mesenteric ischemia is encountered infrequently. To date, there have been no randomized, controlled trials comparing treatment modalities for either acute or chronic mesenteric ischemia. Consequently, decisions on how to treat this condition must be based on a few large case series in which a variety of operations were used.

Overall evaluation and management of acute mesenteric ischemia are addressed more fully elsewhere [see 6:4 *Acute Mesenteric Ischemia*]. In what follows, we focus specifically on the operative techniques used to treat mesenteric ischemia (whether chronic or acute) and discuss the available literature supporting their use. The appropriate technique for a particular patient varies according to the individual anatomy and the particular intraoperative findings.

The relevant surgical procedures may be conveniently divided into those employed for chronic mesenteric ischemia and those employed for acute ischemia.

Procedures for Chronic Intestinal Ischemia

PREOPERATIVE EVALUATION

J. E. Dunphy, in 1936, was the first to suggest that timely diagnosis and intervention for mesenteric artery occlusive disease may prevent intestinal infarction.¹ It is now clear that optimal treatment of mesenteric ischemia depends on prompt diagnosis and that a high index of suspicion is vital.

Patients with chronic intestinal ischemia generally, but not always, report experiencing colicky, dull, or aching abdominal pain, primarily located in the epigastrium but occasionally radiating to the back. Symptoms typically begin 15 to 30 minutes after eating and may last as long as 3 hours. Peritonitis is not a characteristic of reversible intestinal ischemia; rather, it is indicative of intestinal infarction. Chronic postprandial abdominal symptoms result in markedly reduced food intake (so-called food fear),² which generally leads to weight loss.

Physical examination often yields no significant abdominal findings. Abdominal bruits may be audible, but they are a non-specific sign. Patients often, but not always, show evidence of atherosclerotic disease in other vascular territories. Bowel habits vary, ranging from normal elimination to diarrhea or constipation.

Useful diagnostic tests include duplex ultrasonography, contrast angiography, and magnetic resonance angiography (MRA). Duplex scanning is effective in detecting visceral artery stenosis [see *Figure 1*] and may allow earlier detection of visceral artery stenosis associated with chronic mesenteric ischemia.^{3,4} By itself, however, it is not sufficient for planning a mesenteric revascularization procedure.

Arteriography is the primary imaging procedure employed in planning mesenteric revascularization for chronic intestinal ischemia [see *Figures 2 and 3*]. Lateral and anteroposterior views of the aorta are required for full evaluation of the severity of vis-

ceral stenosis or occlusion and the extent of collateral development. In most cases, a transfemoral Seldinger technique is suitable, though in the setting of iliofemoral occlusive disease, a transaxillary approach is occasionally required. Between 60 and 100 ml of contrast material is required for appropriate lateral and anteroposterior views of the abdominal aorta. Visceral artery lesions are usually ostial but may extend beyond the orifice of the vessel as a posterior plaque, especially in the superior mesenteric artery (SMA). Selective catheterization of the main intestinal arteries is rarely necessary and may be dangerous. Appropriate magnification views generally allow characterization of the proximal SMA beyond its origin, even without selective catheterization of the SMA. Intra-arterial digital subtraction techniques are usually adequate for lateral views, and they require less contrast material than other techniques. Arteriography also demonstrates coexisting lesions of the aorta and of the renal and iliac arteries that may be important in planning revascularization.

OPERATIVE PLANNING

Essentially all patients with peripheral artery disease have concomitant coronary artery disease (CAD). Although no symptoms of CAD may be evident, care must still be taken to provide perioperative cardiac protection. Perioperative beta blockade and antiplatelet therapy should be routinely employed in all patients undergoing elective procedures.

If the patient is undergoing a bypass procedure, the choice of graft material should be addressed. In general, prosthetic grafts

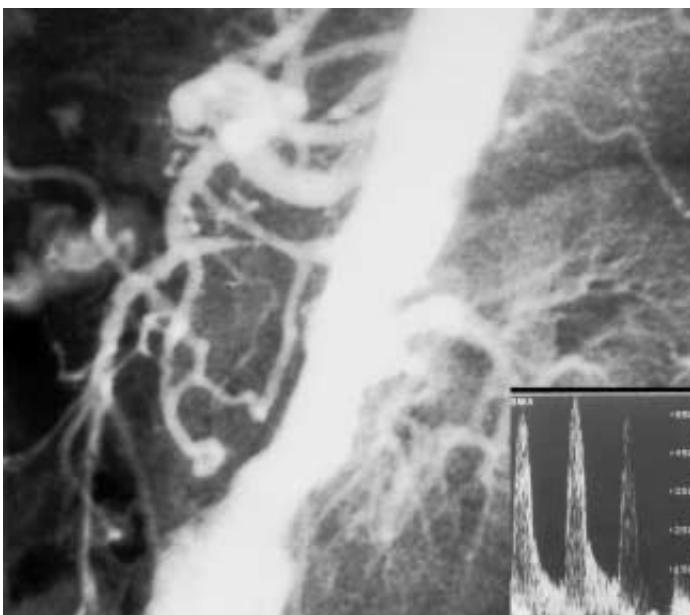

Figure 1 Example of duplex spectral waveform with comparative arteriogram in patient with SMA stenosis.

Figure 2 Lateral aortogram clearly shows moderate stenosis of proximal celiac artery and occlusion of SMA (arrow) in patient with intestinal ischemia.

work well for mesenteric artery bypass. However, the entire abdomen and both legs should still be included in the operative field in case autologous vein proves necessary for the bypass conduit. Autologous vein is often required in cases involving bowel resection and may also be preferable for bypasses to smaller visceral vessels. If an autologous vein bypass procedure is planned, preoperative duplex scanning of the greater saphenous and femoral veins is recommended to facilitate selection of the best available vein for the conduit.

OPERATIVE TECHNIQUE

Visceral Endarterectomy

Visceral endarterectomy for treatment of mesenteric ischemia was first described in 1958 by Shaw and Maynard,⁵ who performed endarterectomy of the SMA in a blind retrograde fashion through a distal arteriotomy. At present, retrograde endarterectomy cannot be recommended.

The SMA can be approached directly once control of the suprarenal aorta has been obtained.⁶ A longitudinal incision is made across the origin of the SMA, and an endarterectomy is performed. In most patients, the exposure is limited. This direct approach may be considered when the SMA is widely separated from the renal arteries and the visceral aorta is relatively free of disease; however, this scenario is uncommon.

A more versatile endarterectomy technique is transaortic endarterectomy.⁷ This procedure involves a posterolateral approach to the aorta, in which the aorta is exposed transperitoneally with medial visceral rotation. Alternatively, a completely retroperitoneal approach may be taken. The main disadvantage of the retroperitoneal approach is that it restricts the surgeon's ability to assess the bowel at the completion of revascularization.

Transaortic endarterectomy *Step 1: incision and initial approach.* A midline incision is recommended. A complete medial visceral rotation is performed, with the left kidney left in its bed.

Step 2: exposure. The lateral aorta is exposed, and the celiac artery and the SMA may be identified anteriorly; the left renal artery lies posteriorly.

Step 3: endarterectomy. A trapdoor incision is made in the aortic wall in such a way as to encompass the orifices of the SMA and the celiac artery. Partial occlusion of the aorta with a clamp is sometimes possible, but in most cases, complete aortic occlusion is required. If necessary, the aortotomy can be extended distally and posteriorly to include the renal artery orifices as well.

Among the advantages of this operation are that it permits simultaneous endarterectomy of the aorta and all visceral vessel orifices and that it does not require the use of prosthetic material [see Figure 3]. The disadvantages include the potential risks associated with suprarenal clamping (e.g., cardiac overload, renal and lower-extremity embolization, and ischemia). Because of

Figure 3 Lateral aortogram showing so-called coral reef atheroma involving visceral aorta with occlusion of origin of SMA.

these risks, the need for more extensive dissection, and the unfamiliarity of most surgeons with this procedure, arterial bypass procedures are generally preferred for treatment of chronic mesenteric ischemia.

Mesenteric Arterial Bypass

Technical considerations *Single-vessel versus multiple-vessel revascularization.* There are two schools of thought on the extent of revascularization for chronic mesenteric ischemia. Proponents of so-called complete revascularization advocate revascularization of both the celiac artery and the SMA and suggest that this approach makes recurrent ischemia less likely should one graft or graft limb undergo thrombosis.⁸ In a 1992 study, overall graft patency and survival were better in patients who underwent multiple-vessel bypass than in those who underwent single-vessel bypass. The investigators concluded that multiple-vessel bypass patients were likely to remain asymptomatic because of the presence of additional grafts or graft limbs that remained patent.⁸

Others maintain that the critical vessel involved in chronic mesenteric ischemia is the SMA and argue that bypass to the SMA alone is a relatively simple procedure that relieves symptoms of mesenteric ischemia. In a 2000 study evaluating 49 patients who underwent bypass to the SMA alone, the 9-year primary assisted graft patency rate was 79% and the 5-year survival rate was 61%⁹—results equivalent to those noted in contemporary studies of multiple-vessel revascularization for chronic intestinal ischemia.¹⁰

Antegrade versus retrograde bypass. Mesenteric bypass grafts may originate either above or below the renal arteries. Bypass grafts are considered antegrade if they originate on the anterior surface of the abdominal aorta cephalad to the celiac artery, ret-

rograde if they originate from the infrarenal aorta or a common iliac artery. Antegrade bypass from the supraceliac aorta, using either prosthetic material or autologous vein, has certain advantages, including a straight graft configuration that minimizes turbulence and graft kinking and, typically, reduced atherosclerotic calcification in the supraceliac aorta.¹¹ The disadvantages of antegrade bypass are similar to those of visceral endarterectomy and derive from the need to clamp the supraceliac aorta for the proximal anastomosis. As with visceral endarterectomy, partial occlusion clamping is theoretically possible but not always practical. Clamping of the supraceliac aorta may increase the risk of cardiac events, visceral or renal emboli, and ischemia. One prerequisite for use of the supraceliac aorta in an antegrade bypass is that the vessel must be angiographically normal to ensure that it can safely be clamped. It should also be kept in mind that reoperation on the supraceliac aorta is difficult: once this site has been used, reexposure generally is not safe.

Antegrade bypass *Step 1: incision and initial approach.* Supraceliac aorta–visceral artery bypass is performed through an upper midline incision. Self-retaining retractors are helpful.

Step 2: exposure. The dissection begins with division of the gastrohepatic ligament and retraction of the left lobe of the liver to the right, followed by incision of the diaphragmatic crus and exposure of the anterior aspect of the aorta.

Step 3: choice of graft. In clean cases with no intestinal necrosis or perforation, we use woven Dacron bifurcated grafts. If a single-vessel bypass is to be performed, a single limb is cut from the bifurcated graft. Autologous vein grafts are usually reserved for

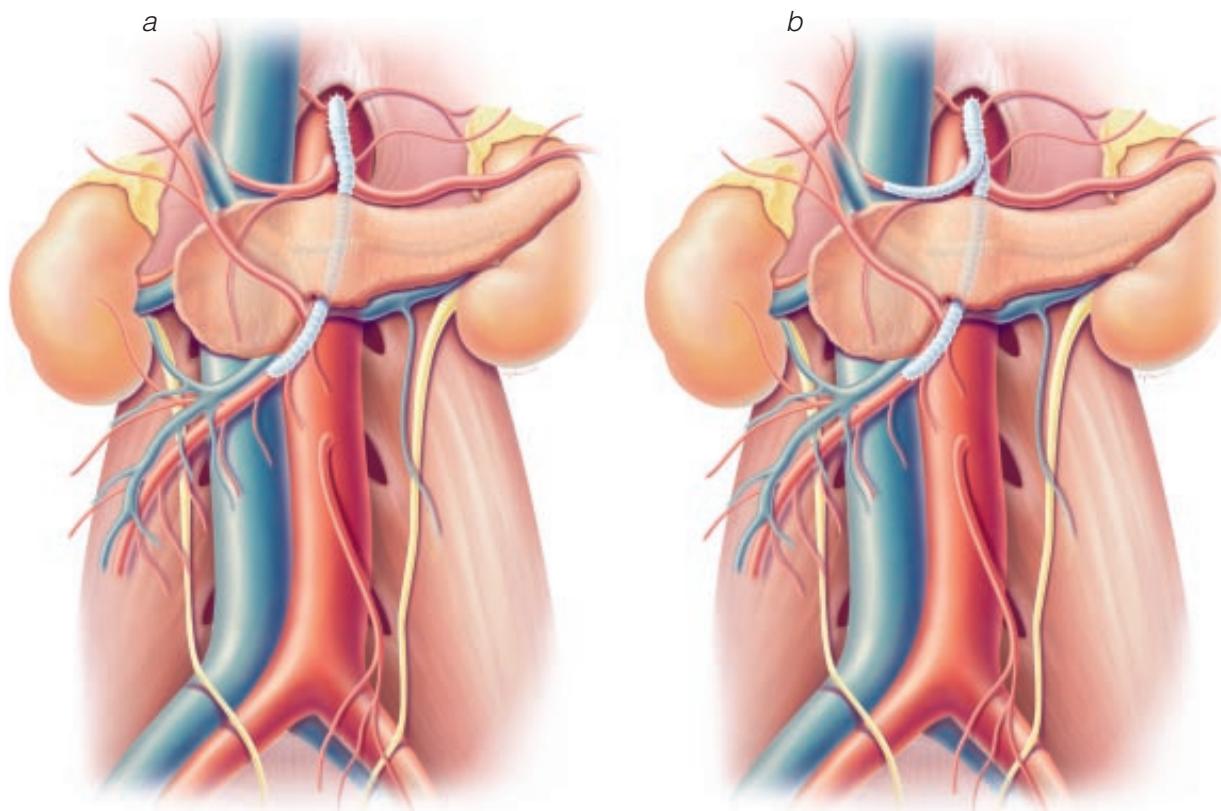

Figure 4 Arterial bypass: antegrade. Shown is bypass from supraceliac aorta to SMA alone (a) or to hepatic artery and SMA (b).²⁸

contaminated cases. The femoral vein is an excellent autogenous conduit for mesenteric arterial bypass.

Step 4: anastomosis of graft to supraceliac aorta and visceral artery. If the celiac artery alone is to be revascularized, the usual procedure is to perform an end-to-side proximal anastomosis to the aorta, followed by an end-to-side distal anastomosis to the common hepatic artery. If the SMA alone is to be revascularized, it is generally necessary to tunnel the graft beneath the pancreas to the inferior border of the pancreas, then perform an end-to-side anastomosis to the SMA at that level [see Figure 4a]. Extreme care must be exercised in developing the retropancreatic tunnel. If this area appears too narrow or is scarred as a result of previous pancreatic inflammation, the graft should be tunneled anterior to the pancreas to ensure that it is not compressed and to avoid causing bleeding from disrupted pancreatic veins.¹² If a prepancreatic tunnel is required, an autogenous conduit should be considered because the graft will be lying adjacent to the posterior wall of the stomach. If both the celiac artery and the SMA are to be revascularized from the supraceliac aorta, a bifurcated prosthetic graft is attached to the supraceliac aorta proximally, with one distal limb anastomosed to the hepatic artery and the other to the SMA [see Figure 4b].

Retrograde bypass In a retrograde bypass, the infrarenal aorta or a common iliac artery is used as the inflow vessel. One clear advantage of this procedure is that the approach to the infrarenal aorta is more familiar to most surgeons. Another is that dissection and clamping of the infrarenal aorta are less risky than dissection and clamping of the supraceliac aorta. Yet another is that the surgeon can work within a single operative field. Once the self-retaining retractor is placed, the operation on the infrarenal aorta and the SMA can be performed without further adjustment of the retractor.

Step 1: incision and initial approach. Here too, a midline incision and a transperitoneal approach are preferred. The transverse mesocolon is retracted upward, and the ligament of Treitz is divided.

Step 2: exposure. After division of the ligament of Treitz, the duodenum and the small bowel are retracted to the right. The SMA may then be identified arising from beneath the inferior border of the pancreas. The retroperitoneum is divided distally along the aorta to a point just beyond the level of the aortic bifurcation. The distal aorta and both common iliac arteries are assessed to allow determination of the proper location for the proximal anastomosis.

Step 3: choice of graft. As a rule, grafts made of Dacron or of ringed, reinforced expanded polytetrafluoroethylene (ePTFE) are preferred. Problems may arise when retrograde bypasses are performed with autologous vein grafts, in that such grafts are prone to kinking when the viscera are replaced. When a retrograde vein bypass is performed, the graft may be brought straight up from the right iliac artery so that it lies between the aorta and the duodenum, then anastomosed to the posteromedial wall of the SMA.

Step 4: anastomosis to infrarenal aorta or common iliac artery and SMA. Our preference is to use the area near the junction of the aorta with the right common iliac artery for the proximal anastomosis. (Short grafts originating from the midportion of the infrarenal aorta, though commonly used, are prone to kinking when the viscera are returned to their normal position.) The graft

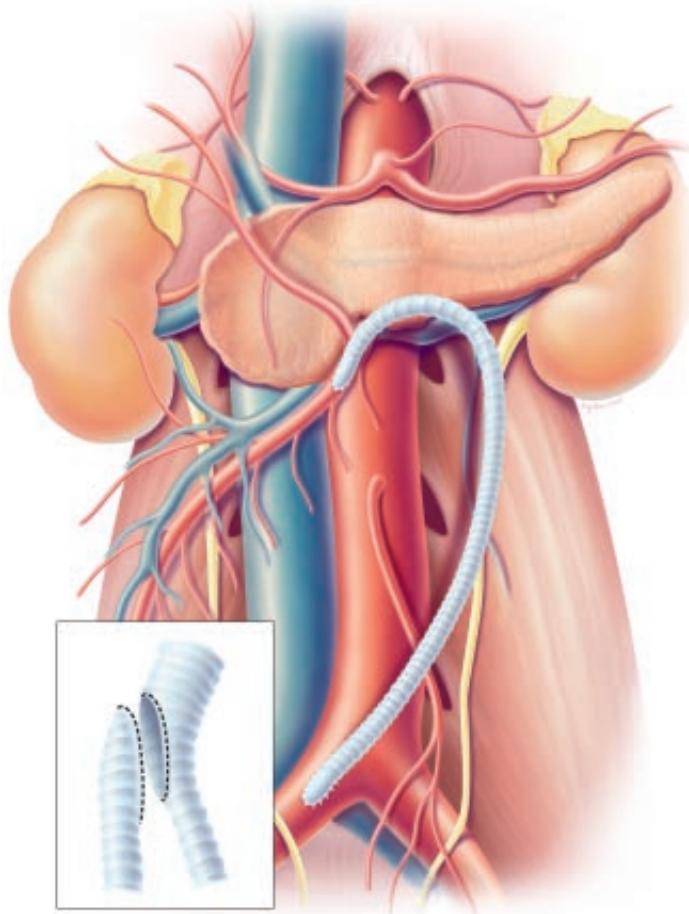

Figure 5 Arterial bypass: retrograde. Shown is bypass from iliac artery to SMA.²⁸

to the SMA is passed cephalad, turned anteriorly and inferiorly 180°, and anastomosed to the anterior wall of the SMA just beyond the inferior border of the pancreas.¹² In this manner, a gentle C loop is formed that, if placed correctly, keeps the graft from kinking when the viscera are restored to their anatomic position after retractor removal [see Figure 5]. The ligament of Treitz and the parietal and mesenteric peritoneum are closed over the graft to exclude it from the peritoneal cavity.

Endovascular Techniques

Early reports describing the use of percutaneous transluminal angioplasty (PTA) to treat visceral atherosclerotic lesions indicated that initial technical success rates were as high as 80% but that recurrence rates ranged from 20% to 40%.^{12,13} In a 1996 study of PTA in 19 patients who were considered high risk, the initial success rate was 95%, and the recurrence rate was 20% at 28 months.¹⁴ In a subsequent study of 25 patients who underwent angioplasty and stenting of the celiac artery or the SMA for chronic visceral ischemia, the initial technical success rate was 96%, and the initial clinical response rate was 88%.¹⁵ At 6 months, 92% of the stents remained patent.

COMPLICATIONS

Technical

The main technical complication of mesenteric bypass is acute graft thrombosis. This event is rare, but when it occurs, prompt

recognition is essential to prevent intestinal infarction. Kinking and compression of the graft are the most common causes of this condition. If the retrograde graft is too long, the redundancy makes it more susceptible to kinking. Similarly, if the graft is not positioned so as to form a gentle C loop, it is at risk for kinking when the viscera are returned to their normal position. An antegrade graft that is too long is equally at risk for kinking and occlusion. When an antegrade bypass is tunneled behind the pancreas, an adequate amount of space must be present to ensure that the graft is not compressed. In general, prosthetic grafts are more resistant to kinking and compression than vein grafts are.

Identification of perioperative graft occlusion is hindered by postoperative incisional pain, fluid shifts, fever, and leukocytosis, all of which are common in the postoperative period and may mask signs of intestinal ischemia. Patients with chronic mesenteric ischemia often have symptoms only when eating and thus may be asymptomatic in the postoperative period until they resume oral feeding. For these reasons, we advocate evaluating the graft early in the postoperative period with either conventional contrast angiography or computed tomographic angiography [see Outcome Evaluation, below].

Additional technical complications may occur as a result of clamp placement. Clamping of the supraceliac aorta can lead to renal atheroemboli or ischemia. These problems can be minimized by using a supraceliac clamp only on an angiographically normal aorta.

Systemic

Myocardial infarction is the most common cause of mortality in patients treated for mesenteric ischemia. Pulmonary compromise is also a common systemic complication of mesenteric revascularization. Renal failure after mesenteric revascularization is more common in patients with preoperative renal insufficiency.¹⁶ Mortality is markedly increased when renal failure occurs postoperatively.¹⁶ Postoperative renal insufficiency can be minimized by administering mannitol, furosemide, and, possibly, vasodilators intraoperatively.

Patients who undergo mesenteric revascularization occasionally experience a profound reperfusion syndrome manifested by acidosis, pulmonary compromise, and coagulopathy. We recommend administering sodium bicarbonate (to minimize the effects of metabolic acidosis) and mannitol (for its free radical-scavenging properties) before restoring intestinal perfusion.

OUTCOME EVALUATION

Restoration of pulsatile flow to the small bowel usually results in immediate active peristalsis and intestinal edema. The technical success of surgical revascularization is assessed intraoperatively through visual examination of the intestine and continuous-wave Doppler examination of the distal mesenteric vasculature and the bowel wall. Doppler signals should be heard along the antimesenteric border, and pulses should be palpable in the mesentery. Intraoperative duplex scanning may also be used to visualize anastomotic sites directly.¹⁷

Electromagnetic flow measurements can be helpful in evaluating the adequacy of mesenteric revascularization. Such measurements must be made after all packs and retractors have been removed. In most cases, the flow rate through the graft should be between 500 and 800 ml/min, but flow rates as high as 1,000 ml/min may be recorded.¹²

To confirm technical success after mesenteric revascularization, we advocate routine postoperative imaging of the graft. Ideally, this is done early in the postoperative period. Catheter-

based contrast angiography is optimal for evaluating the bypass graft and the distal vasculature, allowing identification of anastomotic stenoses, kinking, or, in the case of autologous grafts, narrowing caused by valves [see Figure 6a]. If a technical defect is discovered, reoperation and correction are required to ensure prolonged patency. In the past few years, we have started evaluating selected patients perioperatively with CT angiography. This modality is less invasive than traditional contrast angiography, but it still requires administration of contrast material and exposure to radiation [see Figure 6b].

Duplex ultrasonography has been used for postoperative graft surveillance after mesenteric revascularization.¹⁸ At present, there are no validated criteria for determining what constitute normal velocities within a mesenteric bypass graft. Undoubtedly, duplex-derived peak systolic velocities and end-diastolic velocities depend on the caliber of the graft, whether the graft supplies both the celiac artery and the SMA, and the length of the graft. The lack of validating data notwithstanding, we routinely use postoperative duplex scanning to establish baseline values and to permit comparisons for follow-up evaluation of graft patency. If markedly elevated, focal peak systolic velocities are recorded—especially if they increase on serial examinations—a contrast angiogram should be obtained to confirm graft stenosis. Duplex scanning can be difficult in the early postoperative period because of incisional tenderness and the increased intra-abdominal gas associated with postoperative ileus.

Procedures for Acute Intestinal Ischemia

PREOPERATIVE EVALUATION

As in the evaluation of patients with possible chronic mesenteric ischemia, a high index of suspicion is of primary importance in the evaluation of patients with possible acute mesenteric ischemia [see 6:4 *Acute Mesenteric Ischemia*]. Most cases of acute intestinal ischemia result either from thrombosis of a preexisting stenotic lesion or from embolization¹⁹ (most frequently to the SMA). Cardiac emboli are the most common variety, though tumor emboli²⁰ and atheroemboli are seen as well. Atheroemboli generally result from iatrogenically induced cholesterol embolization caused by aortic catheterization. The prognosis for acute intestinal ischemia of embolic origin is more favorable than that for ischemia of thrombotic origin. Emboli typically lodge distally in the SMA distribution, and therefore, the proximal intestine is still partially perfused.¹⁹ In contrast, thrombotic occlusion occurs at the origin of the vessel, resulting in complete interruption of midgut perfusion.

Acute, severe abdominal pain that is out of proportion to the physical findings is the classic manifestation and is strongly suggestive of intestinal ischemia. The duration of symptoms does not appear to correlate with the degree of intestinal infarction.²¹ Peritonitis is initially absent, but vomiting and diarrhea may be present, and occult gastric or rectal bleeding may be identified in as many as 25% of patients.²¹

There are no reliable serum markers for acute intestinal ischemia. Leukocytosis, hyperamylasemia, or elevated lactate levels may be present, but these findings are insensitive and inconsistent. Abdominal radiographs may reveal dilated bowel loops and, occasionally, thickened bowel wall, but these findings are similarly inconsistent. In theory, duplex ultrasonography may be helpful, but in practice, its applicability is often limited by the gaseous visceral distention frequently associated with acute intestinal ischemia.

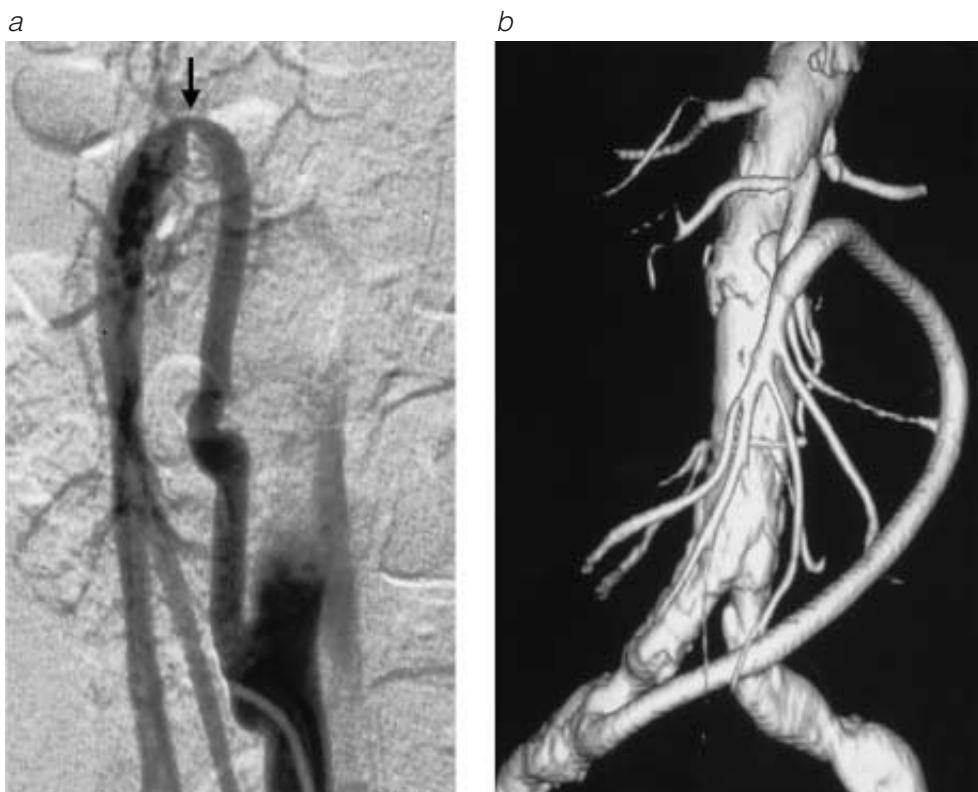

Figure 6 Routine postoperative imaging is performed to confirm technical success after revascularization. (a) Postoperative arteriogram shows iliac artery-SMA saphenous vein graft with kink (arrow). This problem was asymptomatic and was corrected by reoperation on postoperative day 5. (b) Postoperative CT arteriogram shows retrograde iliac artery-SMA prosthetic graft. C (hook) configuration of distal anastomosis provides antegrade flow into SMA.

The use of preoperative arteriography to diagnose acute ischemia is controversial. Acute intestinal ischemia is a true surgical emergency, and delaying treatment to perform arteriography could result in further intestinal infarction. Angiography may be considered in patients who have abdominal pain without any other signs or symptoms of systemic illness [see Figure 7]. In patients who have rebound tenderness, rigidity, or evidence of toxicity or shock, emergency exploration is indicated.

OPERATIVE PLANNING

Patients with acute intestinal ischemia who present with evidence of toxicity must be resuscitated expeditiously to ensure that surgical intervention is not delayed. Once it is determined that surgery is indicated, no further delay is justified. The patient is placed supine on the operating table, and the entire abdomen and both legs are prepared. As in operative treatment of chronic intestinal ischemia, the possibility that autologous vein will be needed for bypass grafting must be anticipated.

OPERATIVE TECHNIQUE

Intraoperative Considerations

Mesenteric revascularization and bowel resection The goals of surgical therapy are to restore normal pulsatile inflow, to ensure that questionably viable bowel is adequately perfused, and to resect any clearly nonviable bowel. During abdominal exploration, the viability of the intestine and the status of the blood flow to the SMA are assessed with an eye to determining the appropriate treatment. The surgeon should be prepared to perform both intestinal revascularization and intestinal resection. Seg-

ments of clearly viable bowel are often interspersed with segments of marginally viable bowel and segments of necrotic bowel. Acutely ischemic bowel that is not yet necrotic may appear deceptively normal. Mildly to moderately ischemic bowel may exhibit

Figure 7 Preoperative arteriogram shows embolic occlusion of SMA distal to its origin.

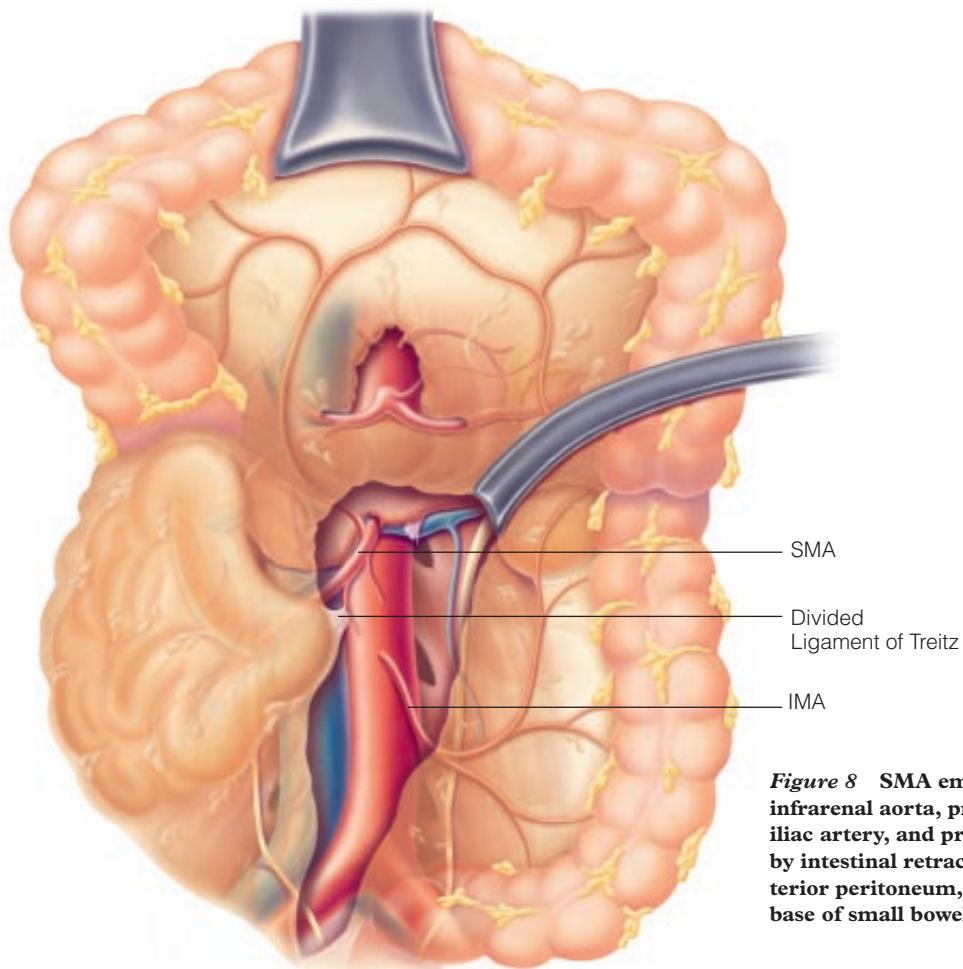

Figure 8 SMA embolectomy. Exposure of infrarenal aorta, proximal right common iliac artery, and proximal SMA is achieved by intestinal retraction and division of posterior peritoneum, ligament of Treitz, and base of small bowel mesentery.²⁹

loss of normal sheen, absence of peristalsis, and dull-gray discoloration. Other objective signs of ischemia are the absence of a palpable pulse in the SMA or in its distal branches, the absence of visible pulsations in the mesentery, and the absence of flow on continuous-wave Doppler examination of the vessels of the bowel wall. The small bowel may be deeply cyanotic yet still viable. In most cases, if there is any doubt, bowel resection should not be performed until after revascularization.

The distribution of ischemic changes provides valuable information about the cause of the ischemia. SMA thrombosis often results in ischemia to the entire small bowel, with the stomach, the duodenum, and the distal colon spared; in severe cases, the entire foregut may be ischemic. In contrast, ischemia secondary to SMA embolism generally spares the stomach, the duodenum, and the proximal jejunum because the emboli tend to lodge at the level of the middle colic artery rather than at the origin of the SMA. The choice of operation for revascularizing the bowel depends on the underlying causative condition. Embolectomy is indicated for arterial embolism, whereas bypass is indicated for thrombotic occlusion.

Revascularization of the acutely ischemic intestine In patients with very advanced intestinal ischemia, widespread bowel necrosis may be obvious. This situation invariably proves fatal, and thus, revascularization is not indicated. In many patients, however, substantial portions of the bowel are ischemic but not frankly necrotic. Whether such bowel segments can be restored to viability cannot be accurately predicted. In most instances, therefore, revascularization should precede resection.

Restoration of normal flow to the SMA can produce remarkable changes in an ischemic bowel. Because these changes do not always occur immediately, it is often necessary to preserve questionably viable portions of the bowel initially and then perform a second-look laparotomy within 12 to 36 hours. If the questionably viable bowel is not in significantly better condition at the time of the second-look operation, it should be resected. Occasionally, however, even a third look is prudent. Revascularized intestine that was profoundly ischemic may swell dramatically. Temporary abdominal closure with mesh may permit tension-free abdominal closure, prevent abdominal compartment syndrome, and perhaps even improve intestinal perfusion by reducing intra-abdominal pressure.

Superior Mesenteric Artery Embolectomy

Step 1: incision and initial approach Again, a midline incision is made, and a transperitoneal approach is taken.

Step 2: exposure of SMA at root of mesentery The SMA is exposed after division of the ligament of Treitz at the base of the transverse colon mesentery. The duodenum and the small bowel are retracted to the right [see Figure 8]. The visceral peritoneum is incised above the ligament of Treitz, just cephalad to the third portion of the duodenum. The SMA should be readily palpable in this location as it crosses over the third portion of the duodenum. The dissection is continued to obtain sufficient proximal and distal control of the vessel. Heparin is administered, and the vessel is clamped proximally and distally.

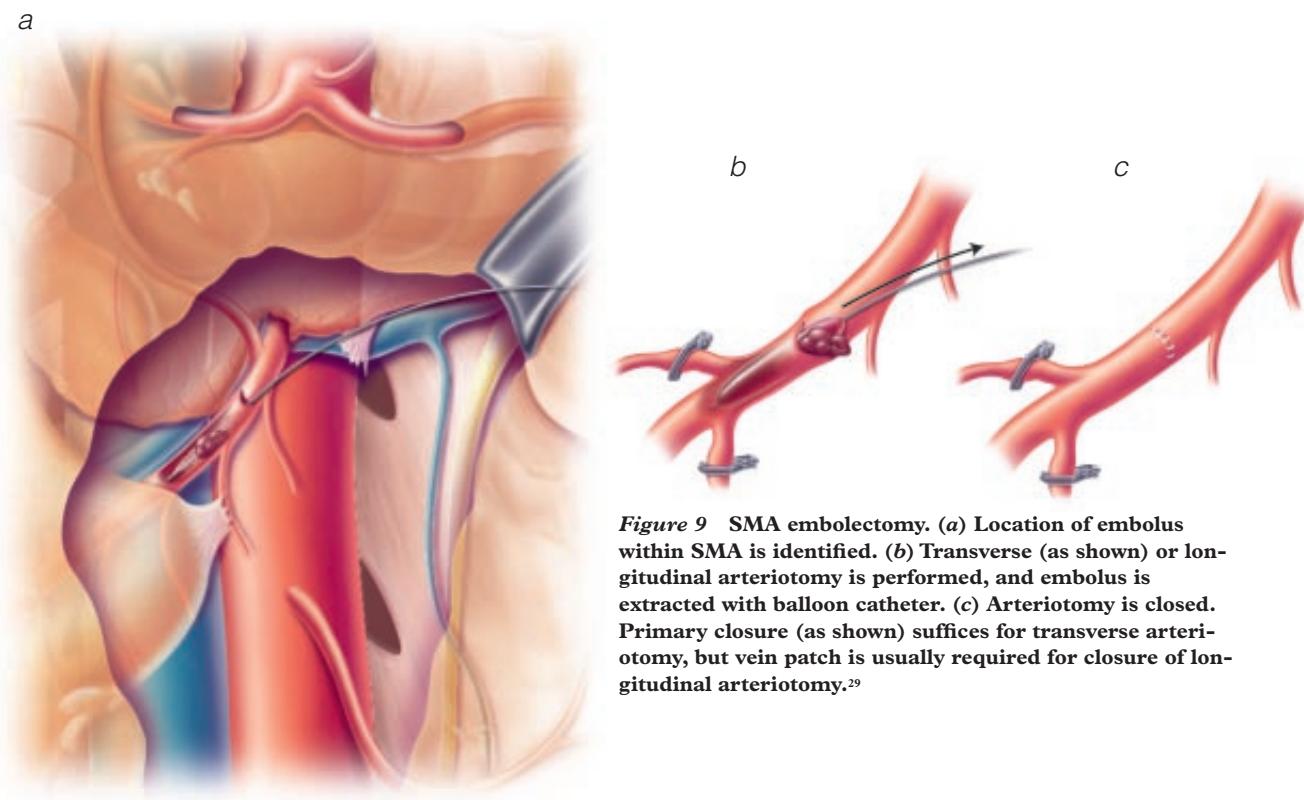

Figure 9 SMA embolectomy. (a) Location of embolus within SMA is identified. (b) Transverse (as shown) or longitudinal arteriotomy is performed, and embolus is extracted with balloon catheter. (c) Arteriotomy is closed. Primary closure (as shown) suffices for transverse arteriotomy, but vein patch is usually required for closure of longitudinal arteriotomy.²⁹

Step 3: arteriotomy An arteriotomy is then made in the SMA. The incision may be either transverse or longitudinal. We prefer to perform a longitudinal arteriotomy if there is any possibility that a bypass graft may be needed. The arteriotomy should be made approximately 2 to 3 cm distal to the origin of the SMA, though alternative placements may be appropriate on occasion, depending on the anatomy and the estimated location of the occlusion [see Figures 9a, b].

Step 4: embolectomy Proximal embolectomy should be performed first to ensure adequate inflow. A 3 or 4 French balloon catheter is sufficient in most cases. If very good pulsatile inflow is not achieved after embolectomy, then thrombosis of a stenotic lesion is likely to be the underlying cause of the acute intestinal ischemia, and a bypass graft should be placed. Even when inflow is apparently adequate, a bypass should be strongly considered if the proximal SMA is palpably abnormal.

The narrowness and fragility of the distal SMA and its branches can make distal embolectomy particularly challenging. It is best to use a 2 French embolectomy catheter for this procedure. The catheter must be passed gently, without undue force.

Step 5: closure Once all possible thrombus has been removed, the arteriotomy is closed. A transverse arteriotomy may be closed primarily with interrupted monofilament sutures [see Figure 9c]; however, a longitudinal arteriotomy frequently must be closed with an autologous vein patch. If adequate flow is not restored after the clamps are removed, the arteriotomy is used as the distal anastomotic site of a bypass graft.

Superior Mesenteric Artery Bypass

Patients with SMA thrombosis who are seen early enough and who have no intestinal necrosis may undergo SMA bypass grafting with a prosthetic conduit. At exploration, many of these

patients have fluid within the peritoneal cavity. This finding is not, in itself, a contraindication to the use of a prosthetic graft. However, if the patient has necrotic bowel that must be resected or if perforation has occurred, a prosthetic graft should not be used. In these situations, an autologous vein graft is preferred. A good-quality vein is mandatory; if the saphenous vein is inadequate, the femoral vein may be used instead.

The techniques of mesenteric bypass for acute intestinal ischemia are identical to those for chronic intestinal ischemia. Because these patients are often acutely ill, it is vital to perform the operation rapidly and efficiently. In the acute setting, bypass to the SMA alone is strongly preferred [see Figure 10]. As a rule, a retrograde approach, using the infrarenal aorta or a common iliac artery for inflow, is best; the supraceliac aorta is used for inflow only if the infrarenal vessels are unsuitable for this purpose. Even highly calcified iliac arteries can be used for inflow, provided that there is no significant pressure gradient and that the surgeon is familiar with intraluminal balloon occlusion techniques for proximal and distal control.

Endovascular Techniques

It would seem reasonable that endovascular therapies might come to play a role in the treatment of acute intestinal ischemia, given that a preoperative angiogram is usually feasible in stable patients. Several groups have reported treating acute arterial embolism with intra-arterial thrombolysis^{22,23}; others have reported treating acute embolism, as well as thrombotic occlusion, with PTA.^{24,25} Although a degree of anecdotal success with these techniques has been achieved in selected cases, it should be kept in mind that reliance on endovascular therapy alone for presumed acute intestinal ischemia runs the risk of missing bowel necrosis. After endovascular therapy, frequent clinical reevaluation is necessary to identify patients with persistent intestinal ischemia. Abdominal exploration should be very strongly considered in

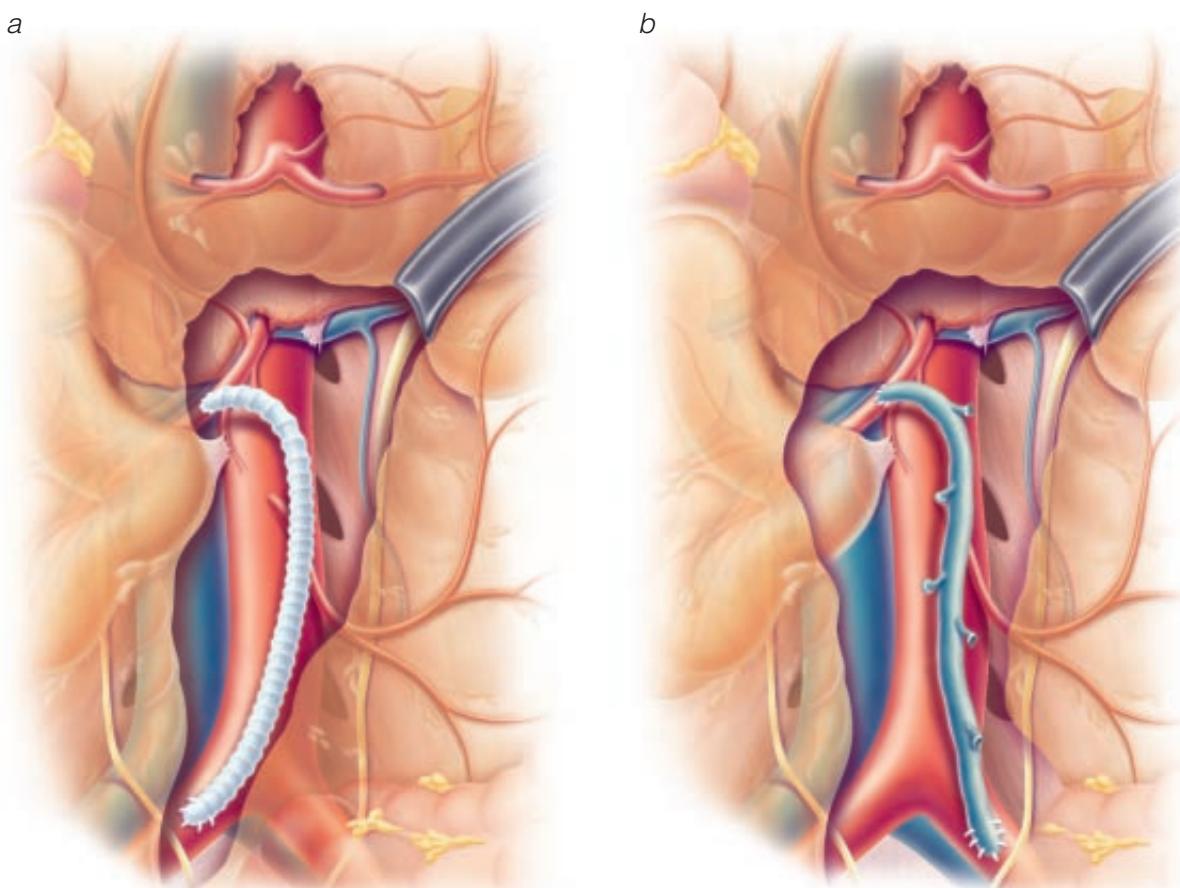

Figure 10 SMA bypass. (a) Iliac artery-SMA bypass with prosthetic graft is suitable for cases in which SMA thrombosis produces ischemic but salvageable bowel. (b) Iliac artery-SMA bypass with saphenous vein is suitable for cases in which some segments of necrotic or perforated bowel must be resected.²⁹

most cases, even if the angiographic result of endovascular treatment is good.

TROUBLESHOOTING

Occasionally, patients present with emboli that have lodged in the small arterial branches of the SMA. These vessels are often too small to allow the passage of embolectomy catheters, and bypass beyond the point of obstruction frequently is not possible. In these situations, resection of marginally viable bowel is the best option.

As noted (see above), avoidance of graft kinking is crucial for preventing early graft failure. Graft failure can have an even greater adverse effect on bowel viability in the setting of acute ischemia than in the setting of chronic intestinal ischemia.

Recovery after revascularization is often prolonged. Early and prolonged parenteral nutrition may be necessary in patients with extensive bowel infarction. Only rarely, however, is lifelong parenteral nutrition required.

OUTCOME EVALUATION

The techniques employed to evaluate the success of mesenteric revascularization for acute ischemia include clinical inspection, continuous-wave Doppler ultrasonography, and I.V. administration of fluorescein. Clinical inspection entails visual assessment of

pulsatile flow in the mesenteric arcades, peristalsis, bleeding from cut surfaces, and, of course, color. In one study, clinical parameters were found to be 82% sensitive and 91% specific for bowel viability.²⁶

We routinely use a sterile continuous-wave Doppler ultrasound flow detector to evaluate pulsatile flow on the bowel surface. Grossly discolored bowel with no Doppler signal after a period of observation should be resected; marginal bowel with no Doppler signal is an indication for second-look laparotomy.

With the fluorescein fluorescence method, 10 to 15 mg/kg of fluorescein is injected intravenously, and the intestine is inspected with a Wood lamp. A complete absence of fluorescence is diagnostic of nonviability; rapid, confluent, bright fluorescence is diagnostic of viability. There is, however, a large gray area between these two extremes in which interpretation is subjective. In one study, the I.V. fluorescein method was found to be 100% sensitive and specific for detecting nonviable bowel.²⁷ The disadvantages of this technique are that it requires special equipment and that it exposes the critically ill patient to the risk of an adverse reaction to the dye. Other assessment methods (e.g., surface oximetry, infrared photoplethysmography, and laser Doppler velocimetry) are available, but at present, they are mostly experimental and are not in general use for evaluation of bowel viability.

17 REPAIR OF FEMORAL AND POPLITEAL ARTERY ANEURYSMS

Amir Kaviani, M.D., and Patrick J. O'Hara, M.D., F.A.C.S.

Femoral and popliteal artery aneurysms constitute the majority of peripheral aneurysms. Recognition of these aneurysms is increasing, perhaps because of better surveillance of the aging population, as well as improvements in and more widespread use of vascular imaging modalities.¹ Femoral and popliteal aneurysms rarely rupture, but they have a significant potential for limb-threatening complications such as embolization and thrombosis. Large aneurysms can also exert a mass effect and thereby cause compression of veins or nerves.

In general, with both femoral and popliteal aneurysms, elective repair and reconstruction tend to be associated with significantly better postoperative outcomes than is emergency repair undertaken after a limb-threatening complication. Specific treatment decisions may be influenced by the presence or absence of symptoms of aneurysmal disease. There is little disagreement regarding optimal management of symptomatic femoral or popliteal aneurysms, but there is some controversy regarding optimal management of aneurysms that are asymptomatic when detected, especially if they are small. The extent of aneurysmal disease may also influence management choices. For example, a more extensive and complex reconstruction is required for treatment of diffuse arteriomegaly than is necessary for treatment of a focal femoral or popliteal aneurysm.

Lower extremity aneurysms may be either true aneurysms, in which the degenerative process involves all three layers of the arterial wall, or pseudoaneurysms, which result from trauma, anastomotic disruption, or infection. The pathogenesis of true (i.e., degenerative) lower extremity aneurysmal disease has not been definitively established, but it is known that the disease is much more common in men than in women; in fact, men with true femoral or popliteal aneurysms may outnumber women with such lesions by more than 30 to 1.^{2,3} One of the factors proposed as a possible contributor to aneurysm formation is turbulent flow beyond a relative stenosis. At the groin, the inguinal ligament may act as a constricting band, and at the popliteal level, the tendinous hiatus, the heads of the gastrocnemius, and the popliteal ligament may compress the artery in certain susceptible individuals. In addition, there is evidence for the existence of a genetic predisposition to true aneurysm formation in the femoral and popliteal arteries, in view of the demonstrated association of femoral and popliteal aneurysms with abdominal aortic aneurysms.⁴ Accordingly, all patients presenting with femoral or popliteal aneurysms should be carefully evaluated for other aneurysms, especially in the aortoiliac segment and in the contralateral limb.

Regardless of the underlying cause of disease, repair of peripheral artery aneurysms follows the same basic principles applicable to repair of aneurysms in other locations. Specifically, the objectives of treatment are (1) to eliminate the embolic source, (2) to minimize the risk of rupture, (3) to eliminate the mass effect produced by the aneurysm (if present), (4) to restore adequate distal limb perfusion, and (5) to accomplish all of the preceding objectives in a durable fashion. In what follows, we describe key com-

ponents of the management of femoral and popliteal artery aneurysms, with specific attention to preoperative planning and intraoperative exposure and technique.

Repair of Femoral Artery Aneurysms

True (degenerative) aneurysms of the femoral artery are relatively unusual. They are generally confined to the common femoral artery, but in approximately 50% of cases, they extend to the femoral artery bifurcation. According to a classification scheme proposed by Cutler and Darling in 1973, femoral artery aneurysms are classified as type I if they are confined to the common femoral artery and as type II if they involve the orifice of the profunda femoris artery.⁵ This classification scheme is convenient for the discussion of operative repair, in that type II aneurysms frequently necessitate more extensive surgical reconstruction than type I aneurysms do.

Like peripheral aneurysms elsewhere, true femoral artery aneurysms are frequently associated with abdominal aortic aneurysms, as well as with aneurysms in other locations. In a large series of patients with multiple aneurysms, 95% of patients with a femoral artery aneurysm had a second aneurysm, 92% had an aortoiliac aneurysm, and 62% had an aneurysm in the contralateral femoral artery.⁶ The natural history of these lesions is not fully understood; it may be relatively benign unless they are symptomatic or large at presentation.

Femoral pseudoaneurysms, on the other hand, are increasingly encountered after trauma (e.g., iatrogenic catheter injury) or after arterial reconstruction. These lesions, especially those arising from disrupted anastomoses, are thought to have a more ominous course if untreated. Aneurysms confined to the superficial femoral artery or the profunda femoris artery alone are distinctly unusual and are often of mycotic or traumatic origin.

PREOPERATIVE EVALUATION

Asymptomatic patients may present with a smooth, fusiform, nontender, pulsatile mass discovered either during physical examination or incidentally on imaging studies done for other reasons. Symptoms may result from local compression of the femoral nerve, which causes pain in the groin or the anterior thigh, or compression of the femoral vein, which may be associated with lower extremity edema and skin changes suggestive of venous stasis. Arterial symptoms (e.g., claudication or lower extremity ischemia) may be present in as many as 40% of patients with femoral artery aneurysms. Atheroemboli originating from the aneurysm can cause painful ischemic lesions; however, such lesions may also be partly a result of concomitant atherosclerotic occlusive disease rather than a direct result of the aneurysm itself.⁶

Complications of femoral artery aneurysms include thrombosis, embolization, and rupture. In one series of 45 patients with 63 aneurysms, nearly one half (47%) of the patients had experienced a complication by the time of initial presentation.⁴ Acute thrombo-

Figure 1 Shown is an example of extensive atheroembolization to the foot. The source of the atheromatous debris may be a proximal aneurysm or an ulcerating atherosclerotic lesion.

sis, because it involves compromise of both the profunda femoris artery and the superficial femoral artery, may result in a critically threatened limb that initially exhibits sensory or motor deficits and eventually manifests frank gangrene. Acute thrombosis secondary to a femoral artery aneurysm is associated with substantial morbidity: limb loss is reported to occur in more than 28% of cases.⁶ Patients with gradual or chronic thrombosis, who have had time to develop collateral circulation, may present with claudication.

Embolization from a femoral artery aneurysm may be clinically silent or, if extensive, may present as the so-called blue toe syndrome [see **6:5 Pulseless Extremity and Atheroembolism**]. Embolic debris originating in the aneurysm may lodge in the digital arteries or obstruct the microcirculation, leading to characteristic painful distal ischemic lesions, despite the presence of palpable distal pulses [see **Figure 1**]. In more severe cases, obstruction of

the outflow bed may compromise blood flow to the entire limb, resulting in limb-threatening ischemia. Rupture of a femoral pseudoaneurysm is not unusual, especially if the lesion is enlarging. Rupture of a true femoral artery aneurysm, however, is a relatively uncommon event, with reported rupture rates ranging from 1% to 12%, and is accompanied by severe groin pain, ecchymosis, and swelling.^{3,6}

Femoral artery aneurysms can usually be diagnosed by means of physical examination alone. Ultrasonography is a useful adjunctive measure for delineating the aneurysm, as well as for screening patients for associated popliteal or aortoiliac aneurysms [see **Figure 2a**]. CT and MRI scans can be helpful in delineating the extent and morphology of the aneurysm, as well as the status of the adjacent arteries, especially in obese patients [see **Figure 2b**]. Once the diagnosis has been made, angiography should be performed to establish the extent of aneurysmal and associated occlusive or embolic disease by providing detailed information about the inflow and outflow vessels [see **Figure 3**]. In selected circumstances (e.g., the presence of recent thrombosis of the outflow bed), arteriography may provide the opportunity for a trial of thrombolytic therapy to improve outflow. Good judgment must be exercised, however, in that there may not be enough time for adequate thrombolysis if the limb is severely ischemic.

Finally, preoperative evaluation should include careful assessment and optimization of comorbid medical conditions often present in patients with femoral artery aneurysms. Because cardiac complications are a major source of early postoperative and late morbidity in this population, special emphasis should be placed on evaluating patients for associated coronary artery disease by means of cardiac stress testing or coronary angiography and on following evaluation with appropriate treatment when indicated. Similarly, imaging of the contralateral limb and the aortoiliac vessels is prudent to detect associated aneurysms and establish treatment priorities.

OPERATIVE PLANNING

Repair is clearly indicated for all symptomatic femoral aneurysms, irrespective of cause. Patients who present with limb-threatening complications require expeditious intervention. Asymptomatic femoral pseudoaneurysms should also be repaired once the diagnosis is established because they are often associated with

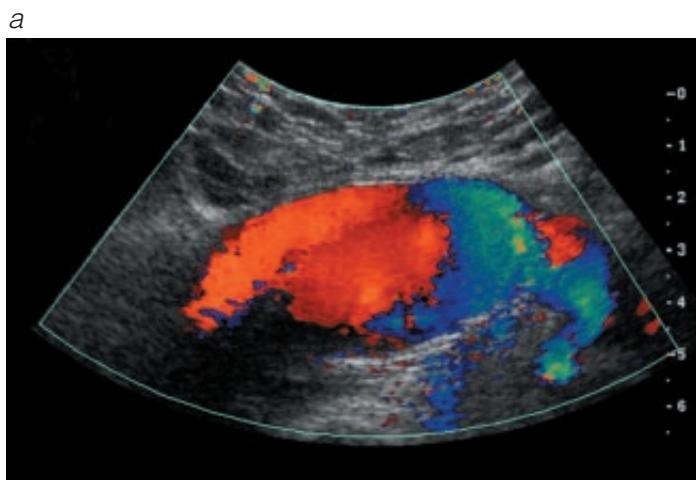

Figure 2 (a) Shown is a duplex ultrasonogram of a left common femoral artery aneurysm (sagittal view). (b) Shown is a CT scan of a left common femoral aneurysm (arrow). In practice, multiple slices are used to delineate the proximal and distal extent of the aneurysm.

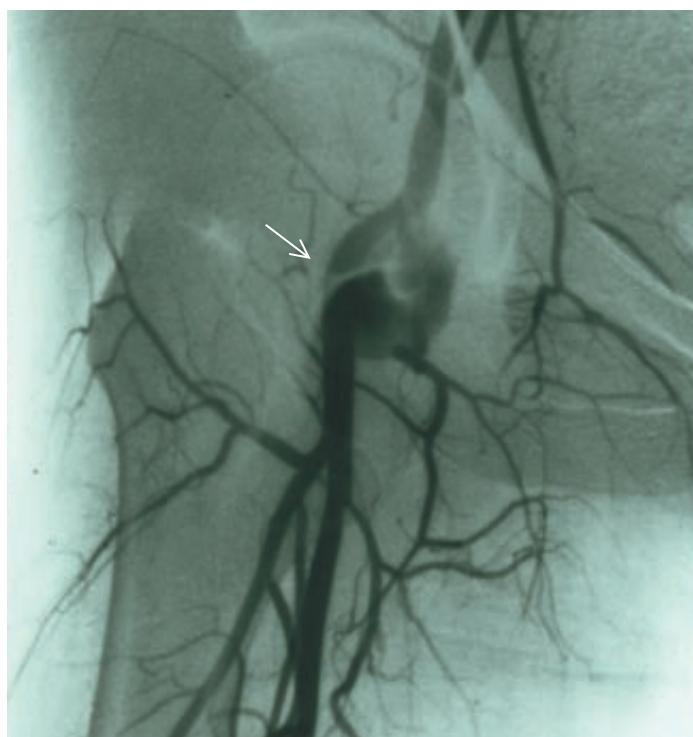

Figure 3 Anteroposterior arteriogram demonstrates a localized common femoral artery aneurysm (arrow).

complications. Currently, however, there is no firm consensus on the indications for treatment of asymptomatic true femoral aneurysms, because the natural history of these lesions is not known with certainty and is thought to be relatively benign. Furthermore, no specific aneurysm size has been identified at which the incidence of complications increases dramatically, though it

appears that symptomatic lesions tend to be larger than asymptomatic ones. Most surgeons, however, would probably agree that true femoral artery aneurysms larger than 2.5 cm in diameter should be repaired in good-risk patients, especially if the aneurysm is known to have enlarged. Smaller asymptomatic true femoral artery aneurysms, particularly in high-risk patients, should be followed, with intervention reserved for cases in which symptoms develop or the lesion enlarges significantly. On occasion, it may also be necessary to repair a small asymptomatic true femoral aneurysm in conjunction with an aortofemoral or femoropopliteal bypass graft procedure in order to avoid performing an anastomosis to a diseased artery.

OPERATIVE TECHNIQUE

At present, endovascular approaches to definitive treatment of femoral artery aneurysms are limited because the femoral artery crosses the groin crease and is subject to repeated flexion and extension stresses in this location. Current endoprostheses are likely to fail at this site because of kinking, migration, or metal fatigue. Furthermore, the femoral incision required for standard surgical repair is not extensive and is usually well tolerated by most patients. Consequently, the potential advantages of an endovascular approach are less apparent with respect to the repair of femoral artery aneurysms than they are with respect to repair of abdominal or thoracic aneurysms.

Small femoral pseudoaneurysms arising after catheter diagnostic or interventional procedures may resolve over time or, sometimes, may be managed with ultrasound-guided compression or thrombin injection at the time of diagnostic imaging. Surgical repair is usually reserved for pseudoaneurysms that enlarge, become symptomatic, or do not resolve spontaneously [see Figure 4]. A potential advantage of open repair of large pseudoaneurysms is the capacity for decompression of large hematomas, which may be especially important if continued anticoagulation is likely to be required.

The common femoral artery may be approached through

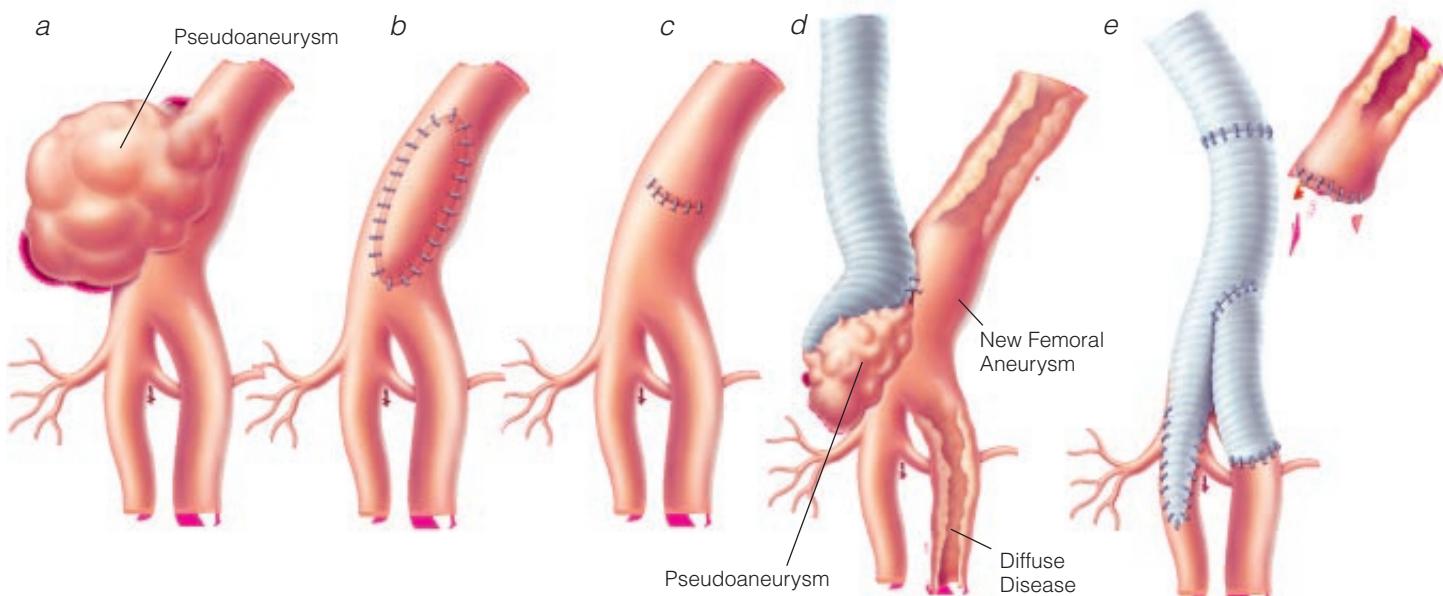

Figure 4 Repair of femoral artery aneurysms (pseudoaneurysms) (a). Depicted are commonly employed options for repair of femoral artery pseudoaneurysms: (b) primary closure and (c) patch angioplasty with either autogenous or synthetic patch material. Also depicted is repair of anastomotic femoral pseudoaneurysms (d). An interposition graft is placed to the profunda femoris (e), and a jump graft is placed to the superficial femoral artery.

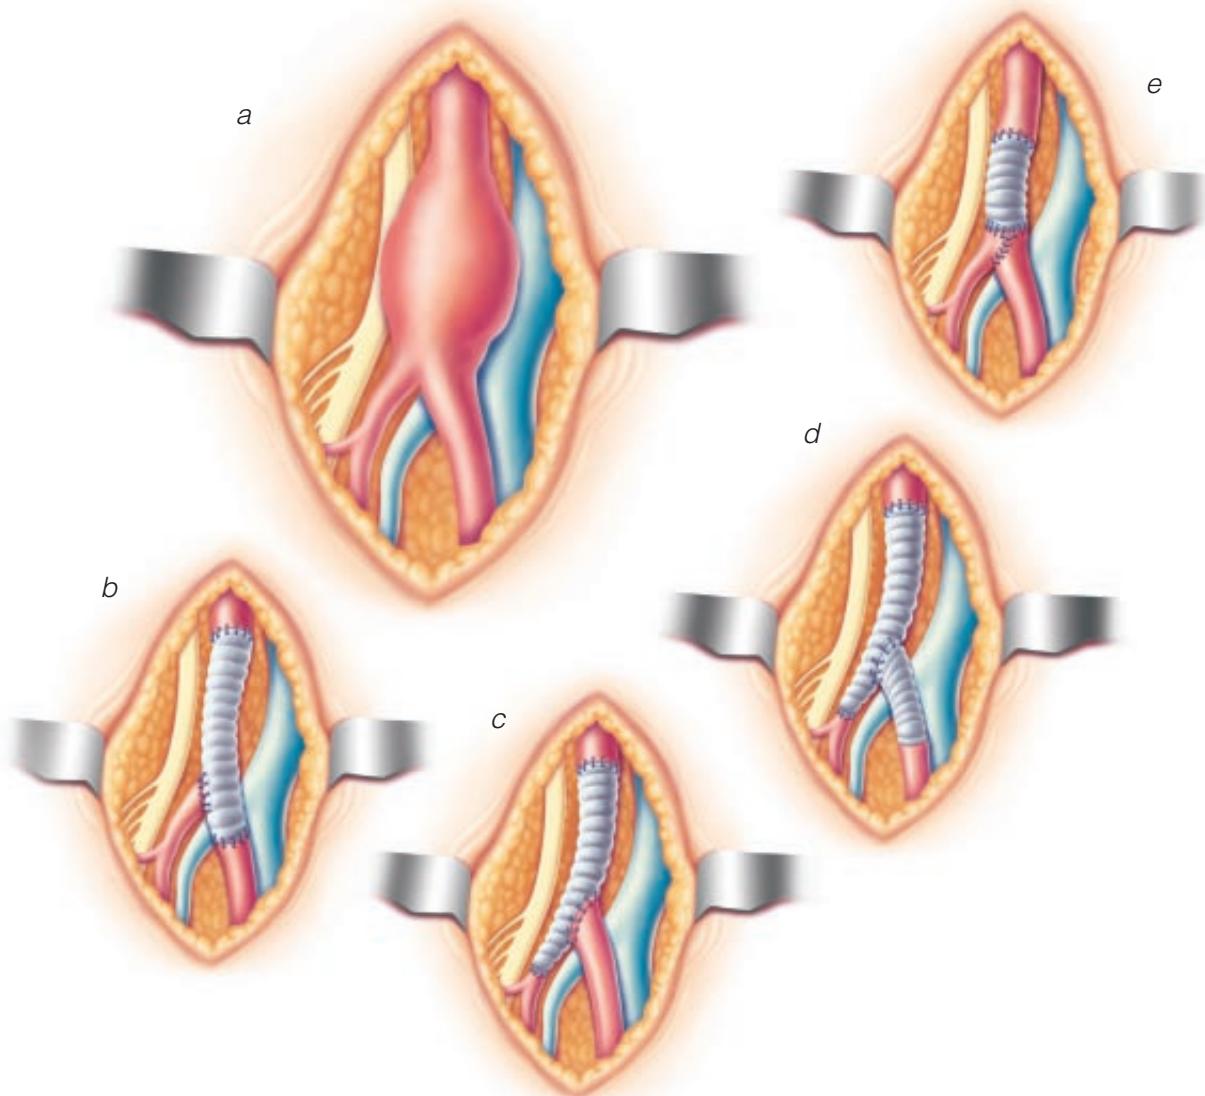

Figure 5 Repair of femoral artery aneurysms (type II true aneurysms) (a). Depicted are commonly employed options for repair of true femoral artery aneurysms involving the origins of the profunda femoris and superficial femoral arteries (type II femoral aneurysms). (b) The profunda femoris artery may be implanted into an interposition graft placed to the superficial femoral artery. (c) The superficial femoral artery may be implanted into an interposition graft placed to the profunda femoris artery. (d) An interposition graft may be placed to the profunda femoris artery, with a jump graft to the superficial femoral artery. Alternatively, the superficial femoral artery may be reimplanted into the interposition graft if there is sufficient length to allow the reconstruction to be performed without tension. (e) Syndactylization of the profunda femoris and superficial femoral arteries may be done to form a common outflow channel for a synthetic interposition graft originating from the common femoral artery or the distal external iliac artery.

either a longitudinal or an oblique incision over the femoral artery. The usual preference, however, is a longitudinal incision angled approximately 20° medially, which permits exposure of the distal profunda femoris artery without the creation of a skin flap. Both the distal extent of the femoral aneurysm and the degree of associated occlusive disease may influence the configuration of open surgical repair [see Figure 5]. Type I aneurysms, which spare the origins of the profunda femoris and superficial femoral arteries, are usually managed by constructing a short interposition graft with the proximal anastomosis at the level of the distal external iliac artery or the proximal common femoral artery [see Figure 6]. Occasionally, if proximal control of the retroperitoneal iliac artery is required, a flank incision may be needed. When it is necessary to repair additional proximal or distal aneurysms, the short femoral interposition graft may also act as the recipient of an aortofemoral or iliofemoral graft [see 6:12 Aortoiliac Reconstruction]

or as the origin of a femorodistal bypass graft [see 6:18 Infrainguinal Arterial Procedures].

If the femoral aneurysm is more extensive, a bypass from the common femoral artery to the profunda femoris artery with a jump graft to the superficial femoral artery is usually preferred [see Figures 5d and 7]. This approach allows the surgeon to work sequentially from the deep tissue planes to the more superficial ones.

Alternatively, some surgeons favor implantation of the distal profunda femoris artery into an interposition graft placed between the common femoral artery and the superficial femoral artery [see Figure 5b]. Others have described joining the superficial and deep femoral arteries at their bifurcation to form a common outflow tract that serves as the distal anastomotic end point for the interposition graft, a technique sometimes referred to as syndactylization [see Figure 5e]. Application of these two methods

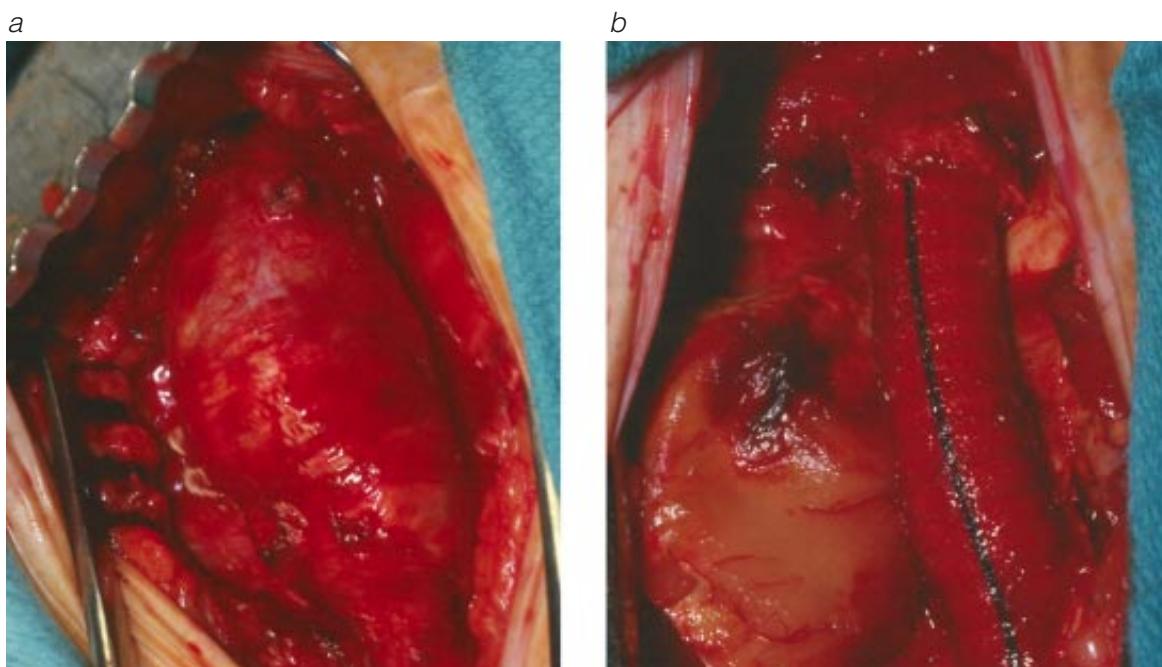

Figure 6 Repair of femoral artery aneurysms (type I true aneurysms). Shown is a type I true aneurysm of the common femoral artery (a) before and (b) after reconstruction with a Dacron interposition graft.

may be hampered by the presence of associated occlusive disease, which is frequently present. Nevertheless, the surgeon should be familiar with all of the available options for reconstruction and should be prepared to adapt his or her choice of reconstruction method to the details of the local anatomy.

For treatment of noninfected femoral aneurysms, especially anastomotic pseudoaneurysms, synthetic grafts have been used with good results; they usually offer a better size match with the native femoral arteries [see Figure 4d]. If local infection is present or the potential for wound complications is high, autogenous grafts are preferred.

OUTCOME EVALUATION

The results of operative repair of femoral artery aneurysms are generally excellent. In published series, the perioperative mortalit-

ty ranges from 0 (for isolated asymptomatic femoral aneurysm repair) to approximately 4% (if aneurysm repair is combined with more extensive aortic procedures).⁵⁻⁷ The reported 5-year patency rate for saphenous vein and Dacron interposition grafts used for repair of isolated femoral artery aneurysms is 80% to 83%.^{5,7} In general, patients who are operated on before they show evidence of impaired limb perfusion fare better than those presenting with lower extremity complications.⁶

Repair of Popliteal Artery Aneurysms

Aneurysms of the popliteal artery are the most commonly encountered peripheral aneurysms. Unlike femoral aneurysms, popliteal aneurysms are more likely to be true (i.e., degenerative) aneurysms than pseudoaneurysms. True popliteal aneurysms typically occur in men in their fifth and sixth decades. Their clinical importance lies in their propensity to cause limb-threatening complications. When true popliteal aneurysms are left untreated, the future incidence of thromboembolic events in initially asymptomatic patients is high. In one series of patients who were managed conservatively, only 32% had no complications at 5 years' follow-up.⁸ Multiple aneurysms are common in this population, and it has been reported that nearly 50% of patients presenting with a popliteal aneurysm have associated abdominal aortic aneurysms and that 40% may also have coexisting femoral artery aneurysms.^{4,8,9} In the largest reported series, 70% of these patients had a popliteal artery aneurysm in the contralateral extremity.¹⁰ The clear link between the presence of popliteal aneurysms and the presence of other associated aneurysms underscores the importance of careful investigation of all patients who present with a newly diagnosed popliteal artery aneurysm. In approximately 50% of cases, popliteal artery aneurysms are confined to the popliteal artery itself; in the remaining cases, aneurysmal degeneration may extend proximally to involve the superficial femoral artery or distally down to the level of the tibioperoneal trunk.⁹

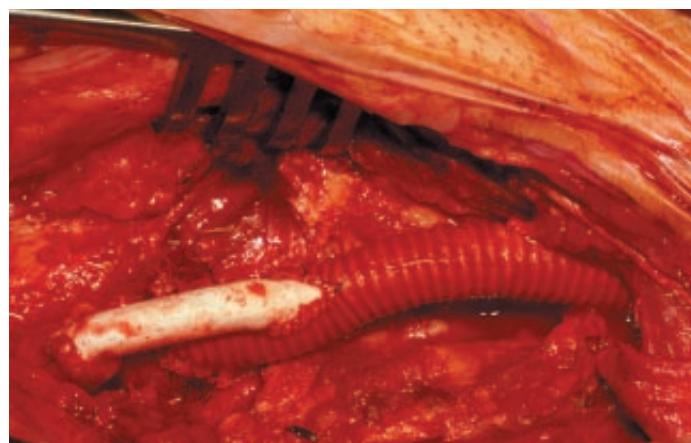

Figure 7 Repair of femoral artery aneurysms (type II true aneurysms). Shown is the repair of a type II femoral artery aneurysm with a Dacron interposition graft to the profunda femoris artery and a polytetrafluoroethylene (PTFE) jump graft to the superficial femoral artery.

PREOPERATIVE EVALUATION

Popliteal artery aneurysms may be asymptomatic on initial presentation. The diagnosis is usually suspected on the basis of the detection of a prominent pulsatile mass behind the knee during physical examination. The mass is often best felt with the knee in a slightly flexed position. Small aneurysms may be more difficult to detect during physical examination, especially if thrombosis has already occurred. A high index of suspicion, usually based on recognition of an aneurysm in another location, is helpful in identifying these lesions.

The most frequent initial presentation of a symptomatic popliteal aneurysm is the development of acute limb-threatening ischemia as a consequence of arterial occlusion from thrombosis of the aneurysm or distal embolization.^{9,11} Early manifestations (i.e., those occurring before complete occlusion of the popliteal artery itself) may be limited to painful petechial hemorrhages or localized gangrenous changes in the digital arteries that result from microembolization [see Figure 1]. In some series, claudication has been a presenting symptom in 40% to 75% of patients with popliteal aneurysms.⁹ Rupture is a distinctly unusual event: fewer than 5% of patients present with this complication.⁹ In rare instances, patients with very large popliteal aneurysms may present with symptoms resulting from compression of adjacent structures, such as paresthesias or neuropraxia involving the lower leg (from direct popliteal nerve compression) or deep vein thrombosis, superficial varicosity formation, and phlebitis (from popliteal vein compression).

Plain radiographs of the knee may demonstrate calcium in the aneurysm wall; however, once the diagnosis is suspected, it is best confirmed by means of ultrasonography [see Figure 8], computed tomography, or magnetic resonance imaging. These imaging modalities are particularly helpful in distinguishing popliteal aneurysms from other space-occupying lesions of the popliteal fossa (e.g., Baker's cyst).

Angiography is less useful for the diagnosis of popliteal artery aneurysms: it demonstrates only the flow channel of the vessel, and any intramural thrombus that is present may obscure the presence of the popliteal aneurysm. Nevertheless, angiography plays a valuable role in the planning of operative reconstruction because

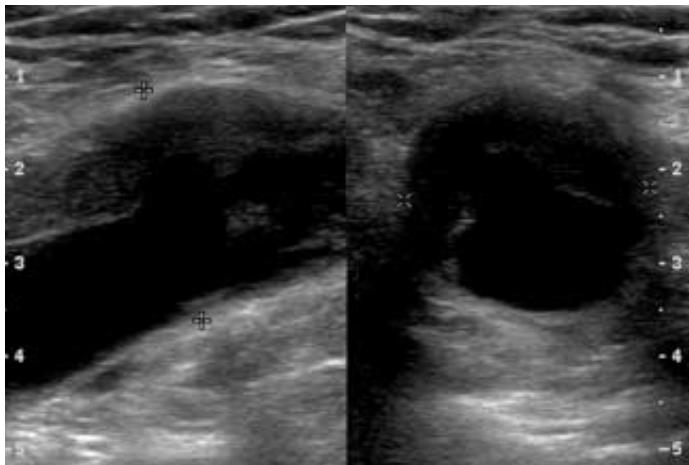

Figure 8 Repair of popliteal artery aneurysms. Ultrasonographic examination of the right popliteal artery demonstrates a 2.6 cm right popliteal artery aneurysm, shown in both sagittal (left) and transverse (right) views.

it can delineate the extent of aneurysmal involvement of the popliteal and adjacent arteries and detect the presence of associated occlusive disease [see Figure 9]. In addition, as noted (see above), it may facilitate the use of adjunctive thrombolytic therapy, which may be particularly beneficial if the outflow bed has been severely compromised by distal thrombosis or embolization. The goal of thrombolysis of occluded outflow vessels is to uncover a suitable target vessel that can be used to provide outflow for a surgical bypass; this modality is particularly useful in this setting, in that intraoperative balloon thromboembolectomy sometimes cannot clear sufficient thrombus from small vessels to maintain long-term graft patency. In one study of selected patients with poor outflow, thrombolytic therapy followed by surgical repair yielded results that compared favorably with those of isolated surgical repair, and the combined approach was associated with lower amputation rates.¹² It should be kept in mind, however, that thrombolytic therapy is more rapid and effective if thrombosis is recent and the volume of thrombus is not large. If limb ischemia

Figure 9 Repair of popliteal artery aneurysms. Preoperative arteriograms illustrate two common varieties of popliteal artery aneurysm. Extent of disease influences choice of reconstruction. (a) The aneurysm is localized to the popliteal artery. (b) Arteriomegaly extends proximally to involve the superficial femoral artery.

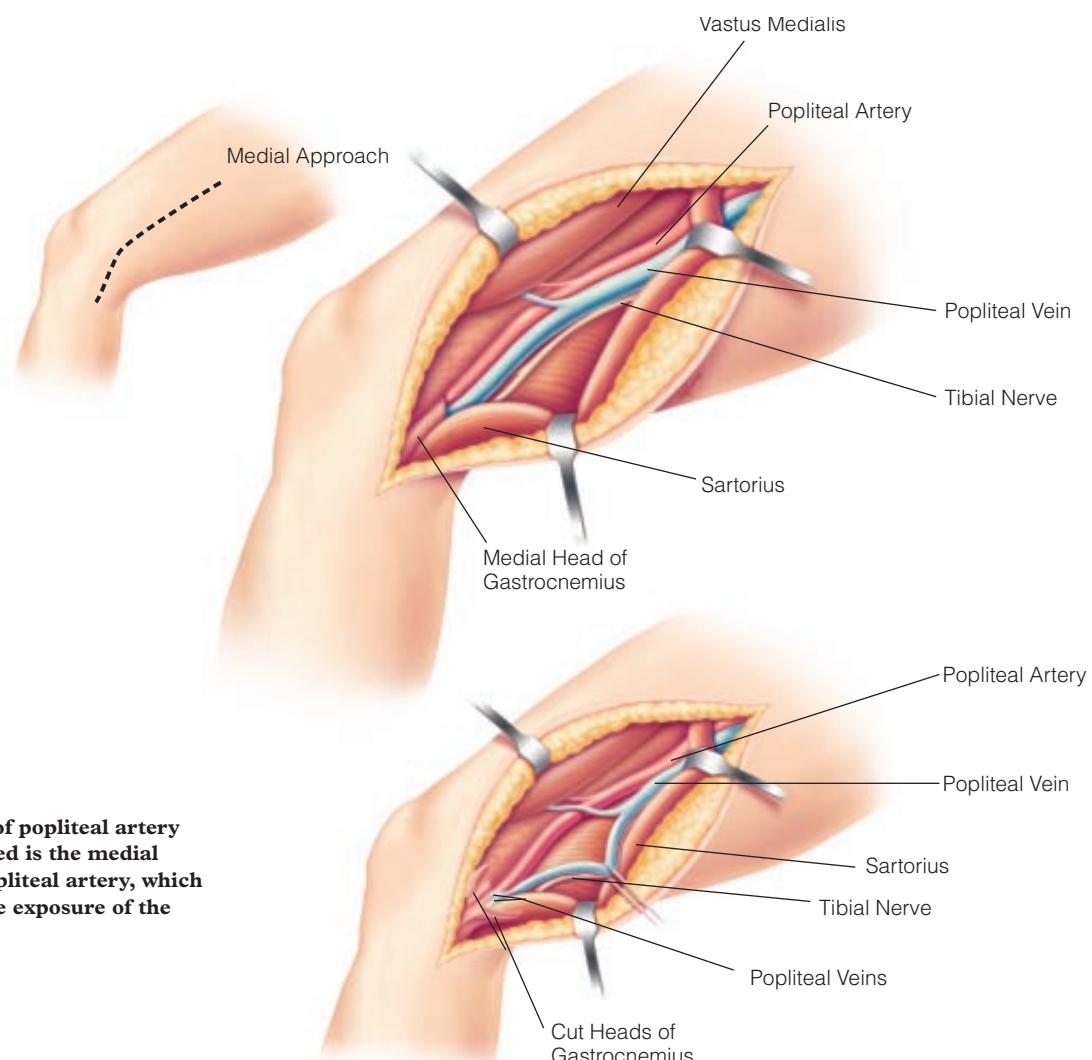

Figure 10 Repair of popliteal artery aneurysms. Depicted is the medial approach to the popliteal artery, which can afford complete exposure of the vessel.

is severe, the length of time required to establish reperfusion may be prohibitive, and it may be best to proceed with direct surgical intervention before irreversible tissue loss occurs.

In patients with popliteal artery aneurysms, as in those with femoral artery aneurysms, there is a high incidence of associated atherosclerotic disorders: nearly 50% have some degree of myocardial dysfunction, and nearly two thirds are hypertensive.¹³ Consequently, preoperative evaluation of patients under consideration for popliteal aneurysm repair should include careful optimization of associated coexisting medical conditions, especially associated coronary artery disease.

OPERATIVE PLANNING

There is a consensus that all patients with symptomatic popliteal aneurysms should undergo expeditious operative repair; conservative management in these cases is associated with a substantial risk of limb loss, especially in the presence of limb-threatening ischemia. There is also general agreement that asymptomatic popliteal aneurysms should be repaired upon diagnosis; such lesions are associated with the development of limb-threatening complications in a substantial number of patients. In a series of 94 patients with asymptomatic popliteal artery aneurysms who were followed for nearly 7 years, 18% of the limbs with aneurysms eventually became symptomatic (25% acutely and 75% chronically), and 4% had to be amputated.¹⁴ In this cohort, aneurysm size

greater than 2 cm, the presence of mural thrombus, and poor distal lower extremity runoff were significant predictors of the development of symptoms. In a meta-analysis of the published literature that encompassed nearly 2,500 popliteal artery aneurysms, nearly 35% of the patients who were treated conservatively eventually experienced ischemic complications, and 25% of the patients who required surgical treatment for an ischemic complication eventually required amputation.¹⁵ Given these results, most surgeons would agree that surgical repair of asymptomatic popliteal artery aneurysms is indicated for all but extremely high risk patients.

Although the likelihood that popliteal aneurysms will give rise to complications does not appear to be related to the size of the aneurysms, optimal management of small asymptomatic popliteal aneurysms remains controversial—in part because of problems with their definition, especially in the presence of generalized arteriomegaly. Factors believed to be associated with the eventual development of ischemic complications include size greater than 2 cm, deformation of the artery itself, and the existence of intraluminal thrombus. The presence of these factors, especially if the popliteal aneurysm is localized, makes a case for operative repair.

OPERATIVE TECHNIQUE

The primary therapeutic objectives of popliteal artery aneurysm repair are (1) to eliminate the aneurysm as a source of emboli or thrombosis and (2) to maintain distal perfusion in a dur-

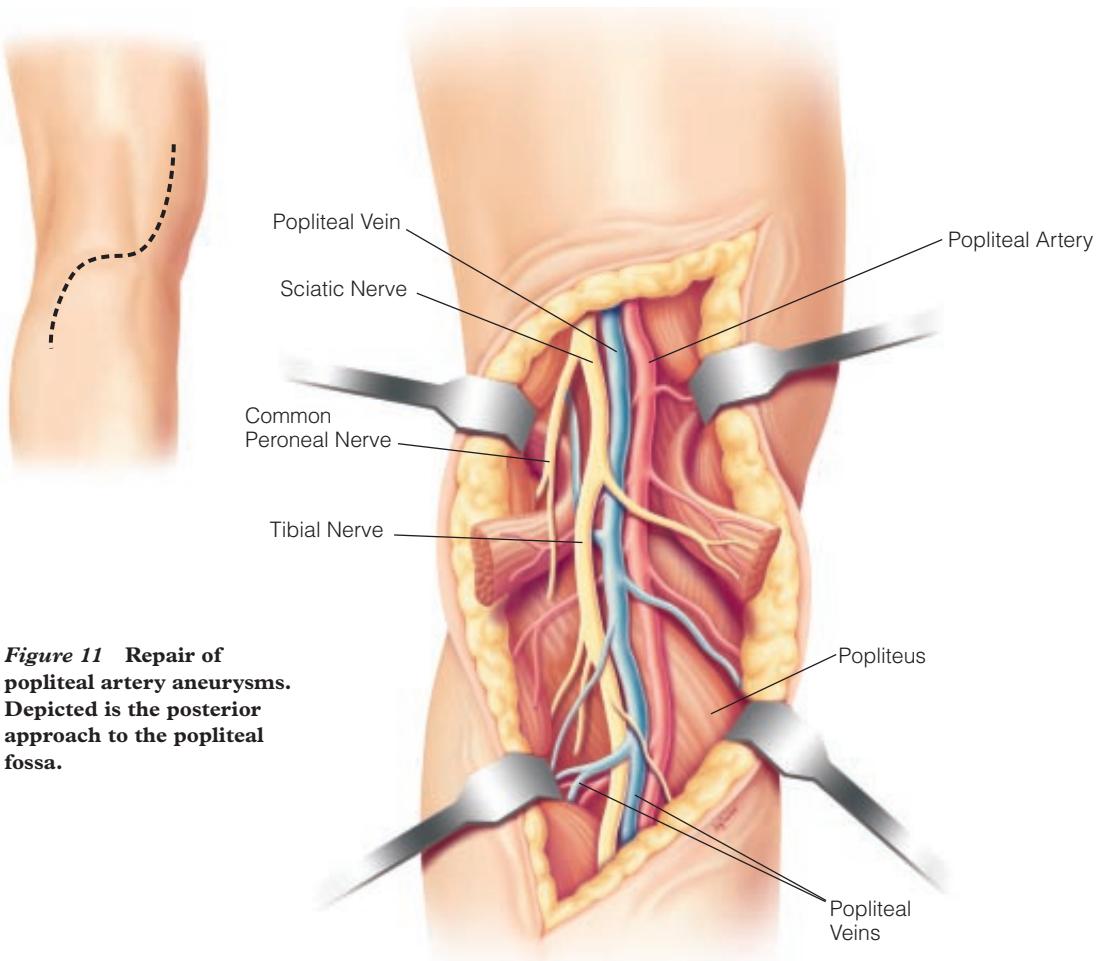

Figure 11 Repair of popliteal artery aneurysms. Depicted is the posterior approach to the popliteal fossa.

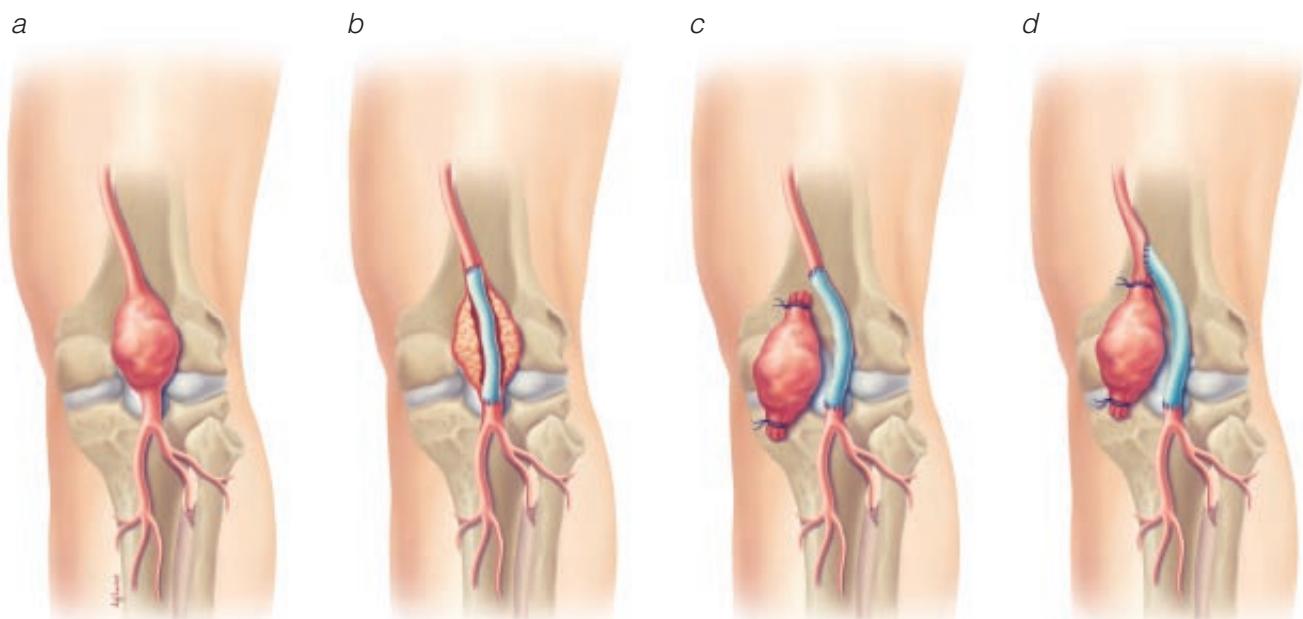

Figure 12 Repair of popliteal artery aneurysms (a). Depicted are various bypass configurations that can be employed for repair of popliteal aneurysms. (b) An interposition graft may be placed within a large aneurysm. (c) If the graft and the artery are sufficiently well matched in terms of size, ligation and bypass of the aneurysm with end-to-end proximal and distal anastomoses may be employed. (d) If there is a significant size mismatch between the graft and the artery, ligation and bypass of the aneurysm with an end-to-side proximal anastomosis may be employed.

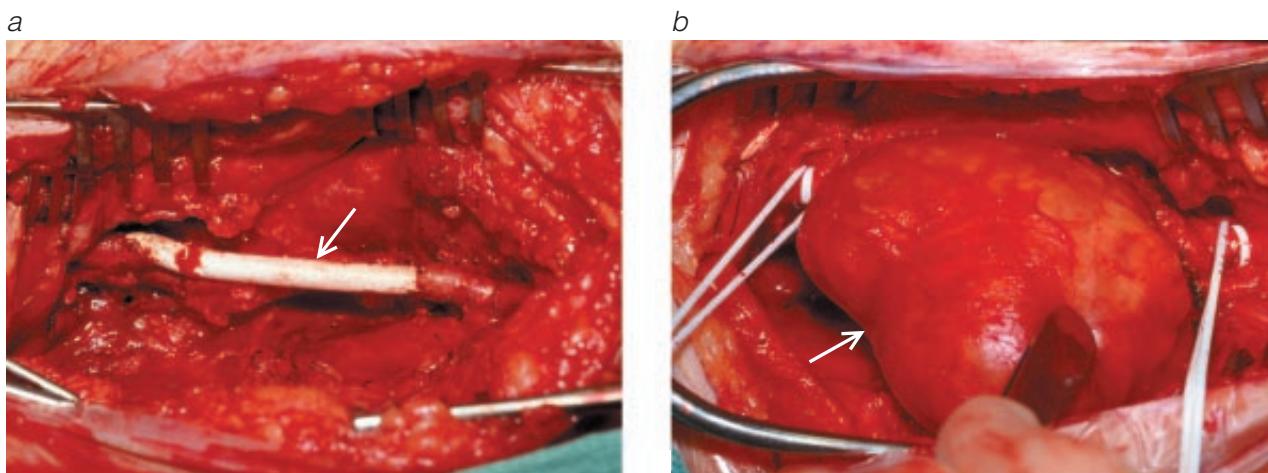

Figure 13 Repair of popliteal artery aneurysms. (a) Operative photograph shows a large popliteal aneurysm (arrow) exposed via the medial approach. (b) A PTFE interposition graft (arrow) is placed within the aneurysm sac, which has been decompressed. Saphenous vein is the preferred graft material, but a synthetic conduit may be required if the autogenous conduit is unavailable or inadequate. Collateral inflow into the sac has been interrupted.

able fashion. Other objectives are to prevent hemorrhage resulting from rupture, to eliminate the mass effect exerted by large aneurysms, and to prevent recurrence. Several reports have evaluated endovascular treatment of popliteal aneurysms with covered stents delivered under fluoroscopic guidance^{16,17}; however, to date, the results have been inferior to those of open surgical treatment. At present, endovascular treatment of popliteal aneurysms remains investigational and should be confined to those patients who are considered to be at unacceptable risk with standard surgical therapy. If endovascular therapy is employed, close late follow-up is necessary to detect fracture or migration of the stent, as well as expansion or thrombosis of the aneurysm.

The two most important factors influencing the surgical approach to popliteal aneurysm repair and the configuration of the reconstruction used are (1) the extent of the aneurysmal disease and (2) the size of the aneurysm. In most settings, the medial approach with the patient in the supine position is preferred. This approach allows exposure of the entire popliteal artery, if necessary, through division of the semimembranosus, semitendinosus, and gastrocnemius tendons, which can be repaired at the time of closure. In addition, it offers the most flexibility for expanding the reconstruction if the aneurysm is large, extensive, or multilobed [see Figure 10]. The posterior approach to the popliteal artery, which is favored by some surgeons, can also provide adequate exposure of localized popliteal aneurysms, but it requires that the patient be prone [see Figure 11]. Although it is well tolerated, the posterior approach precludes exposure of the common and superficial femoral arteries or the greater saphenous vein and offers less flexibility for proximal or distal extension. Familiarity with both approaches permits the vascular surgeon to choose the one that best suits the given clinical situation.

A small, localized popliteal artery aneurysm with few side branches may be treated with simple proximal and distal ligation of the aneurysm sac, accompanied by construction of a bypass graft with a short segment of autologous saphenous vein. The venous graft may be tunneled in the anatomic position, deep to the medial head of the gastrocnemius muscle. The proximal and distal anastomoses are fashioned in either an end-to-end or an end-to-side configuration, depending on the compatibility of the graft's diameter with that of the artery [see Figure 12].

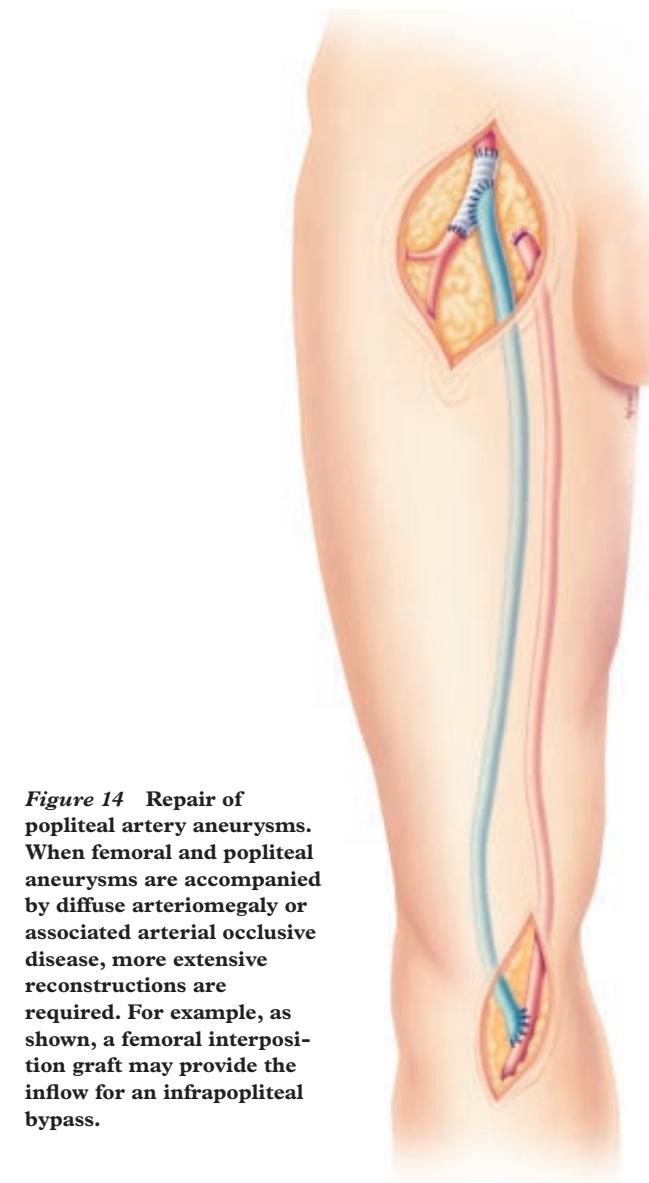

Figure 14 Repair of popliteal artery aneurysms. When femoral and popliteal aneurysms are accompanied by diffuse arteriomegaly or associated arterial occlusive disease, more extensive reconstructions are required. For example, as shown, a femoral interposition graft may provide the inflow for an infrapopliteal bypass.

Figure 15 Repair of popliteal artery aneurysms. Preoperative and postoperative arteriograms show a localized popliteal artery aneurysm (arrow, left) and its subsequent repair with a saphenous vein interposition graft (arrow, right).

In the case of a large aneurysm for which evacuation of mural thrombus is required to relieve mass effect symptoms, it may be feasible to construct a short interposition graft [see Figure 13]. Opening the sac also allows ligation of the feeding geniculate branches, which may help minimize the risk of late enlargement of the aneurysm sac associated with recurrence of mass effect symptoms.

If the superficial femoral artery is severely involved with occlusive or aneurysmal disease, it may be necessary to construct a long saphenous vein bypass graft originating from the common femoral artery, in either an *in situ* or a reversed configuration [see Figure 14]. The distal anastomotic site is determined on the basis of the preoperative angiographic findings, in conjunction with intraoperative assessment.

As a rule, grafts constructed from autogenous vein are preferred, but synthetic grafts may be required if the autogenous vein is unavailable or inadequate. An effort should be made to keep graft length to the minimum necessary to treat the aneurysmal disease. Intraoperative completion angiography is recommended to allow detection and correction of technical problems with the reconstruction before closure [see Figure 15].

OUTCOME EVALUATION

In a study from the Cleveland Clinic that described the surgical management of 110 popliteal aneurysms, there were eight (7.3%) early postoperative deaths.⁹ Six (75%) of the eight early postoperative deaths were attributable to cardiac complications—an observation that highlights the need for careful cardiac evaluation, when feasible, before the treatment of popliteal artery aneurysms.

The presence of symptoms, the adequacy of the outflow bed on presentation, and the choice of autogenous graft material for reconstruction are the main factors that influence limb salvage and graft patency rates after repair of popliteal artery aneurysms. In one study, the 5-year patency rate for saphenous vein grafts was 92% for patients who had asymptomatic popliteal aneurysms and in whom good outflow vessels were identified, compared with 66% for a matched cohort with known occlusive disease.¹⁸ In other studies that included similar patients, the 10-year patency rate was in excess of 80%, and the limb salvage rate was approximately 95%.^{9,19}

Patients who undergo urgent surgical treatment of popliteal aneurysms that were symptomatic on presentation have less favorable outcomes. In one study, when thrombosis of the popliteal aneurysm was apparent on presentation or distal outflow was poor, the 5-year patency rate was approximately 50%, and the limb salvage rate was only 60%.²⁰ Several studies documented the influence of the choice of conduit graft material on bypass durability; each demonstrated that patency rates were nearly four times higher with saphenous vein grafts than with nonvenous alternative grafts.^{8,14,21} Limb salvage rates were also higher with autogenous saphenous vein grafts. For example, in one report, 23% (7/31) of the popliteal artery bypasses performed with a prosthetic conduit resulted in limb loss, whereas only 2% (1/42) performed with a saphenous vein graft resulted in amputation.¹⁴

In the past few years, instances of continued expansion of the popliteal aneurysm sac despite ligation and bypass have been reported.²² This phenomenon may result from inadequate ligation of the aneurysm sac, but it may also result from retrograde perfusion of the sac via patent geniculate collateral vessels. Consequently, it seems advisable to ligate all large collateral vessels feeding the aneurysm sac at the time of the initial aneurysm repair. If the aneurysm is large, it may be necessary to perform the ligation from within the evacuated sac.

18 INFRAINGUINAL ARTERIAL PROCEDURES

William D. Suggs, M.D., F.A.C.S., and Frank J. Veith, M.D., F.A.C.S.

Since the early 1980s, there have been enormous advances in the treatment of lower-extremity ischemia secondary to infrainguinal arteriosclerosis. Effective interventional management strategies have been developed for virtually all patterns of arteriosclerosis underlying limb-threatening ischemia.^{1,2} Bypasses to the infrainguinal arteries using segments of autologous vein have become routine for limb salvage. As this technique has evolved, the distal limits of revascularization have been extended. Bypasses to arteries near the ankle or in the foot can now be offered to patients who have no patent arteries suitable for more proximal bypasses. In addition, bypasses to distal tibial or tarsal vessels may be performed in some patients whose popliteal arteries are patent but who have three-vessel distal occlusive disease and forefoot gangrene.^{3,4} Frequently, patients who require very distal bypasses have already undergone vascular reconstruction; these patients may be candidates for alternative approaches, such as a popliteal-distal bypass or a tibiotibial bypass.⁵⁻⁷

Patients with limbs threatened by distal tibial occlusive disease present an ongoing challenge to the vascular surgeon. Provided that careful attention is paid to obtaining high-quality preoperative angiograms and that the surgeon is willing to consider alternative approaches, it is generally possible to achieve good results from limb salvage procedures.

It should be kept in mind that only patients with threatened limbs—manifested by rest pain, frank gangrene, or nonhealing ulcers—should be considered candidates for infrainguinal bypass. Patients who have gangrene that extends into the deeper tarsal region of the foot, who have a severe organic mental syndrome, or who are nonambulatory are not candidates for limb salvage surgery and should be treated with primary amputation instead.^{1,2}

Preoperative Evaluation

HISTORY AND PHYSICAL EXAMINATION

A careful history and a thorough physical examination are crucial for accurate assessment of the extent of the patient's atherosclerotic disease. In the course of the history, the examiner should pay particular attention to distinguishing true rest pain from other causes of pain (e.g., arthritis and neuritis). Significant ischemic pain is usually associated not only with decreased pulses but also with other manifestations of ischemia (e.g., atrophy, decreased skin temperature, marked rubor, and pain that is relieved when the foot is dangled). In the course of the physical examination, the examiner should look for and assess the extent of any underlying infection and should closely examine any surgical scars for clues to the nature and extent of any previous vascular operations involving the use of the saphenous vein. In addition, a careful pulse examination should be performed to assess the patient's baseline arterial status; these baseline measure-

ments provide a basis for comparison if the disease subsequently progresses and may help determine the approach to be used to salvage the threatened limb.

NONINVASIVE TESTING

Noninvasive tests are helpful in that they provide semiquantitative assessment of the circulation and help confirm the diagnosis made on the basis of the history and the physical examination. Such test measurements include the ankle-brachial index (ABI) and pulse volume recordings (PVRs).

The ABI is determined by dividing the ankle pressure in each lower limb by the higher of the two brachial pressures. Normal circulation typically yields an ABI of 1.0 to 1.2; claudication, an ABI of 0.40 to 0.95; and limb-threatening ischemia, an ABI of 0 to 0.5. It is vital to remember, however, that lower-extremity pressure measurements are less reliable in patients with heavily calcified vessels (e.g., diabetics and patients with end-stage renal disease). In these patients, ABIs are falsely elevated as a result of the higher cuff pressures required to occlude calcified vessels, which in some cases are not occluded even with pressures higher than 300 mm Hg.

PVRs are obtained by means of calibrated air-cuff plethysmography. Standard blood pressure cuffs are placed at different levels of the lower extremity, and the increases in pressure within the cuffs resulting from the volume increase during systole are recorded as pulse waves. Tracings exhibiting a brisk rise during systole and a dicrotic notch are characterized as normal, those exhibiting loss of the notch and a more prolonged downslope are characterized as moderately abnormal, and those exhibiting a flattened wave are characterized as severely abnormal. Absolute amplitudes on PVRs are not directly comparable between patients; however, serial PVRs from a single patient are highly reproducible and thus are quite useful for following the course of severe peripheral vascular disease in individual cases.⁴ One disadvantage of PVRs is that they cannot differentiate proximal femoral disease from iliac occlusive disease.⁸

IMAGING

Duplex Scanning

Duplex scanning is a useful noninvasive method of assessing the aortoiliac and infrainguinal arterial systems. Several studies have evaluated the ability of duplex scanning to predict iliac artery stenosis. A 1987 trial found that duplex scanning was highly sensitive (89%) and specific (90%) in predicting iliac stenosis of 50% or greater.⁹ Three subsequent trials corroborated these findings, reporting sensitivities ranging from 81% to 89% and specificities ranging from 88% to 99%.¹⁰⁻¹² This noninvasive modality may be especially useful for improving evaluation of diabetic patients before invasive procedures (e.g., angiography and angioplasty).¹⁰

Duplex scanning has also been used to allow infrapopliteal bypasses to be performed without preoperative angiography. In one study, a limb salvage rate of 86% was achieved with this approach, and completion arteriography matched the runoff status predicted by duplex scanning in 96% of cases.¹³ In a study from our own institution, we were able to perform femoropopliteal bypasses without preoperative arteriography and were able to perform distal bypasses with confirmatory arteriograms at the time of operation.¹⁴

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA), a noninvasive modality that does not require contrast agents, often yields good arterial images and may, in fact, be more sensitive than angiography in imaging distal lower-extremity runoff vessels.^{15,16} More recently, developments such as gadolinium enhancement, multistation examination, and the floating table technique have further improved the resolution of MRA,¹⁷⁻¹⁹ to the point where many institutions that use current forms of MRA no longer routinely obtain preoperative angiograms. MRA, in combination with arterial duplex scanning, has the potential to replace contrast arteriography in the assessment of patients with distal arterial occlusive disease.

Arteriography

Until MRA and duplex scanning become more widely available, contrast angiography will remain the gold standard for the evaluation of patients with distal arterial occlusive disease. A complete evaluation of the existing arterial disease from the aorta to the pedal vessels is necessary for diabetic patients, who frequently have multilevel occlusive disease. Obtaining intraarterial pressure measurements at the time of angiography significantly improves detection of clinically significant stenosis. The systolic pressure gradient across the lesion should also be measured: gradients greater than 15 mm Hg are considered hemodynamically significant.²⁰

In the general population, arteriography has a complication rate of only 1.7% to 3.3%.²¹ Elderly patients with severe aortoiliac or infrainguinal disease must be carefully evaluated before the procedure because they are more likely to experience local and systemic complications than patients in the general population are. For the majority of patients, the transfemoral approach is the safest; however, for patients with weak or nonpalpable femoral pulses, other approaches (e.g., translumbar, transbrachial, or transaxillary) may be preferable. These alternative approaches are associated with higher rates of local complications, including hematomas, pseudoaneurysms, dissections, thrombosis, and embolization.

Renal insufficiency is an important complication of angiography: 6.5% to 8.2% of patients who undergo arteriography experience some degree of impairment associated with contrast agents.^{22,23} Patients who have preexisting azotemia and whose baseline creatinine concentrations exceed 2.0 mg/dl are at highest risk for renal complications after angiography. Elderly patients typically have lower creatinine clearances for a given serum creatinine level and thus should always be considered at higher risk for nephrotoxicity. All possible precautions should be taken to limit the renal insult. There is some evidence to suggest that the use of low-osmolar contrast agents can decrease the incidence of renal impairment,^{24,25} but the data are not unanimous on this point.²⁶ Adequate hydration and administration of oral acetylcysteine before arteriography are highly effective in dimin-

ishing the risk of contrast nephropathy. Administration of mannitol, which has an osmotic diuretic effect, helps prevent contrast toxicity as well. These measures, coupled with judicious use of contrast agents, should minimize renal impairment associated with arteriography.

Femoropopliteal Bypass

Patients whose limbs are clearly threatened and who have undergone arteriographic examination should undergo femoropopliteal bypass when the superficial femoral artery or the popliteal artery is occluded and when arteriography indicates that a patent popliteal artery segment distal to the occlusion has luminal continuity with any of its three terminal branches (even if one or more of these branches ends in an occlusion anywhere in the leg). Even if the popliteal artery segment into which the graft is to be inserted is occluded distally, femoropopliteal bypass to this segment can be considered.^{27,28} If the isolated popliteal segment is shorter than 7 cm or if there is extensive gangrene or infection in the foot, a femorodistal artery bypass or a sequential bypass is sometimes performed in one or two stages.

OPERATIVE TECHNIQUE

Femoropopliteal bypass may be carried out either above or below the knee.

Above-the-Knee Bypass

For above-the-knee bypass, the patient is placed in the supine position with the thigh externally rotated and the knee flexed approximately 30°. This position affords easy exposure of the femoral and popliteal arteries as well as of the saphenous vein.

Harvesting of saphenous vein The greater saphenous vein is harvested through intermittent skip incisions starting in the groin and proceeding distally toward the knee [see Figure 1]. Multiple short skin incisions heal better than a single long one and are less likely to result in skin necrosis.

Dissection of the saphenous vein begins at the groin. This proximal incision is also used for exposure of the femoral artery. The saphenofemoral junction is carefully mobilized, and the tributaries are ligated with fine silk close to where they enter the main trunk, with care taken not to impinge on the wall of the trunk. As dissection continues distally, the main trunk of the saphenous vein is progressively elevated, and all tributaries are identified and ligated. The vein is then removed from its bed and

Figure 1 Femoropopliteal bypass: above knee. Shown is the appropriate position of the leg. Interrupted skin incisions are made in the thigh and upper leg to permit harvesting of the saphenous vein.

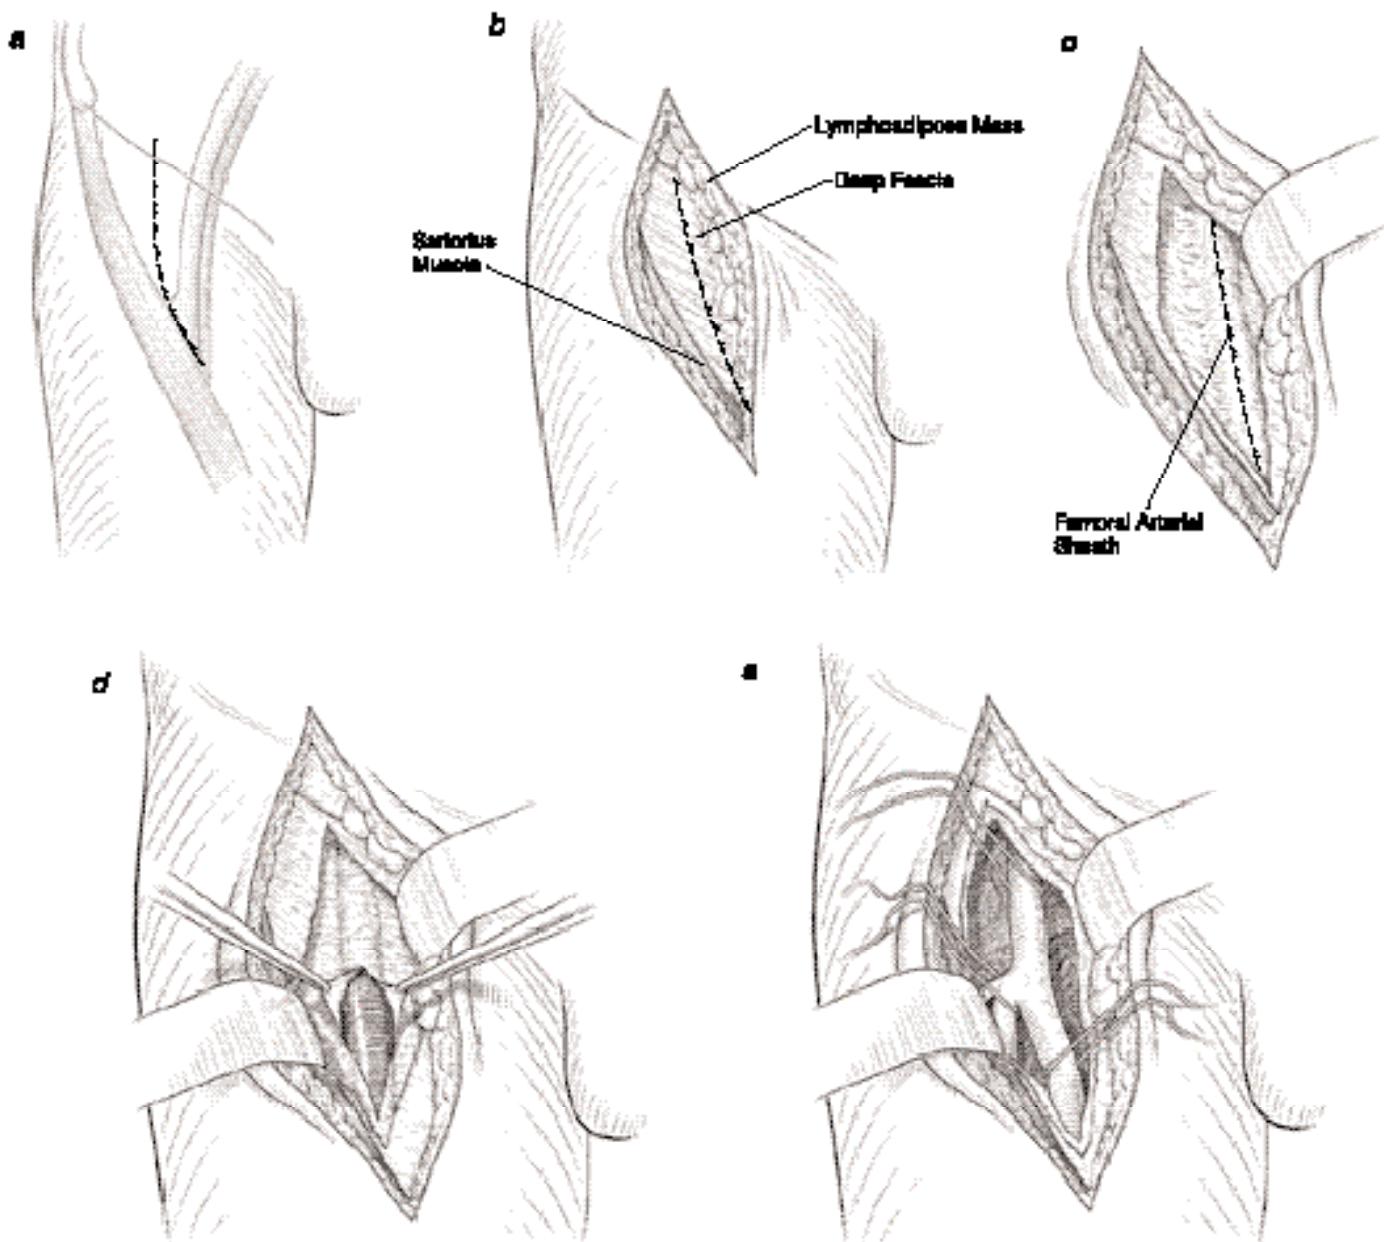

Figure 2 Femoropopliteal bypass: above knee. Depicted is exposure of the femoral artery. (a) A curved 4 to 5 in. skin incision is made slightly lateral to the pulsation of the femoral artery. (b) Lymphoadipose tissue is retracted to expose the deep fascia overlying the course of the femoral artery. (c) The deep fascia is incised, exposing the femoral arterial sheath, which is then opened along its axis (d). (e) The common and superficial femoral arteries are mobilized and encircled with Silastic vessel loops.

immediately placed into a basin containing heparinized saline (or heparinized whole blood) at a temperature of 4° C or cold Hanks solution. A small cannula is passed through the distal end of the divided vein, and the vessel is irrigated with cold Hanks solution to expel any liquid blood or clot and to locate any leaks. If a leak is found, it is repaired with 6-0 Prolene.

Step 1: exposure of femoral artery A slightly curved skin incision, with the concavity facing the medial aspect, is made starting at a point slightly above the inguinal crease and extending distally for 10 to 12.5 cm [see Figure 2a]. The incision should be slightly lateral to the pulsation of the femoral artery so as to avoid the lymphatics as much as possible. Any minor bleeding or

divided lymphatic vessels should be controlled with electrocoagulation or fine ligatures. Self-retaining retractors are placed both proximally and distally in the wound, and the lymphoadipose tissue is gently retracted medially [see Figure 2b].

The deep fascia is opened along the femoral artery [see Figure 2c], and the sheath of the artery is opened along its axis [see Figure 2d]. The common and superficial femoral arteries are mobilized, and Silastic loops are placed around them [see Figure 2e]. These vessels are then elevated slightly, and the origin of the deep femoral artery comes into view lateral and posterior to the common femoral artery and just proximal to the superficial femoral artery. Dissection of the origin of the deep femoral artery must be done carefully so as not to injure the collateral

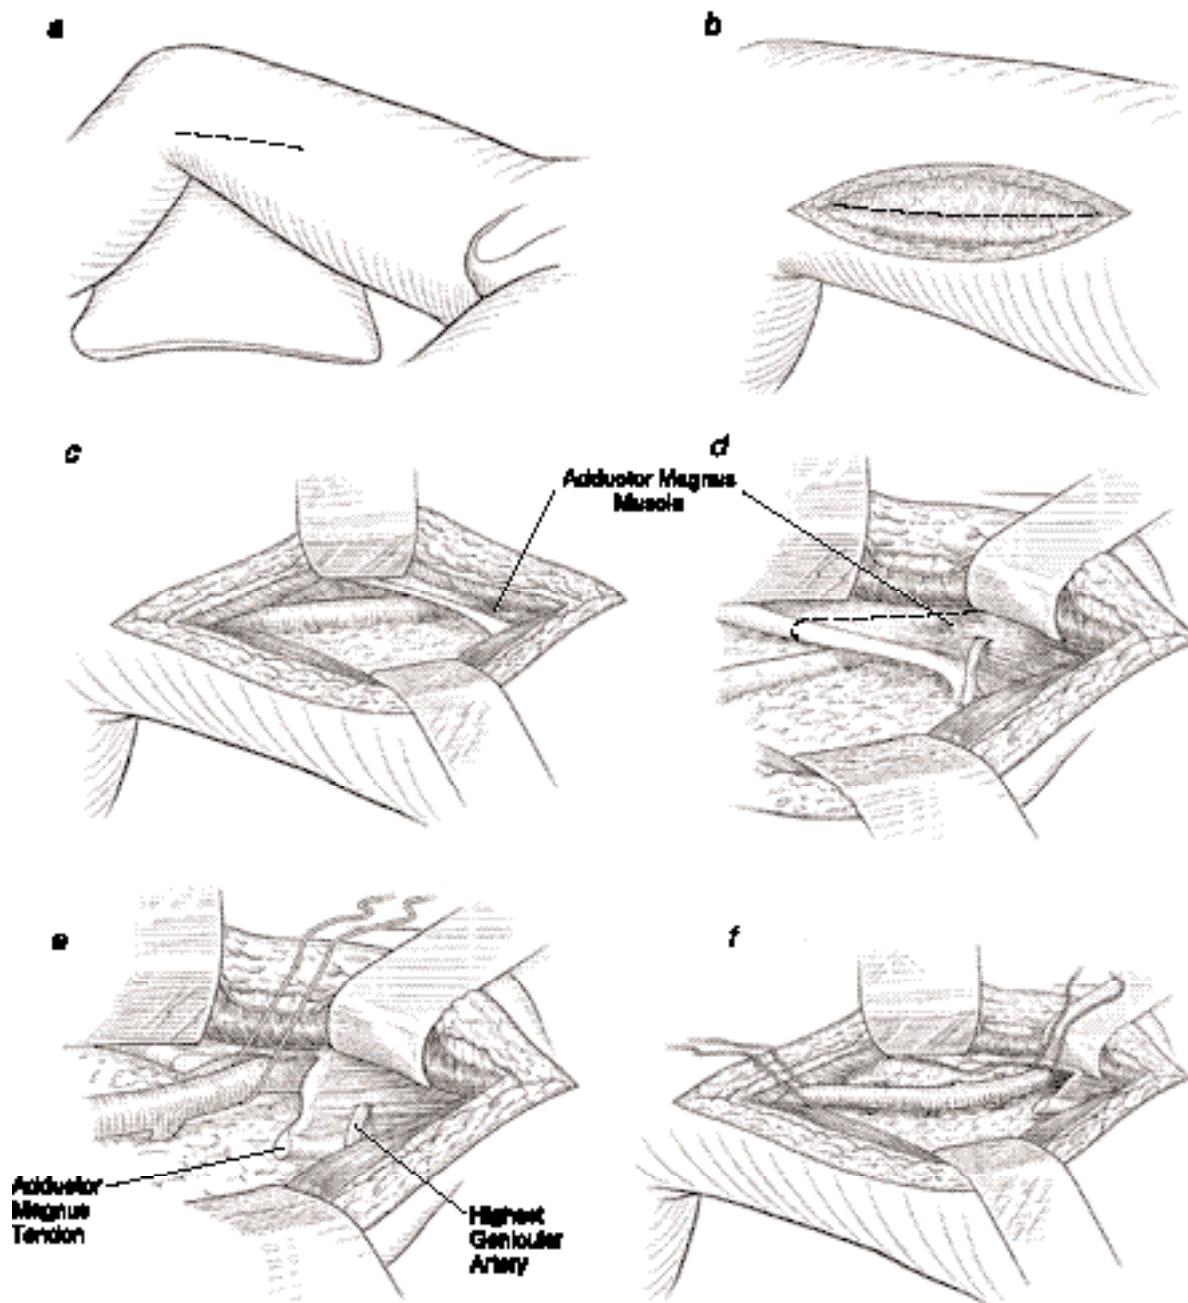

Figure 3 Femoropopliteal bypass: above knee. Depicted is medial exposure of the proximal popliteal artery. (a) An incision is made in the lower third of the thigh, anterior to the sartorius muscle. (b) The deep fascia is incised, and the sartorius muscle is retracted posteriorly, allowing the popliteal artery to be readily palpated. (c) The popliteal arterial sheath is opened, exposing the vessel and its surrounding venules. The adductor magnus tendon may be seen covering the proximal end of the artery (d), and it may have to be divided (e) to provide better exposure of the artery. (f) The popliteal artery, freed of the venous plexus, is mobilized between two vessel loops.

vessels coming off the artery at that level and the one or two branches of the satellite veins that cross the anterior portion of its initial segment. If mobilization of the deep femoral artery proves difficult, the satellite vein branches can be divided and ligated.

Step 2: exposure of proximal popliteal artery For the approach to the popliteal artery, the surgeon moves to the opposite side of the table. An incision is made in the lower third of the thigh anterior to the sartorius muscle and is extended close to the medial aspect of the knee [see Figure 3a]. The deep fascia anterior to the sartorius muscle is opened, and the sartorius

muscle is detached from the vastus medialis muscle and retracted posteriorly. The popliteal artery is identified by palpation; it is the most superficial structure palpable through this exposure [see Figure 3b]. The overlying fascia is incised, and the adipose tissue usually present at this level is dissected until the vascular bundle is reached.

The sheath of the artery is opened [see Figure 3c]. At this level, there is almost always a network of venules surrounding the artery, which must be carefully dissected away from the arterial wall. Division of the adductor magnus tendon may be required to yield adequate exposure of the proximal portion of the

popliteal artery [see Figures 3d and 3e]. The venous network is separated from the arterial adventitia, and the various branches are divided and ligated. The popliteal vein is then separated from the artery—a process that, because of the intimate connection between the two vessels, is sometimes quite difficult. In separating the vein from the artery, care must be taken not to injure any of the genicular branches of the artery. The popliteal artery is freed for a length of approximately 1.5 to 2 in., and vessel loops are placed around it [see Figure 3f].

If the proximal popliteal artery appears markedly sclerotic and unsuitable for anastomosis to the graft, the exposure must be extended to the middle portion of the artery. To achieve this extended exposure, the hamstring muscles and their tendons are mobilized and retracted posteriorly, and the medial head of the gastrocnemius muscle is divided close to the medial condyle of the femur.

Next, the sheath of the popliteal artery is opened farther distally, and the tributaries of the veins surrounding the artery are further dissected away from it. Dissection of the middle portion of the popliteal artery may be facilitated by flexing the knee; this measure relaxes the artery, thereby allowing it to be readily drawn closer to the superficial level of the exposure.

Step 3: creation of tunnel Implantation of the graft may be started in either the popliteal artery or the femoral artery; the former is our usual preference. Before the anastomoses are constructed, a tunnel is created under the sartorius muscle by means of either a tunneler or an aortic clamp with a red rubber catheter attached to it to mark the tunnel.

Step 4: construction of distal anastomosis to popliteal artery Heparin is routinely administered before the vascular clamps are applied. A longitudinal arteriotomy is made in the anterior wall of the artery with a sharp No. 15 knife blade. This arteriotomy is then enlarged with a scalpel or a Potts angled scissors. The length of the opening in the artery should be approximately twice the diameter of the vessel. If the edges of the arteriotomy are calcified and the atheromatous intima overlaps the cut edge, the diseased intima should be excised with arteriotomy scissors.

The saphenous vein segment is then brought into the field. It is reversed so that its proximal end becomes the distal end for the anastomosis. This distal end is then enlarged with a longitudinal incision in its posterior wall, and the right-angle tips of the two sides of the divided posterior wall are cut away. Double-armed sutures are placed through the proximal angle (or heel) of the graft, with the needles going from the outside of the arteriotomy to the inside and then from the inside to the outside. Next, a similar double-armed suture is passed through the distal angle (or toe) of the graft from the outside to the inside and then from the inside to the outside through the end of the arteriotomy.

The edge of the vein is then approximated to that of the arteriotomy with a continuous suture starting at the toe of the graft and proceeding toward the heel [see Figure 4]. When half of the anastomosis has been completed, the edge of the vein graft is separated from the edge of the opposite side of the arteriotomy to permit inspection of the arterial lumen and the completed suture. The other half of the anastomosis is then completed by placing a second continuous suture, starting at the heel and proceeding toward the toe. Finally, the two sutures are tied together midway between the heel and the toe to complete the popliteal anastomosis.

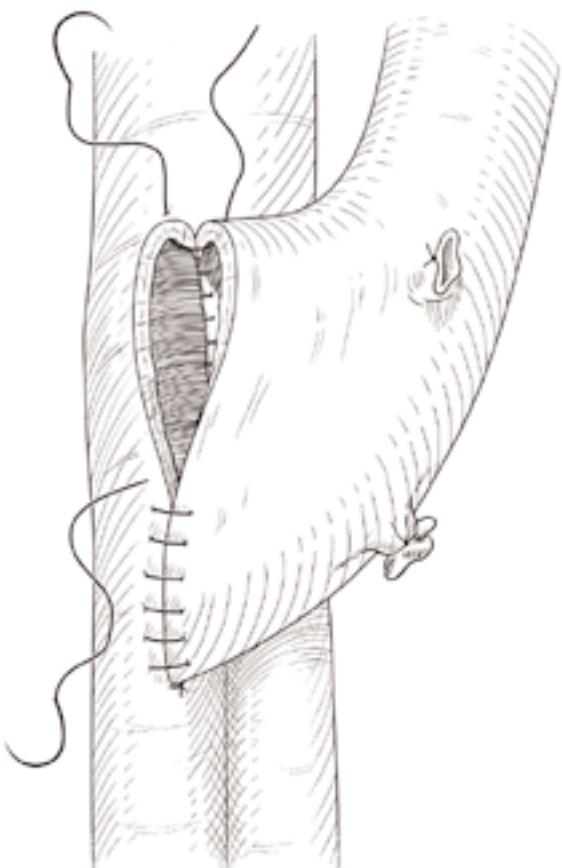

Figure 4 Femoropopliteal bypass: above knee. Shown are details of the anastomotic suturing, which is begun at the distal end and continued to the middle portion of each side of the anastomosis of the artery and the saphenous vein graft. Equal bites of all layers of each vessel are included in each stitch, all of which are placed under direct vision.

Step 5: placement of graft in tunnel The graft is distended by injecting heparinized saline solution into it to test for leaks either from the vein segment itself or from the anastomotic site. The graft is then marked to ensure that it does not become twisted when brought through the tunnel. The graft is brought through the tunnel either by using an aortic clamp or by attaching it to the previously placed red rubber catheter.

Step 6: construction of proximal anastomosis to femoral artery Before the proximal anastomosis is begun, the proper length of the graft should be determined to ensure that there is no redundancy. The proximal end of the graft is split and enlarged in the same fashion as the distal end, and the resulting right-angle corners are similarly trimmed. The graft is then anastomosed to the arteriotomy made in the femoral artery (which, like the popliteal arteriotomy, should be at least twice as long as the vessel is wide). The graft is attached by double-armed needles at its proximal angle and then in a similar fashion at its distal angle. The anastomosis is then completed from each end toward the center, just as the popliteal anastomosis was.

Below-the-Knee Bypass

When occlusion or marked stenosis renders the proximal and middle portions of the popliteal artery unsuitable for graft implantation, the lower portion of the vessel, which is often relatively free of atherosclerosis, may be used for the distal anastomosis instead.

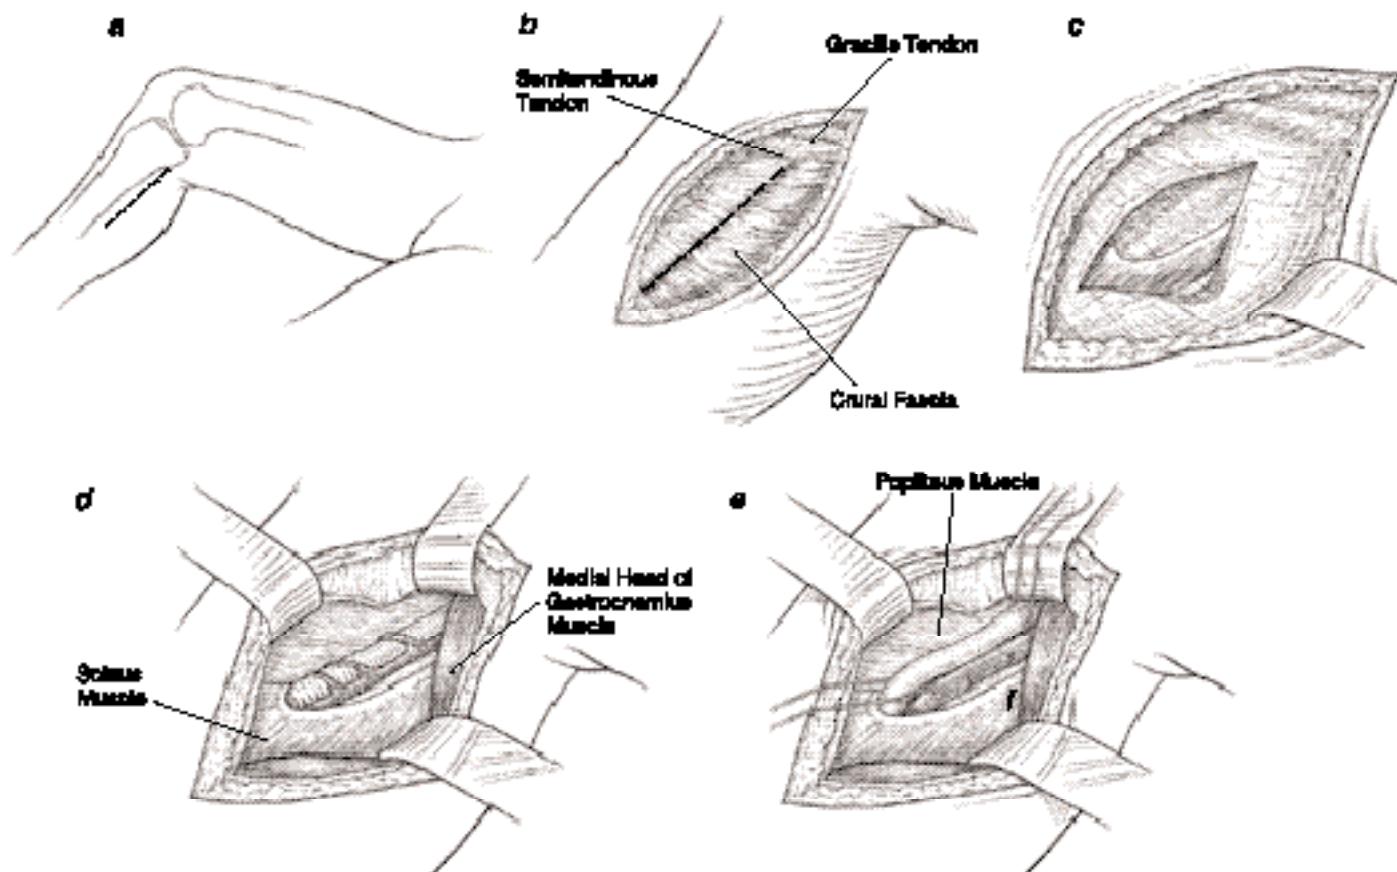

Figure 5 Femoropopliteal bypass: below knee. Depicted is medial exposure of the distal popliteal artery. (a) An incision is made just behind the posteromedial surface of the tibia. (b) The crural fascia is exposed. (c) The fascia is incised, exposing the vascular bundle. (d) The medial head of the gastrocnemius muscle is retracted posteriorly, exposing the distal popliteal vessels and the arcade of the soleus muscle. (e) The distal popliteal artery is freed and mobilized between vessel loops.

Step 1: exposure of popliteal artery With the knee moderately flexed and supported by a rolled sheet placed under it, a vertical skin incision is made just behind the posteromedial surface of the tibia [see Figure 5a], exposing the crural fascia [see Figure 5b]. Care must be taken to avoid injury to the greater saphenous vein during the skin incision. When a saphenous vein graft is to be used, the same incision can serve both for harvesting of the vein and for exposure of the artery.

The crural fascia is opened along its fibers [see Figure 5c], its distal attachments are separated from the semitendinosus and gracilis tendons, and the two tendons are mobilized proximally and, if necessary, divided. The medial head of the gastrocnemius muscle is retracted posteriorly [see Figure 5d] to expose the popliteal artery and vein and the posterior tibial nerve as these structures cross the popliteus muscle posteriorly [see Figure 5e].

It should be noted that (1) the distal popliteal artery has few branches below the inferior geniculate arteries, (2) atheromatous plaques are rarely present at this level, and (3) the arterial wall is often more suitable for graft implantation in this portion of the popliteal wall than it is above the knee.

Step 2: exposure of femoral artery This exposure is accomplished in essentially the same way as it would be in an above-the-knee bypass.

Step 3: creation of tunnel Tunneling for a below-the-knee femoropopliteal bypass is carried out through Hunter's canal,

through the upper popliteal space, and finally through the region behind the popliteus muscle.

Steps 4 through 6 Steps 4, 5, and 6 of a below-the-knee femoropopliteal bypass—the distal anastomosis of the vein graft to the distal popliteal artery, the placement of the graft in the tunnel, and the proximal anastomosis to the femoral artery—are carried out in much the same way as the corresponding steps in an above-the-knee bypass. A completion angiogram should be obtained to confirm the adequacy of the distal anastomosis and verify the position of the graft in the tunnel [see Figure 6].

OUTCOME EVALUATION

Femoropopliteal bypasses performed with segments of the greater saphenous vein are associated with 4-year primary patency rates ranging from 68% to 80% and limb salvage rates ranging from 75% to 80%.²⁹ Femoropopliteal bypasses performed with polytetrafluoroethylene (PTFE) grafts yield comparable patency and limb salvage rates above the knee but are significantly less successful below the knee.³⁰

Newer vein harvesting techniques may help improve outcome further. The use of endoscopic vein harvesting methods has been shown to reduce the incidence of wound complications associated with femoropopliteal bypass.³¹ This approach allows above-the-knee bypasses to be performed through two incisions.

Infrapopliteal Bypass

Bypasses to the small arteries beyond the popliteal artery are performed only when femoropopliteal bypass is contraindicated according to accepted criteria [see Femoropopliteal Bypass, *above*]. Infrapopliteal bypasses are performed to the posterior tibial artery, the anterior tibial artery, or the peroneal artery, in that order of preference. As a rule, a tibial artery is used only if its lumen runs without obstruction into the foot, though bypasses to isolated tibial artery segments and other disadvantaged outflow tracts have been performed and have remained patent for more than 4 years.^{2,3} Generally, the peroneal artery is used only if it is continuous with one or two of its terminal branches, which communicate with foot arteries [see *Figure 7*]. Neither the absence of a plantar arch nor vascular calcification is considered a contraindication to a reconstruction.^{2,7} With both femoropopliteal and infrapopliteal bypasses, stenosis of less than 50% of the diameter of the vessel is acceptable at or distal to the site chosen for the distal anastomosis.

OPERATIVE TECHNIQUE

Bypasses to tibial arteries should be performed with autogenous vein grafts, and either the reversed technique (as previously described [see Femoropopliteal Bypass, *above*]) or the in situ technique [see In Situ Bypass, *below*] may be used. Placement of a tourniquet above the knee allows the distal anastomosis to be performed without extensive dissection of the tibial vessels or the application of clamps.³² Exposure of the inflow vessel (i.e., the femoral artery or the popliteal artery) is achieved in the same way as in femoropopliteal bypass. Accordingly, bypasses to tibial and

Figure 6 Femoropopliteal bypass: below knee. A completion arteriogram from a patient who underwent below-the-knee femoropopliteal bypass for a nonhealing toe amputation site shows runoff through all three tibial vessels.

Figure 7 Infrapopliteal bypass. An arteriogram from a 65-year-old female with rest pain in the right foot who underwent in situ bypass to the middle portion of the peroneal artery shows communication of the peroneal artery with foot arteries and reconstitution of the dorsalis pedis artery.

peroneal arteries are best described in terms of the approaches required for exposure of these vessels and the tunnels required for routing the bypass conduits.

Exposure of Posterior Tibial Artery

The very proximal portion of the posterior tibial artery is approached via a below-the-knee popliteal incision. The deep fascia is incised, and the popliteal space is entered. The gastrocnemius muscle is retracted posteriorly, and the soleus muscle is separated from the posterior surface of the tibia. The distal portion of the posterior tibial artery is approached via a medial incision along the posterior edge of the tibia [see *Figure 8*]; deepening this incision along the posterior tibialis muscle and the posterior surface of the tibia allows exposure of the posterior tibial artery. The tunnel from the popliteal fossa to the distal posterior tibial artery is made just below the muscle fascia, ideally with a long, gently curved clamp.

Exposure of Anterior Tibial Artery

To expose the proximal portion of the anterior tibial artery, an anterolateral incision is made in the leg midway between the tibia and the fibula over the appropriate segment of patent artery [see

Figure 8 Infrapopliteal bypass: posterior tibial artery. Shown are incisions for bypasses to the distal regions of the leg.

Figure 9a] Additional small medial incisions are also required for tunneling. The anterior incision is carried through the deep fascia, and the fibers of the anterior tibial muscle and the extensor digitorum longus muscle are separated to reveal the neurovascular bundle. The accompanying veins are mobilized and their branches divided to allow visualization of the anterior tibial artery, which can then be carefully mobilized [*see Figure 9b*]. With the artery mobilized, further posterior dissection can be performed, and the interosseous membrane can then be visualized and incised in a cruciate fashion.

Careful blunt finger dissection via the anterior incision and from the popliteal fossa via the medial incision facilitates creation of a tunnel without injury to the numerous veins in the area [*see*

Figure 9c]. Alternatively, the tunnel for the bypass may be placed lateral to the knee in a subcutaneous plane.

The distal anterior tibial artery is approached via an anterior incision placed midway between the tibia and the fibula [*see Figure 8*]. A tunnel is made from the distal popliteal fossa across the interosseous membrane (like the tunnel to the peroneal artery) and beneath the deep fascia to a point 5 to 7 cm above the lateral malleolus. Once the distal anastomosis is complete and the graft has been drawn through the tunnel, any tendons that may be distorting or compressing the graft in its course around the tibia are divided; this measure proves necessary in most low anterior tibial bypasses.

Exposure of Peroneal Artery

The peroneal artery is usually approached via the same incision as the posterior tibial artery [*see Exposure of the Posterior Tibial Artery, above*]. The artery is located and isolated just medial to the medial edge of the fibula. In its distal third, however, and in patients with stout calves and ankles, the peroneal artery should be approached via a lateral incision [*see Figure 8*], followed by excision of the fibula.

For lateral exposure of the peroneal artery, a long segment of fibula is freed from its muscle attachments with a combination of blunt and sharp dissection; particular care should be taken in dissecting along the medial edge of the bone because the peroneal vessels run just below this edge and are easily injured by instruments. Next, a finger is passed around the fibula [*see Figure 10a*]; once this is done, the free edge of bone is further developed by

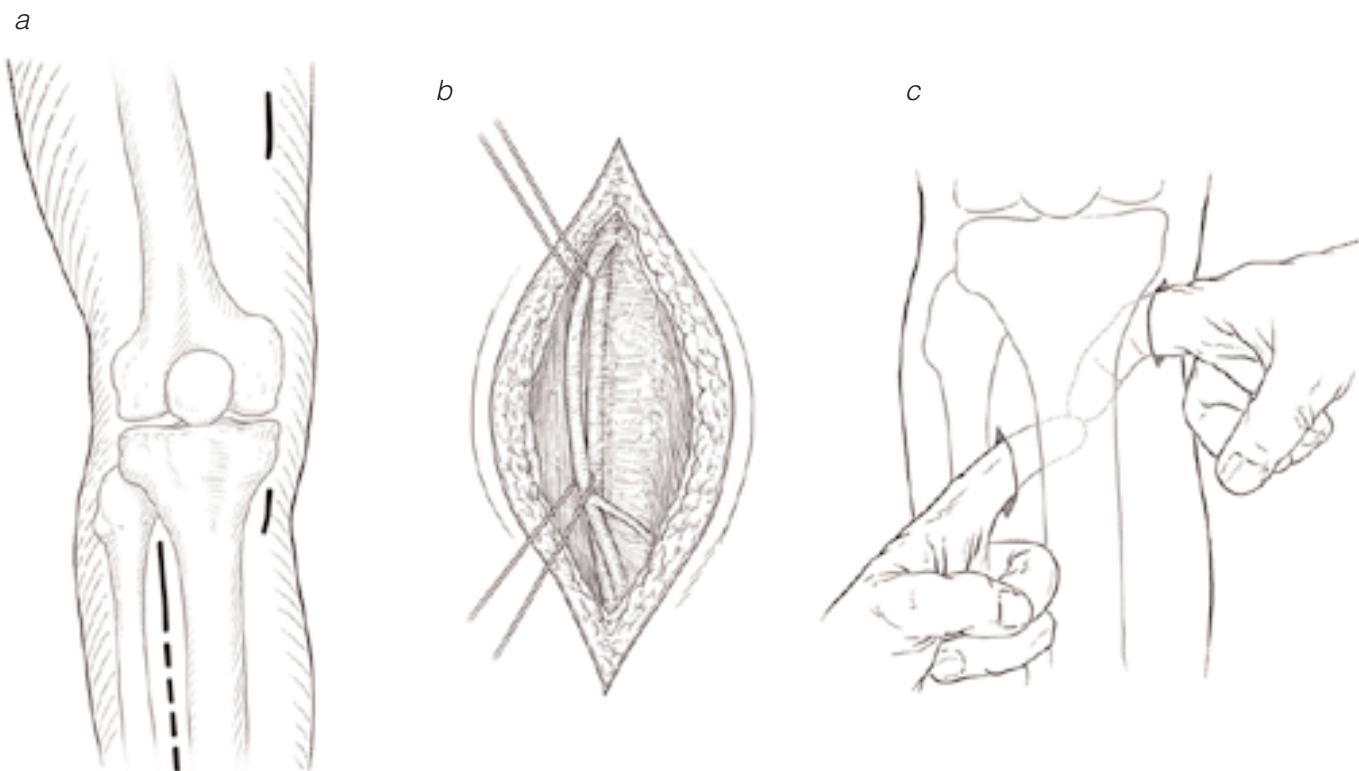

Figure 9 Infrapopliteal bypass: anterior tibial artery. (a) An anterolateral incision is made midway between the tibia and the fibula over the artery; small medial incisions are also made for tunneling. (b) The anterior incision is carried through the deep fascia, the anterior tibial and extensor digitorum longus muscles are separated, the accompanying veins are mobilized and divided, and the anterior tibial artery is mobilized. (c) A tunnel is created with careful blunt finger dissection.

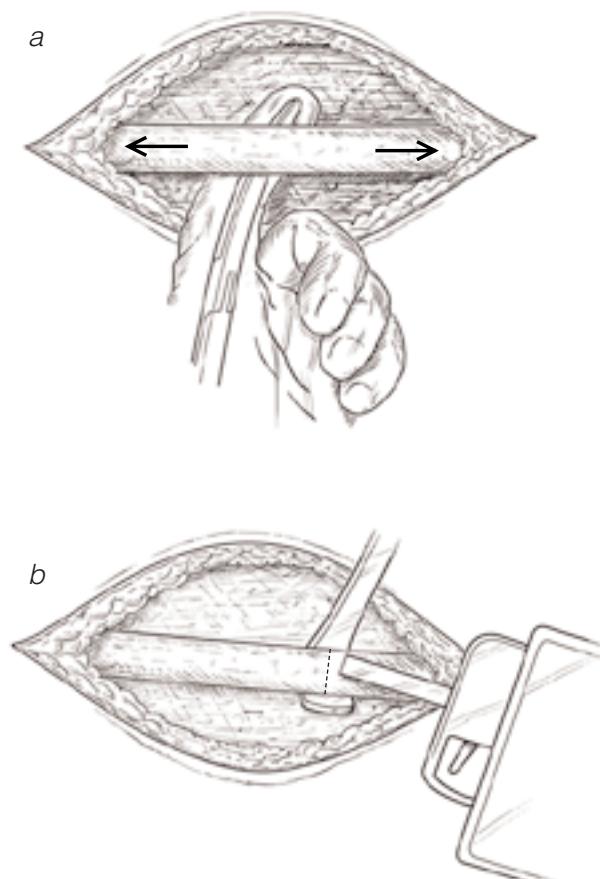

Figure 10 Infrapopliteal bypass: lateral exposure of peroneal artery. Lateral exposure of the peroneal artery typically requires excision of part of the fibula; this is done by (a) passing a finger behind the fibula, developing the free bone edge further with a right-angle clamp, (b) passing a right-angle retractor behind the fibula, and dividing the bone with a power saw.

forcefully pushing a right-angle clamp inferiorly and superiorly [see Figure 10b]. A right-angle retractor is passed behind the bone, and the fibula is divided with a power saw. The peroneal artery can then be dissected free from surrounding veins and used in the construction of the distal anastomosis.

Gentle blunt finger dissection is required to develop a tunnel from this lateral wound to the distal popliteal fossa, and great care should be taken to avoid injury to the numerous veins in the area. Because the peroneal artery is the least accessible of the three leg arteries used for infrapopliteal bypasses and normally has the poorest connections with the arteries of the foot, we recommend that it be used as a distal implantation site only when the anterior and posterior tibial arteries are not suitable.

Exposure of Dorsalis Pedis Artery

When no more proximal procedure is possible, a bypass to the ankle region or the foot may be performed. The dorsalis pedis artery is easily approached via a lateral incision on the dorsum of the foot [see Figure 11a]. The incision is curved slightly and a flap raised so that the incision will not be directly over the anastomosis [see Figure 11b]. If the artery must be approached at the ankle, the extensor retinaculum must be divided. Otherwise, the operation is performed in much the same fashion as a distal anterior tibial bypass [see Figure 12]. The posterior tibial artery can be

approached down to a point several centimeters below the medial malleolus.

In Situ Bypass

In situ bypass is an acceptable alternative to reversed vein bypass. Minimally invasive techniques have been developed to reduce the wound complications encountered when in situ bypass is performed with long incisions.

With the help of a side-branch coil occlusion system, in situ bypass can be performed through the two arterial access incisions. The angioscopic coil device is passed through the proximal greater saphenous vein, and the coils are placed into the side branches under angioscopic guidance [see Figure 13]. As the device is advanced more distally through the vein, the valves are lysed with a flexible valvulotome.

Another approach to side-branch occlusion involves the use of an endoscopic vein harvesting system. Three skin incisions are made: two incisions for arterial access and one 2 cm incision above the knee for insertion of an endoscopic device to locate and clip the side branches of the saphenous vein. Once the proximal anastomosis is complete, the valves are lysed with a flexible valvulotome passed through the distal end of the vein. Completion cineangiography is then performed to confirm side-branch occlusion and to assess the entire reconstruction.³³

OUTCOME EVALUATION

Infrapopliteal bypasses should have 5-year primary patency rates ranging from 60% to 67% and limb salvage rates ranging from 70% to 75% whether they are done with the reversed-vein technique or with the in situ technique.^{34,35} For all such grafts, close patient follow-up and graft surveillance improve secondary

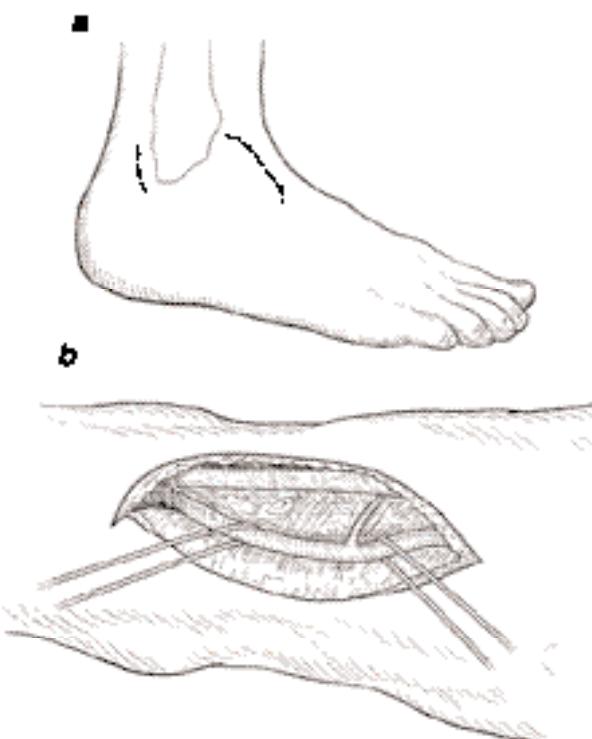

Figure 11 Infrapopliteal bypass: dorsalis pedis artery. (a) The dorsalis pedis artery is approached via an incision on the dorsum of the foot. (b) The incision is curved and a flap raised so that the incision is not directly over the anastomosis.

patency rates. Reduced complications and decreased length of stay have been reported for patients undergoing distal *in situ* bypasses using either the endoscopic or the coil occlusion approach.^{36,37}

Plantar Bypass

Extension of the standard approaches to limb salvage has led to the performance of bypasses to vessels below the ankle joint [see Figures 14 and 15]. Such bypasses are indicated when the more proximal tibial vessels are occluded, which frequently occurs secondary to failure of a more proximal bypass. The technique required for performing bypasses to secondary branches in the foot is essentially the same as that required for performing bypasses to major infrapopliteal vessels.

Optimal illumination by means of head lamps is important for achieving technical success with plantar bypass, and loupe magnification is helpful when the vessel is less than 1.5 mm in diameter. In addition, visualization of perimalleolar and inframalleolar arteries requires excellent preoperative imaging studies.

Figure 12 Infrapopliteal bypass: dorsalis pedis artery. Shown is an arteriogram from a 72-year-old diabetic patient who underwent a popliteal artery–dorsalis pedis artery bypass with a reversed saphenous vein graft for a nonhealing great toe amputation.

Figure 13 Infrapopliteal bypass: *in situ* technique. A completion arteriogram from a patient who underwent an *in situ* bypass with coil occlusion of the side branches shows the two coils (arrows), which have successfully occluded the side-branch veins.

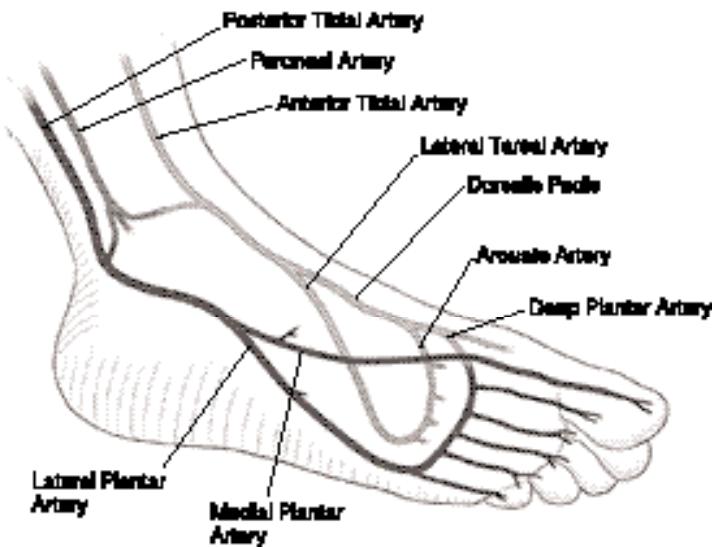

Figure 14 Plantar bypass. Shown are the major arteries of the foot, including the two major branches of the posterior tibial artery.³ The lateral plantar artery is usually the larger and ends in the deep plantar arch.

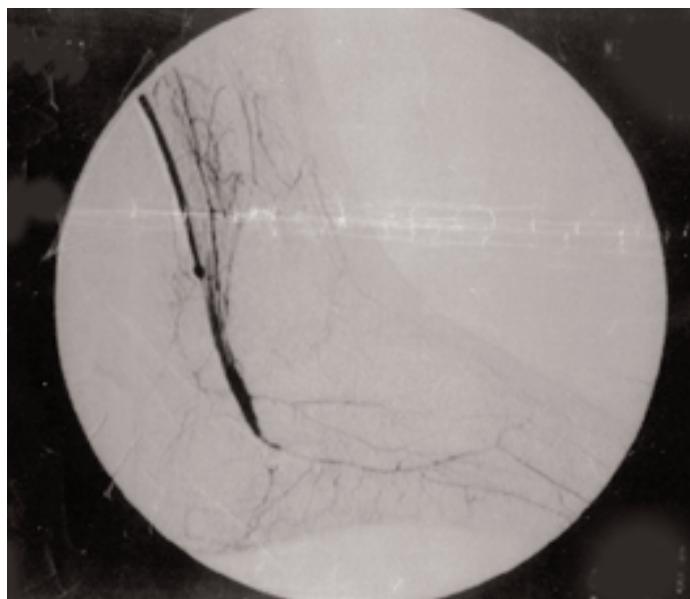

Figure 15 Plantar bypass. A completion arteriogram from a 62-year-old diabetic with nonhealing toe ulcers who underwent a popliteal artery-medial plantar artery bypass with a reversed saphenous vein graft shows the distal anastomosis, with flow visible through a small but patent medial plantar artery.

These very distal bypasses offer a viable alternative to a major amputation. Like infrapopliteal bypasses, they are best described in terms of the anatomic approaches to the distal branch vessels. In what follows, we outline exposure of the plantar and tarsal arteries; exposure of the dorsalis pedis artery is outlined elsewhere [see Infrapopliteal Bypass, above].

OPERATIVE TECHNIQUE

Exposure of Lateral and Medial Plantar Arteries

The lateral and medial plantar branches are the continuation of the posterior tibial artery in the foot [see Figure 16]. The lat-

eral plantar artery forms the deep plantar arch and is larger than the medial plantar artery. If the lateral branch is occluded, the medial branch may enlarge and feed the plantar arch through collateral vessels.

The initial incision is made over the termination of the posterior tibial artery below the malleolus. The artery is isolated, and the incision is extended inferiorly and laterally onto the sole. A direct approach to the individual branches is difficult, for several reasons. First, because the skin of the sole is not easily retracted, adequate exposure of the lateral and medial plantar arteries is hard to obtain if the incision does not follow their course exactly. Second, because these arteries are small in diameter and lie deep within the foot, they can be quite difficult to locate. Third, it is sometimes hard to distinguish the lateral plantar artery from the medial plantar artery. Dissection of the termination of the posterior tibial artery can help the surgeon make this distinction. The lateral branch is usually located inferiorly when the foot is externally rotated on the operating table.

Exposure of the proximal 2 to 3 cm of the plantar branches is accomplished by incising the flexor retinaculum and the adductor muscle of the great toe. More distal exposure of these branches can be obtained by dividing the medial border of the plantar aponeurosis and the extensor digitorum brevis muscle.

Exposure of Deep Plantar Artery and Lateral Tarsal Artery

The deep plantar artery and the lateral tarsal artery are branches of the dorsalis pedis artery. The deep plantar artery originates at the metatarsal level, where it descends into a foramen bounded proximally by the dorsal metatarsal ligament, distally by the dorsal interosseous muscle ring, and medially and laterally by the bases of the first and second metatarsal bones. As the deep plantar artery exits from this tunnel, it connects with the lateral plantar artery to form the deep plantar arch [see Figure 17].

A slightly curved longitudinal 3 to 4 cm incision is made over the dorsum of the middle portion of the foot, and the dorsalis pedis artery is dissected distally down to its bifurcation into the deep plantar and first dorsal metatarsal branches. The extensor hallucis brevis muscle is retracted laterally—or, if necessary,

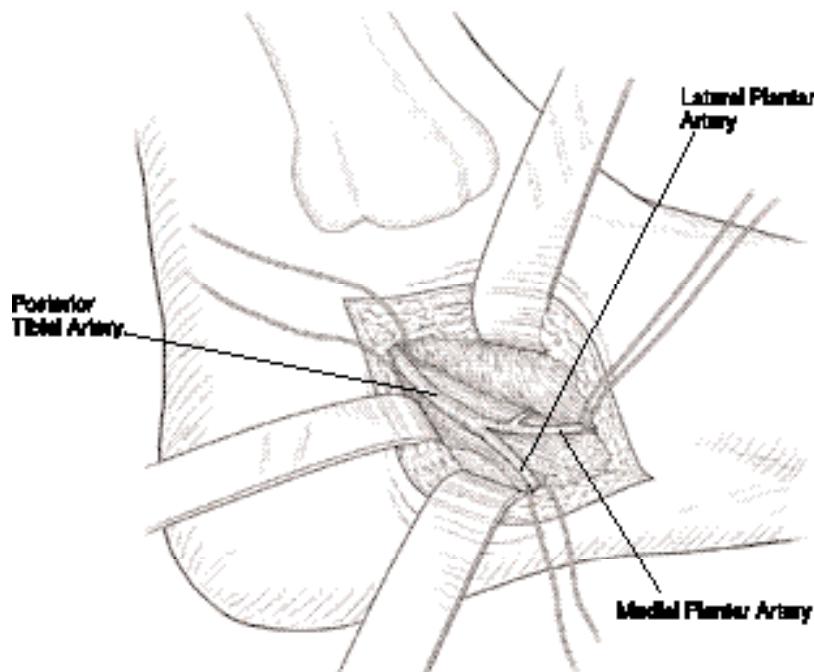

Figure 16 Plantar bypass. Depicted is exposure of the distal portion of the posterior tibial artery. The lateral and medial plantar arteries branch from this vessel and lie beneath the flexor retinaculum and the abductor hallucis muscle, which can be incised.

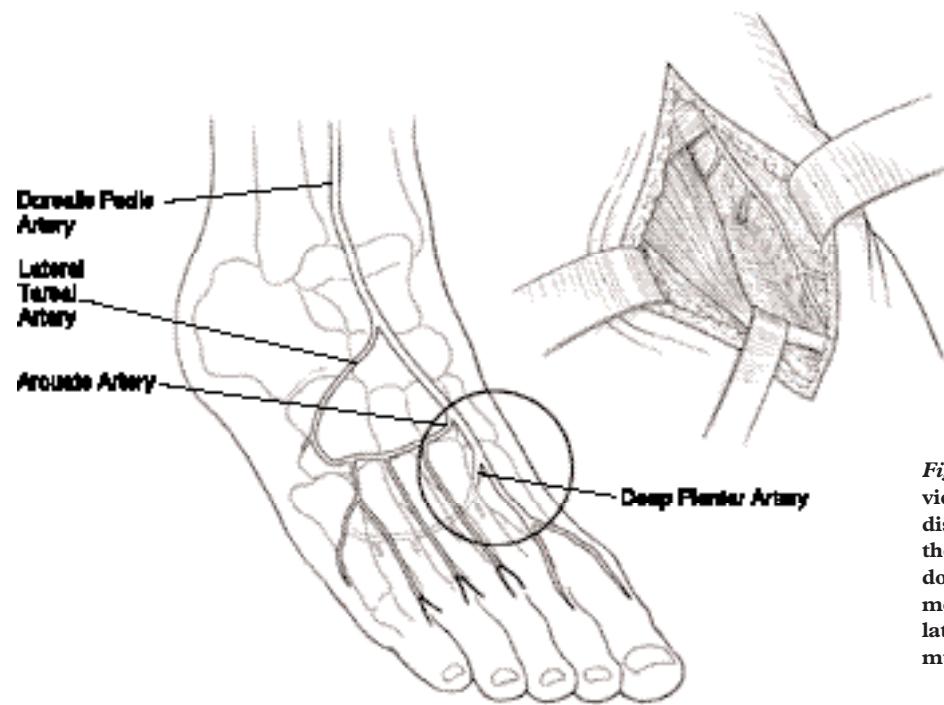

Figure 17 Plantar bypass. Shown is a dorsal view of the arteries of the foot. Exposure of the distal dorsalis pedis artery (insert) highlights the origin of the deep plantar artery and its downward course between the first and second metatarsal bones. This exposure is facilitated by lateral retraction of the extensor hallucis brevis muscle.

transected—and the dorsal interosseous muscle ring is split to allow better exposure of the proximal portion of the deep plantar artery. The periosteum of the proximal portion of the second metatarsal bone is then incised and elevated. A fine-tipped rongeur is used to excise enough of the metatarsal shaft to permit ample exposure of the deep plantar artery.

OUTCOME EVALUATION

Bypasses to the dorsalis pedis artery and its branches have yielded results comparable to those of bypasses to more proximal tibial vessels, with 3-year primary patency rates ranging from 58% to 60% and limb salvage rates ranging from 75% to 95%.³⁸⁻⁴⁰ In one review, patency rates were higher in patients who had an intact plantar arch than in those who did not; however, failure to visualize the plantar arch on preoperative arteriograms does not preclude the performance of these bypasses for limb salvage. With careful follow-up, the assisted primary patency rates for these grafts have been substantially improved.⁴¹ The available reports emphasize the need to repair failing grafts because their secondary patency was much better than that of failed grafts. In one study, patients who required shorter bypasses or had lower preoperative C-reactive protein levels experienced significantly better outcomes.⁴² In some patients, occlusion of the distal tibial vessel necessitates performance of a tibiotalibial bypass to achieve wound healing.⁷

Bypasses to plantar or tarsal vessels performed with vein grafts yield 2-year patency rates ranging from 65% to 75% and limb salvage rates higher than 80%.⁴³ In one report, the primary patency rate for these grafts was 74% at 1 year and 67% at 2 years, and the limb salvage rate was 78% at 2 years.³

Alternative Bypasses Using More Distal Inflow Vessels

Traditionally, the femoral artery has been the inflow site of choice for infrainguinal bypasses. Since the early 1980s, the superficial femoral, deep femoral, popliteal, and tibial arteries have all been used as inflow sources when these vessels were relatively disease free or when the amount of autologous vein available was lim-

ited. Currently, the superficial femoral artery and the popliteal artery are preferentially used for primary bypasses when they are free of disease.

The strategy of utilizing more distal inflow sources is particularly applicable to inframalleolar bypasses, in which very long vein segments would be required to reach the dorsalis pedis or other pedal arteries from the usual more proximal inflow sites. Two studies from the latter half of the 1980s reported that the patency rates in bypasses originating from the superficial femoral and popliteal arteries were comparable to those in bypasses originating from the common femoral artery.^{43,44} In a review of our own experience with popliteal-distal vein graft bypasses,⁵ we reported a patency rate of 65% at 4 years—a figure comparable to rates reported for femorodistal bypasses with reversed or *in situ* vein grafts (67% and 69%, respectively).³⁴ Given these results, surgeons should not hesitate to employ either the popliteal artery or the superficial femoral artery as an inflow source. Use of these more distal inflow sites results in shorter grafts and allows portions of saphenous vein to be preserved for other purposes.

An increasing number of limb salvage procedures are secondary interventions. These secondary procedures are generally more difficult to perform because the access routes to the arteries have been previously dissected and because there frequently is little good autologous vein left. In some cases, patients present with gangrene developing below a functioning bypass or after a previous failed bypass. Some of these patients need nothing more than a short distal extension of their functioning bypass; others have only enough vein left to make up a short graft. For such patients, a tibiotalibial bypass may be an effective alternative revascularization approach.

In 1994, our group reported our 11-year experience with tibiotalibial bypasses, comprising 42 procedures in 41 patients.⁷ Ten of these bypasses were performed because previous bypasses failed; the remainder were performed because the amount of autologous vein available was limited. Approximately 50% of the bypasses were to pedal or tarsal vessels. At 5 years, the patency rate for these grafts was 65%, and the limb salvage rate was 73%.⁷ A subsequent study reported comparable results.⁴⁵

19 LOWER-EXTREMITY AMPUTATION FOR ISCHEMIA

William C. Pevec, M.D., F.A.C.S.

Patients with infected, painful, or necrotic lower extremities can be restored to a better functional level by means of a properly selected and performed amputation. This procedure should be considered reconstructive and restorative. In what follows, I address amputations across the toe, the forefoot, the leg, and the thigh. Because Symes' amputations and hip disarticulations are seldom appropriate on ischemic limbs, I omit discussion of these procedures.

General Preoperative Planning

Selecting the appropriate level of amputation is of primary importance for healing and preservation of function. For an ambulatory patient who has either a palpable pulse over the dorsal pedal or posterior tibial arteries or a functioning infrapopliteal arterial bypass graft, amputation on the foot (either toe amputation or transmetatarsal amputation) is appropriate. For an ambulatory patient who has a palpable femoral pulse and a patent profunda femoris artery, whose skin is warm at least to the level of the ankle, and who has no skin lesions on the proposed amputation flaps, amputation below the knee is appropriate. For a nonambulatory patient who has ischemic rest pain, ulceration, or gangrene, amputation above the knee is appropriate. Arterial reconstruction is not indicated if the extremity is nonfunctional. Below-the-knee amputation does not offer nonambulatory patients any functional advantage; moreover, it is less likely to heal and often results in a flexion contracture at the knee that leads to pressure ulceration of the stump. Above-the-knee amputation depends on pulsatile flow into the ipsilateral internal iliac artery for successful healing. Above-the-knee amputation is also necessary for a patient whose skin is cool at or above the midcalf or who has skin lesions at or proximal to the midcalf.

Several adjunctive measurements (e.g., transcutaneous oxygen tension and segmental arterial pressure) have been used to select the level of amputation but have not proved particularly helpful. Generally, these adjuncts can reliably determine a level of amputation at which healing is virtually ensured, but they cannot reliably determine the level at which an amputation will not heal. Consequently, reliance on such measures to select the level of amputation will result in an unnecessarily high percentage of more proximal amputations.

In most cases, definitive amputation can be accomplished in a single stage. Local cellulitis can usually be controlled beforehand with bed rest and systemic administration of antibiotics. Undrained pus or recalcitrant cellulitis, however, must be treated with debridement and drainage in advance of definitive amputation. This can be accomplished with local soft tissue debridement, single-toe amputation, or guillotine amputation across the ankle.

Careful preoperative medical assessment is essential. Lower-

extremity amputation for ischemia is associated with a mortality of 4.5% to 16%,¹⁻⁶ owing to the poor overall condition of the patient population. Accordingly, optimization of cardiac and pulmonary function and control of systemic infection are mandatory.

Finally, the timing of elective amputation is crucial. Because the loss of a limb is a difficult and frightening thing for a patient to accept, there is a natural tendency to delay amputation for as long as possible. This tendency is understandable but must be weighed against the potential problems associated with delay, such as poor preoperative pain control, which leads to an increased incidence of postamputation phantom limb pain, and extended preoperative immobility, which leads to physical deconditioning and makes prosthetic limb rehabilitation more difficult. A preoperative consultation with a physiatrist can allay some of the patient's anxiety by addressing the expected postoperative course of rehabilitation and thereby removing some of the fear of the unknown.

Toe Amputation

Amputation of the toe can be done either across a phalanx or across a metatarsal bone; the latter procedure is commonly referred to as a ray amputation. Many of the perioperative issues are essentially similar for the two approaches; however, indications and operative details differ somewhat and thus will be described separately.

OPERATIVE PLANNING

As noted (see above), for a toe amputation to heal properly, there must be either a palpable pulse over the dorsal pedal or posterior tibial artery or a functioning bypass graft to an infrapopliteal artery. If tissue necrosis or infection is confined to the distal or middle phalanx, transphalangeal amputation is appropriate; if tissue loss or necrosis involves the proximal phalanx, ray amputation is indicated. If tissue necrosis or infection extends over the metatarsophalangeal joint, either transmetatarsal amputation of the entire forefoot or below-the-knee amputation is usually necessary (see below).

Multiple transphalangeal amputations are functionally well tolerated. If, however, ray amputation of the great toe or of more than one smaller toe is called for, it is preferable to perform a transmetatarsal amputation of the forefoot. Adequate skin coverage is usually difficult to achieve with a great-toe or multiple-toe ray amputation. In addition, ray amputation of more than one of the middle toes often causes central deviation of the remaining outside toes, which can lead to ulcerations secondary to abnormal pressure points. Finally, loss of the first metatarsal head or of several of the other metatarsal heads results in abnormal weight bearing on the remaining metatarsal heads, which may give rise to late ulceration.

OPERATIVE TECHNIQUE

Transphalangeal Amputation

Digital block anesthesia is ideal for transphalangeal amputation. A 25-gauge needle is inserted into the skin over the medial aspect of the dorsum of the proximal phalanx and advanced until the bone is encountered. The needle is then withdrawn slightly, and a small amount of fluid is aspirated to confirm that the tip of the needle is not in a blood vessel. Next, 0.5 to 1.0 ml of lidocaine, 0.5% or 1.0% without epinephrine, is slowly injected. The needle is then carefully advanced medial to the bone until the tip can be felt pressing against (but not puncturing) the plantar skin. Again, the needle is withdrawn slightly, fluid is aspirated, and 0.5 to 1.0 ml of lidocaine is injected. The same technique is repeated on the lateral aspect of the proximal phalanx. In this way, all four digital nerve branches are blocked. If multiple toe amputations are required, an ankle block, epidural anesthesia, spinal anesthesia, or general anesthesia can be used.

An incision is made to create dorsal and plantar skin flaps. Typically, these flaps are equal in length; however, depending on the location of the skin lesion, either the dorsal flap or the plantar flap can be left longer [see Figure 1]. Care must be taken not to create excessively long flaps, which may lack sufficient perfusion for healing, or to create undermined bevels with the scalpel [see Figure 2], which will lead to epidermolysis of the suture line.

The incision is extended down to the phalanx, and the soft tissues are gently separated from the bone with a small periosteal elevator. All tendons and tendon sheaths are debrided because the poor vascularity of these tissues may compromise the healing of the toe. The phalanx is transected at the level of the apices of the skin incisions [see Figure 1]. Care must be taken not to leave the remaining bone segment too long: this places undue tension on the skin flaps and is a primary cause of poor healing. The best way of transecting the phalanx is to use a pneumatic oscillating saw. Manual bone cutters can splinter the bone, and manual saws can cause extensive damage to the soft tissues. The bone is always transected across the shaft: because of the poor vascularity of the articular cartilage, disarticulation across a joint typically leads to poor healing.

Hemostasis is achieved with absorbable sutures and limited use of the electrocautery. Excessive tissue manipulation and electrocauterization should be avoided. The skin edges are carefully approximated with simple interrupted nonabsorbable monofilament sutures; perfect apposition is necessary to maximize the potential for primary healing. The sutures must not be placed too close to the skin edges, because the heavily ker-

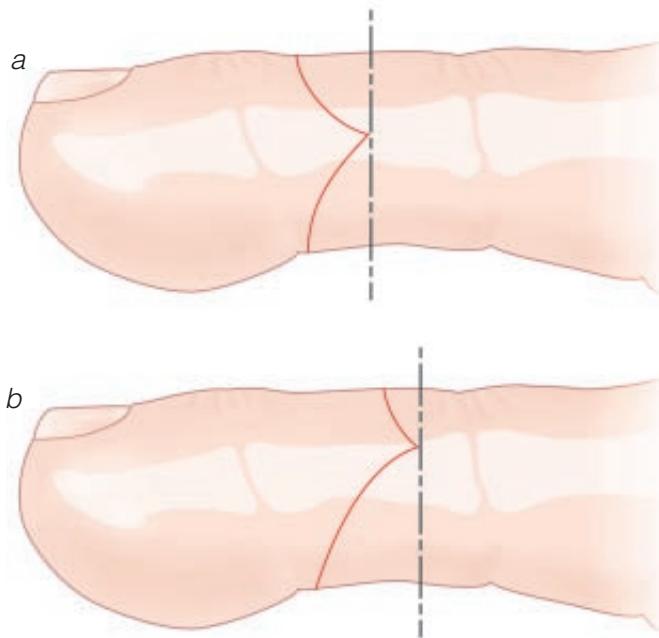

Figure 1 Toe amputation: transphalangeal amputation. Transphalangeal amputation can be performed either with dorsal and plantar flaps of equal length (a) or with a plantar flap that is longer than the dorsal flap (b). The phalanx is transected at the level of the apex of the skin flaps (dashed line). The bone is transected through the shaft of the phalanx, never across the joint.

tinized skin of the foot is easily lacerated. The final step is the application of a soft dressing.

Ray Amputation

For ray amputation [see Figure 3], spinal, epidural, or general anesthesia can be employed. A so-called tennis-racket incision is made—that is, a straight incision along the dorsal surface of the affected metatarsal bone coupled with a circumferential incision around the base of the toe. The goal is to save all available viable skin on the toe; this skin is used to ensure a tension-free closure, and any excess skin can be debrided later, at the time of closure. Again, undermined bevels are avoided. The incision is taken down to the bone, and the soft tissues are separated from the distal metatarsal bone with a periosteal elevator. Dissection must be kept close to the affected metatarsal head to prevent injury to the adjacent metatarsophalangeal joint, which can lead to necrosis of the adjacent toe. The metatarsal bone is transected across the shaft with a pneumati-

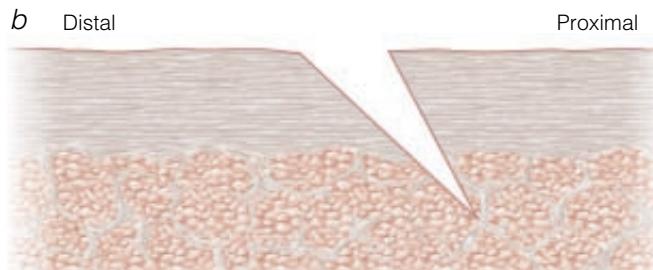

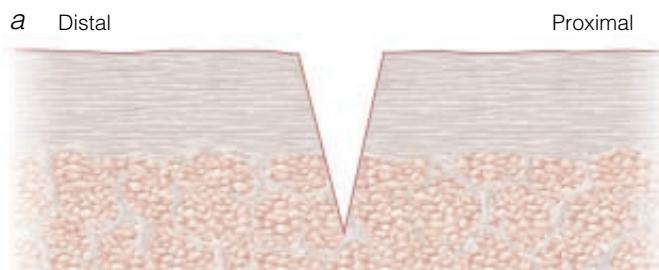

Figure 2 In a lower-extremity amputation, the skin is always incised perpendicular to its surface (a). Given the varying contours encountered during extremity amputation, it can be difficult to maintain the perpendicular orientation of the scalpel; however, an incision that undermines the proximal skin flap (b) will devascularize the epidermis and lead to necrosis of the suture line.

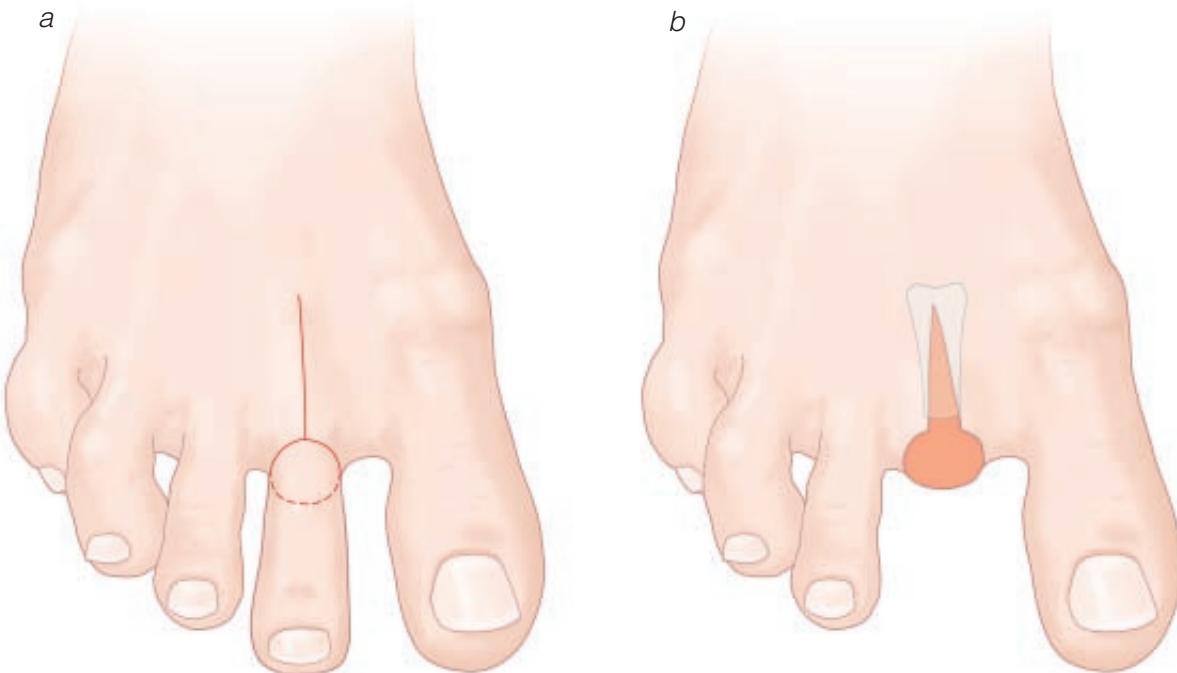

Figure 3 Toe amputation: ray amputation. (a) A longitudinal incision is made along the dorsum of the shaft of the metatarsal bone of the affected toe. A circumferential incision is then made around the phalanx. The circumferential incision should be placed as distal on the toe as there is viable skin so that as much skin as possible is retained for closure of the wound. (b) The metatarsal bone is transected across its shaft, proximal to the metatarsal head; the joint is never disarticulated.

ic oscillating saw. The tendons and the tendon sheaths are debrided.

Meticulous hemostasis is achieved with absorbable sutures and limited use of the electrocautery. The skin is approximated with simple interrupted nonabsorbable monofilament sutures [see Figure 4]. If sufficient viable skin was preserved, a flap of plantar skin is rotated dorsally, and the incision is closed in the shape of a Y. Alternatively, the medial and lateral edges are shifted (one proximally and the other distally), the corners are trimmed, and the incision is closed in a linear fashion. A soft supportive dressing is applied.

COMPLICATIONS

Complications of toe amputation include bleeding, infection, and failure to heal. Because even a small amount of bleeding under the skin flaps can prevent proper healing, meticulous hemostasis is mandatory. In most cases, infection and failure to heal are attributable to poor patient selection and poor surgical technique; the usual result is a more proximal amputation.

OUTCOME

For optimal healing, there must be an extended period (2 to 3 weeks) during which no weight is borne by the foot that underwent toe amputation. Once healing is complete, the patient should be able to walk normally, with no need for orthotic or assist devices. Beginning ambulation too early can disrupt healing flaps and necessitate more proximal amputation, which lengthens the hospital stay and increases long-term disability. For these reasons, toe amputation in patients with arterial occlusive disease is not an outpatient procedure. Patients are kept on bed rest and instructed in techniques (e.g., use of a wheelchair, a walker, or crutches) that allow them to function without stepping on the foot that was operated on. Hospital discharge is delayed until such techniques are mastered.

Transmetatarsal Amputation

OPERATIVE PLANNING

As noted (see above), transmetatarsal amputation is indicated if there is tissue loss in the forefoot involving the first metatarsal head, two or more of the other metatarsal heads, or the dorsal forefoot. It is contraindicated if there is extensive skin loss on the plantar surface of the foot or on the dorsum proximal to the mid-shaft of the metatarsal bones. The peroneus longus and the peroneus brevis insert on the proximal portions of the fourth and fifth metatarsal bones; if these insertions are sacrificed, inversion of the foot results, eventually leading to chronic skin breakdown from the side of the foot repeatedly striking the ground during ambulation. Transmetatarsal amputation is also contraindicated if there is a preexisting footdrop (peroneal palsy).

OPERATIVE TECHNIQUE

Spinal, epidural, or general anesthesia may be employed for transmetatarsal amputation. Placement of a tourniquet on the calf is a useful adjunctive measure. This step greatly reduces intraoperative blood loss. More important, the bloodless operative field that results allows more accurate assessment of tissue viability and hence more precise selection of the level of amputation; in a field stained with extravasated blood, it is easy to leave behind nonviable tissue that will doom the amputation. Use of a tourniquet is, however, contraindicated in patients who have a functioning infrapopliteal artery bypass graft.

After sterile preparation and draping, the leg is elevated to help drain the venous blood, and a sterile pneumatic tourniquet is placed around the calf, with care taken to pad the skin under the tourniquet and to position the tourniquet over the calf muscles, where it will not apply pressure over the fibular head (and the common peroneal nerve) or other osseous prominences. The tourniquet is then inflated to a pressure higher than the systolic

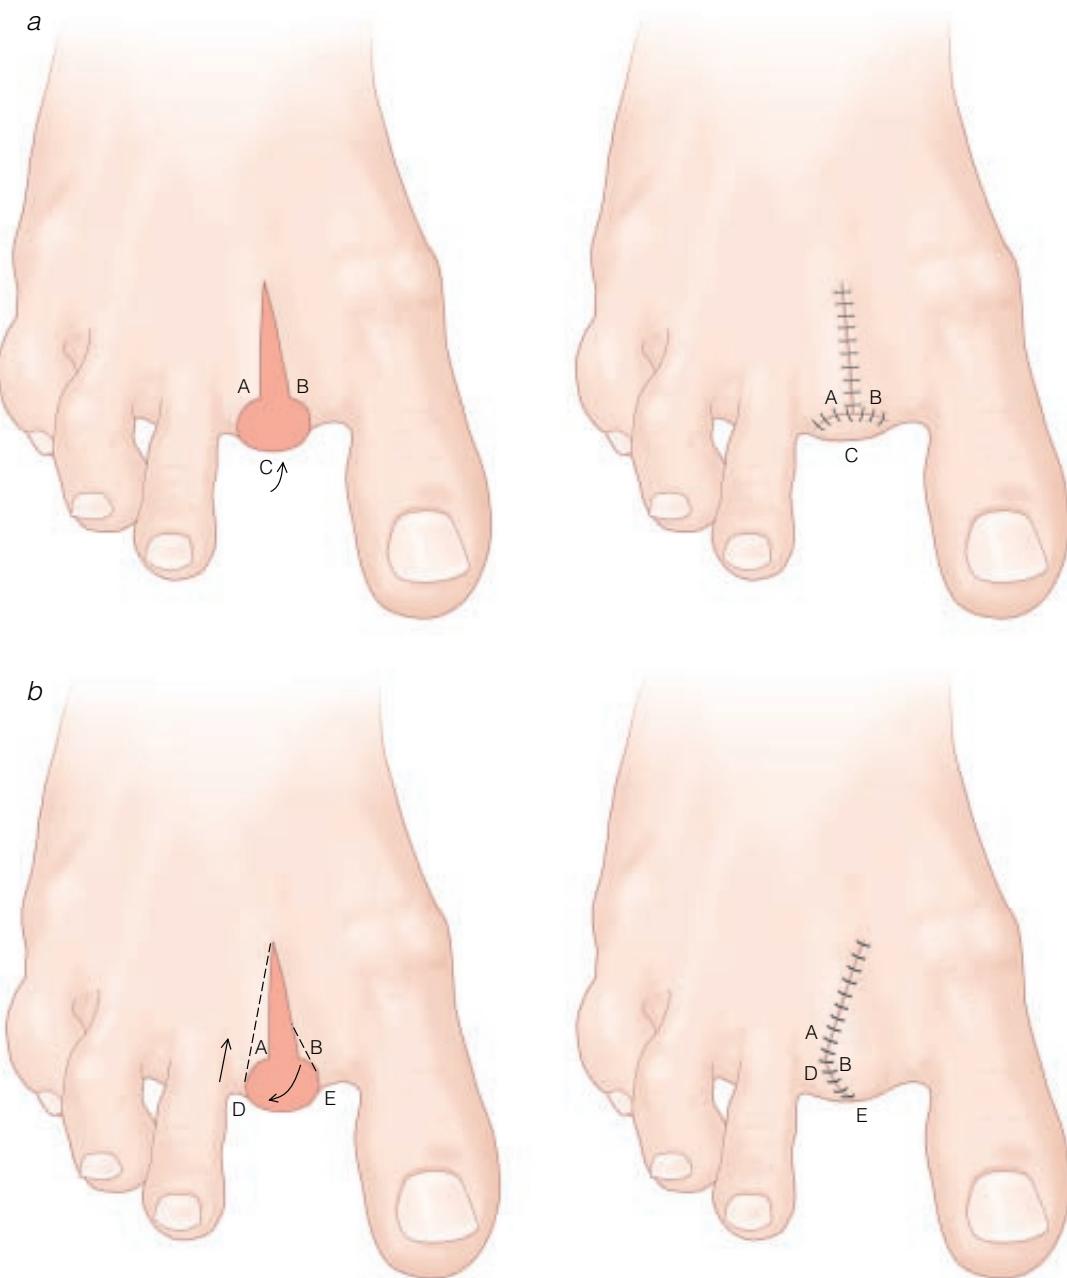

Figure 4 Toe amputation: ray amputation. (a) If adequate skin is available, a plantar flap can be rotated dorsally and the skin closed in a Y configuration. This closure is technically easy to perform; however, there is a risk of skin necrosis at corners A and B. (b) Alternatively, the skin can be closed in a linear fashion. Corners A and B are gently trimmed. Corner B is shifted distally toward point D as corner A is shifted proximally. A slight dog-ear will result at point E; however, it will diminish with time.

blood pressure. In patients who do not have diabetes mellitus, a tourniquet inflation pressure of 250 mm Hg is typically employed; in patients who have diabetes mellitus and calcified arteries, a pressure of 350 to 400 mm Hg is preferred.

An incision is made across the dorsum of the foot at the level of the middle of the shafts of the metatarsal bones, extending medially and laterally to the level of the center of the first and fifth metatarsal bones, respectively [see Figure 5]. The dorsal incision is curved proximally at the medial and lateral edges to ensure that no dog-ears remain at the time of closure. The dorsal incision is continued perpendicularly through the soft tissues on the dorsum down to the metatarsal bones. The plantar incision is extended distally to a point just proximal to the toe crease.

Care is taken not to bevel the skin incisions.

A plantar flap is created by making an incision with the scalpel adjacent to the metatarsophalangeal joints; the incision is then carried more deeply to the level of the midshafts of the metatarsal bones on their plantar surfaces. The periosteum of the first metatarsal bone is scored circumferentially with the scalpel, and the soft tissue is dissected away from the first metatarsal bone with a periosteal elevator to a point about 1 cm proximal to the dorsal skin incision. The first metatarsal bone is then transected perpendicular to its shaft at the level of the dorsal skin incision with a pneumatic oscillating saw. This process is repeated for each individual metatarsal bone, with care taken to follow the normal contour of the forefoot by cutting the lateral metatarsal bones at

Figure 5 Transmetatarsal amputation. The skin incisions are shown from various angles. The metatarsal shafts are divided in their midportions (dashed line). The metatarsal bone transection is at the level of the apices of the skin incision, and the lateral metatarsal bones are cut slightly more proximally than the medial metatarsal bones, in a pattern reflecting the normal contour of the forefoot.

a level slightly proximal to the level at which the more medial bones are transected. All visible digital arteries are clamped and tied with absorbable ligatures. If a tourniquet was used, it is deflated at this time. All tendons and tendon sheaths are debrided from the wound.

Meticulous hemostasis is achieved with absorbable sutures and limited use of the electrocautery. Any sharp edges on the metatarsal bones are smoothed with a rongeur or a rasp. The wound is irrigated to flush out devitalized tissue and thrombus. The plantar flap is trimmed as needed. The dermis is approximated with simple interrupted absorbable sutures, and the knots are buried. Because the edge of the plantar flap is generally longer than the edge of the dorsal flap, the sutures must be placed slightly farther apart on the plantar flap than on the dorsal flap if perfect alignment is to be obtained. It is imperative to achieve the correct skin alignment with the dermal suture layer. Once this is accomplished, the skin edges are gently and perfectly apposed with interrupted vertical mattress sutures of nonabsorbable monofilament material. Finally, a soft supportive dressing with good padding of the heel is applied; casts and splints are avoided because of the risk of ulceration of the heel or over the malleoli.

COMPLICATIONS

If a tourniquet is not used, intraoperative blood loss can be substantial; the blood pools in the sponges and drapes, often out of the anesthesiologist's field of view. Consequently, good communication between the surgeon and the anesthesiologist is crucial for preventing ischemic complications secondary to hemorrhage.

Postoperative complications include bleeding, infection, and failure to heal, all of which are likely to result in more proximal amputation. They can best be prevented by means of careful patient selection and meticulous surgical technique.

OUTCOME

For proper healing, postoperative edema must be avoided and the plantar flap protected against shear forces. To prevent swelling, the patient is kept on bed rest with the foot elevated for

the first 3 to 5 days. This step is particularly important if the transmetatarsal amputation was performed simultaneously with arterial reconstruction, which carries a high risk of reperfusion edema of the foot. After 3 to 5 days, the patient is instructed in techniques for moving in and out of the wheelchair without stepping on the foot. The foot that was operated on should not bear any weight at all for at least 3 weeks; early weight-bearing may disrupt the healing of the plantar flap and necessitate more proximal amputation.

Once healed, patients should be able to walk independently with standard shoes. There is, however, a risk that they may trip over the unsupported toe of the shoe. In addition, the pushoff normally provided by the toes is lost after transmetatarsal amputation, and this change results in a halting, flat-footed gait. These problems can be obviated by using an orthotic shoe with a steel shank (to keep the toe of the shoe from bending and causing tripping) and a rocker bottom (to provide a smooth heel-to-toe motion).

Guillotine Ankle Amputation

OPERATIVE PLANNING

Guillotine amputation across the ankle is indicated when a patient presents with extensive wet gangrene that precludes salvage of a functional foot (e.g., wet gangrene that destroys the heel, the plantar skin of the forefoot, or the dorsal skin of the proximal foot). In such patients, initial guillotine amputation through the ankle is safer than extensive debridement: the operation is shorter, less blood is lost, the risk of bacteremia is reduced, and better control of infection is possible. Guillotine amputation is also indicated in patients with foot infections who have cellulitis extending into the leg. Transection at the ankle, perpendicular to the muscle compartments, tendon sheaths, and lymphatic vessels, allows effective drainage and usually brings about rapid resolution of the cellulitis of the leg, thus permitting salvage of the knee in many cases in which the knee might otherwise be unsalvageable.

OPERATIVE TECHNIQUE

General anesthesia is preferred for guillotine ankle amputation; regional anesthesia is relatively contraindicated for critically ill patients who are in a septic state. Anesthesia is required for no more than 15 to 20 minutes.

A circumferential incision is made at the narrowest part of the ankle (i.e., at the proximal malleoli) regardless of the level of the cellulitis [see Figure 6]. This placement takes the line of incision across the tendons, thereby preventing bleeding from transected muscle bellies. The incision is then carried through the skin and soft tissues to the bone. If the arteries are patent, the assistant applies circumferential pressure to the distal calf. The distal tibia and fibula are then divided with a Gigli saw. Hemostasis is achieved with suture ligation and electrocauterization. A moist dressing is applied.

OUTCOME

After the procedure, the patient is kept on bed rest and given systemic antibiotics. Formal below-the-knee amputation can be performed when the cellulitis resolves, usually within 3 to 5 days. Routine dressing changes are unnecessary—first, because they are painful, and second, because the decision to proceed with formal below-the-knee amputation is based on the extent of the cellulitis in the calf, not on the appearance of the transected ankle.

Below-the-Knee Amputation

OPERATIVE PLANNING

Below-the-knee amputation is indicated when the lower extremity is functional but the foot cannot be salvaged by arterial reconstruction or by amputation of one or more of the toes or the forefoot. Healing can be expected if there is a palpable femoral pulse with at least a patent deep femoral artery, provided that the skin is warm and free of lesions at the distal calf. Before formal below-the-knee amputation, infection should be controlled with antibiotic therapy, debridement, and, if indicated, guillotine amputation. It is advisable to obtain consent to possible above-the-knee amputation beforehand in case unexpected muscle necrosis is encountered below the knee.

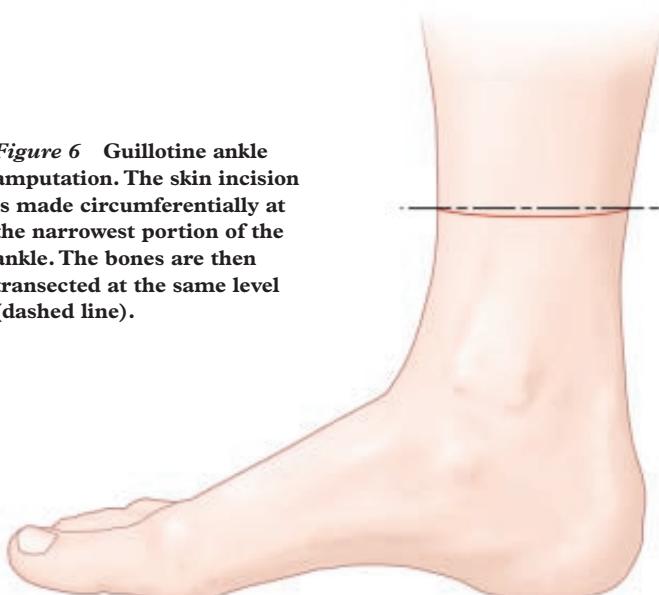

Figure 6 Guillotine ankle amputation. The skin incision is made circumferentially at the narrowest portion of the ankle. The bones are then transected at the same level (dashed line).

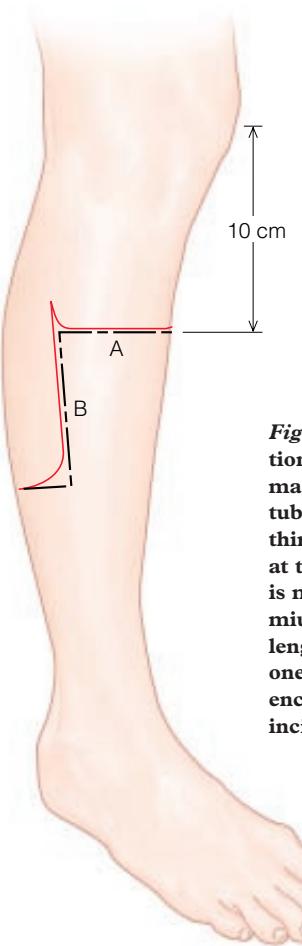

Figure 7 Below-the-knee amputation. The transverse incision (A) is made 10 cm distal to the tibial tuberosity. Its length is equal to two thirds of the circumference of the leg at that level. The posterior incision (B) is made parallel with the gastrocnemius-soleus muscle complex. The length of the posterior flap is equal to one third of the measured circumference of the leg. The corners of the incisions are curved to avoid dog-ears.

As with any amputation, the surgeon's preoperative interaction with the patient should be as positive as possible. A constructive perspective to convey is that the amputation, though regrettably necessary, is in fact the first step toward rehabilitation. A well-motivated patient whose cardiopulmonary status is not too greatly compromised can generally be expected to walk again, albeit at an increased energy cost. In this regard, a preoperative discussion with a physiatrist can be very helpful, as can a meeting with an amputee who is doing well with a prosthesis. By inculcating a positive attitude in the patient before the procedure, the surgeon can greatly improve the patient's chances of achieving full rehabilitation, as well as decrease the time needed for rehabilitation.

OPERATIVE TECHNIQUE

Epidural, spinal, or general anesthesia is appropriate for below-the-knee amputation. The lines of incision should be marked on the skin. The primary level of amputation is determined by measuring a distance of 10 cm from the tibial tuberosity [see Figure 7]. The circumference of the leg at this level is then measured by passing a heavy ligature around the leg and cutting the ligature to a length equal to the circumference. The ligature is folded into thirds and cut once more at one of the folds, so that two segments of unequal length remain. The longer segment of the ligature, which is equal in length to two thirds of the leg's circumference 10 cm below the tibial tuberosity, is used to measure the anterior transverse incision; this incision is centered not on the tibial crest but on the gastrocnemius-soleus muscle complex. The shorter segment, which is one third of the leg's circumfer-

ence at this level, is used to measure the posterior flap; the line of the posterior incision runs parallel with the gastrocnemius-soleus complex. To prevent dog-ears, the medial and lateral ends of the anterior transverse incision are curved cephalad before meeting the posterior incision, and the distal corners of the posterior incision are curved as well.

Blood loss can be reduced by using a sterile pneumatic tourniquet. A gauze roll is passed around the distal thigh. The leg is elevated to drain the venous blood, and the tourniquet is applied over the gauze roll. The tourniquet is inflated to a pressure of 250 mm Hg (350 to 400 mm Hg if the patient has heavily calcified arteries). The assistant elevates the leg, and the incision on the posterior flap is made first, followed by the anterior transverse incision; this sequence helps prevent blood from obscuring the field while the incisions are being made. The incisions are carried fully through the dermis, and the skin edges are allowed to separate and expose the subcutaneous fat. Care is taken to keep the scalpel perpendicular to the skin so as not to bevel the incision, which can lead to necrosis of the epidermal edges [see Figure 2].

The anterior muscles are transected with the scalpel in a direction parallel to the transverse skin incision. The tibia is scored circumferentially, and a periosteal elevator is used to dissect the soft tissues away from the tibia for a distance of approximately 3 to 4 cm. The tibia is then transected just proximal to the transverse skin incision. Dividing the tibia more than 1 cm proximal to the anterior skin incision will cause the thin skin of the anterior leg to be pulled taut over the cut end of the tibia by the weight of the posterior flap, thereby leading to skin ulcer-

ation. The tibia is transected perpendicularly, with a cephalad bevel of the anterior 1 cm to keep from creating a sharp point at the tibial crest [see Figure 8]. The tibia can be transected with either a Gigli saw or an oscillating saw; because of the unpleasant sound of the power saw, the Gigli saw is preferred if the patient is under regional anesthesia. Sedation should be augmented in awake patients before division of the tibia. Benzodiazepines provide good sedation and amnesia.

The lateral muscles are divided, and the fibula is scored circumferentially. A periosteal elevator is used to dissect the soft tissues away from the fibula to a point 2 to 3 cm cephalad to the level at which the tibia was transected. The fibula is then transected with a bone cutter at least 1 cm cephalad to the tibial transection level. The distal end of the tibia is lifted with a bone hook, and division of the posterior muscles is completed with an amputation knife. The specimen is then handed off the field.

The anterior tibial, posterior tibial, and peroneal arteries and veins are clamped, and the tourniquet is released. Clamps are placed on all other bleeding vessels. The posterior tibial and sural nerves are placed on gentle traction and clamped proximally. The distal nerves are transected, and the proximal nerves are allowed to retract into the soft tissues so as to prevent painful neuromas at the end of the stump. All clamped structures are then ligated with absorbable ligatures. The nerves are ligated because their nutrient vessels can bleed significantly. The distal anterior tip of the tibia is smoothed with a rasp to decrease the risk of skin ulceration over this osseous prominence. The stump is gently irrigated to remove all thrombus and devitalized tissue and to reveal any bleeding sites that may have been missed. Electrocauterization is rarely necessary.

The deep muscle fascia—not the Achilles tendon—is approximated with simple interrupted absorbable sutures, with care taken to align the posterior flap with the anterior incision. The dermis is approximated as a separate layer with simple interrupted absorbable sutures; if correctly placed, the dermal sutures should take all tension off the skin. The skin edges are then accurately apposed with interrupted vertical mattress sutures composed of monofilament nonabsorbable material. A carefully padded posterior splint or cast is applied to prevent flexion contracture.

COMPLICATIONS

The most common complications after below-the-knee amputation are bleeding, infection, and failure to heal, all of which are likely to result in a more proximal amputation, frequently accompanied by loss of the knee. Prevention of these complications depends on careful patient selection, preoperative control of infection, and meticulous surgical technique.

To walk with a prosthetic leg, the patient must be able to fully extend and lock the knee; thus, flexion contracture at the knee is a major complication. Such contractures are usually attributable either to poor pain control or to noncompliance with knee extension exercises. Good perioperative analgesia is of vital importance because knee flexion is the position of comfort and the patient will be unwilling to extend the knee if doing so proves too painful. To maintain knee extension, the patient should be placed in either a cast or a splint in the early postoperative period. Once postoperative pain has abated, the splint or cast can be removed. At this point, the patient must be taught extension exercises, in which the quadriceps muscles are contracted to maintain the length of the hamstring muscles. If a patient spends all of his or her time in a sitting position with the knee flexed, a flexion contracture will quickly develop. Once this happens, the patient may find it very difficult to regain full knee extension, and without full

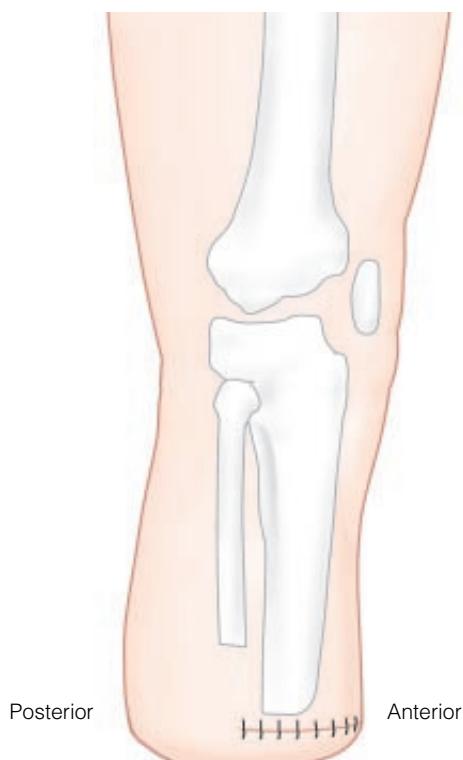

Figure 8 Below-the-knee amputation. In this lateral view of the right leg, the tibia is beveled anteriorly, and the anterior portion is smoothed with a rasp. The fibula is transected at least 1 cm proximal to the level of transection of the tibia.

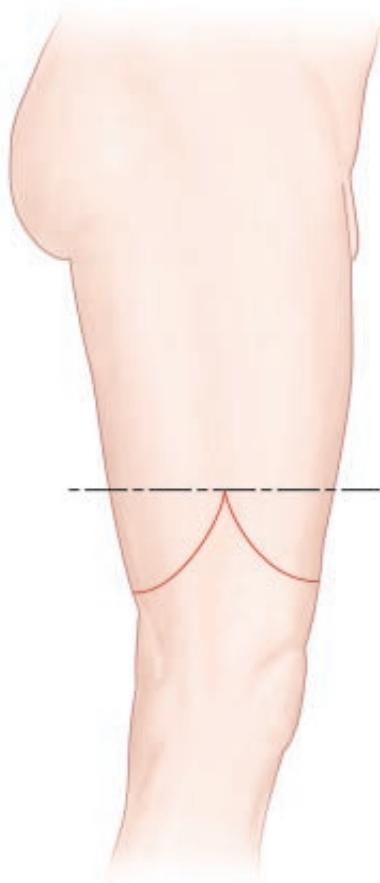

Figure 9 Above-the-knee amputation. Broadly based anterior and posterior flaps are created. The femur is transected along the dashed line, at the apices of the skin flaps. The skin flaps and the level of transection of the femur can be placed more proximally if clinically indicated.

knee extension, prosthetic limb rehabilitation is impossible.

Phantom sensation is a common complication after below-the-knee amputation but is rarely of any consequence. Phantom pain, on the other hand, can be devastating. Sometimes, phantom pain develops as a consequence of unintentional suggestions made to the patient by medical personnel who fail to distinguish between the two entities. For example, a patient remarks to a medical attendant that he or she can still feel the amputated foot and toes, and the attendant suggests in response that the patient has phantom pain; the patient then focuses on the sensation and exaggerates the severity of the foot and toe discomfort, setting up a cycle of ever-worsening pain. This scenario is even more likely if the patient has had prolonged ischemic rest pain before the amputation. Phantom pain can be prevented by (1) encouraging early amputation in a patient with a hopelessly ischemic foot (while taking into account the patient's need to come to grips with the prospect of amputation), (2) providing good pain control in the early postoperative period, and (3) assuring the patient that phantom sensation after a below-the-knee amputation is common and that any discomfort in the foot immediately after the operation period will vanish once he or she begins walking again with a prosthetic leg.

Ulceration of the skin over the transected anterior portion of the tibia is another serious complication that may preclude successful prosthetic limb fitting. This complication is also best managed through prevention, which depends on meticulous surgical technique. As noted (see above), the anterior tibial crest must be carefully beveled and smoothed at the level of transection, and the tibia must not be transected more than 1 cm proximal to the anterior skin incision.

With a standard below-the-knee prosthetic leg, weight is borne

on the femoral condyles, the patella, and the tibial tuberosity. Breakdown of the stump can occur if weight is borne on the distal portion of the stump. Several decades ago, Jan Ertl described a tibiofibular synostosis designed to allow distal weight-bearing; however, this technique has not been widely adopted.⁷

OUTCOME

Shortly after the amputation, the patient should be encouraged to start working on strengthening the upper body; upper-body strength is critical for making transfers and for using parallel bars, crutches, or a walker. In patients who have preoperative intractable ischemic rest pain, postoperative administration of epidural analgesia can break the cycle of pain. Once postoperative pain is adequately controlled, patients are taught to transfer in and out of a wheelchair. A compression garment is used on the stump once the sutures have been removed and the stump is fully healed.

Prosthetic rehabilitation begins when the stump achieves a conical shape. Unfortunately, a number of patients who have undergone amputation for ischemia are unable to walk with a prosthetic limb because of comorbid medical conditions and general debility. In many cases, however, even if full ambulation is impossible, patients can maintain relative independence if the knee is salvaged by using a combination of a prosthetic leg and a walker for transfers and movement around the house.⁶

Above-the-Knee Amputation

OPERATIVE PLANNING

Above-the-knee amputation is indicated if the lower extremity is unsalvageable and there is no femoral pulse. The presence of pulsatile flow into a well-developed ipsilateral internal iliac artery usually ensures healing, but even when there is more severe arterial occlusive disease in the pelvis, healing can sometimes be achieved. Above-the-knee amputation is also indicated if there is tissue necrosis or uncontrollable infection extending cephalad to the midleg. Above-the-knee amputation is the procedure of choice in the case of gangrene or ulceration of a completely nonfunctional lower extremity.

OPERATIVE TECHNIQUE

Epidural, spinal, or general anesthesia may be used for above-the-knee amputation. For the best functional results, it is desirable to keep the femur as long as possible. A longer stump improves the prognosis for prosthetic limb rehabilitation and provides better balance for sitting and transfers. Healing potential, however, is lower with a longer stump; therefore, if the pelvic circulation is severely compromised, a shorter stump should be fashioned.

Anterior and posterior flaps of equal length are marked on the skin. The flaps should be wide and long [see Figure 9], and their apices should be centered on the line dividing the anterior and posterior muscle compartments. The posterior incision is made first to minimize the presence of blood in the operative field. The anterior incision is made second and carried through the anterior muscles in a plane parallel to the skin incision. The skin incisions are carried through the dermis, and the skin edges are allowed to separate and expose the subcutaneous fat; as in other amputations, they should be perpendicular to the skin surface so as not to undermine the skin.

If the superficial femoral artery is patent, the artery and vein are isolated and clamped after the sartorius is divided but before

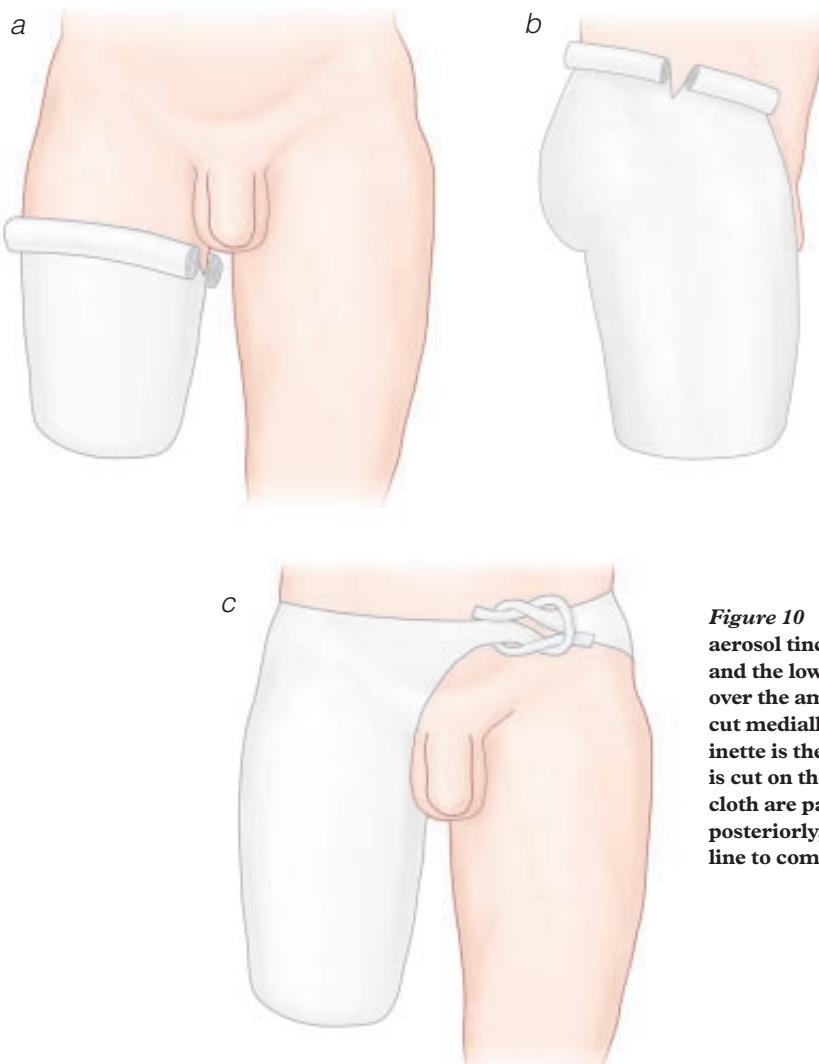

Figure 10 Above-the-knee amputation. (a) After an aerosol tincture of benzoin is applied to the thigh, the hip, and the lower abdomen, a 4 in. wide stockinette is rolled over the amputation stump. The cuff of the stockinette is cut medially at the groin. (b) The remainder of the stockinette is then rolled laterally up over the hip, and the cuff is cut on the lateral midline. (c) The two resulting strips of cloth are passed around the waist, one anteriorly and one posteriorly, and these strips are tied on the anterior midline to complete the dressing.

the remainder of the anterior muscles are divided. The femur is scored circumferentially. The soft tissues are dissected away from the femur to the level of the apices of the flaps, and the femur is divided with an oscillating saw at this level. If the end of the resected femur extends beyond the apices of the flaps, the wound cannot be closed without tension. The posterior flap is completed with an amputation knife, and the specimen is handed off the field.

All bleeding points are clamped and tied with absorbable sutures. The sciatic nerve is placed on gentle traction, clamped, divided, and ligated, and the transected nerve is allowed to retract into the muscles. The deep fascia is approximated with interrupted absorbable sutures, with adjustments made for any discrepancy in length between the two flaps. The dermis is approximated with interrupted absorbable sutures; the dermal sutures should take all tension off the skin. The skin edges are then carefully apposed with interrupted vertical mattress sutures.

A nonadherent dressing is placed on the suture line and covered with dry, fluffed gauze bandages. An aerosol tincture of benzoin is sprayed on the thigh, the hip, and the lower abdomen. When the benzoin is dry, a cloth stockinette with a diameter of 4 in. is stretched over the stump [see Figure 10]. The cuff of the stockinette is cut medially at the groin, and the stockinette is rolled laterally above the hip, where the cuff is then cut on the midaxillary line. This process yields two strips of cloth, one ante-

rior and one posterior, which are passed around the patient's waist and tied on the anterior midline.

If the patient is a candidate for prosthetic limb rehabilitation, a traction rope is passed through a hole cut in the distal end of the stockinette and tied. The rope is hung over the end of the bed and tied to a 5 lb weight; this step helps prevent flexion contracture at the hip.

The stockinette need not be removed for the wound to be inspected. A window is cut in the distal end of the stockinette, and the gauze is removed. Once the incision has been inspected, fresh gauze is applied, and the window in the stockinette is closed with safety pins.

COMPLICATIONS

Postoperative complications include bleeding, infection, and failure to heal, all of which are likely to result in the need for surgical revision of the amputation stump. Control of preoperative infection and meticulous surgical technique and hemostasis are necessary to prevent these complications.

Flexion contracture of the hip is a major complication of above-the-knee amputation. Such contractures preclude successful prosthetic limb rehabilitation. In dealing with this complication, prevention is far more effective than treatment: once a flexion contracture at the hip becomes fixed, it is very difficult to reverse. If a patient is a candidate for prosthetic limb reha-

bilitation, the traction weight mentioned earlier (see above) can be very helpful. As soon as postoperative pain is controlled, the patient should be taught to spend three periods daily in a prone position to help extend the hip. He or she should then be taught exercises for maintaining range of motion in the hip before prosthetic limb rehabilitation is initiated. Flexion contracture of the hip is less of a problem in nonambulatory patients; however, it can still lead to wound breakdown and chronic skin ulceration.

Gottschalk noted that loss of the adductor magnus leads to

abnormal abduction of the femur. Accordingly, he proposed preservation of the adductor magnus and myodesis of the transected muscles to the femur to improve the biomechanics after above-the-knee amputation.^{8,9}

OUTCOME

Once postoperative pain has abated, patients are mobilized to wheelchair transfers. The prognosis for successful prosthetic limb ambulation in patients undergoing above-the-knee amputation for ischemia is very poor.

20 VARICOSE VEIN SURGERY

John F. Golan, M.D., F.A.C.S., Donald M. Glenn, P.A.-C., John J. Bergan, M.D., F.A.C.S., and Luigi Pasquarella, M.D.

Varicose veins are a common problem, accounting for approximately 85% of the venous conditions treated. Over the past decade, management options for varicose veins and venous insufficiency of the lower extremity have become more diverse. Operative vein stripping is rapidly being replaced with a variety of endovenous techniques, ranging from laser vein obliteration to radiofrequency (RF) closure to foam sclerotherapy. Conventional surgical stripping has a poor image with the public, being associated with large unsightly incisions, severe postoperative pain, and a significant risk of recurrence. Current evidence indicates that patients experience less pain and return to work more quickly after endovenous treatment of varicosities than after surgical vein stripping.¹ In addition, the elimination of the word stripping from the technical description has facilitated the public's growing preference for endovenous therapy over conventional surgical therapy (even though the basic therapeutic principles are essentially similar for the two approaches).

As a consequence of the minimally invasive nature of endovenous therapy, treatment of vein disease is moving from the hospital to the office. This shift has allowed a diverse group of physicians (e.g., dermatologists, gynecologists, and cardiologists) to enter a field that previously had been left to surgeons. Accordingly, to remain up to date with respect to the treatment of vein disease, it is essential for surgeons to acquire the knowledge and skills required to use the new endovenous techniques. In this chapter, we review the procedures, results, and complications associated with endovenous therapy, as well as traditional surgical techniques.

Terminology

All physicians treating lower-extremity venous disease should be familiar with the current names for the veins of the thigh and leg, as specified in the 2001 revision of the official terminologia anatomica by the International Interdisciplinary Consensus Committee on Venous Anatomical Terminology.² Failure to employ current standardized terminology can hinder data exchange in translated research studies. In addition, retention of the traditional nomenclature can result in potentially dangerous clinical scenarios. For instance, ultrasonographically diagnosed thrombosis of the superficial femoral vein might, because of the term used for the vein, be erroneously interpreted as superficial thrombophlebitis instead of true deep vein thrombosis (DVT). To prevent these and other errors, a more accurate delineation of the branches of the common femoral vein is required. Thus, the terms femoral vein (instead of superficial femoral vein) and deep femoral vein (instead of profunda femoris) are now employed.

Of particular significance for the purposes of this chapter is that the greater (long) saphenous vein is now referred to as the great saphenous vein (GSV), and the lesser (short) saphenous vein is now referred to as the small saphenous vein (SSV). In addition, the terms saphenofemoral junction and saphenopopliteal junction have been accepted into the official nomenclature—a change that is especially relevant to endovenous treatment of varicose veins. Various other changes in the names of lower-extremity and pelvic veins were also

recommended in the Committee's consensus statement; however, these changes have little bearing on the current discussion and thus are not addressed further here.

Indications for Varicose Vein Surgery

The indications for surgical treatment of varicose veins are well established [see Table 1]. Although many physicians believe that varicose veins are nothing more than a cosmetic nuisance, this is in fact true only for some men. Women, for the most part, have specific symptoms (e.g., aching, burning pain, and heaviness) that are related to their varicose veins and are exacerbated by the presence of progesterone. Such symptoms develop with prolonged standing or sitting and reach maximal levels on the first day of the menstrual period, when progesterone levels are at their peak. Men, lacking progesterone, have few such symptoms until the varicose veins progress with aging to the point where they press on somatic nerves. In general, the severity of the symptoms bears no relation to the size of the vessels being treated. Telangiectasias can produce symptoms identical to those of varicose veins, and such symptoms can be relieved by simple sclerotherapy [see 6:21 Sclerotherapy].

Longitudinal studies have shown that large varicose veins can produce venous ulcerations within 15 years. Given that the incidence of venous ulceration is 20% in patients who are first seen with large varicose veins, large varicosities constitute an indication for surgery. Various skin changes characteristic of chronic venous insufficiency precede the development of venous ulceration.

Varicose thrombophlebitis is followed by recurrent varicose thrombophlebitis in nearly every case, at intervals ranging from a few weeks to many months. Nevertheless, superficial thrombophlebitis, which can be quite disabling, can be prevented by removing varicose vein clusters.

It is true that for many women, the undesirable appearance of varicose veins is a major reason for seeking surgical treatment. When questioned, however, such patients often admit to having symptoms such as pain, heaviness, and fatigue. Typically, they do not relate these symptoms to the varices themselves but instead attribute them to prolonged standing during daily work.

Table 1 Indications for Varicose Vein Surgery

- Pain: leg aching, leg heaviness
- Patchy burning (venous neuropathy)
- Swelling: foot, ankle, leg
- Dermatitis: focal, extensive
- Lipodermatosclerosis
- Ulceration: present or healed
- Superficial thrombophlebitis
- External hemorrhage
- Appearance

Preoperative Evaluation

DUPLEX MAPPING

Over the years, surgical treatises have devoted a great deal of space to clinical examination of the patient with varicose veins. Numerous clinical tests have been described, many of which carry the names of famous persons interested in venous pathophysiology. This august history notwithstanding, the Trendelenburg test, the Schwartz test, the Perthes test, and the Mahorner and Ochsner modifications of the Trendelenburg test are, for the most part, useless in preoperative evaluation of patients today.³ There is no doubt that clinical evaluation can be improved by using handheld Doppler devices. In our view, however, preoperative evaluation is best performed by combining duplex scanning with physical examination.⁴ Duplex mapping defines individual patient anatomy with considerable precision and provides valuable information that supplements the physician's clinical impression. This information allows the physician to develop a strategy that will treat abnormal refluxing veins while leaving normal portions of the venous system in place, thereby minimizing operative trauma and reducing long-term recurrence.

A protocol for duplex mapping of incompetent superficial veins has been published.⁴ In essence, the examination consists of interrogating specific points of reflux with the patient standing [see Table 2]. Forward flow is produced with muscular compression, and reverse flow is then assessed in the crucial areas that are important to subsequent procedural planning.

The patient is placed in an upright position so that the leg veins are maximally dilated. No clothing is worn on the lower extremities from the waist down, except for nonconstricting underwear. The patient is instructed to inform the sonographer of any sensation of light-headedness, faintness, dizziness, or nausea. These symptoms seem to be associated with the overall atmosphere of the room and the presence of Doppler velocity signals; they appear to be less likely to occur when the examination itself is performed silently. If a tendency to fainting because of vagovagal reflux is encountered, the examination may have to be modified so that the patient is in a semiuipright position instead.

Examination should include both lower extremities, though post-treatment examinations may target a single extremity or a single area of an extremity. The full length of the axial venous system from ankle to groin is examined. The probe is aligned transversely so that specific named veins can be identified and their relations to other limb structures determined. The veins are scanned by moving the probe up and down along their courses. Double segments, sites of tributary confluence, and large perforating veins (along with their deep venous connections) are identified. (Perforating veins are those that course from the subcutaneous tissue through deep fascia to anastomose with one of the named deep venous structures; communicating veins are those that anastomose with one another within a single anatomic plane.) Varicose veins are often arranged in multiple parallel channels. It is unnecessary to follow reflux into all of the varicose clusters, because these are obvious to the treating physician. Augmentation of flow (distal compression) is done sharply, quickly, and aggressively, and pressure is applied to the calf to activate the gastrocnemius-soleus pump. When a color or pulsed-wave Doppler device is used, the probe is angled to provide an insonation angle of 60° or less.

For the anterior examination, the patient faces the sonographer with his or her weight borne on the lower extremity that is not being examined. The non-weight-bearing extremity is then evaluated. The common femoral vein and the saphenofemoral junction are assessed with the Valsalva maneuver and with distal compression and release. If reflux is present, the diameter of the refluxing GSV is not

ed for subsequent use in selecting the proper endovenous catheter during saphenous ablation.

The GSV is identified on the basis of its relation to the deep and superficial fascia that ensheathes it to form the saphenous compartment. High-resolution B-mode ultrasonographic imaging of the superficial fascia in the transverse plane has shown that this structure reflects ultrasound strongly, yielding a characteristic image of the GSV known as the saphenous eye [see Figure 1]. The saphenous eye is a constant marker that is clearly demonstrable in transverse sections of the medial aspect of the thigh and that readily differentiates the GSV from varicose tributaries and other superficial veins. Casual examination of the thigh often reveals an elongated, dilated vein that is incorrectly assumed to be the GSV. This mistaken assumption can be corrected by means of ultrasound scanning with the saphenous eye as an anatomic marker.

Venous reflux can be elicited manually by calf muscle compression and release, by the Valsalva maneuver, or by pneumatic tourniquet release. In terms of efficacy, there is no difference between pneumatic tourniquet release and manual compression and release. However, pneumatic tourniquet release is cumbersome and requires two vascular sonographers, which makes the manual compression and release method very attractive by comparison. If saphenofemoral reflux lasting longer than 0.5 second is present, the diameter of the GSV is recorded 2.5 cm distal to the saphenofemoral junction.

The examination continues distally along the GSV, with distal augmentation of flow performed at intervals to check for reflux. Reflux frequently ends in the region of the knee. The point at which reflux stops is recorded in terms of distance from the floor in centimeters. The femoral vein (i.e., the vessel formerly termed the superficial femoral vein) is checked at midthigh for reflux and vein wall irregularities.

The posterior examination is also done on the non-weight-bearing lower extremity, with attention paid to reflux in the popliteal vein, the saphenopopliteal junction, and the SSV. The Valsalva maneuver may be used to stimulate reflux, as may distal augmentation and release. Valsalva-induced reflux is halted by competent proximal valves. The SSV is followed from its retromalleolar position on the lateral aspect of the ankle proximally to the saphenopopliteal junction, and augmentation maneuvers are performed every few centimeters.

The termination of the SSV is noted. If the vein terminates proximally in the vein of Giacomini, the femoropopliteal vein, or another vein, a specific check is made for a connection to the popliteal

vein. If the SSV shows reflux, the distance from the saphenopopliteal junction to the floor is measured and recorded.

A search for incompetent perforating veins is necessary only in limbs with chronic venous insufficiency (CVI) manifested by hyperpigmentation, atrophie blanche, woody edema, scars from healed ulceration, or actual open ulcers. Incompetent perforating veins in limbs without CVI are associated with varicose veins and can be controlled with varicose phlebectomy. Identification of perforating veins in the lower extremity can be difficult even for the experienced sonographer.

Procedural Planning

For varicose vein treatment to be successful, two goals must be met: (1) reflux must be ablated from the deep veins to the superficial veins, and (2) all branch varicosities must be removed. Reflux must be eliminated from all major problem areas, including the saphenofemoral junction, the saphenopopliteal junction, and the midthigh Hunterian perforator vein. To identify these problem areas, careful preoperative duplex mapping of major superficial venous reflux is essential. All varicose vein clusters are meticulously marked before operation; they may be difficult to identify during the procedure, when the patient is supine.

At present, three techniques are approved for the elimination of axial reflux in the GSV and the SSV: (1) traditional surgical stripping, (2) laser vein ablation (i.e., endovenous laser therapy [EVLT]), and (3) radiofrequency (RF) ablation. Regardless of which technique is employed, the principal goals of treatment (see above) are the same. In addition, the procedure must be done in a manner that optimizes cosmetic results and minimizes complications.

Endovenous Procedures

Current endovenous techniques for treating varicose veins are based on three major developments: (1) the availability of laser and RF probes that deliver heat endovenously, (2) the introduction of tumescent anesthesia, and (3) the evolution of duplex ultrasonography. Tumescent anesthesia allows physicians to use large volumes (500 ml) of dilute (0.1%) lidocaine in a single session while achieving anesthesia levels equivalent to those achieved with 1% lidocaine. In this way, the entire thigh portion of the GSV can be safely anes-

thetized (and consequently obliterated) at one time. Epinephrine can be added to the solution to improve postoperative hemostasis, increase venous contraction around the heat-generating catheter, and lengthen the duration of postprocedural analgesia. A common formula for the tumescent anesthesia solution is 450 ml of normal saline mixed with 50 ml of 1% lidocaine with epinephrine (1:100,000 dilution) and 10 ml of sodium bicarbonate to buffer the acidity of the lidocaine.

Duplex ultrasonography has revolutionized treatment of varicose veins. It dramatically enhances physicians' ability to evaluate the cause of varicosities and to tailor treatment so that only the diseased vein segments are ablated while the normal segments are preserved. It also serves to guide placement of sheaths and heat-generating catheter tips, allowing these devices to be situated very precisely within the vein.

TECHNIQUE

Laser Vein Ablation

Laser vein ablation [see Figure 2] may be performed either in the office or in the hospital. Reimbursement issues make in-office treatment advantageous for most physicians. Neither conscious sedation nor noninvasive monitoring is required. On occasion, a nervous patient may benefit from administration of an oral anxiolytic agent 1 to 2 hours before the procedure.

Standard surgical preparation and draping are indicated, including the use of sterile gowns, masks, drapes and aseptic technique. Depending on the results of the preoperative physical examination and duplex ultrasonography, the GSV, the SSV, the anterior accessory saphenous vein, or the posterior accessory saphenous vein may be treated, either alone or in combination with other vessels as necessary. The GSV is usually treated from the upper third of the calf to the saphenofemoral junction. If the calf portion of the GSV is to be treated, tumescent anesthesia should be liberally employed to reduce the risk of saphenous nerve injury. The SSV is treated from the distal third of the calf to the point where it angles toward the popliteal vein in the popliteal fossa. The relation of the sural nerve to the distal third of the SSV precludes safe treatment of this portion of the vein, and the proximity of the popliteal nerve to the SSV in the popliteal fossa precludes safe treatment of the most proximal portion of the vein. The procedure does not allow flush ligation of the saphenofemoral junction, but current evidence suggests that this measure may not be indicated: flush ligation eliminates normal venous drainage from the saphenofemoral junction and may increase the risk of neovascularization of the saphenofemoral junction and recurrence of varicosities.

The saphenous vein being treated is accessed with a micropuncture system after a small amount of lidocaine (sufficient to raise a small skin wheal) is injected into the dermis. The position of the 0.015-in. wire in the saphenous vein is confirmed by means of ultrasonography. A 4 French catheter is then passed over the wire, allowing the placement of a 0.035-in. wire for access to the proximal portion of the saphenous vein. Next, the 0.035-in. wire is positioned at the appropriate saphenous junction, and a 5 French vascular sheath is advanced over the wire to the junction. The sheath is positioned either just below the superior epigastric vein or 1 to 2 cm distal to the junction of the GSV; if the SSV is being treated, the tip is positioned 2 to 3 cm below the junction at the point where the vein makes its transition from an oblique course to a parallel path under the fascia of the leg. The 600 µm laser fiber is then passed to the tip of the sheath, which is pinned and pulled to expose the tip of the laser fiber. The rigidity and sharpness of the laser fiber makes advancing its tip dangerous. Most laser systems allow the fiber to be locked to the sheath, so that the

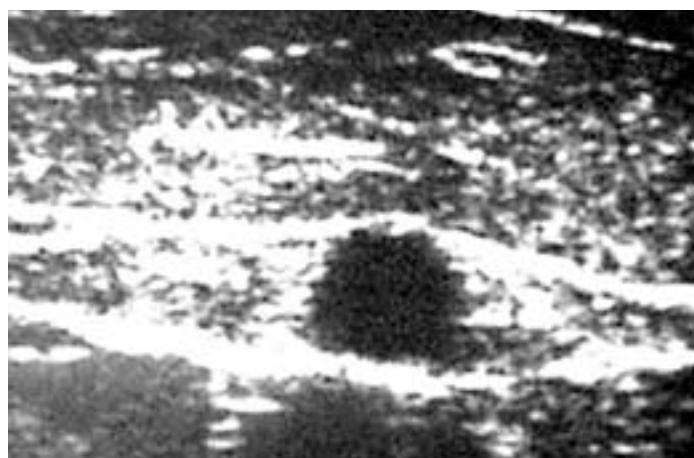

Figure 1 Shown is an ultrasonographic image of the so-called saphenous eye. Correct identification of this marker is crucial to correct performance of the preoperative ultrasonographic reflux examination.

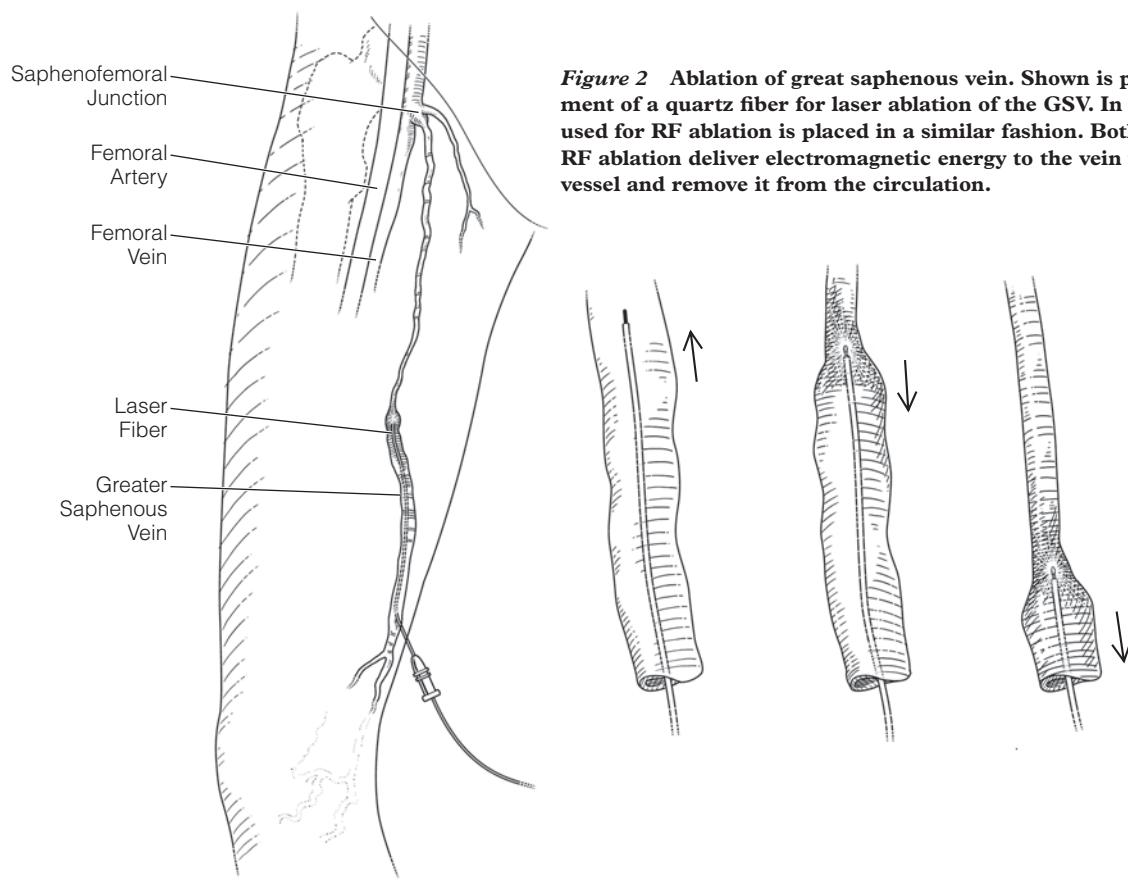

Figure 2 Ablation of great saphenous vein. Shown is percutaneous placement of a quartz fiber for laser ablation of the GSV. In practice, the catheter used for RF ablation is placed in a similar fashion. Both laser ablation and RF ablation deliver electromagnetic energy to the vein wall to destroy the vessel and remove it from the circulation.

two devices can be advanced and positioned as a single unit.

To this point in the procedure, no anesthesia other than the initial dermal injection has been employed. The next step, accordingly, is to initiate tumescent anesthesia, with or without epinephrine, along the saphenous compartment. The addition of epinephrine to the anesthetic solution results in improved constriction of the vein around the laser sheath, particularly when a saphenous vein larger than 12 mm in diameter is being treated; it also prolongs the analgesic effect of lidocaine, providing pain relief for as long as 6 to 8 hours after the procedure. A particular benefit of tumescent anesthesia is that the large volume of the injectate constitutes a heat sink that absorbs the heat created by the laser, thereby eliminating injury to surrounding soft tissue structures (e.g., nerves, fat, and skin). Further protection against injury is provided by rapid pullback of the laser fiber. As a result, the reported incidence of thermal skin or nerve injuries with laser vein ablation is almost zero.

Administration of the tumescent anesthesia solution starts at the sheath entry site and continues proximally until the entire vein segment to be treated exhibits a circumferential zone of echolucence. The vein is generally treated in the saphenous compartment between the superficial and deep fasciae of the leg. The anesthetic is administered via a 22-gauge needle with a 20 ml syringe or, alternatively, via a 10 ml autodfill syringe or a Klein pump (both of which have the advantage of allowing more rapid administration with less risk of needle-stick injury to the staff). The needle is kept in a static position during administration, and the fluid is allowed to dissect up and down the fascial compartment.

Besides providing pain relief, tumescent anesthesia serves to move the saphenous vein being treated away from any structure that might be injured by the heat produced by the laser (e.g., the skin and the femoral vein). A 1 cm distance between the skin and the laser fiber is optimal. More liberal amounts of tumescent anesthesia

solution are administered when the vein being treated lies in close proximity to one or more nerves (e.g., the SSV and the calf portion of the GSV). As a rule, we prefer not to treat the subdermal portions of the GSV with laser ablation; the presence of an inflamed and tender vein just beneath the dermis is likely to lead to increased postoperative pain and noticeable skin discoloration. The superficial segments of the GSV are best treated with phlebectomy at the time of laser ablation.

When administration of the tumescent anesthesia solution is complete, the position of the laser fiber's tip is again confirmed. As the vein constricts, it also shortens, and this process may advance the tip of the laser fiber into the saphenofemoral or saphenopopliteal junction. If the tip is found to have moved in this manner, it is withdrawn until it is again 1 to 2 cm below the junction. A quick scan down the vein is done to confirm that the entire vein is surrounded by the anesthetic solution and is at least 1 cm from the skin.

At this point, the laser may be safely activated. The laser is always used in the continuous mode. The power setting may range from 10 to 12 W, depending on the physician's personal preference. We typically employ a 10 W setting for veins smaller than 10 mm and a 12 W setting for veins larger than 10 mm. The essential point is that between 50 and 100 J must be delivered to each centimeter of vein treated; according to one study, 70 J/cm is the ideal amount for reliable long-term vein obliteration.⁵ Energy delivery can easily be determined as the laser fiber is withdrawn. Most laser sheaths have markings 1 cm apart, and the laser machines have digital readouts that indicate the total amount of energy (J) delivered in real time. A simple calculation after 10 cm of the catheter has been withdrawn provides instant feedback on the energy delivered per centimeter of vein. On the 12 W power setting, delivery of the recommended amount of energy generally necessitates a pullback rate of 1 cm every 4 to 5 seconds (2.0 to 2.5 mm/sec). One group has advocated

delivery of 140 J/cm proximally (pullback rate of 1 mm/sec) and roughly 70 J/cm distally (pullback rate of 3 mm/sec), theorizing that for long-term success, more energy is required proximally.⁶ At the completion of the procedure, the laser is deactivated before the fiber is withdrawn from the skin. Ultrasonography is then performed to confirm that the common femoral vein and the superficial epigastric vein are patent and that the GSV is occluded.

An adhesive strip (e.g., Steri-Strip; 3M, St. Paul, Minnesota) covered by a transparent surgical adhesive dressing is applied over the entry site. The patient is then placed in a prescription compression stocking, which is worn for 1 to 2 weeks after the procedure. Whereas most physicians use a class 2 (30 to 40 mm Hg) compression stocking, we have switched to using a class 1 (20 to 30 mm Hg) stocking without observing any changes in complications (e.g., post-operative pain and swelling) or results. This switch has enhanced patient satisfaction, in that a class 1 stocking is easier to don and more comfortable to wear.

A 2003 study that followed 499 limbs over 2 years demonstrated a varicosity recurrence rate of less than 7% after ablation of the GSV with an 810 nm diode laser.⁷ This rate is comparable to or lower than those reported after traditional surgical stripping, RF ablation, and ultrasound-guided sclerotherapy. Several smaller studies documented similar outcomes, making it evident that laser vein ablation is both effective and safe when compared to other means of treating varicose veins [see Table 3].^{1,6,8-11}

At present, the question of how to manage residual varicosities after laser ablation remains controversial. The two main options are (1) to perform phlebectomy simultaneously with laser vein ablation and (2) to perform laser ablation alone, then observe the patient for spontaneous regression of varicosities. When the residual varicosities are left untreated, 10% to 20% of patients show sufficient regression to render further intervention unnecessary; however, 5% to 10% of patients experience superficial thrombophlebitis in the residual varicosities as a consequence of stasis from altered venous drainage. If delayed treatment of residual varicosities proves necessary, it may be accomplished with either phlebectomy or sclerotherapy, depending on the physician's preference. Our treatment of choice is laser vein ablation with concurrent phlebectomy. This approach adds only 10 to 20 minutes to the length of the procedure while offering the patient a more rapid and complete resolution of visible varicose veins and greatly reducing the risk of secondary thrombophlebitis.

Radiofrequency Ablation

In an attempt to minimize postoperative discomfort while main-

taining the benefits of saphenous vein ablation, RF alternating current has been employed to effect rapid thermic electrocoagulation of the vein wall and its valves. This approach is exemplified by the Closure procedure (VNUS Medical Technologies, Inc., San Jose, California). Prolonged exposure to the high-frequency energy results in total loss of vessel wall architecture, disintegration, and carbonization.¹² Ultrasonographic follow-up shows that treated saphenous veins disappear after the 2-year point. Clinical observations suggest that patients are much more comfortable after RF ablation than after surgical stripping.¹³

The technique of RF ablation is somewhat similar to that of laser ablation [see Figure 2] but differs in several important respects [see Laser Vein Ablation, above]. After percutaneous access is obtained, either a 6 or an 8 French RF radiofrequency catheter is placed 1 to 2 cm from the saphenofemoral junction, and tumescent anesthesia is instituted. The probe is connected to the RF generator box, the tines of the probe are exposed, and the unit is activated. The catheter is pulled back slowly (1 cm every 30 seconds) while its temperature and impedance are monitored. In the procedure as originally performed, the catheter was heated to 85° C, but current approaches often involve heating the catheter to 90° or 95° C with the aim of shortening the pullback time (to compete with the shorter pullback times characteristic of laser ablation). In general, however, pullback times are still somewhat longer with RF ablation than with laser ablation, allowing more dissemination of heat to surrounding tissue; postprocedural paresthesia continues to be reported in about 12% of cases.¹⁴ The technical results of RF ablation are excellent: with the Closure procedure, the closure rate at 4 years is 89%.¹⁴ However, the continued occurrence of paresthesias and the slower pullback times associated with RF ablation still appear to make laser vein ablation a safer and more rapid procedure.

The issue of recurrent varicosities after obliteration of the GSV without disconnection of the saphenofemoral junction tributaries is unsettled at present. It does appear, however, that endovenous RF ablation of the GSV (e.g., with the Closure procedure) prevents subsequent neovascularization in the groin. Many centers have reported that neovascularization does not occur in the absence of a groin incision.

The specific goal of endoluminal treatment of venous reflux is obliteration of the saphenous vein. Follow-up to 4 years shows that RF ablation with the Closure procedure accomplishes this goal.¹⁴

OUTCOMES AND COMPLICATIONS

Both EVLT and RF ablation have proved to be effective and safe

Table 3 Complications of Laser Vein Ablation and Radiofrequency (RF) Ablation in Selected Studies¹⁵

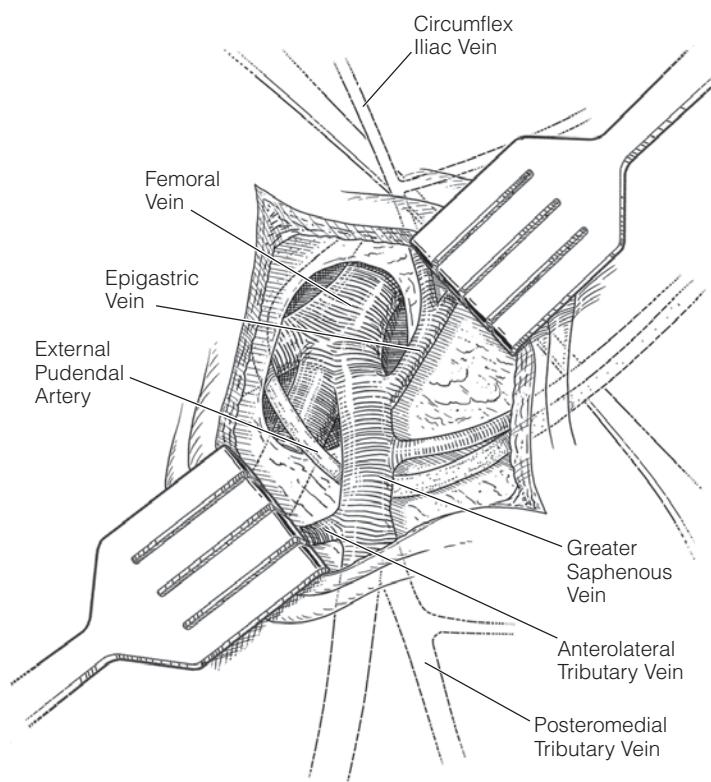

Figure 3 Shown are a typical saphenofemoral junction and the most important tributary vessels. The classic surgical approach dictates total disconnection of all tributaries at this junction.

for the treatment of venous reflux disease. Several studies that followed treated limbs for 2 years or longer have shown that with respect to efficacy, these modalities are equivalent or superior to standard surgical techniques.^{7,11,15,16} It is noteworthy that neovascularization seems to be almost nonexistent with endovenous procedures; this result appears to be related exclusively to standard ligation surgery.

Multiple studies have reported similar end-point results for EVLT and RF ablation: long-term occlusion of the GSV is consistently achieved at rates approaching or exceeding 90%. In general, EVLT has somewhat better long-term success rates, ranging from 92% to 95%; RF ablation generally yields success rates between 85% and 91%. The incidence of DVT (which is more accurately described as extension of thrombus from the treated vein into the deep venous system) is low with both procedures but is slightly higher with RF ablation. No cases of life-threatening pulmonary embolism have been reported with either EVLT or RF ablation, and both are associated with only negligible rates of superficial thrombophlebitis, cellulitis, (excessive) pain, and transient paresthesias.

A 2006 study stressed the importance of treating the posterior thigh circumflex vein so as to lower the incidence of recanalization.¹⁵ A large posterior thigh circumflex vein can drain cool blood into the segment being ablated, thus inhibiting proper heating of the refluxing segment and making adequate closure more difficult. Accordingly, the authors recommended ablating any posterior thigh circumflex veins larger 4 mm in tandem with the primary procedure.

Surgical Vein Stripping

Ligation of the GSV at the saphenofemoral junction [see Figure 3] has been widely practiced in the belief that it would control gravitational reflux while preserving the vein for subsequent arterial bypass.

It is true that the GSV is largely preserved after proximal ligation¹⁷; however, reflux continues, and hydrostatic forces are not controlled.¹⁸ Recurrent varicose veins are more frequent after saphenous ligation than after stripping.¹⁹ Varicosities also recur more frequently after ligation and sclerotherapy than after stripping and sclerotherapy.²⁰ A prospective, randomized trial that compared proximal GSV ligation and stab avulsion of varices with stripping of the thigh portion of the GSV and stab avulsion of varices showed the latter approach to be superior.^{21,22} Routine GSV stripping reduces the rate of recurrent varicosities and the need for reoperation for recurrent saphenofemoral incompetence.

Although it can be argued that the GSV should be retained for possible use in arterial bypass grafting, the relatively high (> 20%) reoperation rate makes this strategy undesirable. Almost three quarters of limbs that undergo GSV ligation alone have an incompetent GSV on follow-up duplex imaging. Until studies show a clear advantage to retaining the GSV in defined patient populations, surgical stripping should remain a routine part of primary GSV surgery. In several studies, preservation of the patency of the GSV and continuing reflux in this vein were found to be the factors most frequently associated with recurrence of varicosities.²³⁻²⁵ In one study of patients who underwent reoperation for relief of recurrent variceal symptoms, two thirds of the patients required removal of the GSV as part of the procedure.²³

Over the past 100 years, ankle-to-groin stripping of the GSV has been the dominant approach to treatment of varicose veins.²⁶⁻²⁸ It has been argued, however, that routine stripping of the leg (i.e., ankle-to-knee) portion of the GSV is inadvisable. One argument against this practice is that there is a significant risk of concomitant saphenous nerve injury [see Figure 4].¹⁹ Another argument is that whereas the objective of GSV removal is detachment of perforating veins emanating from the GSV in the thigh, the perforating veins in the leg are actually part of the posterior arch vein system rather than of the saphenous vein system. This latter argument notwithstanding, preoperative ultrasonography often demonstrates that the leg portion of the GSV is in fact directly connected to perforating veins. It is clear, however, that elimination of the refluxing thigh portion of the GSV frequently eliminates reflux in the calf portion of the vein, even when the calf portion is left behind. Therefore, removal of the GSV from ankle to knee generally is not necessary. If reflux subsequently becomes a problem in this portion of the vein, it can usually be controlled with sclerotherapy.

OPERATIVE TECHNIQUE

The surgical approach to vein stripping must be tailored to the individual patient and the individual limb being treated. As a rule, general or spinal anesthesia is required, though the procedure can also be performed with tumescent anesthesia. Groin-to-knee stripping of the GSV should be considered in every patient requiring surgical intervention.²⁹ In nearly all patients, this measure is supplemented by removal of the varicose vein clusters via stab avulsion or some form of sclerotherapy [see Table 4].

Step 1: Placement of Incisions

Preoperative marking, if correctly performed, will have documented the extent of varicose vein clusters and identified the clinical points where control of varices is required. Incisions can then be planned. As a rule, incisions in the groin and at the ankle should be transverse and should be placed within skin lines. In the groin, an oblique variation of the transverse incision may be appropriate. This incision should be placed high enough to permit identification of the saphenofemoral junction [see Figure 3]. The use of a portable ultrasound unit in the operating room facilitates placement of the inci-

sion directly over the saphenofemoral junction. Generally, throughout the leg and the thigh, the best cosmetic results are obtained with vertical incisions. Transverse incisions are used in the region of the knee, and oblique incisions are appropriate over the patella when the incisions are placed in skin lines.

A major cause of discomfort and occasional permanent skin pigmentation is subcutaneous extravasation of blood during and after saphenous vein stripping. Such extravasation can be minimized by using tumescent anesthesia around the vein to be stripped.

The practice of identifying and carefully dividing each of the tributaries to the saphenofemoral junction has been dominant over the past 50 years. The rationale for this practice is to avoid leaving behind a network of interanastomosing inguinal tributaries. Accordingly, special efforts have been made to draw each of the saphenous tributaries into the groin incision so that when they are placed on traction, their primary and even secondary tributaries can be controlled. The importance of these efforts has been underscored by de-

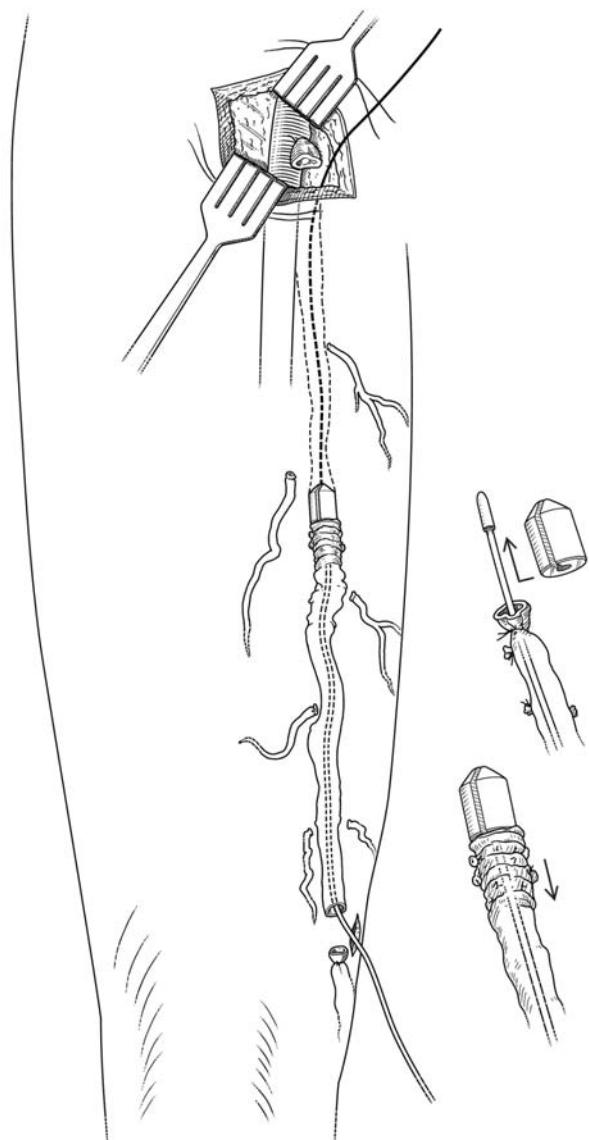

Figure 4 Surgical stripping of great saphenous vein. Illustrated is an early attempt to minimize distal incisions and prevent saphenous nerve injury at the knee. The stripper and its obturator are pulled to knee level, then retrieved through the groin incision. (Note division of perforating and communicating veins.)

scriptions of residual inguinal networks as an important cause of varicose vein recurrence.²³ Currently, however, this central principle of varicose vein surgery is under challenge, on the grounds that groin dissection can lead to neovascularization and hence to recurrence of varicosities [see Outcome Evaluation, below].

Step 2: Introduction of Stripping Device

Preoperative duplex studies having already demonstrated incompetent valves in the saphenous system, a disposable plastic Codman stripper can be introduced from above downward; alternatively, an Oesch stripper can be employed.³⁰ Both of these devices can be used to strip the GSV from groin to knee via the inversion technique [see Figure 5]. This approach has been shown to reduce soft tissue trauma in the thigh.³¹

In the groin, the stripper is inserted proximally into the upper end of the divided internal saphenous vein and passed down the main channel through incompetent valves until it can be felt lying distally approximately 1 cm medial to the medial border of the tibia at a point approximately 4 to 6 cm distal to the level of the tibial tubercle. The GSV is anatomically constant in this location, just as it is in the groin and ankle. If the GSV is removed from the groin to this level, both the midthigh perforating vein, which usually enters the GSV, and the most distal incompetent perforating veins, which are in the distal third of the thigh, will be treated.

A small incision is made over the palpable distal end of the stripper. The GSV will subsequently be divided through this incision, and the stripper and the inverted vein will be delivered through it. In exposing the GSV at knee level, the superficial fascia must be incised because the vein lies between this structure and the deep fascia of the thigh.

If the stripper passes unimpeded to the ankle, it can be exposed there with an exceedingly small skin incision placed in a carefully chosen skin line. Passage of the stripper from above downward to the ankle serves to confirm the absence of functioning valves, and stripping of the vein from above downward is unlikely to cause nerve damage. At the ankle, the vein should be carefully and cleanly dissected to free it from surrounding nerve fibers. If this is not done, saphenous nerve injury will result, and the patient will experience numbness of the foot below the ankle.

Step 3: Removal of Saphenous Vein

The previously placed stripper is pulled distally to remove the GSV. Although plastic disposable vein strippers and their metallic equivalents were designed to be used with various-sized olives to remove the GSV, in fact, a more efficient technique is simply to tie the vein to the stripper below its tip so that the vessel can then be inverted into itself and removed distally, usually at knee level.

Phlebectomy for Management of Residual Varicosities

Management of residual varicose veins after vein stripping traditionally has been done at the same time as the surgical procedure.

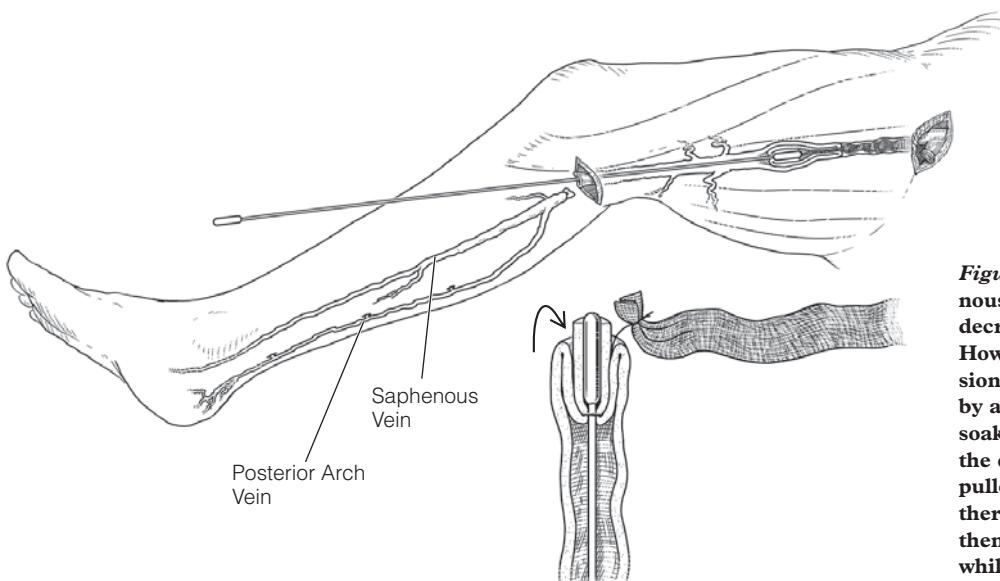

Figure 5 Surgical stripping of great saphenous vein. Inversion stripping of the GSV decreases soft tissue trauma in the thigh. However, tearing of the vein occurs on occasion. This problem may be largely prevented by attaching a corner of a 2 in. gauze roll soaked in lidocaine-epinephrine solution to the end of the stripper. As the stripper is pulled, the gauze is drawn into the vein, thereby assisting hemostasis. The gauze can then be left in place for 10 to 20 minutes while the stab wounds from the avulsion part of the procedure are being closed.

Management of residual varicose veins after vein ablation is more controversial. Currently, many physicians who treat vein disease are not familiar with the surgical technique of phlebectomy and therefore elect to wait for varicosities to regress after vein ablation. In 10% to 20% of cases, enough regression of varicose veins occurs after ablation that no further treatment is required. If delayed treatment proves necessary, it may be accomplished by means of either phlebectomy or sclerotherapy, depending on the physician's preference.

The technique of phlebectomy is easy to learn. A tumescent anesthesia solution is infused between the skin and the superficial fascia of the leg in the area of the previously marked varicosities. The infusion of the anesthetic tends to dissect the GSV away from the surrounding tissue and causes vasoconstriction. Vertical incisions 1 to 3 mm in length are made where appropriate. In the anterior knee and ankle regions, where skin lines are obviously horizontal, incisions are hidden in the lines [see Figure 6]. Varicosities are exteriorized by means of hooks or forceps; particularly useful for this purpose are specially designed vein hooks such as the Varady dissector, the Muller hook, and the Oesch hook [see Figures 7 and 8].³² Nothing should penetrate the skin other than the small end of the hook. Usually, the vein is easily distinguished from the surrounding fat by its taut rubber band feel. The vessel is brought out of the skin, then removed proximally and distally by using a hand-over-hand technique with mosquito clamps. Eventually, the vein tears in each direction, but because of the epinephrine in the tumescent anesthesia solution, very little bleeding occurs. The procedure is continued in a proximal-to-distal direction until all varicose clusters have been removed; generally, between 10 and 15 incisions are required for removal of all clusters. Veins of any size can be removed by means of this technique, even in the office setting. In patients who have had superficial phlebitis or have previously undergone sclerotherapy, the veins typically are fibrotic and adherent to the surrounding tissue and cannot be easily removed. If treatment of such veins proves necessary at some point in the future, sclerotherapy is generally the method of choice.

When all phlebectomies have been completed, small elastic strips are used to close the skin incisions. A compressive dressing is applied for 24 hours to minimize bleeding, bruising, and swelling. When the procedure is done properly, the incisions are invisible by 6 to 8 weeks and the patients are very happy with the results. Experienced workers in Europe have achieved marked refinements of phlebectomy techniques for varicose clusters.³³

COMPLICATIONS

Surgical removal of the GSV on an outpatient basis still requires two incisions, one in the groin and the other near the knee. Postoper-

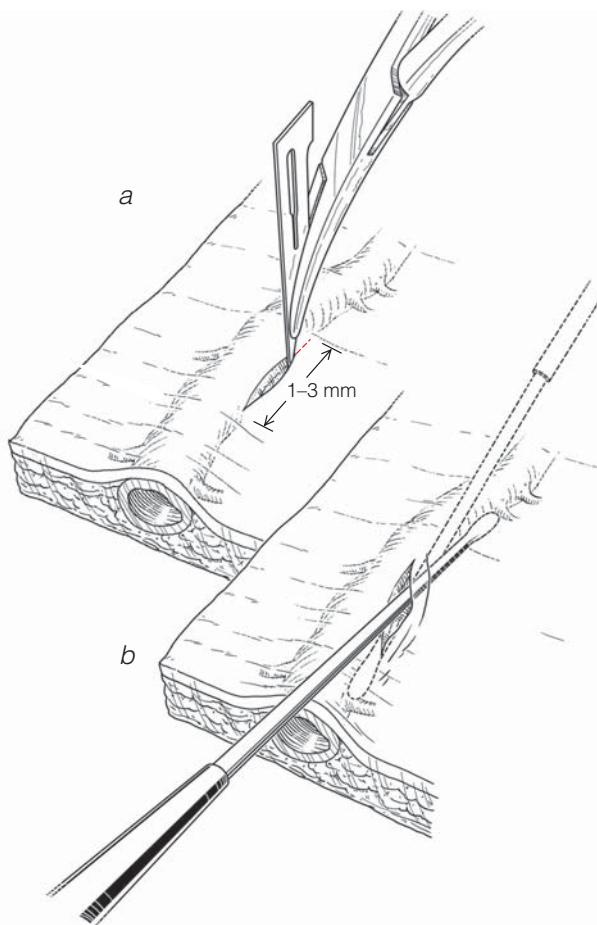

Figure 6 Surgical stripping of great saphenous vein: phlebectomy for residual varicosities. (a) Skin incisions for stab avulsion of varicosities are limited with respect to both length and depth. (b) The dissector blade facilitates mobilization of the vein before removal.

ative compression bandaging is standard, and most patients experience little downtime. Some, however, do experience hematoma, pain, and extensive bruising. These three complications are linked; thus, every effort should be made to prevent oozing. The most feared complication of varicose vein surgery is venous thromboembolism, but the incidence of this complication is quite low (probably about 1%). In countries where postoperative immobilization, hospitalization, and delayed ambulation are employed for patients with varicosities, prophylaxis against venous thromboembolism is common. In the United States, however, this measure is generally considered unnecessary in these patients. The most common complication of varicose vein surgery is recurrence of varicosities, which is experienced by 15% to 30% of patients treated.²⁴

To speak of permanent removal of varicosities implies that all potential causes of recurrence have been considered and that surgical management has been planned so as to address them. There are four principal causes of recurrence of varicose veins, three of which can be dealt with at the time of the primary operation.

One cause of recurrent varicosities is failure to perform the primary operation correctly. Common errors include missing a duplicated saphenous vein and mistaking an anterolateral or accessory saphenous vein for the GSV. Careful and thorough anatomic identification will help minimize such errors. It has long been held that a second cause of recurrent varicose veins is failure to do a proper groin dissection; however, it is now known that such dissection causes neovascularization in the groin, leading to recurrence of varicose veins [see Outcome Evaluation, below]. A third cause is failure to remove the GSV from the circulation. A reason often cited for this failure is the desire to preserve the GSV for subsequent use as an arterial bypass, but it is clear that the preserved GSV continues to reflux and continues to elongate and dilate its tributaries, thereby producing more varicosities even after primary operative treatment has removed the varicose veins present at the time. A fourth cause of recurrent varicosities is persistence of venous hypertension through nonsaphenous sources—chiefly perforating veins with incompetent valves. Muscular contraction generates enormous pressures that are directed against valves in perforating veins. Venous hypertension induces a leukocyte endothelial reaction, which, in turn, incites an inflammatory response that ultimately destroys the venous valves and weakens the venous wall.³⁴ The perforating veins most commonly associated with recurrent varicosities are the midthigh perforating vein, the distal thigh perforating vein, the proximal anteromedial calf perforating vein, and the lateral thigh perforating vein, which connects the deep femoral vein to surface varicosities.

In addition to the four principal causes of recurrent varicosities, there is a fifth cause, which is beyond the operating surgeon's control—namely, the genetic tendency to form varicosities. This tendency results in the development of localized or generalized venous wall weakness, localized blowouts of venous walls, or stretched, elongated, and floppy venous valves.^{35,36}

OUTCOME EVALUATION

As a rule, when undesirable outcomes occur after surgical saphenous vein stripping, they become evident quite early.²¹ As noted (see above), it has long been accepted practice to dissect tributary vessels at the saphenofemoral junction very carefully, taking each of the vessels back beyond the primary and even the secondary tributaries if possible.³¹ In practice, however, such dissection appears to cause neovascularization in the groin³⁷; surveillance with duplex ultrasonography supports this finding.³⁸ It has now been amply confirmed that neovascularization causes recurrent varicose veins. Clearly, this is a significant disadvantage of standard surgical treatment of varicosities. This disadvantage has been a major impetus for the development of less invasive alternatives to surgical saphenous vein stripping [see Endovenous Procedures, *above*, and Foam Sclerotherapy, *below*]. These alternatives are proving to be effective and may be superior to surgical stripping, if only because they are not followed by groin neovascularization.

Foam Sclerotherapy

The prospect of a rapid, minimally invasive, and durable treatment of varicose veins is an attractive one. Current evidence suggests that these objectives may be achieved without operative intervention by using sclerosant microfoam [see Figure 9]. In 1944 and 1950, E. J. Orbach introduced the concept of a macrobubble air-block technique to enhance the properties of sclerosants in performing macrosclerotherapy.^{39,40} At the time, few clinicians evinced much interest in the subject, and the technique languished.

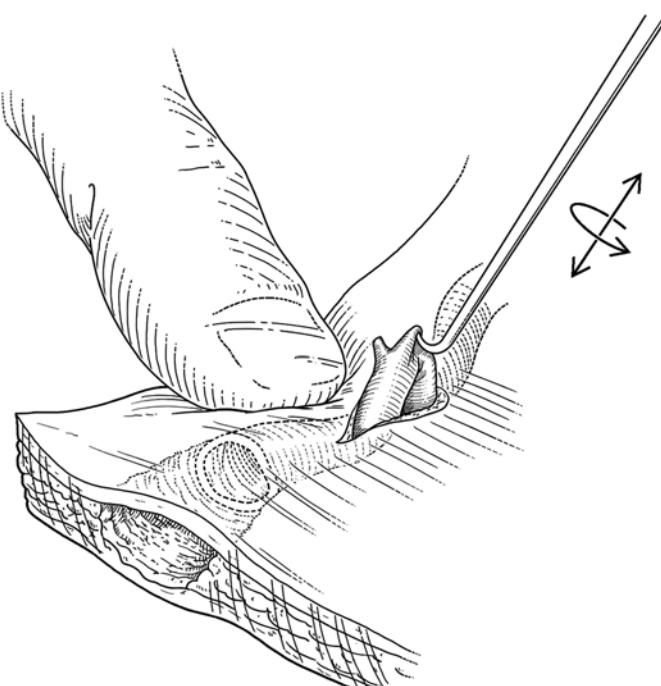

Figure 8 Surgical stripping of great saphenous vein: phlebectomy for residual varicosities. The varix is exteriorized with a hook, then divided to permit proximal and distal avulsion.

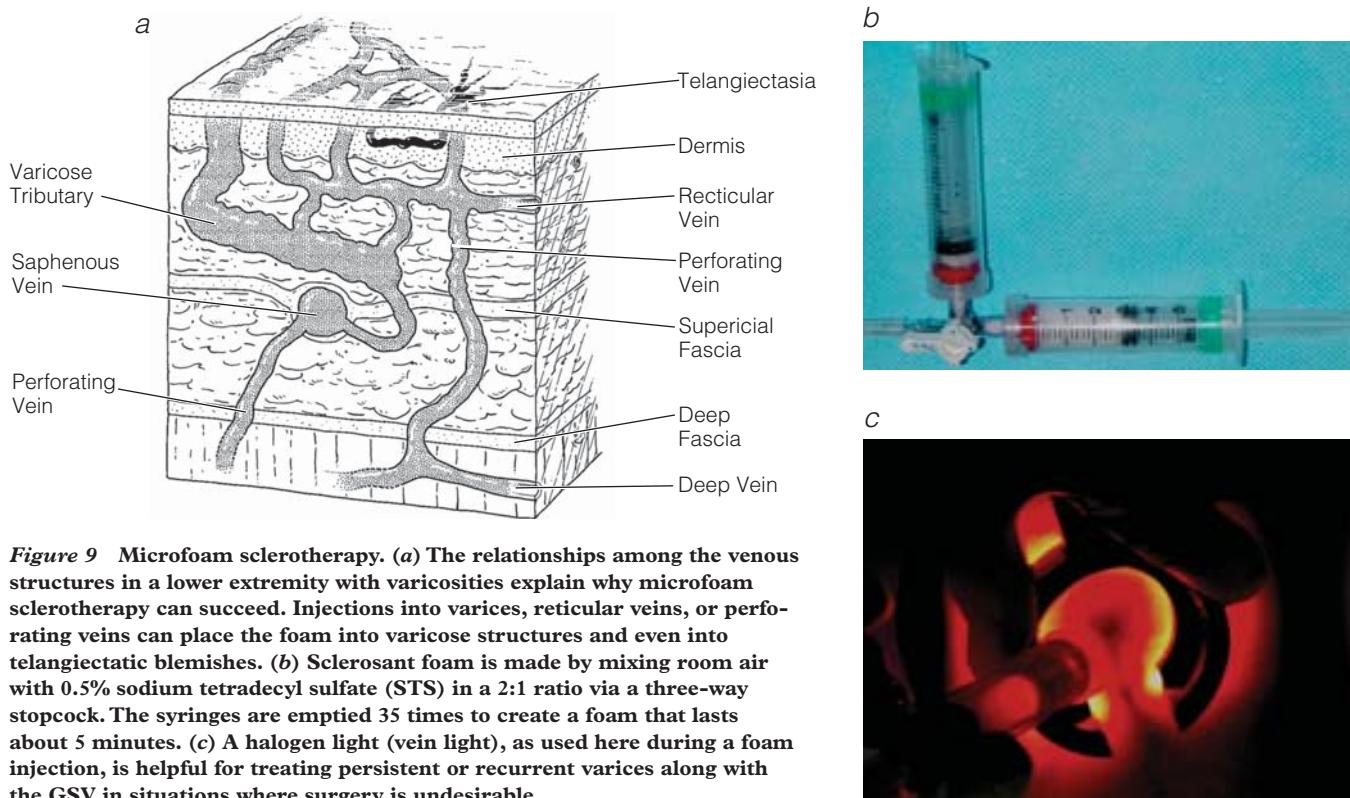

Figure 9 Microfoam sclerotherapy. (a) The relationships among the venous structures in a lower extremity with varicosities explain why microfoam sclerotherapy can succeed. Injections into varices, reticular veins, or perforating veins can place the foam into varicose structures and even into telangiectatic blemishes. (b) Sclerosant foam is made by mixing room air with 0.5% sodium tetradecyl sulfate (STS) in a 2:1 ratio via a three-way stopcock. The syringes are emptied 35 times to create a foam that lasts about 5 minutes. (c) A halogen light (vein light), as used here during a foam injection, is helpful for treating persistent or recurrent varices along with the GSV in situations where surgery is undesirable.

Half a century later, the work of Juan Cabrera and colleagues in Granada attracted the attention of some phlebologists and reawakened interest in using foam technology for the treatment of venous insufficiency.⁴¹ These investigators showed that foam sclerotherapy was technically simple and worked well in small to moderate-sized varicose veins, and they demonstrated that the limitations of liquid sclerotherapy could be erased by using microfoam. Their 5-year report represents the longest observation period to date for microfoam sclerotherapy for varicose veins. In most of the cases, a single injection sufficed to treat saphenous veins and varicose tributaries. Extensive vasospasm was seen immediately, but compression was applied after treatment. Complete fibrosis of the saphenous vein was achieved in 81% of cases, and patency with reflux persisted in only 14%. Tributary varicosities disappeared in 96% of cases. Vessels that remained open and were refluxing were successfully closed with retreatment.

A subsequent study demonstrated that even severely affected

limbs could be safely and effectively treated by means of foam sclerotherapy combined with compression.⁴² In this study, limbs affected by lipodermatosclerosis, atrophie blanche, or even open venous ulcers showed statistically significant improvement after the injection of a foamed sclerosant followed by compression with a medical-grade stocking or an Unna boot. The study results also underscored the importance of applying compression immediately after the injection of the sclerosant. Limbs that underwent foam sclerotherapy and compression healed better and more quickly than limbs that were treated by sclerotherapy alone.

If subsequent work continues to confirm these favorable results, it may be that microfoam sclerotherapy will eventually replace all other methods of varicose vein treatment. As of December 2006, however, foam sclerotherapy had not been approved by the United States Food and Drug Administration, because of concerns about potential air embolization after the injection of the sclerosant.

21 SCLEROTHERAPY

William R. Finkelmeier, M.D., F.A.C.S.

Sclerotherapy involves the injection of a caustic solution (a sclerosant) into an abnormal vein so as to cause localized destruction of the venous intima and obliteration of the vessel. It is not a new technique, having been practiced since the early 20th century, but it has evolved significantly over the past 50 years.¹ Improvements in the technology used (e.g., hypodermic syringes, fine needles, sclerosants, compression technique, and duplex ultrasonography) have greatly enhanced the results achievable with sclerotherapy. To ensure optimal results, it is essential to have a thorough knowledge not only of the technique but also of the indications, expected outcomes, and possible complications associated with the procedure.

Sclerotherapy is primarily used to treat small varicose veins, reticular veins, and spider veins. The prevalence of varicose and spider veins is well documented: they affect millions of people in the United States alone.¹ The incidence is two to three times higher in women than in men and increases with age. The precise etiology of varicose veins and spider veins is unknown. Heredity, pregnancy, female sex, obesity, an occupation that requires long periods of standing, and a low-fiber diet all have been implicated as causative factors. The choice of treatment method for varicose veins and spider veins must be individualized for each patient. Although sclerotherapy is only one of a number of techniques available for treatment, it is an important therapeutic tool and a key component of a vascular surgeon's armamentarium.

Preoperative Evaluation

Proper evaluation of the patient before sclerotherapy is the most important step in achieving successful results. Such evaluation should include a thorough clinical arterial and venous examination. Close attention should be paid to the size, location, and distribution of vessels; these variables are critical for determining the appropriate treatment. Any patient who is believed to have axial reflux or whose clinical complaints far exceed the findings from physical examination should undergo venous duplex ultrasonography.

Venous duplex ultrasonography has revolutionized the treatment of varicose and spider veins. It is reproducible and noninvasive, and it can objectively identify areas of reflux in the greater and lesser saphenous systems, as well as detect pathologic conditions in the deep venous system and incompetent perforating vessels. Duplex ultrasonography can also identify the lesser saphenous–popliteal junction and facilitate skin mapping in preparation for surgery.

Patients with duplex-documented axial reflux or reflux from the greater or lesser saphenous junction are best managed by means of surgical correction of the reflux rather than primary treatment with sclerotherapy. In a 1993 randomized study, ligation and stripping were compared with compression sclerotherapy in 164 patients who had symptomatic primary varicose veins.² After 5 years, 74% of the patients treated with sclerotherapy were considered to have had treatment failures, compared with only 10% of the patients treated surgically. In a 1991 trial, real-time color duplex ultrasonography was used to evaluate 89 limbs in 55 patients who had previously undergone

sclerotherapy of the greater saphenous vein.³ Obliteration of the greater saphenous vein was noted in only 20% of the injected limbs and in only 6% of the limbs below a refluxing junction. These poor results from sclerotherapy were confirmed in a subsequent study.⁴ The superiority of surgical treatment was also demonstrated in a randomized 10-year study comparing surgery with sclerotherapy alone.⁵

Ultrasound-guided sclerotherapy has also been advocated. The advantages of this approach are that it allows much higher concentrations of the sclerosant solution and that it permits direct visualization of the injections. Reported recurrence rates are still quite high, however: 22.8% at 1 year and 27.2% at 2 years.⁶ A number of authors, primarily in the dermatologic literature, have advocated ultrasound-guided foam sclerotherapy for patients with axial reflux.^{7,8} The longevity of the results achieved with this technique is still in question, and further studies (including randomized trials) are needed for validation.

Given the available data, my preferred approach in patients with axial reflux is to ligate the greater saphenous vein, strip the vein at least to the knee, and then ligate the lesser saphenous vein before sclerotherapy. Patients who do not have axial reflux and whose vessels are less than 6 mm in diameter can be treated successfully with sclerotherapy alone. Varicose veins more than 6 mm in diameter are best treated surgically by means of phlebectomy, either with a hook or with a transilluminated powered phlebectomy device. The cosmetic results are far better and the recovery time much shorter with the surgical option.

Operative Planning

PATIENT PREPARATION

Before undergoing sclerotherapy, the patient should receive a thorough explanation of the procedure, including the possible risks and complications [see Table 1]. He or she should be informed about the expected outcomes and the length of time needed for healing. In particular, it should be emphasized that multiple treatments are usually necessary to eliminate varicosities. Most patients can expect to undergo four or five treatments in a 6-month period. Time and patience are essential for achieving an optimal outcome.

Because sclerotherapy is primarily cosmetic and therefore rarely reimbursable, it is important to have a clear understanding regarding costs. A good-faith estimate of the cost per procedure should be provided to the patient before treatment is initiated. It is advisable to have the patient sign a copy of this estimate so that there is no subsequent misunderstanding about the costs to be incurred during the course of therapy.

To reduce bruising, aspirin and antiplatelet agents should be avoided for 10 days before treatment. On the day of the procedure, the patient should be asked to refrain from applying lotion to the legs so that the tape applied after treatment will adhere better to the skin [see Table 2]. The patient should sign and date an informed consent form. Once informed consent is obtained, photographs of the areas

Table 1 Complications of Sclerotherapy

	Complication	Comment
Common	Itching	Usually mild; lasts for 1–2 days
	Hyperpigmentation	Occurs in about 20%–30% of patients treated; usually fades in a couple of weeks but may take several months to a year to resolve totally; lasts longer than 1 yr in 1% of cases
	Telangiectatic matting	Occurs in approximately 10% of patients treated; usually resolves in 3–12 mo if left untreated but in rare cases can be permanent
	Pain	Lasts 1 to, at most, 7 days
	Bruising	May be minimized by avoiding aspirin and ibuprofen for 10 days before and after each treatment session
	Minor allergic reaction	Typically resolves within about 1 hr
Rare	Ulceration at injection site	Can take 4 to 6 wk to heal completely; small scar may result
	Anaphylaxis	Incidence is extremely low
	PE or DVT	Incidence is extremely low

DVT—Deep venous thrombosis PE—pulmonary embolism

to be treated should be taken. Either a digital camera or a conventional 35 mm camera may be used. Digital photography offers much greater flexibility, in that there is no need to wait for film development. The pictures should be standardized as much as possible with respect to lighting and background. The problem areas are photographed again after treatment, and additional pictures are obtained during subsequent treatments to document progress. The aim is to give patients a reliable means of objectively comparing the legs' appearance before and after sclerotherapy [see Figures 1 through 3]. Such photographs often reassure patients that significant cosmetic improvement has been achieved and encourage them to continue treatments.

MATERIALS

Sclerosants cause thrombosis and subsequent fibrosis when injected into a blood vessel. An ideal sclerosant would exert this effect reliably while also being inexpensive, widely available, approved by the Food and Drug Administration (FDA), and non-toxic. In addition, it would be painless on injection and would not cause hyperpigmentation or ulceration with extravasation. Unfortunately, this ideal sclerosant does not exist. All of the solutions currently available have disadvantages.

Sclerosants may be classified into two main categories: osmotic agents and detergents. Hypertonic saline (HS) is the most widely used osmotic agent. FDA-approved as an abortifacient, it is commonly employed to treat superficial telangiectasias. HS in a 23.4% concentration damages the endothelial cells of the vessel walls through hyperosmolarity-induced dehydration. Such damage leads to thrombosis and fibrin deposition. Sodium tetradecyl sulfate (STS) and polidocanol (POL) are the most widely used detergent agents in the United States. These agents form aggregates on endothelial cell surfaces and cause endofibrosis by disrupting the integrity of the cells.

In the United States, HS has been used to treat spider and varicose veins for more than 50 years. Because it is a naturally occurring bodily substance, it does not cause allergic reactions; however, it causes patients much more pain and discomfort than either STS or POL does.⁹ Adding lidocaine to HS reduces the pain associated with the injections without significantly decreasing the effectiveness of treatment or increasing the incidence of complications.¹⁰ Even

with the addition of lidocaine, injection of HS is associated with some degree of patient discomfort. Moreover, HS is more viscous than STS and thus more difficult to administer. Extravasation of HS is also associated with a higher risk of skin necrosis.

Table 2 Sample Instructions to Patients after Sclerotherapy

NEXT APPOINTMENT _____ TIME _____

Be sure to keep your follow-up appointment so the physician can monitor your progress.

Please be considerate and give our office at least 72 hours' notice if you are unable to keep an appointment. This will allow us time to call patients who are on the waiting list for an appointment.

Please walk for a few minutes before driving home.

Wear your support hose for 48 continuous hours.

After 48 hours, remove the hose, cotton balls, and tape before getting your legs wet.

After 48 hours, wear your support hose for a minimum of 7 days during the waking hours. Note, you may continue to wear them longer if you prefer.

Do not run, do high-impact aerobics, lift weights with your legs, or do sit-ups for 2 weeks. These activities can increase the venous pressure in your legs.

For 2 weeks, do not take hot baths or showers or sit in a hot tub. The heat can cause vein dilatation. You may take a warm shower or bath after 48 hours.

Avoid aspirin and ibuprofen products for 10 days before and after each treatment. These products may increase the amount of bruising that may develop from the treatment. Acetaminophen is permitted.

For further information regarding sclerotherapy, please refer to the handout "Sclerotherapy Informed Consent and Before and After Treatment Instructions."

Preparation for Your Next Treatment

Bring your support hose.

Do not apply creams, lotions, or powders to your legs the evening before or the morning of your treatment.

Bring a pair of loose shorts to wear during your treatment.

Avoid aspirin and ibuprofen products for 10 days before and after each treatment. These products may increase the amount of bruising that may develop from the treatment. Acetaminophen is permitted.

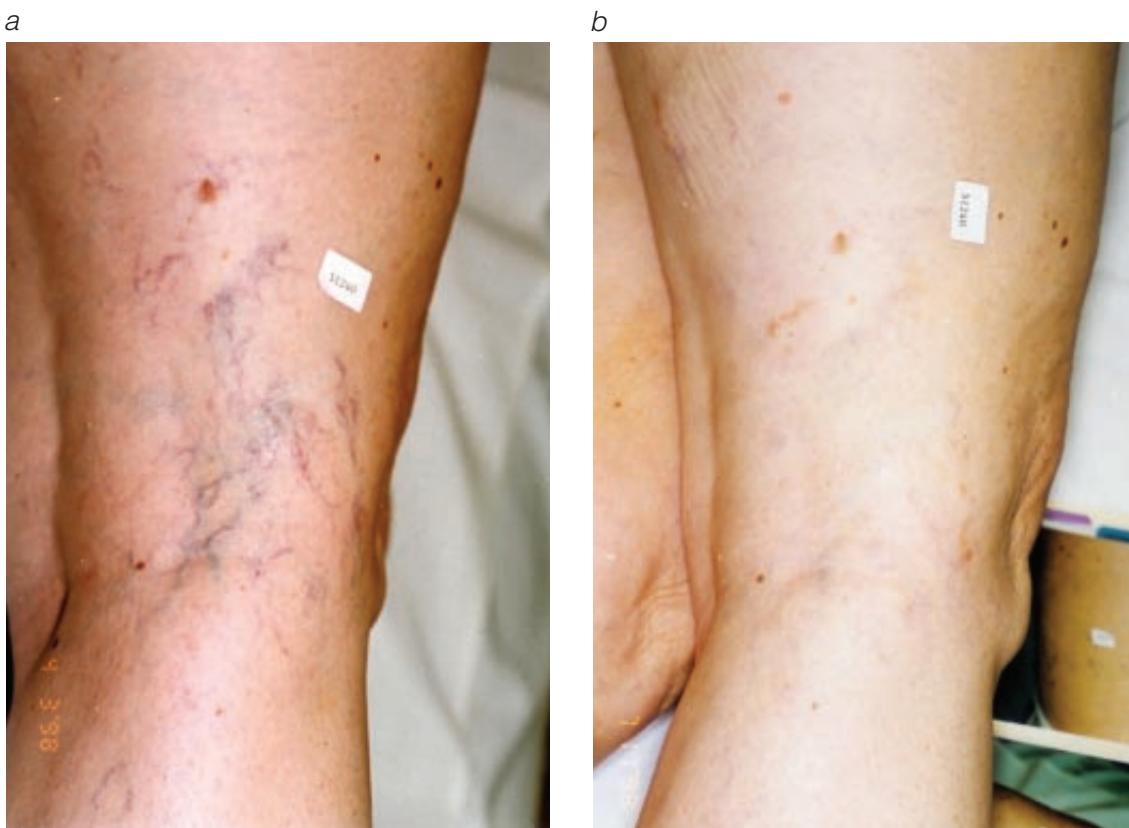

Figure 1 Sclerotherapy. Shown is a 63-year-old woman (a) before and (b) after two treatments with 0.2% STS.

Of the detergent sclerosants, both STS and POL are widely used in the United States, but only STS is FDA approved. FDA approval of POL has been pending for years, and it is unclear why it has not yet been granted. POL appears to be a very good sclerosant, comparable to STS: it is safe, relatively painless, and highly effective in all vein types.^{11,12} In a 2002 randomized study comparing STS with POL, both agents were found to be safe and effective, yielding a 70% clinical improvement, and there were no significant differences in adverse effects, aside from a small decrease in ulcerations with POL.¹³ Nevertheless, until POL is approved by the FDA, we recommend that it not be used. Two other FDA-approved detergent sclerosants are available: sodium morrhuate (SM) and ethanolamine oleate (EO). However, both SM and EO are associated with an unacceptably high risk of complications, including but not limited to ulceration and anaphylactic reactions, and hence are rarely used. For these reasons, my practice is to use STS for sclerotherapy, and the ensuing technical discussion will focus solely on this agent.

Sclerotherapy is an outpatient procedure performed in the physician's office. Aside from the sclerosant, very few special materials are needed [see Table 3]. Because there is a risk of significant allergic reactions (albeit an extremely small risk), a fully stocked resuscitation cart including intubation equipment should be available and checked regularly to confirm that all equipment is up to date and ready for immediate use.

Technique

A variety of sclerotherapy techniques have been developed. Typically, each individual practitioner develops his or her own variation of the procedure.

STEP 1: POSITIONING AND SKIN PREPARATION

Sclerotherapy is best performed with the patient supine. On very rare occasions, it may be necessary to puncture a vein with the patient standing. However, the sclerosant is not injected until the patient has been returned to the supine position, thus allowing the vein to empty.

The skin is wiped with alcohol swabs to increase the visibility of the vessels. The sclerosant is then placed in plastic 3 ml syringes. These syringes fit more easily in the hand than tuberculin syringes do and are less cumbersome to use. In addition, because injection pressure is inversely proportional to the squared radius of the plunger, a 3 ml syringe generates less pressure than a 1 ml syringe does. The endothelial cells in these small vessels are quite fragile, and using a syringe that generates less pressure substantially reduces the risk of vessel disruption.

STEP 2: CHOICE OF SCLEROSANT CONCENTRATION

The solution concentration selected depends on the size of the vessel. I use 0.2% STS for vessels less than 2 mm in diameter and 0.5% for larger vessels. The volume per injection site is generally less than 0.5 ml, but larger volumes may be preferable for reticular or small varicose veins.

At present, there is enthusiasm in the literature for the use of foam sclerotherapy, a technique in which air is repetitively injected into STS to create a foam.¹⁴ This technique is ultimately based on the work of Orbach, who in 1944 advocated expelling blood from the vein by injecting small boluses of air before injecting the sclerosant.¹⁵ The rationale for foam sclerotherapy is that the foam displaces blood in the vessel, resulting in less dilution of the solution. The sclerosant then has more contact with the surface area of the venous endothelium and thus can sclerose the endothelial cells more efficiently at

Figure 2 Sclerotherapy. Shown is a 52-year-old woman (a) before and (b) after two treatments with 0.5% STS.

lower concentrations. Of the various methods of creating a foam sclerosant solution,¹⁶ that described by Tessari and coworkers appears to be the easiest.¹⁷ In this approach, air is injected into the solution via a three-way stopcock and two syringes. Because of the size of the bubbles in a foam solution, foam sclerotherapy is best suited to treatment of reticular and varicose veins. Spider telangiectasias are best treated with standard solutions.

STEP 3: INJECTION OF SCLEROSANT

I use 30-gauge needles for all sclerotherapy treatments; some physicians prefer 27-gauge needles for larger reticular and small varicose veins. The needle is bent at a 45° angle, with the bevel up. Countertraction is applied with the nondominant hand, and the needle is inserted parallel to the vessel and the skin surface [see *Figure 4*]. As the vessel is entered, the sclerosant is gently injected. The slight reduction of pressure that occurs when the vessel is entered becomes increasingly easy to appreciate as the physician accumulates experience with sclerotherapy. Blanching of the vein is another signal of entry into the vessel. If the solution is injected outside the vein, a small superficial wheal will appear, in which case the injection should be discontinued and a new site selected for injection. Such wheals are unlikely to be a problem when STS concentrations lower than 0.25% are used. When more concentrated solutions are used in larger veins, aspiration of blood ensures correct placement of the needle within the vein before injection.

STEP 4: COVERAGE AND COMPRESSION OF INJECTION AREAS

After injection, cotton balls or foam or gauze pads are secured with tape and applied to the injection areas. Compression hose (20 to 30 or 30 to 40 mm Hg) are then applied. Studies have

shown that using some type of bandage or pad in addition to support hose is beneficial. The degree of compression achieved with this approach can be as much as 50% greater than that achieved with support hose alone.¹⁸ Gauze pads or cotton balls are more cost-effective than foam pads while providing comparable compressive effects.¹⁹

Compression approximates the endothelial surfaces of the vein walls after sclerotherapy, thereby reducing thrombus formation and promoting sclerosis of the vessel. It also enhances the calf muscle pump function to help clear any solution that has progressed into the deep venous system. Reduction of thrombus formation after sclerotherapy is important for minimizing hyperpigmentation. In a multicenter randomized trial that evaluated patients who underwent bilateral sclerotherapy but who received compression to only one leg, hyperpigmentation and edema were significantly greater in the uncompressed leg.²⁰

Varying recommendations have been made as to how long compression hose should be worn after sclerotherapy. A controlled comparative trial of the effects of compression in patients with reticular and telangiectatic veins found that patients who wore hose for 3 weeks exhibited greater improvement (e.g., less hyperpigmentation) than those who wore no hose.²¹ However, the improvement in patients wearing hose for 3 weeks was not appreciably greater than that in patients wearing hose for 1 week. I find that it is difficult to get patients to wear compression hose for several weeks. Therefore, I have adopted the standard practice of instructing the patient first to wear the hose for 48 hours without removing them, then to wear them during waking hours only for the next 7 days.

Once the compression hose are in place, the patient is asked to walk for 15 minutes before leaving the office. This further assists

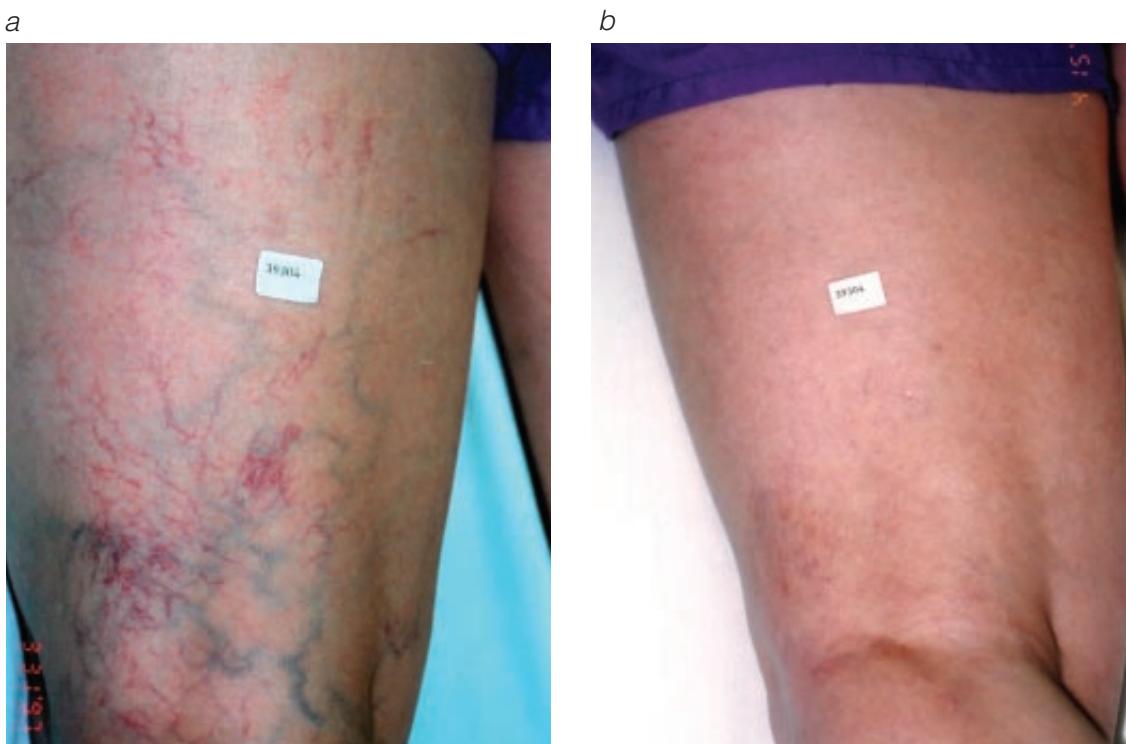

Figure 3 Sclerotherapy. Shown is a 36-year-old woman (*a*) before and (*b*) after four treatments with a combination of 0.5% and 0.2% STS. Mild hyperpigmentation may be seen on the lateral thigh.

in clearing any solution that may have progressed into the deep venous system.

STEP 5: SCHEDULING OF RETREATMENT

As noted (see above), multiple treatments are usually required for optimal outcome. Therefore, all patients are instructed to return in 4 to 6 weeks for assessment and possible retreatment. After this interval, vessels requiring further treatment are apparent, and additional injections can be performed. The average patient undergoes four or five treatments.

Complications

Although sclerotherapy is generally quite safe, complications do occur. Physicians must therefore be cognizant of the potential risks and prepared to treat any adverse events that arise. The most significant complications of sclerotherapy are allergic reactions (either minor or major), skin necrosis, hyperpigmentation, deep venous thrombosis (DVT), and telangiectatic matting. Cramping, pain, edema, and blistering from tape or compression may be observed as well.

Minor allergic reactions are quite common. For example, localized urticaria and edema may occur secondary to histamine

release. In the vast majority of cases, such reactions are self-limited, typically resolving in less than 1 hour. Itching often accompanies this response, but it usually resolves by the time the patient leaves the office. Should reactions persist, oral antihistamines or, on rare occasions, steroids may be required.

With the sclerosants used today, anaphylactic reactions are extraordinarily rare but can be life-threatening. The incidence of anaphylaxis with STS is not known with precision but is certainly very low. The reaction is usually mediated by immunoglobulin E and occurs within minutes of exposure. Appropriate emergency

Figure 4 Sclerotherapy. Illustrated is the standard hand position for sclerotherapy. Countertraction is applied with the nondominant hand.

Table 3 Materials Needed for Sclerotherapy

Alcohol swabs	Cotton balls and tape
Protective gloves	18-gauge needles
3 ml syringes	4 x 4 in. gauze pads
30-gauge needles	Adhesive bandages

Figure 5 Sclerotherapy. Shown is skin necrosis on the left posterior calf of a 48-year-old woman after ultrasound-guided sclerotherapy.

measures must be undertaken immediately, including subcutaneous administration of epinephrine, delivery of supplemental oxygen, and securing of the airway. The patient should then be given antihistamines and transferred to an emergency department for continued evaluation and treatment. As noted (see above), a properly stocked emergency response cart, including endotracheal intubation supplies and medications, is essential in any office where sclerotherapy is performed. Periodic review of procedures with staff and maintenance of the emergency medications and supplies is imperative.

Skin necrosis occurs with 0.2% to 1.2% of sclerotherapy injections.²² It is a potentially devastating complication and is often unpreventable. Depending on the extent of necrosis, healing may take months. The main causes of necrosis are extravasation of the sclerosant into subcutaneous tissue, inadvertent injection into an arteriole, and vasospasm. Extravasation of the sclerosant can destroy tissue, with the degree of damage determined by the type, concentration, and amount of sclerosant used [see Figure 5]. Necrosis is rare when small amounts of dilute (< 0.25%) STS are given, but extensive skin and soft tissue necrosis has been observed when higher concentrations of STS (3%) are administered to treat varicose veins.²³ Inadvertent injections into the arteriole feeding the telangiectasia is impossible to prevent and probably occurs frequently. In a 2001 study, pulsatile Doppler sounds could be detected above spider vein complexes in 72% of cases.²² Backwash of the solution through arteriovenous shunts may cause occlusion of the arteriole and skin necrosis. Blanching of the skin often occurs with intra-arteriolar injections. Skin massage or, if spasm persists, application of nitroglycerin ointment to the skin may increase microcirculation. Why ulcerations develop in some patients but not others is unknown. The question of whether it is related to injection pressure or injectate volume also remains unanswered.

Hyperpigmentation [see Figure 6] is quite common, occurring in a significant percentage of patients, and it may be caused by any of the

Figure 6 Sclerotherapy. Shown is residual hyperpigmentation in a 56-year-old woman after treatment with 0.2% STS.

Figure 7 Sclerotherapy. Shown is telangiectatic matting in a 43-year-old woman after treatment with 0.2% STS.

sclerosants in current use. It is more common in persons with dark complexions and in those with dark-purple vessels. Fortunately, hyperpigmentation usually resolves with time, but the process can take months. Postsclerotherapy compression lowers the incidence of hyperpigmentation, and removal of any intraluminal thrombi remaining after sclerotherapy reduces the degree of hyperpigmentation present. The latter is accomplished by puncturing the skin with an 18-gauge needle and manually expressing the thrombus. There is no firm consensus on how hyperpigmentation should be treated once it develops. Some authorities recommend the use of fade creams, whereas others advocate laser treatments to lighten the pigmentation. A 2001 study found that 80% depigmentation could be

achieved with weekly subcutaneous injections of the chelating agent deferoxamine mesylate.²⁴ That various different treatments continue to be recommended suggests that none of them is clearly superior at eliminating hyperpigmentation. The passage of time appears to be the most reliable therapy.

The precise incidence of DVT after sclerotherapy is unknown but appears to be extremely low overall. The risk is somewhat higher when more concentrated solutions are used or larger volumes administered; however, it may be minimized by performing sclerotherapy only for established indications. Treating axial reflux and larger vessels surgically, with sclerotherapy limited to an adjunctive role, will reduce the volume and concentration of solution needed. Ambulation in the physician's office after treatment will help wash away any solution that has progressed into the deep venous system.

The development of tiny new red vessels at an area of previous injection is called telangiectatic matting [see Figure 7]. Like ulceration, it is unpredictable. Excessive pressure during injections is thought to play a causative role, but the exact etiology is unknown. Telangiectatic matting is very difficult to treat once it has developed. Occasionally, it resolves spontaneously, but more often, it must be addressed by means of either repeat sclerotherapy with treatment of the feeding reticular vein or laser therapy. Treatment of telangiectatic matting may in fact be the one potential efficacious use for laser-type devices in treating diseased leg veins.

Cost Considerations

I strongly believe that all sclerotherapy, with the exception of that performed for spontaneous hemorrhage, is cosmetic. Accordingly, in the practice to which I belong, patients seeking sclerotherapy for reasons other than hemorrhage are informed well in advance that the procedure is cosmetic and not reimbursable, and they receive a good-faith estimate of expected costs in writing. As noted (see above), venous ligation is the treatment of choice for symptomatic axial reflux and large varicose veins; therefore, sclerotherapy for these conditions is considered medically unnecessary.

Obtaining reimbursement from insurance carriers for sclerotherapy performed to treat small varicose veins or hemorrhage is frustrating at best. Both physicians and patients have contributed to the problem in the past by filing inappropriate claims for reimbursement of cosmetic procedures. This past misuse of insurance coverage has made it difficult to obtain reimbursement even for the one solid medical indication for sclerotherapy, hemorrhage.

22 VASCULAR AND PERITONEAL ACCESS

Bernard Montreuil, M.D.

Vascular Access via Arteriovenous Fistulas

The number of patients with end-stage renal disease (ESRD) in the United States has increased steadily since 1980. The prevalence of ESRD in the United States population has quintupled since 1980, from 271 to nearly 1,400/million. It is estimated that by 2030, there may be 2.24 million patients with ESRD. Almost 60% of these patients are expected to be diabetic, half to be 65 or older, and half to be nonwhite.¹

Extracorporeal dialysis of blood was introduced in 1943 by Kolff and associates²; however, application of this approach was hindered by the requirement for repeated and routine access to the circulation. The full potential of hemodialysis for patient salvage was realized only after the introduction of the external arteriovenous (AV) shunt by Quinton and colleagues in 1960³ and of the endogenous AV fistula (AVF) by Brescia and coworkers in 1966.⁴ The subsequent introduction of synthetic vascular prostheses has permitted continued access in patients who have exhausted peripheral venous sites⁵; however, the long-term performance of such prostheses remains inferior to that of autogenous fistulas. The creation and maintenance of functioning vascular access, along with the associated complications, constitute the most common cause of morbidity, hospitalization, and cost in patients with end-stage renal disease.

The ideal vascular access route permits a flow rate that is adequate for the dialysis prescription (≥ 300 ml/min), can be used for extended periods, and has a low complication rate. The native AVF remains the gold standard. In 1997, the National Kidney Foundation Dialysis Outcome and Quality Initiative (NKF-DOQI)⁶ organized multidisciplinary work groups that evaluated all available data on vascular access and concluded that quality of life and overall outcome could be improved significantly for hemodialysis patients if two primary goals were achieved:

1. Increased placement of native AVFs: a minimum of 50% of new dialysis patients should have primary AVFs.
2. Detection of dysfunctional access before thrombosis of the access route occurs.

This report, which contains clinical practice guidelines on all aspects of vascular access, was updated in 2001.⁷

PREOPERATIVE EVALUATION

At least 4 to 6 weeks—preferably 3 to 4 months—is required for a native AVF to heal and mature before it can be used. Therefore, access planning should be done early in the course of progressive renal failure. Patients should be referred for surgical treatment when creatinine clearance approaches 25 ml/min, the serum creatinine level reaches 4 mg/dl, or dialysis is likely to be necessary within 1 year. Every effort should be made not to puncture forearm veins, particularly the cephalic veins of the nondominant arm; the dorsal hand veins may be used for venipuncture. Subclavian

vein catheterization should also be avoided because of the risk of central vein stenosis, which may preclude the use of any part of the ipsilateral arm for vascular access.

Assessment of Venous System

A history of subclavian vein cannulation or transvenous pacemaker placement is associated with a 10% to 40% rate of central vein stenosis or thrombosis.⁸ Previous injuries or operative procedures involving the arm, the neck, or the chest, including previous vascular access, also may give rise to significant venous abnormalities. Physical signs of venous outflow obstruction include extremity edema, differences in arm size, and development of collateral veins. All of these historical and physical findings call for investigation by means of phlebography or color flow duplex scanning.⁹ Central vein stenosis greater than 50% is a contraindication to creation of an ipsilateral distal AVF: it is a predictor of venous hypertension and edema in the arm and of poor function in the fistula.

Selection of the ideal vein for access is facilitated by distending the veins with a tourniquet around the upper arm. In particular, the cephalic vein is palpated from the region of the anatomic snuff-box to the area above the elbow. Percussion of the vein is performed to confirm that it is patent and to rule out stenosis from previous venipuncture. The fingertips of one hand are positioned over the vein at the elbow, and the vein is gently tapped distally with the other hand. If the vein is patent and of substantial diameter, a fluid wave is felt over the proximal vein.

Assessment of Arterial System

A history of arterial trauma or catheterization, diabetes mellitus, or peripheral arterial disease may be associated with chronic damage to the arterial system. Physical examination involves palpation of the pulses (including both brachial and axillary pulses) and comparison of blood pressure in the arms. A difference of more than 20 mm Hg between the two sides suggests proximal arterial occlusive disease, which may cause the AVF to fail as a result of inadequate inflow. An Allen test is also performed to confirm that the palmar arch is patent, to determine which artery is the dominant vascular supply to the hand, and to ensure that the ulnar artery can support the hand if the radial artery must be divided. Any abnormality on physical examination should be further investigated by means of arterial studies in the vascular laboratory; in select cases, angiography may be indicated.

Noninvasive Preoperative Assessment

Systematic use of noninvasive evaluation in the vascular laboratory permits objective assessment of arterial and venous conduits. If necessary, venous conduits other than the cephalic and basilic veins may be identified,¹⁰ and both arterial and venous segments may be mapped with skin marks to facilitate the oper-

ative procedure. The aims are to increase the use of autogenous fistulas and to raise the early and late patency rates by decreasing the use of suboptimal veins and arteries. When an all-autogenous policy is followed, approximately 80% of patients are candidates for a native AVF.

Complete noninvasive assessment includes segmental pressure measurements of the upper extremity, arterial waveform recording, and arterial and venous duplex studies. A tourniquet should be placed on the arm, and tapping and stroking maneuvers should be used to distend the vein maximally. Established criteria [see Table 1] are then applied to determine whether venous outflow and arterial inflow are likely to be satisfactory.

OPERATIVE PLANNING

Choice of Type of AVF

Multiple varieties of AV fistulas have been used in hemodialysis patients. According to the NKF-DOQI report,⁶ the order of preference for AV fistulas in patients requiring long-term hemodialysis is as follows:

1. Wrist (radiocephalic) primary AV fistula.
2. Elbow (brachiocephalic) primary AV fistula.
3. AV graft of synthetic material.
4. Transposed brachiobasilic AV fistula.

If neither of these can be constructed, access may be achieved via either of the following:

3. AV graft of synthetic material.
4. Transposed brachiobasilic AV fistula.

All of these fistulas should be established in the nondominant arm, if possible.

The distal radiocephalic AVF remains the gold standard in terms of ease of creation and long-term results. Its advantages considerably outweigh its disadvantages—namely, a higher primary failure rate (10% to 15%) and a long maturation time (1 to 4 months). Radiocephalic AVFs may be constructed either in the anatomic snuff-box or just above the wrist crease. Although the radial artery is smaller in the snuff-box than it is at the classic Brescia-Cimino fistula site, the long-term results at the two sites are comparable if only arteries of adequate diameter are used.¹¹

An alternative method of creating an AVF in the forearm that was not mentioned in the NKF-DOQI report is vein transposition.¹² Preoperative duplex ultrasonography often identifies veins that, except for their deep subcutaneous location, are suitable for AVF formation. In addition, the basilic vein in the forearm is often spared and is frequently suitable for AVF formation; however, use of this vein *in situ* for needle cannulation and hemodialysis may necessitate placing the forearm in an uncomfortable position. In the great majority of cases, such veins can be successfully transposed to a superficial tunnel in the midportion of the volar aspect of the forearm, and the resulting fistula theoretically has the same advantages as a radiocephalic fistula in terms of long-term patency and complication rates. This aggressive approach to autogenous forearm fistula formation also has the advantage of preserving more proximal vessels for future access placement.

If duplex ultrasonography does not identify an adequate forearm vein conduit, a brachiocephalic primary AVF is the next choice. It is easy to create and has the advantage of providing higher blood flow than the wrist fistula. The cephalic vein in the upper arm, because of its position and superficial location, is easy to cannulate and easily covered (a potential cosmetic benefit). The elbow AVF has a theoretical advantage in diabetic patients, in whom medial calcification of the distal radial artery commonly prevents the gradual arterial dilatation required for full matu-

Table 1 Noninvasive Criteria for Selection of Upper-Extremity Arteries and Veins for Dialysis Access Procedures¹⁰

Venous examination

- Venous luminal diameter ≥ 2.5 mm for autogenous AVFs, ≥ 4.0 mm for bridge AV grafts
- Absence of segmental stenoses or occluded segments
- Continuity with the deep venous system in the upper arm
- Absence of ipsilateral central vein stenosis or occlusion

Arterial examination

- Arterial luminal diameter ≥ 2.0 mm
- Absence of pressure differential ≥ 20 mm Hg between arms
- Patent palmar arch

ration of a radiocephalic fistula. In fact, some authors consider an upper-arm autogenous AVF (either a brachiocephalic or a transposed basilic vein fistula) the preferred approach in this particular subgroup of patients¹³; however, this view has been challenged by studies that found no difference between diabetic and nondiabetic patients with respect to prognosis for wrist fistulas.^{14,15} Disadvantages of brachiocephalic fistulas include higher frequencies of arm swelling and steal syndrome than are seen with forearm fistulas.

If the cephalic vein in the upper arm is unsuitable, the remaining options include prosthetic grafting and basilic vein transposition. An AVF using transposed basilic vein has all the attributes of an autogenous fistula and consequently is preferred to a graft despite being more difficult to create. Its protected, deep subfascial position and large caliber make it a high-quality conduit for hemodialysis access. Its advantages over a prosthetic graft include the avoidance of the distal venous anastomosis (which causes the majority of stenoses in synthetic graft fistulas) and higher primary and secondary patency rates.^{16,17} Flow rates are high in basilic vein fistulas because of the large size of the vein, and the infection rate is relatively low. Furthermore, thrombosis of a brachiobasilic fistula does not compromise the integrity of the axillary vein and thus does not preclude subsequent use of a prosthetic conduit at the same site. Therefore, when a functional brachiocephalic fistula cannot be achieved, a transposed brachiobasilic fistula should be considered before an upper arm graft is placed.¹⁸

If no veins in either upper extremity are suitable for a native AVF, then the use of prosthetic material should be considered. Two options are available. First, if a segment of vein at least 15 cm long is available but is too far from the artery to be used in the creation of a fully native fistula, a jump graft can be constructed between the artery and the vein, and the arterialized vein can be used as the needle conduit for dialysis. Second, the graft itself can be used as the needle conduit for dialysis. The data currently available suggest that extruded polytetrafluoroethylene (ePTFE) is preferable to other biologic and synthetic materials: ePTFE grafts are less likely to disintegrate with infection, they are more widely available, they remain patent longer, and they are easily handled by surgeons. Grafts may be placed in straight, looped, or curved configurations on either the forearm or the upper arm.

OPERATIVE TECHNIQUE

Autogenous AVFs

Radiocephalic fistula The arm is placed on an arm board

in 90° of abduction. A tourniquet is applied to the upper arm to distend the cephalic vein, and the vein's course is marked on the skin. The tourniquet is then released.

Local anesthesia using 0.5% or 1% lidocaine without epinephrine is usually adequate for construction of an autogenous AVF at the wrist or the antecubital fossa. General anesthesia may depress cardiac output and thus may, by reducing fistula flow, exert a negative impact on the success of the fistula. Conversely, brachial or supraclavicular regional anesthesia may cause peripheral vasodilatation and thus increase arterial blood flow.

A longitudinal incision is placed either in the anatomic snuffbox, between the tendons of the extensor pollicis longus and the extensor pollicis brevis [see Figure 1], or midway between the cephalic vein and the radial artery, proximal to the wrist skinfold [see Figure 2]. In the anatomic snuff-box, the cephalic vein overlies the radial artery, so that minimal mobilization is required to approximate the two vessels. Slightly more mobilization is required to approximate the cephalic vein to the radial artery above the wrist without kinking or twisting. A comparable length of radial artery, found under the deep fascia, is also isolated. Care is taken to preserve the superficial branch of the radial nerve, which lies lateral to the radial artery and is separated from it by the brachioradialis muscle.

Four types of anastomoses can be constructed: side to side, end of vein to side of artery, end to end, and end of artery to side of vein. The side-to-side anastomosis [see Figure 3a] yields the highest flow through the fistula but may be associated with venous congestion of the hand. Over time, arterial pressure may render the valves of the distal vein incompetent, resulting in retrograde flow toward the hand and venous hypertension. The end of artery–side of vein anastomosis [see Figure 3b] also presents a risk of venous hypertension. This configuration reduces the risk of distal steal by preventing retrograde flow into the fistula, but at the price of lower flow through the fistula. Of the four options, the end of artery–end of vein variation [see Figure 3c] produces the least distal arterial steal and venous hypertension but yields the lowest flow.

The preferred configuration of the anastomosis is end of vein to side of artery [see Figure 3d]. Dividing the vein reduces the risk of venous congestion in the hand; moreover, by allowing retrograde flow from the distal radial artery and the ulnar artery into the vein, which contributes approximately 30% of the total flow of the fistula, this approach yields maximal blood flow through the fistula. There is a risk of steal syndrome with such fistulas, but this problem is easily corrected by ligating the radial artery distal to the

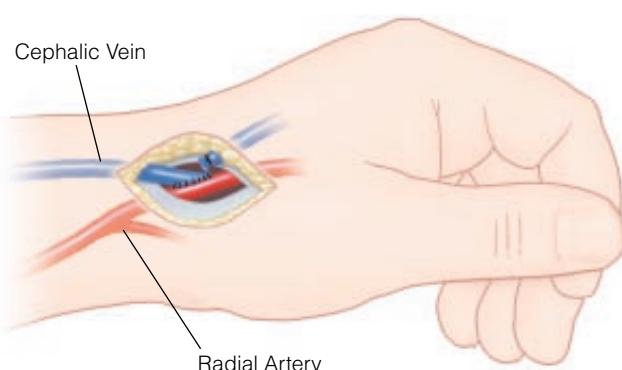

Figure 1 Vascular access via AVFs: radiocephalic fistula. Shown is the anatomic snuff-box fistula, with the end of the cephalic vein anastomosed to the side of the radial artery.

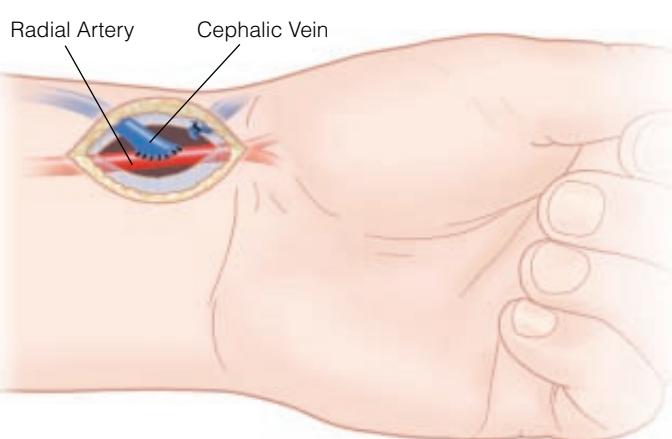

Figure 2 Vascular access via AVFs: radiocephalic fistula. Shown is the Brescia-Cimino fistula. An incision is made midway between the radial artery and the cephalic vein, and the end of the vein is anastomosed to the side of the artery.

fistula, thereby converting the anastomosis to an end-to-end configuration.

Vascular control is obtained with small vessel loops or Heifets clamps. Heparinization is not needed unless the artery is an end artery. A 1 cm arteriotomy is performed, and the vein is ligated and divided distally and tailored to match the arteriotomy. Coronary dilators are then inserted gently to verify patency and to ensure that the vessel lumina are large enough: the artery should easily admit a 2 mm dilator; the vein, a 3 mm dilator. The vessels are then anastomosed in the desired configuration with a fine continuous monofilament suture (6-0 or 7-0 polypropylene) placed by means of standard techniques. The vessels can be probed with the coronary dilators before the anastomosis is completed, to confirm that the vein is not twisted or to overcome any arterial spasm. Once vascular control is released, a thrill should be easily felt over the fistula and for a moderate distance along the venous conduit. The skin is closed with an absorbable suture.

Vein transposition in the forearm The artery and the vein selected for the primary AVF are identified and mapped preoperatively by means of duplex ultrasonography. Positioning and anesthetic considerations are essentially the same as for a radiocephalic fistula.

A longitudinal incision is made directly over the mapped vein, beginning at its distal end and extending toward the antecubital fossa for a distance of at least 15 cm [see Figure 4a]. The vein is gently skeletonized and mobilized by ligating and dividing all side branches. The targeted artery (either the radial or the ulnar) is identified and dissected through a separate incision. A superficial subcutaneous tunnel is made between the two incisions with a blunt tunneling instrument, and the vein is passed through the tunnel [see Figure 4b]. The vein should be marked along its length with a marking pen before tunneling; this step provides a visual check that allows the surgeon to confirm that the vein is not twisted as it passes through the tunnel. A 1 cm anastomosis is then carried out in the same fashion as for a radiocephalic fistula (see above).

An alternative technique that may be employed in patients with atherosclerotic disease of the forearm arteries involves mobilizing the forearm segment of either the cephalic or the basilic vein, transposing it to form a U-shaped loop, and anastomosing it to the brachial, proximal radial, or proximal ulnar artery in the antecubital fossa.¹⁹

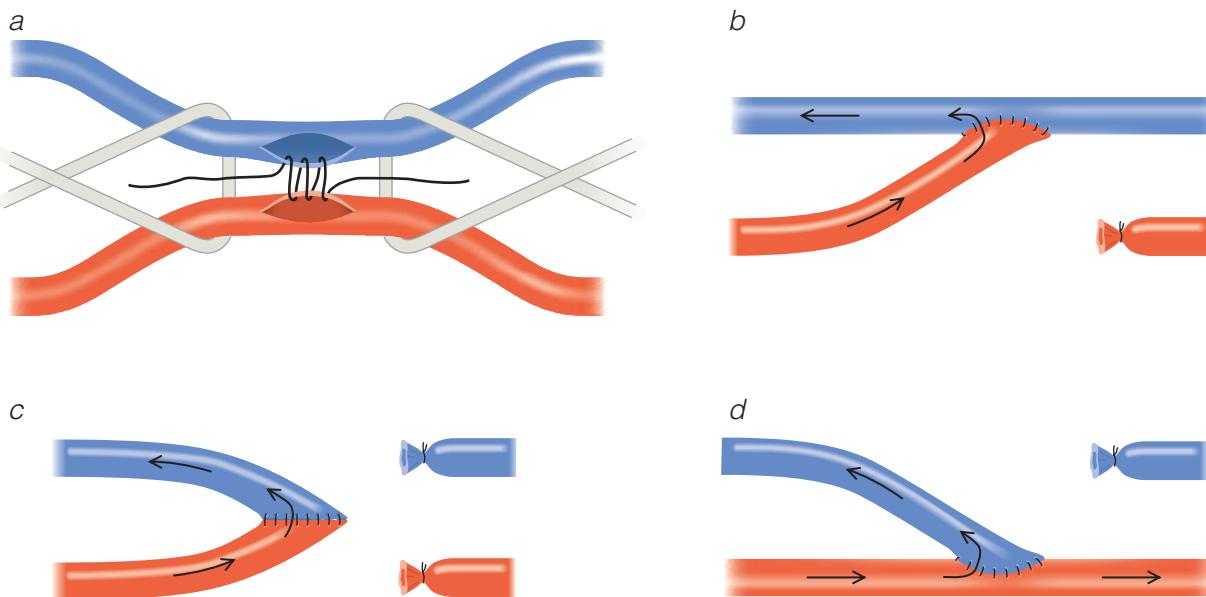

Figure 3 Vascular access via AVFs: radiocephalic fistula. Four anastomotic configurations are possible for an autologous radiocephalic fistula: (a) side of artery to side of vein, (b) end of artery to side of vein, (c) end of artery to end of vein, and (d) end of vein to side of artery (the preferred configuration).

Brachiocephalic fistula After adequate local anesthesia, a transverse incision is made 1.5 cm distal to the antecubital crease to expose the superficial antecubital venous system [see Figure 5a].²⁰ If the median cubital vein is patent, sufficiently wide, and in continuity with the cephalic vein, it is dissected so that the perforating branch of the antecubital venous system (*vena mediana cubiti profunda*) can be located. The bicipital aponeurosis is divided, and the perforating branch is followed down to the deep system. In the process, the brachial artery is also exposed, as are the origins of the radial and ulnar arteries.

Once the patient is fully heparinized, the confluence of the brachial vein and the perforating vein is identified, and part of the brachial vein is excised so as to form a venous patch. The perforating vein is gently dilated, so that any valves are rendered incompetent, and the proximal median cubital vein is ligated to prevent diversion of blood flow into the basilic vein. The perforating vein is then anastomosed to the brachial artery in an end-to-side fashion [see Figure 5b].²¹ To prevent subsequent steal syndrome, the arteriotomy should be no larger than 5 to 6 mm.

Other techniques may be used if the perforating vein is very large or very small. If the perforating vein is 5 mm or more in diameter, it may be anastomosed directly to the artery without a patch. If the vein is less than 2.5 mm in diameter, it should not be used; instead, the median cubital vein should be ligated and divided and the cephalic end of the vein anastomosed directly to the brachial artery in an end-to-side fashion [see Figure 5c]. If the median cubital vein is too small, the incision is extended laterally and proximally to allow mobilization of the cephalic vein. The length of this incision depends on the extent to which the cephalic vein must be mobilized to ensure a tension-free end-to-side anastomosis. The accessory cephalic vein, though located far laterally, may also be used.

Repeated venipunctures in the antecubital fossa frequently render the antecubital venous system unsuitable for AVF construction. In such cases, two options are available if the patient has at least 15 cm of good-quality cephalic vein in the upper arm. The first option is to mobilize a sufficient length of the cephalic vein in the distal upper arm through a longitudinal incision, to transpose it medi ally

through a superficial tunnel, and then to anastomose it in an end-to-side fashion to the brachial artery, which has been exposed above the elbow through a separate incision. The second, which avoids extensive dissection of the cephalic vein, is to place two short longitudinal incisions over the brachial artery and the cephalic vein a few centimeters above the elbow crease, to tunnel a short segment of 6 mm ePTFE graft between the two incisions, and to anastomose the ePTFE graft to both the brachial artery and the cephalic

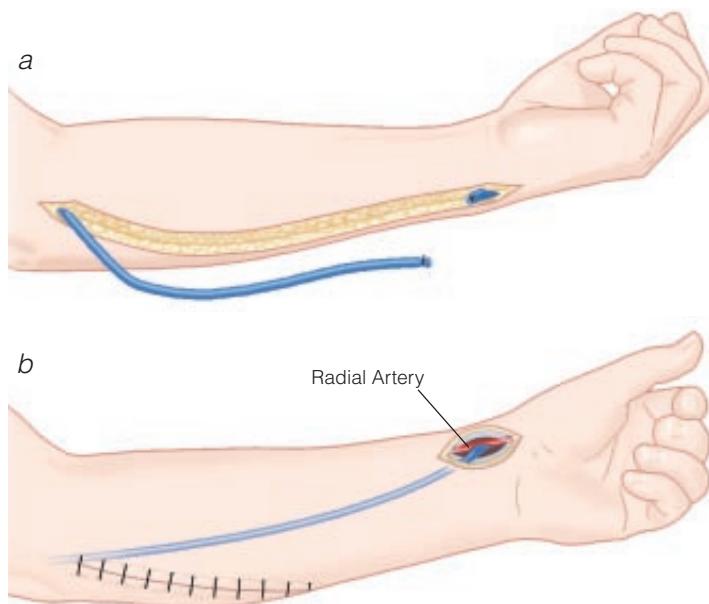

Figure 4 Vascular access via AVFs: vein transposition in the forearm. (a) The selected vein, identified by duplex ultrasonography, is completely mobilized. (b) The vein is transposed through a superficial tunnel in the midportion of the volar aspect of the forearm and anastomosed to the radial artery in an end-to-side fashion.

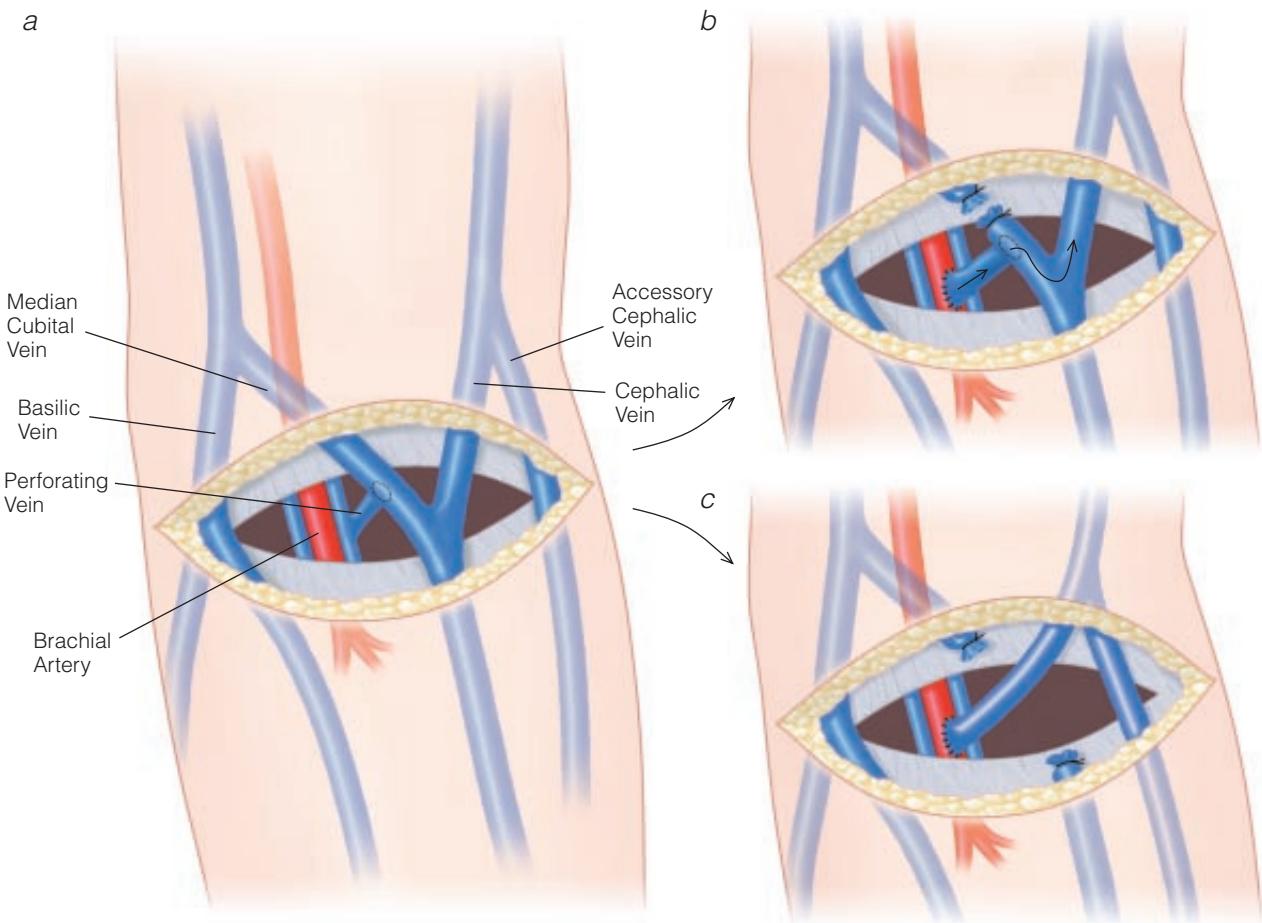

Figure 5 Vascular access via AVFs: brachiocephalic fistula. (a) A transverse incision exposes the antecubital venous system (including the perforating branch) and the brachial artery under the bicipital aponeurosis. (b) An end-to-side anastomosis is made between the perforating vein and the brachial artery. (c) If the perforating vein is too small, the cephalic vein is mobilized and anastomosed to the brachial artery in an end-to-side fashion.

vein in an end-to-side fashion [see Figure 6].²² The cephalic vein is used as the needle conduit for this type of bridge AV graft.

Brachiobasilic fistula The technique for constructing a brachiobasilic fistula was described first by Dagher and associates in 1976²³ and then by LoGerfo and colleagues in 1978.²⁴ Local anesthesia can be used, but an axillary block eases the procedure considerably. An oblique incision overlying the median basilic vein is made in the antecubital fossa, and the vein is mobilized. The brachial artery is exposed as usual by dividing the bicipital aponeurosis. The incision is extended along the medial aspect of the upper arm (the so-called hockey-stick incision), and the basilic vein is mobilized from beneath the fascia, with care taken to preserve the medial cutaneous nerve of the forearm [see Figure 7a]. The basilic vein usually pierces the brachial fascia just below the middle of the upper arm, then parallels the course of the brachial artery and vein while remaining superficial to them. At the axillary level, the basilic vein joins the brachial vein to form the axillary vein; this junction constitutes the proximal limit of the dissection.

The distal end of the conduit vein may consist of either the basilic vein or a section of the median cubital vein, which is already exposed. All venous tributaries are ligated and divided. Once this is done, the vein is divided distally, and its anterior surface is marked to help the surgeon avoid axial rotation during transposition. The

vein is then passed through a subcutaneous tunnel on the anterior surface of the arm and anastomosed in an end-to-side fashion to the brachial artery in the antecubital fossa with 6-0 or 7-0 polypropylene [see Figure 7b]. This transposition places the vein in a more superficial location and positions it anterolaterally on the arm, thereby facilitating cannulation during hemodialysis sessions. Closure involves approximating the fascia and the subcutaneous tissue in two separate layers.

A modification of the procedure just described is the so-called elevated basilic vein arteriovenous fistula.²⁵ In this variant, the vein is left in situ rather than transposed anterolaterally, but it is elevated by closing the deep fascia and the subcutaneous tissue beneath the vein. The brachial artery anastomosis is created, and the overlying skin is reapproximated with clips or interrupted sutures. Although the vein remains in its medial location, its new superficial position facilitates cannulation for dialysis.

It should be mentioned that the basilic vein can be elevated either at the time of brachiobasilic AVF creation (the one-stage technique) or as part of a second procedure (delayed elevation) approximately 4 weeks later. The advantage of the latter approach is that operative dissection is facilitated by the use of an arterialized thick-walled vein. In addition, delayed elevation allows assessment of the fistula for size and flow rate before the second stage, which can be abandoned if the vein has failed to mature.²⁶

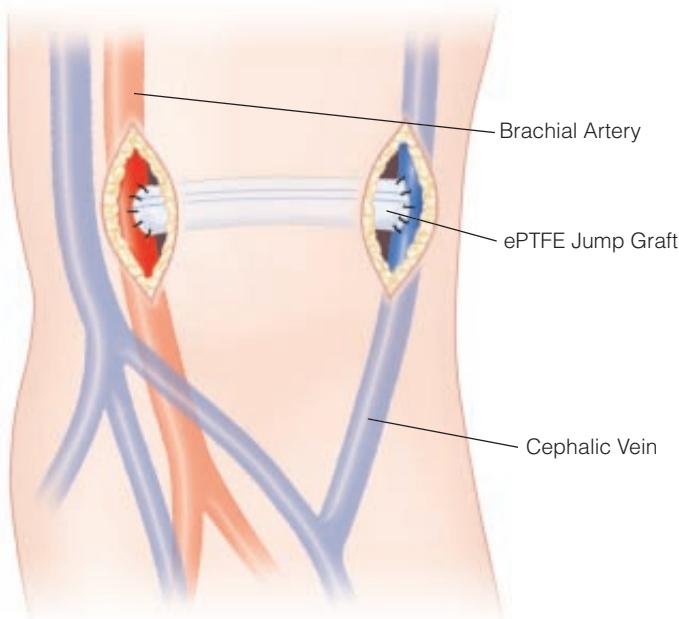

Figure 6 Vascular access via AVFs: brachiocephalic fistula. If the antecubital venous system is unsuitable for AVF construction, one option is to place an ePTFE interposition graft between the brachial artery and the cephalic vein.

Bridge AV Grafts

Bridge AV graft procedures involve placing an interposition graft between an artery and a vein and using that graft as the needle conduit for dialysis. In the forearm, the most common configurations are loop grafts between the brachial artery and an antecubital vein (including the brachial veins)²⁷ and straight bridge AV grafts from the radial artery to an antecubital vein. Most studies report superior patency rates with a loop configuration.²⁸ Adequate results may be obtained with a straight graft in the forearm if the radial artery is at least 2.5 to 3.0 mm in diameter.

Secondary options for bridge AV graft construction include a variety of unusual configurations, including reverse grafts between the axillary artery and the brachial or the antecubital vein and axilloaxillary grafts, which may be looped in the upper arm or may cross the sternum. It is also possible to construct a looped graft between the proximal superficial femoral artery and the proximal saphenous vein or a straight, reversed graft between the distal superficial femoral or popliteal artery and the proximal saphenous or femoral vein [see Figure 8]. Generally, such lower-limb AV grafts are associated with an increased risk of potentially life- or limb-threatening infection; however, infection rates as low as 22% have been reported, making these grafts a viable option when a bridge AV graft in the upper extremity cannot be constructed.²⁹

Either local anesthesia or axillary block is usually appropriate for upper-extremity bridge AV grafts. A single dose of a cephalosporin should be given before the procedure. Separate longitudinal incisions are placed to expose the artery and the vein—except when the procedure involves the brachial artery and the antecubital venous system, which are better exposed through a single transverse incision. A 6 mm or a tapered 4 to 7 mm ePTFE graft is then passed through a superficial tunnel between the two incisions. Both anastomoses are constructed in an end-to-side fashion, beginning with the venous side. Systemic heparinization is used if an end artery is occluded for the arterial anastomosis.

TROUBLESHOOTING

Autogenous AVFs

Although the quality of the AV conduit is assessed preoperatively by means of physical examination and noninvasive studies, it should also be confirmed intraoperatively for optimal results.

Arterial inflow Normally, a strong pulse is felt over the targeted artery; however, dissection may cause spasm, which can render intraoperative assessment difficult. The following three measures will help minimize this problem:

1. Elimination of epinephrine from the anesthetic solution.
2. Gentle dissection and avoidance of direct manipulation of the arterial wall. It may be preferable to use a proximal tourniquet for inflow occlusion so that there is no need to place clamps on small arteries.
3. Local application of a papaverine solution, which relaxes vascular smooth muscle.

If spasm occurs, gentle probing of the artery with coronary dilators may help relieve the spasm and restore full flow.

Stiff, calcified arteries can sometimes be successfully used in the creation of fistulas, but it is difficult to assess flow in such vessels. Quantitative and qualitative analyses of the arterial waveform and the intraluminal diameter by means of duplex scanning can

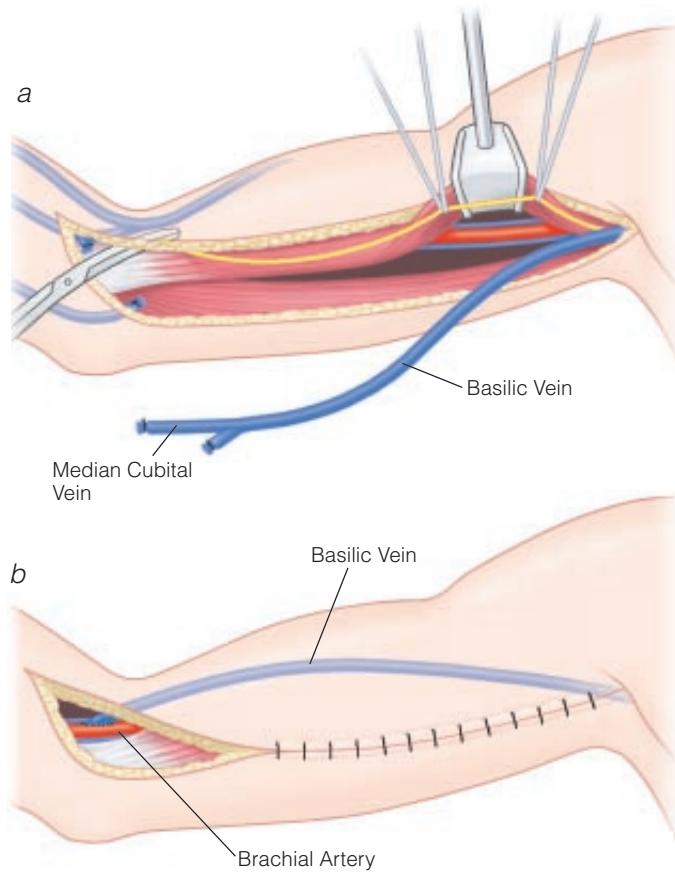

Figure 7 Vascular access via AVFs: brachiobasilic fistula. (a) The basilic vein is completely mobilized from underneath the fascia in continuity with a section of the median cubital vein in the antecubital fossa. (b) The vein is transposed in a subcutaneous tunnel on the anterior surface of the arm and anastomosed to the brachial artery in an end-to-side fashion.

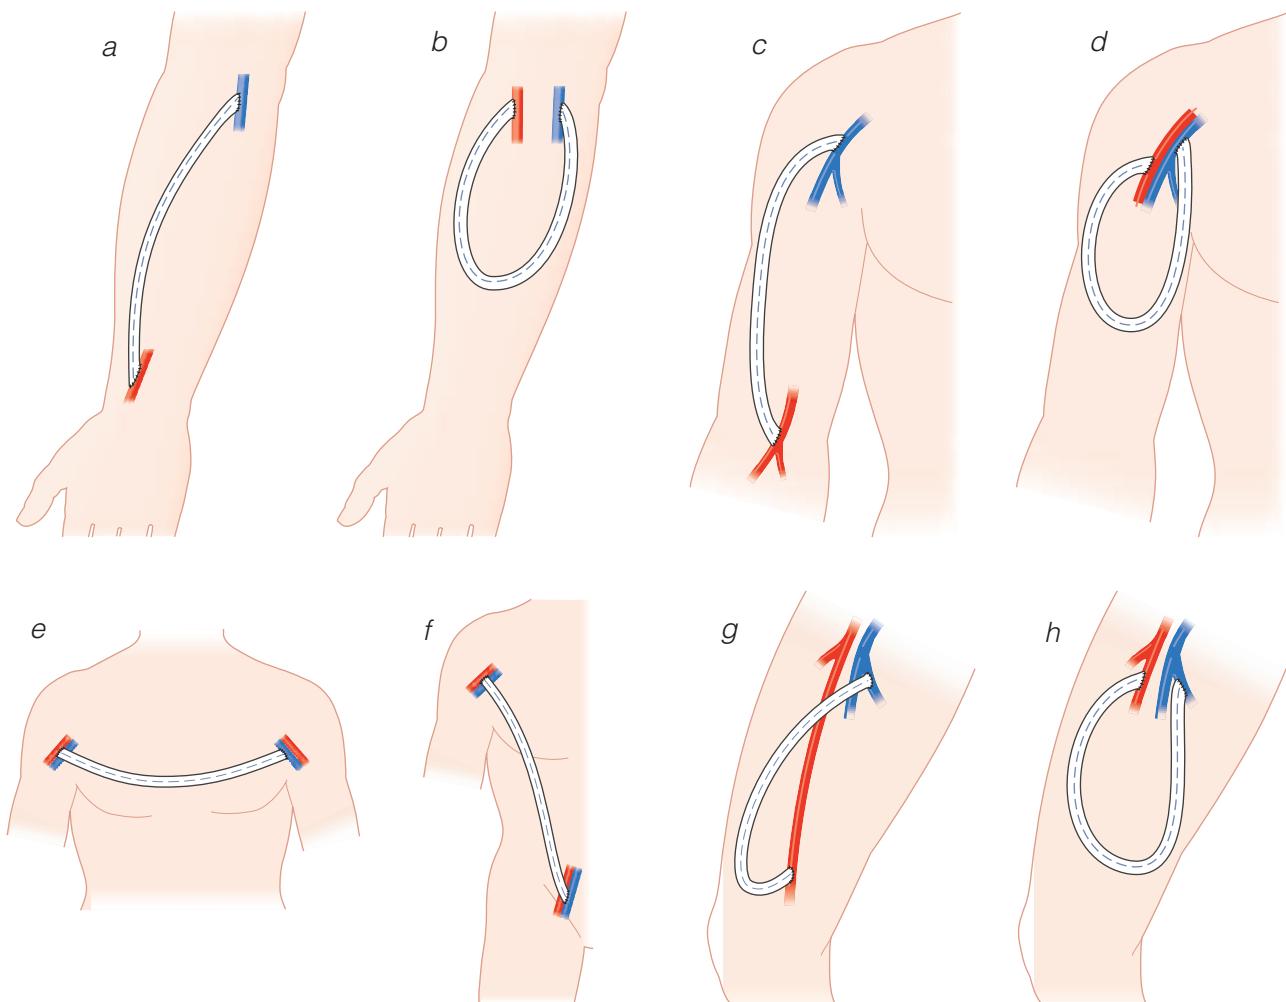

Figure 8 Vascular access via AVFs: bridge AV grafts. Options for bridge graft construction include (a) straight forearm AV graft, (b) loop forearm AV graft, (c) brachioaxillary AV graft, (d) loop axilloaxillary AV graft, (e) axillary artery-contralateral axillary vein AV graft, (f) axillary artery-iliac vein AV graft, (g) distal superficial femoral or popliteal artery-saphenous vein AV graft, and (h) proximal superficial femoral artery-saphenous vein loop AV graft.

help confirm the adequacy of the vessel. Arteries smaller than 1.5 mm are less likely to provide sufficient flow for a fistula. It is particularly important not to place clamps on calcified arteries; a tourniquet is always preferred in this situation.

Venous outflow A venous diameter of at least 2.5 to 3.0 mm is required for successful maturation of an autogenous fistula. The diameter of the target vein should be known preoperatively from the duplex examination and should be confirmed intraoperatively by calibration with coronary dilators. No attempt should be made to dilate the vein, however, because endothelial injury may result.

Webs, thickened valve leaflets, and areas of sclerosis from previous phlebitis or punctures are common in upper-extremity veins and may be the cause of poor venous outflow and fistula failure. Passage of the coronary dilator helps to localize such obstructive lesions, which should be corrected when found. The patency of the proximal vein can be demonstrated by free flow of injected heparinized saline or by successful passage of a Fogarty catheter. The evoked thrill is also a useful maneuver: intermittent, pulsatile injection of saline into the vein, mimicking arterial flow, should produce a palpable thrill over the proximal vein.³⁰ The absence of an evoked thrill suggests the presence of stenosis or areas of thick-

ened, nondistensible vein wall proximally. Intraoperative phlebography is indicated in any doubtful situation.

AV anastomosis Both the artery and the vein should be mobilized sufficiently to ensure that the anastomosis is tension-free once completed. As noted (see above), marking the most superficial aspect of the vein with a sterile pen before mobilization helps ensure that the vein is not rotated when it is approximated to the artery. The ideal anastomosis is constructed by transecting the vein just distal to a bifurcation and using the branch vessel as a patch. Such a spatulated venous conduit facilitates the anastomosis and minimizes the risk of anastomotic stenosis.

For a distal AVF, the anastomosis should be about 10 mm long to ensure that a gradual increase in flow through the fistula can occur. An anastomosis that is too small may impair the normal dilation of the artery and the vein. For AVFs in the antecubital space and the upper arm, in contrast, the arteriotomy should be limited to 5 to 6 mm to prevent excessive shunting.

The anastomosis can be performed with standard vascular techniques. However, construction of the anastomosis with a single continuous suture may have a purse-string effect; accordingly, the use of two separate running sutures may be preferable for small vessels. Interrupted stitches are preferable for very small

vessels. Loupes and microvascular instruments are helpful in this setting.

When the anastomosis is completed, vascular control should be released from the proximal vein and the distal artery first; the resultant back-bleeding will confirm the patency of the palmar arch and reveal any major anastomotic defects. Gentle compression is usually sufficient to obtain hemostasis. Any additional sutures deemed necessary should be placed with great caution because of the risk that they may narrow the anastomosis.

The presence of a pulse rather than a thrill in the arterialized vein indicates inadequate outflow, whereas the absence of either a thrill or a pulse indicates poor inflow. The draining vein should be examined for kinking, twisting, or compression by a fibrous band. If the vein appears to be satisfactory, the anastomosis and the distal vein are inspected and probed with dilators through a venous side branch or a transverse phlebotomy. If no abnormality is identified, the fistula is examined with I.V. contrast studies and fluoroscopy. Focal lesions may be corrected by placement of a vein patch or a short interposition graft or by resection and primary reanastomosis. Alternatively, a short segment of the vein may be excised and the anastomosis repositioned more proximally.

AV Grafts

Skin incisions Incisions should be placed so that neither the graft nor the anastomoses lie directly beneath them. Proper placement reduces the risk of skin erosion, minimizes the risk that the graft will become infected if a surgical site infection occurs, and maximizes the length of conduit available for needle insertion. The subcutaneous tissue and skin should be closed in separate layers to minimize the risk of graft infection in the event of skin dehiscence.

Tunneling The tunnel should be made atraumatically with a Kelly-Wick bidirectional tunneler. It should be superficial to the muscle fascia but no more than 5 mm beneath the skin surface. To decrease the risk of hematoma, there should be a close fit between the diameter of the graft and that of the tunnel, and the graft should be placed before systemic heparinization is initiated.

For a loop configuration, a counterincision at the apex of the tunnel permits the tunnel to be created in two passes of the Kelly-Wick tunneler. This approach gives the tunnel a smooth curve and limits kinking of the graft. In the forearm, this transverse counterincision is usually made 3 to 4 cm proximal to the wrist skinfold [see Figure 9]. Careful observation of the stripe on the graft as it is passed through the tunnel helps prevent twisting.

Venous anastomosis To minimize arterial occlusion time, the venous anastomosis is usually performed first. The vein must be at least 4 mm in diameter; venous diameter and patency are verified by passing coronary dilators or a Fogarty catheter through the vessel and irrigating it with heparinized saline. Before the anastomosis is performed, the vein and all distal branches are ligated to prevent venous hypertension and arm edema.

If no veins of adequate diameter are available, either two adjacent veins or a portion of a transverse communicating vein can be used to construct a venoplasty that will increase the net diameter of the venous outflow tract. Alternatively, the deep brachial or axillary veins can be used for outflow. The latter option is often required when the superficial veins have been exhausted in a patient who has previously had AVFs.

Arterial anastomosis Systemic heparin is given only if an end artery is occluded for anastomosis. The artery should have a lumen of at least 3 mm, and the arteriotomy should be no more

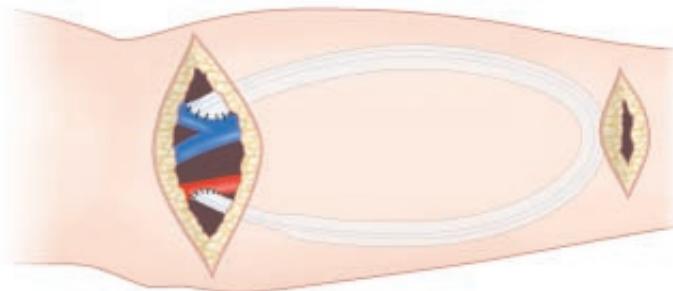

Figure 9 Vascular access via AVFs: bridge AV grafts. With a loop forearm graft, tunneling of the graft is facilitated by making an incision 1.5 cm distal to the elbow crease to expose the brachial artery and the antecubital venous system, followed by a counterincision at the apex of the tunnel 3 to 4 cm proximal to the wrist skinfold.

than 6 mm long to prevent distal ischemia. ePTFE sutures are useful for arterial anastomoses: because they have the same diameter as the attached needles, needle-hole bleeding is minimized.

Before the arterial anastomosis is completed, the graft is unclamped and allowed to fill with venous blood; this step prevents air embolism when arterial control is released. When the anastomosis is complete, a thrill should be palpable over the venous outflow tract rather than directly over the graft.

Graft type The choice between a tapered 4 to 7 mm ePTFE graft and a 6 mm straight graft is a matter of personal preference. The tapered graft was introduced to reduce the incidence of steal syndrome by increasing the resistance to flow through the prosthesis; however, it has not been shown to provide consistent protection from ischemic complications. Both types of graft are also available in either a standard or a thin-wall configuration; the only randomized study published to date reported superior results with the standard configuration.³¹ Stretch ePTFE appears to yield better results than the older, nonstretch grafts.³²

FOLLOW-UP

Upon discharge, the patient is instructed to elevate the arm so as to reduce edema. Regular hand and arm exercise, though not of proven benefit, is nonetheless recommended until the fistula matures.

Physical examination of the fistula, including inspection and palpation for pulse and thrill, should be done on a weekly basis. The patient should also be advised to seek prompt medical attention if the quality of the thrill changes. Normally, a thrill is palpable throughout the cardiac cycle, though it is more intense during systole. Disappearance of the diastolic component of the thrill is generally a consequence of outflow obstruction. Such obstruction (usually from venous or anastomotic stenosis) may also cause intensification of the thrill or bruit. In addition, diminished flow or outflow stenosis may cause the thrill to be converted to a pulse. Any of these abnormal findings is an indication for a diagnostic procedure: salvage attempts are much more likely to succeed if carried out before thrombosis has occurred.

ePTFE AV grafts should not be used until at least 14 days have passed since placement or until the swelling has subsided enough to allow palpation of the graft. This waiting period allows adhesions to form between the subcutaneous tunnel and the graft, thereby decreasing the risk of hematoma in the graft tunnel, which may ruin the access site. A minimum of 1 month is required before a primary AVF may be cannulated. It is preferable, however, to

wait until the fistula matures fully, which may take 3 to 4 months.

COMPLICATIONS

Venous Stenosis

Venous stenosis, either at the anastomosis (particularly with ePTFE grafts) or in the body of the vein, is a common complication of AVF construction. Prophylactic intervention for venous stenoses reduces the rate of thrombosis and graft loss, and stenoses detected before thrombosis occurs are more responsive to therapy than those detected afterward. Intervention is indicated when stenosis of 50% or greater (documented by duplex ultrasonography or fistulography) is accompanied by a hemodynamic, functional, or clinical abnormality (e.g., decreased access blood flow, elevated static or dynamic venous pressure, increased recirculation, reduced delivered dialysis dose, or arm edema). Prophylactic intervention for anatomic stenosis is not warranted when such findings are absent.³³

Although the question of whether angioplasty or surgical revision is the preferable method of intervention remains controversial, experience to date suggests that surgical revision tends to provide better long-term results. This difference may derive from the elasticity of intimal hyperplastic lesions, whose rapid recoil may limit the efficacy of angioplasty. As a rule, if angioplasty is required more than twice within 3 months, the patient should be referred for surgical revision. Treatment options include patch angioplasty for localized or anastomotic stenoses, bypass for longer stenoses, relocation of the venous anastomosis to a new vein, and resection of the stenotic segment with interposition grafting.

Central venous stenosis Stenotic or occlusive lesions of the central veins develop in as many as 40% of patients who have previously undergone subclavian hemodialysis catheter placement for temporary vascular access.⁸ When a vascular access graft or fistula is placed distal to these lesions, they may become symptomatic, resulting in venous hypertension, arm edema, low access flow, or thrombosis. Percutaneous intervention with transluminal angioplasty is the preferred treatment; the tendency for central venous stenosis to recur soon after treatment³⁴ may be circumvented by the addition of a stent. Stents are particularly helpful for treating rigid or kinked stenoses, for sealing dissections or circumscribed perforations, and for reestablishing the patency of chronically occluded veins. Surgical repair of central venous obstruction is a major undertaking and is reserved for those occasional cases in which percutaneous procedures have failed in a patient with no alternative access site.

Arterial Stenosis

Arterial stenosis is relatively uncommon. It should be corrected if it is associated with diminished access flow and elevated arterial prepump pressure. Arterial stenosis may be suspected even before dialysis is initiated if a patent vein does not enlarge significantly within several weeks of fistula creation. Angiography provides a definitive diagnosis. Stenosis of the distal artery, the anastomosis, or the distal vein is best treated with reanastomosis proximal to the stenotic area. More proximal stenosis may have to be treated with conventional arterial reconstruction.

Early Thrombosis

Early thrombosis is defined as thrombosis occurring within 3 months of access construction. It is usually the result of technical factors or of inadequate assessment of the arterial or venous

conduit. The following are the most common causes of early thrombosis:

1. Inadequate arterial inflow caused by proximal arterial disease.
2. Narrowing of the anastomosis during construction.
3. Kinking or twisting of the vein proximal to the anastomosis or in a subcutaneous tunnel.
4. Undetected occlusion of venous outflow.
5. Compression of the fistula by a hematoma resulting from either inadequate hemostasis during the procedure or early puncture of the fistula with subsequent extravasation of blood.

If early thrombosis is thought to be caused by technical complications and not by the use of marginal vessels, reexploration is worthwhile. Reexploration usually involves takedown of the anastomosis, thrombectomy of the conduit, reevaluation of both arterial inflow and venous outflow, corrective measures as needed, and reanastomosis. Both autogenous AVFs and AV grafts may be profitably reexplored. With an autogenous AVF, reexploration should be done within 24 hours of thrombosis to minimize ischemic endothelial injury.

Late Thrombosis

Autogenous AVFs Little information is available on success rates for treatment of thrombosis in autogenous AVFs; however, it seems that neither percutaneous nor surgical techniques offer good results. Thrombosis of an autogenous AVF most commonly results from an aneurysm of the fistula, hyperplastic stenosis at the anastomosis or in the vein just distal to the anastomosis, fibrosis at an area of repeated needle punctures, or kidney transplantation.

The surgical approach should include exposure of the vein just distal to a clinically apparent or suspected venous stenosis. The vein is opened longitudinally and the thrombus evacuated. Adequacy of venous outflow is assessed with a Fogarty catheter or coronary dilators. If a segment less than 4 mm in diameter is encountered, the problem is corrected with patch angioplasty, vein bypass, or resection and primary anastomosis. (The last of these three approaches is often easy to perform because the tortuosity of the vein allows easy mobilization and length extension.) Central vein stenosis is corrected with intraoperative balloon angioplasty.

When the venous side of the AVF is in satisfactory condition, the thrombus is removed from the arterial limb. Any suspected anastomotic or proximal arterial stenosis should be corrected [see AV Grafts, below]. If the thrombosis resulted from a fistula aneurysm containing adherent thrombus, the aneurysm should be repaired to prevent its recurrence.

AV grafts About 85% of AV graft thromboses are caused by stenosis of the venous anastomosis or of the draining vein (as a result of intimal hyperplasia), and most instances of graft loss are attributable to such stenosis. Treatment of a thrombosed graft has only a 10% chance of success if the underlying venous stenosis is not addressed. Although arterial stenoses are less common causes of late thrombosis, they should be sought out and corrected as well. Before treatment is initiated, information about recent graft performance should be obtained. Signs of venous or outflow stenosis include increasing venous resistance and prolonged bleeding from puncture sites. Inadequate flow rates and increased negative pressures during dialysis are associated with stenosis of the arterial inflow. Hypotension or excessive graft compression can explain spontaneous thrombosis in a previously well-functioning graft.

Graft thrombosis may be corrected either with surgical

thrombectomy or with pharmacomechanical or mechanical thrombolysis. On the whole, technical success and long-term patency rates are similar for the two approaches, though there is some evidence for a trend toward longer primary patency with surgical management.³⁵ The choice between these two approaches continues to be controversial, and the decision should generally be based on local expertise. To date, neither surgical treatment nor endovascular management has produced unassisted patency rates higher than 50% at 6 months. If graft thrombosis occurs repeatedly in a given patient, plans for a new access site should be considered.

If surgical treatment is chosen, it should be carried out in an operating suite with the capacity for intraoperative fluoroscopy. Unless preoperative findings indicate that an arterial lesion is present, the incision is made at the venous anastomosis, and an adequate length of graft and outflow vein is mobilized. A transverse graftotomy is made within 1 or 2 mm of the suture line, any clot found on the venous side is removed with suction and a forceps, and the anastomosis is inspected. The anastomosis is calibrated but not dilated: if a 5 mm dilator passes easily through the venous anastomosis, then thrombectomy alone is often sufficient treatment. A 4 French Fogarty catheter is passed proximally into the right atrium and pulled back slowly with the balloon inflated to check for proximal venous stenosis and to evacuate clot. Any abnormality encountered is an indication for operative phlebography. The presence of a venous abnormality does not rule out the possibility of a coexisting arterial defect; both should be corrected if found.

After the venous anastomosis is examined, a 4 French Fogarty catheter is used to evacuate any clot in the graft itself. Thrombectomy at the arterial anastomosis is delayed until any structural problems in the body of the graft are corrected; this delay permits the structural corrections to be carried out in a bloodless field. Narrowing in the body of the graft is usually caused by fibrous material adherent to the wall, which can be removed with the aid of a curette, an endarterectomy instrument, or suction. Once the body of the graft is clear, any thrombus present at the arterial anastomosis is removed. Free passage of the Fogarty balloon catheter suggests that there is no arterial anastomotic stenosis. The arterial anastomosis may be examined under direct vision if necessary to ensure complete removal of the compacted thrombus at the arterial end of the graft.

The graft is filled with heparinized saline before the arterial or the venous anastomosis is repaired. When the arterial side of the graft is involved, a new arterial anastomosis usually suffices to solve the problem. A new arterial site proximal to the old one is selected, and either the graft is moved to the new site or a new free segment is added.

More commonly, the defect is at the venous anastomosis. In this case, the graftotomy is extended longitudinally through the anastomosis. If the stenosis is short, smooth, and hyperplastic, a small patch angioplasty is adequate for repair. If the stenosis is long or if the vein is sclerotic, revision to a new venous outflow site is preferred. The graft can be reanastomosed to another nearby vein, or the stenosis can be bypassed by anastomosing an ePTFE graft of appropriate size to a more proximal segment of the original vein. Joints may be crossed if necessary, in which case an externally supported prosthesis is used.

Steal Syndrome

The incidence of symptomatic steal syndrome has been reported to be approximately 2% for autogenous AVFs and as high as 4% for AV grafts. Ischemic complications result from preferential

diversion of arterial flow into the low-pressure venous outflow of the fistula. When collateral arterial flow is inadequate or when proximal or distal occlusive arterial disease is present, distal ischemia occurs. In some cases, the flow into the venous side of the fistula is sufficient to induce reversal of the flow in a portion of the artery distal to the fistula, a phenomenon referred to as steal. Unfortunately, there is no reliable method of predicting the development of symptomatic steal after the construction of an autogenous AVF or AV graft.

The ischemia is usually mild and is characterized by coldness, numbness, and pain during dialysis. In most cases, the problem resolves without treatment within a few weeks. If the patient experiences constant pain, severe numbness, a nonhealing ischemic fissure, digital cyanosis or gangrene, or finger contracture, the ischemia should be corrected. The differential diagnosis of vascular steal syndrome includes the neuropathies of uremia and diabetes as well as secondary hyperparathyroidism. Carpal tunnel syndrome—an uncommon but distinct condition occurring in hemodialysis patients—presents with symptoms similar to those of vascular steal but can be differentiated from steal on the basis of the characteristic electromyographic findings.

A classic indicator of clinically significant steal is that digital pulse waves are absent or markedly diminished on digital photoplethysmography (PPG) or pulse volume recordings (PVR) but rise to normal amplitude and contour when the fistula is compressed [see Figure 10]. Digital pressures lower than 50 mm Hg and a digital-brachial index lower than 0.47 are also indicative of clinically significant distal ischemia.³⁶ A significant difference in segmental or digital pressure between the two arms with the fistula compressed may be indicative of superimposed arterial disease proximal or distal to the fistula, in which case arteriography is indicated before surgical correction. Identification of reversed flow distal to the fistula on duplex studies is not, in itself, sufficient reason to conclude that clinically significant steal is present: steal is a common phenomenon and is a physiologic consequence of the rheology of the fistula in 73% of autogenous AVFs and 92% of AV grafts.³⁷

The goal of treatment is to reduce steal to a level where there is both adequate residual flow volume for dialysis and adequate perfusion to the hand to eliminate ischemic symptoms. Treatment options include the following:

1. Elimination of the fistula. This is the simplest form of treatment and invariably corrects ischemia; however, it raises the vexing problem of reestablishing access in another extremity.
2. Reducing the flow but maintaining patency. Usually, this option involves narrowing a portion of the access to reduce flow. One technique for accomplishing this narrowing is to excise an elliptical portion of the graft or vein just distal to the anastomosis and reapproximate the edges or to plicate the graft or outflow vein with mattress or continuous sutures [see Figure 11a through c].³⁸ Another technique is to band the fistula or

Figure 10 Vascular access via AVFs. Shown are digital photoplethysmographic waveforms on an arm with steal syndrome before and during fistula compression.

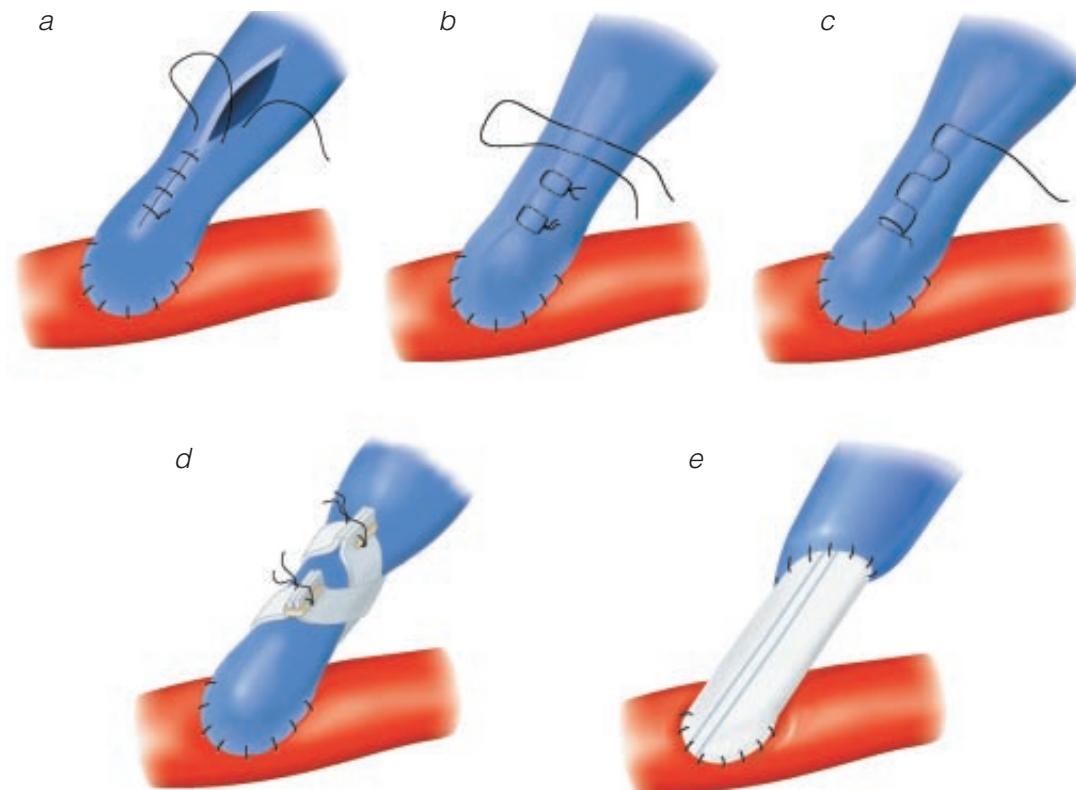

Figure 11 Vascular access via AVFs. One option for treating steal is to decrease blood flow in the access conduit. Methods that may be used include (a) excision of a portion of the vein or graft, (b) plication with mattress sutures, (c) plication with continuous sutures, (d) placement of a crossed ePTFE band with application of hemostatic clips, and (e) interposition of a 4 mm ePTFE graft.

graft with a crossed ePTFE band.³⁹ The tails of the band are secured with hemostatic clips, and once the appropriate degree of narrowing has been achieved, the clips are held in place with a figure-eight suture of 5-0 polypropylene [see Figure 11d]. Both techniques should narrow the outflow over a fairly long distance (≥ 1 cm). A third technique involves interposing a small-diameter (4 mm) ePTFE graft between the artery and the vein or graft⁴⁰ [see Figure 11e]; however, this technique does not allow progressive calibration of the narrowing to achieve the desired hemodynamic result.

3. Ligation of the source of steal, with distal revascularization when necessary. When steal occurs in a patient who has a radiocephalic fistula at the wrist with flow reversal in the radial artery distal to the fistula (documented by duplex scans) and whose ulnar artery and palmar arch are patent and competent to perfuse the hand, it is easily treated by ligating the radial artery distal to the fistula.⁴¹ The effect of this treatment is easily demonstrated by compressing the radial artery distal to the fistula, which should relieve the ischemia. With a more proximal fistula, in which ligation of a terminal artery would inevitably result in severe distal ischemia, the distal artery is ligated and an arterial bypass established from a point 5 cm proximal to the fistula to a point just distal to the ligation [see Figure 12]. This so-called distal revascularization-interval ligation (DRIL) procedure, originally reported by Schanzer and coworkers,⁴² is an elegant way of both preserving adequate flow through the fistula and reversing the ischemia. The pathway of steal is eliminated, and antegrade flow into the extremity is restored through the bypass.⁴³ This technique is particularly helpful when concomitant arterial stenosis proximal or

distal to the fistula contributes to the distal ischemic process, because the bypass can be positioned so as to bypass the arterial stenosis as well.

With any of these techniques, intraoperative assessment is required to ensure adequate residual flow volume in the fistula (assessed by intraoperative duplex scanning) and adequate distal perfusion (assessed by evaluation of digital PPG or PVR waveforms). The goal is to achieve a digital pressure of at least 60 mm Hg, a digital-brachial index of 0.6 or greater, and a residual flow of at least 300 ml/min in the fistula (a level of flow that is adequate both for hemodialysis and for maintenance of patency).⁴⁴

Inadequate Maturation of Vein

Failure of a fistula to mature may result from either inadequate inflow or venous abnormality. Physical examination combined with Doppler ultrasonography or fistulography should identify the underlying cause. If stenosis is not identified in a nonmaturing radiocephalic fistula, venous side branches may be draining critical flow from the primary vessel; ligation of these branches sometimes leads to successful maturation. Median cubital vein ligation may be attempted, as may temporary banding of the main venous channel in the antecubital fossa. Banding is accomplished by narrowing the vein with a 3-0 Vicryl tie over a 4 mm probe. The Vicryl resorbs in 3 to 4 weeks, during which period it is hoped that the increased resistance to flow will cause dilatation of the vein.⁴⁵ If none of these measures succeed, another access site should be sought.

True Aneurysm (Autogenous AVFs)

Aneurysmal dilatation of the vein develops in 5% to 8% of autog-

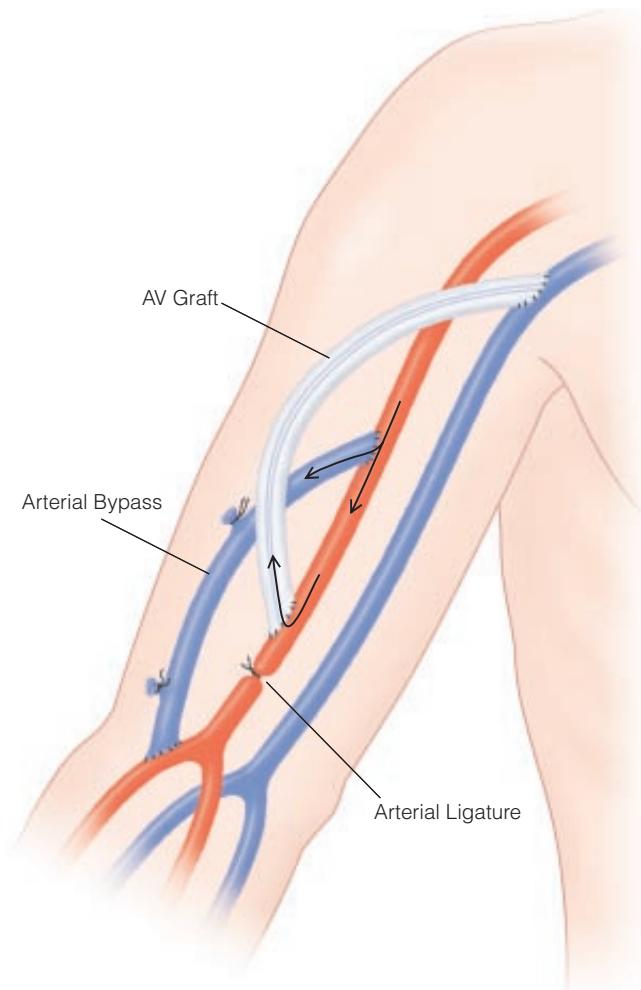

Figure 12 Vascular access via AVFs. Another option for treating steal is to ligate the source. Shown is the so-called DRIL procedure, which involves arterial ligation distal to the takeoff of the AV graft or the autogenous AVF and arterial bypass from a point 5 cm proximal to the fistula to a point just distal to the ligation.

enous AVFs as a result of high pressure applied to a vein wall weakened by repeated punctures. Usually, the course of such aneurysms is benign and does not preclude use of the fistula; however, large aneurysms containing mural thrombus have been reported to cause late thrombosis and embolization. On rare occasions, progressive enlargement can compromise circulation to the skin above the aneurysmal vein, leading to incomplete hemostasis when the needle is withdrawn and ultimately to graft rupture. Skin compromise and progressive enlargement are therefore indications for surgical correction. Surgical revision is also recommended if the aneurysm involves the arterial anastomosis or is associated with stenosis of the venous outflow.

Options for revision include total excision of the aneurysm with primary reanastomosis, exclusion of the aneurysm with vein bypass grafting, and partial excision in which part of the vein wall is kept as the arterial conduit. The last option frequently results in early recurrence as the vein wall continues to weaken and dilate with time.

Pseudoaneurysm (AV Grafts)

Pseudoaneurysms occur in prosthetic AV grafts and are usually small and asymptomatic. They can be prevented by allowing sufficient time after graft placement to ensure firm fibrous encapsulation of the graft and by avoiding repeated needle insertion at the same site. On occasion, however, pseudoaneurysms are precipitated by underlying venous stenosis, which should be documented and corrected whenever present. Urgent surgical repair is indicated if the pseudoaneurysm is expanding rapidly or is causing ischemia of the overlying skin. Elective repair is indicated if the diameter of the false aneurysm is more than twice that of the graft.

Infection

Infection is the second most common cause of loss of AV access, occurring in 0% to 3% of autogenous AVFs and 6% to 25% of AV grafts. Infection may be acquired during surgery or cannulation of the conduit and is most often caused by *Staphylococcus aureus*.

Autogenous AVFs Infection of an autogenous AVF should be treated aggressively with 6 weeks of antibiotic therapy, much as subacute bacterial endocarditis would be. Local measures, such as drainage of a perifistular abscess, may be necessary. In rare instances, infection-induced anastomotic pseudoaneurysm or septic emboli necessitate takedown of the fistula.

AV grafts Generally, both antibiotic therapy and surgical treatment are necessary for cure. An antibiotic regimen that covers gram-negative organisms, staphylococci, and streptococci should be given until culture results are available. In most cases, complete excision of the prosthetic graft is required,⁴⁶ along with vein patch reconstruction of the artery. If the anastomosis is not grossly involved, a small cuff of ePTFE may be left on the arterial side and used to close the arterial defect; this does not seem to alter the prognosis.

In selected cases of well-localized infection, it is possible to resect only the infected portion of the graft and to restore the continuity of the fistula by placing a new conduit in a clean subcutaneous tunnel away from the infected area. A useful approach to managing an infected forearm loop graft is to resect the graft and reconstruct the fistula with an immediate anastomosis between the artery and the arterialized vein remaining after graft excision. Superficial surgical wound infections occurring in the postoperative period can sometimes be treated successfully with aggressive local debridement in combination with systemic administration of antibiotics. Deeper wound infections occurring in the postoperative period must be assumed to involve the entire graft, given that the graft is not yet well incorporated.

OUTCOME EVALUATION

Thrombotic events are the leading cause of access loss. For the most part, they result from venous outflow stenosis that can be detected before thrombosis occurs. An organized monitoring approach that includes regular assessment of the clinical parameters of the access and of the adequacy of the dialysis should be implemented in every dialysis center.⁶ Such a proactive approach can be expected to reduce the incidence of thrombosis and increase patency.

Physical examination of the AV graft or autogenous AVF should be performed weekly and should include not only inspection and palpation for changes in the physical characteristics of the pulse or thrill but also a search for indirect signs of graft dysfunction (e.g., arm swelling, prolonged bleeding after needle withdrawal, and aneurysm or pseudoaneurysm). In addition to physical examination, the NKF-DOQI committee recommends routine access monitoring at least monthly with one or more of the following techniques:

1. Intra-access flow assessment using Doppler flow, magnetic resonance imaging, or ultrasound dilution online during dialysis. A trend toward decreasing flow or a flow rate lower than 600 ml/min for an AV graft and lower than 200 to 300 ml/min for an autogenous AVF is predictive of a high likelihood of access stenosis and eventual thrombosis.
2. Static or dynamic venous pressure measurement. Progressively increasing pressures or pressures that exceed the threshold value determined by each center's own protocol are predictive of significant venous outlet stenosis.
3. Urea and nonurea recirculation measurement. Recirculation is defined as the percentage of flow that is recirculated from the venous line into the dialyzer inflow by retrograde blood flow through the fistula. A recirculation value exceeding 10% to 20% is significant and usually indicates low arterial blood flow or venous stenosis.
4. Delivered dialysis dose. A decrease is associated with venous outflow stenosis.
5. Arterial prepump pressure. An elevated negative pressure is a sign of inflow insufficiency.

Data should be tabulated and tracked within each dialysis center as part of a quality assurance/continuous quality improvement (QA/CQI) program.⁷

Vascular Access via Percutaneous Catheters

Percutaneous venous catheterization is a useful method of gaining immediate access to the circulation; however, it is associated with significant risks, and the use-life of this type of access is shorter than that of AVFs. Percutaneous catheterization should be reserved for patients with acute renal failure who have an immediate need for dialysis and for patients with chronic renal failure in whom a permanent vascular or peritoneal access route either cannot be established or has not yet matured.

PREOPERATIVE EVALUATION

A history is taken, a physical examination is performed, laboratory data are reviewed, and radiologic studies are ordered as for AVFs [see *Vascular Access via Arteriovenous Fistulas, above*]. Any finding that might affect the integrity of the central venous system should be noted.

A history or physical signs of previous central venous catheterization, a history of major injury or operation in the area where the catheter is to be inserted, a body mass index greater than 30 or less than 20, and an increasing number of insertion attempts are all known risk factors for perioperative complications from the insertion of venous access devices.⁶ If there is any question about the patency of the central venous system, duplex scanning⁴⁷ or phlebography is indicated.

On physical examination, the surgeon should note the patient's body type, assess the flexibility of the patient's neck and shoulders, and evaluate the patient's ability to tolerate the Trendelenburg position without dyspnea or discomfort. Chest x-rays are reviewed to verify the patient's pleuropulmonary status and to identify any bony deformities.

The only laboratory study absolutely necessary is a complete blood count (including the platelet count and the differential count); prothrombin and partial thromboplastin times are required if the patient is receiving anticoagulant therapy. The effects of warfarin or heparin should be reversed before the procedure; patients with platelet counts lower than 50,000/mm³ should undergo platelet transfusion immediately before and during catheter placement.⁴⁸

OPERATIVE PLANNING

Choice of Type of Catheter

Different catheter designs have been studied and used, but at present, none of them appears to have a proven advantage over the others. Generally, the catheters best suited for hemodialysis are high-flow, large-diameter (12 French or larger) devices with external ports. Silicone catheters are more flexible, are less likely to give rise to injury or thrombosis, and remain patent longer than polyethylene, polyvinyl chloride, and polytetrafluoroethylene catheters. Silicone catheters are available in both noncuffed (temporary) and cuffed (semipermanent) double-lumen configurations through which flow rates of 250 ml/min or higher can be achieved [see *Figure 13*]. The venous and arterial orifices are separated by 1 to 2 cm; recirculation is thereby limited to 5%.

Noncuffed (temporary) catheters Noncuffed catheters can be percutaneously inserted into the internal jugular, subclavian, or femoral vein without the need for fluoroscopic guidance. They are suitable for immediate use and provide acceptable flow rates (250 ml/min). Their main disadvantages are their high rates of infection, thrombosis, and venous stenosis and their short use-life (2 to 3 weeks). For these reasons, noncuffed catheters should be reserved for patients in whom access is expected to be needed for less than 3 weeks, and they should be inserted no earlier than required.

Cuffed (semipermanant) catheters Cuffed catheters are placed in a subcutaneous tunnel under fluoroscopic guidance. They are free of some of the shortcomings of noncuffed catheters; in particular, they are associated with lower infection rates and permit higher flow rates. Cuffed catheters are preferred when temporary access is required for longer than 3 weeks, par-

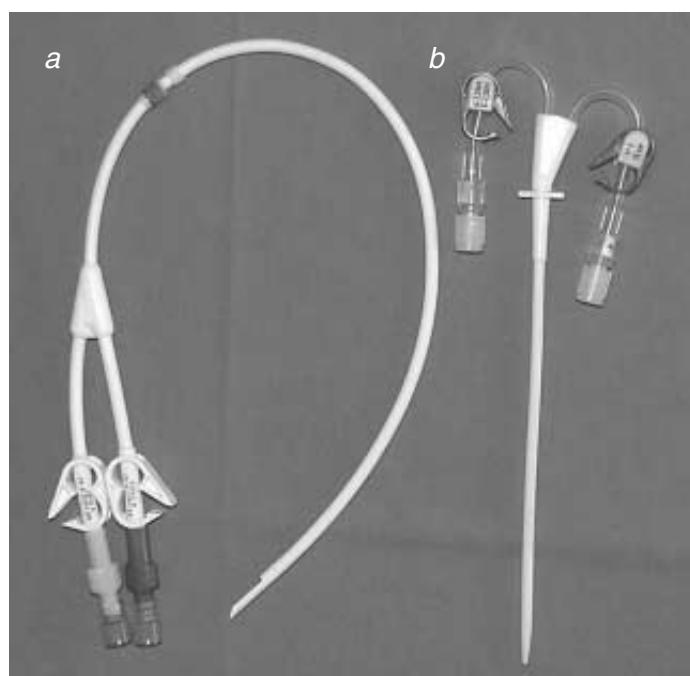

Figure 13 Vascular access via percutaneous catheters. Catheters used for hemodialysis include (a) cuffed double-lumen (semipermanent) catheters, introduced by means of the peelaway sheath technique, and (b) noncuffed double-lumen (temporary) catheters, introduced by means of the Seldinger technique.

ticularly for patients in whom a primary AV fistula is maturing but who require immediate hemodialysis. Semipermanent catheters have been used for as long as 4 years, but long-term follow-up data on large numbers of patients are lacking.⁴⁹ Most patients readily accept this approach to dialysis: cuffed catheters allow so-called no-needle dialysis with high flow rates, they eliminate the problem of vascular steal, and they have no effect on cardiac function. In addition, patients appreciate that the access site is hidden from view, does not limit physical activity, and does not require particular care between treatments.

Choice of Insertion Site

The subclavian veins have given way to the right internal jugular vein as the preferred site of primary central access. This site has four main advantages: (1) it offers a consistent, predictable anatomic location with palpable landmarks, (2) it provides a short, straight course to the superior vena cava, (3) success rates are high, and (4) the risk of complications is diminished in comparison with other catheter insertion sites.⁵⁰ Of particular importance is that the risk of subclavian vein stenosis is decreased; this complication is a major concern for dialysis patients, who may require subsequent construction of an AVF in the ipsilateral arm. The right internal jugular vein is preferable to the left as an access site because the latter calls for longer catheters, which increase the risk of kinking and diminish flow rates. The left internal jugular vein approach is also associated with a high rate of stenosis or thrombosis of the left brachiocephalic vein and may hinder subsequent use of the left arm for an AVF. Placement of the catheter in a subclavian vein either via the percutaneous approach or via cutdown on the cephalic vein should be reserved for cases in which neither jugular vein can be used.⁶

The right internal jugular vein can be catheterized percutaneously, or it can be surgically exposed and catheterized via direct needle puncture or phlebotomy (venous cutdown). The cutdown approach on the internal jugular vein or the external jugular vein

allows greater control over the vessel than the percutaneous approach does and is preferred in patients who have a bleeding diathesis, patients whose body habitus or venous anatomy limits percutaneous access, and patients in whom a percutaneous attempt at placement has failed.

A less commonly used approach is femoral vein catheterization. It is technically easy and has few immediate complications, but it necessitates hospitalization (because the patient cannot ambulate) and is associated with high infection rates that limit use of the catheter to 5 days. Alternatively, access to the inferior vena cava can be gained by cannulating the greater saphenous, inferior epigastric, right gonadal, and lumbar veins. It is also possible to cannulate the azygos vein and the right atrium directly via thoracotomy.

OPERATIVE TECHNIQUE

Right Internal Jugular Vein Approach

Step 1: patient preparation Noncuffed catheters may be inserted at the bedside; cuffed catheters should be inserted in a standard OR with facilities for fluoroscopy.

The anatomy is surveyed before preparation and draping. Important anatomic landmarks include the sternal notch, the clavicle, and the sternocleidomastoid muscle. The carotid artery should be palpated lateral to the trachea, under the medial (sternal) head of the sternocleidomastoid muscle. The internal jugular vein lies lateral and slightly anterior to the carotid artery, between the sternal head and the clavicular head of the sternocleidomastoid muscle.

The patient is placed supine in the Trendelenburg position so that the neck veins are distended and the risk of air embolism is minimized. The head is extended and turned slightly to the left to expose the right side of the neck and keep the chin from interfering with the procedure. The neck should not be overextended or overrotated, however, because either of these actions flattens out

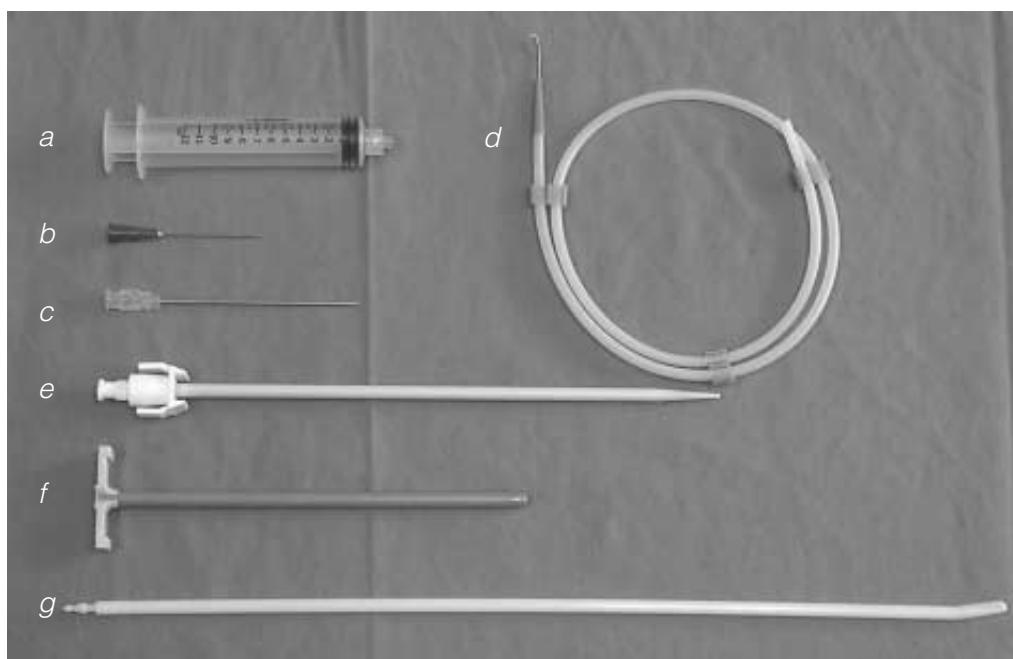

Figure 14 Vascular access via percutaneous catheters. The equipment used in percutaneous catheter insertion includes (a) a 5 ml syringe, (b) a 22-gauge finder needle, (c) an 18-gauge needle, (d) a guide wire, (e) a dilator, (f) a peelaway sheath, and (g) a plastic subcutaneous tunneler.

the vein, making it more difficult to cannulate, and may increase the risk of arterial puncture by causing the internal jugular vein to overlie the carotid artery.

Step 2: cannulation of right internal jugular vein The jugular vein is located with a 22-gauge finder needle. This needle is left in place and used to guide the subsequent placement of an 18-gauge needle, through which the guide wire is passed. Use of the smaller needle minimizes the consequences of arterial or pleural puncture occurring during blind attempts at venous puncture.

After local anesthesia is administered, the fingers of the left hand are gently positioned on the carotid pulse to provide an anatomic landmark. The right hand locates the internal jugular vein by applying negative pressure to the 22-gauge finder needle mounted on a 5 ml syringe [see Figure 14]. The needle is inserted at the apex of the triangle formed by the two heads of the sternocleidomastoid muscle and directed toward the ipsilateral nipple at an angle of 30° from the plane of the skin. Alternatively, the needle may be inserted under the medial border of the sternocleidomastoid muscle and directed toward the thoracic inlet while the carotid artery is dislocated medially, or it may be inserted under the lateral border of the sternocleidomastoid muscle and directed toward the contralateral nipple.

Once the vein is located, the syringe is disconnected from the finder needle, which is left in place. The vein is then repunctured with an 18-gauge needle oriented parallel to the finder needle. When venous backflow is obtained, the 18-gauge needle is reoriented at a more acute angle to the skin and is advanced 2 to 3 mm. The syringe is disconnected and the needle hub occluded to prevent air embolism. A 0.035-in. guide wire with either a J tip or a flexible straight tip is then inserted through the needle, and the needle is withdrawn over the wire.

Troubleshooting. Because of the predictable anatomic location of the right internal jugular vein, the first attempt at cannulation is successful in the majority of cases. If the first attempt fails, the finder needle should be withdrawn and its tip reoriented slightly laterally; however, the needle should not be entirely withdrawn from the skin puncture site. An orderly, systematic search performed in this manner often identifies the vein while posing little risk of carotid artery injury as long as the carotid artery remains palpable medially. To avoid lacerating deep structures, the needle orientation should be changed only when the needle is inserted very superficially. If the vein cannot be located after several passes of the needle, the finder needle is withdrawn completely and the anatomy reassessed.

Alternative puncture sites may be attempted. In more technically challenging cases, a cutdown can be performed on the external or internal jugular vein through a small transverse incision. Cannulation of the veins can also be carried out under ultrasonographic guidance. In fact, the NFK-DOQI committee recommends routine real-time ultrasound-guided insertion to reduce insertion-related complications. The internal jugular vein is usually imaged with the probe placed either parallel or perpendicular to the long axis of the vein. Placing the probe perpendicular gives the vessel a more typical circular appearance.⁵¹ Aside from the ultrasound-guided vein cannulation, the rest of the procedure is performed essentially as previously described.

When the 18-gauge needle is advanced, the lumen of the jugular vein is often compressed; as a result, the needle may transfix the front and back walls almost simultaneously. The needle tip should be advanced only slightly beyond the expected depth, then slowly withdrawn, with gentle aspiration maintained on the

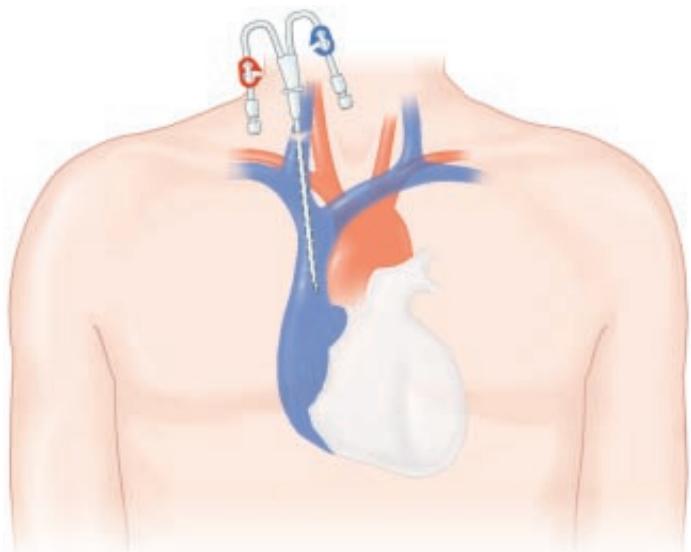

Figure 15 Vascular access via percutaneous catheters: Seldinger technique. Shown is a noncuffed (temporary) catheter inserted in the right internal jugular vein.

syringe. Entry into the vein is confirmed by the sudden and easy return of venous blood.

Pulsatile back-bleeding of bright-red blood from the needle usually indicates arterial puncture. If any doubt exists, the aspirated blood can be compared with a simultaneously obtained arterial sample, or the 18-gauge needle can be connected to a pressure transducer. Whenever there is any possibility of arterial puncture, it is preferable to withdraw the needle rather than take the risk of creating a large hole in the artery with a dilator.

The guide wire should be inserted with caution because any forceful movement can result in perforation of the vein wall. The risk is minimized by using a soft-tipped or J-tipped wire. The wire should advance easily into the vein without resistance; if it does not, the guide wire and the needle should be withdrawn together to ensure that the tip of the guide wire is not sheared off and does not embolize.

Step 3 (Seldinger technique): insertion of noncuffed catheter A small nick is made at the point where the guide wire enters the skin [see Figure 15]. The dilator is passed over the wire only far enough to enter the vein; it is then removed, and the catheter is inserted over the wire. The catheter tip should be placed in the superior vena cava, above the right atrial junction. This position is typically 15 to 18 cm from the puncture site if the catheter is placed in the right internal jugular vein; an additional 3 to 5 cm is required for the left internal jugular vein approach. The guide wire is then retrieved, venous blood is aspirated from both ports, and each lumen is flushed with heparinized saline. The catheter is anchored to the skin.

Troubleshooting. Dilators are relatively inflexible, and their stiffness increases with size. Consequently, they can easily perforate the vein wall if inserted deeper than the point of entry into the vein. Catheters may also cause perforation, though less commonly. The risk of catheter-related perforation is increased with the left internal jugular vein approach and the subclavian vein approach because catheters inserted from the left side must traverse the innominate vein and enter the superior vena cava at an acute angle, and this course increases the possibility that the tip of the catheter will perforate the right lateral wall of the superior

vena cava. No resistance should be felt when the catheter is inserted. In addition, the guide wire should move freely within the catheter during insertion; such free movement suggests that the catheter is not compressing the wire against the wall of the vein.

Manual control of the guide wire must be maintained at all times; without such control, pushing a catheter or dilator over the wire can cause the wire to be completely advanced into the vein.

Inadvertent placement of a dilator or catheter into the carotid artery makes a large hole in the vessel wall, thereby creating the potential for substantial bleeding when the device is removed. In such cases, the catheter should be left in the artery, and a vascular surgeon should be consulted.

Step 3 (peelaway sheath technique): insertion of cuffed catheter

A small transverse incision is made at the point where the guide wire enters the skin. Once adequate local anesthesia is achieved, a subcutaneous tunnel is created between the guide-wire entry point and a site on the chest wall at least 10 cm away [see Figure 16]. The position of the catheter is estimated by laying the catheter out along its intended tract; the course forms an inverted U, with the apex at the entry point of the guide wire and the tip of the catheter 5 cm caudad to the angle of Louis (at the second or third intercostal space). The position of the Dacron cuff is noted, and a stab wound is made in such a way that the cuff will be positioned in the subcutaneous tunnel, 2 cm from the wound. This placement simplifies removal of the catheter, prevents the cuff from eroding through the skin, and reduces the incidence of inadvertent catheter dislodgment. The exit wound should be at least 3 to 4 cm from the nipple-areola complex to allow space for the dressing.

A plastic subcutaneous tunneler is attached to the catheter and used to pull the catheter through the tunnel so that the tip emerges adjacent to the guide wire. The venous dilator is then inserted over the wire to effect entry into the vein. Once entry is effected, the dilator is removed and inserted into the peelaway sheath, and sheath and dilator are introduced together into the vein over the guide wire. The guide wire and the dilator are removed, and the open end of the peelaway sheath is occluded with the fingers to prevent air embolism and bleeding. The flushed catheter is then inserted into the peelaway sheath and its position confirmed via fluoroscopy. When the catheter is well positioned, the peelaway sheath is cracked, peeled apart, and removed. Both lumina are tested for easy aspiration of blood and irrigated with heparinized saline. The two incisions are closed with absorbable sutures, and an adequate dressing is applied.

Troubleshooting. Because the procedure is performed under fluoroscopic guidance, fluoroscopy should be used to confirm that the position of the guide wire is satisfactory before the catheter is inserted. If the guide wire is not satisfactorily positioned, a 14-gauge plastic I.V. catheter is placed over the wire into the vein, and the wire is removed and repositioned through the catheter.

The peelaway sheath must be inserted to its full length, which means that the dilator must be inserted to its full length as well. Bending the dilator and the sheath into a gentle curve that matches the curve of the vein minimizes the risk of venous wall perforation, particularly if the left internal jugular vein approach or the subclavian vein approach is used.

If resistance is encountered when the catheter is inserted through the sheath, the usual cause is a kink in the sheath. In most instances, partial withdrawal of the sheath resolves the problem. If this step is taken and the catheter still cannot be advanced, the guide wire and the dilator can be reinserted through the sheath,

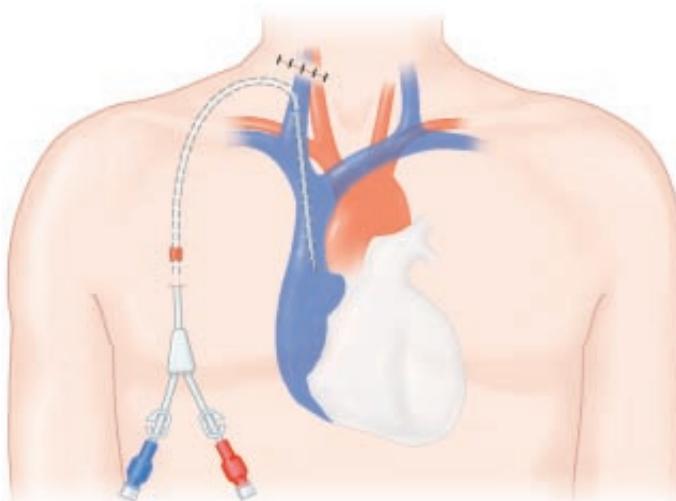

Figure 16 Vascular access via percutaneous catheters: peelaway sheath technique. Shown is a cuffed (semipermanent) catheter inserted in the right internal jugular vein and placed in a subcutaneous tunnel.

which is then replaced. The right internal jugular vein approach usually allows easy placement of the catheter through the peel-away sheath into the right atrium after removal of the dilator and the guide wire. In the left jugular vein approach or the subclavian vein approach, the guide wire should be left in place and the catheter inserted over the guide wire so that the catheter can be more readily advanced into the appropriate position.

Step 4: evaluation The location of the catheter tip should be documented with a chest x-ray after the procedure. To reduce the risk of complications (e.g., central vein thrombosis or perforation of the right atrium), the tip should be located at the junction of the right atrium and the superior vena cava.⁵²

Subclavian Vein Approach

The patient is positioned and prepared in much the same way as for the right internal jugular vein approach. The arms are at the sides, and a small roll is placed between the shoulder blades to allow full exposure of the infraclavicular area. An insertion site is selected 2 to 3 cm caudad to the midpoint of the clavicle, far enough from its inferior edge to allow the needle to remain parallel to the clavicle as it passes beneath its inferior border. A slightly lateral position is preferred to prevent kinking of the peelaway sheath or compression of the soft silicone catheter between the clavicle and the first rib.

Local anesthesia should include the clavicular periosteum. The 18-gauge needle is advanced into the space between the clavicle and the first rib in the direction of a finger placed in the suprasternal notch. The needle is oriented as horizontally as possible, and the bevel of the needle is oriented downward to decrease the risk that the guide wire will pass upward into the ipsilateral internal jugular vein.

Careful technique helps prevent pneumothorax and puncture of the subclavian vein. For example, “walking” the tip of the needle down the clavicle, so that it passes as closely underneath the clavicle as possible, reduces the risk of deep puncture and thus of pneumothorax. The rate of complications is directly related to the number of puncture attempts made; consequently, if the subclavian vein is not punctured on the second or third attempt, one should resist the temptation to make additional needle thrusts.

Once the vein is cannulated, the catheter may be inserted by means of either the Seldinger technique or the peelaway sheath technique as previously described [see Right Internal Jugular Vein Approach, above].

A chest x-ray will confirm the positioning of the tip of the catheter and the presence or absence of kinking. It will also rule out so-called pinch-off, which is a narrowing or notching of the catheter as it passes through the tight space between the clavicle and the first rib that may result in transection and embolization of the catheter tip.

Femoral Vein Approach

Femoral venipuncture is performed below the inguinal ligament just medial to the palpated femoral arterial pulse. The catheter is inserted by means of the Seldinger technique. The catheter should be at least 19 cm long to reach the inferior vena cava, thereby minimizing recirculation.

COMPLICATIONS

Early

In more than 5% of catheter insertions, the catheter is improperly positioned. Such malpositioning may cause central venous perforation, venous thrombosis, or device malfunction. The most common positioning error is entry of a subclavian catheter into the ipsilateral internal jugular vein; less commonly, the catheter tip may inadvertently be placed in an axillary, internal mammary, azygos, or hepatic vein. Placement of the tip within the more cephalad portion of the superior vena cava at an obtuse angle to the venous wall or directly in the heart increases the risk of perforation. Catheter malpositioning is diagnosed by means of fluoroscopy or chest x-ray; management involves immediate repositioning of the catheter with the help of guide wires and fluoroscopy.

Guide-wire embolism can be prevented by being careful not to withdraw the wire through the 18-gauge needle, which can shear off the tip of the wire. Catheter embolism, though rare, may occur when a subclavian venous catheter is inserted too medially and as a consequence is compressed between the costoclavicular ligament, the clavicle, and the first rib. Such compression may lead to biomaterial fatigue, fracture of the catheter, or embolization. Embolized portions of a guide wire or catheter should be removed by means of interventional radiologic techniques to prevent thrombotic complications.

Air embolism occurs when air is inadvertently aspirated into the patient's venous system while the catheter is being inserted, removed, or used. It is easily prevented by using a fingertip to cover all potential communication sites between the venous lumen and the outside air, including the needle hub before guide-wire insertion, the open end of the peelaway sheath just before catheter insertion, and the disconnected external ports of catheters. Patients whose pulmonary status is compromised or who have aspirated large volumes of air may experience respiratory distress. Cardiovascular collapse, caused by obstruction of right ventricular outflow by gas bubbles, can also result. Auscultation may reveal a characteristic millwheel precordial murmur. The patient should be placed in the left lateral decubitus position with the foot of the table elevated so as to trap the air pocket away from the right ventricular outflow tract, and immediate ventilatory support for hypoxemia should be instituted.

Internal hemorrhage may occur at any site, usually as a result of perforation of a central venous or arterial structure during needle puncture or insertion of a guide wire, a dilator, or a catheter. Mediastinal hemorrhage, manifested by mediastinal widening on

chest x-ray, occurs in fewer than 1% of all insertions.⁵³ It is usually self-limited in that the bleeding generally tamponades before hemodynamic compromise occurs.

If both a vascular structure and the parietal pleura are lacerated, hemothorax may result. The chest x-ray will suggest the diagnosis. Treatment includes placement of a thoracostomy tube and early consultation with a thoracic surgeon. Fortunately, the bleeding ceases spontaneously in most cases.

Pericardial tamponade, the most lethal complication of central venous catheterization, may arise as a consequence of perforation into the pericardial space, either through the wall of the vein or through the heart. It can occur immediately, or it can appear hours to days later as a result of delayed perforation by the catheter tip. Proper positioning of the catheter tip is the key to preventing pericardial tamponade. Treatment involves pericardiocentesis, creation of a pericardial window, or median sternotomy, depending on the patient's clinical status.

Cardiac arrhythmias are frequent during catheter insertion; atrial and ventricular arrhythmias occur in as many as 41% and 11% of patients, respectively.⁵⁴ These arrhythmias are usually benign; fewer than 1% call for cardioversion.

Pneumothorax occurs in 1% to 4% of attempts at percutaneous catheter placement. The incidence varies according to the experience of the operator and the site selected; in particular, it is higher with the subclavian approach. The presence of pneumothorax may be suggested by air in the syringe during attempts at vein cannulation and may be confirmed by chest x-ray. If the pneumothorax is asymptomatic, with less than 25% lung collapse, it can be treated conservatively; if it is large, symptomatic, or increasing in size, placement of a thoracostomy tube is indicated. Tension pneumothorax is an unusual but important complication that calls for immediate chest tube decompression.

Inadvertent puncture of a lymphatic duct may occur during left subclavian vein or left internal jugular vein catheterization in patients with hepatic portal hypertension or superior vena caval obstruction. The diagnosis is usually made when clear or milky fluid is aspirated in the syringe during vein cannulation; however, if the duct is punctured at the junction with the vein, the appearance of blood mixed in with the lymphatic fluid may mask the complication. Once lymphatic duct puncture is recognized, the procedure should be abandoned, and pressure should be applied to the site until lymphorrhagia abates. If the complication is recognized late on the basis of spontaneous leakage of lymph around the catheter, either the catheter can be removed or the leak can be stopped with a purse-string suture around the catheter. If persistent fluid drainage, subcutaneous edema, mediastinal enlargement, or chylothorax is noted, the leak is ongoing, and the catheter should be removed.

Late

Central venous thrombosis Catheter-associated central venous thrombosis is more common than was once believed. It is often asymptomatic because of the rich venous collateral circulation in the area. Central venous thrombosis has been estimated to occur in 13% to 35% of catheter insertions⁵⁵ and to carry less than a 10% risk of pulmonary embolism and a 19% risk of post-phlebitic syndrome. The incidence of catheter-associated thrombosis is correlated with the following factors:

1. Placement site. The incidence of thrombosis or stenosis is as high as 38% with subclavian vein catheters but less than 10% with internal jugular vein catheters.
2. Site of catheter entry. Surgical cutdown causes less endothelial

- injury than percutaneous puncture and dilation of the vein and may therefore be less likely to cause thrombosis.
3. Catheter tip position. Catheters placed high in the superior vena cava, near the brachiocephalic vein, are more likely to cause thrombosis.
 4. Catheter size. Larger, stiffer catheters are more likely to traumatize the endothelium and to obstruct flow.
 5. Catheter material. Silicone is less thrombogenic than other materials.
 6. Duration of catheter placement. The incidence of thrombosis increases with the duration of catheter placement.
 7. Underlying hypercoagulable state.
 8. Associated catheter infection.

The diagnosis is easily made by means of duplex scanning or phlebography. Treatment involves removal of the catheter and administration of anticoagulant therapy. Asymptomatic patients who have no alternative sites for venous access should undergo anticoagulation without removal of the catheter. Thrombolytic therapy through the catheter, though never evaluated in a prospective randomized study, may be useful if the thrombosis is new or symptomatic, is progressing in the face of standard therapy, or is associated with catheter occlusion in a patient with no alternative site of venous access.

Catheter malfunction Catheter malfunction is the most common noninfectious complication of central venous catheterization. Malfunction is defined as either (1) failure to achieve a blood flow rate of at least 300 ml/min on two consecutive occasions or (2) failure to achieve a blood flow rate of 200 ml/min on a single occasion. In addition, partial or complete so-called withdrawal occlusion, in which solutions can be infused but blood cannot be withdrawn, may occur, as may complete occlusion.

Early catheter malfunction is usually caused by improper positioning of the catheter tip proximal to the distal superior vena cava, positioning of the tip against the venous wall, or subcutaneous kinking of the catheter. The precise cause can be determined via chest x-ray and contrast study. Malpositioning of the catheter tip can be corrected by using a tip deflector wire inserted through the lumen of the catheter, by snaring the catheter via the femoral approach and repositioning it, or by replacing the catheter.

Late catheter malfunction is usually caused by intraluminal thrombi; less commonly, it is caused by extraluminal thrombi (e.g., fibrin tails or sheaths enveloping the distal portion of the catheter) or central venous thrombosis. Most late catheter dysfunction can be successfully managed with thrombolytic therapy. Thrombolysis with urokinase was once first-line treatment for this complication because of its high success rate (up to 90%) and its ease of administration.⁵⁶ However, urokinase is no longer available in the United States market for this indication. (It was reintroduced and approved by the FDA in 2002, but only for the treatment of massive pulmonary emboli and pulmonary emboli accompanied by unstable hemodynamics.) Protocols using tissue plasminogen activator and recombinant urokinase have been employed, with promising results. If catheter function fails to improve with thrombolysis, imaging of the catheter with infused contrast material will allow identification and correction of other problems. Residual thrombus in the catheter lumen can be treated by means of intracatheter infusion of a thrombolytic agent, catheter embolectomy, or catheter exchange over a guide wire. Fibrin sheaths around the catheter can be treated by means of thrombolysis, fibrin sheath stripping with a snare,⁵⁷ or catheter exchange.

Cuffed catheter infection Infection is the most common

complication of venous catheterization for vascular access, occurring in as many as 30% to 40% of patients. It is also one of the leading causes of catheter removal and morbidity in dialysis patients. Gram-positive bacteria, principally *S. aureus* and *S. epidermidis*, are the most commonly isolated organisms, though gram-negative bacteria and fungi may also be involved.

The clinical spectrum of catheter infection includes exit-site infection, tunnel infection, systemic line sepsis, and suppurative thrombophlebitis.

Exit-site infection. The characteristic signals are localized erythema, induration, tenderness, and exudate at the catheter exit site. Systemic symptoms are absent, and blood cultures are negative. Treatment involves local wound care and application of topical antibiotics. The catheter need not be removed.

Tunnel infection. If the inflammatory process extends along the entire course of the subcutaneous tunnel, a more extensive cellulitic process, with or without purulent discharge, results. Initially, tunnel infection can be treated with parenteral antibiotics and local measures; however, it usually does not respond to this regimen, and removal of the catheter is often required. If a new catheter is called for, it should use a different tunnel and exit site.

Systemic line sepsis. This condition is manifested by systemic symptoms and signs of bacteremia in a patient who has a central venous catheter in place but exhibits no local evidence of catheter or tunnel infection and has no other identifiable source of infection. It is defined on the basis of the following two criteria: (1) in comparison with peripheral blood, a 10-fold increase in colony-forming units (CFU)/ml blood drawn from the catheter, or (2) in the absence of a positive peripheral blood culture, more than 1,000 CFU from blood drawn through the device. Empirical I.V. antibiotic treatment (including coverage for penicillin-resistant staphylococci) should be administered through the catheter. This measure will eliminate the clinical sepsis syndrome in 70% of patients. Once the antibiotics are discontinued, however, there is a 40% risk of reinfection; for this reason, catheter exchange over a guide wire, using the same tunnel and exit site, is recommended once bactericidal levels have been obtained⁵⁸ and the sepsis syndrome has resolved. I.V. antibiotics should be continued for 3 weeks thereafter. If the patient is unstable or still symptomatic after 24 to 36 hours of antibiotic therapy, removal of the catheter is mandatory. The catheter should also be removed if fungemia is suspected or confirmed.

Suppurative thrombophlebitis. When arm edema occurs in addition to systemic sepsis, suppurative thrombophlebitis of a great vein should be suspected. The diagnosis may be confirmed by means of duplex scanning or contrast phlebography. Treatment involves catheter removal, systemic I.V. antibiotic therapy, and heparin anticoagulation and is successful in more than 50% of patients. Vein excision is associated with significant morbidity and consequently is not indicated. Patients who do not respond to treatment can be treated with vena caval filter placement and central vein thrombectomy.

Noncuffed catheter infection The presence of exit-site infection, tunnel infection, or systemic line infection mandates removal of all noncuffed catheters.

OUTCOME EVALUATION

To improve dialysis outcomes and to maintain or improve quality of care for dialysis patients, percutaneous catheterization should be performed only in selected cases. Given that percutaneous catheterization is associated with higher complication rates, morbidity, and mortality than AV fistulization, the goal should be to use

percutaneous catheters in fewer than 10% of hemodialysis patients requiring long-term vascular access. In those cases in which central catheter placement is the best available option, the use of a consistent technique by skilled operators should, according to the NFK-DOQI, reduce the risk of serious complications necessitating intervention to 2% or lower.

Peritoneal Access

Clinical use of peritoneal dialysis was first described back in 1923,⁵⁹ but it was not until 1976 that technical refinements made this procedure a valid alternative to hemodialysis.⁶⁰ The advantage of peritoneal dialysis is that it offers the patient increased autonomy and independence, in that all the dialysis sessions are performed at home. Moreover, there are fewer dietary restrictions, and anticoagulation is unnecessary. According to the NFK-DOQI committee,⁶¹ peritoneal dialysis is indicated for the following patients:

1. Patients who prefer peritoneal dialysis or refuse hemodialysis;
2. Patients who cannot tolerate hemodialysis (e.g., some patients who have congestive or ischemic heart disease or extensive vascular disease or in whom vascular access is problematic, including the majority of young children); and
3. Patients who prefer home dialysis but who have no assistant to help with hemodialysis or whose assistant cannot be trained for home dialysis.

Absolute contraindications to peritoneal dialysis are as follows:

1. Loss of more than 50% of the peritoneal surface or the presence of adhesions too extensive to permit adequate flow of the dialysate (a history of laparotomy is not a contraindication in itself);
2. The absence of an assistant in the home of a patient who does not have the autonomy or intellectual capacity to perform peritoneal dialysis on his or her own;
3. The presence of a surgically irreparable hernia;
4. Loss of integrity of the diaphragm, which can lead to the appearance of a hydrothorax; and
5. Severe respiratory insufficiency, in which case the increase in intra-abdominal volume caused by the dialysate could compromise respiratory function.

Inflammatory bowel disease and frequent episodes of diverticulitis are relative contraindications to peritoneal dialysis; it must be assumed that the risk of transmural contamination with secondary peritonitis is higher in these patients. Morbid obesity is also a relative contraindication because of technical problems related to installation of the dialysis catheter. With a newly implanted vascular prosthesis, a waiting period of at least 4 months is required to minimize the risks of contamination of the prosthesis.

PREOPERATIVE EVALUATION

Preoperative patient evaluation includes a complete physical examination to look for hernias, eventration, or weakness of the abdominal wall; if any of these are found, surgical repair must be performed, either before or simultaneously with insertion of the catheter. Care is taken to determine the catheter's exit site from the skin in advance, with the patient standing. Ideally, the exit site should be on the left side to avoid the cecum (either above or below the belt line), should not lie on a scar, and should not be in an abdominal fold. Patients' nares should be swabbed to check for nasal carriage of *S. aureus*; eradication of nasal carriage has been shown to yield significant improvements in exit-site infection rates.

OPERATIVE PLANNING

Choice of Type of Catheter

The ideal catheter for peritoneal access would be simple, safe, and durable and would provide reliable, rapid flow of the dialysate without leaks or infection. The silicone rubber double-cuff straight Tenckhoff catheter, first described in 1968,⁶² remains one of the most widely used catheters for this purpose.

Since the introduction of the Tenckhoff catheter, a number of different catheters have been developed with the objective of minimizing the complications inherent in these devices—namely, infusion or pressure pain, obstruction, catheter migration, external cuff extrusion, and infection. The various catheters may be defined according to the characteristics of their intraperitoneal and extraperitoneal segments [see Figure 17].

Intraperitoneal segment A straight catheter is, in theory, more traumatic to surrounding tissues, more likely to cause pain during injection of the dialysate (jet effect), and more susceptible to obstruction by the intestinal ansa (loops of bowel) or the adjacent omentum. A coiled tip adds bulk to the tubing, thus facilitating separation of the parietal and visceral layers of the peritoneum, and provides more side holes for outflow. Although coiled tips are very widely used and are available with almost all types of catheters, their theoretical advantages, to date, have not translated into superior results in randomized studies.^{63,64}

Other catheter modifications are the addition of perpendicular disks that move the intestine and the omentum away from the lateral holes and the use of the T-fluted design, which has grooved limbs positioned against the parietal peritoneum for better drainage and less risk of migration.

Extraperitoneal segment *Single versus double cuff.* A Dacron cuff is always positioned in the rectus abdominis. A second cuff, when present, is positioned in the subcutaneous tunnel about 2 cm from the exit site. Use of a second cuff creates an additional barrier against bacterial contamination of the subcutaneous tunnel and provides solid anchoring that prevents the catheter from moving in a pistonlike fashion. Even though the randomized studies done to date have yielded inconsistent results,^{65,66} double-cuff catheters are generally recommended in preference to single-cuff catheters.

Straight versus permanent bend. The literature demonstrates that orienting the subcutaneous tunnel laterally and caudally in relation to the intraperitoneal entry site significantly reduces the risk of peritonitis associated with exit-site or tunnel infection. It is reasonable to think that installing a straight catheter in an arcuate tunnel would increase the risk of migration of the intraperitoneal segment, as well as the risk of external cuff extrusion resulting from the pushing force exerted by the catheter's resilience (shape memory). To mitigate this problem, a catheter with an inverted U-shaped permanent bend between the two cuffs (the so-called swan neck catheter) was developed. The advantage of this device is that it can follow the shape of the subcutaneous route in an unstressed state.^{67,68} It is also available with an additional curvature of 90° at the intraperitoneal entry site, so that it can be oriented parallel to the abdominal wall.

Disc-ball deep cuff. With this type of catheter, the parietal peritoneum is sewn between a Dacron disc and a silicone ball. In theory, this approach improves the anchoring of the peritoneum and reduces the risk of leakage and catheter extrusion.

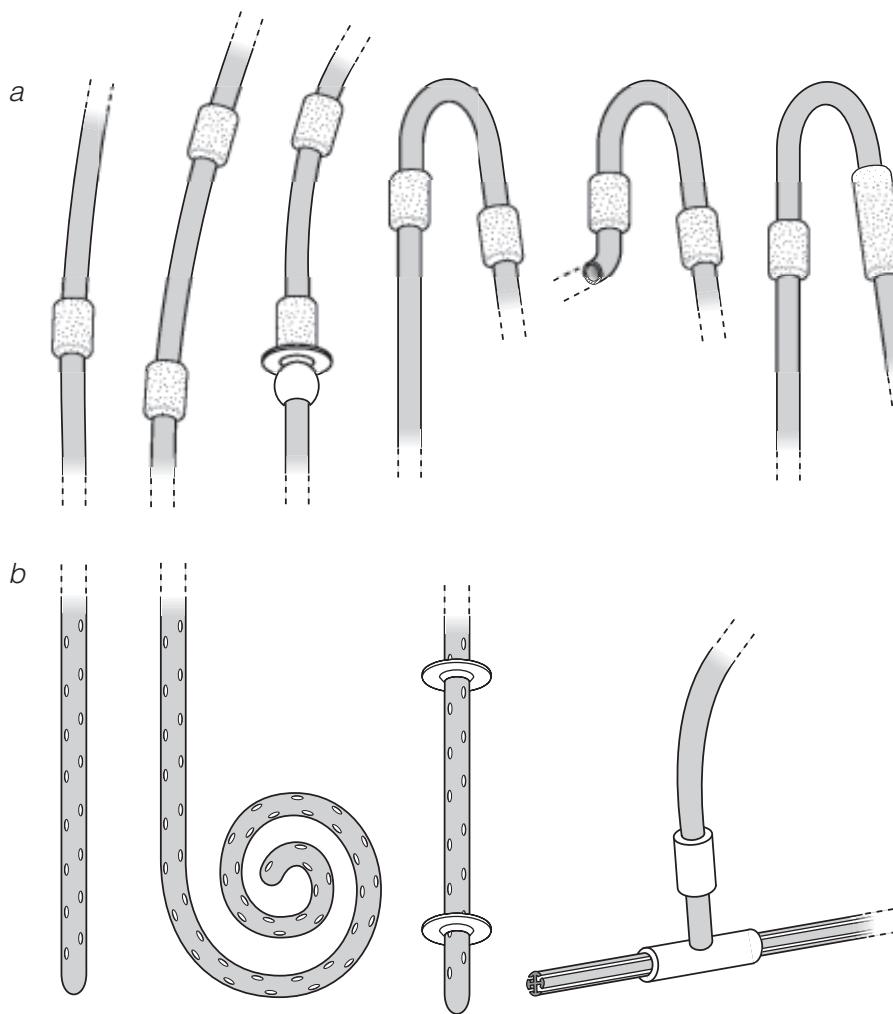

Figure 17 Peritoneal access. Shown are various configurations for extraperitoneal and intraperitoneal segments of peritoneal access catheters. (a) Extraperitoneal segment configurations (left to right): single-cuff, double-cuff, disc-bead double-cuff, swan neck, Cruz "pail handle," Moncrief-Popovich. (b) Intraperitoneal segment configurations (left to right): straight Tenckhoff, curled Tenckhoff, straight Tenckhoff with perpendicular discs, T-fluted.

OPERATIVE TECHNIQUE

Of the several insertion techniques described to date, the surgical approach remains the most widely used. Regardless of which approach is used, there are certain well-accepted basic principles that are applicable to all and that must be observed for all peritoneal access procedures.⁶⁹

The deep cuff should be positioned in the rectus abdominis, and the peritoneum and the posterior rectus sheath must be sealed around the catheter. The presence of muscle tissue on the perimeter results in better vascularization and stronger fibrous tissue ingrowth, which reduces the risk of hernia, leakage and catheter extrusion. The superficial cuff should be positioned about 2 cm from the exit site. The exit site should be directed downward and laterally in relation to the entry site. The intraperitoneal portion of the catheter should be positioned between the visceral and the parietal peritoneum, with its end in the pelvic cavity beyond the lower edge of the omentum.

Most insertion procedures are performed with the patient under local anesthesia in an outpatient setting and under sterile conditions (as in an OR). On the morning of the procedure, the patient showers with chlorhexidine soap. Even though no conclusive study on this practice has been done, most authorities recommend giving an antistaphylococcal antibiotic 1 hour beforehand and 6 to 12 hours afterward. Bowel preparation and prevention of constipation are essential. Emptying the bladder before the procedure is mandatory as well.

Step 1: Insertion of Catheter

Surgical approach Any type of catheter may be inserted via the surgical approach. A longitudinal paramedian incision 2 to 3 cm long is made about 2 to 3 cm below the level of the umbilicus, then carried more deeply through the anterior rectus sheath. The muscle fibers are retracted to expose the posterior rectus sheath and the peritoneum. A purse-string suture of 2-0 absorbable material is placed in the posterior rectus sheath [see Figure 18a], and a small incision is made in the peritoneum. The catheter is then inserted between the abdominal wall and the omentum, with its end positioned in the pelvic cavity beyond the lower edge of the omentum. The peritoneum is tightly closed around the catheter below the level of the deep cuff with the purse-string suture [see Figure 18b]. The anterior rectus sheath is then closed over the deep cuff [see Figure 18c], with care taken to orient the catheter upward.

Troubleshooting. Exact positioning is the key determining factor for proper catheter function. The catheter can be guided into its desired position with long forceps or with the help of a lubricated guide wire. If adhesions impeding catheter insertion are encountered, they are lysed under direct visual observation, and the incision is extended as needed. Peritoneoscopy or laparoscopy may be helpful in this situation. If there is any doubt regarding the exact position of the catheter, a plain radiograph will confirm it.

Seldinger technique The Seldinger technique does not allow direct visual observation of the peritoneal cavity and can

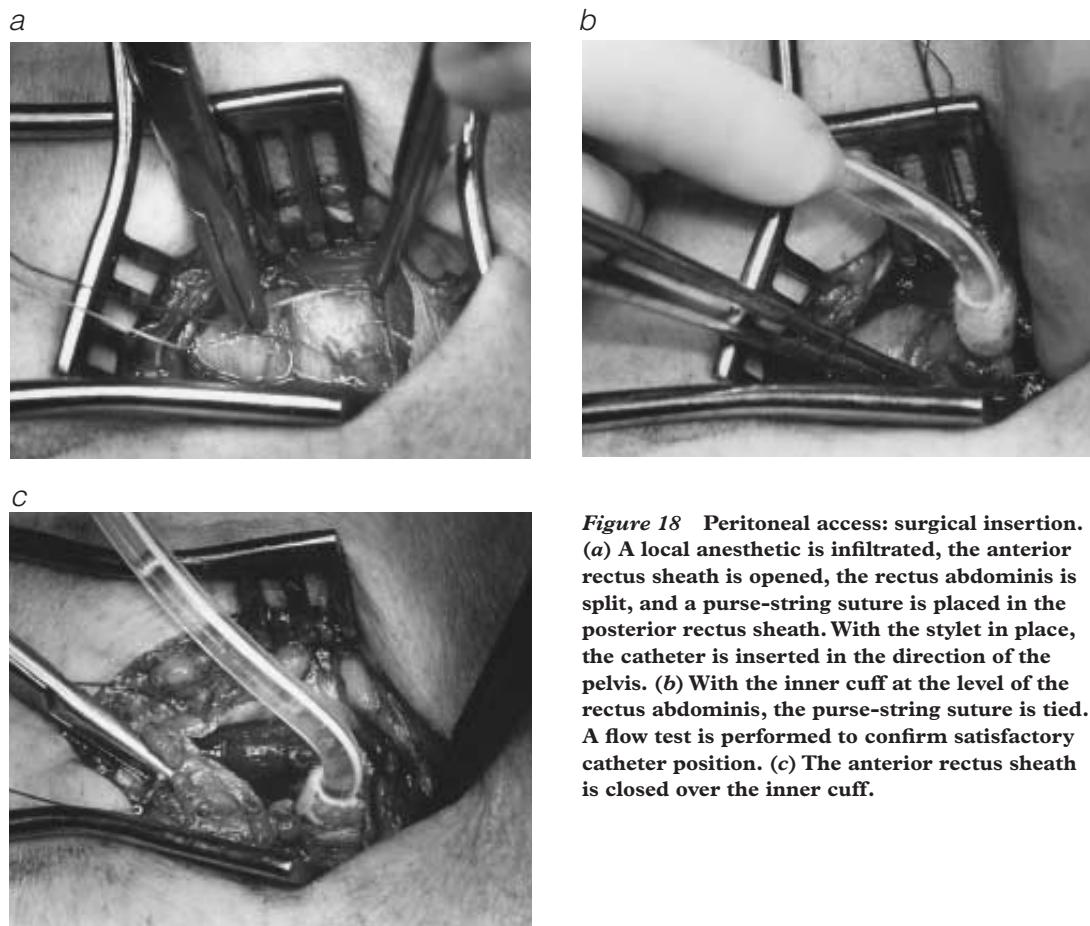

Figure 18 Peritoneal access: surgical insertion. (a) A local anesthetic is infiltrated, the anterior rectus sheath is opened, the rectus abdominis is split, and a purse-string suture is placed in the posterior rectus sheath. With the stylet in place, the catheter is inserted in the direction of the pelvis. (b) With the inner cuff at the level of the rectus abdominis, the purse-string suture is tied. A flow test is performed to confirm satisfactory catheter position. (c) The anterior rectus sheath is closed over the inner cuff.

only be used for Tenckhoff catheters. It is contraindicated in obese patients and patients with previous laparotomies in whom numerous adhesions are suspected. Initially, the Seldinger technique is similar to the surgical approach, but shorter incisions may be used. After the rectus abdominis is split, the peritoneal cavity is punctured with a needle and prefilled with fluid. A guide wire is then placed, and a dilator and a split sheath (similar to that used for internal jugular vein catheters) are inserted over the wire. The guide wire and the dilator are removed, and the catheter inserted blindly through the split sheath. The deep cuff is positioned in the rectus abdominis, and the split sheath is separated and removed.

Peritoneoscopic approach Peritoneoscopy-assisted implantation of dialysis catheters was developed by nephrologists, who remain its primary users.⁷⁰ In this technique, a peritoneoscope 2.2 mm in diameter (Y-TEC; Medigroup, Inc., Naperville, Illinois) is inserted through the rectus sheath into the peritoneal cavity and advanced under direct visual observation into the largest and clearest area of the intraperitoneal space. The scope is then removed, leaving a surrounding guide sheath through which the peritoneal dialysis catheter is passed to the selected location. Because of the small diameter of the sheath, the tissues close tightly around the deep cuff when the sheath is removed. Two randomized studies found that peritoneoscopic catheter placement reduced the risk of leakage, lowered the rate of catheter-related infection, and improved catheter survival.^{71,72} A drawback to this technique is that whereas the surrounding guide sheath can be positioned under direct visual observation (because it

is introduced at the same time as the peritoneoscope), the exact position of the catheter cannot be confirmed visually afterward, because the scope cannot be reintroduced after insertion of the catheter. Another drawback is that the equipment required is specific to this technique and therefore is not available everywhere.

Laparoscopic approach One of the advantages of laparoscopic catheter insertion is that the equipment required is readily available and familiar to most surgeons. Two 5 to 10 mm trocars are used, one in a paramedian location at the catheter insertion site and one in a pararectus location on the opposite side of the abdomen. This placement allows the catheter to be inserted under continuous videolaparoscopic monitoring. The use of N₂O gas for pneumoperitoneum eliminates pain during insufflation and thus permits this procedure to be performed with the patient under local anesthesia. In addition, laparoscopic insertion gives the surgeon the option of performing other procedures simultaneously as needed, such as lysis of adhesions, partial omentectomy, fastening of the catheter to the parietal peritoneum, and herniorrhaphy.^{73,74}

Step 2: Tunneling of Catheter

Tunneling is accomplished in the same manner regardless of the insertion technique used. The key is to determine and mark precisely on the skin both the path of the subcutaneous tunnel and the position of the superficial cuff in relation to the exit site. To this end, the surgeon may curve the catheter to the desired shape and lay it over the skin or may use a stencil designed for

this application. A short incision, no longer than the diameter of the catheter, is made at the exit site, and a tunneler or a similar device is advanced into the subcutaneous tunnel, with care taken to follow the curvature of the tunnel. The end of the catheter is attached to the tunneler and brought through the exit site [see Figure 19]. The exact position of the superficial cuff is then confirmed. No suture is placed at the catheter exit site. A two-layer closure is performed on the incision at the insertion site.

Moncrief-Popovich technique A variant technique has been described in which the extraperitoneal portion of the catheter is completely buried under the skin in a subcutaneous tunnel.⁷⁵ The rationale for this technique is that because of the absence of an opening in the skin, ingrowth of tissue into the cuffs of the catheter can occur without risk of bacterial contamination from the exit site. As initially described, the technique used a catheter with a superficial cuff 2.5 cm long, but it is now performed with standard dual-cuff Tenckhoff catheters. When a minimum of 4 to 6 weeks has elapsed or when the patient needs to be started on dialysis, the catheter end is exteriorized via an incision positioned 2 cm from the superficial cuff. This technique appears to have theoretical advantages in terms of rates of infection and peritonitis, but the evidence available at present is inconclusive.^{76,77}

Step 3: Maintenance of Catheter

The patency of the catheter must be confirmed during the insertion procedure. It should be possible to inject 60 ml of 0.9% saline without resistance and to aspirate 30 to 40 ml without difficulty. A dry dressing is applied, and the catheter is fastened to the skin with tape to prevent trauma to the exit site and the consequent risk of bacterial contamination. Immobilization of the catheter should be maintained for 4 to 6 weeks (the approximate time required for complete healing of the subcutaneous tunnel and the exit site). The dressing should not be changed more than once a week for the first 2 to 3 weeks. Daily exit-site care should not be started until 2 to 8 weeks after the procedure.

Experience with the Moncrief-Popovich technique has shown that there is no advantage in irrigating the catheter on a regular basis before it is actually used for dialysis. The break-in period should be at least 2 weeks; ideally, it should be 4 to 6 weeks to minimize the risk of leakage.

Step 4: Removal of Catheter

When catheter removal is indicated, the initial incision is repeated and the catheter is dissected circumferentially to the deep cuff, which is then dissected out of the rectus abdominis with the electrocautery. The catheter is sectioned, the intra-abdominal portion removed, and the anterior and posterior rectus sheath repaired with sutures. The wound is closed. The superficial cuff is dissected out from the outside, and removal of the subcutaneous portion of the catheter is completed. The exit site is left to heal by second intention.

COMPLICATIONS

The complications relevant to the access surgeon may be divided into infectious and noninfectious complications.

Infectious

Infectious complications are directly responsible for as many as 2% of deaths in patients on peritoneal dialysis, about two thirds of cases of catheter loss, and one third of transfers from peritoneal dialysis to hemodialysis.

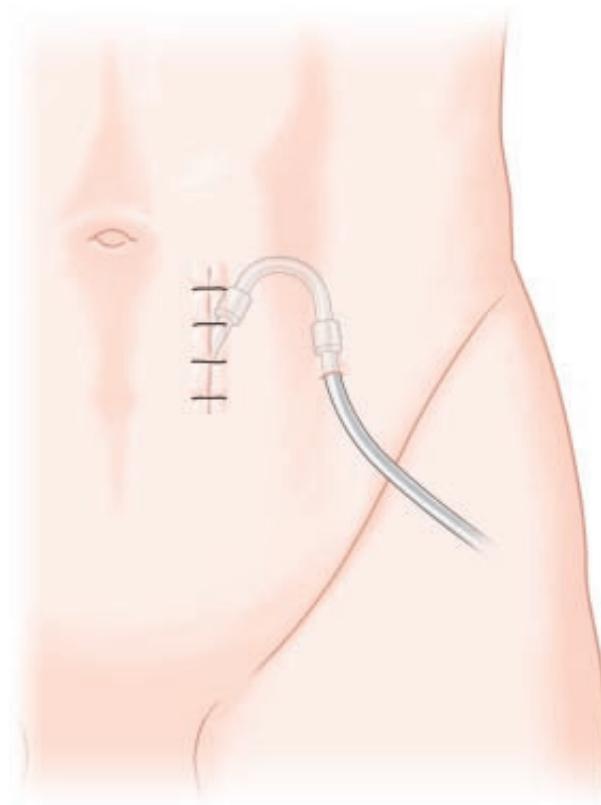

Figure 19 Peritoneal access. The end of the catheter is attached to a tunneler and brought out through the exit site, emerging downward and laterally.

Peritonitis Peritonitis [see 8:18 *Intra-abdominal Infection*] is the most common infectious complication of peritoneal access, with about one episode occurring every 20 to 30 patient-months. The causative microorganisms are gram-positive cocci (especially *S. aureus* and *S. epidermidis*) in 60% to 70% of cases and gram-negative rods in 15% to 25% of cases. The presence of a polymicrobial or anaerobic flora or a high level of amylase (> 50 UI/L) in the dialysate is strongly suggestive of a perforated viscus, pancreatitis, or another intra-abdominal catastrophe.

Initial empirical treatment should be guided by the results of Gram staining and adjusted according to the culture results.⁷⁸ In the presence of recurring peritonitis caused by *S. aureus*, an underlying occult tunnel infection should be excluded. If the causative organism is a coagulase-negative staphylococcus, the presence of a bacterial biofilm on the catheter wall should be suspected, a condition that sometimes responds to instillation of a thrombolytic agent. In the presence of peritonitis refractory to medical treatment, peritonitis associated with a tunnel infection, fungal peritonitis, or a perforated viscus, removal of the catheter must be considered.

Exit-site infection Exit-site infection is signaled by the presence of purulent or bloody drainage from the exit site, arising either spontaneously or after pressure on the sinus; swelling; erythema 13 mm or more in diameter from border to border; and regression of epithelium in the sinus.⁷⁹ This condition leads to peritonitis in 25% to 50% of cases, and the organisms involved are similar to those found in peritonitis.

Treatment consists of empirical antibiotic therapy based on the results of Gram staining and adjusted according to the culture results. It must be continued for a minimum of 2 weeks; in some

cases, prolonged treatment (4 to 6 weeks) may be necessary. If the response to therapy is not satisfactory, an external-cuff or tunnel infection should be suspected and treated as appropriate. Failure of medical treatment, especially when associated with peritonitis involving the same microorganism, is an indication for catheter removal. It should be noted that positive cultures coming from normal-appearing exit sites indicate colonization and do not call for treatment.

Tunnel infection Tunnel infection is signaled by the presence of erythema, edema, or tenderness over the subcutaneous catheter pathway, sometimes associated with sanguineous, purulent, or thick drainage occurring either spontaneously or when pressure is applied to the catheter tunnel. This type of infection often is hidden and develops in association with exit-site infection; in such cases, ultrasonography of the subcutaneous tunnel helps to specify the diagnosis.

Treatment of this condition is more difficult than treatment of exit-site infection, in that antibiotics are typically ineffectual when used alone. If the pathogen is a gram-positive organism, unroofing the infected portion of the catheter tunnel and shaving the superficial cuff can prolong catheter survival by a few weeks; however, if the pathogen is a gram-negative bacterium, this technique is ineffectual. In most cases, complete removal of the catheter is the definitive treatment, especially if the deep cuff is infected. In the absence of underlying active peritonitis, it is possible to carry out insertion of a new catheter in uninfected territory simultaneously with removal; to date, the results of this approach have been promising. A more conservative option is to leave an interval of about 3 weeks between removal of the old catheter and implantation of the new one.

Noninfectious

Early leakage (< 30 days after implantation) Early leakage is the result of failure to close the peritoneum tightly enough around the catheter. It is diagnosed clinically on the basis of the presence of dialysate at the exit site.

Treatment consists of complete stoppage of peritoneal dialysis treatments for 1 to 2 weeks to reduce intra-abdominal pressure and thereby promote spontaneous healing, coupled with administration of an antistaphylococcal antibiotic to address the associated risk of exit-site or tunnel infection. When treatment fails, exploratory surgery with repair of the tissues around the deep cuff remains the best option.

Late leakage (> 30 days after implantation) Late leakage of dialysis fluid in the subcutaneous tissues is more difficult to diagnose than early leakage. It may appear in the form of edema of the abdominal wall or genital edema, a condition that should be distinguished from patent processus vaginalis. It may also be manifested by drainage problems during treatment. The exact site of the leakage is difficult to establish clinically but can usually be determined by means of computed tomography after infusion of 2 L of dialysis fluid containing radiocontrast material.

Treatment consists of surgical repair. If treatment fails, the catheter must be removed.

Malpositioning Migration of the end of the catheter out of the pelvic cavity results in pain secondary to irritation of the abdominal wall or, more often, in poor catheter drainage. The diagnosis is made by means of a plain radiograph. If the catheter has migrated into the left upper quadrant, spontaneous repositioning can be expected as a consequence of peristalsis, which acts

to favor downward movement of the catheter; for this reason, taking laxatives is recommended. If the catheter has migrated into the right upper quadrant, peristalsis favors movement in the opposite direction, and spontaneous repositioning is much less likely.

If conservative treatment fails, the catheter may be repositioned under fluoroscopic guidance by means of intraluminal manipulation with a stiff guide wire. If the problem recurs, surgical treatment (most often laparoscopic) is indicated to reposition the catheter and, if necessary, fasten it to the bladder dome or to the parietal peritoneum.

Hernias Because of the increase in intra-abdominal pressure inherent in peritoneal dialysis, hernia is a common complication, affecting 10% to 25% of patients. The main types of hernias encountered, in descending order of frequency, are umbilical, inguinal (e.g., patent processus vaginalis), catheter incision site, ventral, catheter exit site, epigastric, incisional, cystocele, enterocele, and obturator. The clinical importance of this complication is that as many as 10% to 15% of hernias, particularly those located at the catheter site or related to other abdominal incisions, are associated with intestinal obstruction arising from strangulation. For this reason and because of the tendency of hernias to enlarge with time, surgical repair is indicated in all cases. In the postoperative period, intermittent low-volume peritoneal dialysis may be continued with the patient in a supine position, but ideally, complete interruption of dialysis for 3 to 4 weeks is advised.

Obstruction Obstruction-related problems can affect either the drain phase alone (isolated outflow failure) or both the infusion and the drain phase (inflow/outflow failure).

Inflow/outflow failure. Obstruction of both the infusion and the drain phase is usually secondary to an obstruction of the catheter by fibrin, blood clot, or tissue ingrowth inside the lateral holes. A catheter kink should also be excluded. Forced injection of heparinized serum sometimes eliminates the obstruction. If it does not, injection of thrombolytic agents into the catheter may be attempted. More invasive treatments that may be employed include cleaning out the catheter with a Fogarty catheter, using an intraluminal brush, or replacing the catheter.

Isolated outflow failure. Extraluminal obstruction of the catheter may be caused by migration out of the pelvic cavity (sometimes in fibrous adhesion pockets), omental wrapping, stool-filled bowel enwrapping the catheter (constipation), or occlusion of the catheter holes by adjacent organs. Adjacent tissues can act as a ball valve, allowing ingress of fluid but occluding catheter pores when drainage is attempted. A plain radiograph, with or without dynamic catheterography, usually clarifies the diagnosis. Catheter migration, if present, is treated as described (see above). Constipation is treated with laxatives. For other causes of isolated outflow failure, the laparoscopic approach is increasingly used; this approach enables the surgeon to reposition the catheter under direct visual observation and then proceed with lysis of adhesions, partial omentectomy, and fastening of the catheter.

Superficial cuff extrusion Extrusion of the superficial cuff most often develops in the presence of an exit-site infection but may develop in isolation if the cuff is positioned too close to the exit site. Such extrusion results in chronic irritation and ischemia with necrosis of the surrounding tissues. Generally, part of the cuff can be exteriorized with simple traction on the catheter. In such cases, the cuff should be shaved off the

catheter with a scalpel and the surrounding necrotic tissues debrided.

OUTCOME EVALUATION

It is estimated that approximately 20% of transfers from peritoneal dialysis to hemodialysis are secondary to a catheter-related problem. It is therefore essential that the insertion of peritoneal dialysis catheters be performed by a competent and experienced

team. In fact, despite the development of new insertion techniques and the availability of increasingly sophisticated catheters, the most important prognostic factor remains the quality of the surgical procedure and the postoperative care. Analysis of the different implantation protocols described in the literature shows that the so-called center effect is in fact a remarkable confounding factor. Regardless of the technique used, the catheter survival rate should be at least 80% at 1 year.

23 ENDOVASCULAR PROCEDURES FOR LOWER-EXTREMITY DISEASE

Heather Y. Wolford, M.D., and Mark G. Davies, M.D., Ph.D., F.A.C.S.

Endovascular procedures are increasingly being applied to the treatment of lower-extremity vascular disease: for many common vascular conditions, minimally invasive approaches have become important supplements to (or even supplanted) conventional open surgical approaches.¹ The evolution of these endovascular techniques is likely to result in a corresponding evolution in the therapeutic decision-making process for patients with lower-extremity vascular disease. Research into the long-term outcomes of lower-extremity endovascular procedures will be necessary for a better understanding of the indications for treatment and of the risks and benefits for patients.

Arterial Procedures

Arterial conditions of the lower extremity that may be treated with endoluminal therapy include chronic ischemia, acute ischemia, and aneurysmal disease. The fundamental skill set and the basic techniques employed are the same for all of these conditions. Accordingly, the ensuing discussion first reviews the basics of endovascular therapy and then focuses on specific areas of chronic, acute, and aneurysmal arterial disease of the lower extremity that are amenable to endoluminal intervention.

BASIC ENDOVASCULAR PROCEDURES

Preprocedural Evaluation

Clinical evaluation The first step in the intervention consists of a thorough history and a careful physical examination. Patients should be specifically asked about chronic renal insufficiency, current or past anticoagulant therapy, and previous vascular and endovascular interventions. Lower-extremity pulses should be assessed, and the degree of ischemia present should be determined [see Table 1]. Basic serum biochemical and hematologic data should be obtained and reviewed. The results of any previous imaging studies should also be obtained and reviewed. Patients with serum creatinine concentrations higher than 1.5 mg/dl should be considered for a renal protection protocol [see Table 2], and at the time of the procedure, the use of an alternative contrast

agent to decrease total nephrotoxic dye volumes (see below) may be considered. Patients taking oral hypoglycemic agents are asked to stop doing so on the day of the procedure and not to resume for 48 hours after the procedure. In general, to prevent bleeding complications, it is preferred that the international normalized ratio (INR) be lower than 1.6 and the platelet count higher than 50,000/mm³ at the time of intervention.

If a therapeutic intervention is planned, the patient should be given aspirin, 81 mg/day, and clopidogrel, 75 mg/day, for at least 3 days beforehand. If there is not enough time to do this, the patient may be given clopidogrel, 150 to 300 mg, within the 2 hours preceding the procedure.

Investigative studies Imaging is required before any intervention. Noninvasive vascular ultrasonographic studies document the initial status of the arterial blood supply and allow localization of the culprit lesions. The ankle-brachial index (ABI) (or, in diabetics and patients with incompressible ankle vessels, the toe-brachial index), pulse-volume recordings (PVRs), and segmental pressures quantify arterial perfusion and define areas of stenosis or occlusion within each leg. Duplex ultrasonography is an alternative to PVRs and segmental pressures and provides further diagnostic information that allows the interventionalist to identify involved vessel segments and lesions amenable to percutaneous therapy. These objective measurements serve as a baseline against which postinterventional results may be assessed.

Generally, noninvasive studies provide sufficient information to allow one to proceed with diagnostic angiography and possible endoluminal intervention. In many cases, however, additional studies are required to refine the interventional plan and to reduce the time and resources required. Computed tomographic angiography (CTA) provides two-dimensional images of the arterial system, which are then postprocessed to generate three-dimensional reconstructions. It is particularly effective for imaging tibial vessels. The main drawbacks of CTA are the time necessary to reconstruct the images, the possibility of interference from metal implants, and the contrast load involved. Magnetic resonance angiography (MRA) also provides potentially helpful preprocedural

Table 1 Classification of Critical Ischemia

Grade	Limb Status	Prognosis for Limb	Capillary Refill	Motor Changes	Sensory Loss	Arterial Doppler US	Venous Doppler US
I	Viable	Not threatened	Intact	None	None	+	+
IIa	Threatened	Salvageable	Slow	None	Partial	-	+
IIb	Threatened	Salvageable with emergency intervention	Slow or absent	Diminished function	Partial	-	+
III	Irreversible	Nonsalvageable	Absent	No function	Complete	-	-

Table 2 Renal Protection Strategies

Oral Therapy	Other Strategies
N-acetylcysteine, 600 mg p.o., b.i.d., for total of four doses; first dose given 12 hr before procedure	Hydration with normal saline, starting 1 hr before procedure and continued for 3 hr after procedure
Theophylline, 200 mg I.V., given 30 min before procedure, or 200 mg p.o., b.i.d., starting 24 hr before procedure and continued for 48 hr after procedure	Sodium bicarbonate drip, 154 mEq/L, starting 1 hr before procedure and continued for 6 hr after procedure Use of alternative contrast agent

information and has the advantage of using gadolinium, which is a relatively low risk contrast agent for patients with renal insufficiency. The main drawbacks of MRA are relatively poor patient tolerance of the machine, the tendency to overestimate lesion severity, the long image acquisition time, and the variability in image quality as one proceeds distally in the leg. Patients with limited arterial access will benefit from a cross-sectional imaging algorithm: such an approach allows one to perform a focused angiogram and to make more efficient use of resources during a therapeutic intervention.

Preprocedural Planning

Choice of arterial access site The common femoral artery (CFA) contralateral to the affected side is the arterial access site most commonly employed. If the patient has an occluded CFA or a “hostile groin,” a radial, high brachial, or axillary artery approach may be chosen instead; however, access at these sites is associated with a relatively higher incidence of complications. Ideally, to facilitate manual compression, the access site should lie over a flat bony prominence. An antegrade ipsilateral CFA approach is a useful alternative to contralateral access if there is a contraindication to working from the contralateral side (e.g., significant contralateral iliac disease, a heavily scarred groin, recent application of a vascular closure device, or a bifurcated aortic graft) and if preoperative imaging has demonstrated that there is an adequate working distance (generally, at least 15 to 20 cm) between the CFA access point and the target lesion. If an antegrade approach fails, a retrograde approach may be employed to target ipsilateral iliac arterial disease from the CFA or superficial femoral artery (SFA) disease from the popliteal artery.

Selective Lower-Extremity Angiography

Technique Standard methods of obtaining vascular access for angiography are described in more detail elsewhere [see 6:8 *Fundamentals of Endovascular Surgery*]. For selective angiography of the lower extremity, a 4 or 5 French diagnostic sheath is initially placed in the CFA contralateral to the affected extremity. A 4 or

5 French multi-side-hole diagnostic catheter (in a straight, curved, or pigtail configuration) is then placed over a wire into the infrarenal aorta. After the initial aortic films are obtained in the anteroposterior (AP) projection, the diagnostic catheter is moved down to a point 2 to 3 cm above the aortic bifurcation, and a series of pelvic images are taken in the AP and lateral projections.

The aortic bifurcation is generally traversed with a curved catheter; the curve of the tip should be similar to the angle of the bifurcation. A wire is maneuvered into the iliac system and positioned in the external iliac artery or the CFA, and the curved diagnostic catheter is advanced to the point where its tip lies within the distal external iliac artery and its holes are beyond the ostium of the internal iliac artery.

Once the catheter has been correctly positioned, further contrast injections are performed. Complete lower-extremity images, which should include tibial and pedal vessels (in AP and magnified lateral foot views), are taken before the intervention so that preprocedural status can be compared with postprocedural status and any distal complications can be recognized. Contrast doses commonly employed for digital subtraction arteriography (DSA) depend on the specific arterial segment being addressed [see Table 3].

Alternative contrast agents. Standard angiography is performed with an iodinated nonionic contrast agent. In patients with creatinine concentrations higher than 1.5 mg/dL, an alternative contrast agent may be preferable. Carbon dioxide may be used to image the abdominal aorta, the iliac arteries, and, occasionally, the proximal leg arteries. As the vessels become smaller, however, CO₂ images become less clear. Elevating the legs may help in obtaining adequate imaging to the level of the knees. For CO₂ imaging, a 60 mL syringe is connected to a three-way stopcock, and CO₂ from a tank is loaded into the syringe through the stopcock assembly while the stopcock is submerged in normal saline and manually kept under pressure. The submerged system is flushed with CO₂ several times to purge any residual air. The CO₂-containing syringe is connected to an indwelling catheter, and the CO₂ is then injected forcefully by hand while the fluoroscopy unit is activated. The resulting images must undergo postprocessing to be viewed correctly. CO₂ imaging should not be used above the diaphragm or in the visceral artery segment of the aorta.

Gadolinium may also be used to image the pelvic vessels and the proximal leg arteries. Like CO₂ images, gadolinium images become less clear as the lower-extremity arteries become smaller and more distal. Gadolinium is loaded into the power injector or injected by hand, like standard contrast agents. Doses higher than 0.3 mmol/kg may be nephrotoxic.²

Troubleshooting If crossing the aortic bifurcation proves difficult, changing to a hydrophilic wire (e.g., a 0.035-in. soft or

Table 3 DSA Imaging Techniques with Power Injector

Arterial Segment Imaged	View	Contrast Dosage	Delay
Infrarenal aorta	AP	10–20 mL/sec for 2 sec	No
Iliac arteries	AP/oblique	3–10 mL/sec for 2–3 sec	No
CFA and SFA	AP	3–10 mL/sec for 2–3 sec	Flow dependent
Tibial arteries	AP	3–5 mL/sec for 3–4 sec	Yes

AP—anteroposterior CFA—common femoral artery SFA—superficial femoral artery

stiff glide wire) may help. Occasionally, if one has trouble advancing the 5 French catheter, using a 4 French hydrophilic catheter may mitigate the problem. Attempts at passing the bifurcation should not be abandoned until several different angled catheters have been tried. If all such attempts fail and contralateral access is imperative, ipsilateral puncture with introduction of a snare to grasp the contralateral wire in the abdominal aorta should be considered. Alternatively, DSA may be performed from the aortic bifurcation; however, the contrast loads will be significantly higher in this situation.

Crossing of Lesion

The diagnostic imaging studies and the preliminary angiogram should suffice to identify a lesion that is amenable to endovascular therapy. Once such a lesion is identified, wire access across the target lesion is required to establish a platform for subsequent intervention.

Technique Iliac lesions may be approached either in a retrograde fashion from the ipsilateral CFA or in an antegrade fashion from the contralateral CFA if there is adequate working distance between the bifurcation and the iliac lesion. For more distal lesions, when a contralateral CFA approach is used, a guide sheath is required to stabilize catheters and wires. A wire is placed in the external iliac artery on the affected side (see above), and the diagnostic catheter placed across the bifurcation is replaced with a stiff sheath, such as a 6 French Balkin sheath (Cook Incorporated, Bloomington, Indiana), which has a curve that naturally rests over the bifurcation. Occasionally, it is difficult to get the sheath to cross the bifurcation. In such a situation, the initial wire may be exchanged for a stiffer wire, such as a 0.035-in. Amplatz wire (Cook Urological, Spencer, Indiana), and the sheath may be placed over this wire. The use of a reinforced or stiff guide sheath eliminates the mechanical disadvantage of a wire that moves away from the limb with all manipulations, and it solidifies unilateral limb access for subsequent angiography during the therapeutic portion of the procedure.

Once the sheath is in place, a long, angled end-hole catheter and a glide wire are directed toward the specific vessel segment being treated and carefully manipulated so as to cross the target lesion. Road mapping, fluoroscopy fade, or intermittent puffing of contrast material through the guide catheter can delineate the contours of the vessel, identify the correct path to take, and help keep the wire within the true lumen. In general, a stenosis can be crossed by a curved or J-tip wire, a 0.035-in. hydrophilic glide wire, or a Wholey wire (a 0.035-in. wire with a floppy tip; Mallinckrodt, St. Louis, Missouri). The hydrophilic coating on the glide wire makes it more prone to dissection than the other wires are. With angled catheters, it is essential to use torque devices to direct the tip of the wire in the appropriate direction. In some cases, using a TAD II wire with a 0.018-in. distal tip and a 0.035-in. main body (Mallinckrodt, St. Louis, Missouri) makes access through a tight lesion easier to obtain; in addition, it provides a transition to a larger, more robust wire, which can be a very effective platform. For tibial stenoses, a 0.014-in. or 0.018-in. system is generally employed to cross tighter lesions. To stabilize the 0.014-in. wire, a 3 or 4 French catheter may be used as a guide catheter, placed just proximal to the lesion.

Occlusions can be difficult to cross, particularly when significant calcification is apparent on the plain films obtained before angiography. The techniques employed are the same as those used to cross a stenosis. The goal is to traverse the occlusion and gain access to the true lumen distally; accordingly, a J-tip or Wholey

wire may be preferred, in that hydrophilic wires tend to create dissection planes. Often, the occlusion cannot be crossed, and a subintimal plane must be developed. A glide wire is used to gain access near the proximal portion of the lesion at a branch point and allowed to deform in such a way as to form a loop; the wire is then pushed forward, supported by a 4 or 5 French catheter. Often, the true lumen is accessed without any difficulty, and the location of the wire within the lumen is confirmed by contrast injections. Occasionally, however, reentry into the true lumen proves difficult. Various manipulations and techniques may be employed to help with this technical issue. In addition, two systems have been developed with this potential problem in mind. The CrossPoint IVUS catheter (Medtronic, Minneapolis, Minnesota) combines an intravascular ultrasound probe with a puncture needle and allows one to visualize the true lumen, enter it with a hollow needle, and pass a wire to maintain access. The Outback catheter (LuMend, Redwood City, California) has a special tip that microdissects the plaque to facilitate reentry into the true lumen. If these options fail, retrograde puncture and retrograde passage of a wire, with interval snaring to "floss" the occlusion, may be considered.

Troubleshooting In crossing occlusions, the following three points must be emphasized.

1. Care must be taken to ensure that the operator is in the true lumen.
2. To preserve subsequent bypass targets, the next segment of the vessel must not be compromised by an overly aggressive attempt to regain access from a subintimal dissection plane.
3. Wire access across the lesion must be maintained at all times.

A low-dose intravenous bolus of heparin (2,000 to 5,000 IU) must be given before any intervention to help prevent the thrombosis that may result from manipulation and transient occlusion of the lesion.

Angioplasty and Stenting

Technique *Angioplasty.* Angioplasty is the initial treatment for most lower-extremity lesions. It may be the only therapeutic intervention required, or it may be employed as a prelude to stent deployment as a means of ensuring that the arterial lumen is wide enough to allow free passage of a platform. Angioplasty balloons exist in several varieties, which are reviewed in more detail elsewhere [see 6:8 *Fundamentals of Endovascular Surgery*]. In general, a noncompliant balloon is chosen that is 1 to 2 mm smaller than the normal or anticipated final vessel diameter for the area of the vasculature being addressed. The normal vessel diameter may be estimated on the basis of operator experience, measured with a radiopaque ruler placed alongside the vessel, or quantitated with the calibration software available on most imaging systems.

Once the balloon has been successfully maneuvered into position across the lesion, it is inflated with a manual inflation device to allow controlled delivery of a defined pressure load. Inflation is continued until the waist of the balloon disappears or maximal balloon inflation pressure (8 to 15 atm on most standard balloons) is reached. If an optimally sized balloon or stent will not cross a highly stenotic lesion, preangioplasty dilatation with a lower-profile, smaller-diameter balloon is required.

If the lesion is in close proximity to or involves a bifurcation (e.g., the aortic bifurcation, the femoral bifurcation, or the tibioperoneal trunk), care must be taken to prevent occlusion of the other branching vessel during dilatation of the target lesion. To this end, most interventionalists advocate use of the so-called kissing balloon technique, which involves simultaneous dilatation or

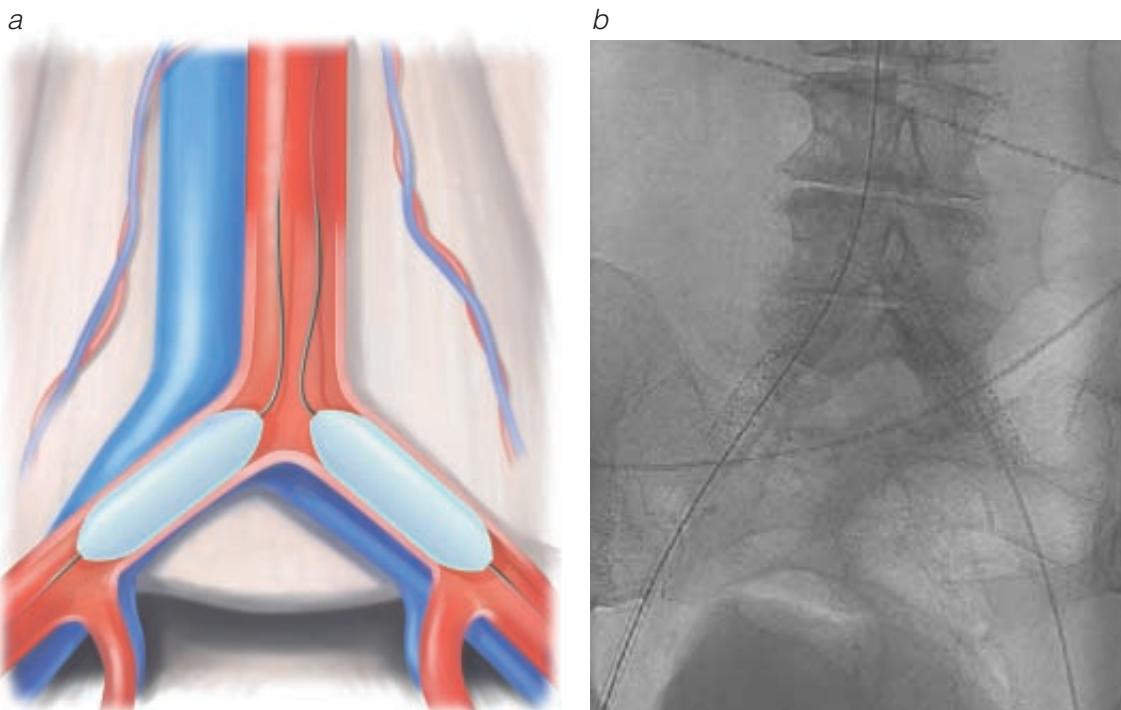

Figure 1 Basic endovascular techniques: angioplasty and stenting. Shown is the so-called kissing balloon technique. The patient presented with bilateral claudication, a decreased ABI on exercise treadmill testing, and a duplex ultrasonogram that suggested iliac occlusive disease. (a) Illustration shows two balloons “kissing” in the common iliac arteries. (b) Radiograph shows two stents “kissing” in the iliac arteries.

stenting of both branching vessels of the bifurcation to preserve both lumina. This technique is most commonly employed for proximal common iliac artery lesions [see Figure 1]. Alternatively, one may place a guard wire in the unaffected vessel and use this wire as a safety measure if there is a danger of luminal compromise, or one may deploy a balloon in the unaffected ostium while the affected ostium is treated.

Stenting. Basic stent choices are discussed more fully elsewhere [see 6:8 *Fundamentals of Endovascular Surgery*]. Stents may be placed either primarily or as a secondary procedure when initial angioplasty yields inadequate results (generally defined as either greater than 30% residual stenosis or the occurrence of an angioplasty-related complication, such as arterial wall perforation or flow-limiting dissection). Stents are generally sized according to the normal diameter of the adjacent vessel; 10% to 15% oversizing is acceptable. If the stent will be crossing two vessel segments with mismatched diameters (e.g., the common iliac artery and the external iliac artery), it is preferable to use a self-expanding stent, which is better able to adjust to such mismatching. Treatment of specific arteries is discussed more fully in connection with management of chronic lower-extremity ischemia [see Procedures for Chronic Lower-Extremity Ischemia, below].

Adjuncts to angioplasty and stenting. Over the past few years, several innovative devices have been developed that expand on the basic concepts of angioplasty and stenting in the lower extremities. One such device is the PolarCath cryoplasty balloon (Boston Scientific, Natick, Massachusetts) [see Figure 2a]. This device delivers cold thermal energy to the vessel wall in the form of nitrous oxide (-10° C) and is inflated to a pressure of 8 atm. It is presumed that the freezing of the vessel allows a more controlled vessel wall injury

and concomitantly promotes apoptosis and reduces the restenosis response. To date, the PolarCath has been employed mainly in the SFA; it is currently being tested for use in the tibial vessels. In initial reports, anatomic patency rates in the femoropopliteal arteries have exceeded 80% at 1 year for TransAtlantic Inter-Society Consensus (TASC) grade A, B, and C lesions.³

Another such device is the Peripheral Cutting Balloon (Boston Scientific, Natick, Massachusetts) [see Figure 2b], which is increasingly being used on lower-extremity vascular lesions, particularly those that proved resistant to balloon angioplasty. This device consists of a noncompliant balloon that has four thin blades placed longitudinally around it; it is available in sizes ranging from 2 mm to 8 mm, and it operates over a 0.018-in. platform. The theoretical rationale for its use is that fracturing or cutting the lesion in a controlled pattern may reduce the severity of the vessel injury while achieving a satisfactory luminal response and mitigating the restenosis response. Initial results in stenotic vein grafts have been encouraging, with 95% patency reported at 11 months' follow-up in one small study.⁴

Directional atherectomy devices are being used to treat chronic atherosclerotic leg ischemia in the belief that debulking the lesion will allow greater increases in luminal diameter than the conventional methods of angioplasty and stenting, which merely displace plaque. Multiple different systems are available, all of which appear to be yielding roughly equivalent results. One of the more widely used directional atherectomy devices is the SilverHawk Plaque Excision System (FoxHollow Technologies, Redwood City, California), which consists of a catheter that is compatible with a 0.014-in. wire and that has a rotating blade at the tip. As the blade shaves plaque off the vessel wall, the shavings are stored in the tip of the catheter. When the storage unit in the tip becomes full, the catheter is removed and cleaned, then reinserted. Initial intermediate-term results have been satisfactory; however, wider

(a) Shown is the PolarCath peripheral dilatation system, comprising an inflation unit, a cryoplasty balloon, a cord attached to a separate power module, and a nitrous oxide cartridge. (b) Shown is the Peripheral Cutting Balloon, with an enlarged view of an atherotome. (Images provided courtesy of Boston Scientific, Natick, Massachusetts).

use of this device will depend on the results of the multicenter TALON registry.⁵

Drug-eluting stents have become popular for use within the coronary circulation, but at present, they are only in the initial stages of investigation for treatment of lower-extremity arterial disease. Initial trials with the sirolimus-coated S.M.A.R.T. stent (Cordis, Miami Lakes, Florida) showed a nonsignificant trend toward decreased restenosis rates.⁶

Troubleshooting Angioplasty can result in either non-flow-limiting or flow-limiting dissections. If dissection occurs, reinflation of the balloon over the dissection for 5 to 10 minutes may anneal the flap to the wall. If balloon reinflation fails and flow is still disrupted, a stent should be placed.

In situ thrombosis of the vessel occasionally occurs after angioplasty or stent placement. If it develops in a patient who underwent angioplasty alone, the thrombosed vessel may be stented open. If this measure fails or if the in situ thrombosis develops after stent placement, a thrombolysis catheter is placed across the lesion and a single bolus of a thrombolytic agent administered. If this approach yields suboptimal results, an indwelling catheter is placed for a 12- to 24-hour infusion [see Procedures for Acute Lower-Extremity Ischemia, *below*]. Alternatively, mechanical thrombectomy with a rheolytic catheter may be considered. Finally, restenting with an open or covered stent is an option, but it may result in distal embolization.

Perforation of the vessel can occur during angioplasty or recanalization. Perforations that are small or that occurred during a failed recannulization need not be treated. Perforations associated with persistent extravasation of contrast may be managed primarily with balloon tamponade (20 minutes of inflation, with intermittent deflations to allow distal circulation and reversal of anticoagulation) and secondarily with placement of a covered stent.

Endoluminal intervention to treat plaque can result in distal embolization of cholesterol or plaque or distal dislodgment of thrombi. Mechanical or pharmacologic thrombolysis remains the mainstay option in such cases. If, however, one is concerned about

a possible nonthrombotic embolic event, aspiration or open embolectomy may be required to achieve satisfactory reconstitution of flow.

When a vessel is heavily calcified, a self-expanding stent may be unable to deploy and may be effectively “jailed” in the lesion. In this situation, wire access must be maintained, and a low-profile balloon should be used to enlarge the operating lumen so that a high-pressure balloon can then be introduced. The introduction of a series of balloons with successively larger diameters will eventually allow the stent to be deployed. Balloon perforation often occurs in these cases, and care should be taken to extract the perforated balloon intact.

Unplanned stent dislodgment is rare but not unknown. If it occurs, the errant stent may be fixed in place by placing an additional overlapping stent. Alternatively, a balloon may be inflated distal to the tip of the dislodged stent and used to move the stent to another vessel, where it may be safely deployed.

Complications The most common complications of angioplasty and stenting in the lower extremities are access-related issues, including hematoma, arteriovenous fistula formation, and pseudoaneurysm. The incidence of hematoma can be minimized by using the smallest sheath possible, waiting for normalization of the activated clotting time before pulling the sheath, and holding manual pressure for 30 minutes after the procedure. Devices designed for vessel closure after percutaneous intervention are available but have not been proved to reduce the incidence of access-related complications.⁷ With several of these closure devices, it is recommended that access of the groin not be attempted for up to 90 days after insertion.

PROCEDURES FOR CHRONIC LOWER-EXTREMITY ISCHEMIA

Preprocedural Evaluation

Patients presenting with chronic lower-limb ischemia are evaluated as previously outlined [see Basic Endovascular Procedures, Preprocedural Evaluation, *above*]. Patients with claudication are

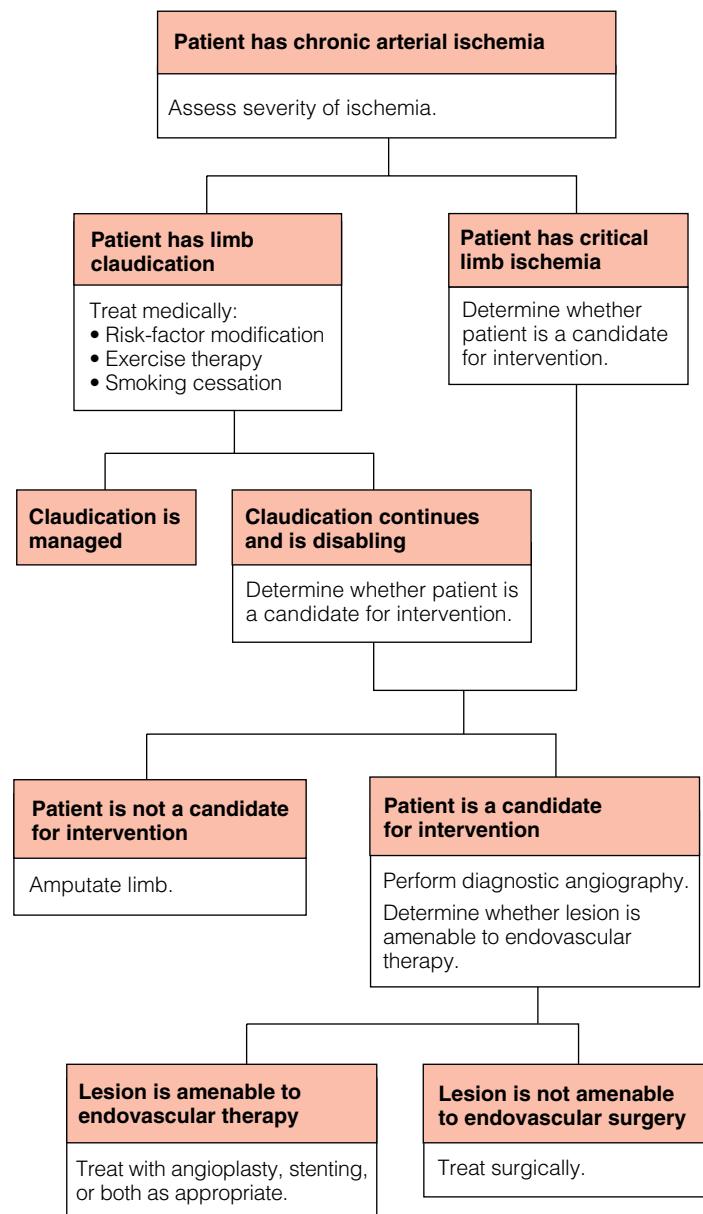

Figure 3 Algorithm illustrates workup of patients with chronic lower-extremity ischemia.

managed medically by controlling risk factors, instituting exercise therapy, and providing advice on smoking cessation.⁸ In patients with disabling claudication, rest pain, or tissue loss, diagnostic imaging studies are performed with the intent of identifying and subsequently treating any lesion that is amenable to endovascular therapy [see Figure 3]. If an intervention is indicated, patients are pretreated with antiplatelet agents as appropriate.

Technique

Techniques and protocols for diagnostic angiography and accessing the target lesion have been outlined [see Basic Endovascular Procedures, above]. If it is unclear whether a vessel has a hemodynamically significant stenosis, arterial pressures can be measured across the lesion by connecting an end-hole catheter to a pressure transducer. A drop of more than 10 mm Hg in systolic blood pressure or more than 5 mm Hg in mean arterial pressure across the lesion is considered significant. The area in question

should also be subjected to a chemical challenge. Local intra-arterial delivery of a vasodilator (e.g., papaverine, 30 mg; priscoline, 25 mg; or nitroglycerin, 200 µg) will create distal vasodilatation, accentuate the translesional gradient, and, in many cases, unmask a significant lesion that might otherwise be missed.

Iliac lesions may be treated either by means of primary angioplasty, with stenting reserved for cases in which angioplasty yields unsatisfactory results, or by means of primary stenting. Either balloon-expandable or self-expanding stents may be used in the iliac vessels. Highly calcified lesions and lesions in smaller iliac vessels (< 7 mm) generally are best treated with self-expanding stents. Lesions in the external iliac artery or the femoral artery (including the CFA, the profunda femoris [PF], and the SFA) are best treated with angioplasty alone. In these vessels, stents usually are placed only when angioplasty has been unsuccessful or dissection or vessel rupture has occurred. As a rule, stenting for SFA lesions is best done with self-expanding stents, though very focal lesions may be treated with balloon-expandable stents. Stenting is relatively contraindicated in the popliteal artery; the extended range of motion across the nearby joint often leads to stent fracture. At present, stents are not used as primary therapy in infrapopliteal vessels. If stenting is required at infrapopliteal sites, coronary balloon-mounted platforms are the only available choices.

Postprocedural Care

After the procedure, patients require at least 2 to 12 hours of bed rest. Hydration with I.V. infusion of normal saline should be initiated, and appropriate dosages of renal-protective agents should be given. Aspirin, 81 mg/day, should be given on a long-term basis, and clopidogrel, 75 mg/day, should be administered for 30 days.

Outcome Evaluation

In most series, rates of technical success (defined as less than 30% residual stenosis) have exceeded 90%. Secondary patency rates for iliac interventions at 10 years have exceeded 50%.⁹ Angioplasty and stenting in the SFA have been studied, for the most part, in a retrospective fashion. Intermediate-term data have suggested patency rates of 70%, 60% and 50% at 1, 3, and 5 years, respectively. The reported clinical benefit has generally exceeded the anatomic patency rates.¹⁰⁻¹² None of the randomized studies published to date have found primary stenting to have any advantage over primary angioplasty in the femoral vessels.¹³⁻¹⁶ Factors indicative of a poor prognosis include intervention for more advanced limb ischemia, diabetes, complete occlusion (as opposed to stenosis), lesions longer than 10 cm, and poor distal runoff.⁸ The use of TASC criteria to stratify lesions anatomically helps predict which patients are likely to benefit most from endovascular therapy in the SFA.¹⁷ In one study that included almost 400 SFA interventions, patients who had TASC A and B lesions experienced significantly better outcomes than those who had TASC C and D lesions, with an overall 6-year patency rate of 52%.¹⁰ Currently, angioplasty is being evaluated for use in infrapopliteal disease. Some initial success has been reported, though it still appears that this approach is best reserved for patients in whom open surgical management is relatively contraindicated.¹⁸

PROCEDURES FOR ACUTE LOWER-EXTREMITY ISCHEMIA

Preprocedural Evaluation

The initial decision in managing acute lower-extremity ischemia limb should be whether to proceed directly to surgery or to obtain a diagnostic angiogram and consider endovascular therapy. The Working Party on Thrombolysis developed a consensus

Table 4 Contraindications to Thrombolysis

Relative Contraindications	Absolute Contraindications
Recent surgery (within 2 wk)	Active internal bleeding
Recent trauma (within 1 mo)	Recent stroke (within 2 mo)
History of coagulopathy	Intracranial pathology
Pregnancy or recent delivery	

on how to approach patients with acute arterial ischemia. The main message of this consensus was that classifying patients according to their grade of ischemia is essential to forming treatment plans [see 6:5 *Pulseless Extremity and Atheroembolism*.¹⁹ Grade IIa and early grade IIb ischemia may be amenable to endoluminal therapy, including thrombolysis. Established grade IIb ischemia is best treated by means of surgical embolectomy or thrombectomy, with intraoperative angiography, intraoperative thrombolysis, and over-the-wire embolectomy as options. Grade III ischemia is nonsalvageable and generally necessitates amputation [see 6:19 *Lower-Extremity Amputation for Ischemia*].

Arterial Thrombolysis

Thrombolysis, either pharmacologic or mechanical, is the mainstay of endovascular therapy for acute arterial ischemia.²⁰ Relative and absolute contraindications to thrombolytic therapy have been established [see Table 4].

Technique An initial diagnostic angiogram of the affected limb is obtained, with care taken to gain arterial access in such a way that thrombolytic therapy is not prevented. The standard approach is from the contralateral groin (see above). To reduce the chances of access site hematoma during administration of a thrombolytic agent, access should be gained at a substantial distance from the occlusion. Crossing the lesion involves identifying the origin of the occlusion. In cases of native vessel occlusion, this is generally a straightforward process. If a bypass graft is occluded, one may be able to visualize a stump of the graft, which will aid in direct management [see Figure 4]. The standard methods of crossing a stenosis or an occlusion [see Basic Endovascular Procedures, Crossing of Lesion, above] should be employed.

Once the lesion has been crossed securely with a wire, an infusion catheter (e.g., a 3 French multi-side-hole catheter) is advanced over the wire and situated in the occlusion. An infusion wire may also be inserted through the infusion catheter in a coaxial fashion and placed distally to increase the area of direct lysis, to protect the outflow vessel, or to address two separate lesions [see Figure 5]. The position of the catheter and the wire are then documented by means of fluoroscopy. With the infusion catheter left securely in place, the thrombolytic infusion is begun. Often, it helps to insert a guide sheath into the contralateral iliac system to prevent dislodgment and facilitate subsequent access.

Pharmacologic agents. The use of thrombolytic drugs has been refined over the past decade. In the United States, urokinase and tissue plasminogen activator (t-PA) have been the most widely used agents. Urokinase was popular in the 1980s and 1990s, but its temporary withdrawal from the market in 1998 because of manufacturing problems allowed physicians to become more comfortable working with t-PA. At present, recombinant t-PA (rt-PA) (e.g., alteplase) is the lytic agent most commonly used in the United States. Reteplase is a newer recombinant agent that is similar to rt-PA but has a longer half-life and a less specific affinity for

fibrin.^{21,22} To prevent buildup of clot around the sheath, all patients undergoing pharmacologic thrombolysis also receive heparin in a continuously administered low dosage (200 to 500 U/hr); higher dosages are associated with a substantially increased risk of hemorrhagic complications.

Mechanical adjuncts to thrombolysis. Several mechanical adjuncts are available to reduce thrombolytic time or enhance the completeness of clot dissolution. These adjuncts can also be beneficial when thrombolytic therapy is contraindicated.

Various mechanical thrombectomy systems are commercially available. One such system is the AngioJet system (Possis Medical, Minneapolis, Minnesota). The Angiojet consists of a pump drive unit and a 4 to 6 French catheter, which is passed over a 0.035-in. wire to the target area. The catheter has two lumens: one is used to pulse heparinized normal saline at a pressure of 10,000 psi, and the other contains the wire and serves as the route by which clot debris

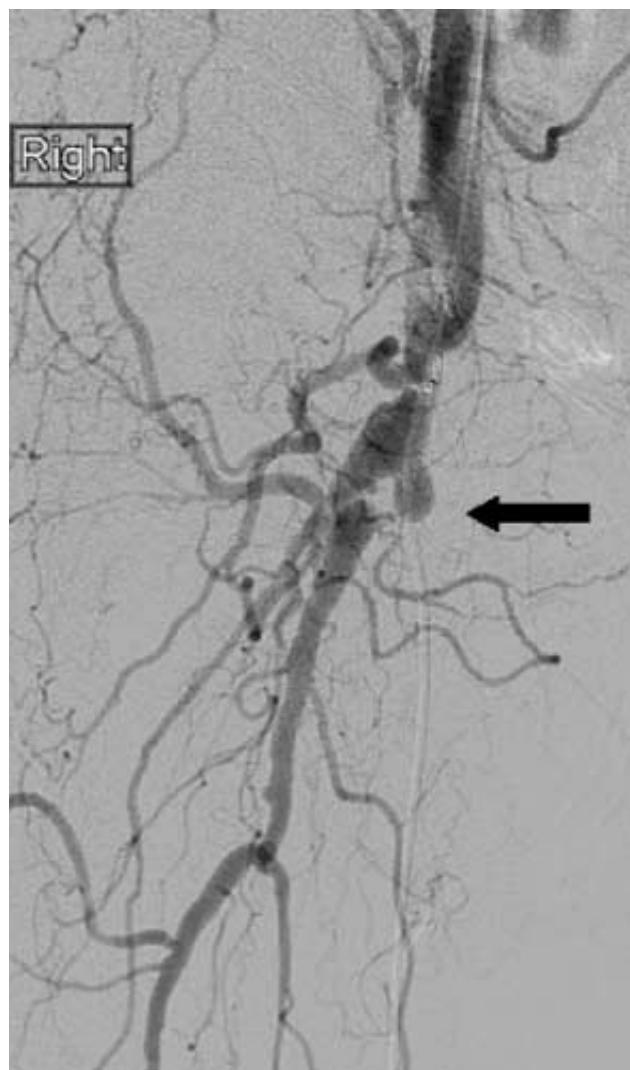

Figure 4 Arterial thrombolysis. Patient presented with grade IIa ischemia, and duplex ultrasonography showed evidence of an occluded femoropopliteal reverse saphenous vein bypass graft. Angiogram taken from the ipsilateral external iliac artery demonstrating a patent but diseased CFA and a patent PF. The SFA is occluded. The stump of the occluded arterial bypass graft is visible (arrow).

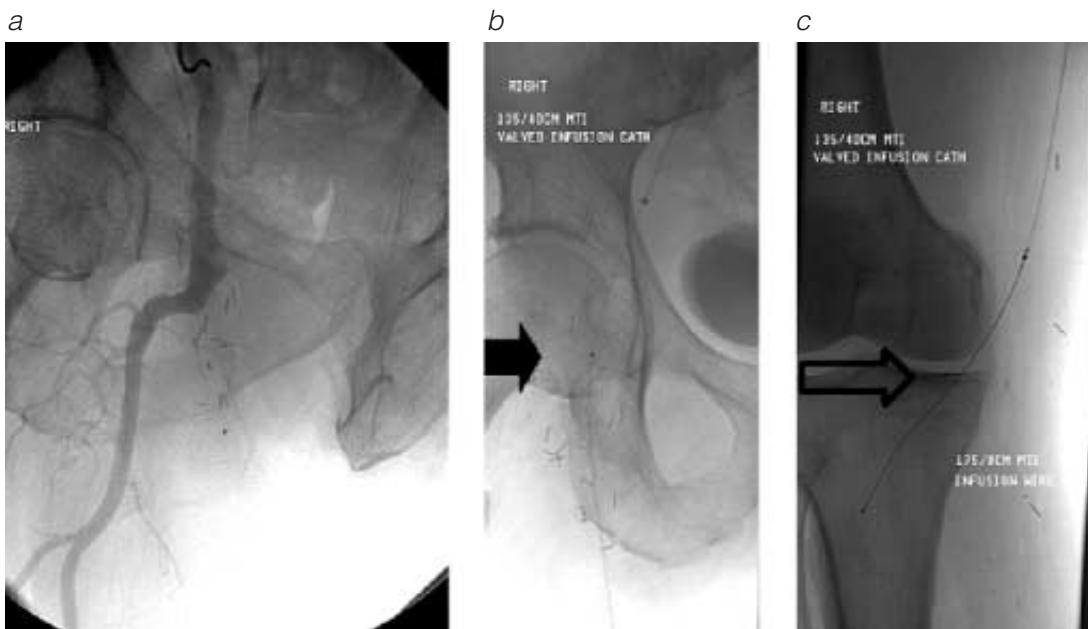

Figure 5 Arterial thrombolysis. Follow-up imaging of the patient in Figure 4 illustrates the use of a thrombolytic infusion catheter. (a) Shown is the proximal end of the occluded CFA-popliteal artery bypass graft. (b) The infusion catheter (black arrow) is placed. (c) The infusion wire rests in the distal bypass graft (hollow arrow), increasing the infusion length for the thromolytic agent.

is removed. The power pulse spray technique, with rt-PA added to the saline (10 mg in 100 ml) and delivered by the rheolytic catheter directly into the clot, may also be employed to help dissolve clot. In this technique, the system is modified so that the outflow circuit is closed and the unit pulses the saline-rt-PA mixture into the clot, allowing simultaneous lysis and maceration. Once the thrombus has been treated and an additional 15-minute interval has elapsed, conventional catheter therapy is employed to remove the clot and the residual rt-PA. The advantage of this approach is that it permits high-dose lysis while imposing only a low systemic load.²³ If more than 750 ml of saline is used with the AngioJet catheter during a single session, there is a significant risk of acute renal impairment secondary to hemolytic debris.

Also used for mechanical thrombectomy are wall-contact instruments such as the Arrow-Trerotola device (Arrow International, Reading, Pennsylvania). Such devices result in significant endothelial damage and distal clot embolization and thus are better suited for hemodialysis grafts. Another option is the Helix Clot Buster (ev3, Plymouth, Minnesota), which creates a vortex at the catheter tip that macerates the clot into microscopic fragments; it differs from the AngioJet in that it lacks an aspirating port. The Oasis thrombectomy catheter (Boston Scientific, Natick, Massachusetts) also fragments thrombus into small particles. The use of these devices in the setting of acute arterial occlusion was addressed in a comprehensive review published in 2001.²⁴ All of these devices may be used either in place of or in addition to pharmacologic thrombolysis.

At present, the evidence supporting the use of mechanical thrombectomy devices in the setting of acute limb ischemia is modest. One retrospective study demonstrated successful recanalization in approximately 60% of patients.²⁵ At our own institution, we have found these devices to be useful in decreasing the clot burden on the second or third t-PA check (24 to 36 hours after commencement of the infusion), after the clot has been softened by the initial pharmacologic lysis. It remains to be seen whether this approach reduces the overall time needed for thrombolytic therapy.

Over-the-wire embolectomy is another mechanical means of removing clot. Newer designs of the standard Fogarty embolectomy catheter have been developed that include an inner lumen, so that the catheter can be passed over a 0.035-in. wire. Use of these devices facilitates fluoroscopically guided embolectomy and ensures that the catheter can be passed to all target vessels. Over-the-wire embolectomy provides an efficient percutaneous method of removing clot without any need for the constant monitoring that pharmacologic thrombolysis requires.

This embolectomy technique may be supplemented by intraoperative catheter-directed thrombolytic therapy when postoperative imaging reveals residual clot or inadequate perfusion. Under fluoroscopic guidance, an end-hole catheter or a multi-side-hole infusion catheter is guided over a wire into the target vessel or vessels, and a thrombolytic agent (e.g., rt-PA, 0.5 mg/kg over 30 minutes) is directly infused with inflow occlusion. Imaging is recommended both before and after thrombolysis. Adjunctive use of an embolectomy catheter may also be beneficial. If, however, there is still no perfusion after adequate thrombolytic therapy and embolectomy, the situation generally is not retrievable, and alternative therapies should be explored. In the clinical trials of perioperative thrombolytic therapy published to date, success rates ranged from 64% to 100%. Bleeding was the most common complication.

Postprocedural care After the intervention, the patient is observed in a monitored unit by personnel trained in the management of thrombolytic therapy. Lower-extremity neurovascular examinations are carried out frequently (every 1 to 2 hours). The patient's clinical status is also monitored for evidence of bleeding, including access-site hematoma, neurologic changes, and hypotension. Repeat angiograms are performed at 12-hour intervals (or sooner if clinical examination reveals significant deterioration) to assess the progress of lytic therapy and to allow changes in catheter positioning. Some physicians recommend following fibrinogen levels and discontinuing the lytic agent if levels fall below 150 mg/dl. Other end points for the thrombolytic therapy are failure to

progress, complete lysis of the target thrombus, or significant bleeding complications necessitating discontinuance of lysis.

Once lysis is discontinued, the heparin dosage should be increased to achieve therapeutic levels of anticoagulation. Any lesions unmasked by thromolytic therapy should be treated, either by endovascular means or with an open procedure. Whether long-term anticoagulation is indicated depends on the patient's circumstances and the specific cause of the thrombosis.

Troubleshooting Many of the issues raised in connection with basic arterial access techniques arise during attempts at thrombolysis. Occasionally, the interventionalist experiences significant difficulty in accessing an occluded bypass graft. Thrombolysis of these occluded grafts can often be facilitated by employing a double-puncture technique, in which both a retrograde and an antegrade puncture of a bypass graft are performed under ultrasonographic guidance, allowing the infusion catheters to be placed so as to cover the entire length of the graft [see Figure 6].²⁶ With this approach, there is no need for CFA puncture, which is often made difficult by the presence of scar tissue, and the problem of finding access to the graft takeoff is eliminated. If a lesion cannot be

crossed, the thromolytic agent may be delivered just proximal to the lesion for 2 to 4 hours after initiation of therapy, but the chances of a good outcome with this approach are diminished.

Whereas it is common for clinical findings to worsen slightly (as a result of distal microembolization) before improving—the so-called storm before the calm phenomenon—dramatic worsening of the physical findings calls for urgent angiography. Possible reasons for ischemic progression include propagation of clot (treatable by performing open embolectomy or thrombectomy), displacement of the lysis catheter (treatable by repositioning the catheter), or distal embolization of clot resulting in obstruction of the principal runoff vessels (treatable by advancing the infusion catheter or wire more distally, employing a rheolytic catheter, or performing open embolectomy or thrombectomy).

Complications General access-site complications—including hematoma, pseudoaneurysm formation, ischemia to the contralateral leg from an occlusive sheath, nerve damage (which is more common with axillary or brachial puncture secondary to an axillary sheath hematoma), arterial dissection of the access vessel, and distal embolization of the clot—are also seen with thromboly-

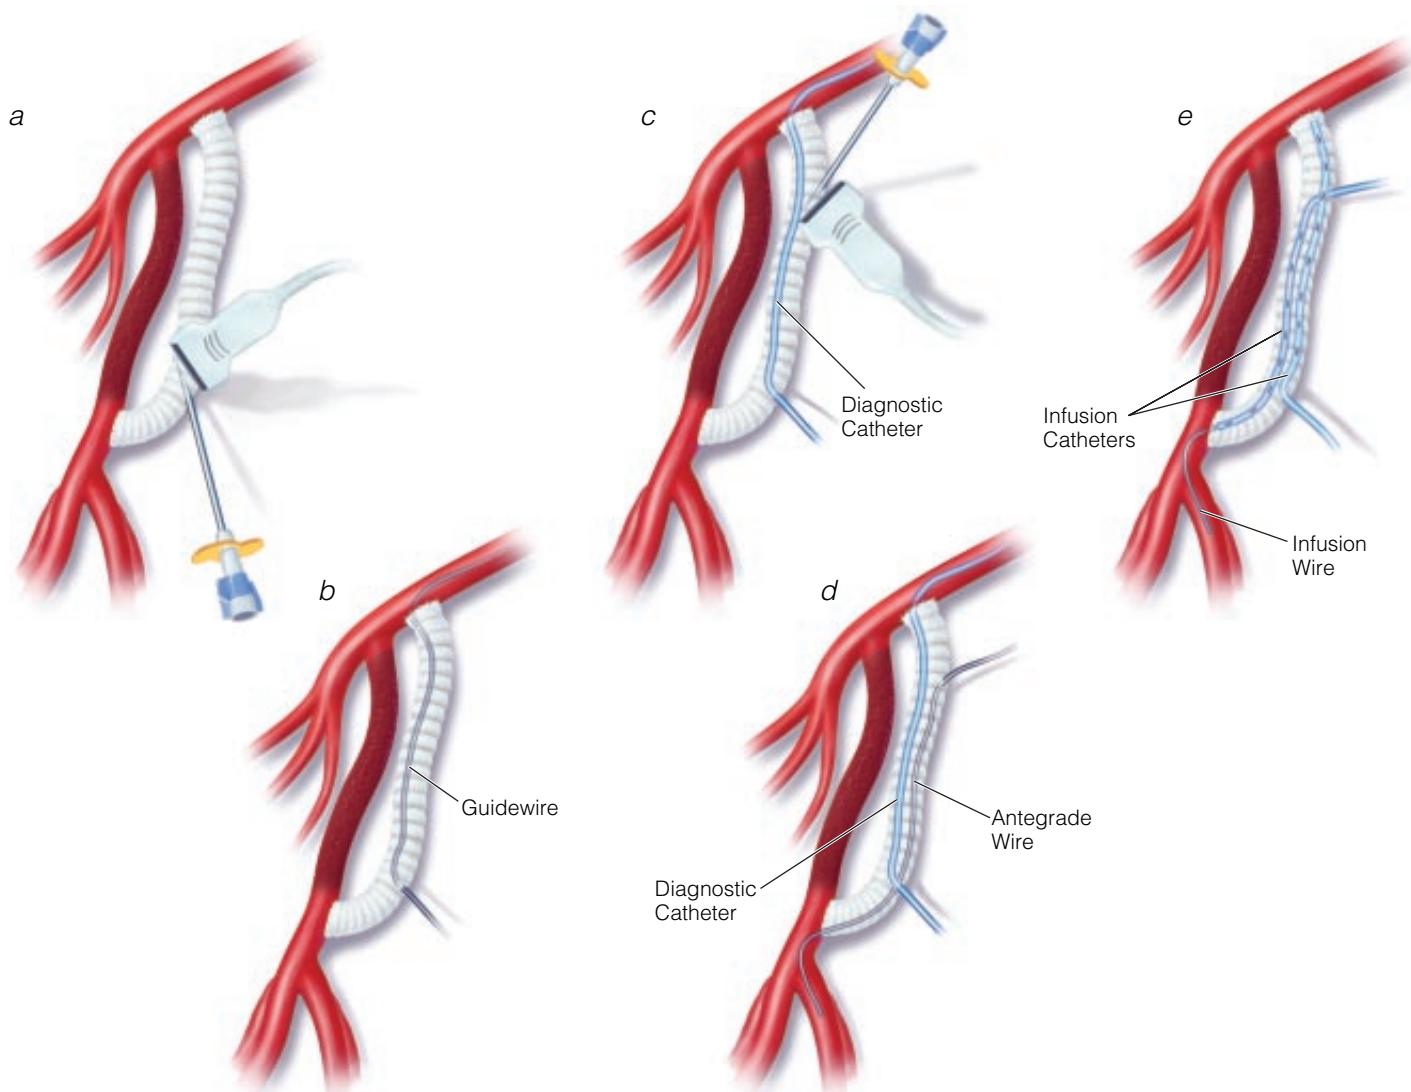

Figure 6 Arterial thrombolysis. Illustrated is ultrasound-guided double puncture of an arterial bypass graft for thrombolysis.²⁶

Table 5 Prospective, Randomized, Controlled Trials of Arterial Thrombolytic Therapy

Trial (Date)	N	Lytic Agent	Limb Salvage Rate at 1 Yr (Surgery vs. Lytic Therapy)	30-Day Mortality (Surgery vs. Lytic Therapy)	Bleeding Complication Rate with Lytic Therapy

ic therapy. Bleeding complications have presented a significant hurdle for thrombolytic therapy. Early studies that used therapeutic doses of heparin and higher doses of thrombolytics reported unacceptable rates of intracranial hemorrhage and other bleeding complications. Currently, most physicians employ rt-PA doses in the range of 0.25 to 0.50 mg/hr without compromising results. Overall, rates of bleeding complications with urokinase and rt-PA range from 5% to 10%, and the incidence of intracranial hemorrhage is less than 2%.²² As with open surgical therapy, compartment syndrome can complicate reperfusion of the ischemic limb; this complication should be checked for on serial clinical examinations.

Outcome evaluation The use of thrombolysis to treat acute lower-extremity arterial occlusion has been extensively studied. The results of the major prospective, randomized trials [see Table 5] showed thrombolytic therapy to be equivalent to surgery with respect to limb salvage and mortality and superior with respect to the need for complex surgical intervention. Most of these major trials were performed with urokinase and t-PA. The information gained from them has helped surgeons determine which patients are good candidates for thrombolytic therapy. Factors predictive of successful thrombolysis include symptoms of less than 14 days' duration, prosthetic graft occlusion, and high medical risk for open operation. Factors predictive of a poor outcome include chronic occlusion, native artery occlusion, and a lesion that cannot be crossed with a wire.²⁷

PROCEDURES FOR LOWER-EXTREMITY ARTERIAL ANEURYSMS

Ultrasound-Guided Thrombin Injection

Pseudoaneurysms of the CFA are a complication of femoral access for therapeutic procedures and are often amenable to percutaneous therapy. The pseudoaneurysm is visualized with a 7.5-MHz duplex ultrasound probe. Contraindications to injection of the sac are the presence of a wide mouth and no discernible neck, the development of an arteriovenous fistula, compression of adjacent structures by the pseudoaneurysm, and skin changes overlying the pseudoaneurysm. If infection is a possibility, the procedure should not be attempted. The ABI should be determined and duplex ultrasonography of the groin performed before injection.

Once it is certain that the pseudoaneurysm meets the criteria for thrombin injection, the sac is injected in the fundus area, away from the native artery, under direct ultrasonographic visualization and after infiltration of a local anesthetic. Usually, 1,000 units of thrombin is injected, and injection may be repeated one or more times. With multilobular aneurysms, serial injections into each fundus may be required to achieve complete resolution.

Factors associated with successful treatment are a long, narrow pseudoaneurysm neck and a sac diameter smaller than 8 cm.

Overall success rates may exceed 95%. Complications include distal native artery thrombosis and distal embolization, which generally can be treated with I.V. heparin.²⁸

Placement of Covered Stent

Treatment of lower-extremity aneurysms with covered stents is currently being studied. Isolated iliac artery and SFA lesions, though rare, lend themselves to endovascular repair [see Figure 7]. Initial data suggest that repair of popliteal aneurysms with covered stents is also feasible in high-risk patients.²⁹ Newer stents are being developed that are better able to withstand the stresses imposed by the repetitive motion of the knee joint.

Venous Procedures

As endovascular therapy for arterial disease continues to evolve, techniques learned in the arterial tree are increasingly being applied to the venous system. At present, the main venous disease processes being treated with endovascular techniques are iliofemoral deep vein thrombosis (DVT) and superficial reflux of the greater saphenous system causing symptomatic varicose veins.

VENOUS THROMBOLYSIS

Lower-extremity DVT can have a significant impact on patients' quality of life. Multiple studies indicate that approximately 50% of patients experience postthrombophlebitic syndrome (PTS) and that the majority of patients with PTS report that physical and emotional well-being are negatively affected.³⁰ The goals of venous lysis are to relieve obstruction and to preserve valve function.

Preprocedural Evaluation

If DVT is less than 1 month old, a trial of lytic therapy is appropriate. The ideal candidate for such therapy has a symptomatic clot with lower-extremity swelling, is young and mobile, is not in a hypercoagulable state, and has no contraindications to lysis. Currently, lytic therapy is more commonly employed in active patients, whose quality of life is more likely to be negatively affected by PTS. In cases of unprovoked DVT or recurrent DVT, a hypercoagulability workup is indicated.³¹ Venous thrombosis is discussed more fully elsewhere [see 6:6 *Venous Thromboembolism*].

Technique

The initial diagnostic venogram can be obtained via almost any venous access site. Our preference is to perform an ipsilateral popliteal vein stick with the patient in the prone position; the posterior tibial vein or the contralateral femoral vein can also be used. The popliteal vein is accessed with a micropuncture needle under ultrasonographic guidance by means of a Seldinger technique.

The micropuncture sheath is then replaced with a 5 French sheath over a 0.035-in. wire. The diagnostic venogram is performed through the sheath or with a straight multi-side-hole diagnostic catheter.

As in arterial thrombolysis [see Arterial Procedures, Procedures for Acute Lower-Extremity Ischemia, Arterial Thrombolysis, above], a 3 French infusion catheter is advanced over the wire and positioned within the clot. Longer lesions can be managed with a coaxial infusion catheter-wire system. The lytic infusion is started, and a low-dose intravenous heparin infusion is initiated through the sheath. Mechanical thrombectomy and power pulse spray thrombectomy can efficiently debulk thrombus and may be beneficial in patients with phlegmasia caerulea dolens.³² The patient is kept in a monitored floor bed, and repeat venograms are performed every 12 to 24 hours.

In some patients, May-Thurner syndrome (compression of the iliac vein by the overlying iliac artery) develops; it is treated by placing a venous stent in the iliac vein to help reduce the effect of external compression and presumably treat the initiating factor. Venous stents are larger than corresponding arterial stents in a given vascular bed. Because of the increased compliance of the venous wall, self-expanding stents are preferred for use in veins.

Once lysis either is complete or has been continued for 72 hours, the lytic infusion is stopped, and the heparin infusion is increased to therapeutic levels. The patient is placed on warfarin therapy and should be treated in accordance with current algorithms for DVT [see 6:6 Venous Thromboembolism].

Complications

Reported rates of bleeding complications after venous lysis are higher than those after arterial lysis, typically ranging from 10% to 15%.³³ Pulmonary embolism, though rare in this setting, is known to occur, presumably as a result of partially lysed clot breaking off. To prevent this complication, some authors advocate prophylactic placement of an inferior vena cava (IVC) filter.³⁴ Ongoing development and wider use of retrievable IVC filters may accelerate the application of this adjunctive technique.

Outcome Evaluation

In a large retrospective study of 312 cases of iliofemoral and femoropopliteal DVT treated with urokinase infusion, greater

than 50% lysis was achieved in 83% of the patients; 11% experienced complications, and 1% had pulmonary emboli.³³ Small prospective, randomized trials found that thrombolysis yielded increased patency and decreased venous reflux in comparison with standard anticoagulation therapy.³⁵ Retrospective studies indicated that this improved venous patency and valve function might translate into better quality of life than would be achieved with anticoagulation alone.³⁶

TREATMENT OF SAPHENOFEMORAL VENOUS REFLUX

The application of endovascular techniques to saphenofemoral venous reflux has significantly changed the treatment of this condition.³⁷ Over the past decade, two minimally invasive approaches have been developed to replace standard high ligation and stripping of the greater saphenous vein (GSV): radiofrequency ablation (RFA) and endolaser obliteration.

Preprocedural Evaluation

Initially, symptomatic varicose veins are treated conservatively, with compression stockings. If conservative methods fail to provide relief, a varicose vein-related complication develops, and there is evidence of significant superficial reflux on duplex ultrasonography, the patient may be considered for endovenous treatment of GSV reflux.

Preprocedural Planning

GSV ablation procedures may be performed either in an office or in an operating or procedure room. If an office setting is chosen, the patient must be able to tolerate a small amount of discomfort with light sedation. The interventionalist must be certified to deliver conscious sedation and must be laser qualified if providing laser therapy. The procedure room, whether in an office or a medical facility, should be equipped with a procedure table capable of a steep Trendelenburg position, a high-resolution duplex ultrasonography device, and the appropriate ablation equipment. For more symptomatic side-branch varicosities, stab avulsions may be needed; as a rule, these are best done in the OR.

Technique

RFA of GSV The development of the Closure system (VNUS Medical Technologies, Sunnyvale, California) has allowed

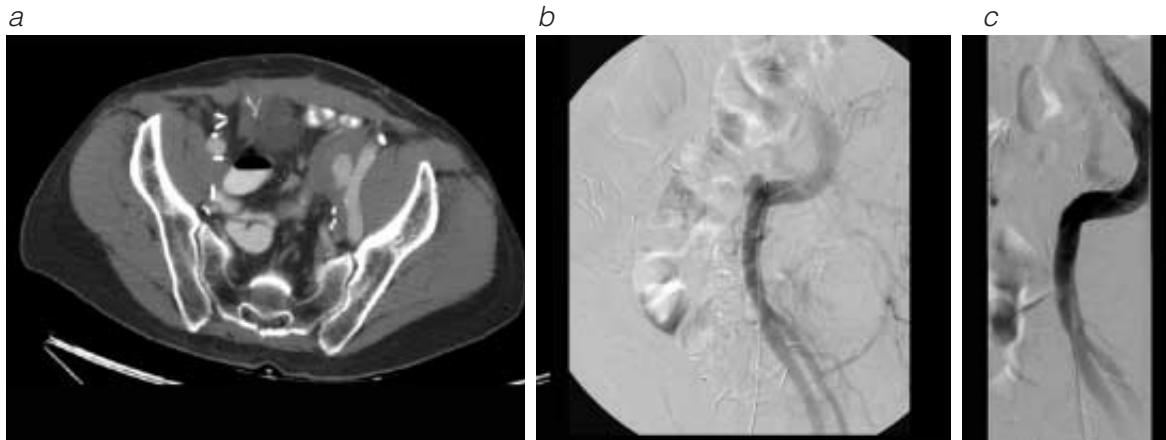

Figure 7 Placement of covered stent. Shown is endovascular repair of an external iliac artery aneurysm. The patient presented with left groin pain several months after undergoing urologic surgery. (a) CT scan demonstrates a left external iliac artery pseudoaneurysm. (b) Angiogram demonstrates the same pseudoaneurysm. (c) Shown is the left external iliac artery after covered stent placement successfully excluded the pseudoaneurysm.

the application of RFA to GSV reflux therapy. Before the procedure, the GSV is mapped by means of ultrasonography. The patient is placed in the Trendelenburg position with a tourniquet around the upper thigh. Access to the GSV is obtained at the knee with an introducer needle and a wire threaded into the vein, and the needle is then replaced with a proprietary sheath. The Closure catheter is threaded through the sheath, and the tip is placed under ultrasonographic guidance just proximal to the takeoff of the superficial epigastric vein at the saphenofemoral junction (SFJ). A mixture of normal saline (500 ml), 1% lidocaine with epinephrine (50 ml), and sodium bicarbonate (5 mg) is injected under ultrasonographic guidance through the sheath and into the area surrounding the GSV to provide anesthesia, improve impedance, and protect the overlying tissues from exposure to the heat (so-called tumescent anesthesia).

The Closure device is then connected to the RFA delivery system, deployed, and pulled back at a controlled rate (initially, 1 cm every 30 seconds), with both impedance and temperature checked periodically. Manual compression, particularly in the upper thigh, may help in obtaining optimal numeric values on the RFA unit, as well as increase the efficiency of ablation. After the catheter has been withdrawn into the sheath, it is removed, and ultrasonography is performed to confirm that the GSV has been obliterated.

Endovenous laser treatment of GSV Access to the GSV is obtained as in RFA (see above), and a wire is advanced under ultrasonographic guidance to a point above the SFJ. A 600 µm laser fiber is placed over the wire and positioned just distal to the SFJ in the GSV. A tumescent anesthetic solution is injected. Laser energy is delivered (e.g., with an 810 nm diode laser) as the laser fiber is pulled back. One advantage endolaser obliteration has over

RFA is that the laser wire can be pulled back relatively quickly (up to 18 mm/min).

Complications

The most serious complication associated with any of these endovenous techniques is DVT. There have been several reports of DVT resulting from RFA of the GSV, with incidences as high as 16%.³⁸ As of September 2005, four instances of pulmonary embolism from these clots had been reported in the United States Food and Drug Administration's Manufacturer and User Facility Device Experience (MAUDE) database (<http://www.fda.gov/cdrh/maude.html>), with at least one patient dying of a pulmonary embolism after the procedure.

Lower-extremity DVT has also been reported after endovenous laser therapy. Other problems include saphenous nerve paresthesias along the course of the GSV, bruising, skin burns, and superficial phlebitis. If endovenous laser therapy fails to obliterate the GSV, the problem can be remedied by prompt high ligation at the time of ablation. Clot in the common femoral vein can be treated with standard anticoagulation. Clot abutting the common femoral vein can be treated with clopidogrel, 75 mg/day orally for 1 month; serial ultrasonograms should be obtained to confirm that the clot is not propagating.

Outcome Evaluation

Overall, good results are obtained with endovenous treatment of GSV reflux. In one study of patients who underwent RFA of the GSV, 85% of patients had complete occlusion of the GSV at 2 years, and 90% of all patients were free of GSV reflux at that time.³⁹ In a study of patients who underwent endolaser obliteration, similar results were obtained: ultrasonographic surveillance documented a 93% rate of complete GSV closure at 2 years.⁴⁰

24 RAYNAUD PHENOMENON

Tina R. Desai, M.D., F.A.C.S., and Ryan Headley, M.D.

Raynaud phenomenon is an episodic, exaggerated vascular response to cold or emotional stimuli, typically involving the fingers. The classic triphasic color change, first described by Maurice Raynaud in 1862, consists of initial pallor (secondary to vaso-spasm), followed first by cyanosis (from deoxygenation of the static blood) and then by rubor (as blood flow to the digits is restored and reactive hyperemia ensues).¹ This classic manifestation of Raynaud phenomenon occurs in as many as two thirds of affected patients; however, less common variants of the phenomenon (e.g., pallor followed by cyanosis alone and pallor followed by rubor alone) also exist.

Raynaud phenomenon occurs throughout the world. Overall, it tends to be more common in colder climates. In warmer areas of the United States and Spain, the prevalence ranges from 3% to 5%, whereas in cooler areas, the prevalence ranges from 15% to 20%.²⁻⁴ In a study of the African-American population, the prevalence was 3%.⁵

Classification

Raynaud phenomenon is generally classified as either primary or secondary. Primary Raynaud phenomenon occurs as an isolated finding in an otherwise healthy individual; secondary Raynaud phenomenon is caused by an associated disease (in most cases, an autoimmune disease) or by identifiable environmental or chemical exposure [see Table 1].⁶ The two types are distinguished from each other on the basis of clinical criteria, and the distinction has significant prognostic implications.

With primary Raynaud phenomenon, the typical age of onset is 15 to 30 years, symptoms are generally symmetrical and less severe, patients are more likely to be female, and multiple family members may be affected.⁷ With secondary Raynaud phenomenon, the typical age of onset is greater, symptoms are usually more severe, and a systemic inflammatory disorder is commonly involved. In fact, Raynaud phenomenon is a prominent component of many autoimmune disorders, occurring in 90% of patients with scleroderma, 10% to 45% of patients with systemic lupus erythematosus (SLE), one third of patients with Sjögren syndrome, 20% of patients with dermatomyositis or polymyositis, and 10% to 20% of patients with rheumatoid arthritis.⁸ In 0% to 13% of patients who present with primary Raynaud phenomenon, an identifiable connective tissue disorder develops within a few years after presentation.^{9,10} The best predictors of transition to such a disorder are (1) serologic findings that are positive for autoantibody and (2) suggestive physical findings (e.g., abnormal nailfold capillary patterns, cutaneous telangiectasias, puffy fingers, and sclerodactyly).^{6,10}

Clinical Evaluation and Investigative Studies

CHARACTERISTIC FINDINGS

Exacerbation of Raynaud phenomenon typically occurs after direct exposure of an extremity to cold temperatures [see Sidebar]

Pathophysiology of Raynaud Phenomenon], but an attack may also be elicited by generalized cooling of the entire body. In addition, attacks may be precipitated by any stimulation of the sympathetic nervous system, especially at times of emotional stress.

As a rule, Raynaud phenomenon is more likely to affect the hands than the feet. It is characterized by the sudden occurrence of cold digits in association with sharply demarcated pale skin—the so-called ischemic phase. Eventually, the skin may become cyanotic. Subsequently, rapid restoration of blood flow to the digits results in reactive hyperemia—the reperfusion phase. Attacks typically start in a single digit and spread symmetrically to other digits, eventually involving both hands. Other sites may be involved as well—notably, the ears, the nose, the nipples, the face, and the knees. Ischemic attacks may be accompanied by mottling of the

Table 1 Conditions Associated with Raynaud Phenomenon²⁰

skin on the arms and legs. During the ischemic phase, patients may complain of paresthesias and clumsiness in the involved extremities. In the most severe cases of secondary Raynaud phenomenon, critical ischemia may cause painful digital ulceration.

Raynaud phenomenon should be differentiated from simple "cold hands" (a more common and benign condition). In patients with Raynaud phenomenon, cold hands occur in conjunction with clearly distinguished skin-color changes. Moreover, recovery takes longer than it does in patients who merely have cold hands. The guidelines for diagnosing Raynaud phenomenon are based on a history of color change on exposure to cold or other stimuli. A history of repeated episodes of biphasic skin-color change on exposure to cold is indicative of Raynaud phenomenon. A history of uniphasic skin-color change with paresthesias on exposure to cold is suggestive. In the absence of any skin-color change, Raynaud phenomenon is ruled out.¹¹ Generally, additional diagnostic tests are unnecessary; however, both evaluation of digital pressure response to cooling and laser Doppler assessment of skin perfusion pressure have been employed in this setting. There is evidence to suggest that laser Doppler assessment of skin perfusion pressure is capable of distinguishing between normal control subjects, persons with primary Raynaud phenomenon, and persons with secondary Raynaud phenomenon.¹²⁻¹⁴

Raynaud phenomenon should also be differentiated from carpal tunnel syndrome and other neuropathies, which may cause cold sensitivity but do not induce the skin-color changes characteristic of Raynaud phenomenon. Patients who have asymmetrical, persistent, or positional symptoms should undergo a full evaluation for possible large vessel occlusive disease, embolism, or thoracic outlet compression, any of which might lead to hand-color changes. Raynaud phenomenon may also be a reflection of a more generalized vasospastic disorder (e.g., migraine headache or Prinzmetal angina).^{15,16}

HISTORY AND PHYSICAL EXAMINATION

Once a diagnosis of Raynaud phenomenon has been established—or, at least, strongly suspected—a thorough history and physical examination can help distinguish between primary and secondary forms of the condition. The presence of specific symptoms of connective tissue disease (particularly arthralgia, myalgia, and dry mucous membranes), extended exposure to vibrating machinery, or antecedent use of certain medications is suggestive of secondary Raynaud phenomenon. The earliest specific diagnostic criteria for primary Raynaud phenomenon were described by Allen and Brown in 1932.¹⁷ More current criteria take advantage of modern diagnostic tools and serologic testing. Primary Raynaud phenomenon is suspected when attacks are symmetrical and episodic, when the history and the physical examination reveal no evidence of tissue gangrene or a possible underlying causative condition, when antinuclear antibody titers and erythrocyte sedimentation rates are normal, and when nailfold capillary examination yields unremarkable results.¹⁸

TESTING FOR SUSPECTED SECONDARY RAYNAUD PHENOMENON

If secondary Raynaud phenomenon is suspected on the basis of the history and the physical examination, more specific testing is appropriate. A particularly helpful test is nailfold capillaroscopy. The bases of the fingernails of the fourth and fifth digits are examined with a handheld ophthalmoscope set to 10 to 40 diopters after a drop of immersion oil is placed on each nailfold. The normal vascular pattern, seen in healthy control subjects and patients with primary Raynaud phenomenon, consists of delicate

Pathophysiology of Raynaud Phenomenon

Blood flow to the skin is regulated by a complex interaction between the endothelium, vascular smooth muscle, circulating hormones, and neural plexus. Patients with Raynaud phenomenon demonstrate an exaggerated vasomotor response to otherwise benign stimuli, notably cold exposure. Normally, on exposure to cold, blood flow to the skin is reduced in an effort to preserve core temperature. This natural response is mediated primarily by the sympathetic nervous system via the neurotransmitter norepinephrine, which causes contraction of vascular smooth muscle in the cutaneous arterial beds. This cold-induced vasoconstriction of cutaneous vascular smooth muscle appears to be mediated specifically by the alpha₂ receptor.⁴⁰

It has been suggested that the cold-induced vasoconstriction seen in primary Raynaud phenomenon is the result of exaggerated activity of the alpha₂ receptors. This suggestion was supported by the results of experiments that blocked the cold-induced vasoconstriction in primary Raynaud phenomenon by delivering alpha₂ receptor antagonists locally.⁴¹ The mechanism of this Raynaud-specific hyperactive response has not been fully elucidated, though there is evidence to indicate that the response may, in part, be attributable to increased activity in the protein tyrosine kinase signal transduction pathway.⁴² Endothelial derangements may also contribute to the pathogenesis of primary Raynaud phenomenon through increased plasma concentrations of endothelin and decreased levels of nitric oxide.^{43,44}

In secondary Raynaud phenomenon, it is generally accepted that vascular damage from the underlying disease (especially in the case of scleroderma) is responsible for the disruption of normal vasoconstrictor homeostasis. Activated or damaged endothelial cells exacerbate vasospasm and further damage perfusion by mediating the proliferation and contraction of smooth muscle cells; enhancement of procoagulant activity and reduction of fibrinolysis promote the formation of intravascular microthrombi, and the release of chemotactic and adhesion factors activates local inflammatory processes.²⁰

"hairpin" capillary loops. However, the pattern seen in patients with Raynaud phenomenon secondary to an underlying cause (e.g., scleroderma, dermatomyositis, or undifferentiated connective tissue disease) often includes enlarged capillary loops, with evidence of angiogenesis, architectural derangements, and areas of decreased vascularity.¹⁹ Serologic markers provide additional support for the diagnosis of secondary Raynaud phenomenon: the anti-Smith antibody is specific for SLE, and the anti-topoisomerase and anti-RNA polymerase antibodies are highly specific for scleroderma-spectrum disorders. Among experts, there is little doubt that patients with Raynaud phenomenon who test positive for autoantibodies are at higher risk for the eventual development of a connective tissue disease.²⁰

Management

Management of Raynaud phenomenon generally consists of lifestyle modification and medical treatment, with surgical options limited to severe or refractory cases. Nonpharmacologic treatment generally suffices for primary Raynaud phenomenon, but it is often inadequate for management of secondary Raynaud phenomenon, which is usually more severe. Mild forms of Raynaud phenomenon are managed with lifestyle modification, including maintenance of total body warmth (as well as warmth of hands and fingers), avoidance of cold and emotional stress, cessation of smoking, discontinuance of the use of vibrating tools, and avoidance of vasoconstricting substances (e.g., caffeine, cocaine, beta

blockers, and decongestants). Biofeedback training has also been shown to be of some utility in reducing symptoms of Raynaud phenomenon, though several studies have questioned its value, especially in comparison to that of medical management.^{21,22}

Calcium channel blockers are the vasodilators most commonly used to treat Raynaud phenomenon. Nifedipine, diltiazem, felodipine, and amlodipine are all effective, though they tend to be more effective in patients with the primary form of the condition than in those with the secondary form. One meta-analysis found short-acting nifedipine, 10 to 20 mg three or four times a day, to be moderately effective at reducing symptoms in patients with Raynaud phenomenon and scleroderma.²³ A large clinical study found sustained-release nifedipine to be useful as well.²² Despite some variability in the published reports, calcium channel blockers remain the first choice for medical treatment after failure of nonmedical treatment.

Other vasodilators have also been shown to be effective. In one study, losartan, an angiotensin receptor blocker, proved to be more effective than nifedipine in reducing the frequency and severity of episodes of both primary and secondary Raynaud phenomenon.²⁴ Topical nitrates provide a degree of benefit as well.²⁰ Because serotonin may be partially involved in the pathogenesis of Raynaud phenomenon, a number of studies have focused on the use of serotonin reuptake inhibitors and serotonin receptor antagonists.²⁵ In a small open-label trial that included both patients with primary Raynaud phenomenon and patients with the secondary form of the condition, fluoxetine was more effective than nifedipine in reducing the severity and frequency of attacks over a 6-week period; the effect was most pronounced in female patients and in patients with primary Raynaud phenomenon.²⁶ In another study, ketanserin, a selective serotonin receptor antagonist that is no longer available in the United States, significantly reduced the number of attacks over a 3-month period.²⁷ Intravenous prostaglandins have also been used with success. In one report, iloprost, given as a 5-day infusion, was beneficial in severe cases of Raynaud phenomenon, mitigating symptoms and enhancing the healing of ischemic ulcers²⁸; unfortunately, iloprost is also unavailable in the United States. Of the I.V. prostaglandins currently available in the United States, alprostadil (prostaglandin E₁ [PGE₁]) and epoprostenol (PGI₂) have achieved, at best, mixed results,^{29,30} whereas prazosin has been employed with some success against primary and secondary Raynaud phenomenon (though its effectiveness seems to be limited in patients with scleroderma).³¹

Some authors have advocated low-dose aspirin therapy for Raynaud phenomenon, but to date, trials of antiplatelet therapy have yielded disappointing results.²⁸ In a placebo-controlled, randomized trial published in 2003, cilostazol increased blood vessel diameter in patients with primary and secondary Raynaud phenomenon but did not bring about any improvement in symptoms.³² In smaller studies, some success was achieved with tissue

plasminogen activator and with low-molecular-weight heparin; however, these agents were found to carry significant bleeding risks and thus have not been widely accepted for treatment of Raynaud phenomenon.^{28,33}

For refractory, severe Raynaud phenomenon, surgical management, most often involving some form of sympathectomy, is recommended. Both central and distal sympathectomy have been employed for this purpose; initial success rates are good, but there is a high incidence of recurrent symptoms.

For many years, open cervicothoracic sympathectomy was commonly performed for symptomatic treatment of Raynaud phenomenon (which was thought to result from an overactive sympathetic response), but the results were mixed.^{34,35} The open form of the procedure was associated with substantial morbidity and frequent recurrence of symptoms, and as a result, it has now been largely abandoned. Some surgeons have advocated performing thoracoscopic sympathectomy [see 4:7 *Video-Assisted Thoracic Surgery*] to treat severe Raynaud phenomenon that is refractory to medical management, but the benefits and durability of this approach have not been established. In this procedure, the ipsilateral pleural space is approached thoroscopically, with the patient under general anesthesia. The sympathetic chain is identified as it courses down the ribs near the costovertebral junction, and the second through fourth thoracic sympathetic ganglia lying between the ribs are cauterized. Bilateral sympathectomy may be performed in a sequential fashion during the same operation. Approximately 90% of patients experience immediate relief of symptoms after thoracoscopic sympathectomy, but the majority also experience recurrence of symptoms.^{36,37} Proponents of this procedure argue that these recurrent symptoms are not as severe as the original preoperative symptoms and that patients who undergo the operation as treatment of ulceration exhibit continued long-term healing. Nonetheless, in our view, it is advisable to reserve thoracoscopic sympathectomy for selected cases of Raynaud phenomenon that are refractory to medical management.

At present, localized digital sympathectomy using microsurgical techniques is generally preferred to proximal sympathectomy for treatment of nonhealing ulcerations in patients with severe, refractory Raynaud phenomenon.³⁸ This procedure involves stripping the adventitia, along with digital sympathetic fibers, from the involved digital arteries, with the patient under either regional or general anesthesia. In one small study of seven patients, it was suggested that this digital sympathectomy could be extended to include the palmar arch, the radial and ulnar arteries proximal to the wrist, and the nerve of Henle, which is responsible for the sympathetic innervation of the distal ulnar artery.³⁹ The investigators found that by 1.5 years after adventitial stripping of the proximal radial and ulnar arteries with resection of the nerve of Henle, all ischemic ulcerations had resolved.

25 UPPER-EXTREMITY REVASCULARIZATION PROCEDURES

John Byrne, M.CH., F.R.C.S.I.(Gen), Philip S. K. Paty, M.D., F.A.C.S., and R. Clement Darling III, M.D., F.A.C.S.

Vascular surgeons are commonly called on to treat patients with acute arm ischemia. Elective arm revascularization is an infrequently performed procedure, one that usually prompts surgeons to resort to reference texts. Even in busier centers, elective arm reconstructions currently account for only 3.2% of elective limb revascularizations. Balloon angioplasty has largely replaced surgical bypass in the treatment of subclavian occlusions; however, the very growth of endoluminal approaches to arm revascularization has led to a paradoxical increase in the need for so-called prophylactic carotid-subclavian bypass in patients with thoracic aneurysms. In addition, the rising incidence of diabetes and the longer survival times reported in patients with renal impairment have led to increased use of distal bypass procedures in the arm (analogous to pedal bypass procedures in the leg [*see 6:18 Infrainguinal Arterial Procedures*]). Finally, the growing number of dialysis access procedures performed has led to an increased incidence of arm ischemia resulting from these operations.

In this chapter, we describe the technical aspects of the procedures employed for emergency and elective arm revascularization. We also touch on pharmacologic alternatives to elective revascularization and briefly consider the potential role of minimally invasive techniques (e.g., thoracoscopic sympathectomy).

Procedures for Acute Arm Ischemia

Acute arm ischemia accounts for one fifth of all episodes of acute limb ischemia. It occurs twice as often in females as in males. Brachial embolectomy is the most common treatment. After successful brachial embolectomy, 95% of patients are symptom free¹; however, the operative mortality may be as high as 12%.² Most reports that address acute arm ischemia include only those patients who are treated surgically. In fact, between 9% and 30% of patients who present to vascular surgeons with acute arm ischemia are managed conservatively, either because they are unfit for surgery or because they have minimal symptoms. These conservatively managed patients are probably underrepresented in the literature. In the few reported series, assessment of symptoms and disability has been largely inconsistent. However, in a 1964 series that included 95 patients, 32% of those who were managed conservatively were left with abnormal function in the arm after treatment.³ In a 1977 report, 75% of the conservatively managed patients had poor functional outcomes.⁴ In a 1985 study, 50% of the conservatively managed patients had persistent forearm claudication.⁵ The conclusion to be drawn is that although conservative management is appropriate for some patients with acute arm ischemia, every effort should be made to restore blood flow in patients who have a reasonable life expectancy.

BRACHIAL EMBOLECTOMY

Preoperative Evaluation

Patients with acute arm ischemia tend to be slightly older at presentation than patients with leg ischemia (74 years versus 70

years).⁶ Usually, there is an underlying embolic source (e.g., cardiac dysrhythmia). Most arm emboli (75%) are of cardiac origin. The brachial artery is the most common site of emboli (60% of cases), followed by the axillary artery (26%). In situ thrombosis accounts for 5% of episodes of arm ischemia.⁷

Selection of patients All patients with acute-onset arm ischemia are candidates for embolectomy. Conservative management should be considered only for patients who are terminally ill or unfit for surgical intervention.

Alternative therapy Some authors have achieved good results by using thrombolysis to treat acute occlusion of the axillary artery or the brachial artery.⁸ However, in a 2001 series that included 38 patients with 40 occlusions treated with thrombolysis, the success rate of this approach was only 55%, and eight patients had to undergo surgical thrombectomy after thrombolysis failed.⁹ Excellent outcomes have also been reported for the treatment of acute arm ischemia with rotational thrombectomy devices (e.g., Rotarex; Straub Medical, Wangs, Switzerland). To date, however, no large published studies have evaluated these devices, and clinical experience with them is currently limited to case reports.¹⁰

Operative Planning

In most patients with acute arm ischemia, diagnosis is straightforward and surgical treatment relatively easy. Some instances of acute arm ischemia, however, are caused by an inflow lesion in the subclavian artery (SA) (e.g., from ulcerated plaques, a thrombosed SA aneurysm, or an arterial thoracic outlet syndrome). In such situations, even a technically perfect embolectomy will fail to restore normal hand perfusion.

The majority of brachial embolectomies are performed with local anesthesia, with or without monitored conscious sedation.

Operative Technique

The origins of the ulnar and radial arteries are exposed by means of a so-called lazy S incision [*see Figure 1a*], which prevents the elbow contracture that can occur with a vertical incision. The skin and the subcutaneous tissues are divided. Care is taken to preserve the superficial veins, especially the median antecubital vein, which may be needed to patch the brachial artery. The bicipital fascia is incised, and the brachial artery is found between the tendon of the biceps laterally and the median nerve medially [*see Figure 1b*]. Dissection is continued distally until the ulnar and radial arteries are encountered. The radial artery is a continuation of the brachial artery; the ulnar artery comes off the brachial artery medially and, within 2 to 3 cm of its origin, dives beneath the pronator and epitrochlear muscles. It is important to expose the origins of both forearm arteries because the embolectomy catheter must be passed down each vessel. If the catheter is blindly passed down the brachial artery, it will probably travel down the radial artery.

An arteriotomy (usually vertical) is made in the brachial artery. Clot may be encountered at the bifurcation; if so, it is readily

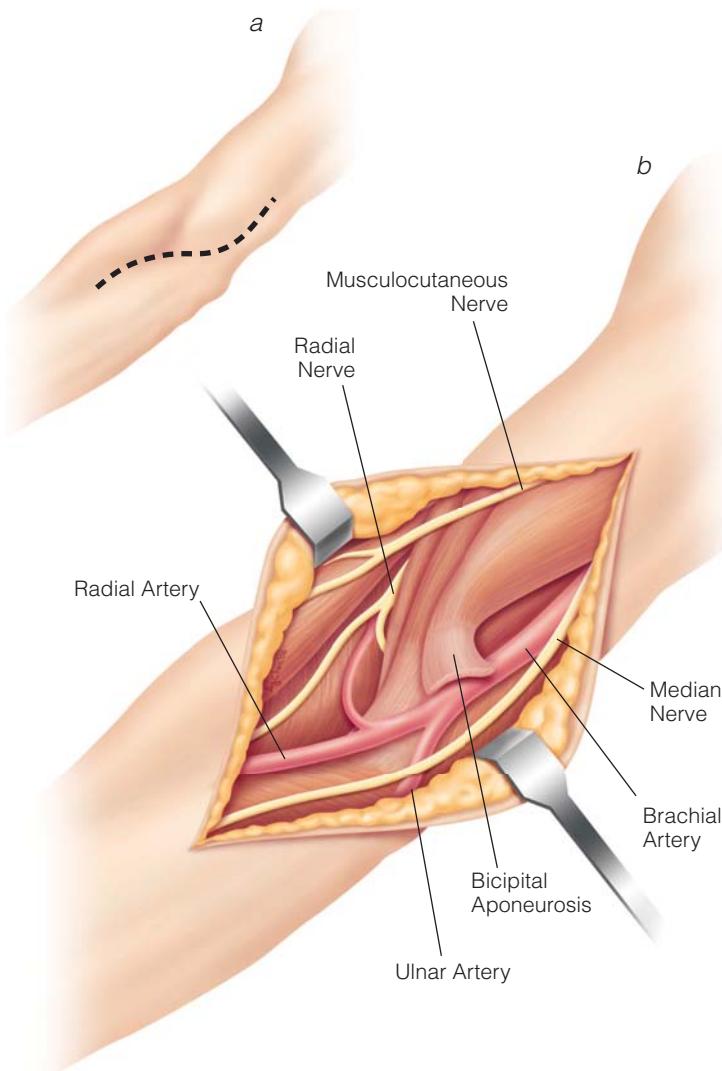

Figure 1 Brachial embolectomy. Shown are (a) a lazy S skin incision and (b) the main nerves and vessels exposed.

removed. In some cases, the brachial artery is pulseless, which indicates that the embolus is lodged more proximally. Once inflow is established, a size 2 or 3 embolectomy catheter is passed distally down each forearm artery. The arteriotomy is then closed either primarily or with a vein patch. A segment of vein may be harvested from the antecubital fossa. Adequate flow in the radial and ulnar arteries is confirmed by means of an intraoperative Doppler probe.

Occasionally, the hand continues to appear ischemic even after an adequate embolectomy. This persistent ischemia is caused either by an unrecognized inflow lesion or by embolization to the digital arteries that has been occurring over an extended period. In these patients, an arch aortogram with selective views of the affected arm should be performed immediately after operation. Any lesion in the SA or the innominate artery can be treated with angioplasty and stenting.

Postoperative Care

The mainstay of postoperative management is adequate anticoagulation. Embolization recurs after successful embolectomy in one third of patients if systemic anticoagulation is not instituted. It may recur even in the face of oral anticoagulation: in a 1989 study, 11% of patients given warfarin after embolectomy sus-

tained a further embolic episode, and all had ongoing atrial fibrillation.⁶ Patients are routinely followed up by means of noninvasive studies 4 to 6 weeks after operation.

FOREARM FASCIOTOMY

Unlike calf fasciotomies, which are commonly necessary for leg ischemia, forearm fasciotomies are rarely required for acute arm ischemia. They are more commonly required for traumatic injuries to the arm (e.g., crush injuries or supracondylar fractures of the humerus) or for iatrogenic injuries (e.g., inadvertent infusion of fluid into the muscle compartments of the forearm). Forearm fasciotomies are immediately effective when they are performed, and the incisions, though extensive, usually heal quickly.

Preoperative Evaluation

The forearm muscles are typically tense and tender, though the diagnosis can be difficult to make. One option for assessment is to test compartment pressures with a needle and a transducer; if the intracompartmental pressure is higher than 30 mm Hg, fasciotomy may be indicated. Another option is insonation of the radial and ulnar arteries; if the signal is absent or severely obstructed, fasciotomy may be indicated. Neither of these techniques, however, is reliable. As with lower-extremity ischemia, even the finding of a pulse does not eliminate the need for fasciotomy. The decision whether to perform the procedure is made on clinical grounds.¹¹ The relevant dictum is "If one is thinking about a fasciotomy, it is probably indicated."

Selection of patients Awareness of the diagnosis is crucial. Any patient with the traumatic or iatrogenic conditions previously mentioned (see above) should be considered to be at risk for compartment syndrome.

Alternative therapy There is no alternative to fasciotomy. Failure to recognize the problem or undue delay in performing adequate fasciotomies will lead to forearm muscle ischemia and a Volkmann's ischemia contracture, resulting in a useless hand.

Operative Planning

Because this procedure is rarely performed, the surgeon may find it useful to mark the incisions on the skin with an indelible pen before operation. The operation is generally performed with general anesthesia, but if the patient is profoundly ill, it may be performed with local anesthesia instead.

Operative Technique

Both a volar and a dorsal incision are required [see Figure 2]; there is no single-incision option, as there is for leg fasciotomy. On the volar aspect of the arm, a curvilinear incision is made to allow decompression of the flexor compartment. Because this compartment is supplied by a single vessel (the interosseous artery) and lacks any collateral circulation, it is particularly susceptible to ischemia. On the dorsal aspect, a vertical incision is made to release the dorsal compartment. Because of its deep location in the forearm, the median nerve is especially susceptible to compartment syndrome. At the level of the elbow, the bicipital aponeurosis is divided so that it can be decompressed. At the wrist, the flexor retinaculum is divided in much the same way as in a carpal tunnel decompression. In severe cases, the deep intramuscular fascia enveloping the flexor digitorum superficialis, the flexor digitorum profundus, and the flexor pollicis longus may be opened as well. As a rule, the skin incisions are loosely approximated to facilitate later closure. In any case, the incisions usually heal very well.

Postoperative Care

Regular dressings are applied to the area. Often, delayed primary closure of the fasciotomy sites may be performed once the muscle edema has resolved. Further pressure measurements may be performed to confirm that all muscle compartments have been released.

Procedures for Chronic Arm Ischemia

The etiology of chronic arm ischemia is diverse. Although atherosclerosis is still the major cause, other potential causes (including thoracic outlet syndrome and iatrogenic injury, as well as rarer causes such as Takayasu arteritis, giant cell arthritis, and radiation-induced injury) must also be considered. Initial assessment is carried out by means of noninvasive studies (e.g., pulse-volume recordings [PVRs] and duplex ultrasonography), followed by magnetic resonance angiography (MRA) or computed tomographic angiography (CTA). Confirmation of the findings obtained from these studies may be obtained by means of arch and arm angiography. As a rule, any occlusive lesions found will be in the innominate, subclavian, axillary, or forearm arteries. Each location calls for a different treatment stratagem.

AORTOSUBCLAVIAN BYPASS AND EXTRATHORACIC OPTIONS FOR INNOMINATE ARTERY OCCLUSION

Innominate artery reconstruction is a major surgical procedure. In one major series, the reported operative mortality was 5.4%.¹² Currently, innominate artery bypass is rarely performed, having been largely supplanted by balloon angioplasty and stenting. Nevertheless, there are still some patients who, for technical

reasons, may not be candidates for endovascular procedures (e.g., those with an occluded stent and those in whom the anatomy is unsuitable). In patients for whom it is indicated, innominate artery bypass has durable beneficial effects and thus is an option worth considering, despite its potential for significant morbidity.

Preoperative Evaluation

Arm ischemia is the typical presentation for patients with innominate artery occlusion. Cerebrovascular symptoms related to the vertebral or carotid arteries are the second most common presentation.

In many patients, noninvasive imaging yields the first indication of innominate artery stenosis. It is difficult, however, to distinguish between an occlusion in the proximal SA and one in the innominate artery on a duplex ultrasonogram. Contrast angiography is the gold standard for making this distinction. As with all major vascular procedures, standard cardiac investigations and clearance are mandatory.

Selection of patients Innominate artery bypass is the operative standard for selected patients with upper-extremity ischemia. In patients who are at particularly high risk, however, extrathoracic options (e.g., carotid-carotid bypass or, rarely, axilloaxillary crossover grafting) should be considered. We prefer carotid-carotid crossover for higher-risk patients. Cerebrovascular considerations (e.g., asymptomatic high-grade lesions [i.e., > 70% occlusion] or ulcerated plaques with greater than 50% luminal narrowing) may also warrant intervention.

Alternative therapy Indirect or extra-anatomic approaches to innominate artery reconstruction include axilloaxillary crossover grafting, carotid-carotid crossover, and femoroaxillary bypass. In general, these approaches are reserved for higher-risk patients in whom endovascular therapy is not an option.

Operative Planning

Operative planning must take into account relevant anatomic details. It is important to keep in mind that the anatomy of the aortic arch is not invariable: in 30% of patients, there are variations in the arch anatomy that may make innominate artery bypass more difficult. The most common variation is an innominate artery that branches into a right common carotid artery (CCA) and a right SA, with the right CCA and the right SA coming directly off the arch. In 16% of patients, however, the innominate artery and the right CCA may have a common ostium. In 8% of patients, the left CCA comes off the innominate artery, leaving the left SA as the only other artery coming off the arch. In 6% of patients, the left vertebral artery comes off the arch between the left CCA and the left SA. In fewer than 1% of patients, the right SA comes off the descending aorta as the last arch branch, then travels behind the esophagus (as the retroesophageal right SA) to reach the right supraclavicular fossa.¹³

Operative Technique

The innominate artery is approached via a median sternotomy.¹⁴ A sternal retractor is placed and opened. The thymus is divided along its midline with the electrocautery, and the inferior thymic vein is ligated and divided. The brachiocephalic vein is identified as it crosses the innominate artery, then mobilized and placed in a vessel sling. The pericardium is opened from the ventricular surface to a point just below the origin of the innominate artery. It is held away from the operative field with stay sutures.

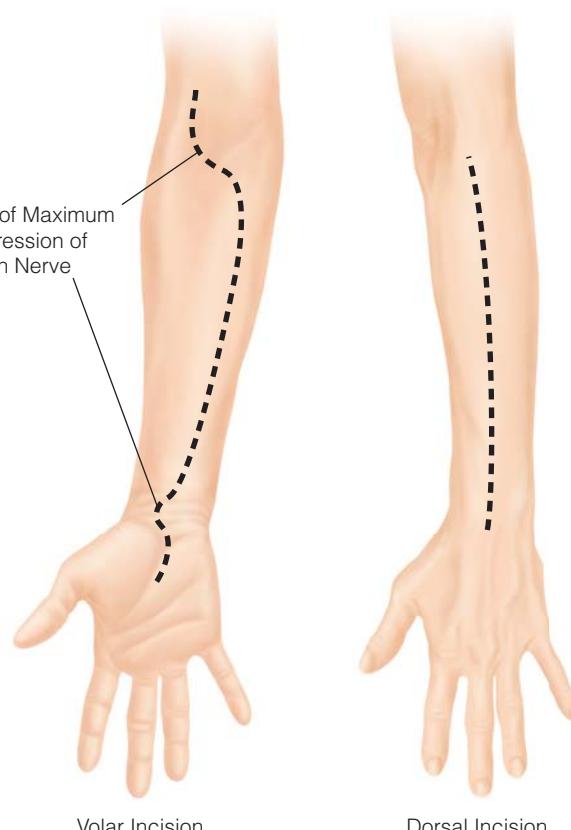

Figure 2 Forearm fasciotomy. Shown are (a) a volar incision and (b) a dorsal incision in the forearm.

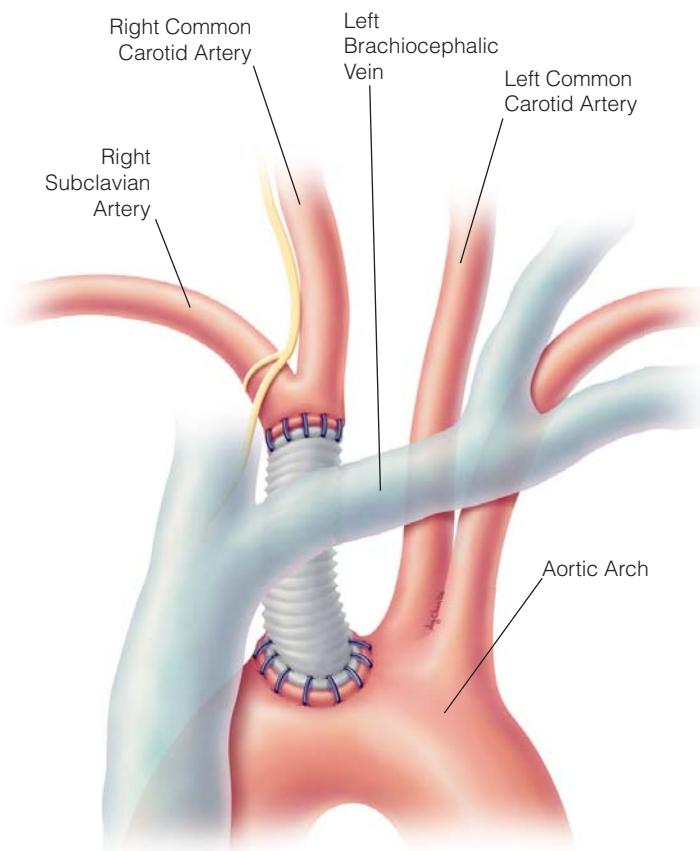

Figure 3 Innominate artery bypass. One end of the graft is sewn to the aorta in an end-to-side fashion, and the other is sewn to the common ostium of the right SA and the right CCA in an end-to-end fashion.

The ascending aorta is then exposed. Fat and visceral pericardium are cleared from the anterior and lateral walls of the aorta to allow placement of a partial exclusion clamp.

The brachiocephalic vein is retracted downwards, and dissection is continued distally along the innominate artery toward the origins of the right SA and the right CCA. Care must be taken to keep from injuring any major nerves, particularly the right recurrent laryngeal nerve.

Some authors have employed a partial median sternotomy approach to the innominate artery, which is useful when access to the distal half of the innominate artery is required and access to the ascending aorta is not required. The advantage of this approach is that it preserves the lower sternum, thereby enhancing the stability of the chest and reducing postoperative pain. The incision extends only to the fourth intercostal space.

After heparinization, a partial exclusion clamp is placed on the ascending aorta, and an arteriotomy is made. An 8 mm graft is sutured to the aorta in an end-to-side fashion with 3-0 or 4-0 polypropylene. If the innominate artery is occluded, the right CCA and the right SA are clamped, and the innominate artery is divided and oversewn. The graft is then sewn to the common ostium of the SA and the CCA in an end-to-end fashion [see Figure 3]. Flow is confirmed with a Doppler probe, as with all the reconstructions we describe in this chapter.

Postoperative Care

After the operation, patients are observed in the intensive care unit. In general, anticoagulation is not indicated. After

recovery, patients are followed by means of noninvasive graft surveillance.

CAROTID-SUBCLAVIAN BYPASS OR TRANSPOSITION

Most patients with SA stenosis or occlusion require no treatment. In many cases, overt symptoms are absent, and the diagnosis is made serendipitously when a reduced pulse pressure is encountered in one arm. For patients with symptomatic lesions, balloon angioplasty with stent insertion is currently the treatment of choice, having been shown to be a durable and effective therapy.^{15,16} Elective bypass is typically reserved for lesions that are not amenable to balloon angioplasty. As stenting of thoracic aortic aneurysms becomes more common, however, stents are increasingly being applied across the origin of the left SA to facilitate proximal fixation, which means that a carotid-subclavian transposition or bypass is required to maintain flow. Thus, the growth of endovascular surgical treatment of thoracic aortic aneurysms has, paradoxically, created a growing population of patients who require a carotid-subclavian bypass. It is important, therefore, that this procedure remain part of the armamentarium of all vascular surgeons.

Preoperative Evaluation

A healthy CCA is an excellent inflow source for an SA bypass procedure. Before operation, the CCA should be evaluated with duplex ultrasonography, supplemented by arteriography. Aortic arch anomalies (e.g., the presence of a bovine aortic arch) should be identified. In patients with contrast allergies or renal impairment, MRA may be employed. In the future, CTA may prove to be the modality of choice.

Selection of patients It is important to confirm that arm symptoms are in fact caused by subclavian disease. In young patients, the possibility of thoracic outlet syndrome should be considered. In older patients, the differential may include cervical disc problems or osteoarthritis. In patients with thoracic aortic aneurysms, our threshold for treatment is a diameter of 5 cm. Given the complexity of the anatomy and the potential for nerve injury, some surgeons are reluctant to perform carotid-subclavian bypass or transposition, instead favoring axilloaxillary crossover grafting. However, axilloaxillary crossover has a lower patency rate than carotid-subclavian bypass or transposition, and its subcutaneous placement and prominence make it less acceptable to most patients. In addition, instances of erosion through the skin have been reported.

Alternative therapy Subclavian artery balloon angioplasty is less invasive than surgical bypass and is a durably effective procedure that is well tolerated by most patients.¹⁷ However, patients who have recurrent stenosis or whose lesions are too close to the vertebral arteries may not be candidates for angioplasty. For such patients, prosthetic bypass or reimplantation of the subclavian artery is an ideal option. The temptation to perform a lesser procedure (e.g., axilloaxillary bypass) should be resisted.

Operative Planning

The two key considerations in the planning of the operation are (1) whether to perform a bypass or a transposition and (2), if a bypass is chosen, whether to use autologous vein or synthetic material as the conduit. For a bypass, prosthetic grafts, being short and of large caliber, are generally considered preferable to autologous vein grafts^{18,19}: they are less likely to become kinked or give rise to intrinsic disease, and the long-term patency of prosthetic reconstructions is excellent.

Transposition of the SA is an excellent alternative to carotid-subclavian bypass, with long-term patency rates approaching 100%.²⁰ Preoperative consent should include acknowledgment of the potential for injury to the phrenic nerve or the brachial plexus.

Operative Technique

The patient is placed in the supine position, with a towel roll placed between the scapulae. The neck is tilted toward the contralateral shoulder. A transverse incision is made 1 cm superior to the clavicle. The underlying platysma and the lateral portion of the sternocleidomastoid muscle are divided in the line of the incision. The underlying omohyoid muscle and the external jugular veins are divided, and the scalene fat pad is mobilized and retracted laterally and cephalad. Minor lymphatic vessels are identified and ligated. The internal jugular vein is visible medially in the carotid sheath, and the carotid artery is usually situated posteriorly. Every effort should be made to keep from injuring the vagus nerve and the thoracic duct on the left; the risk of thoracic duct injury may be minimized by not dividing the lymphatic tissue lying between the phrenic nerve and the lateral border of the internal jugular vein. The anterior scalene muscle is divided as far caudad as possible to reveal the SA; care must be taken to avoid the overlying phrenic nerve, which courses diagonally in a lateral-to-medial direction along the anterior surface of the muscle.

A bypass from the CCA to the SA is then performed in an end-to-side fashion with a 6 mm or 8 mm prosthetic graft [see Figure 4]. The graft is usually tunneled under the internal jugular vein. Often, the graft-SA anastomosis is constructed first. A clamp is placed on the proximal graft, and the anastomosis to the CCA is

constructed. The CCA is mobilized so that once two straight vascular clamps are placed and rotated anteriorly, the graft-CCA anastomosis may be performed more easily. Once the bypass has been completed, flow is restored—first to the arm, then to the proximal SA, and finally to the distal CCA, so as to minimize the carriage of embolic debris to the brain. Flow should then be assessed with a pencil Doppler probe.

After completion of the bypass, the scalene fat pad is tacked to its former medial and inferior attachments; failure to do so may leave a visible defect in this area. The wound is drained with a closed suction apparatus. An upright chest x-ray is obtained to rule out pneumothorax or hemidiaphragmatic elevation secondary to phrenic nerve injury. Postoperative evaluation of bypass patency is accomplished by physical examination with palpation of pulses at the wrist. Further objective documentation of patency is obtained by means of PVRs, duplex ultrasonography, or both.

Postoperative Care

The major postoperative complication is phrenic nerve injury and resulting paralysis of the hemidiaphragm [*see 4:3 Paralyzed Diaphragm*]. Another significant complication is lymphatic leakage, which may occur as a result of either minor or major duct injury. Adequate wound drainage and prompt recognition of the lymphatic leak are the keys to management. Minor leaks usually seal with adequate drainage. If drainage is excessive, the patient will have to be maintained on parenteral nutrition with a formula that includes medium-chain triglycerides. On occasion, thoracic duct ligation via thoracotomy or thoracoscopy may be necessary. Other complications include pneumothorax, brachial plexus injury, and stroke.

Patients are followed with serial PVRs of the arm and duplex ultrasonography of the grafts.

AXILLOBRACHIAL BYPASS

Axillobrachial bypass may be performed to treat severe occlusive disease in the axillary or proximal brachial arteries. It is infrequently performed for chronic ischemia and more frequently performed for shoulder trauma. In the latter setting, it is often associated with brachial plexus injuries.

Preoperative Evaluation

Axillobrachial bypass is not commonly performed on an elective basis. The axillary and proximal brachial arteries seem to be remarkably impervious to the effects of systemic atherosclerosis. In those rare cases in which this procedure is indicated, preoperative evaluation of the affected arm with selective angiography is appropriate. Vein mapping should be performed. It is important to confirm that the patient's symptoms derive from arm ischemia and not from other conditions (e.g., neuropathy).

Alternative therapy If arm ischemia is truly symptomatic at this level, sympathectomy may be considered [*see Alternative Therapies for Chronic Arm Ischemia, below*]. Angioplasty may be an option for axillary artery lesions, but it is infrequently performed in this setting, and data on its effectiveness and durability are relatively sparse.

Operative Planning

Autogenous vein is the conduit of choice for axillobrachial bypass. Prosthetic bypasses have lower patency rates than venous bypasses in this setting and should therefore be avoided. The greater saphenous vein is the preferred source of the venous conduit, though the use of the cephalic vein *in situ* has also been described.

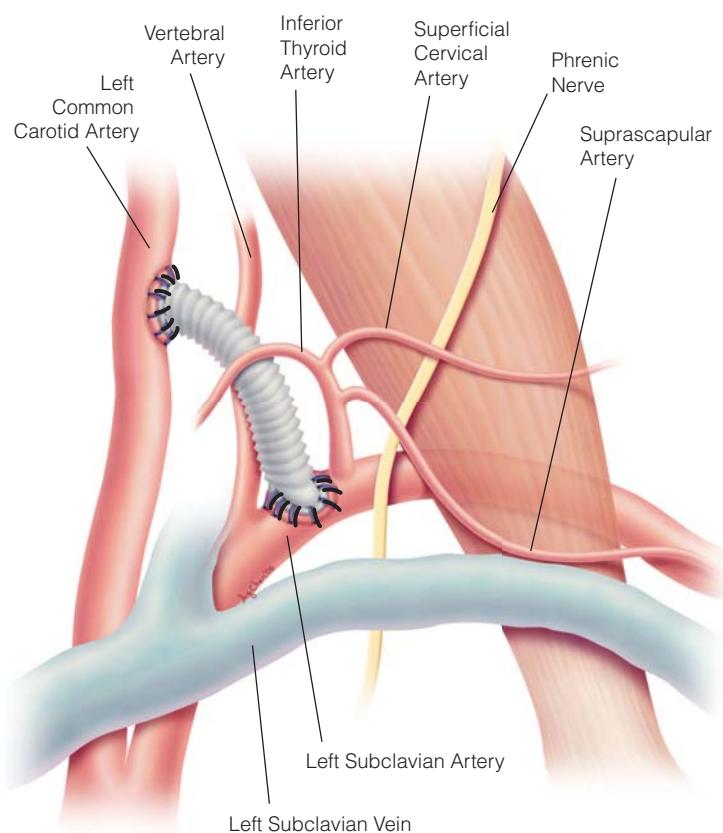

Figure 4 Carotid-subclavian bypass. One end of the graft is sewn to the left SA in an end-to-side fashion, and the other is sewn to the left CCA in an end-to-side fashion.

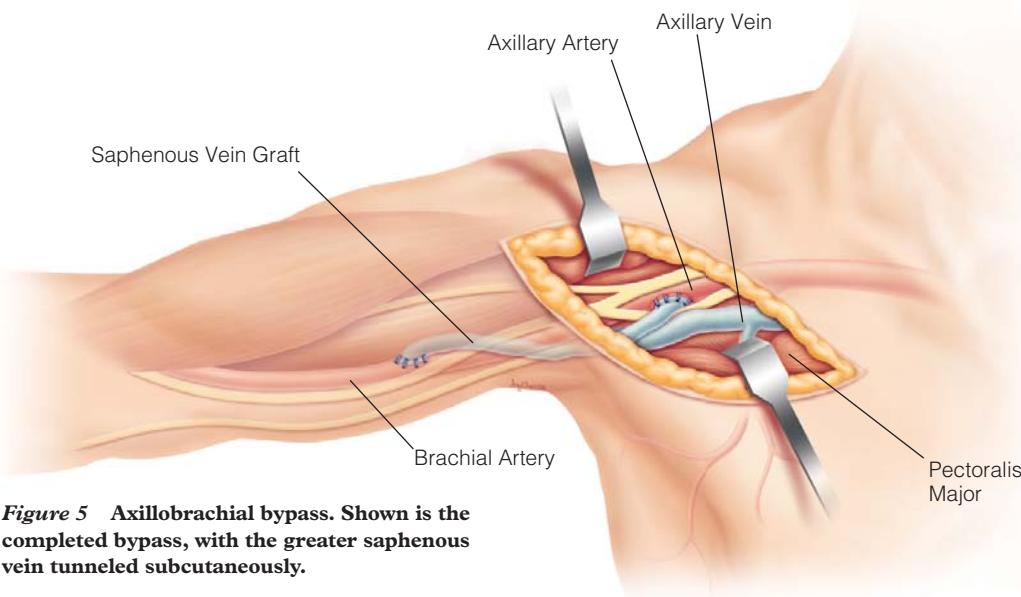

Figure 5 Axillobrachial bypass. Shown is the completed bypass, with the greater saphenous vein tunneled subcutaneously.

Operative Technique

The patient is placed in the supine position, and the arm is draped circumferentially. A previously mapped leg is draped in preparation for vein harvesting. The axillary artery is approached via a transverse incision placed 2 cm below the middle third of the clavicle. The underlying pectoralis major is divided in the line of the decussation between its sternocostal and clavicular portions. Despite the assurances of most operative texts, the decussation is not always readily apparent. Division of the pectoralis major exposes the clavipectoral fascia, which is then divided. The axillary artery is identified cephalad to the axillary vein and is carefully dissected, with care taken not to injure the surrounding branches of the brachial plexus. The second part of the axillary artery is exposed by dividing the pectoralis minor.

If necessary, the distal third of the axillary artery may be exposed. An oblique incision is made along the lateral margin of the pectoralis major with the arm abducted 90° relative to the thorax. Once the subcutaneous tissue is divided, the axillary sheath is located near the posteroinferior border of the coracobrachialis. Care should be taken to keep from injuring the medial and lateral cords of the brachial plexus medially and the median and ulnar nerves laterally.

By preference, bypasses originating from the axillary artery are tunneled anatomically along the axis of the axillary and brachial arteries. Alternatively, they may be positioned subcutaneously; however, subcutaneous bypasses are more susceptible to distraction injuries caused by forcible abduction of the shoulder. Accordingly, some degree of redundancy should be built into a subcutaneous bypass.

The middle or the distal portion of the brachial artery is exposed as necessary. The proximal or the middle third of the vessel is exposed by making a medial incision over the bicipital groove, with care taken to keep from injuring the basilic vein and the cutaneous nerves located within the subcutaneous tissue. Traction on or transection of the median antebrachial cutaneous nerve may lead to hyperesthesia or anesthesia along the medial dorsal surface of the forearm; these problems occasionally occur after dialysis access procedures (e.g., basilic vein transposition) and can be highly debilitating, sometimes even rendering the fistula unusable. The brachial sheath is then incised longitudinally. The median nerve is the most superficial structure encountered

within the sheath. It is gently mobilized and retracted to afford access to the brachial artery. Any venous branches that cross the artery should be divided carefully, and every effort should be made to keep from injuring the posteriorly located ulnar nerve.

In contrast, the distal third of the brachial artery and its bifurcation are exposed in the antecubital fossa. A lazy S or sigmoid incision [see *Figure 1a*] is made to expose the brachial artery while avoiding wound contracture. The bicipital aponeurosis is then incised to expose the brachial artery, which is sandwiched between the biceps tendon laterally and the median nerve medially. Further dissection exposes the origins of the ulnar and radial arteries.

After systemic heparinization, the venous conduit is harvested, and its side branches are ligated with fine polypropylene suture ligatures or silk ties. The vein is distended with a solution containing dextrose 70 (500 ml I.V.), heparin (1,000 U), and papaverine (120 mg). The excised conduit may be employed in either a reversed or an orthograde (nonreversed) orientation, depending on the taper of the conduit. If the orthograde orientation is used, the proximal anastomosis is performed, the conduit is distended, and the valves are lysed with a retrograde Mills valvulotome. In either case, the conduit is tunneled anatomically wherever possible; in this way, it will be less prone to movement, distraction, or distortion. After tunneling, the distal anastomosis is constructed [see *Figure 5*]. Immediately upon completion of the bypass, patency and augmentation of flow are assessed with a pencil Doppler probe.

Major potential complications include injuries to the brachial plexus, the median nerve, or the ulnar nerve. Such injuries usually are caused by traction and may be minimized by careful dissection during operative exposure. The median and ulnar nerves and the brachial plexus are also vulnerable to direct thermal injury; accordingly, dissection with the electrocautery should be avoided.

Postoperative Care

Postoperatively, the patency of the bypass is documented by surveillance with noninvasive studies. In general, duplex ultrasonography is valuable for determining the patency of the reconstruction and for detecting any early flow abnormalities in the venous conduit. Graft infection should be watched for and appropriately treated if found.

DISTAL REVASCULARIZATION-INTERVAL LIGATION AND REVISION USING DISTAL INFLOW

The rising incidence of diabetes in the United States has led to a corresponding rise in the number of patients in whom vascular access is required for hemodialysis.^{21,22} As reconstructions become more complex, these patients are increasingly coming under the care of vascular surgeons. An unfortunate consequence of the growing number of upper-arm fistulas is that the incidence of dialysis-associated steal syndrome (DASS) is increasing as well. DASS is rare after Cimino or radiocephalic fistula procedures,²³ but it occurs in 6% to 8% of patients who undergo upper-arm brachial artery-based fistula or graft procedures.^{24,25} DASS may present in either an acute form (characterized by severe rest pain and obvious ischemia developing within 24 to 48 hours after operation) or a chronic form (characterized by symptoms and signs developing several weeks or even months after the original operation), each of which is managed in its own distinct fashion.

In cases of acute ischemia that develops within 24 to 48 hours after an upper-arm fistula procedure, the fistula should be ligated to restore flow down the native arteries. In cases of chronic ischemia, however, the aim is to preserve the fistula and avoid ligation. To this end, there are two main surgical options that should be considered. The first option is distal revascularization–interval ligation (DRIL), which involves the creation of a venous bypass from the proximal portion of the brachial artery to the distal portion of the vessel [see Figure 6]. The brachial artery distal to the origin of the fistula is ligated, flow to the distal arm is restored, and the fistula is preserved.²⁶ The second option is revision using distal inflow (RUDI), which involves ligation of the fistula at its origin, followed by reestablishment of the fistula by means of a venous bypass from the radial or the ulnar artery.²⁷ By using a

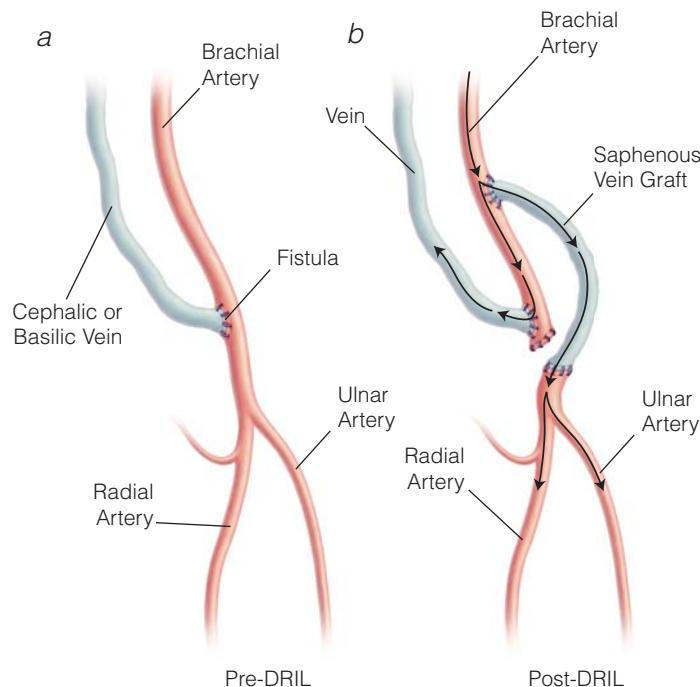

Figure 6 Distal revascularization–interval ligation (DRIL). In patients with a brachial artery-based fistula (a), chronic ischemia may develop weeks or months after the procedure. The best established surgical treatment option is DRIL (b), which preserves the fistula by creating a venous bypass between the proximal brachial artery (above the origin of the fistula) and the distal brachial artery.

smaller distal artery as the inflow source, RUDI lengthens the fistula and preserves antegrade flow in the brachial artery.

Of the two options, DRIL is better established and more widely used at present. It is our preferred option and thus is the primary focus of the ensuing description. Nevertheless, there are aspects of the DRIL procedure that many vascular surgeons find counterintuitive—namely, the ligation of a healthy artery and the bypassing of a normal arterial segment with a venous conduit. There does seem to be a good argument in favor of RUDI. Long-term evaluation of this procedure is awaited.

Preoperative Evaluation

Preoperative evaluation for DRIL should follow the same pattern as that for any elective procedure performed to treat arm or leg ischemia. Preoperative angiography is performed with vein mapping to identify an adequate source of a venous conduit. Cardiac clearance is obtained.

Selection of patients DRIL is generally reserved for patients with chronic arm ischemia in whom a fistula has been established that must be preserved. If the option of creating a new fistula in the other arm is available, DRIL is probably a less appropriate choice than simply ligating the original fistula.

Alternative therapy Besides simple ligation of the offending fistula, which is an option that should always at least be considered in these patients, there are two techniques that deserve mention as alternatives to DRIL. The first technique is aimed at preventing steal from an upper-arm fistula (always a laudable aim). In this technique, the fistula is formed by extending the cephalic vein or the basilic vein down the arm and anastomosing it to the proximal ulnar artery or the radial artery just below the brachial bifurcation so as to preserve part of the blood supply to the hand. The median cubital vein may also be used.²⁸

The second technique is RUDI [see Figure 7]. This procedure differs from DRIL in that it is the fistula, not the native arterial supply, that is placed at risk by the surgical revision, so that in the event of graft failure, the fistula is lost but the arm is not endangered.

Operative Planning

We do not use prosthetic grafts for this procedure; we prefer to use autogenous vein for the graft, usually a segment of the greater saphenous vein from the leg. As a rule, the operation is performed with the patient under general anesthesia.

Operative Technique

A vertical incision is made in the upper arm at the level of the proximal brachial artery. The skin and the subcutaneous fat are divided, and the proximal brachial artery is sharply dissected free. The portion of the brachial artery distal to the origin of the fistula is also dissected free. An adequately long segment of vein is obtained and prepared. Anticoagulation is initiated, and a proximal end-to-side anastomosis is fashioned with 6-0 polypropylene. The vein graft is tunneled subcutaneously, and a distal end-to-end anastomosis to the distal brachial artery is created. Some surgeons prefer an end-to-side distal anastomosis with ligation of the brachial artery proximal to the anastomosis. Adequate flow is confirmed by means of intraoperative Doppler ultrasonography.

Postoperative Care

Postoperative anticoagulation is generally not warranted; however, a postoperative graft surveillance protocol is initiated. If the

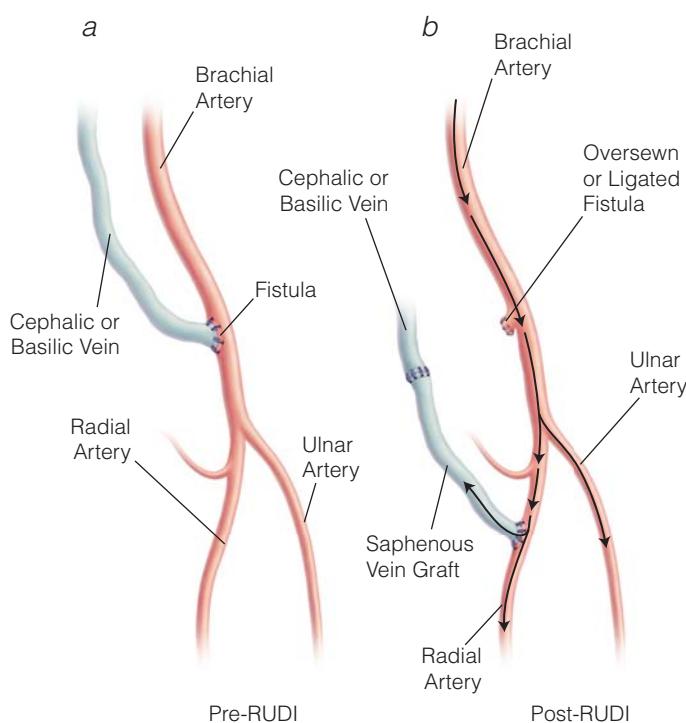

Figure 7 Revision using distal inflow (RUDI). Another option for patients with a brachial artery-based fistula (*a*) is RUDI (*b*), which involves ligating the fistula at its origin, lengthening the original venous graft with an additional vein segment, and reestablishing the fistula by anastomosing the lengthened graft to the radial artery (as shown) or the ulnar artery.

venous graft becomes occluded, the fistula is ligated. This step frequently leads to resolution of the symptoms of arm ischemia.

HAND REVASCULARIZATION

Patients with rest pain in the hands and digital ulcers often have significant comorbid conditions (e.g., collagen vascular or rheumatologic disorders, end-stage renal disease, or hypercoagulable states). In addition, patients who have received organ transplants and are taking immunosuppressive medications may experience severe occlusion of forearm or palmar arteries. Younger patients with hand ischemia are often manual laborers who have hypothenar hammer syndrome. Patients with established signs and symptoms of hand ischemia have little to lose by undergoing revascularization: there are few viable therapeutic alternatives.

Aggressive treatment of hand ischemia is worthwhile, in that it achieves rapid relief of symptoms and offers the opportunity for hand and limb salvage. The techniques resemble those employed for distal bypass in the leg [see 6:18 *Infrainguinal Arterial Procedures*]. Early results from several centers indicate that hand bypass procedures can be performed with low morbidity and good long-term patency.^{29,30} Postoperative life expectancy, however, is often limited by the comorbid conditions present.

Preoperative Evaluation

Preoperative evaluation for hand bypass should follow the same protocol as that for any elective revascularization: preoperative angiography to delineate anatomy with vein mapping to identify a venous conduit.

Many patients with hand ischemia have intractable pain from ulcerative lesions, gangrene, or both. Their main requirement is adequate relief of pain; improved hand function is a secondary

consideration. Vascular reconstruction offers a chance to gain both. The alternative to attempted arm salvage is amputation.

Selection of patients At our institution (Albany Medical Center), all patients with rest pain, digital necrosis, or nonhealing ulcers are evaluated for possible palmar artery reconstruction, provided that they are surgical candidates. Reconstruction is feasible in approximately half of the patients who have renal disease or diabetes.

Alternative therapy Sympathectomy, in various incarnations, has been employed in the treatment of hand ischemia. Isolated reports of success notwithstanding, the experience of most vascular surgeons with sympathectomy in this setting has not been favorable.

Operative Planning

Fortunately, exposure of the palmar vessels beyond the wrist is not as difficult as might be imagined [see Operative Technique, below]. Nevertheless, because hand bypass procedures are relatively new territory for many vascular surgeons, operative planning may benefit from a brief review of the normal anatomy. The hand is supplied with blood by the superficial and deep palmar arches. The superficial palmar arch is supplied by a branch of the radial artery and by the ulnar artery. The deep palmar arch is supplied by the radial artery itself and by a deep branch of the ulnar artery.

Venous grafts are preferred to prosthetic grafts for hand bypasses. All venous grafts are tunneled anatomically. In a radial artery reconstruction, the graft is tunneled over the anatomic snuff box onto the dorsum of the hand, between the thumb and the index finger, to join the deep palmar arch. In an ulnar artery reconstruction, the venous graft takes a less circuitous course, passing superficial to the flexor retinaculum at the wrist to join the superficial palmar arch.

Operative Technique

The donor limb that will provide the venous graft is prepared. The brachial artery is exposed as described previously [see Procedures for Acute Arm Ischemia, Brachial Embolectomy, Operative Technique, above].

The course of the radial artery in the forearm follows an oblique line from the brachial artery pulse medial to the biceps tendon to the styloid process of the radius. In the midforearm, the radial artery is medial to the brachioradialis and lateral to the flexor carpi radialis. A lateral longitudinal incision is made, and the muscles are separated to reveal the radial artery. At the wrist, the radial artery is exposed by making a longitudinal incision between the tendon of the flexor carpi radialis and the tendon of the brachioradialis. This is the site of the radial artery pulse in normal persons. Here, the artery is superficial, and exposure is relatively straightforward. Care must, however, be taken not to injure the superficial branch of the radial nerve, which is often located near the lateral aspect of the artery. Injury to this nerve branch can result in troublesome paresthesia along the lateral aspect of the thumb.

The course of the ulnar artery runs from the medial epicondyle of the humerus to the pisiform bone. In the midforearm, the ulnar artery lies beneath the deep fascia between the belly of the flexor digitorum laterally and the belly of the flexor carpi ulnaris medially. The ulnar nerve joins the artery on its lateral aspect for the distal two thirds of the vessel's length; this nerve may be injured if not carefully identified and preserved. At the wrist, the ulnar artery is lateral to the tendon of the flexor carpi ulnaris. It is exposed by locating this tendon (which is the most medial tendon palpable at

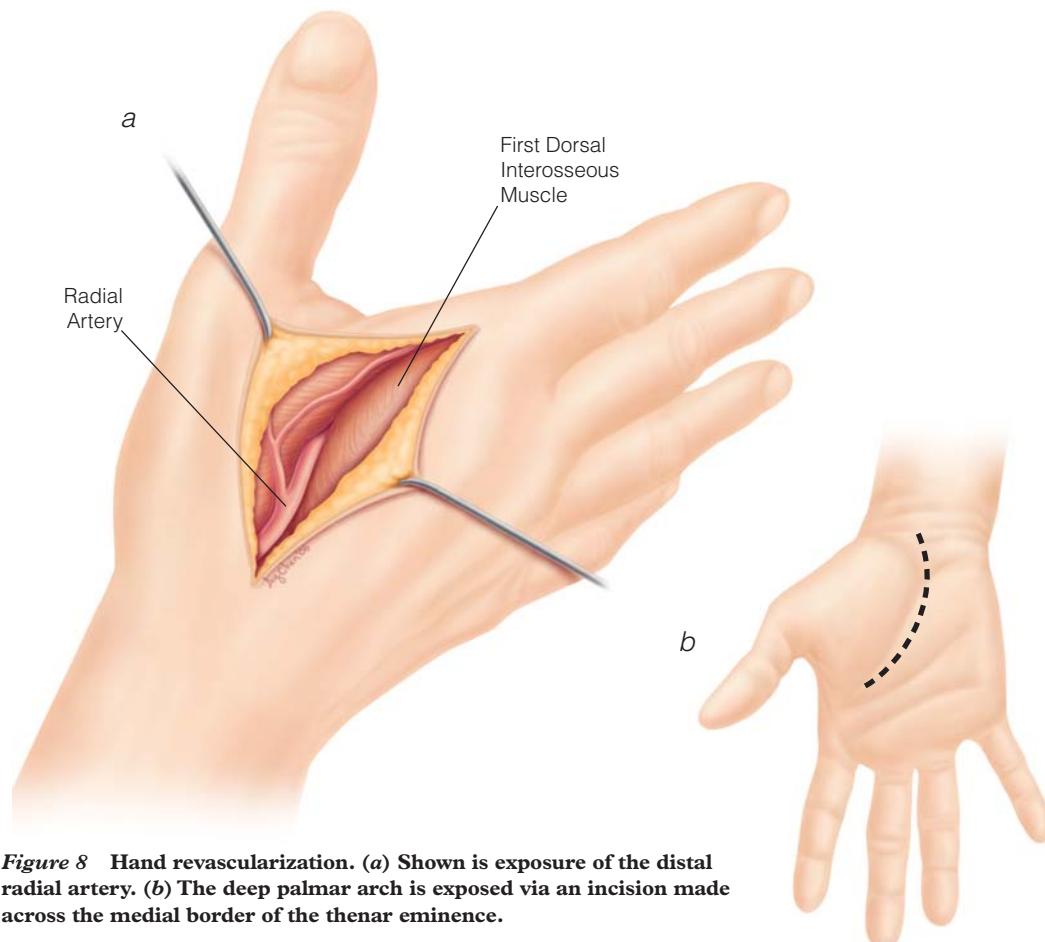

Figure 8 Hand revascularization. (a) Shown is exposure of the distal radial artery. (b) The deep palmar arch is exposed via an incision made across the medial border of the thenar eminence.

the wrist) and making a vertical skin incision lateral to it. Although the ulnar artery lies deeper than the radial artery at the wrist, it is just as easily exposed. Superficial to the ulnar artery, palmar cutaneous branches of the ulnar nerve may be identified; these should also be preserved.

Grafts originating from the brachial artery are tunneled in the subcutaneous plane. Subcutaneous tunneling facilitates physical examination to determine the patency of the bypass, as well as surveillance of the bypass with duplex ultrasonography. Alternatively, if good-quality basilic or cephalic veins are present, an *in situ* bypass may be performed.

Exposure of radial artery and deep palmar arch Exposure of the radial artery is relatively straightforward. Generally, it may be accomplished as previously described (see above). Alternatively, it may be accomplished by making a vertical incision over the anatomic snuff box (which lies between the extensor pollicis longus tendon posteriorly and the tendons of the extensor pollicis brevis and the abductor pollicis longus anteriorly). This incision is then deepened through the subcutaneous tissues to expose the radial artery in the floor of the snuff box [see Figure 8a]. This area contains no significant nerves and thus is often chosen as a site for hemodialysis access.

The deep palmar arch is much less accessible than the radial artery. Consequently, exposure of this vascular structure is considerably more difficult than exposure of the radial artery. The deep palmar arch extends across the palm, level with the proximal border of the outstretched thumb. To expose it, an incision is made along the medial border of the thenar eminence [see Figure 8b]. Extensive dissection of the superficial and deep flexor tendons of

the hand and division of the oblique head of the adductor pollicis are then required to provide access to the origin of the deep palmar arch.

Exposure of ulnar artery and superficial palmar arch

Like exposure of the radial artery, exposure of the ulnar artery and the superficial palmar arch is fairly straightforward. In reality, these vessels are no smaller than the tibial and pedal vessels in the leg. A curved incision is made along the lateral border of the hypothenar eminence [see Figure 9a]. The aponeurotic layer is divided, and the artery is exposed in the upper part of the palm at the origin of the superficial palmar arch. There are no major nerves in the vicinity, and it usually is not difficult to expose a reasonable length of artery for an arterial anastomosis [see Figure 9b]. Alternatively, the superficial palmar arch may be exposed in the palm by making an incision along one of the larger vertical or oblique skin creases.

Postoperative Care

As with all venous grafts, postoperative graft surveillance is essential. Routine postoperative anticoagulation generally is not warranted.

Alternative Therapies for Chronic Arm Ischemia

THORACOSCOPIC SYMPATHECTOMY AND DIGITAL SYMPATHECTOMY

Our experience with sympathectomy in the treatment of patients with critical hand ischemia or digital ulceration has been, frankly, disappointing. When we do perform sympathectomy, we

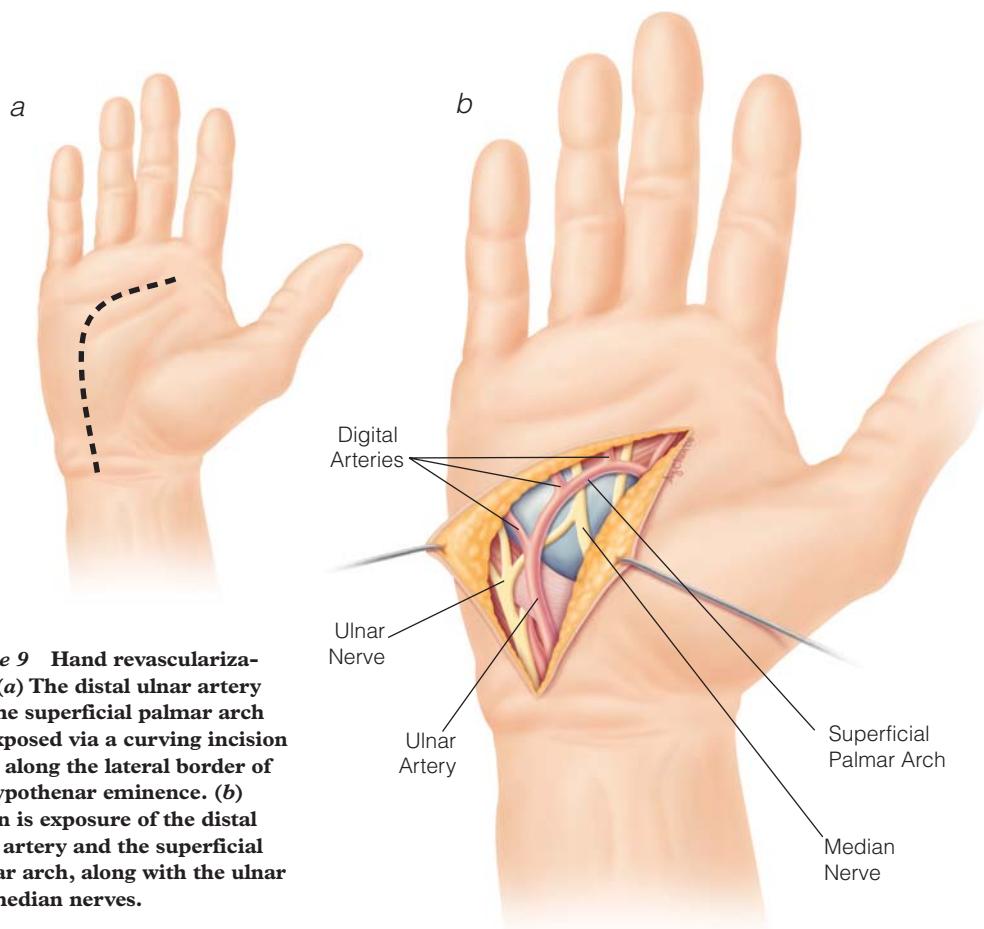

Figure 9 Hand revascularization. (a) The distal ulnar artery and the superficial palmar arch are exposed via a curving incision made along the lateral border of the hypothenar eminence. (b) Shown is exposure of the distal ulnar artery and the superficial palmar arch, along with the ulnar and median nerves.

prefer the thoracoscopic approach to the traditional cervical route. Either way, however, the results have been discouraging; any improvements noted prove to be only temporary. Sympathectomy may help alleviate pain in these patients, but even in this regard, the results are, at best, unpredictable. A review of the literature seems to support this conclusion. Admittedly, the available data on thoracoscopic sympathectomy for digital ischemia are sparse: to date, only three reports encompassing 21 patients have been published.³¹⁻³³ In contrast, there is a wealth of data on thoracoscopic sympathectomy for hyperhidrosis.

An alternative technique has been devised in which a very distal sympathectomy is performed at the level of the origin of the proper digital arteries. The sympathectomy site is exposed via a palmar approach, and a 3 to 4 mm length of the adventitia is removed from the proper digital arteries distal to the junction of the distal perforating artery with the common digital artery. This procedure appears to be well tolerated, and data from small series attest to its value in selected patients with digital ulcers.³⁴

PROSTACYCLINS

The prostacyclin analogue iloprost has been used in Europe to treat patients with hand ischemia. Although iloprost therapy appears to be reasonably effective in patients with vasospastic disorders, such as Raynaud syndrome [see 6:24 *Raynaud*

Phenomenon],³⁵ the results in patients with peripheral ischemia are less encouraging. At present, iloprost is mainly used to treat patients with digital ulcers caused by systemic sclerosis, systemic lupus erythematosus, mixed connective tissue disease, or cutaneous polyarteritis nodosa. There are no good data on its use to treat patients with digital ulcers caused by diabetes mellitus, atherosclerosis, or renal impairment; however, a study of iloprost therapy for arterial leg ulcers found that the success rate was lower than 50%.³⁶

GUANETHIDINE BLOCKS

Transvenous regional guanethidine blocks have also been employed to treat critical digital ischemia. Patients receive a single block, with 5 mg of guanethidine in 60 ml of normal saline injected into a superficial vein of the affected hand under 30 minutes of arterial arrest. In successful cases, hyperemia is induced in the treated upper limb, and blood flow to the fingers improves. The effects of these blocks are said to persist for up to 1 month. Patients who have finger ulcers, however, appear to be less responsive than those whose only symptom is pain. The advantages of this treatment approach are that it is free of side effects and that it can be repeated for as long as necessary³⁷; the disadvantage is that it *must* be repeated at monthly intervals for as long as necessary.

Approach to Suspected Renovascular Disease

Vascular disease that affects the renal arteries is an increasingly common clinical scenario encountered by general and vascular surgeons. As a result of heightened clinical awareness and advances in vascular imaging, more patients than ever before are being identified as having some degree of atherosclerotic or fibromuscular renovascular disease. The vast majority of these lesions cause no symptoms, are hemodynamically insignificant, or both. Some, however, are severe enough to alter renal perfusion pressure, leading to changes in blood pressure regulation and renal function. Symptomatic renovascular disease can have a variety of manifestations, ranging from mild renovascular hypertension to congestive heart failure and ischemic nephropathy.

Our purpose in this chapter is to outline an approach to the diagnosis and management of renovascular disease that is based on an understanding of the relevant pathophysiology [see Discussion, Pathophysiology of Renovascular Hypertension, below]. The procedures employed for surgical and endovascular treatment of renovascular disease are described in greater depth in other chapters [see 6:22 Open Procedures for Renovascular Disease and 6:23 Endovascular Procedures for Renovascular Disease].

Incidence and Risk Factors

In the United States, hypertension affects approximately 24% of the entire population and 50% of persons over the age of 60 years.¹ It is an independent risk factor for increased cardiovascular morbidity and mortality: cardiovascular risk doubles for every 20/10 mm Hg increase in blood pressure.² In fact, it is the number-one modifiable risk factor associated with increased cardiovascular morbidity and mortality. Data from the National Health and Nutrition Examination Survey (NHANES) revealed that 30% of hypertensive persons in the United States were unaware that they had hypertension, that more than 40% of hypertensive persons were not being treated for their condition, and that in two thirds of hypertensive patients who were being treated, blood pressure was not maintained below the recommended target level of 140/90 mm Hg.

An estimated 90% to 95% of cases of hypertension are classified as essential or idiopathic, with the remaining 5% to 10% considered to be secondary to another cause. Secondary hypertension is sometimes refractory to usual medical treatment, the reason being that the underlying pathophysiologic state must be identified and treated in addition to the hypertension itself. There are many possible causes of secondary hypertension [see Table 1], and it can be difficult to determine which one is operative in a given clinical situation. As a result of the increasing use of diagnostic

imaging, renal artery stenosis (RAS) is frequently diagnosed in hypertensive patients. However, the precise contribution RAS makes to hypertension and renal dysfunction is not always clear, and therefore, the patient's response to treatment may not be readily predictable.

The natural history of RAS consists of continued narrowing of the renal artery. Studies in which duplex ultrasonography (DUS) was employed to follow untreated patients with greater than 60% renal artery stenosis documented a 20% progression of disease per year, with 11% of patients progressing to renal occlusion within 2 years.³ RAS is associated with loss of renal mass, which is a surrogate marker for renal function. Occlusion of a renal artery is associated with substantial loss of renal size and function. Historical studies of the clinical course of RAS suggested that chronic renal failure developed within 6 years in as many as 27% of patients with RAS.⁴

The two main conditions associated with RAS are atherosclerosis and fibromuscular dysplasia. The former accounts for the vast majority of renovascular lesions. Atherosclerotic RAS is typically located at the aortic orifice or the proximal renal artery and probably represents spillover of aortic atherosclerotic disease [see Figure 1]. It is most commonly found in patients older than 50 years who have signs of atherosclerosis in other vascular beds. RAS associat-

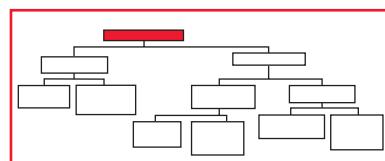

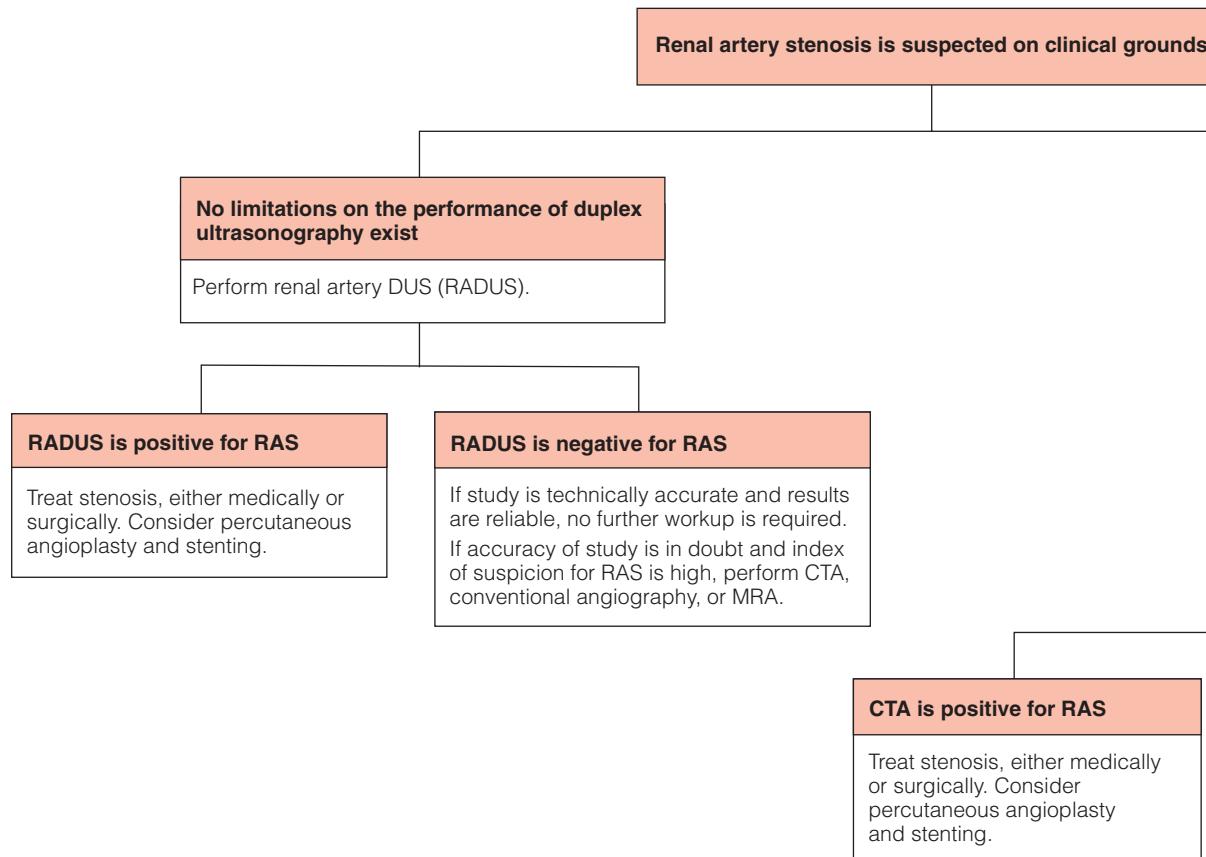

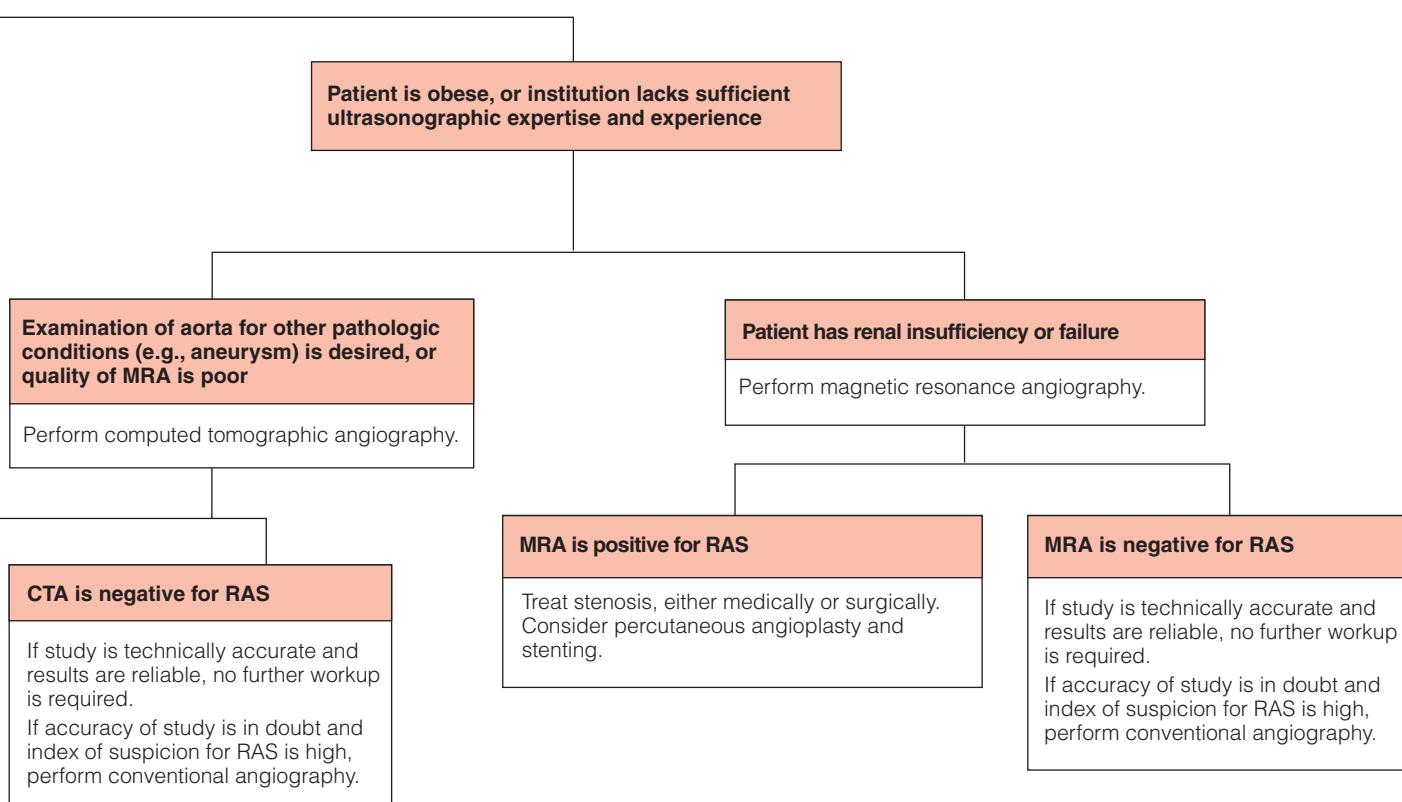

Table 1 Screening Tests for Secondary Causes of Hypertension

Diagnosis	Diagnostic Study
Chronic renal disease and salt retention	Serum creatinine, GFR
Renal artery stenosis	DUS, MRA, CTA
Primary hyperaldosteronism	24-hr urinary aldosterone
Pheochromocytoma	24-hr urinary metanephrine, normetanephrine
Cushing syndrome or chronic steroid use	History, cortisol, dexamethasone suppression test
Thyroid or parathyroid disease	TSH, calcium, serum PTH
Coarctation of aorta	CTA
Sleep apnea	Sleep study with oxygen saturation
Effect of medication	History, drug screen

CTA—computed tomographic angiography DUS—duplex ultrasonography GFR—glomerular filtration rate MRA—magnetic resonance angiography PTH—parathyroid hormone TSH—thyroid-stimulating hormone

Approach to Suspected Renovascular Disease

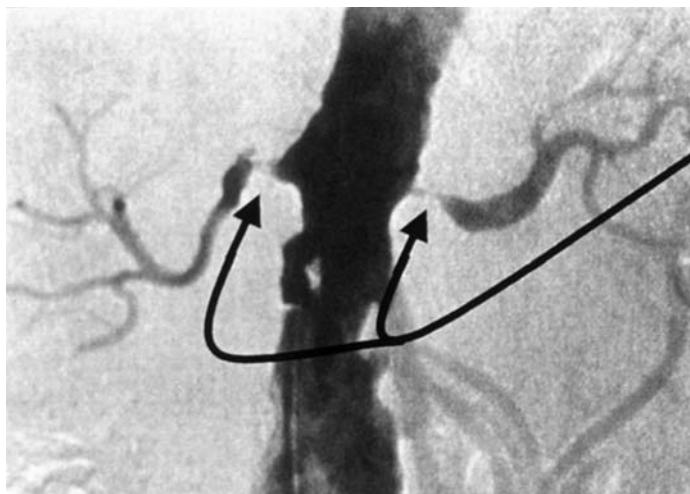

Figure 1 Shown is severe bilateral RAS with poststenotic dilation in a severely diseased aorta.

ed with fibromuscular dysplasia is usually seen in patients younger than 40 years and usually affects the middle and distal segments of the renal artery. These lesions have a characteristic “string of beads” appearance.

Population-based studies indicate that hemodynamically significant atherosclerotic RAS is present in approximately 6% of persons older than 65 years, with a somewhat higher incidence in men (9.1%) than in women (5.5%). Incidental RAS is seen in approximately 20% of patients undergoing coronary angiography and in 35% to 50% of patients undergoing peripheral vascular angiography for occlusive disease of the aorta and the lower extremity. The prevalence of renovascular disease corresponds to the overall atherosclerotic burden. In the vast majority of patients, no direct causal relation between significant RAS and hypertension or ischemic nephropathy can be identified. Efforts to define such a relation are confounded by the fact that the same population in which renovascular disease is prevalent is also at risk for essential hypertension, diabetes, and baseline renal insufficiency. Other risk factors associated with renovascular disease include smoking, increased age, and hyperlipidemia.

RAS is believed to be the cause of hypertension in only 3% to 5% of the 90 million hypertensive persons in the United States. In those with mild hypertension (the vast majority), it plays only a negligible role; however, it plays a significantly larger role in those with severe systemic hypertension. (The severity of a case of hypertension is related to the patient’s blood pressure without medication, not necessarily to the difficulty or ease with which blood pressure can be controlled medically.) At the extremes of age (i.e., in the very young and the elderly), severe hypertension is substantially more likely to be renovascular than essential in origin [see Table 2].

Patients with RAS are at higher risk for cardiovascular morbidity and mortality than similar patients without RAS are. One series, in which patients underwent renal angiography after coronary angiography, found that 4-year survival was significantly decreased in patients with incidentally discovered RAS.⁵ Several series have suggested that the risk of adverse cardiovascular events is high in this population and exceeds the risk that might have been expected on the basis of the severity of hypertension.^{6,7} Blood pressure control—measured by the number of antihypertensive medications used, as well as by systolic and diastolic pressures—is the most commonly used end point in series examining treatment

of RAS. These studies make the points that cardiovascular risk is high in RAS patients and that blood pressure control may be a poor surrogate for clinical outcome. At present, it is not known whether the higher cardiovascular morbidity and mortality associated with RAS are attributable to the effects of renal ischemia or to the systemic effects of activation of the renin-angiotensin-aldosterone system (RAAS) [see Discussion, Pathophysiology of Renovascular Hypertension, below] or whether RAS is simply a marker of more advanced atherosclerotic disease.

Ischemic nephropathy may be defined as a progressive decline in renal function secondary to global renal ischemia. It is estimated that for 5% to 15% of the patients in whom end-stage renal disease necessitating dialysis develops each year, ischemic nephropathy is the underlying cause of the decline in renal function.^{8,9}

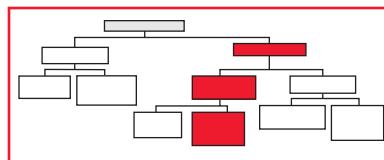

Investigative Screening Studies

Screening for suspected RAS is performed to identify those patients who are most likely to benefit from renal artery interventions aimed at managing hypertension or renal insufficiency. The decision regarding which screening test or tests to perform is not, however, a simple and obvious one. All of the noninvasive studies currently in use have their strengths and weaknesses, many of which are institution dependent. Constant improvements in technology and institutional variations in reporting standards, techniques, and published results have further complicated the process of determining the optimal first-line screening method. A variety of physiologic tests have been employed to screen for RAS and assess the contribution of RAS to hypertension or ischemic nephropathy. Peripheral plasma renin assays, rapid-sequence intravenous pyelography (for indirect assessment of differences in renal filtration), and isotope renography have all proved insufficiently sensitive to be useful for screening purposes. Catheter-based angiography has been widely used to screen for RAS, but technical improvements in DUS, computed tomographic angiography (CTA), and magnetic resonance angiography (MRA) have caused many physicians to prefer one or another of these imaging modalities for this purpose. A thorough understanding of the strengths and limitations of all of the screening tests, as well as an informed awareness of specific institutional limitations, is required to define the place of each test in one’s preferred diagnostic approach.

IMAGING

Contrast Arteriography

Of the several noninvasive or functional studies that are used to diagnose RAS and renovascular hypertension, none has displaced catheter-based contrast arteriography from its role as the diagnostic gold standard. In many institutions, however, CTA is now considered preferable to formal catheter-based arteriography as an easily reproducible screening test for RAS. The obvious drawback of CTA, as compared with the other imaging modalities, is the necessity of administering iodinated contrast material and the consequent risk of contrast-induced nephropathy (CIN). We frequently use CTA for the diagnosis of RAS in cases where concomitant aortoiliac aneurysmal or occlusive disease is suspected [see Figure 2].

“Drive-by” renal arteriography In a 1992 study of screening renal angiography (the largest such study published to date), 1,235 consecutive patients underwent renal arteriography at

Table 2 Clinical Clues to Diagnosis of Renal Artery Stenosis

- Onset of hypertension at extremes of age (< 30 or > 60 yr)
- Severe hypertension at > 55 yr
- Accelerated, resistant, or malignant hypertension
- Unexplained renal insufficiency or failure
- Renal dysfunction associated with initiation of ACE inhibitor or ARB therapy
- Unexplained congestive failure, pulmonary edema, or both
- Unexplained atrophic kidney or size discrepancy between kidneys
- Abdominal bruit

the conclusion of coronary angiography.¹⁰ Approximately 30% of these patients were found to have evidence of RAS, and 15% had greater than 50% stenosis. A 2001 study confirmed that RAS is associated with an increased risk of myocardial infarction, stroke, and death and that its presence in patients with coronary disease doubles the risk of mortality even when coronary revascularization is performed.⁵ This same study found that the severity of RAS was also predictive of mortality: 4-year survival was significantly lower (47%) in patients with bilateral RAS than in those with unilateral RAS (59%). The addition of nonselective renal arteriography in cases where the patient's serum creatinine concentration was lower than 2.0 mg/dl was associated with minimal additional cost and no clinically significant deterioration in renal function.

In 2006, on the basis of the findings from these studies, the American Heart Association (AHA) published a science advisory that made recommendations concerning routine renal arteriography in patients undergoing coronary angiography.¹¹ The AHA concluded that screening renal arteriography can reasonably be performed at the time of cardiac catheterization in patients at increased risk for RAS who are candidates for revascularization; however, it made no recommendation regarding concomitant treatment of RAS discovered during cardiac catheterization. In most cases, such a combined intervention is not feasible, whether because of the lack of preprocedural informed consent about renal artery endovascular intervention, the risk of CIN, or both.

Duplex Ultrasonography

In many institutions, including our own, renal artery duplex ultrasonography (RADUS) is currently used as the first-line screening test for RAS. Compared with other imaging modalities, RADUS has several unique advantages. In B mode, it provides direct images of the renal arteries, as well as a clear picture of contralateral kidney size (see below). It allows ongoing surveillance of lesions and interventions. It also achieves excellent imaging through renal stents, which on MRA appear only as flow voids. Finally, unlike CTA or even gadolinium-enhanced MRA, RADUS carries no risk of CIN.

Before RADUS is performed, the patient should fast overnight, should be given simethicone (to minimize interference on the images caused by bowel gas), or both. The study is done from both the anterior approach and the oblique flank approach; the latter is particularly helpful in obese patients, whose body habitus may severely limit the accuracy of the study. The renal arteries are imaged at their aortic origin and in their middle and distal segments. The peak systolic and end-diastolic arterial velocities are measured in

B mode with a Doppler angle of less than 60°. The ratios between the velocities in the renal artery and those in the aorta are determined, and the Doppler spectral waveform is recorded [see Figure 3]. The normal Doppler spectral waveform of the low-resistance renal vascular bed shows continuous diastolic flow.

Figure 2 CTA in a woman with a 7 cm infrarenal abdominal aortic aneurysm and chronic renal insufficiency shows severe bilateral stenosis of the renal artery origins and small, atrophic kidneys.

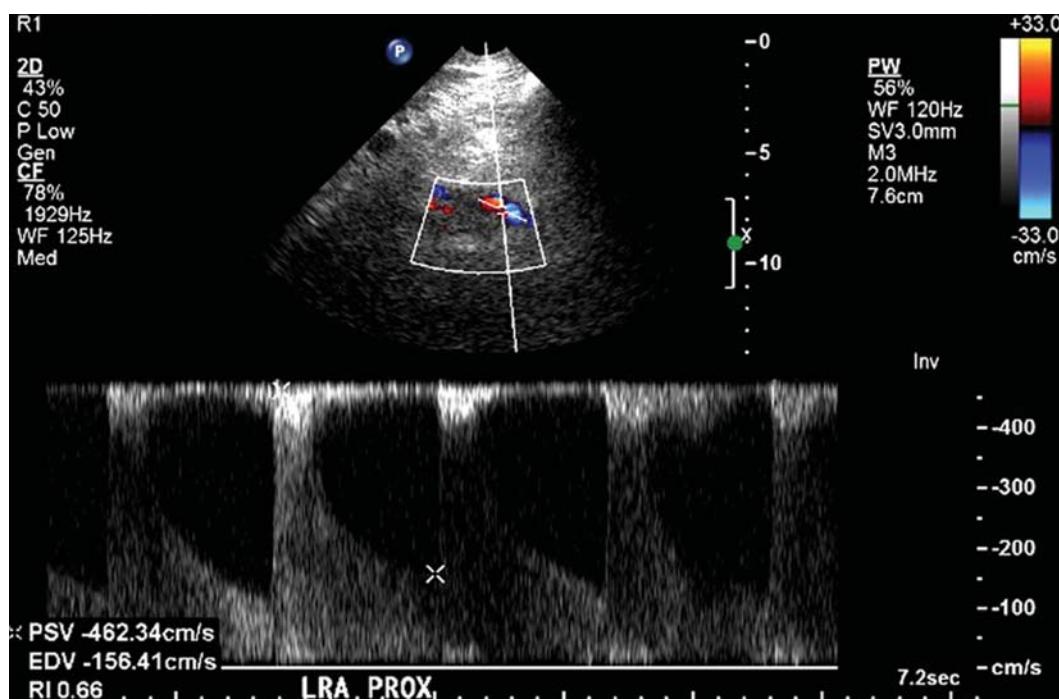

Figure 3 DUS focused on the proximal left renal artery reveals severe stenosis with markedly elevated peak systolic velocity (PSV) and end-diastolic velocity (EDV).

The size of the contralateral kidney is a useful surrogate marker for kidney function. A significant discrepancy in size and mass between the two kidneys should prompt the ultrasonographer to search for significant RAS or an occluded renal artery.

Doppler examination of the renal parenchyma is also employed as a means of indirectly evaluating RAS. This technique, performed via a flank approach, is very useful with obese patients and with cases in which examination is hindered by the presence of bowel gas. The acceleration time (the interval from the onset of the upstroke of the arterial waveform to the systolic peak), the acceleration index (the slope of the acceleration curve), and the resistive index (a measure of the resistance within the renal circulation) are determined. There is evidence to suggest that a normal resistive index (< 80) before renal revascularization (whether endovascular or surgical) predicts improvement with respect to blood pressure, renal function, and freedom from dialysis.¹² The resistive index itself, however, is not useful in predicting the degree of stenosis, because it may already be elevated in elderly patients and those with renal parenchymal disease.

One disadvantage of RADUS is that the diagnostic value of the images can be limited by the patient's body habitus or the presence of overlying bowel gas. In addition, RADUS can be time consuming to perform (requiring 30 to 60 minutes), and its accuracy is highly dependent on the experience of the ultrasonographer. Finally, polar or accessory renal arteries can easily be missed on RADUS, potentially leading to a false negative study result.

Magnetic Resonance Angiography

Many practitioners prefer MRA as the initial screening test for RAS. One advantage of renal MRA in this setting is that the quality of the results is less dependent on operator technique than is the case with RADUS. Gadolinium-

enhanced MRA is the technique of choice, in that the presumably less nephrotoxic gadolinium enhances visualization of the renal arteries. Multiplanar reconstruction (MPR) and maximum-intensity projection (MIP) techniques provide three-dimensional anatomic detail that is superior to what can be obtained with contrast arteriography [see Figure 4]. On a two-dimensional arteriogram, vessel overlap can cause the examiner to miss a severe stenosis; this problem rarely arises with three-dimensional images. We find renal MRA to be especially helpful in evaluating patients with RAS and ischemic nephropathy necessitating endovascular intervention.

Before the intervention is carried out, we review the axial MRA images of the aorta and the origins of the renal vessels. Working from these images, we rotate the image intensifier camera so as to obtain a perpendicular view of the renal orifice [see Figure 5]. This step allows us to use smaller quantities of contrast material and cannulate the renal orifice more quickly during endovascular intervention. It must be kept in mind that MPR and MIP postprocessing techniques are well known to exaggerate or even create the appearance of a stenosis and that the original source axial images must therefore be evaluated. The three-dimensional data set is digitally subtracted from the precontrast source images to create the contrast MRA images. Other signs of significant RAS include poststenotic dilation, loss of cortical medullary differentiation, and delayed renal enhancement or asymmetric filling of the collecting system during contrast injection.

The utility of MRA can be limited by several factors that are capable of degrading the acquired data. The presence of nearby metal (e.g., clips or stents) and air-tissue interfaces can lead to focal signal drop-out and simulate stenosis or obstruction. Movement by the patient during the scan (or even bowel peristalsis) can result in degraded, blurred images. The timing of the contrast bolus must be right to ensure adequate visualization of the arterial vessels. A contrast bolus that is delivered too late will not opacify the vessels and will appear as a stenosis, whereas a bolus that is

delivered too early will opacify the veins, resulting in so-called venous contamination of the images. We have found that the image quality attained with MRA is highly dependent on the institution where it is performed.

MRA is contraindicated in patients with pacemakers, automatic implantable cardioverter defibrillators (AICDs), brain aneurysm clips, cochlear implants, or metal fragments in the eyes. It is not contraindicated in patients with vascular stents, coils, or inferior vena cava filters, nor is it contraindicated in those with metal orthopedic devices, heart valves, or dental devices and materials.

Captopril Renal Scintigraphy

Radionuclide imaging is a noninvasive and safe means of evaluating renal blood flow and excretory function. The addition of an angiotensin-converting enzyme (ACE) inhibitor, such as captopril, to isotope renography improves the sensitivity and specificity of the test. In the presence of unilateral RAS, administration of captopril is associated with a 30% reduction of the glomerular filtration rate (GFR) in the affected kidney. The contralateral kidney shows a rise in the GFR, an increase in urine flow, and enhanced salt excretion, leading to marked retention of the isotope in the cortex of the affected kidney. The presence of significant renal dys-

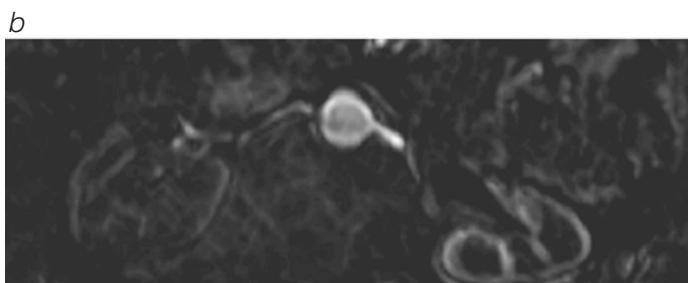

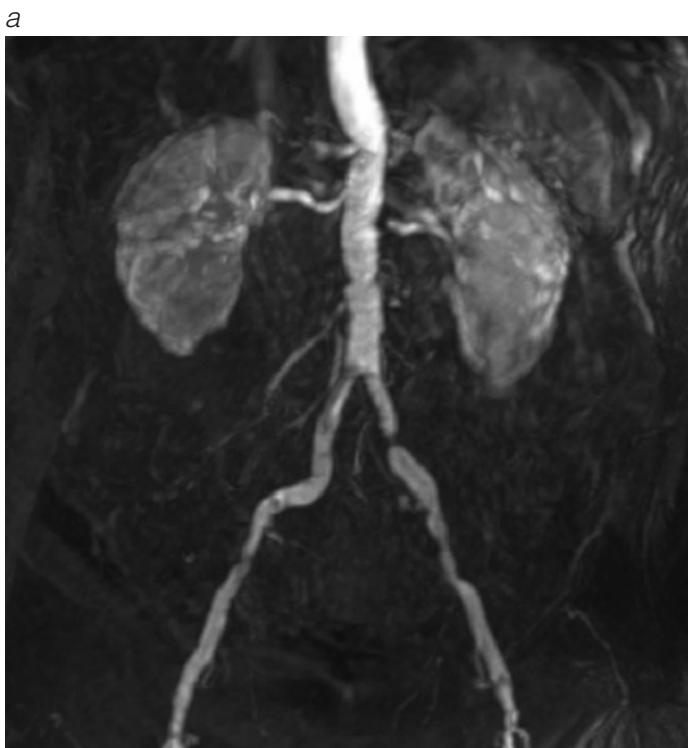

Figure 4 (a) Gadolinium-enhanced MRA reveals signal dropout (flow void) at the origin of the left renal artery, signifying severe stenosis. (b) Axial MRA image reveals severe right renal artery stenosis.

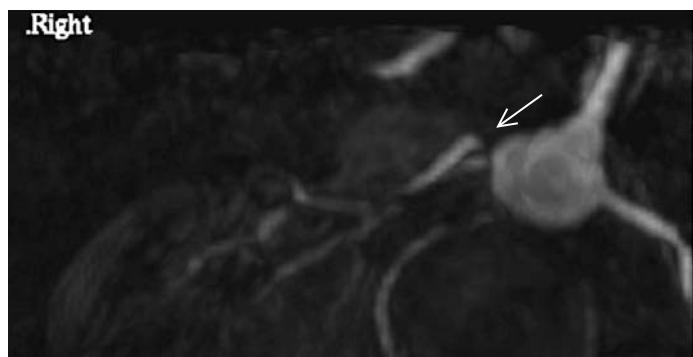

Figure 5 For optimal viewing of the right renal artery during endovascular intervention, the C arm should be set to a 30° left anterior oblique position. Evaluation of axial MRA images before the procedure is begun facilitates cannulation and limits the amount of contrast material used.

function at baseline (serum creatinine concentration greater than 2.0 mg/dL), bilateral RAS, or both adversely affects the sensitivity and specificity of captopril renal scintigraphy, thereby limiting its utility as a screening test. In addition, the necessity of discontinuing ACE inhibitors and angiotensin-receptor blockers (ARBs) before the study may preclude the use of this test in patients with severe hypertension. Improvements in DUS, CTA, and MRA have now relegated captopril renal scintigraphy to secondary status as a screening modality.

Contrast-Induced Nephrotoxicity

The increasing use of diagnostic imaging studies (e.g., CTA and MRA) and catheter-based interventions in patients with significant RAS has made treatment and prevention of CIN important issues in this patient population. Current strategies for preventing CIN have generally involved one of three approaches: (1) providing hydration, (2) using low-osmolar or iso-osmolar iodinated contrast agents, and (3) administering the free radical scavenger *N*-acetylcysteine.

Intravascular volume depletion is an important risk factor for the development of CIN. Although to date, no randomized, controlled trials comparing hydration with placebo have been published, it has been standard practice for some time to institute hydration (usually intravenous) before administering a contrast agent. A small randomized, controlled trial from 2003 that compared I.V. hydration (0.9% saline, 1 mL/kg, starting 12 hours before infusion of contrast material) with unlimited oral fluid intake found I.V. hydration to be far superior for preventing CIN.¹³ In a subsequent study, 119 patients at a single center were randomly assigned to receive a 154 mEq/L infusion of either sodium chloride or sodium bicarbonate both before and after administration of contrast material (starting with a 3 mL/kg bolus 1 hour before contrast administration and continued at a rate of 1 mL/kg/hr for 6 hours afterward).¹⁴ Sodium bicarbonate hydration was found to reduce the incidence of CIN from 13.6% to 1.7%. Although this study is probably underpowered from a statistical perspective, the findings are suggestive. Sodium bicarbonate hydration is inexpensive and well tolerated and has become standard practice at most institutions.

The optimal choice of contrast media for preventing CIN has also been a subject of debate. There is evidence that the use of iso-osmolar nonionic contrast agents (e.g., iodixanol [Visipaque; GE Healthcare, Princeton, New Jersey]) yields significantly lower rates of CIN than the use of low-osmolar contrast agents (e.g., iohexol [Omnipaque; GE Healthcare, Princeton, New Jersey]) in

patients with diabetes or baseline renal insufficiency who undergo cardiac or vascular angiography.¹⁵

N-acetylcysteine, a thiol-containing antioxidant, is believed to act as a free-radical scavenger to prevent toxic effects on the renal tubular epithelium. Multiple clinical studies have examined the question of whether administration of *N*-acetylcysteine is beneficial in preventing CIN, but the results have been mixed. Although pooled meta-analyses have recommended giving *N*-acetylcysteine to patients who are at high risk, the overall effect of this measure is small in comparison with that of simple hydration. Nevertheless, *N*-acetylcysteine is inexpensive and generally well tolerated, and its use in those at high risk for CIN may reasonably be recommended.

On the basis of the existing evidence regarding prevention of CIN, we routinely preadmit patients with baseline serum creatinine concentrations higher than 2.5 mg/dl for overnight hydration, usually with saline; we then switch to sodium bicarbonate hydration (see above) before administering the contrast agent. We also use *N*-acetylcysteine (600 orally twice daily on the day before, the day of, and the 2 days after contrast administration) in this high-risk patient subset. Patients with serum creatinine concentrations between 1.5 and 2.5 mg/dl receive sodium bicarbonate hydration on the day of the procedure. We try to limit the amount of contrast material given during the procedure, and we currently favor iodixanol over iohexol in patients with baseline serum creatinine concentrations higher than 1.5 mg/dl or other risk factors for CIN (e.g., diabetes or a solitary kidney). Because of its substantial cost, we do not routinely use iodixanol in all patients. Well-hydrated persons with normal renal function receive I.V. saline before and after the procedure. In such patients, we routinely use iohexol, without other adjuncts.

LABORATORY TESTS

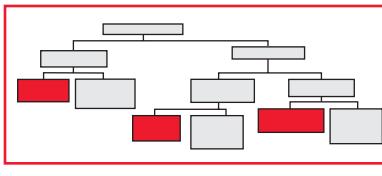

Renal-Vein Renin Assay

When hemodynamically significant RAS is found, functional studies may be indicated to determine the physiologic significance of the lesion. One such study involves measuring the renin concentration in blood samples from the two renal veins to determine whether unilateral renin hypersecretion is occurring. If the ratio of the renin concentration in the affected side to that in the unaffected side is greater than 1.5, the assay is considered to have yielded a positive result. The sensitivity and specificity of this test are diminished by the presence of bilateral RAS or RAS of a solitary kidney. Other factors that may reduce the reliability of the results include the inherent limitations of the renin assay itself and the potential for sampling errors. Because of the invasive nature of the selective renin assay and the concerns about its accuracy, we do not routinely use this test in RAS patients.

Management

MEDICAL THERAPY

Given the known association between RAS and systemic cardiovascular disease, medical treatment aimed at preventing or retarding further progression of systemic atherosclerosis is clearly a paramount concern in the management of RAS patients. Measures for modifying cardiovascular risk factors include effective blood pressure control, weight reduction, smoking cessation, lipid-lowering therapy, and antiplatelet therapy. It is the responsibility of the surgeon evaluating a patient with RAS to use this opportunity to ensure

that appropriate cardiovascular risk factor modification measures are being undertaken. After consultation with the patient's primary care provider, we routinely provide prescriptions for a cholesterol-lowering medication (e.g., a 3-hydroxy-3-methylglutaryl coenzyme A [HMG-CoA] reductase inhibitor) and an antiplatelet drug (e.g., acetylsalicylic acid [ASA]) if the patient has not already been taking these agents.

It is worth remembering that although medical treatment may lead to significant reductions in cardiovascular morbidity and mortality, no medical therapy has yet been shown to prevent the progression of ischemic nephropathy and renal failure. For patients with these latter conditions, renal revascularization is likely to be preferable to medical therapy.

Antihypertensive Agents

Both ACE inhibitors and ARBs have proved to be safe and effective for the treatment of hypertension in the setting of renovascular disease. In addition to their effects on the RAAS, these agents have been shown to reduce proteinuria and glomerular scarring in patients with a variety of renal diseases. Close clinical supervision is necessary when ACE inhibitors or ARBs are given to patients with renal insufficiency or failure. In this population, serum creatinine and potassium levels should be obtained weekly for 2 to 3 weeks after antihypertensive therapy with an ACE inhibitor or an ARB is started. These patients are at increased risk for acute renal failure (ARF); if ARF develops, the medications should be promptly discontinued. Patients with significant RAS who take ACE inhibitors or ARBs are also at risk for ARF when severely dehydrated; accordingly, they should be instructed to refrain from taking these agents when affected by severe vomiting, diarrhea, or dehydration. As a rule, ARF that occurs in this latter setting responds rapidly to fluid rehydration and temporary suspension of the ACE inhibitor or ARB. Once renal function has returned to baseline, the medications can usually be safely restarted.

It is important to be aware that some antihypertensive drugs may be associated with lack of energy (e.g., beta blockers and calcium channel blockers) or chronic cough (ACE inhibitors), either of which may have substantial effects on patient compliance. Several studies have shown that as many as 50% of such medications are changed or discontinued within 6 months. Proponents of renovascular revascularization have cited such studies as evidence favoring aggressive use of open or endovascular treatment of RAS over reliance on medical therapy alone.

Lipid-Lowering Agents

Lipid-lowering therapy with HMG-CoA reductase inhibitors (also referred to as statins) effectively reduces total and low-density lipoprotein (LDL) cholesterol levels while increasing high-density lipoprotein (HDL) cholesterol levels. There is compelling level 1 evidence that this reduction of total and LDL cholesterol levels markedly lowers the incidence of secondary cardiovascular events and mortality. There is, however, no direct evidence that lipid control has an effect on the progression of renal artery disease, though one might reasonably suspect that it would.

Statins generally are well tolerated, but on occasion, they may be associated with hepatic toxicity (0.5% to 3% of cases) or myositis. Accordingly, liver function tests should be performed at baseline and again 3 months after the start of therapy. If a threefold or greater increase in aminotransferase levels is noted, the statin should be discontinued, and alternative therapy with another lipid-lowering medication (e.g., a fibrate, a bile acid sequestrant, a cholesterol absorption inhibitor, or nicotinic acid) should be started in conjunction with diet modification.

Muscle injury is uncommon with statin therapy alone: myalgias occur in 2% to 11% of patients, myositis in 0.5%, and rhabdomyolysis in fewer than 0.1%. Myositis associated with statin therapy is treated by switching to another HMG-CoA reductase inhibitor. Routine measurement of serum creatine kinase levels is not recommended, but patients taking statins should be warned about the risk of myositis and weakness and instructed to stop statin therapy if such side effects occur.

Antiplatelet Agents

Antiplatelet therapy has been shown to reduce the risk of secondary events in patients with coronary artery disease and carotid stenosis. The data currently available do not conclusively demonstrate that antiplatelet therapy has a beneficial effect on RAS, but given that RAS is a manifestation of systemic atherosclerosis, antiplatelet therapy appears warranted on the same grounds that statin therapy would be. After endovascular intervention to treat RAS, we typically place patients on ASA, 81 mg/day, and clopidogrel, 75 mg/day, for 4 to 6 weeks while the stent is undergoing endothelialization. After this period, patients are switched to ASA, 325 mg/day. Admittedly, there is no direct evidence supporting this practice in patients with RAS who undergo endovascular intervention; however, data extracted from the coronary stenting literature suggest that such an approach may be reasonable.

ENDOVASCULAR AND OPEN SURGICAL THERAPY

Despite the relatively high prevalence of RAS, especially in persons who have atherosclerosis in other vascular beds, there is currently no consensus on diagnosis, therapy, or follow-up. In the absence of well-designed, evidence-based studies, many practitioners have adopted a "find it and fix it" approach to managing RAS. The endovascular and surgical interventions employed to treat RAS are described more fully elsewhere [see 6:22 *Open Procedures for Renovascular Disease* and 6:23 *Endovascular Procedures for Renovascular Disease*]. We ourselves generally take an aggressive stance toward the application of renal artery stenting, especially in patients with evidence of ischemic nephropathy (who presumably would be the patients most likely to benefit from renal revascularization).

It must be admitted, however, that the current evidence for renal artery percutaneous intervention is circumstantial at best. Clearly, there are three possible outcomes associated with renal revascularization. Some patients derive tremendous benefit from the procedure, showing substantial improvements in blood pressure and renal function. Others (a very small subset) experience a rapid decline in renal function, probably resulting from either atheroembolization or CIN associated with the procedure itself. Still others exhibit no changes in renal function, number of antihypertensive medications used, or blood pressure control. Unfortunately, there are, at present, no good methods of reliably predicting which patients will benefit from renal revascularization.

Several uncontrolled reports suggested that hypertension and renal function may improve after successful renal artery stenting. However, three small trials evaluating angioplasty alone (i.e., without stenting)

were unable to demonstrate any beneficial effect on blood pressure.¹⁶⁻¹⁸ Proponents of renal artery intervention have argued that these three trials were flawed by their failure to include stenting and by the fact that blood pressure control may be a poor surrogate clinical end point. These studies were plagued by several other weaknesses as well, including high rates of crossover to angioplasty and marked variations in the medical therapy provided. The inclusion of stenting as a component of endovascular treatment of RAS is now considered the standard of care by many, in that it significantly improves technical success rates and lowers the incidence of restenosis.

Revascularization of RAS with stenting treats the root cause of the neurohormonal activation that leads to end-organ heart and kidney damage; best medical therapy, when adequately carried out, yields substantial reductions in cardiovascular morbidity and mortality in and of itself. Consequently, it is difficult to detect significant differences between best medical therapy alone and best medical therapy plus renal artery stenting. Until sufficient evidence (from adequately powered, well-designed, and unbiased trials) has been accumulated to confirm or rule out such differences, the debate regarding the benefits of percutaneous renal artery revascularization will continue.

To date, no trials comparing best medical therapy with best medical therapy plus angioplasty and stenting have been completed. Currently, however, patients are being recruited into a clinical trial sponsored by the National Heart, Lung, and Blood Institute, which is likely to answer several important questions about the management of RAS that have not been answered by previous studies. This study, known as the Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) trial, is expected to yield important information about which groups of RAS patients benefit from endovascular intervention. A total of 1,080 patients will be enrolled in the trial and will be randomly assigned to receive either best medical therapy or best medical therapy with angioplasty and stenting. The primary outcome evaluated will be adverse cardiovascular and renal events. Best medical therapy will be provided on the basis of current evidence-based guidelines, which include tight control of blood pressure (< 140/90 mm Hg; < 130/80 mm Hg in patients with diabetes or proteinuria), treatment of hypercholesterolemia (LDL concentration < 100 mg/dl) and diabetes (glycated hemoglobin [HbA_{1c}] level < 7 mg/dl), smoking cessation, and antiplatelet therapy (with ASA, clopidogrel, or ticlopidine). All patients will receive an ARB as the first-line antihypertensive agent, and a specific stepwise algorithm will be implemented for patients requiring combination antihypertensive therapy. All patients will undergo diagnostic angiography to assess the severity of their lesions. Patients will be followed for as long as 5 years with an eye to both primary end points (e.g., death, stroke, myocardial infarction, ARF, and dialysis) and secondary end points (e.g., hypertension, medication use, quality of life, and cost). It is expected that enrollment in the CORAL trial will conclude in 2009, though interim data will probably be reported earlier. This important study should make a major contribution to determining the appropriate role of endovascular stenting in the management of RAS.

Discussion

Pathophysiology of Renovascular Hypertension

The seminal studies performed by Goldblatt and associates in the 1930s demonstrated that reduction of renal perfusion can result in sustained elevation of arterial pressures.¹⁹ Later work revealed that the renin-angiotensin-aldosterone system plays an intricate and crit-

ical role in this process. The RAAS maintains vascular tone, water and salt balance, and cardiac function. It works through the sympathetic nervous system and the actions of several hormones to maintain hemodynamic stability. The RAAS is activated through several mechanisms, including hypotension and decreased intravascular

volume. These mechanisms cause decreased renal perfusion and the secretion of renin from the juxtaglomerular apparatus within the kidneys. Renin cleaves angiotensinogen in the liver to form angiotensin I; ACE then transforms angiotensin I into angiotensin II in the lung. Angiotensin II is a potent vasoconstrictor (considerably more potent than epinephrine) and is implicated in end-organ damage to the heart and the kidney.^{20,21} Angiotensin II promotes the release of aldosterone from the adrenal cortex, and this release of aldosterone leads to the reabsorption of sodium in the distal convoluted tubules of the kidney, resulting in increased intravascular volume.

In patients who have unilateral RAS with a normal contralateral kidney, the elevation of blood pressure is renin dependent and is characterized by increased peripheral vascular resistance. Such patients are considered to have volume-independent hypertension, in that the normal contralateral kidney compensates for the unilateral RAS by increasing its excretion of fluid. In patients who have bilateral RAS or unilateral RAS with no contralateral kidney, intravascular volume increases and renin secretion decreases over time. Such patients are considered to have volume-dependent or Goldblatt hypertension.

Ischemic injury to the affected kidney, hypertensive nephrosclerosis of the contralateral kidney, and smooth muscle hypertrophy in the peripheral blood vessels may all contribute to sustained hypertension independently of RAAS activity. In addition, both the sympathetic nervous system and the central nervous system contribute to hypertension associated with RAS.²² Several neuroendocrine systems activated by RAS have also been shown to have deleterious cardiovascular effects. Besides increasing peripheral resistance, angiotensin II is thought to cause smooth muscle hypertrophy (both in peripheral arteries and in cardiac myocytes), plaque rupture, endothelial dysfunction, and inhibition of fibrinolysis.²³⁻²⁵ An elevated angiotensin II level is believed to cause left ventricular hypertrophy (LVH) on occasion, even in cases where blood pressure is well controlled.²⁶ Angiotensin II also interacts with tumor growth factor- β , platelet-derived growth factor, and endothelin, each of which has been implicated in the development of vascular muscle hypertrophy, cardiac myocyte hypertrophy, and renal parenchymal damage. Clearly, RAS and activation of the RAAS have systemic effects that go beyond simply causing hypertension.

1 INITIAL MANAGEMENT OF LIFE-THREATENING TRAUMA

Frederick A. Moore, M.D., F.A.C.S., and Ernest E. Moore, M.D., F.A.C.S.

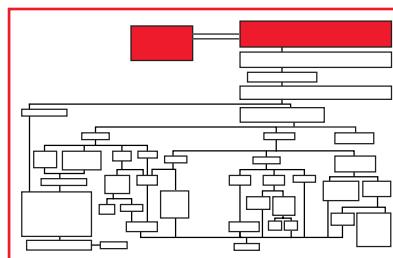

Initial Approach to the Critically Injured Patient

Salvage of the critically injured patient is optimized by a coordinated team effort in an organized trauma system. Management of life-threatening trauma must be prioritized according to physiologic necessity for survival—that is, active efforts to support airway, breathing, and circulation (the ABCs) are usually initiated before specific diagnoses are made. In this chapter, we outline a systematic approach to severely injured patients within the so-called golden hour. The discussion is divided into prehospital care and emergency department management; the ED component is further divided into (1) primary survey with initial resuscitation, (2) evaluation and continued resuscitation, and (3) secondary survey with definitive diagnosis and triage.

Prehospital Care

INTERVENTION AT INJURY SITE

Resuscitation and evaluation of the trauma patient begins at the injury site. The goal is to get the right patient to the right hospital at the right time for definitive care. First responders (typically, firefighters and police) provide rapid basic trauma life support (BTLS) and are followed by paramedics and flight nurses with advanced trauma life support (ATLS) skills. Medical control is ensured by preestablished field protocols, radio communication with a physician at the base hospital, and subsequent trip audits. Management priorities of BTLS on the scene are (1) to assess and control the scene for the safety of the patient and the prehospital care providers, (2) to tamponade external hemorrhage with direct pressure, (3) to protect the spine after blunt trauma, (4) to clear the airway of obstruction and provide supplemental inspired oxygen, (5) to extricate the patient, and (6) to stabilize long-bone fractures. Whereas the benefits of BTLS are undisputed, the merits of the more advanced interventions remain controversial.^{1,2} Airway access, once considered a major asset of the care provided by paramedics and flight nurses, has now been questioned, not only because missed tracheal intubation is a concern but also because unintentional hyperventilation (hypocarbia) is detrimental in the setting of traumatic brain injury (TBI) and during cardiopulmonary resuscitation (CPR).³⁻⁵ Moreover, the value of I.V. fluid administration remains controversial.^{6,7}

FIELD TRIAGE

Prehospital trauma scores have been devised to identify critically injured trauma victims, who represent about 10% to 15% of

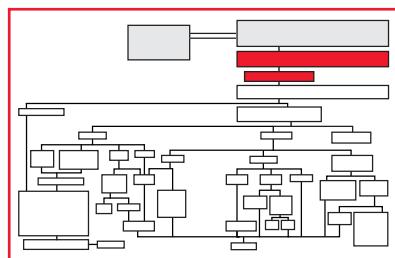

all injured patients. When it is geographically and logically feasible, critically injured patients should be taken directly to a designated level I trauma center or to a level II trauma center if a level I trauma center is more than 30 minutes away. The currently available field trauma scores, however, are not entirely reliable for identifying critically injured patients⁸: to capture a sizable majority of patients with life-threatening injuries, a 50% overtriage is probably necessary. Advance transmission of key patient information to the receiving trauma center facilitates the organization of the trauma team and ensures the availability of ancillary services.⁹

DECLARATION OF DEATH AT SCENE

The determination that care is futile during prehospital evaluation is best made on the basis of the cardiac rhythm. Asystole justifies declaration of death at the scene, and recent profound bradycardia (heart rate < 40 beats/min) has been shown to signal an unsalvageable situation.¹⁰⁻¹²

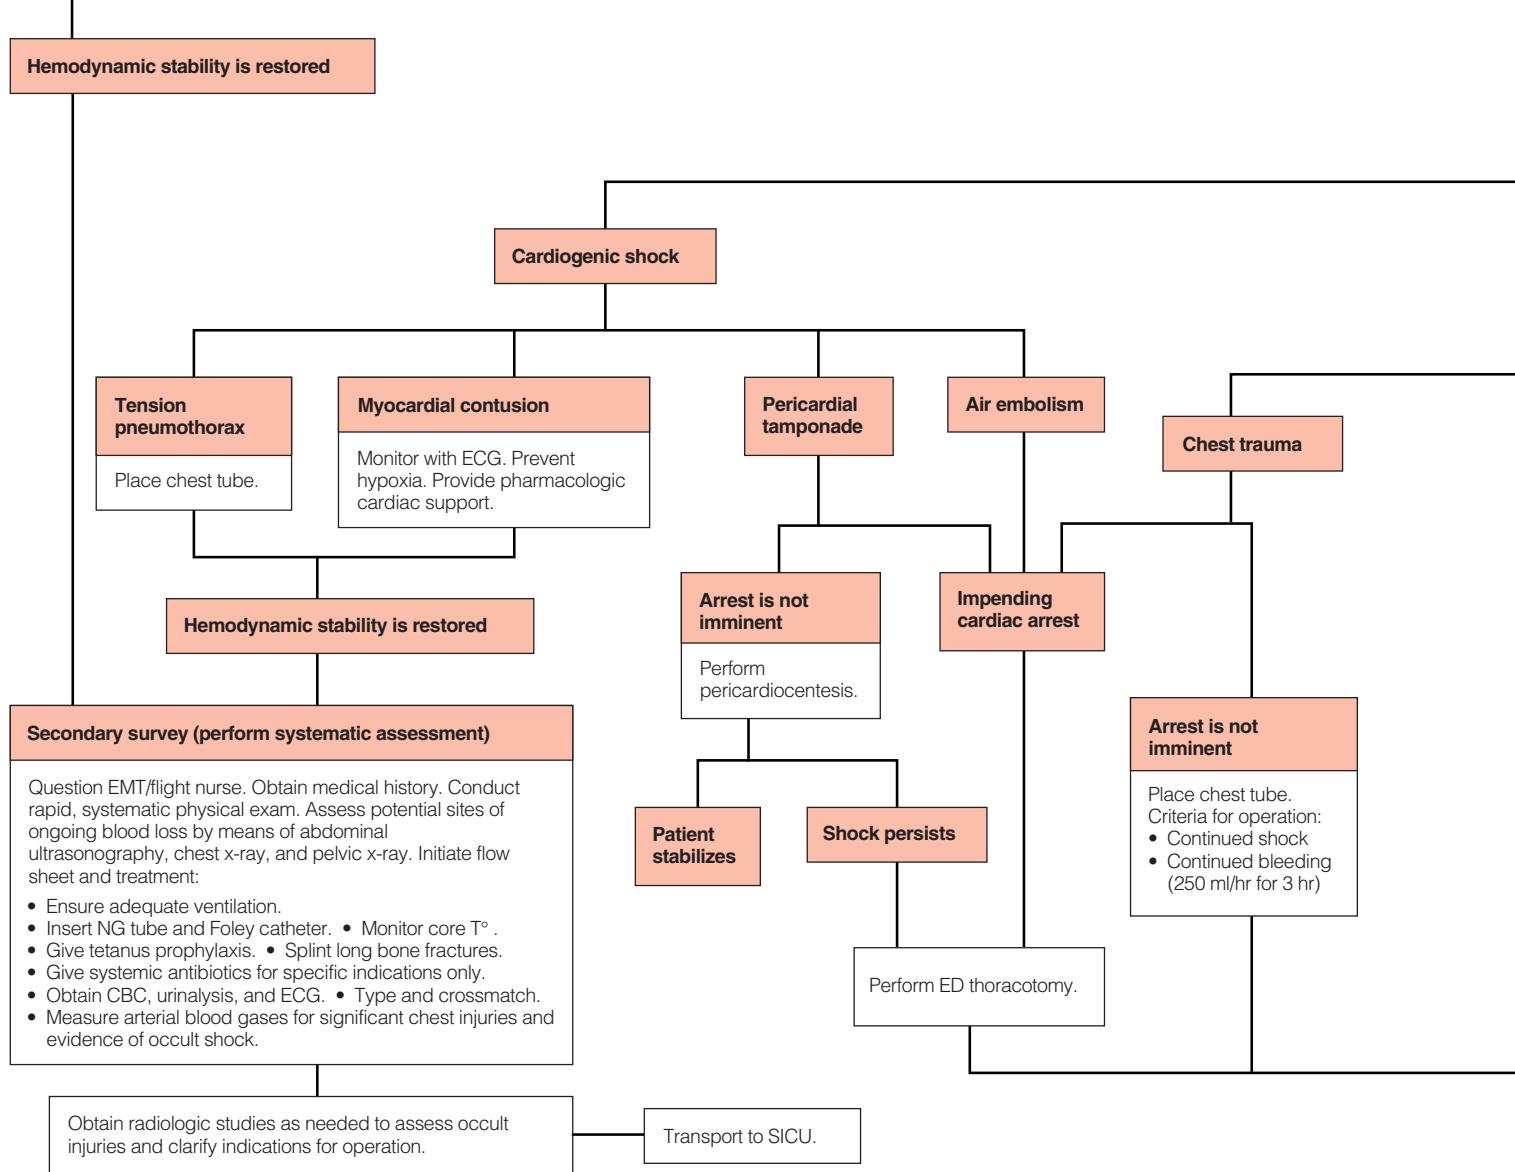

Emergency Department Management

ARRIVAL AT HOSPITAL UNDER ACTIVE CARDIOPULMONARY RESUSCITATION

Prehospital pulseless electrical activity (PEA) in injured patients has a dismal prognosis, and it has been proposed that such patients should be declared dead in the field.¹³ Unfortunately, most first responders do not use the cardiac rhythm to decide whether to initiate CPR. When a patient arrives in the ED after prehospital CPR has been initiated, the critical question is whether to perform a resuscitative thoracotomy. The prognosis for blunt trauma patients is poor because the major causes of cardiopulmonary arrest after blunt trauma (e.g., massive brain injury, high spinal cord injury, and exsanguination from multiple injuries) are difficult to reverse. In contrast, patients with stab wounds to the heart are frequently salvageable if cardiac arrest occurs because of cardiac tamponade. In most cases, the heart can be resuscitated by simply decompressing the pericardium, given that blood volume is usually maintained. Guidelines for terminating resuscitation are based on the mechanism of injury, the duration of CPR, the presence of signs of life (e.g., pupillary response, respiratory effort, or motor activity), and the presence of asystole documented by cardiac monitoring [see Table 1].¹⁴

Initial Approach to the Critically Injured Patient

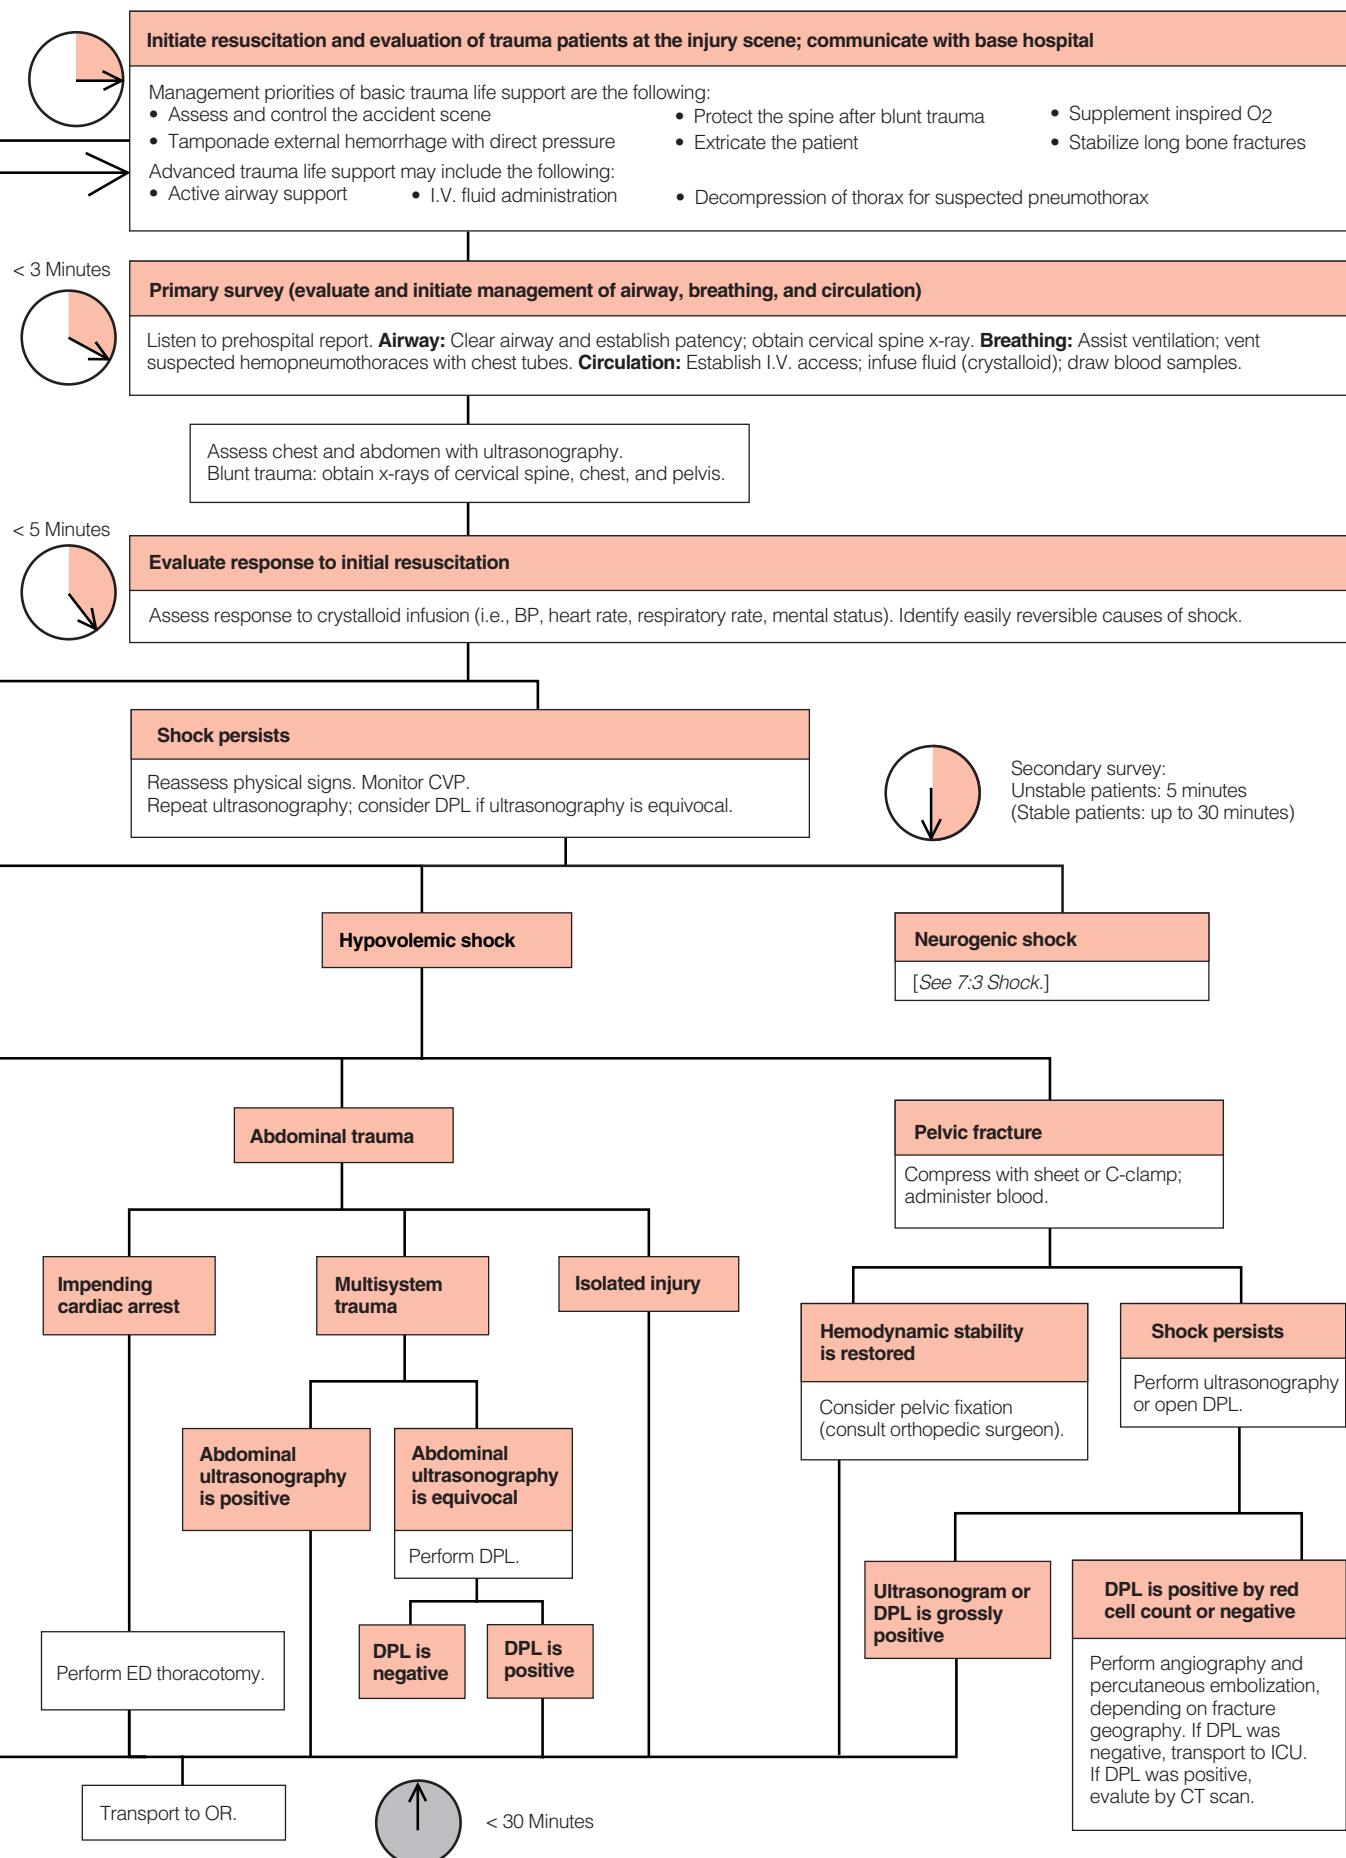

Table 1 Guidelines for Declaring Patients Dead on Arrival

Penetrating trauma	Prehospital CPR for > 15 min with no signs of life Asystole without wound that could cause pericardial tamponade
Blunt trauma	Prehospital CPR for > 5 min with no signs of life Asystole

PRIMARY SURVEY AND INITIAL RESUSCITATION

During initial assessment, an empirical sequence of lifesaving therapeutic and diagnostic procedures is pursued. The ultimate goal is to establish adequate oxygen delivery to the vital organs. This is accomplished by first progressing through the ABCs: airway control with cervical spine precautions, assisted breathing with ventilation, and empirical tube thoracostomy to relieve a pneumothorax if indicated. These maneuvers are carried out to maximize oxygen delivery to the alveoli. Support of the circulation (tamponade of external bleeding and fluid administration) is instituted to restore effective blood volume, thereby enhancing myocardial performance and thus oxygen delivery to the tissues.

Unstable patients fall into two categories: those who respond to initial intervention and those who do not. Early nonresponders are challenging because they require an immediate lifesaving intervention. The challenge is to perform the correct intervention before the patient dies. Patients who respond to initial interventions can be equally challenging because a subset of them have only a finite time window before shock recurs. Multiple diagnoses

must be considered before correct definitive triage is possible. The clinician must rapidly formulate a differential diagnosis and then sequentially initiate the appropriate diagnostic tests.

Airway and Breathing

After blunt trauma, airway control should proceed on the assumption that an unstable cervical spine fracture exists; thus, hyperextension of the neck must be avoided. Airway management in the seriously injured victim can usually be accomplished with simple techniques, but it is occasionally challenging. Evaluation begins by asking the patient a question such as "How are you?" A response given in a normal voice indicates that the airway is not in immediate jeopardy; a breathless, hoarse response or no response at all indicates that the airway may be compromised.

Airway obstruction and hypoventilation are the most likely causes of respiratory failure. The critical decision is whether active airway intervention is needed. The first maneuver is to clear the airway of debris and to suction secretions. In the obtunded patient, this procedure is followed by elevation of the angle of the mandible to alleviate pharyngeal obstruction and placement of an oropharyngeal or nasopharyngeal tube to maintain airway patency. Supplemental oxygen is given via a nasal cannula (6 L/min) or a nonrebreathing oxygen mask (12 L/min). Airway patency, however, does not ensure adequate ventilation, nor does a normal arterial oxygen saturation (S_aO_2) on pulse oximetry. Clinical evidence of hypoventilation includes poor air exchange at the nose and mouth, diminished breath sounds, and decreased chest wall excursion; the most likely causes are head injury, spinal cord transection, hemopneumothorax, flail chest, and profound shock.

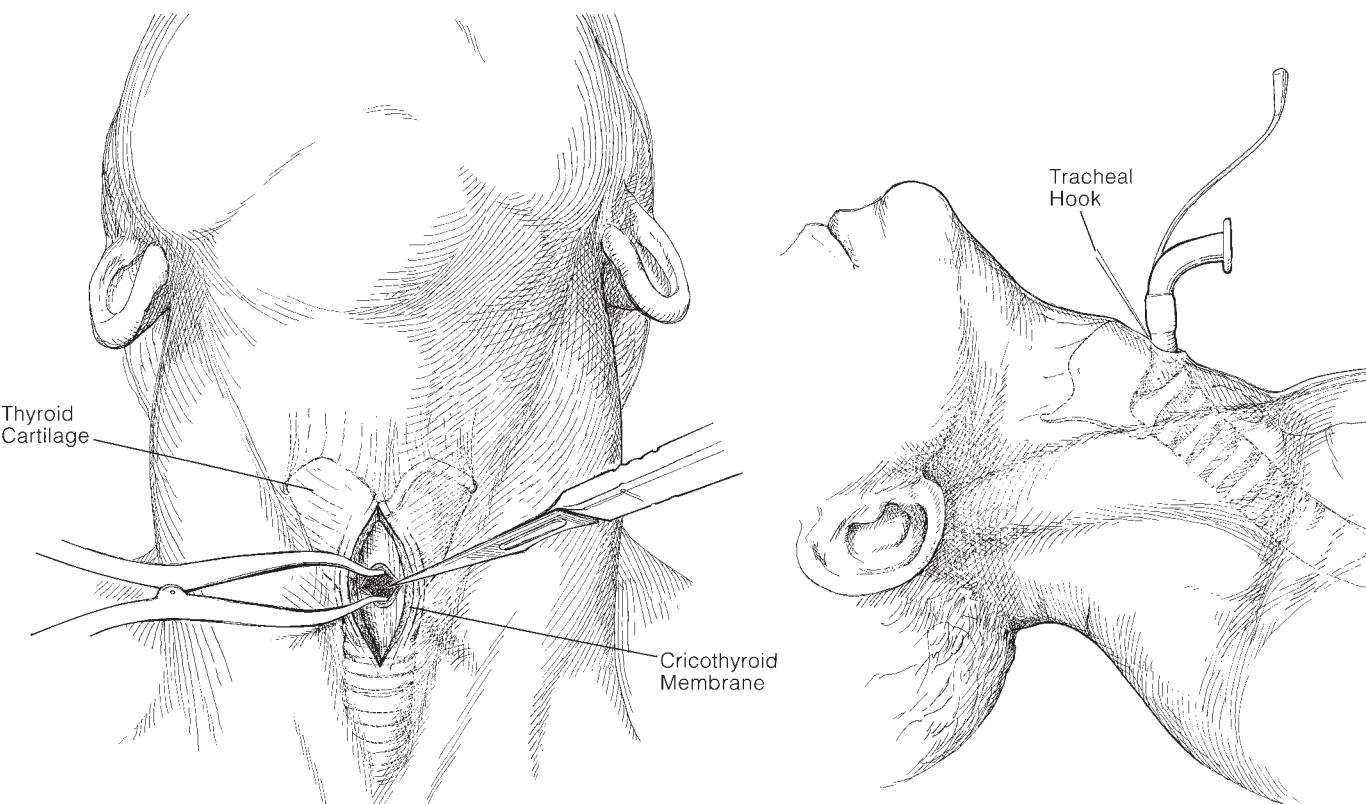

Figure 1 Technique for cricothyrotomy is illustrated here. The larynx is stabilized with one hand, and a 2 cm vertical incision is made over the cricothyroid space. The cricothyroid membrane is palpated and incised horizontally. A Trousseau dilator is inserted and spread vertically for visualization of the subglottic space (left). A tracheal hook is used to retract the inferior border of the thyroid cartilage as a tracheostomy tube with a 6 mm internal diameter is inserted into the trachea (right).

Table 2 10 Steps in Rapid-Sequence Intubation

1. Preparation of equipment and supplies
2. Preoxygenation
3. Sedation to decrease anxiety
4. Premedication to mitigate adverse effects: vecuronium bromide (1 mg) to prevent defasciculations, lidocaine (1.5 mg/kg) to prevent increased ICP with TBI
5. Cricoid pressure
6. Administration of paralytic agent: succinylcholine (1.0–1.5 mg/kg), vecuronium bromide (0.6–1.2 mg/kg) if succinylcholine contraindicated
7. Intubation
8. Confirmation of tube position by auscultation and capnography
9. Securing of airway
10. Chest x-ray

ICP—intracranial pressure TBI—traumatic brain injury

Suspected hemopneumothoraces should be vented with large-bore chest tubes inserted via the midlateral thorax.

Cervical spine protection is integral to airway management but should not be allowed to delay necessary intervention. The majority of significant spinal injuries in adults arriving alive at the ED are at the C5 to C7 levels. In children 8 years old or younger, the most frequent site of spinal injury is between the occiput and the C3 level. Significant spinal cord injury without radiographic abnormalities (i.e., the SCIWORA syndrome) is a relatively rare event (0.5% of patients undergoing radiography), and the data on its relative frequency in children and in adults are conflicting.^{15,16} A fractured cervical spine is usually tender to direct palpation in alert patients, but pain may be masked by distracting injuries.^{17,18} Even good-quality cross-table lateral cervical spine films may not detect 15% of unstable fractures. Accordingly, in high-risk patients, a cervical collar is left in place until the cervical spine has been radiologically evaluated for bony and ligamentous integrity.¹⁹

Bag-mask ventilation is an effective temporizing measure, but it consumes the attention of a skilled trauma team member, it may insufflate air into the stomach, and it can be resisted by spontaneously breathing patients. It is also ineffective in the presence of severe maxillofacial trauma. The decision for urgent airway control is made on clinical grounds; there often is no time to obtain a confirmatory arterial blood gas (ABG) analysis.²⁰ Persistent airway obstruction or signs of inadequate ventilation mandate prompt intervention. Patients with expanding neck hematomas, deteriorating vital signs, or severe head trauma are also best managed with an aggressive airway approach. On the other hand, in equivocal situations, an ABG analysis may be decisive.

The best method of airway control depends on (1) the presence of maxillofacial trauma, (2) possible cervical spine injury, (3) overall patient condition, and (4) the experience of the physician. Patients in respiratory distress with severe maxillofacial trauma warrant operative intervention. Cricothyrotomy is the preferred approach in adults and has virtually replaced tracheostomy in the ED [see *Figure 1*]; the rare exceptions are in patients with major laryngeal trauma or extensive tracheal disruption. Percutaneous transtracheal ventilation may be safer than both of these surgical procedures for temporary airway management, particularly in children. In all other patients, the current standard approach is rapid sequence intubation (RSI) of the trachea orally with inline immobilization [see *Table 2*.]^{21,22} In adults, a large (8 mm internal

diameter) cuffed endotracheal tube is inserted to a distance of 23 cm from the incisors. In children, tube size is gauged to equal the diameter of the little finger. The proper depth (in centimeters) to which the tube should be inserted can be estimated by multiplying the tube's internal diameter (in millimeters) by 3. A chest x-ray should be obtained as soon as possible to rule out the possibility of right mainstem intubation.

Intubated patients should be placed on a high fraction of inspired oxygen (F_{1O_2}), and their S_aO_2 should be monitored by means of pulse oximetry. Generally, a low S_aO_2 is easily treated by increasing the F_{1O_2} . Patients who do not respond when the F_{1O_2} is increased to 100% should be treated with low levels of positive end-expiratory pressure (PEEP) once adequate volume status is assured. Positive-pressure ventilation impedes return of blood to the heart; as a result, emergency intubation of a hypovolemic patient can adversely affect cardiac output. Hyperventilation should be avoided. An ABG analysis should be obtained to assess pH and arterial carbon dioxide tension (P_aCO_2).

Circulation

Once alveolar ventilation is ensured, the next priority is to optimize oxygen delivery by maximizing cardiovascular performance. External hemorrhage is controlled by means of manual compression, and empirical volume loading for presumed hypovolemia via large-bore I.V. cannulas is initiated. The size, number, and sites of I.V. catheters depend on the degree of shock present and on estimates of injury severity. If the patient arrives in shock or has obvious multiple injuries, a short 14 French catheter should be placed in each antecubital vein. When vascular collapse precludes peripheral percutaneous access in an adult, the alternative is cannulation of the femoral or the subclavian vein by means of the Seldinger technique. We have found the supraclavicular subclavian approach to be useful in the ED.²³ Venous access should be avoided in regions with potential penetrating vascular injuries (e.g., lower neck, upper chest, pelvis, or groin).

Intraosseous infusion through a cannula placed in the medullary cavity of a long bone is a safe and efficacious method for emergency vascular access in infants and children younger than 6 years. This procedure is typically performed in the anteromedial aspect of the tibial plateau in an uninjured extremity; the distal femur, the distal tibia, and the sternum are other potential sites. Intraosseous infusion generally allows administration of sufficient fluid to facilitate subsequent cannulation of the venous circulation.²⁴ If access remains problematic in children, greater saphenous vein cutdown at the groin is the preferred route because inadvertent femoral artery injury with the percutaneous approach may result in limb-threatening vasospasm.

With establishment of the first I.V. line, blood should be drawn for hematocrit, white blood cell (WBC) count, electrolyte concentrations, blood-group typing, coagulation profile, and toxicology screen as indicated.

Isotonic crystalloid is used for initial resuscitation in the ED.^{25,26} Lactated Ringer solution (LR) is preferred to normal saline (NS) unless the patient has an obvious brain injury. Excessive early administration of crystalloids has been identified as a risk factor for adverse outcomes; accordingly, the amount infused should be closely monitored.²⁷ If the patient does not respond to crystalloid infusion at levels exceeding 30 ml/kg, blood should be administered. LR and banked blood should not be infused through the same I.V. line.

Early empirical blood transfusions are indicated in patients who arrive in severe shock or who have injuries associated with significant bleeding (e.g., a vertical shear pelvic fracture or bilateral

femur fractures), especially if the patients are elderly. Type-specific blood should be available within 20 minutes. If type-specific blood is not available, reconstituted O-negative packed red blood cells (RBCs) may be used. Micropore filters are not used in blood infusion lines in hemodynamically unstable patients, because they impede infusion capabilities.²⁸ In the future, hemoglobin-based oxygen carriers may become available, obviating crossmatching. Protocols for massive transfusions should be established with the blood bank to ensure prompt availability of blood products for patients arriving with life-threatening bleeding.^{29,30}

EVALUATION AND CONTINUED RESUSCITATION

Identification of Hemodynamic Instability

Recognizing the presence of shock and assessing its severity [see 8:3]

Shock are key factors in early decision making. During the initial ABCs, palpation for the presence of pulses can be used to generate an estimate of systolic blood pressure (SBP). In general, a radial pulse is detected when SBP is higher than 80 mm Hg, a femoral pulse when SBP is above 70 mm Hg, and a carotid pulse when SBP exceeds 60 mm Hg. The initial blood pressure measurement should be made with a manual cuff; automatic cuff BP measurement machines may overestimate SBP in hypovolemic trauma patients.³¹ An SBP lower than 90 mm Hg (or an age-adjusted decrease in SBP that exceeds 30 mm Hg) in conjunction with a heart rate higher than 120 beats/min is generally considered indicative of shock. Most patients, however, especially young ones, can compensate for hypovolemia and maintain a normal BP even in the face of significant ongoing hemorrhage. It should be kept in mind that because acute massive blood loss may paradoxically trigger a vagal-mediated bradycardia, the traditional inverse correlation between increased HR and reduced effective blood volume may not hold in the early resuscitation period.³² The initial hemoglobin level is notoriously misleading, whether because the patient has not yet been volume loaded or because there has not been sufficient time for influx of interstitial fluid into the intravascular space. It may therefore be helpful to measure the hemoglobin level again after initial volume loading for purposes of comparison; a decrease greater than 2 g/dl should be grounds for concern.

The size of the base deficit can be a useful measure of the depth of hemorrhagic shock.³³ Whether the base deficit is persisting or declining is more important than its absolute value, but generally a base deficit smaller than -8 mEq/L is indicative of severe shock.

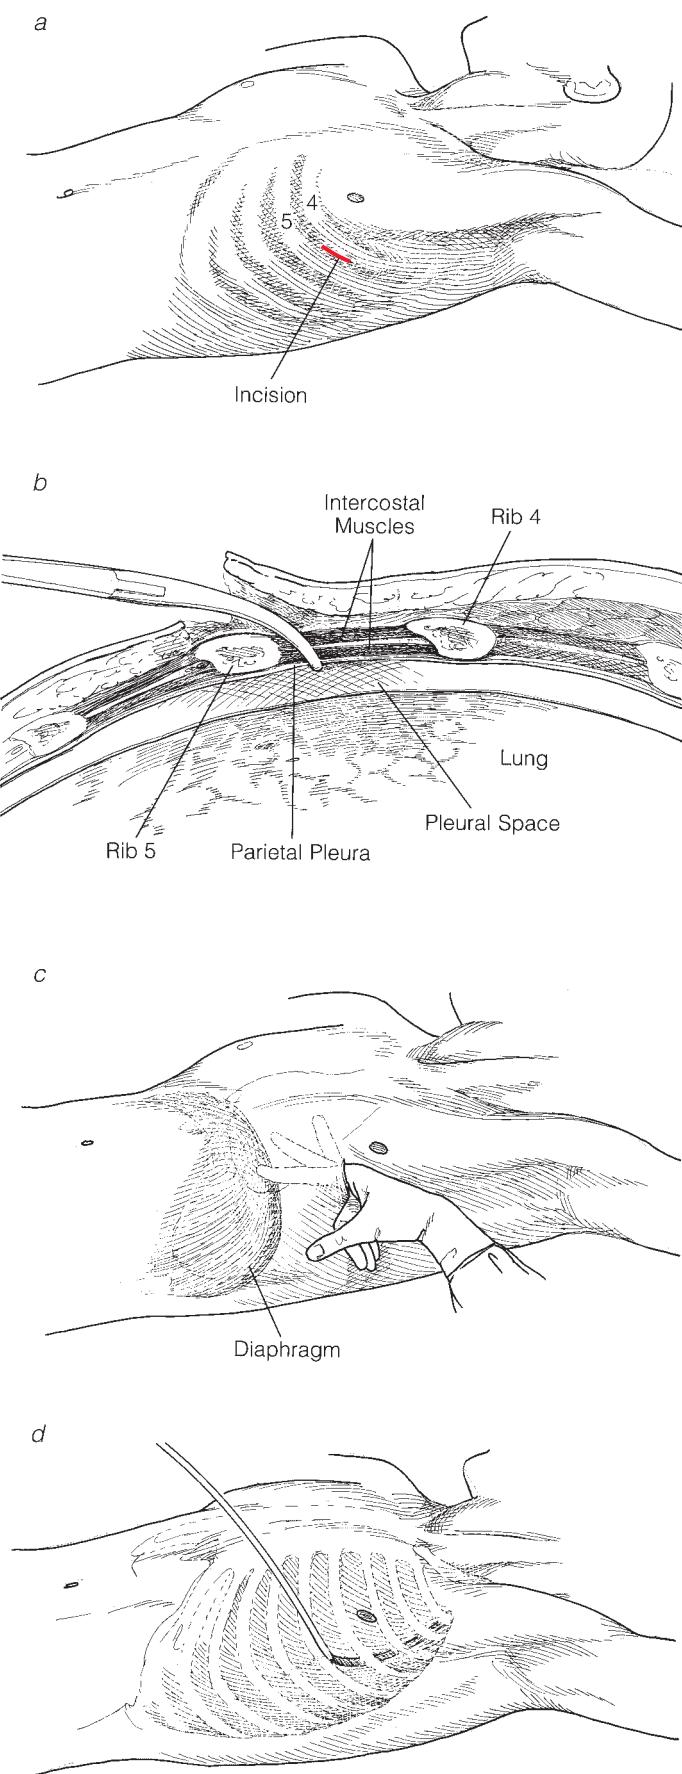

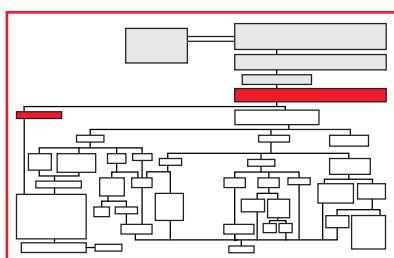

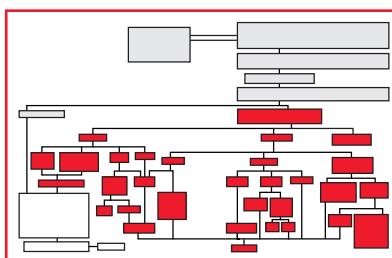

Figure 2 In acute trauma, a tube thoracostomy is performed through the fourth or fifth interspace at the midaxillary line, well above the diaphragm (a). A short subcutaneous tunnel is fashioned over the superior edge of the rib, and the overlying fascia and intercostal muscle are divided sharply. The pleural space is entered by incising the intercostal muscle and the pleura with a heavy scissors (b). A gloved finger is then inserted to confirm penetration of the thoracic cavity and to free up intrapleural adhesions (c). A large-bore tube (36 French) is directed posteriorly toward the pleural apex; the proximal port must be well inside the chest (d). The tube is then secured to the chest wall with No. 5 braided polyethylene suture and connected to a standard collection apparatus.

Measurement of central venous pressure (CVP) is helpful in identifying severe hypovolemia, and serial CVP measurements can be used to assess response to volume loading. Although arterial lines are of limited value in initial ED management, they become increasingly useful as time passes. The end points of initial resuscitation during the time of critical diagnostic testing and triage are as follows: (1) SBP higher than 90 mm Hg, (2) HR lower than 120 beats/min, (3) hemoglobin concentration equal to or greater than 10 g/dl, and (4) CVP equal to or greater than 10 cm H₂O.

Management of Nonresponsive Unstable Patients

Shock that persists despite initial volume loading may derive from severe hypovolemia, cardiogenic causes, or neurogenic causes. Given that neurogenic shock is fairly well tolerated, the key concern at this point is to quickly distinguish hypovolemic shock from cardiogenic shock because cardiogenic shock may necessitate immediate ED intervention. This distinction can reasonably be made by measuring CVP. In hypovolemic shock, CVP is generally less than 5 mm Hg, whereas in clinically significant cardiogenic shock, CVP usually exceeds 20 mm Hg.

The differential diagnosis of traumatic cardiogenic shock depends on the mechanism of injury and may include (1) tension pneumothorax, (2) pericardial tamponade, (3) myocardial contusion, and (4) air embolism. Except in refractory shock, telltale physical signs are frequently hard to discern in a noisy ED, especially when compounded by persistent hypovolemia. Timely diagnosis requires a high index of suspicion. Tension pneumothorax, the most common cause of cardiogenic shock in both blunt and penetrating trauma, is often first confirmed with emergency chest tube placement [see Figure 2].

In traumatic pericardial tamponade, the classic components of Beck's triad (hypotension, muffled heart sounds, and jugular venous distention) are frequently absent, and pulsus paradoxus is rarely detectable. ED ultrasonography is the first test employed by trauma surgeons in patients with high-risk penetrating wounds.³⁴ CVP measurements and pericardiocentesis [see Figure 3] are helpful confirmative tests. Occasionally, a blunt trauma patient can be salvaged through timely diagnosis of a blunt atrial tear.

Myocardial contusion should be suspected in any blunt trauma patient with unexplained cardiogenic shock or persistent arrhythmia. Electrocardiographic changes are usually nonspecific.^{35,36} Fundamental measures include correction of acidosis, hypoxia, and electrolyte abnormalities; judicious administration of fluid; and pharmacologic suppression of life-threatening arrhythmias.

Bronchovenous air embolism into the left atrium from a pulmonary laceration typically occurs after penetrating trauma and probably is more common than is generally recognized.³⁷ Hemodynamic instability develops after positive pressure ventilation is initiated, as air is forced from the pulmonary bronchioles into the adjacent open pulmonary veins and, ultimately, into the coronary arteries. ED thoracotomy is essential for pulmonary hilar cross-clamping, air aspiration from the left ventricle, and cardiac massage. The patient is then transferred to the OR for definitive management of the pulmonary lesion before the hilar clamp is released.

ED thoracotomy is an integral part of the initial management of the patient who arrives in extremis and deteriorates to immi-

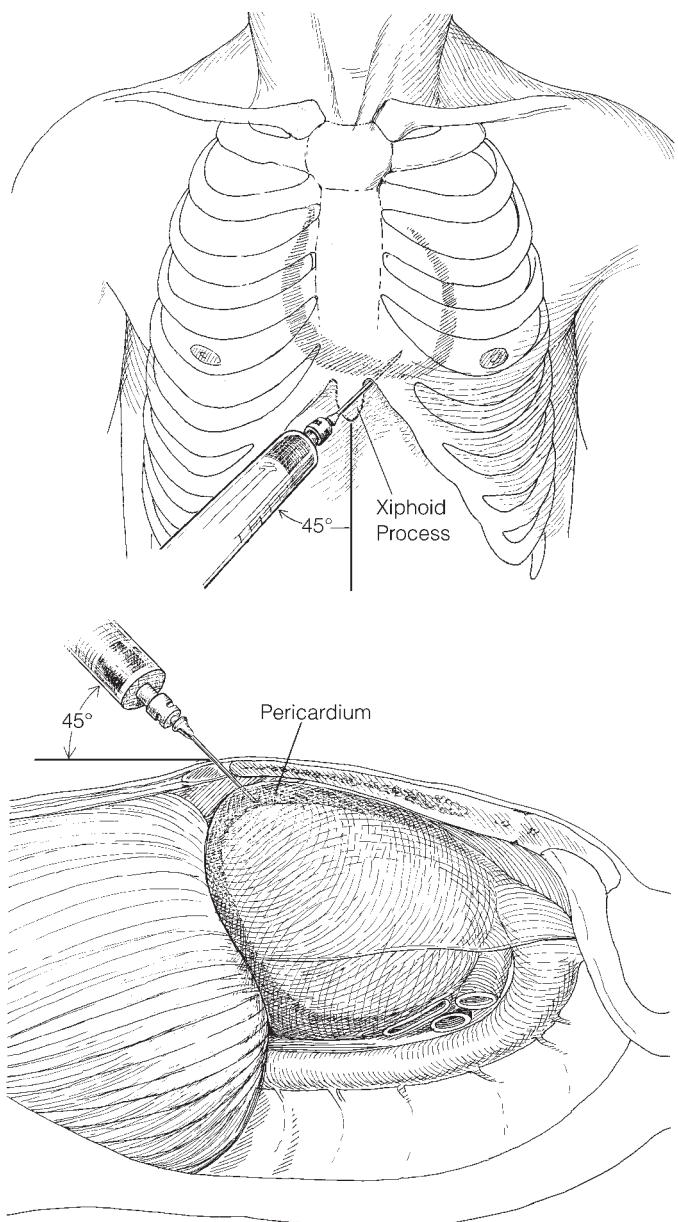

Figure 3 For pericardiocentesis, an 18-gauge spinal needle is inserted at the left xiphoid-costal junction and inserted toward the inferior tip of the left scapula (angled 45° to the patient's right and 45° from the chest wall). The needle is advanced until blood or air is encountered; a "pop" may be appreciated as the needle tip traverses the pericardium. If air is withdrawn, the needle tip should be directed more toward the patient's midline. If blood is withdrawn, 50 ml should be aspirated and injected onto a sheet so that it can be inspected for clots. As a rule, intra-ventricular blood will clot, whereas defibrinated pericardial blood will not clot.

nent cardiac arrest [see Figure 4].³⁸ The physiologic rationale is to minimize the duration of profound shock. ED thoracotomy permits (1) release of pericardial tamponade, (2) control of intrathoracic blood loss, (3) internal cardiac massage, and (4) cross-clamping of the descending thoracic aorta to enhance coronary and cerebral perfusion and to reduce subdiaphragmatic bleeding. Internal cardiac massage should be done bimanually; otherwise, a forceful thumb may rupture the relatively thin right ventricle as it becomes distended. Ventricular lacerations are repaired with pled-

geted horizontal mattress sutures, whereas atrial injuries are controlled with a partially occluding vascular clamp and repaired with a continuous suture [see Figure 5]. Small left ventricular wounds can be closed without pledges. For large left ventricular wounds, skin staples are an alternative means of rapid closure.

SECONDARY SURVEY WITH DEFINITIVE DIAGNOSIS AND TRIAGE DECISIONS

Fortunately, most acutely injured patients arriving in shock can be rendered hemodynamically stable enough to undergo a secondary survey. Diagnosis and treatment proceed simultaneously. Prioritization is imperative and is governed by the severity of shock and its rate of progression. Easily correctable life-threatening injuries should be addressed first before a search is made for occult trauma. Prioritization is also guided by the mechanism of injury. Penetrating trauma typically results in a localized injury, whereas blunt trauma frequently results in multiple injuries involving several body regions. When hemodynamic instability recurs, its cause must be identified and corrected promptly.

The length of time spent in the ED, the decision for urgent operation, and the ordering of special radiologic studies are critical decisions that must take into account the mechanism of injury, the response to resuscitation, and the availability of a staffed operating room or interventional radiology suite. A patient in refractory

shock with a central abdominal gunshot wound, for example, clearly should be transported to the OR in a matter of minutes, but the management of a previously unstable victim of a motor vehicle crash who has a positive ultrasonogram combined with altered mental status, a widened mediastinum on chest x-ray, and an unstable pelvic fracture requires a far more complex decision. In general, however, when priorities conflict, the safest arena for managing critically injured patients is the OR.

Penetrating Trauma

Systematic assessment The secondary survey is more focused in cases of penetrating trauma than in cases of blunt trauma. The priorities are (1) to identify all of the wounds, (2) to decide whether an urgent operation is indicated, and (3) to determine whether additional testing is needed to assist with intraoperative management. The decision-making process is driven by hemodynamic stability and the location of the wounds. Efforts should focus not on resuscitating the patient until vital signs are normal but, rather, on obtaining adequate I.V. access, ensuring that blood products are available, and notifying the OR. Hemodynamically unstable patients should be rapidly sent to the OR with minimal or no testing.

Neck Patients who have an obvious life-threatening injury (e.g., a gurgling wound, pulsatile bleeding, or a compromised airway) or are in severe shock should undergo operation promptly. ED management should be limited to airway control, external compression to control bleeding, I.V. access, and chest x-ray. A neurologic examination should be performed and documented.

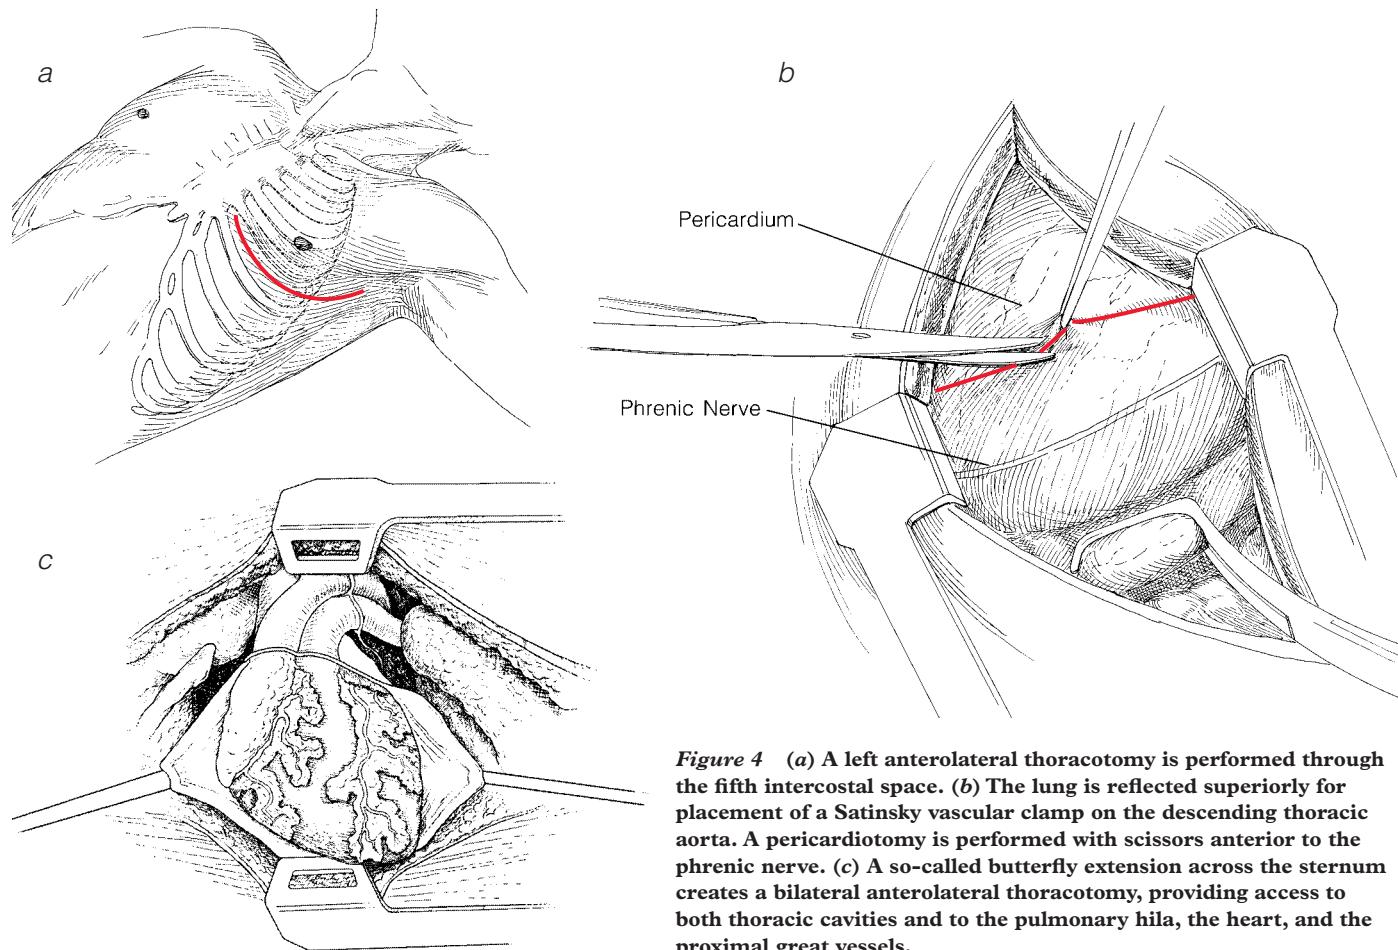

Figure 4 (a) A left anterolateral thoracotomy is performed through the fifth intercostal space. (b) The lung is reflected superiorly for placement of a Satinsky vascular clamp on the descending thoracic aorta. A pericardiotomy is performed with scissors anterior to the phrenic nerve. (c) A so-called butterfly extension across the sternum creates a bilateral anterolateral thoracotomy, providing access to both thoracic cavities and to the pulmonary hilus, the heart, and the proximal great vessels.

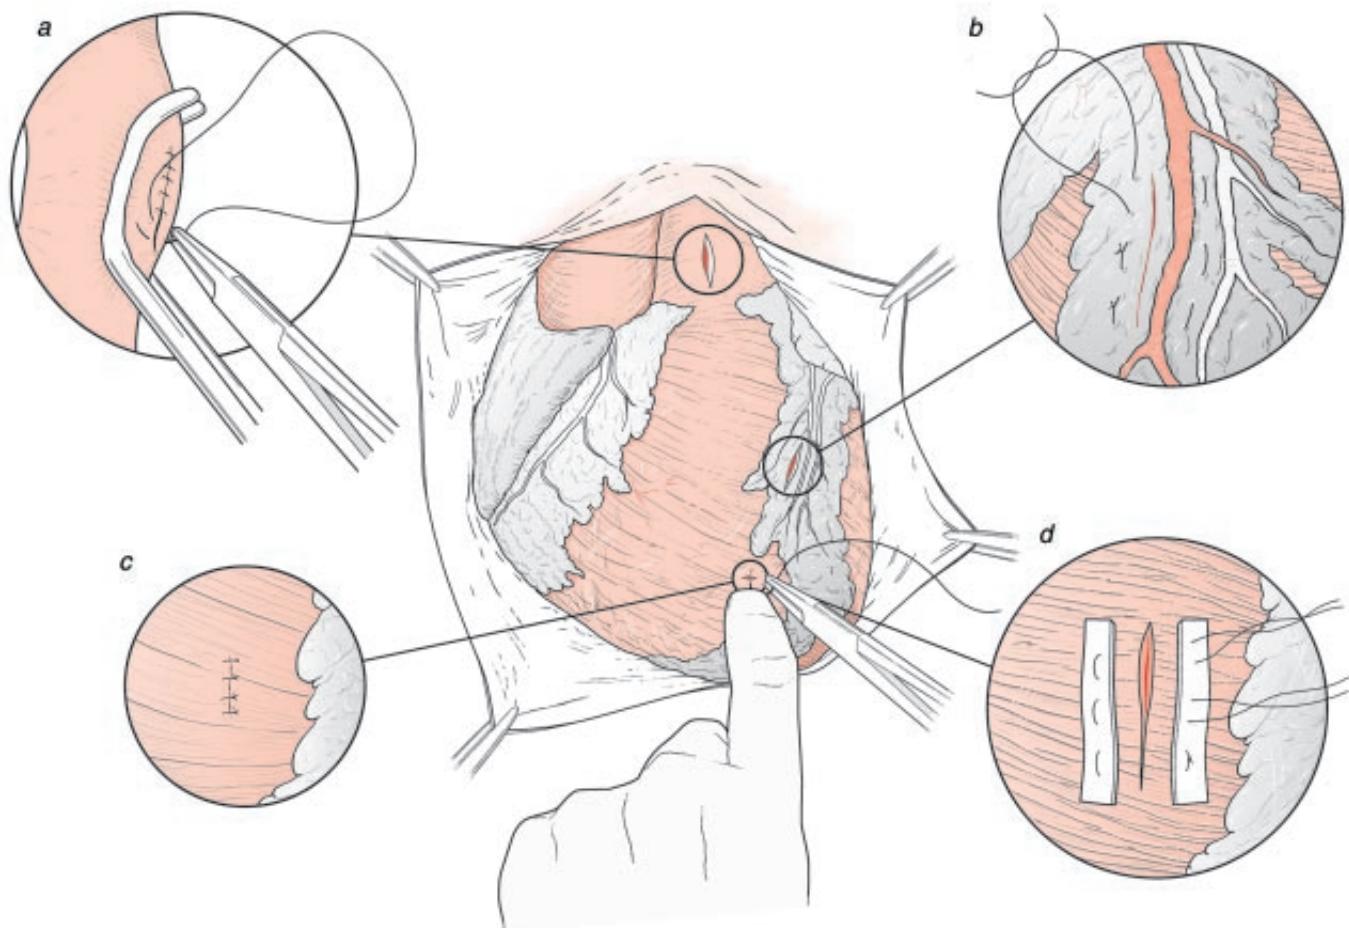

Figure 5 (a) A Satinsky vascular clamp is used to control arterial and major vessel injuries while they are closed with a running suture. (b) For wounds close to coronary arteries, horizontal mattress sutures should be used to spare the arteries. (c) Small wounds to the thick left ventricle can be closed with interrupted simple sutures. (d) Larger wounds should be closed using pledges; staple closure may be preferred for larger ventricular wounds.

Management of hemodynamically stable patients without obvious injury is selective.³⁹ Patients with zone I wounds should undergo CT scanning or angiography to rule out occult vascular injuries. Alert patients with zone II injuries but without significant hematoma, crepitance, dysphonia, or dysphagia may be managed expectantly. A missed esophageal injury is associated with significant morbidity. If there is reason to suspect such an injury, both esophagoscopy and esophagography should be performed. Although individually these tests have false negative rates ranging from 10% to 15%, their combined sensitivity approaches 100%.⁴⁰ Asymptomatic patients with zone III injuries should undergo CT scanning or angiography if there is any suspicion of an occult vascular injury.

Chest In unstable patients with thoracic injuries, a chest tube should be placed into the wounded hemithorax, followed by a chest x-ray to confirm tube placement, lung expansion, hemothorax evacuation, and the presence of foreign bodies. If a cardiac wound is suspected, ED ultrasonography should be performed.³⁴ Persistent instability without evidence of intrathoracic bleeding or pericardial tamponade should raise the suspicion of intra-abdominal bleeding. Occasionally, a high spinal cord injury contributes to hemodynamic instability.

The challenge in this setting is to quickly identify those patients who require an urgent operation. Patients who have wounds close to the heart (i.e., in the so-called mediastinal box), ultrasono-

graphically documented hemopericardium, and persistent tachycardia should undergo pericardiocentesis to relieve any ongoing subendocardial ischemia even if SBP is normal [see Figure 3]. Patients who exhibit persistent signs of pericardial tamponade despite negative results from ultrasonography or pericardiocentesis should be transported to the OR for creation of a subxiphoid pericardial window. In approximately 15% of cases, the results of pericardial aspiration for acute hemopericardium are falsely negative because the blood in the pericardial sac is clotted and cannot be aspirated.

If the patient is in extremis, ED thoracotomy should be performed promptly [see Figure 4]. Most patients experiencing intrathoracic bleeding without pericardial tamponade stabilize after tube thoracostomy and modest volume loading. Urgent thoracotomy is indicated for (1) so-called caked hemothorax [see Figure 6], (2) an initial chest tube output higher than 20 ml/kg, (3) a persistent output higher than 3 ml/kg/hr for 2 consecutive hours, or (4) a 12-hour output exceeding 30 ml/kg. Patients with an initial chest tube output higher than 10 ml/kg should be closely observed for hemodynamic instability in the ICU. Abrupt cessation of chest tube output may be deceptive; if hypotension persists or recurs, a second chest tube should be inserted and another chest x-ray obtained.

Patients with large air leaks, massive subcutaneous emphysema, or a persistent pneumothorax should undergo bronchoscopy to exclude a tracheobronchial injury. Patients with transmediastinal

Figure 6 ED chest x-ray shows a massive hemothorax. If the chest tube fails to evacuate the blood, this is a so-called caked hemothorax, which is an indication for emergency thoracotomy in the OR.

gunshot wounds (GSWs) or penetrating wounds close to the great vessels should undergo CT angiography, formal angiography, or both.⁴¹

Lower chest. Wounds located below the nipples anteriorly or the tips of the scapulas posteriorly may penetrate the diaphragm and cause significant intra-abdominal or retroperitoneal injuries. Such penetration occurs in 10% of stab wounds and 30% of GSWs.⁴² If the patient is unstable, tube thoracostomy, chest x-ray, and abdominal ultrasonography are indicated. If instability persists, the patient should be transported to the OR. If the patient stabilizes after tube thoracostomy, additional testing must be done to exclude associated injuries. Diagnostic peritoneal lavage (DPL) is a good screening test for intra-abdominal injuries. The RBC threshold for abdominal exploration is lowered to 10,000/mm³ because isolated diaphragmatic injuries may not bleed. An intermediate RBC count (1,000 to 10,000/mm³) warrants further evaluation with thoracoscopy or laparoscopy because DPL may contribute this degree of RBC contamination.⁴³ CT scanning may assist in diagnosing occult retroperitoneal injuries, but it is not reliable for excluding penetrating diaphragmatic injuries.⁴⁴

Anterior abdomen Unstable patients should be transported to the OR with minimal resuscitation and testing. Biplanar abdominal x-rays are often helpful in clarifying bullet trajectories; entrance and exit wounds should be marked with radiopaque objects. Intravenous pyelography (IVP) is not indicated, because it takes too much time. Management of stable patients depends on the mechanism of injury. Laparotomy is indicated for GSWs that violate the peritoneal cavity. DPL or laparoscopy is indicated for suspicious tangential GSWs. Laparotomy is indicated in patients with overt peritonitis after a stab wound. In other patients, the stab wound should be explored. If there is no violation of the anterior fascia, the patient can safely be discharged. If the fascia is violated, DPL is indicated; an RBC count higher than

100,000/mm³ mandates laparotomy. Furthermore, an elevated WBC count, amylase level, alkaline phosphatase level, or bilirubin concentration in the lavage fluid may identify hollow viscus injury (HVI); however, threshold values for these measurements have not been established.^{45,46}

Flank, back, and pelvis Unstable patients with injuries to the flank, the back, or the pelvis should undergo immediate laparotomy. Stable patients are difficult to evaluate. With the exception of blood on rectal examination, the findings from physical examination are unreliable. Gross hematuria is indicative of bladder or kidney injury. Triple-contrast CT scanning may be helpful in patients with high-risk wounds.^{44,47} Most retroperitoneal HVIs are identified on the basis of extraluminal gas or fluid rather than of contrast extravasation. Sigmoidoscopy should be performed if a rectal injury is suspected. High-risk wounds should be explored to ensure that retroperitoneal HVIs are not missed; delayed diagnosis is associated with significant morbidity.

Extremities Unstable patients with isolated penetrating injuries to the extremities should be managed with external compression to control bleeding (not with tourniquets or direct vessel clamping), I.V. access with modest volume loading, and prompt triage to the OR for exploration and definitive treatment. Management of stable patients with penetrating extremity injuries begins with a search for “hard” signs of arterial injury (e.g., a large, expanding, or pulsatile hematoma; absent distal pulses; a palpable thrill; an audible bruit; and signs of distal ischemia).⁴⁸ Presence of any of these hard signs prompts further evaluation. If signs of distal ischemia exist, the patient should be taken to the OR, where an on-table angiogram can be performed. If knowledge of the patient’s specific vascular anatomy is needed and no signs of ischemia exist, a formal angiogram is reasonable. If “soft” signs of vascular injury are present, distal blood pressures should be measured in the injured extremity, the contralateral extremity, and, often, the brachial artery. If either the ratio of the BP in the injured extremity to that in the contralateral extremity or the ratio of the BP in the injured ankle to that in the brachial artery is 0.90 or higher, arterial injury is excluded and no additional testing is needed. These ratios are not, however, reliable for excluding arterial injuries in the axilla or the groin. The presence of a good Doppler signal does not exclude a vascular injury.

Blunt Trauma

Systematic assessment The goal is to identify all potentially life- and limb-threatening injuries. A comprehensive assessment is crucial to facilitate triage from the ED to the OR, the CT scanning suite, the interventional radiology suite, or the ICU. The details of the patient’s medical history, as well as the details specifically related to the injury, are critical. The prehospital emergency medical technicians are encouraged to provide a comprehensive account of the event and a thorough patient assessment. A minimal review of the patient’s medical history should include preexisting medical illnesses, current medications (and when they were most recently ingested), allergies, tetanus immunization status, and the time of the last meal. A rapid, systematic physical examination is done, literally from head to toe. Patients are completely disrobed and, once spinal injury is excluded, rolled from side to side so that the back and the flanks can be inspected. A rectal examination is done to look for blood and to evaluate sphincter tone; the perineum and the axillae are inspected; and neurologic function and peripheral pulses are assessed.

The cervical spine is rigidly immobilized, and long-bone frac-

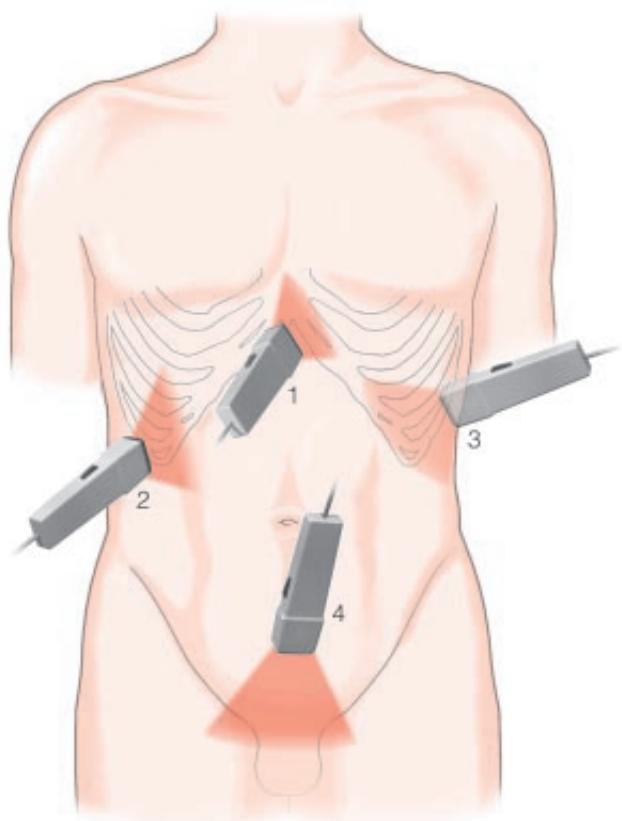

Figure 7 (a) Shown are four transducer positions in the FAST (focused assessment for sonographic evaluation of the trauma patient): (1) pericardial area, (2) right upper quadrant, (3) left upper quadrant, and (4) pelvis.

tures are splinted to minimize pain, blood loss, and soft tissue damage. Insertion of a nasogastric tube decompresses the stomach and reduces the risk of pulmonary aspiration, but because maxillofacial injury may provide a pathway into the cranial vault,⁴⁹ the tube should be placed orally when midfacial fractures are present. Blood in the gastric aspirate may be the only sign of an otherwise occult injury to the stomach or the duodenum.

Placement of a Foley catheter empties the bladder, may disclose hematuria, and permits the physician to monitor urinary output. The Foley catheter should not, however, be inserted until abdominal ultrasonography is completed, and it should not be placed on an urgent basis in male patients with suspected urethral injuries (i.e., those with blood at the meatus, a perineal hematoma, a high-riding prostate, or an extensively displaced anterior pelvic fracture). If urethral injury is suspected, a retrograde urethrogram, followed by a cystogram (to exclude bladder injury) is obtained, prioritized in accordance with the given setting. In females, the urethra is shorter and better protected and thus is rarely injured.

Routine x-rays performed simultaneously with the ABCs include lateral cervical spine, anteroposterior chest, and pelvic films. Once life-threatening injuries have been addressed, thoracic and lumbar spine films should be obtained in patients who complain of back pain, those with neurologic deficits, and those with high-risk mechanisms of injury in whom physical examination is unreliable. X-rays of extremities with suspected fractures (including the joint above and the joint below) should also be obtained.

Given that trauma victims are uniquely susceptible to hypothermia, a rectal or bladder temperature probe is essential in those

who have been exposed to a cold environment or who require massive volume replacement. A core temperature reading lower than 32° C (89.6° F) should be confirmed with an esophageal probe, and rewarming measures appropriate for the degree of hypothermia should be initiated.⁵⁰ Tetanus prophylaxis is routine. Systemic antibiotics should be withheld until a specific indication arises. An electrocardiogram is obtained after blunt chest trauma, and an ABG analysis is done in select patients to confirm adequate ventilation and metabolic balance. In any patient with evidence of hypovolemia, a blood sample should be sent for blood-group typing and coagulation studies if urgent blood transfusion is required.

Rapid hemorrhage control Blunt trauma patients who arrive in shock and remain hemodynamically unstable pose difficult triage decisions. Initial screening must be directed at identifying life-threatening bleeding that necessitates immediate OR intervention. Most hospitals do not have an interventional radiology suite immediately available; early notification is crucial in assembling the team. At our institutions, after normal working hours, this process consumes about 1 hour.

Initial screening focuses on the chest, the abdomen, and the pelvis. A chest x-ray is the most reliable screening test for intrathoracic bleeding; it also confirms the location of endotracheal, nasogastric, and thoracostomy tubes, as well as that of the central venous catheter. The presence of pleural fluid may be difficult to confirm on a supine chest x-ray: 1 L of blood may produce only a hazy appearance in a hemithorax. Hemothoraces should be drained promptly via tube thoracostomy [see Figure 2]. Continued bleeding must be monitored carefully by measuring chest tube output, obtaining serial chest films to detect retained intrapleural blood, and observing vital signs. The criteria used to decide when thoracotomy is indicated are similar to those used in cases of penetrating trauma, but far fewer blunt trauma patients meet these criteria, and intrathoracic bleeding is rarely a reason for immediate OR triage.⁵¹

The abdomen is notoriously difficult to evaluate and is much more likely than the chest to harbor occult life-threatening bleeding. The peritoneal cavity may sequester as much as 3 L of blood with only minimal abdominal distention. Head injury or intoxication frequently alters the patient's response to acute injury, and pain from associated fractures may overshadow peritoneal irritation secondary to bleeding. Ultrasonography [see Figures 7 and 8] is the most rapid method of identifying free blood, but it may yield false negative results in as many as 15% of patients on initial examination.^{52,53} DPL [see Figure 9] remains the most reliable method of identifying significant intraperitoneal hemorrhage: in patients with life-threatening bleeding, its sensitivity approaches 100%.⁵⁴ A grossly positive aspirate (> 10 ml of blood) mandates emergency laparotomy.

Assessment of bony stability by means of physical examination and plain films of the pelvis is crucial for the early identification of major pelvic fractures. Life-threatening hemorrhage occurs most commonly with fracture patterns involving the posterior columns [see Figure 10].^{30,55} Appropriate initial management of unstable patients who have a high-risk pelvic fracture on initial pelvic x-ray includes blood volume replacement (including early blood and fresh frozen plasma [FFP]) and application of a pelvic binder; wrapping with a sheet is also effective [see Figure 11].

The next step is to evaluate the response to initial resuscitation and then perform ultrasonography or DPL to determine whether significant intra-abdominal bleeding is present.^{56,57} An unstable patient with clearly positive findings from ultrasonography or DPL should undergo laparotomy because of the high probability

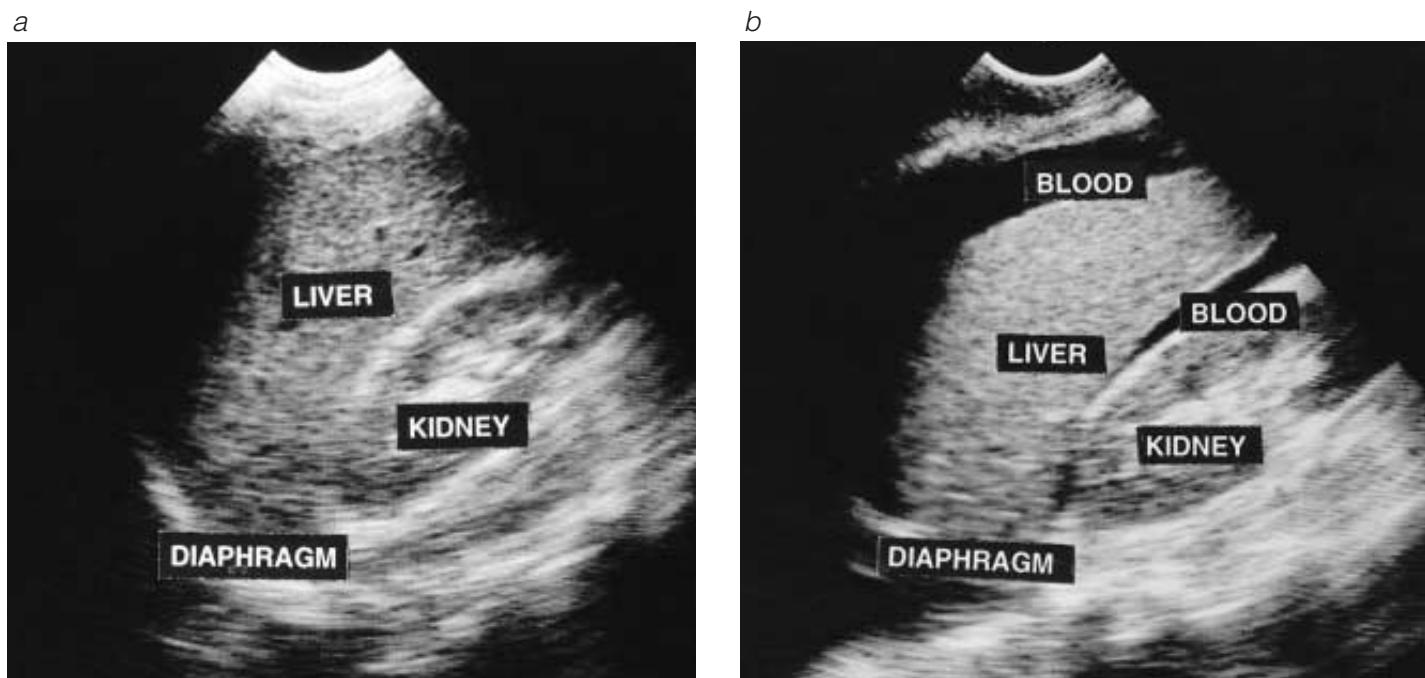

Figure 8 (a) Sagittal ultrasound image of liver, kidney, and diaphragm yields normal findings. (b) Sagittal ultrasound image of right upper quadrant shows blood between liver and kidney and between liver and diaphragm.

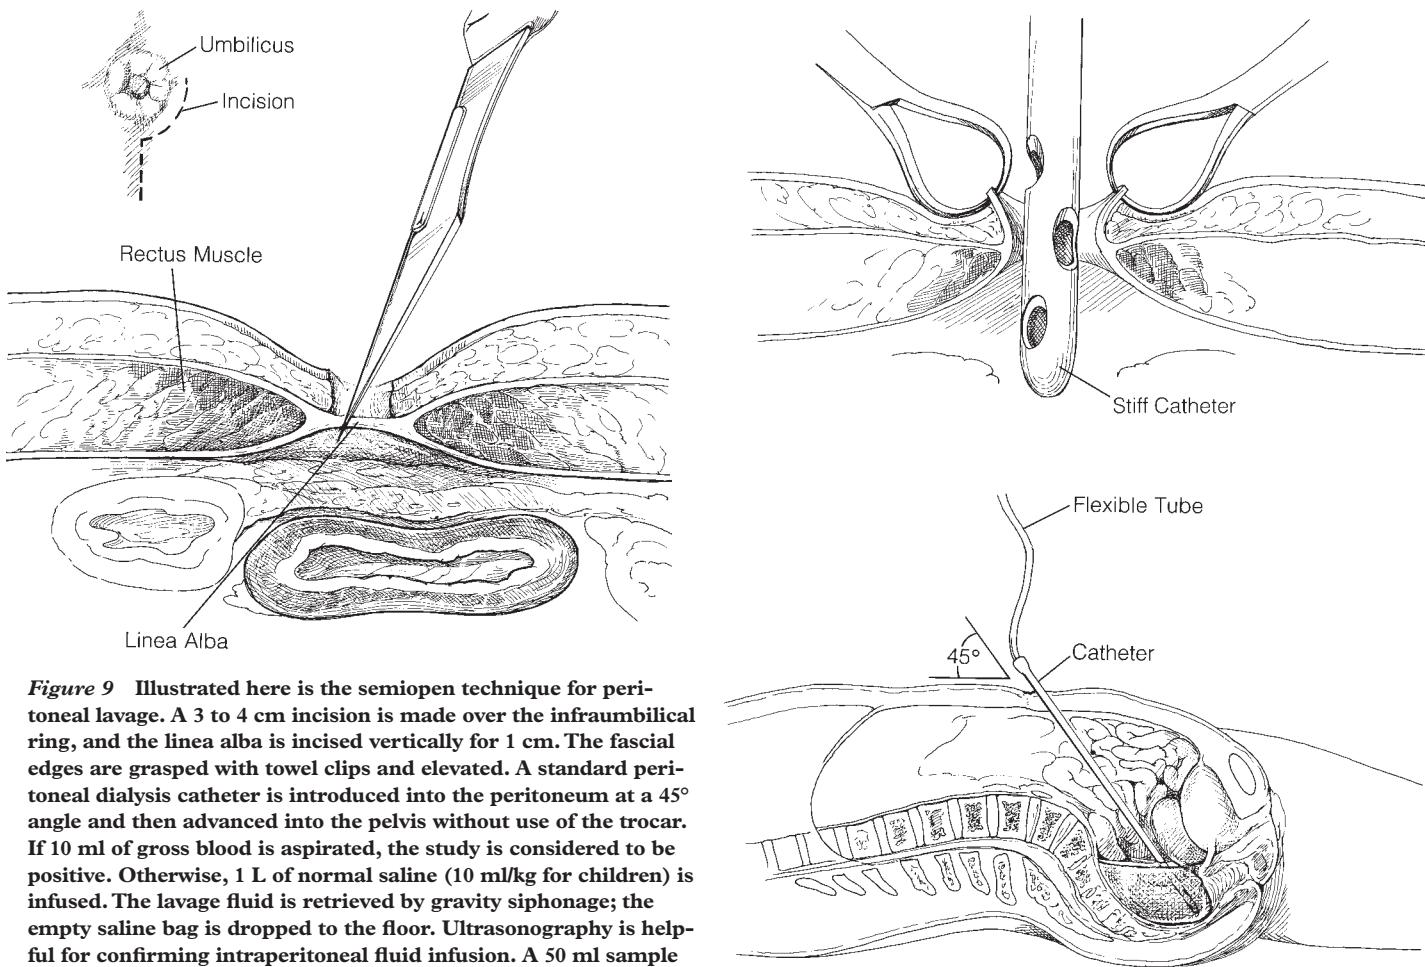

Figure 9 Illustrated here is the semiopen technique for peritoneal lavage. A 3 to 4 cm incision is made over the infraumbilical ring, and the linea alba is incised vertically for 1 cm. The fascial edges are grasped with towel clips and elevated. A standard peritoneal dialysis catheter is introduced into the peritoneum at a 45° angle and then advanced into the pelvis without use of the trocar. If 10 ml of gross blood is aspirated, the study is considered to be positive. Otherwise, 1 L of normal saline (10 ml/kg for children) is infused. The lavage fluid is retrieved by gravity siphonage; the empty saline bag is dropped to the floor. Ultrasonography is helpful for confirming intraperitoneal fluid infusion. A 50 ml sample of the fluid is submitted for laboratory analysis.

Figure 10 Pelvic angiography with selective embolization may be an integral component in the early management of a major pelvic crush injury with continuing hemorrhage.

of major hepatic, splenic, or mesenteric bleeding. If there is a large pelvic hematoma at the time of laparotomy and the patient is unstable, embolization of the internal iliac artery may be performed with a slurry of autogenous clot, microfibrillar collagen, thrombin, and calcium chloride.⁵⁸ A hemodynamically unstable patient in whom the ultrasonogram is normal and DPL yields confirmatory negative results should undergo prompt pelvic arteriography for selective embolization.⁵⁹

Fast track CT scanning to refine triage In unstable patients who respond to initial interventions, the priorities are as follows: (1) identify and quantitate ongoing sources of bleeding, (2) identify TBI, especially in those patients who require immediate craniotomy, and (3) identify any other injuries that call for urgent intervention (e.g., thoracic aortic injury [TAI]) or special precautions (e.g., spine fractures). With the widespread availability of multidetector CT scanners, rapid whole-body imaging is now feasible, permitting accurate triage for these competing priorities. The important question is whether the patient is stable enough to survive for the time such imaging takes. At our institutions, preparation, transport, and scanning take, in all, roughly 40 minutes. The decision to order CT scanning is made early, while the ABCs are being addressed and ultrasonography and initial plain x-rays are being performed, and depends on the age of the patient, any obvious injuries identified, and the patient's hemodynamic stability. The decision is less clear-cut in the common situation in which a previously unstable patient has a positive abdominal ultrasonogram. The key issue here is which injuries identified by CT scanning would alter the decision to perform an urgent laparotomy.

Identification of abdominal injuries The decision to perform an urgent laparotomy in a patient with a positive ultrasono-

gram depends on the patient's hemodynamic stability. A CT scan can be helpful in refining triage by identifying extravasation of I.V. contrast (i.e., a blush) and in diagnosing HVIs. A blush should prompt consideration of angiography. Early angiography is a helpful adjunct in managing liver and kidney injuries, though its role in managing acute splenic injuries remains to be established.⁶⁰⁻⁶⁴ HVIs are notoriously difficult to diagnose; extravasation of oral contrast is rare.^{65,66} When all signs (e.g., unexplained free fluid, bowel wall thickening, mesenteric streaking, and free air) are considered, however, the sensitivity of CT in making the diagnosis approaches 90%. In questionable cases of HVI in stabilized patients, we advocate delayed DPL to search for elevations in WBC count, amylase level, and alkaline phosphatase level.

Identification of traumatic brain injury Approximately 20% of blunt trauma patients who arrive in shock have a TBI.⁶⁷ During initial evaluation, it is important to identify TBI patients who might benefit from an emergency craniotomy. The neurologic examination is of utmost importance. The initial Glasgow Coma Scale (GCS) score in the field should be confirmed with prehospital personnel, and short-acting sedatives/paralytics should then

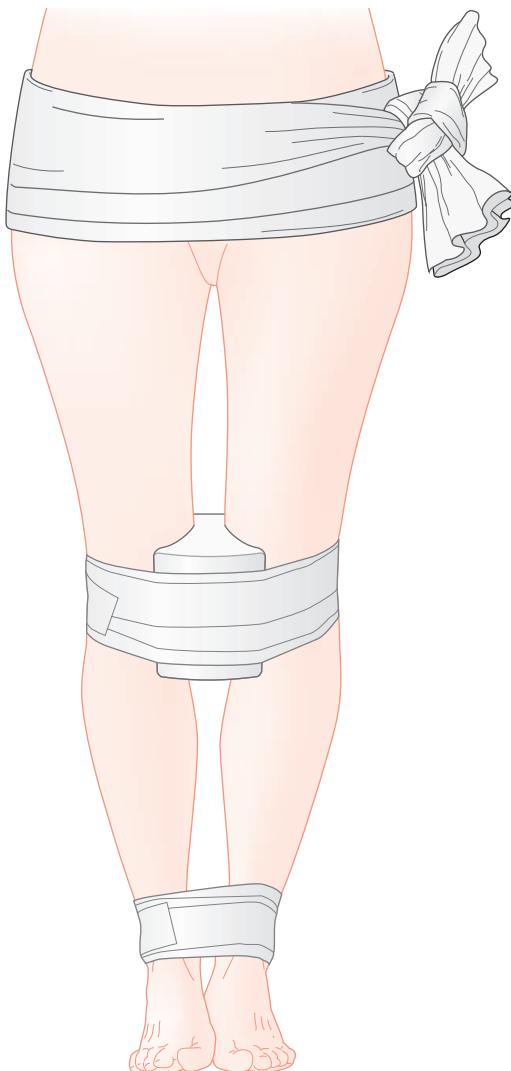

Figure 11 Shown is the wrapping technique currently used for support of a mechanically unstable pelvic fracture.

be given sparingly. A GCS score lower than 8 and a lateralizing neurologic examination indicate a significant risk that emergency craniotomy will be needed and, therefore, justify obtaining a CT scan of the head if hemodynamic stability permits.^{68,69}

Identification of thoracic aortic injury Initial plain films should be examined for evidence of TAI. We use the overpenetrated mediastinal view and specifically look for evidence of a mediastinal hematoma. In the multi-institutional study from the American Association for the Surgery of Trauma (AAST), however, 7% of patients with TAI had a normal ED chest x-ray. We therefore obtain a chest CT scan on the basis of the mechanism of injury.⁷⁰ At our institutions, CT scanning has replaced angiography for the diagnosis of TAI. An occasional angiogram is done to confirm the diagnosis of great vessel injury or to clarify the vascular anatomy before thoracotomy.

The management of TAI has changed markedly over the past decade. Traditionally, a diagnosis of TAI mandated urgent thora-

cotomy.⁷¹ Currently, however, antihypertensive therapy and ICU monitoring allow delayed repair in patients with significant associated injuries.⁷² Delayed repair is safe but is associated with increased infectious complications and longer ICU stays.⁷³

Identification of limb ischemia The absence of distal pulses in a fractured or dislocated extremity should be addressed urgently. Fractures and dislocations should be reduced, and the extremity should be closely examined for signs of ischemia. Distal SBP measurements comparing injured limbs with noninjured limbs (i.e., the ankle-ankle index [AAI] or the ankle-brachial index [ABI]) should be obtained. If the ABI or AAI is less than 0.90 after reduction, CT angiography or formal angiography should be performed to exclude the presence of a vascular injury.^{74,75} A pulseless extremity is best evaluated in the OR by means of on-table angiography. Delayed diagnosis as a result of waiting for formal angiography is a preventable cause of limb amputation.

Discussion

Prehospital Care

ADVANCED TRAUMA LIFE SUPPORT

The growing sophistication of emergency medical services has expanded the scope of prehospital care, but the extent of prehospital interventions remains a highly controversial issue.^{1,2} In trauma, advocates of the so-called scoop-and-run philosophy argue that resuscitative efforts in the field unnecessarily delay provision of definitive care and have detrimental effects on physiology and survival when overzealously applied.^{3,5} At present, there is little evidence to support the use of ATLS in prehospital management of urban trauma patients. ATLS skills may be of value in rural areas where transport time exceeds 30 minutes, but unfortunately, the limited volume of serious trauma in such areas makes it difficult to gain the experience necessary to maintain this expertise.

Airway Management

The goal of initial resuscitation is to restore adequate oxygen delivery to vital organs. Efforts to improve tissue perfusion will be unproductive unless the oxygen content of the circulating blood is sufficient. Airway patency and maintenance of adequate ventilation are thus the initial priorities. However, intubation and positive pressure ventilation inhibit venous return to the heart and detrimentally decrease cardiac output in hypovolemic patients.⁷⁶ In addition, emergency airway control after blunt trauma should be performed with the assumption that an unstable cervical spine fracture exists until such injuries are excluded radiologically, but this policy does not preclude RSI. The current recommendation—orotracheal intubation with in-line manual stabilization of the head and neck—has proved safe in clinical series to date. When orotracheal intubation fails, the laryngeal mask airway (LMA) is a rapid, safe, and effective technique for maintaining temporary airway control until definitive medical care becomes available.⁷⁷ For patients with extensive maxillofacial trauma that precludes oral intubation, cricothyrotomy has been the traditional alternative, but this procedure has some risks, particularly in children.

Prehospital Intubation of Patients with TBI

Because hypoxia has been associated with increased mortality in patients with TBI, aggressive prehospital airway protocols that

include RSI have been instituted. This practice may, however, be associated with worse outcomes.³ Patients intubated in the field are routinely hyperventilated, and this state has adverse physiologic consequences. Increased intrathoracic pressure obstructs venous return to the heart, impairs venous drainage from the brain, and, in hypovolemic patients, decreases cardiac output. Additionally, a low P_aCO_2 causes cerebral vasoconstriction. Routine end-tidal capnometry for TBI patients undergoing field intubation has been proposed as the standard of care for preventing excessive hyperventilation.⁴

Prehospital Volume Resuscitation

A provocative 1994 clinical trial found that for hypotensive patients with penetrating torso injuries, survival improved when fluid resuscitation was delayed until surgical intervention had controlled the source of hemorrhage.⁶ A subsequent subset analysis, however, revealed that survival was improved only in patients who had sustained cardiac injuries, not in patients who had sustained major vascular, abdominal solid organ, or noncardiac thoracic injuries.⁷⁸ Although this clinical trial had some methodologic flaws, it is important because it emphasizes that source control of hemorrhage is an overriding priority in hemodynamically unstable patients.

Whether fluid resuscitation should be withheld until control of hemorrhage is achieved is doubtful; such an approach is clearly not the current standard of care. The point at issue is whether it is preferable to administer fluids to restore oxygen delivery to tissue, thus potentially causing hemodilution and disruption of early hemostatic clots, or to withhold fluid resuscitation, thus prolonging cellular shock to the point where it may be irreversible by the time operative control is accomplished. At present, the rational compromise between these two approaches is hypotensive resuscitation with moderate volume loading.^{79,80} Whereas this approach is becoming the standard of care for penetrating trauma, its application to blunt trauma is not as clear. Some 20% of patients with major torso trauma have a serious concomitant TBI; if they are inadequately resuscitated, reduced cerebral perfusion pressure may lead to devastating secondary brain injury. The anticipated availability of hemoglobin-based oxygen carriers may further confound the hypotensive resuscitation debate.

Resuscitation with Hypertonic Saline

Small-volume hypertonic saline (HS) has been shown to be as effective as large-volume crystalloid in expanding plasma volume and enhancing cardiac output.⁸¹ Furthermore, HS increases perfusion of the microcirculation, presumably by inducing selective arteriolar vasodilation and by reducing the swelling of RBCs and endothelium⁸²; however, this improved microcirculation could lead to increased bleeding. The resuscitative effectiveness of HS can be further enhanced by combining it with dextran (hypertonic saline dextran [HSD]).⁸³

In view of the small volumes needed to achieve the desired effects, there has been great interest in employing these fluids for field resuscitation in both military and civilian settings. A number of trials investigating the use of HS and HSD have been performed. Individually, these trials reported inconsistent results in terms of improved survival; however, collectively, the trials did confirm that a bolus of either HS or HSD was safe.⁸⁴ Meta-analysis of the data suggested that HS was no better than the current standard of care (isotonic crystalloid fluids) but that HSD might be better.⁸³ Subgroup analysis of the data showed that the patients who benefited most from HSD were those who presented with shock and concomitant severe TBI. The results of this analysis agreed with laboratory data showing that in comparison with isotonic crystalloid, both HS and HSD raised cerebral perfusion pressure, lowered intracranial pressure, and reduced brain edema.⁸⁵

The argument in favor of HS resuscitation is even more compelling with the recognition that this approach markedly reduces the inflammatory response (specifically, neutrophil cytotoxicity) in animal models of hemorrhagic shock, ischemia and reperfusion, and sepsis. However, one well-executed trial that tested HS for field resuscitation of TBI patients in shock did not demonstrate any benefits.⁸⁶

Emergency Department Management

EMERGENCY DEPARTMENT RESUSCITATIVE THORACOTOMY

ED thoracotomy is an integral part of the initial management of trauma patients who arrive in extremis.⁸⁷ When blood volume is depleted or pericardial tamponade is present, closed-chest compression is ineffective in maintaining systemic blood flow,⁸⁸ whereas open cardiac massage maintains coronary and cerebral perfusion for as long as half an hour. Adjunctive thoracic aorta occlusion enhances both coronary and cerebral perfusion by maintaining aortic diastolic pressure and increasing carotid systolic pressure. Aortic cross-clamping also decreases subdiaphragmatic bleeding in the event of associated abdominal injury.⁸⁹ These benefits are obtained at the expense of increased myocardial oxygen demand and poor perfusion of the lower torso. Clinical experience suggests that 30 minutes is the limit for prevention of splanchnic ischemic sequelae.

The possibility of patient salvage is largely determined by the mechanism of injury, as well as by the patient's condition at the time of thoracotomy. Success rates approach 50% in patients arriving in shock from a penetrating cardiac wound and 20% in patients with penetrating wounds as a whole. On the other hand, patient outcome is dismal when ED thoracotomy is performed in the setting of blunt trauma; it is now considered futile in patients lacking cardiac activity. Adding laparotomy in the emergency department for definitive control of abdominal hemorrhage has not improved outcomes.⁹⁰

BLOOD VOLUME RESTITUTION

Crystalloid versus Colloid

Resuscitation with isotonic crystalloids has been the standard of care in the United States since the late 1960s. A number of clinical trials were performed in the 1970s and 1980s that compared isotonic crystalloid resuscitation with colloid resuscitation. Individually, these trials were underpowered and reported conflicting results. When subjected to meta-analysis, they yielded no consistent differences in overall outcome.⁹¹ When the same data were subjected to subgroup analysis, however, the use of isotonic crystalloids in trauma patients appeared to be associated with improved survival. A large clinical trial published in 2004 found no differences in outcome between crystalloid and colloid resuscitation in ICU patients, but again, subgroup analysis demonstrated improved outcomes in trauma patients receiving crystalloids.⁹² Although these subgroup analyses are not definitive, they are consistent with the early laboratory studies, which indicated that survival in hemorrhagic shock is optimized by administering isotonic crystalloids and blood in a 3:1 ratio. Subsequent animal studies suggested that the optimal ratio rises to 8:1 in severe shock.^{93,94} However, several current reports suggest that "damage control" surgery combined with aggressive ICU resuscitation appears to be saving the lives of many patients who previously would have exsanguinated, but it also appears to be causing adverse edema in the brain (increased ICP), the lung (worsened pulmonary edema), and the gut (the abdominal compartment syndrome).²⁷

Choice of Crystalloid

The selection of a crystalloid engenders less controversy than the choice between crystalloid and colloid. Although newer formulations (e.g., Ringer's ethyl pyruvate) are being tested clinically,⁹⁵ NS and LR remain the most commonly used fluids. In theory, LR is preferable to NS because it provides a better buffer for metabolic acidosis, but to date, investigators have not documented any important differences in outcome.^{96,97} One laboratory study found that NS and LR were equivalent in the setting of moderate hemorrhagic shock but that, in the setting of massive hemorrhage, NS was associated with greater physiologic derangement (e.g., hyperchloremic acidosis) and higher mortality.²⁵ Clinical experience confirms the adverse effects of iatrogenic hyperchloremia.⁹⁸ NS is preferred, however, when blood is being transfused simultaneously.⁹⁹ There is some concern that the calcium in LR could exceed the chelating capabilities of the citrate in the stored blood, resulting in the formation of clots that could enter the circulation and compromise the microcirculation, but at present, there is no hard evidence that this is a significant issue.

Transfusion Trigger

The optimal hemoglobin level continues to be a subject of lively debate.¹⁰⁰ Early laboratory studies demonstrated that survival was improved when the hemoglobin concentration was maintained in the range of 12 to 13 g/dL.¹⁰¹ Subsequent studies using isovolemic hemodilution models, however, indicated that the optimal level for maintaining oxygen delivery was 10 g/dL, and until relatively recently, this value represented the recommended level for critically ill patients.^{102,103} Currently, there is a growing recognition that administration of stored packed RBCs can adversely affect outcome by modulating the inflammatory response (amplifying early proinflammation and aggravating late immunosuppression) and by impairing tissue perfusion (limiting

access to or obstructing the microcirculation as a consequence of reduced RBC deformability).^{104–106} A 1999 randomized trial found that patients who received transfusions according to a restrictive policy (i.e., transfusion when the hemoglobin concentration fell below 7 g/dL) did as well as, and possibly better than, patients who received transfusions on a more liberal basis (i.e., transfusion when the hemoglobin concentration fell below 10 g/dL).¹⁰⁷ Admittedly, this study was done in a select group of euvolesmic patients; thus, it is not clear precisely how applicable the results are to severely injured trauma patients requiring resuscitation from shock. In addition, if blood transfusions are to be restricted during acute resuscitation, it is not clear which alternative fluids should be used.

Choice of Blood Product

Fully crossmatched blood is rarely available for ED trauma resuscitation. Uncrossmatched type-specific whole blood or packed RBCs can be safely administered,^{108,109} and either alternative is available in most hospitals within 20 minutes. If type-specific blood is unavailable, reconstituted O-negative packed RBCs should be used. Type O-negative blood has no cellular antigens; therefore, the risk of major hemolytic reactions caused by patient antibodies attacking donor RBC antigens is minimal. When O-negative packed RBCs are unavailable, O-positive packed red blood cells may be used. The patient will become sensitized to the Rh factor, which is significant for women of childbearing age.

Blood Substitutes

As a consequence of the limited supply of stored blood and the recognition that transfusions contribute to adverse patient outcomes, there has been a resurgence of interest in blood substitutes. Hemoglobin-based oxygen carriers date back to 1933, when it was shown that hemolysates could transport oxygen in mammals.¹¹⁰ Unfortunately, when these solutions were infused into humans, they had excessively toxic effects (i.e., vasoconstriction, acute renal failure, and abdominal pain), which were attributed to stromal contamination. Although the next generation of carrier solutions was stroma-free, toxic effects persisted and were attributed to the instability of the hemoglobin tetramer, which spontaneously dissociates into dimers and monomers.¹¹¹

One formulation of stabilized tetramer, diaspirin cross-linked hemoglobin, was authorized for a phase III study in trauma patients.¹¹² However, the trial was prematurely stopped because of the unexpectedly high mortality in the treatment group (24/52 [46%], compared with 8/46 [17%] in the control group). Although this event was judged a major setback for clinical implementation of hemoglobin-based oxygen carriers, the product used had already been shown to increase pulmonary and systemic vascular resistance in animals. Tetrameric hemoglobin extravasates from the vascular space, binds nitric oxide within the vessel wall, and thereby results in unopposed vasoconstriction. This issue has been effectively addressed by polymerizing the hemoglobin tetramer. The additional benefit of these larger moieties is that they exert less colloid osmotic activity, which means that a higher dose can be administered.

A further limitation of earlier hemoglobin-based oxygen carriers was that because of the loss of 2,3-diphosphoglycerate, oxygen affinity was greatly increased; the partial pressure of oxygen required to produce 50% saturation (P_{50}) decreased from the normal 26 mm Hg to 12 mm Hg. This problem was addressed by pyridoxylation of the hemoglobin tetramer, which raised the P_{50} to 29 mm Hg. One such polymerized hemoglobin solution has

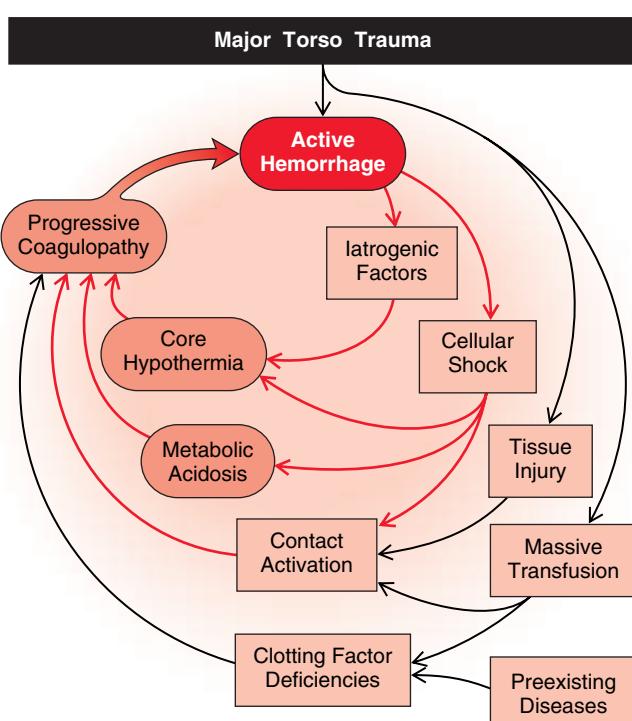

Figure 12 The so-called bloody vicious cycle is a syndrome that has a multifactorial pathogenesis. The usual manifestations include coagulopathy, hypothermia, and metabolic acidosis.¹¹⁸

been tested extensively in phase I and phase II trials in trauma patients and has proved to be safe and effective.^{113,114} A phase III prehospital trial is under way.

EARLY IDENTIFICATION OF NONRESPONDERS

BP and HR are the current standard-of-care monitors of shock resuscitation in the field and in the ED. Both, however, are insensitive markers of early compensated shock; alternative monitors are badly needed for assessing the adequacy of tissue perfusion with a view to avoiding both underresuscitation and overresuscitation. Near-infrared spectroscopy (NIRS), a simple technique that monitors oxygen saturation in tissue, has been shown to track oxygen delivery reasonably well during shock resuscitation and is being tested as an ED monitor.¹¹⁵ Transcutaneous oxygen tension (P_{tcO_2}) monitoring and central venous oxygen saturation (S_{cvO_2}) monitoring have also shown promising results in the ED environment.¹¹⁶

The challenge is to identify as early as possible those patients who are not responding to early interventions. Blind and aggressive volume loading in the hope of normalizing BP and HR, without appropriate emphasis on control of hemorrhage, sets the stage for the so-called bloody vicious cycle or the abdominal compartment syndrome.

BLOODY VICES CYCLE

Among the most devastating complications of massive blood and fluid resuscitation is a bleeding diathesis. Paradoxically, although clotting is accelerated at the capillary level because of shock and tissue damage, the circulating blood becomes hypocoagulable.^{117–119} The pathogenesis of this bloody vicious cycle is complex [see Figure 12]. Factors predictive of a severe coagulopathic state include (1) massive rapid blood transfusion (10 units/4 hr), (2) persistent cellular shock (oxygen consumption index < 110 ml/min/m²; lactate concentration > 5 mmol/L), (3)

progressive metabolic acidosis ($\text{pH} < 7.20$; base deficit $> 14 \text{ mEq/L}$), and (4) refractory core hypothermia ($< 34^\circ \text{ C}$).¹²⁰

Stored blood is deficient in factors V and VIII and platelets but replete with fibrin split products and vasoactive substances. Timely administration of FFP and platelets will minimize the risk of coagulopathy after massive transfusion.^{29,30} Presumptive factor replacement, though not usually indicated in the early resuscitation phase, is appropriate in patients with massive hemorrhage caused by unstable pelvic fracture.

Also germane to the initial period of massive blood transfusion are the potential complications of acidosis, hypothermia, and hypocalcemia. Moderate hypothermia ($< 32^\circ \text{ C}$) causes platelet sequestration and inhibits the release of platelet factors that are important in the intrinsic clotting pathway. In addition, it has consistently been associated with poor outcome in trauma patients.¹²¹ Core temperature often falls insidiously because of exposure at the scene and in the ED and because of administration of resuscitation fluids stored at ambient temperature. The first step is to prevent further heat loss by covering the body (including the head) and infusing warm blood and fluid. Another simple technique is to heat and aerosolize ventilator gases. Active external rewarming with heating blankets and increased room temperature should also be employed. These techniques are not, however, very effective in reversing established hypothermia.

The use of bicarbonate in the treatment of systemic acidosis remains controversial. Moderate acidosis ($\text{pH} < 7.20$) impairs coagulation,¹²² myocardial contractility,¹²³ and oxidative metabo-

lism.¹²⁴ Acidosis in the trauma patient is caused primarily by a rise in lactic acid production secondary to tissue hypoxia and usually resolves when the volume deficit has been corrected. Administration of sodium bicarbonate may cause a leftward shift of the oxyhemoglobin dissociation curve, reducing tissue oxygen extraction, and it may worsen intracellular acidosis caused by carbon dioxide production.¹¹⁹ On the other hand, adrenergic receptors may become desensitized with protracted acidosis. Studies indicate that vasopressin may be more effective than epinephrine as hemorrhagic shock approaches irreversibility.^{125,126} Bicarbonate infusion, therefore, should be limited to persons with protracted shock.

Hypocalcemia caused by citrate binding of ionized calcium does not occur until the blood transfusion rate exceeds 100 ml/min (1 U/5 min). Decreased serum levels of ionized calcium depress myocardial function before impairing coagulation.^{127,128} Calcium gluconate (10 mg/kg I.V.) should be reserved for cases in which there is ECG evidence of QT interval prolongation or, in rare instances, for cases of unexplained hypotension during massive transfusion.

ABDOMINAL COMPARTMENT SYNDROME

Abdominal compartment syndrome has emerged as a virtual epidemic in busy trauma centers that practice damage-control surgery and goal-oriented ICU resuscitation.¹²⁹ This syndrome is an early event, and its clinical trajectory can be accurately predicted within 3 to 6 hours after ED admission.²⁷ At admission to the ICU, high-risk patients have significant intra-abdominal hypertension and are in persistent shock. Contrary to conventional wisdom, they do not respond well to preload-directed resuscitation.¹³⁰ In fact, continued aggressive resuscitation precipitates the full-blown syndrome [see Figure 13].

Fundamental changes are needed in pre-ICU resuscitation. Failure to recognize ongoing bleeding, indiscriminate crystalloid infusion, and failure to prioritize definitive measures for hemorrhage control have been identified as key issues in the ED.¹³¹ We share the belief that colloids may reduce the incidence of abdominal compartment syndrome, but in our view, this possible benefit must be weighed against the potentially detrimental effects of colloids. In severe hemorrhagic shock, the permeability of capillary membranes increases, allowing the entry of colloids into the interstitial space, which can then exacerbate edema and impair tissue oxygenation. The theory that these high-molecular-weight agents plug capillary leaks that occur during neutrophil-mediated organ injury has not been proved.^{132,133} Furthermore, it has been suggested that resuscitation with albumin induces renal failure and impairs pulmonary function.¹³⁴

Similarly, hydroxyethyl starch (Hesastarch; Baxter Healthcare, Deerfield, Illinois) has been shown to induce renal dysfunction in patients with septic shock and in recipients of kidneys from brain-dead donors.¹³⁵ Hesastarch also has a limited role in massive resuscitation because it causes coagulopathy and hyperchloremic acidosis as a result of its high chloride content. Another hydroxyethyl starch preparation (Hextend; BioTime, Berkeley, California) has been developed that purportedly does not cause these adverse effects, but it has not been studied in the setting of massive resuscitation.^{136,137}

In addition, alternative crystalloid solutions are being developed that not only expand the intravascular space and replenish the extracellular fluid but also have anti-inflammatory properties (e.g., Ringer's ethyl pyruvate).⁹⁵ The data currently available suggest that crystalloid administration should be restrained. Alternative means of enhancing tissue oxygen delivery may involve earlier use of inotropic or vasoactive agents.

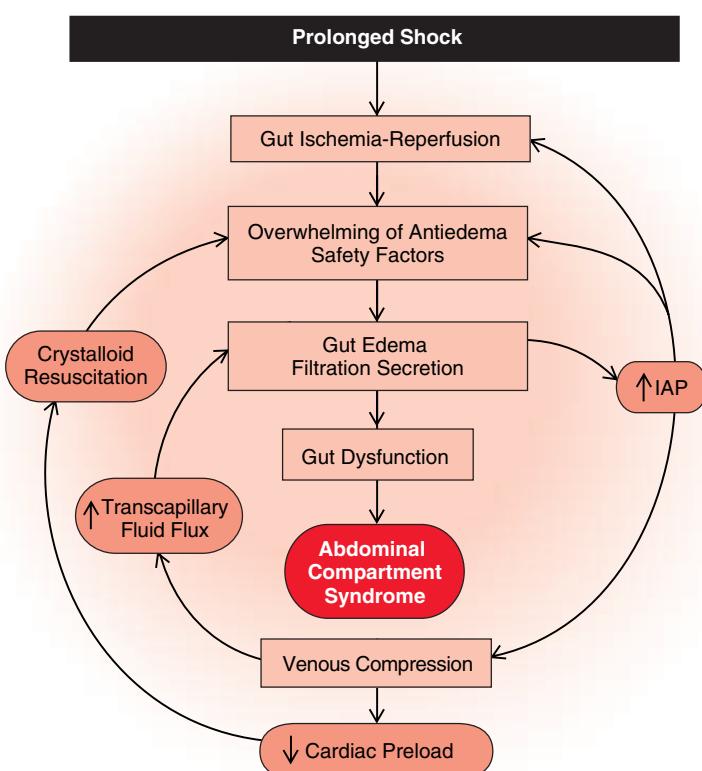

Figure 13 Depicted is the so-called saltwater vicious cycle, which results in the development of abdominal compartment syndrome. The term filtration secretion refers to the process by which increasing gut edema causes interstitial pressure to rise to high levels, leading to disruption of the interstitial matrix. Ultimately, as a result, the villus tips spring leaks, through which interstitial fluid passes into the gut lumen. (IAP—*intra-abdominal pressure*)

2 INJURIES TO THE CENTRAL NERVOUS SYSTEM

Marike Zwienenberg-Lee, M.D., Kee D. Kim M.D., and J. Paul Muizelaar, M.D., Ph.D.

It is estimated that each year, two million patients present to physicians with a primary or secondary diagnosis of head injury. Of these patients, approximately 400,000 are admitted and 70,000 die, most of traumatic brain injury. Thus, brain injury can be considered epidemic. Neurosurgeons, who number 4,000 in the United States, are probably best trained to manage patients with severe head injuries, but initial resuscitation and stabilization are usually performed by emergency department physicians, general surgeons, and trauma surgeons. These professionals are the ones who can make a difference for patients: current understanding of the pathophysiology of traumatic brain injury indicates that treatment during the first few hours is critical and often determines outcome.

Nonetheless, the importance of care immediately after resuscitation and in the ensuing days is not to be underestimated. Patients with multiple system injuries often receive care in surgical intensive care units under the supervision of a general surgeon. Less than optimal management at an early stage has a greater impact overall because of the larger number of patients involved, but less than optimal management at later stages, even in mildly injured patients, has a much more dramatic impact. Initial recovery, followed by relentless decline attributable to insufficient cerebral perfusion, is not an expected outcome. Although we cannot promote healing of the brain by pharmacologic means, we can prevent secondary injury to the brain by ensuring adequate cerebral circulation and oxygenation.

The reported incidence of spinal cord injury in the United States ranges from 29 to 53 per million.¹⁻³ About 50% of the injuries are related to motor vehicle accidents, 15% to 20% to falls, 15% to 20% to interpersonal violence, and the remaining 15% to 20% to sports and recreational activity. In general, the group at highest risk is between 16 and 30 years of age, not unlike the group at highest risk for head injuries. Most of those injured are males: several studies report that the percentage is approximately 75%.⁴ Between 45% and 50% of patients with spinal cord injury have other injuries that seriously affect their prognosis.⁵

The cervical spine is most often involved in spinal cord injury. A major study of trauma outcome, conducted from 1982 to 1989, revealed that the cervical spinal cord was involved in 55% of cases of acute injury, the thoracic spinal cord in 30%, and the lumbar spinal cord in 15%.⁶ In an analysis of 358 patients with spinal cord injury, complete neurologic injury occurred in 78% of the 71 cases of thoracic injury, 60% of the 202 cases of cervical injury, and 65% of the 85 cases of thoracolumbar injury.⁷ Average direct costs of spinal cord injury (including hospitalization, rehabilitation, residence modification, and long-term care) are tremendous. In 1992, it was estimated that lifetime costs (in 1989 dollars) were \$210,379 for a paraplegic and \$571,854 for a quadriplegic.⁸

Initial resuscitation and evaluation of injured patients are discussed more fully elsewhere [see 7:1 Life-Threatening Trauma]. In this chapter, we outline approaches to the management of severe head injury and acute spinal cord injury. In addition, we address the pathophysiology of such injuries to provide the reader with

the understanding required for making appropriate decisions about diagnosis and treatment of injured patients [see Discussion, below].

Head Injury

EMERGENCY DEPARTMENT MANAGEMENT

Because hypoxia and hypotension interfere with cerebral oxygenation, complete and rapid physiologic resuscitation is the highest priority for patients with head injuries. A large study from the Traumatic Coma Data Bank demonstrated that a single observation of systolic blood pressure below 90 mm Hg in the field or hypoxia (arterial oxygen tension [P_aO_2] < 60 mm Hg) was a major predictor of poor outcome.⁹ A multidisciplinary team should provide the patient with an adequate airway and ventilation (intubation, ventilation, and detection of hemothorax or pneumothorax) and restore and maintain hemodynamic stability (with adequate fluid replacement and detection and treatment of any bleeding), all according to the principles developed by the Advanced Trauma Life Support system.¹⁰ The ABCs of emergency care (Airway, Breathing, and Circulation) take precedence, irrespective of neurologic injuries. The initial neurologic assessment, which should take no more than a few seconds, consists of rating the patient's level of consciousness on the Glasgow Coma Scale (GCS) [see Table 1] and assessing the width and reactivity of the pupils. Although the same assessment is made after resuscitation as a guide for prognosis and therapy, it should also be made (and recorded) before resuscitation to permit evaluation of the effect of

Table 1 Glasgow Coma Scale

resuscitative measures and differentiation between primary and secondary neurologic injury.

Early orotracheal intubation and ventilation are recommended for patients with a GCS score of 8 or lower or a motor score of 4 or lower. Other indications for immediate intubation are loss of protective laryngeal reflexes and ventilatory insufficiency, as manifested by hypoxemia ($P_aO_2 < 60$ mm Hg), hypercarbia (arterial carbon dioxide tension [P_aCO_2] > 45 mm Hg), spontaneous hyperventilation (causing $P_aCO_2 < 26$ mm Hg), and respiratory arrhythmia. Indications for intubation before transport are deteriorating consciousness (even if the patient is not in a coma), bilateral fractured mandible, copious bleeding into the mouth (as occurs with fracture of the base of the skull), and seizures. An intubated patient must also be ventilated ($P_aCO_2 \approx 35$ mm Hg).

Fluid replacement should be performed with isotonic solutions such as normal saline, lactated Ringer solution, or packed red blood cells when appropriate. Glucose-based solutions should be avoided in the acute phase. The patient should be examined rapidly and thoroughly for any concomitant life-threatening injuries.

Patients with spinal cord injury above T5 may have severe hypotension as a result of vasogenic spinal shock. Aggressive treatment is indicated, including volume resuscitation and administration of alpha-adrenergic vasopressors. Intracranial hypertension should be suspected if there is rapid neurologic deterioration. Clinical evidence of intracranial hypertension, manifested by signs of herniation, includes unilateral or bilateral dilatation of the pupils, asymmetrical pupillary reactivity, and motor posturing.

Intracranial hypertension should be treated aggressively. Hyperventilation, which does not interfere with volume resuscitation and results in rapid reduction of intracranial pressure (ICP), should be established immediately in cases of pupillary abnormalities. It has been demonstrated that unilateral or bilateral pupillary abnormalities do not result only from compression of the third cranial nerves, as was previously thought, but also derive from compression of the brain stem, with resulting brain stem ischemia.¹¹ Therefore, administration of mannitol is effective because it not only decreases ICP but also increases cerebral blood flow (CBF) through modulation of viscosity. Because mannitol is not used to dehydrate the body, all fluid losses through diuresis must be replaced immediately or even preventively, especially in patients suffering shock as a result of blood loss. Arterial hypertension occurring after a severe head injury may reflect intracranial hypertension (Cushing's phenomenon), especially when accompanied by bradycardia; it should not be treated, because it may be the sole mechanism permitting the brain to maintain perfusion despite increasing ICP.

In the absence of signs of herniation, sedation should be used when required for safe and efficient transport of the patient. Transport time should be kept to a minimum because transport is often accompanied by secondary insults (e.g., hypoxia or hypotension). Pharmacologic paralysis, which interferes with neurologic examination, should be used only if sedation alone is inadequate for safe and effective transport and resuscitation. When pharmacologic paralysis is used, short-acting agents are preferred. Prophylactic hyperventilation, which may exacerbate early ischemia, is not recommended for these patients. Guidelines for the resuscitation and initial treatment of patients with severe head injuries have been established that facilitate management [see Figure 1].

Minimal radiologic evaluation consists of a lateral cervical spine film or a swimmer's view [see Spinal Cord Injury, below]. After hemodynamic stability is achieved, unenhanced computed tomography

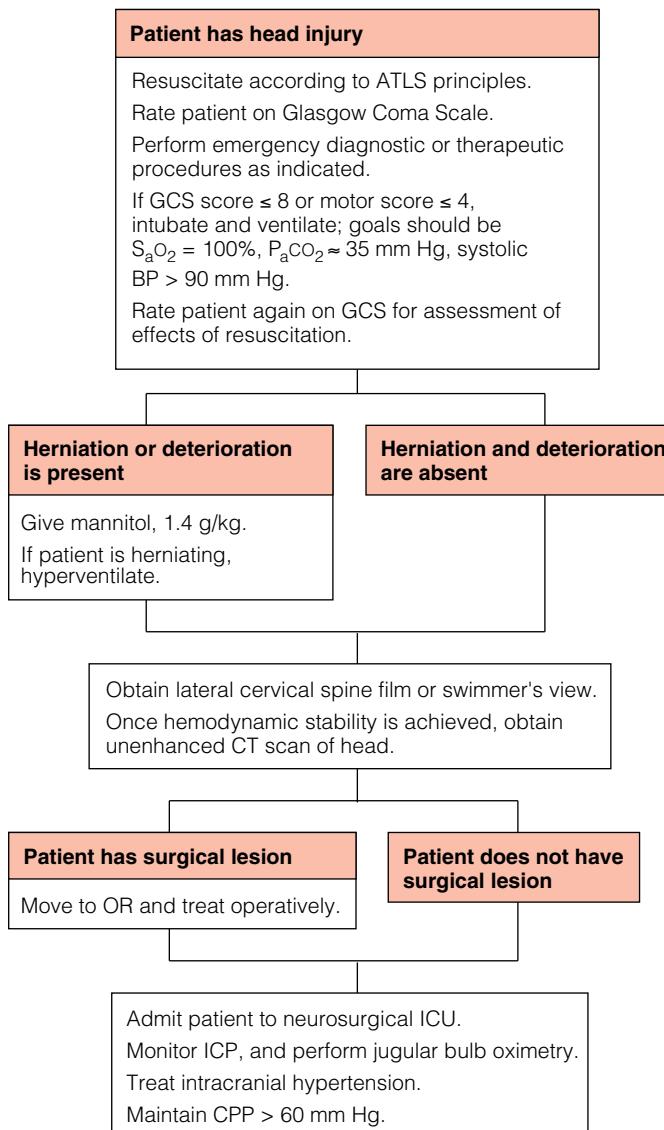

Figure 1 Shown is an algorithm for initial management of the patient with a severe head injury.

mography of the head should be performed in all patients with persistent impairment of consciousness. In patients with a GCS of 14 or 15 who have experienced transient loss of consciousness or have posttraumatic amnesia, head CT is probably necessary only in the presence of certain specific signs and symptoms [see Table 2].¹²

OPERATIVE MANAGEMENT

Rapid evacuation of mass lesions decreases ICP and consequently improves cerebral perfusion pressure (CPP) and CBF; reversal of ischemia soon after removal of a subdural hematoma has been documented.¹³ In addition, ICP may be extremely high in the presence of a subdural hematoma, and this pressure elevation can be rapidly reversed after decompression.¹⁴ Subdural hematomas call for emergency evacuation by a neurosurgeon; evacuation performed within 4 hours of injury has been shown to result in a better outcome.¹⁵

An epidural hematoma, which is a life-threatening neurosurgical emergency, should be evacuated urgently. In cases of tempo-

ral fracture and rapid clinical deterioration, a temporal craniectomy can be performed. If there is no temporal fracture, an unenhanced CT scan should be obtained instead of searching for a lesion with multiple bur holes. In cases of progressive deterioration, moderate hyperventilation ($P_aCO_2 \approx 30$ mm Hg) should be initiated and mannitol (1.4 g/kg) given while the patient is being readied for surgery.^{16,17}

Posterior fossa hematomas, which are rare, also require urgent evacuation, because obstructive hydrocephalus and brain stem compression can result in rapid neurologic deterioration. An intracerebral hematoma causing a midline shift larger than 5 mm is an indication for operative treatment, but surgery can usually be delayed for a few hours.

ICU MANAGEMENT

A GCS score of 8 or lower after resuscitation is an indication for admission to a neurosurgical ICU. The focus of ICU management is prevention of secondary injury and maintenance of adequate cerebral oxygenation. To ensure optimal cerebral oxygenation, CPP, hemoglobin concentration, and oxygen saturation should be optimized; vessel diameter should be maximized; and viscosity should be in the low range. Admission to an ICU does not eliminate the occurrence of secondary insults.¹⁸ In a series of 124 patients admitted to a neurosurgical ICU, more than one episode of hypotension occurred in 73% of all patients, and more than one episode of hypoxia occurred in 40%.¹⁹ In another study, online monitoring of CPP, jugular venous oxygen saturation ($S_{jv}O_2$), local CBF, and local tissue oxygenation was performed in 14 patients who had sustained a severe head injury; 37% of the episodes involving decreased CBF, CPP, and saturation were related to clinical and nursing procedures.²⁰

Monitoring

A variety of bedside devices are currently available for monitoring ICP, local CBF, and local and global cerebral oxygenation.^{18,20,21}

ICP monitoring Monitoring of ICP has never been subjected to a prospective, randomized clinical trial designed to assess its efficacy in improving patient outcome. Nevertheless, many clinical studies indicate that ICP monitoring is useful for early detection of intracranial mass lesions; that it allows calculation of CPP, an important clinical indicator of CBF; that it limits the indiscriminate use of potentially harmful therapies for control of ICP; that it helps determine prognosis; and that it may improve outcome. ICP monitoring is indicated in patients with a GCS score of 3 to 7 after resuscitation and in selected patients with a GCS score of 8 to 12 and an abnormal CT scan at the time of admission. In patients with a GCS score of 8 to 9 and a normal CT scan, ICP monitoring is indicated if the patient is

*Defined as jugular venous oxygen saturation < 50% for longer than 15 min.

older than 40 years, has a systolic BP below 90 mm Hg, and exhibits unilateral or bilateral motor posturing.²¹

Jugular bulb oximetry CBF is an important determinant of neurologic outcome, and the arterial-jugular venous oxygen difference ($A-VDO_2$) is an important indicator of the adequacy of CBF. Monitoring of therapy by measuring CBF and $A-VDO_2$ would be ideal, but there is no practical way of doing this directly and continuously.

An estimate of global $A-VDO_2$ can be obtained from simultaneous monitoring of arterial oxygen saturation (S_{aO_2}) and $S_{jv}O_2$. Jugular venous oxygen saturation is monitored by percutaneous retrograde insertion of a fiberoptic catheter in the internal jugular vein, with the tip of the catheter located in the jugular bulb. The catheter is usually inserted into the jugular vein with the dominant cerebral venous drainage (the right jugular vein in 80% to 90% of the population), but some prefer to insert the catheter at the site of the most significant brain damage. $A-VDO_2$ is calculated according to the following formula:

$$A-VDO_2 = (S_{aO_2} - S_{jv}O_2) \times 1.34 \times Hb + [(P_{aO_2} - P_{jv}O_2) \times 0.0031]$$

The contribution of the variables within the brackets, which is small, is usually ignored for practical purposes. Because calculation of $A-VDO_2$ requires the drawing of blood samples, it can be done only intermittently.

For continuous monitoring, $S_{jv}O_2$, the result of arterial oxygen input and cerebral extraction, is used. In normal individuals, $S_{jv}O_2$ ranges from 50% to 70%. If $S_{jv}O_2$ values below 50% last for more than 15 minutes, they are considered desaturations, resulting from insufficient arterial oxygenation (S_{aO_2}), inadequate oxygen-carrying capacity (Hb concentration), or, when arterial saturation and oxygen-carrying capacity are normal, from inadequate CBF. A 1994 study described a relation between the occurrence of desaturations and neurologic outcome in patients with severe head injuries [see Table 3].²² Without desaturation, mortality was 16%; with one documented desaturation, 42%; and with multiple desaturations, 70%. High $S_{jv}O_2$ values indicate low oxygen extraction, which is the case when the cerebral metabolic rate of oxygen ($CMRO_2$) is low.

The limitations of jugular bulb oximetry should be kept in mind when $S_{jv}O_2$ values are interpreted.^{23,24} Because $S_{jv}O_2$ represents global oxygenation, regional ischemia may go undetected if the ischemic region is too small to be represented in the total hemispheric $S_{jv}O_2$ value. Ischemia may also occur in a part of the brain being drained by the opposite jugular vein. In addition, extracerebral veins drain into the internal jugular vein approximately 2 cm below the jugular bulb. With low flow values, significant extracere-

bral contamination may occur, resulting in deceptively high $S_{jv}O_2$ values. Finally, artifactual readings are often encountered as a result of reduced light intensity when the catheter lodges against the vessel wall. Technical improvements in catheters, however, have markedly reduced the number of artifacts observed.

Tissue oxygen monitoring Tissue oxygen monitoring has been employed for years in Europe to treat patients with brain injuries but was not approved by the Food and Drug Administration for use in the United States until relatively recently. Tissue oxygen tension ($P_{ti}O_2$) in the brain is measured via a fiberoptic monitor locally inserted through a separate bur hole.²⁵ The oxygen pressure recorded thus reflects a combination of oxygen supply and cerebral oxygen extraction, which makes interpretation of the values less than straightforward. Nevertheless, several investigators have demonstrated a relation between low local tissue O_2 values and poor outcome and have documented improved cerebral oxygenation after introduction of resuscitative measures (e.g., optimization of CPP and blood oxygenation).²⁵ In normal persons, $P_{ti}O_2$ ranges from 25 to 30 mm Hg. Critical thresholds for $P_{ti}O_2$ values include prolonged and repeated episodes below 10 to 15 mm Hg and any episode below 5 mm Hg.²⁶

Management of Cerebral Perfusion Pressure

The rationale behind CPP therapy is expressed in Poiseuille's law [see Discussion, Pathophysiology, below]. Although the effect of CPP therapy has not been investigated in a randomized, controlled clinical trial, several studies suggest that a CPP of 70 to 80 mm Hg may be the clinical threshold below which mortality and morbidity increase.²⁷⁻²⁹ In addition, there are now class II data (not yet published as of December 2003) indicating that maintenance of a CPP higher than 60 mm Hg is sufficient to ensure optimal cerebral perfusion and oxygenation (personal communication, American Brain Injury Consortium).

CPP therapy involves manipulation of both arterial BP and ICP, but its objective is the reduction of ICP. If ICP reduction does not achieve a CPP of 60 mm Hg, arterial hypertension is instituted. Mean arterial BP should be raised first by optimizing volume status: ample fluids, including albumin (25 to 30 ml/hr), are administered to maintain central venous pressure at 5 to 10 mm Hg. A pulmonary arterial catheter is suggested for patients older than 50 years and for individuals with known cardiac disease, multiple trauma (particularly chest or abdominal injuries), or a need for vasopressors or high-dose barbiturates. Pulmonary arterial wedge pressure (PAWP) should be maintained between 10 and 14 mm Hg. If necessary, an alpha-adrenergic drug (e.g., phenylephrine, 80 mg in 250 or 500 ml of normal saline) can be combined with the fluids.

Management of Intracranial Pressure

Because ICP is a determinant of CPP, treatment of ICP inevitably affects CPP. Given that the goal is maintenance or improvement of CBF, measures for treating ICP should be evaluated in the light of their effect on CBF. It is not possible to establish an arbitrary threshold for treatment of elevated ICP that would be applicable in all situations. Any interpretation of ICP must be combined with assessment of clinical features and evaluation of CT scan findings. It is possible, for example, to have transtentorial herniation with an ICP of 15 mm Hg in the presence of a mass lesion. Conversely, with diffuse brain swelling, adequate CPP can be maintained despite an ICP as high as 30 mm Hg. As a general rule, ICP values between 20 and 25 mm Hg indicate that therapy should be initiated.

The recommended regimen for treatment of ICP starts with drainage of CSF through a ventriculostomy-ICP catheter and continues as necessary in a stepwise fashion with sedation, paralysis, osmotic therapy, hyperventilation, induction of a metabolic coma, and decompressive surgery [see Figure 2].

Although drainage of CSF has no documented deleterious side effects, it does have the potential to aggravate brain shift. Therefore, only a minimal amount should be drained, sufficient to bring the ICP below 20 mm Hg.

Sedation with morphine sulfate, 2 to 5 mg/hr I.V., is standard treatment; fentanyl, lorazepam, and midazolam are commonly used alternatives. In some centers, propofol is now used for routine sedation. Propofol has a short half-life, which is advantageous for the purposes of neurologic evaluation, but it is expensive and can have deleterious side effects after prolonged use (i.e., > 48 to 72 hours).³⁰

Muscular paralysis is employed by many clinicians as the next step in therapy. Its major downside is that it renders neurologic examination pointless, except for assessment of the pupillary response. In addition, the risk of respiratory complications is increased with neuromuscular blockade.

Mannitol is usually administered in I.V. boluses of 0.25 to 1 g/kg over 10 to 15 minutes until either ICP is controlled or serum osmolarity reaches 320 mOsm/L. It now appears, however, that higher doses (e.g., 1.4 g/kg) may be more effective.^{16,17} Because volume depletion is an important side effect of mannitol therapy, urine losses should be replaced. Hypertonic saline (3% to 10%) may be used in place of mannitol: it appears to be just as effective as or even more effective than mannitol for ICP control, especially in higher concentrations (e.g., 7.5%).³¹ In addition, hypertonic saline is not associated with volume depletion but actually increases intravascular volume. The effect probably is not purely osmotic but is partly related to viscosity, as is the case with mannitol.³²

As noted, hyperventilation reduces ICP (by vasoconstriction) and CBF, which may be at ischemic levels in certain parts of the brain. Therefore, hyperventilation ($P_aCO_2 < 30$ mm Hg) should not be instituted prophylactically but should be reserved for acute decompensation and employed as a short-term temporizing measure until more definitive therapy can be instituted. If P_aCO_2 must be reduced to extremely low levels, hyperventilation can be combined with mannitol, thereby improving CBF by reducing blood viscosity. Jugular bulb oximetry is recommended in these situations because it will determine how much the cerebral vessels can be constricted.

Hemoglobin, Hematocrit, and Blood Viscosity

The hematocrit and viscosity are inversely related, and a balance must be established to optimize oxygenation. If the hematocrit is too high, viscosity increases; if the hematocrit is too low, the oxygen-carrying capacity of blood decreases. Maintaining the hematocrit between 0.30 and 0.35 is recommended: below 0.30, oxygen-carrying capacity falls without a significant change in viscosity, and above 0.35, viscosity increases out of proportion to oxygen-carrying capacity.³³ Preferably, blood that has been banked for less than 2 weeks should be used for transfusion. There are some data indicating that the effect of transfusion on cerebral oxygenation is linearly related to the duration of storage of packed red cells.³⁴

Brain Protection

When oxygen delivery cannot be sufficiently improved, the brain can be protected by decreasing CMRO₂. Barbiturates appear to protect the brain and lower ICP through several mechanisms,

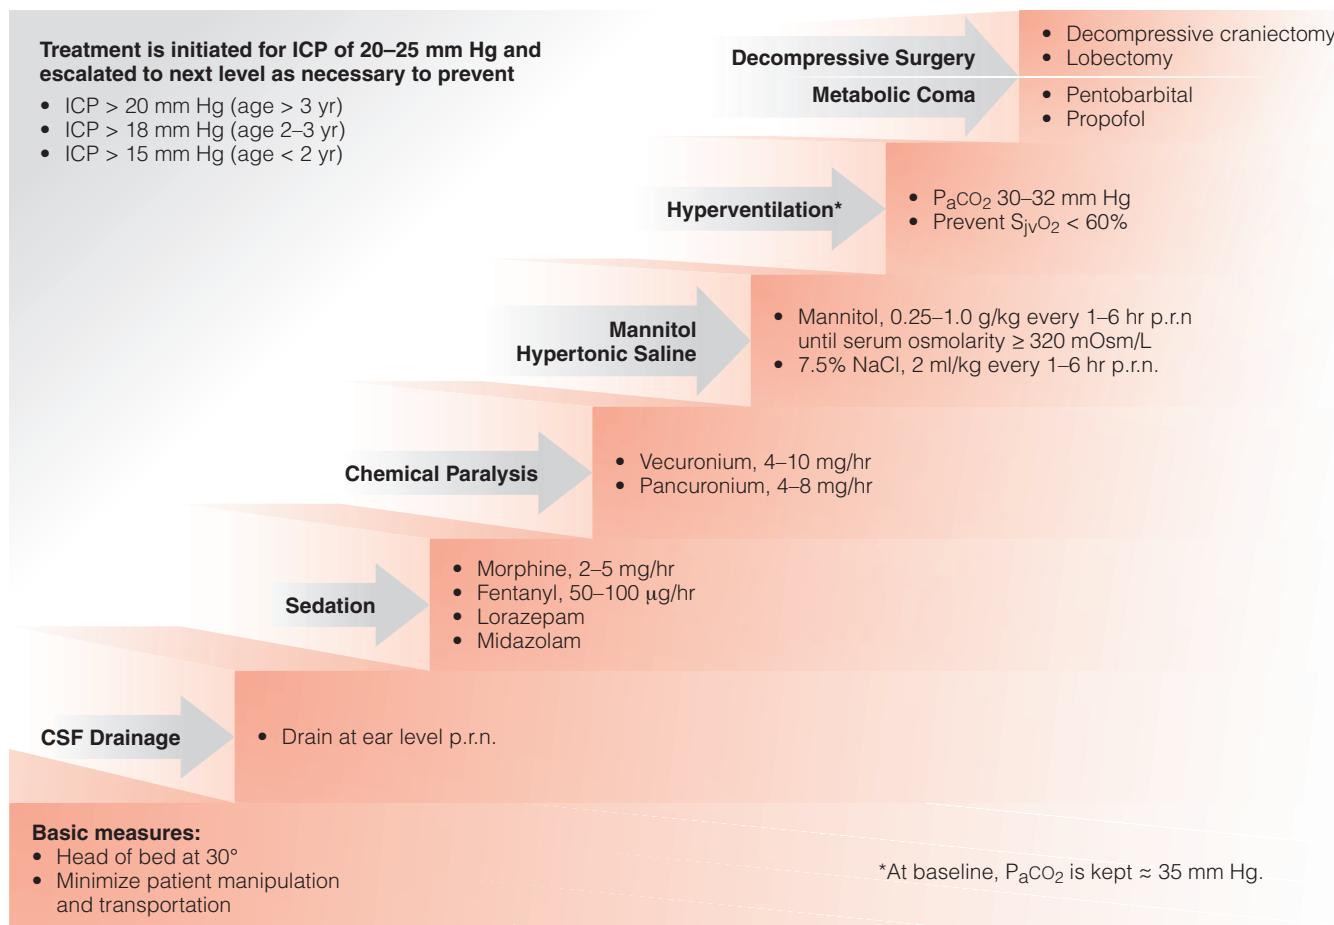

Figure 2 Illustrated is a stepwise approach to the management of ICP.

including alteration of vascular tone, suppression of metabolism, and inhibition of free radical lipid peroxidation. The most important effect may involve coupling of CBF to regional metabolic demands, so that the lower the metabolic requirements, the lower the CBF and the related cerebral blood volume (CBV), with subsequent beneficial effects on ICP and global cerebral perfusion. Barbiturate therapy (usually pentobarbital to a blood level of 4 mg/L) is instituted when other measures to control ICP fail. In one series of 25 patients with an ICP higher than 40 mm Hg, barbiturates not only controlled ICP but also improved outcome.³⁵ Of the patients whose ICP was controlled by barbiturates, 50% had a good recovery; of the patients whose ICP was not controlled, 83% died. In another trial, prophylactic barbiturate therapy failed to improve neurologic outcome.³⁶ Of the barbiturate-treated patients, 54% were hypotensive, compared with 7% of the control subjects; however, this trial was conducted before the present emphasis on maintaining CPP was recognized.

Etomidate, a rapidly acting agent with hypnotic properties similar to those of barbiturates, has fewer adverse effects on systemic BP or ICP. However, it suppresses adrenocortical function, and its solvent, propylene glycol, can cause renal insufficiency.³⁷

Propofol is a sedative hypnotic with a rapid onset and a short duration of action.^{38,39} It depresses CMRO₂, but not as effectively as barbiturates and etomidate do. Studies of patients with head injuries have demonstrated that ICP decreases with administration of propofol, but systemic BP usually decreases as well, resulting in a net decrease in CPP. Blood lactate levels do not increase

when propofol is administered, indicating that cerebral oxygenation is adequate. If propofol is used, correction of hypovolemia is recommended to prevent hypotension associated with bolus injection. Finally, because of its preservative-free, lipid-base vehicle, there is an increased risk of bacterial or fungal infection, and the high caloric content (1 kcal/ml) may be problematic during a prolonged infusion.

Hypothermia produces a balanced reduction in energy production and utilization, decreasing CMRO₂ and CBF proportionally. Protocols for hypothermia include cooling to 32° to 33° C (89.6° to 91.4° F) within 6 hours of injury and maintenance of this temperature for 24 to 48 hours. Hypothermia to 33° C has been shown to be effective for the control of refractory high ICP. Two pilot clinical trials reported improved neurologic outcome,^{40,41} but a multi-center randomized clinical trial failed to demonstrate any overall improvement.⁴² Side effects of therapy, which in this case mainly included medical complications in the elderly patients, resulted in the absence of a treatment effect. In addition, rewarming of patients who were hypothermic on admission appeared to be detrimental. However, a subgroup of patients who were already hypo-thermic on admission (i.e., those younger than 45 years) did benefit from continued treatment with hypothermia, and these patients were subsequently enrolled in a second phase III trial (NABISH-II).

The main side effects of hypothermia are cardiac arrhythmias and coagulation disorders, reported after cooling to 32° to 33° C. Other drawbacks of hypothermia include the difficulty of detect-

ing infection because of the lack of warning signs (e.g., spiking and elevated temperature) and the need for specialized equipment (e.g., rotor beds with cooling control) and personnel to induce and maintain the condition. A body temperature between 35° and 35.5° C may be optimal for treating patients with severe traumatic brain injury.⁴³

Spinal Cord Injury

DIAGNOSIS AND INITIAL MANAGEMENT

In the field, all patients with significant trauma, any trauma patients who lose consciousness, and any patients suffering minor trauma who have complaints referable to the spine or the spinal cord should be treated as if they had a spinal cord injury until proven otherwise [see Figure 3]. If cardiopulmonary resuscitation is necessary, it takes precedence [see 7:1 Life-Threatening Trauma]. The objectives are to maintain adequate oxygenation and maintain BP by administering fluids and vasopressors. The main concerns of management in the field are immobilization before and during extrication from a vehicle (or removal from the scene of another type of accident) and immobilization during transport to prevent active or passive movement of the spine. Subsequently, the patient may require a rigid Philadelphia collar, support from sandbags and straps, a spine board, or a log-roll for turning. A brief motor examination may detect possible deficits.

When the patient arrives at the hospital, care should be taken to provide adequate oxygenation, prevent hypotension, and maintain immobilization. Patients with an injury above C4, who may have respiratory paralysis, may need ventilatory assistance. Lesions above T5 may be accompanied by loss of sympathetic tone and consequently by significant venous pooling and arterial hypotension. Because paralytic ileus is common, usually lasting several days, a nasogastric tube should be placed to prevent vomiting and aspiration. Urinary retention is also a common occurrence, and a Foley catheter should therefore be inserted. Vasomotor paralysis may cause poikilothermia (uncontrolled temperature regulation), and normothermia should therefore be maintained.

A detailed neurologic examination is required to determine whether the injury is complete or incomplete and at what level of the spinal cord the injury occurred. If possible, a history should determine the mechanism of injury (e.g., hyperflexion, extension, axial loading, or rotation). The American Spinal Injury Association (ASIA) (www.asia-spinalinjury.org) has developed a protocol for sensory and motor examination of patients with spinal cord injuries that is precise and relatively easy to follow [see Figure 4].

Spinal shock consists of loss of all or most motor, sensory, and autonomic function below the level of the lesion. It usually develops in the setting of a severe spinal cord injury that occurs over a brief period, and it is most commonly witnessed immediately after the injury (though it may also appear hours later in cases of progressive injury). As originally defined, the term spinal shock referred to arterial hypotension resulting from loss of sympathetic tone after spinal cord injury. Currently, however, most authors use the term to refer to the complex of symptoms associated with the loss of spinal reflex activity below the level of the lesion, which may or may not include arterial hypotension.⁴⁴ The motor component of spinal shock may consist of paralysis, flaccidity, and areflexia. The sensory component may involve both spinothalamic and dorsal column sensory function, and the autonomic component may include systemic hypotension, bradycardia, skin hyperemia, and warmth.

Spinal shock should be differentiated from spinal concussion. Spinal concussion is a poorly understood phenomenon. It is de-

Patient has apparent spinal cord injury

(In the field, all patients with significant trauma, any trauma patient who loses consciousness, and any patient with minor trauma who has complaints referable to the spine or the spinal cord should be treated as having spinal cord injury until proven otherwise.)

Resuscitate according to ATLS principles.

Immobilize spine, and use spine board, cervical orthosis, sandbags, straps, log-roll, and tape on forehead as necessary.

Perform trauma evaluation.

Perform emergency diagnostic or therapeutic procedures as indicated.

Maintain oxygenation; intubate and ventilate as needed.

Maintain systolic BP > 90 mm Hg with volume replacement (isotonic fluids), MAST, vasopressors (dopamine, 2–10 µg/kg/min), and, if bradycardia (< 45 beats/min) occurs, atropine, 0.5–1.0 mg I.V.

Place NG tube to prevent vomiting and aspiration.

Place Foley catheter to prevent urinary retention.

Normalize T°.

Perform detailed neurologic examination.

Evaluate axial skeleton, and obtain x-rays of spine.

Cervical spine: lateral view showing craniocervical and C7-T1 junctions, followed by AP and odontoid views.

Thoracic and lumbosacral spine: AP and lateral views.

Urgent MRI is indicated if (1) there is an incomplete lesion with normal alignment, (2) deterioration occurs, (3) fracture level ≠ deficit level, or (4) a bony injury cannot be identified.

Patient has suspected cervical spine injury

[See Figure 5.]

Patient has suspected thoracolumbar spine injury

[See Figure 6.]

Figure 3 Shown is an algorithm for management of the patient with an acute spinal cord injury.

fined as partial spinal cord sensory or motor deficits that resolve completely within 24 to 72 hours and that are never associated with permanent spinal cord injury. Spinal concussion is rare and has never been described in conjunction with spinal shock.

All patients with possible spine injuries should be examined radiologically. Roentgenography of the cervical spine with the patient in a rigid collar includes a lateral view showing both the craniocervical and the cervicothoracic (C7-T1) junction. If the lateral view is normal and the patient is coherent and has no neck tenderness or neurologic deficit, the collar can be removed for anteroposterior and odontoid views. If the lower cervical spine or the cervicothoracic junction is not well visualized, a lateral view with caudal traction on the arms, or a swimmer's view, is required. If areas of the spine are still not visualized or if there is a neurologic deficit, a CT scan with sagittal reconstruction should be obtained through the poorly visualized levels.

The use of flexion-extension films (i.e., testing of the active range of motion of the cervical spine from maximal anterior-posterior flexion to extension) is typically limited to patients who are

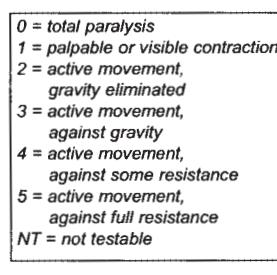

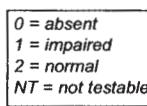

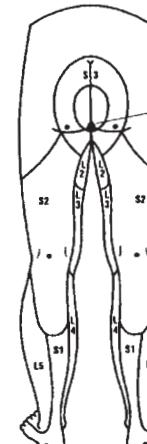

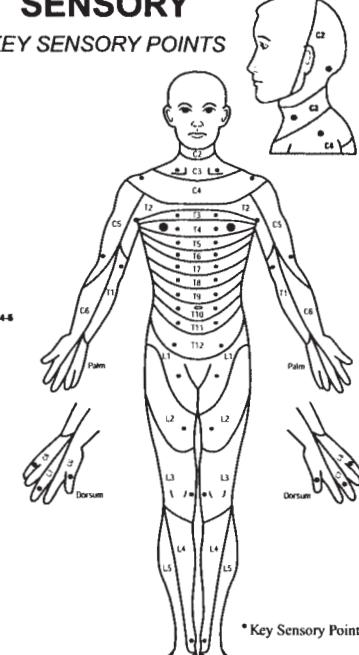

awake and able to cooperate.⁴⁵ Although spinal instability is probably best demonstrated with this type of imaging, it should be noted that in patients with neck pain, muscle spasm can limit range of motion and thereby mask a subluxation. Accordingly, it is recommended that patients with posttraumatic neck pain who are neurologically intact, whose plain radiographs are normal, and who are capable of limited flexion and extension effort (i.e., < 30° of motion) be placed in a rigid cervical collar and reevaluated 1 to 2 weeks later. In comatose patients, dynamic films are sometimes obtained under direct fluoroscopic guidance, though magnetic resonance imaging appears to render such studies unnecessary.

CT is particularly helpful in the further evaluation of fractures diagnosed on plain films: it shows bone in greater detail and at higher resolution than plain films do, it achieves better visualization of fixed subluxations, and it allows more accurate assessment of the central bony canal and the neuronal foramina. CT is highly accurate in visualizing body fractures, Jefferson (C1) and hangman (C2) fractures, and bilateral locked facets. It appears to be less accurate, however, in visualizing transverse C2, posterior ele-

ment, and nondisplaced spinous process fractures. Moreover, it sometimes misses superior articular process fractures.⁴⁶

MRI of the cervical spine is the study of choice for evaluating injury to the soft tissues and ligaments. Intrinsic cord damage (e.g., edema, hematoma, or contusion) and injury to the surrounding ligaments, disks, and paravertebral soft tissues are well visualized. In addition, MRI is helpful in the assessment of brachial plexus injury, though a series of special coronal images is usually required. A fat-suppression image usually identifies ligamentous injury to the posterior elements quite well, and fine-cut gradient echo (GRE) imaging of the transverse ligament of C2 is extremely sensitive in detecting disruption.⁴⁷ The major drawbacks of MRI are the length of the imaging time, which may be a problem in the critically ill trauma patient, the susceptibility to movement artifacts, and the need for MRI-compatible monitoring devices and traction equipment. Moreover, in this setting, it is often difficult to obtain an adequate medical history with regard to implanted medical devices or old bullet fragments, both of which preclude MRI. Radiologic evaluation and clearance of the cervical spine can be facilitated by the use of an established protocol [see Figure 5].

2000 Rev.

Figure 4 Shown is a form developed by the American Spinal Injury Association to record the principal information about motor, sensory, and sphincter function required for accurate neurologic classification of spinal cord injury. For the motor examination, 10 key muscles are tested (left). For the sensory examination, 28 key dermatomes are tested (right).

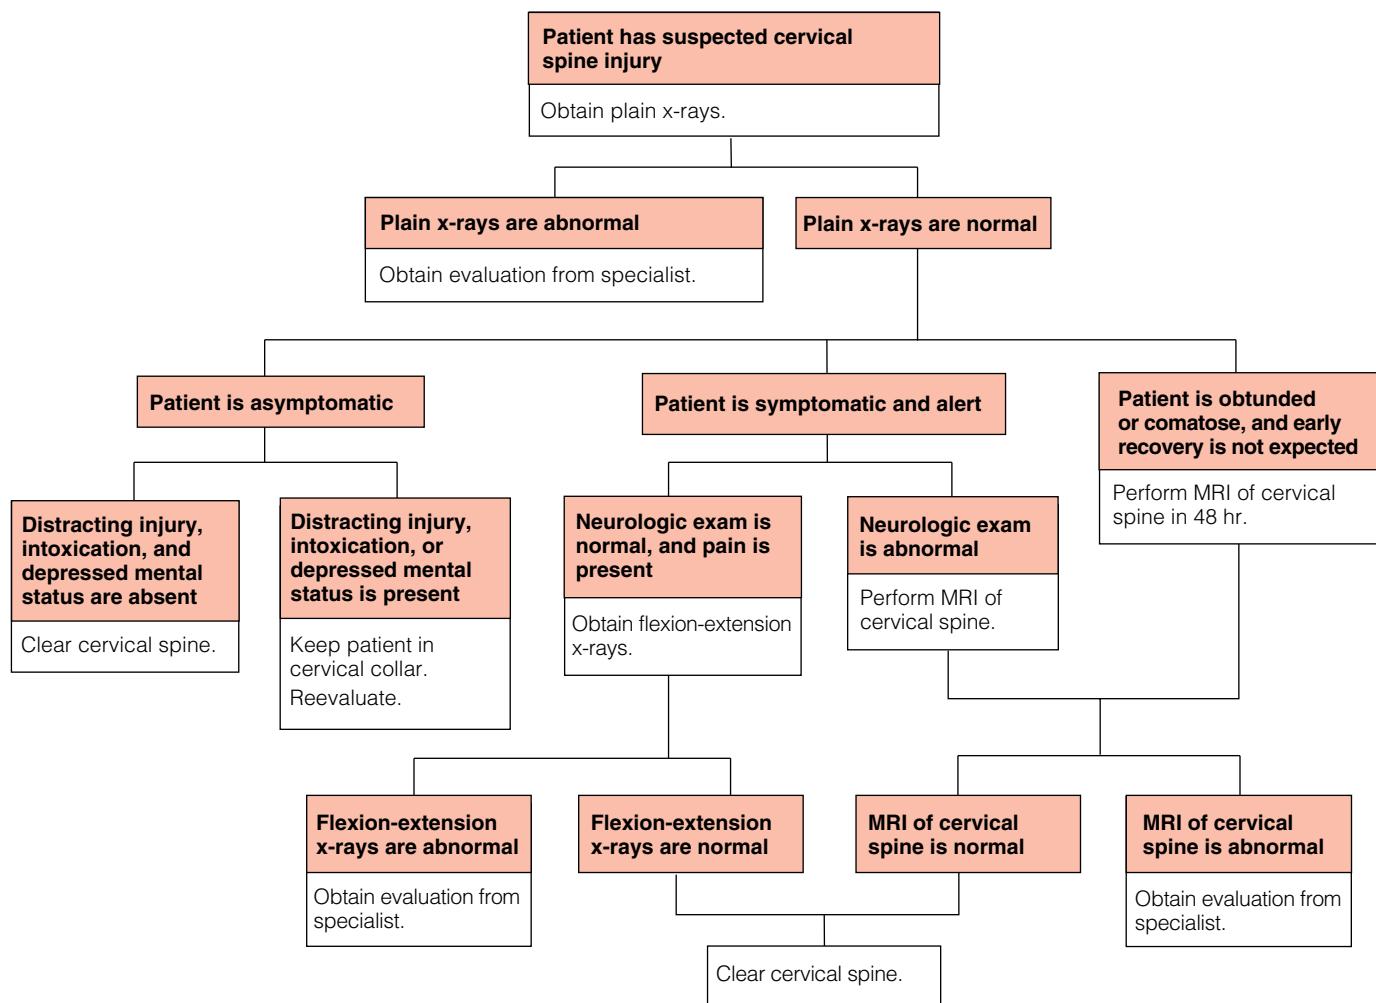

Figure 5 Shown is an algorithm depicting the protocol for radiologic evaluation and clearance of cervical spinal cord injury.

Anteroposterior and lateral views of thoracic and lumbosacral vertebrae should be obtained for all trauma patients who were thrown from a vehicle or fell more than 2 m to the ground, complain of back pain, are unconscious, cannot reliably describe back pain or have altered mental status preventing adequate examination, or have an unknown mechanism of injury or other injuries that suggest the possibility of spinal injury. If a fracture or subluxation is found on the plain films, a CT with sagittal reconstruction extending from one level above the fracture/subluxation to one level below it is recommended.

Indications for urgent MRI include the following: an incomplete lesion with normal alignment (to rule out the possibility of compression); deterioration (worsening deficit or rising level); a fracture level different from the level of deficit; and inability to identify a bony injury (to rule out the possibilities of soft tissue compression, disk herniation, or hematoma that would necessitate surgery). Radiologic evaluation of patients with suspected thoracolumbar spine injuries is also facilitated by use of a protocol [see Figure 6].

In most patients, the spine can be cleared on the basis of plain x-rays and neurologic examination. Obtunded or comatose patients whose plain x-rays are normal but who are at high risk for spine injury (e.g., those injured in high-speed motor vehicle accidents or by falls from great heights) should be evaluated by a spine specialist before spine clearance.

TREATMENT

Traction

The objectives of craniocervical traction are to reduce fracture-dislocations, to maintain normal alignment or immobility of the cervical spine, to prevent further injury, to decompress the spinal cord and roots, and to facilitate bone healing. A common technique is placement of Gardner-Wells tongs, a U-shaped device with pins that are anchored to the skull just above the pinna. Traction is applied with the patient in supine position by adding weights to the traction ring. Alternatively, traction may be applied with the patient in a halo ring. A special traction triangle is then added to the ring. The advantage of this approach is that the patient can be stabilized in a halo vest as soon as reduction is obtained. Furthermore, the halo vest is helpful in dealing with a highly unstable spine that requires instrumentation because the patient can be easily turned onto the operating table without the risk of significant movement of the spine.

Traction should always be applied under strict neurologic monitoring. If the patient's condition deteriorates when the weight is increased, the additional weight should be removed and the patient should immediately undergo imaging (e.g., with plain films, MRI, or both). In the case of a highly unstable fracture, traction should be guided by fluoroscopy rather than serial x-rays.

Pharmacologic Treatment

A number of drugs are known to interfere with the processes of secondary injury. The challenge is to identify the most effective treatment or combination of treatments with the fewest severe side effects—a task requiring many experiments for each treatment tested. Methylprednisolone (MP), thought to act by scavenging free radicals, has been reported to be neuroprotective in patients with spinal cord injuries.⁴⁸⁻⁵⁰ Considerable controversy remains, however, regarding the clinical benefit of MP administration after acute spinal cord injury.

Three multicenter, randomized, controlled clinical trials carried out in the United States evaluated MP in this setting: National Spinal Cord Injury Study (NASCIS) I, NASCIS II, and NASCIS III.⁴⁸⁻⁵⁰ In NASCIS I, reported in 1984, the administration of a 100 mg MP bolus followed by 100 mg/day for 10 days was compared with administration of a 1,000 mg MP bolus followed by 1,000 mg/day for 10 days. There was no placebo group. No difference was noted between the two MP groups with respect to motor or sensory outcome at 6 weeks, 6 months, and 1 year.

Because data from animal studies suggested that the MP doses used in NASCIS I were too low to yield a significant difference in outcome, NASCIS II was initiated in 1985. In this trial, administration of high-dose MP (i.e., a 30 mg/kg bolus followed by 5.4 mg/kg/hour for 23 hours) was compared with administration of naloxone (a 5.4 mg/kg bolus followed by 4 mg/kg/hour for 23 hours) and with placebo. Neurologic outcome was graded by evaluating sensory and motor function at 6 weeks and 6 months

after injury. A total of 14 muscle groups were examined and graded on a scale of 0 to 5. The scores were added, with a total score of 0 indicating no motor activity below the level of the lesion and a total score of 70 representing normal motor function. For sensory assessment, 29 spinal cord segments were similarly evaluated and graded on a scale of 1 to 3. A total score of 29 indicated no response in any segment, and a total score of 87 indicated that all sensory segments were normal. The authors reported a statistically significant mean motor and sensory improvement after MP administration. In the MP group, there was a mean improvement of 16.0 in the motor score, compared with a mean improvement of 11.2 in the placebo group. The mean changes in sensory scores were 11.4 (MP) and 6.6 (placebo) for sensation to pinprick and 8.9 (MP) and 4.3 (placebo) for sensation.

In NASCIS III, patients who received a 24-hour regimen of MP (a 30 mg/kg bolus followed by 5.4 mg/kg/hour), a similar 48-hour regimen, or a 48-hour regimen of tirilazad mesylate (2.5 mg/kg every 6 hours) were evaluated. There was no placebo group. No differences in sensory or motor recovery were observed between groups. In a subgroup analysis, it was noted that in patients whose treatment was initiated more than 3 hours after injury, motor function improved more with the 48-hour MP regimen than with the 24-hour regimen. The Functional Independence Measurement (FIM) did not show any statistically significant differences between groups.

NASCIS II and III have been criticized for flaws in research design and data analysis. For example, patients with a normal motor examination and patients with a combined conus-cauda injury were included. Furthermore, only motor and sensory scores from the right side of the body were reported. Moreover, in the statistical analysis, the only statistically significant results were the result of a post hoc analysis.

A 2000 study presented a statistical reanalysis of the NASCIS II and III data.⁵¹ In this reanalysis, no difference in neurologic recovery between the placebo, 24-hour MP, and 48-hour MP groups was found, but an increased mortality was documented in the 48-hour MP group—a finding that was not reported in the NASCIS studies. Current guidelines take the position that the available medical evidence does not conclusively establish the existence of a significant clinical benefit from administration of MP for either 24 or 48 hours and that the harmful side effects may actually outweigh any clinical benefits.⁵² MP administration is therefore considered a treatment option to be used at the discretion of the treating physician.

The calcium channel blocker nimodipine causes significant increases in blood flow in the spinal cord,^{53,54} but, paradoxically, the dosage necessary to exert this effect is accompanied by significant systemic hypotension. Administration of GM₁ ganglioside, a compound that occurs naturally in the membranes of mammals and is particularly abundant in the CNS, has been shown to have short-term neuroprotective effects and long-term regenerative effects in animal models. In a prospective, placebo-controlled, double-blind study, some improvement in motor, sensory, and bladder function was seen in patients treated with GM₁ ganglioside, but no overall improvement in neurologic outcome was noted.⁵⁵ This agent is currently an optional treatment for patients with spinal cord injuries. Treatment with GM₁ ganglioside is started after the completion of MP therapy and continued for 56 days.

Surgical Treatment

The role of neurosurgery in the treatment of spinal fractures and spinal cord injury remains controversial. There is considerable disagreement as to whether surgery should be performed, what type of surgery should be done, and when should it be done. The

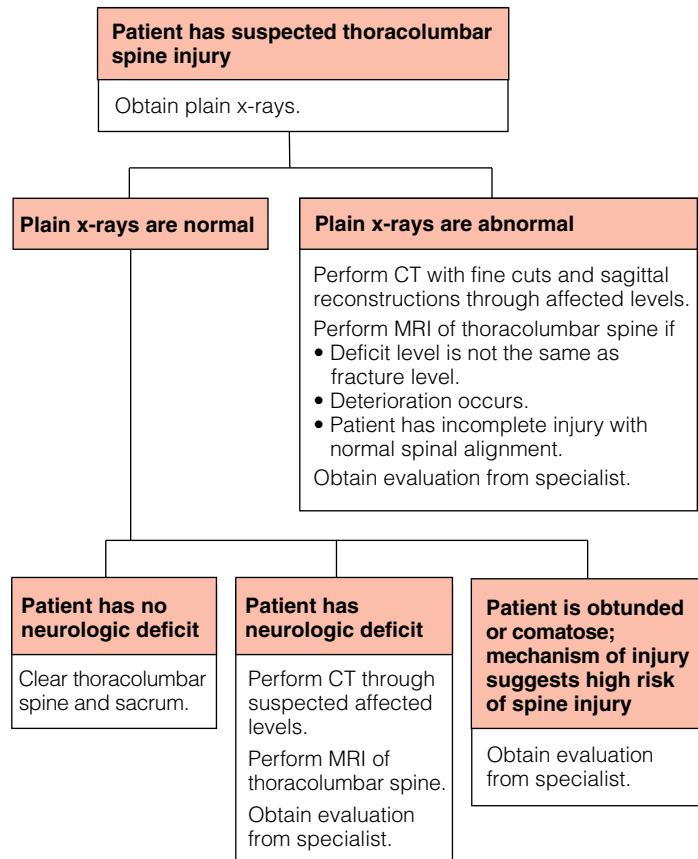

Figure 6 Shown is an algorithm depicting the protocol for radiologic evaluation and clearance of thoracolumbar spinal cord injury.

primary goals of treatment are to decompress and protect underlying neural structures, to restore spinal stability and alignment, to facilitate early mobilization and rehabilitation, and to maximize neurologic recovery.

There is general agreement among physicians that immobilization of the patient to prevent further injury and early stabilization of fractures and dislocations of the spine are necessary. The single widely accepted indication for early urgent surgical treatment is ongoing neurologic deterioration in the presence of spinal canal compromise from bone and disk fragments, hematoma, or unreduced subluxation. Surgical indications still under debate include incomplete spinal cord injury (with persistent spinal cord compression) and complete spinal cord injury with the possibility of some neurologic recovery.

In some studies, early surgical intervention has been associated with an increased risk of systemic complications (especially pulmonary complications) and neurologic deterioration. One group of investigators found that one third of all cases of neurologic deterioration could be attributed directly to surgical intervention; four of 26 patients who underwent spinal surgery within 5 days experienced deterioration, whereas none of the patients treated after 5 days had any neurologic sequelae.⁵⁶

Other studies, however, have not found an increased risk of deterioration with early intervention. One study evaluated 110 patients with cervical spinal cord injury, of whom 88 underwent surgery for spinal stabilization; in the 39 patients treated within 24 hours, the incidence of systemic complications was reduced by 50% in comparison with the incidence in the 49 patients treated 24 hours to 3 weeks after injury.⁵⁷ In addition, the incidence of neurologic deterioration was 0% in the early-stabilization group compared with 2.5% in the late-stabilization group. Data from NASCIS II showed improved outcome in patients undergoing surgery within 24 hours of injury compared with patients treated after 200 hours, but the difference was not statistically significant.⁵⁸

We adhere to the following protocol in treating patients with cervical spine fracture-dislocations. After systemic stabilization, patients are placed in a halo ring and traction as soon as possible. We prefer to set up traction in the neurologic ICU, but this can be done in the emergency department when necessary. Closed reduction is attempted under the guidance of fluoroscopy or serial x-rays, depending on the degree of spinal cord compromise or expected instability. Patients are then secured in their halo vests and undergo MRI evaluation, regardless of whether reduction attempts succeeded or failed. Patients with reduced and realigned injuries and no cord compromise are kept in their halo vests and offered nonurgent surgical stabilization, depending on the nature of the injury. Patients with irreducible fractures or continued compromise of the neural elements are taken to the OR promptly for urgent surgical decompression and fixation, regardless of whether the neurologic injury is complete or incomplete.

The efficacy of early surgical decompression in patients with thoracolumbar fractures is not established, except in cases where the neurologic examination reveals deterioration. Most surgeons, however, advocate urgent decompression in patients who have canal compromise and an incomplete injury; patients who do not fall into this category can be kept on strict spinal precautions, with definitive therapy instituted on a nonurgent basis.

Diagnosis and Treatment of Specific Fractures and Dislocations

Cervical spine Injuries to the cervical spine include atlas fractures, axis fractures, fractures of the lower cervical spine, and atlanto-occipital and atlantoaxial dislocations. Atlanto-occipital

dislocation (AOD) is rare, occurring in approximately 1% of patients with cervical spine injuries. Many of these patients die immediately after trauma as a result of brain stem injury and respiratory arrest. Since the 1980s, advances in emergency patient management in the field, reduced transport time, and better recognition of the condition have improved the survival rate after AOD. Nevertheless, since 1966, fewer than 100 survivors of AOD have been reported in the literature. Patients who survive AOD often have neurologic deficits, such as lower cranial neuropathies, unilateral or bilateral weakness, and quadriplegia. Some 20% of patients, however, exhibit no abnormalities on neurologic examination at presentation. AOD is difficult to diagnose and is often missed on the initial cervical radiograph. Accordingly, a high index of suspicion for this condition should be maintained, particularly when signs such as prevertebral soft tissue swelling on the plain cervical radiograph or subarachnoid hemorrhage at the craniocervical junction on CT are present. Additional investigation with MRI may be necessary.

Because AOD mostly involves ligamentous injury, treatment generally consists of operative fusion. Traction is rarely employed, because even a small weight may cause distraction injury with these highly unstable dislocations.

Atlantoaxial dislocations are often fatal as well. Like AODs, they are highly unstable lesions associated with severe ligamentous injury.

Atlas (Jefferson, or C1) fractures, which represent 5% to 10% of all cervical spine fractures, result from axial loading. Because of the large diameter of the spinal canal and the tendency of fragments to move outward, these fractures usually are not accompanied by significant neurologic injury. However, 40% of patients with an atlas fracture have another cervical fracture as well (usually involving C2). The integrity of the transverse ligament largely determines whether the fracture is stable.⁴⁷ Injuries that involve the midportion of the transverse ligament or the periosteal insertion (e.g., types Ia and Ib) will not heal spontaneously and must be treated with surgical fixation of the C1-C2 complex. In contrast, type II injuries (e.g., avulsion injuries or comminuted lateral mass fractures) will usually heal in a rigid external orthosis (e.g., a halo vest). Most other atlas fractures can be managed in a rigid cervical collar, except for widely displaced or comminuted fractures, which also require that the patient be immobilized in a halo vest.

Axis (C2) fractures account for 10% to 20% of all cervical spine fractures in adults and 70% of cervical fractures in children. The odontoid process is the part of C2 that is most commonly fractured (accounting for 60% of axis fractures). The management of odontoid fractures remains controversial: only class III data are available, which are insufficient to establish practice guidelines.⁵⁹

Three different types of odontoid fractures are recognized. Fractures of the tip of the odontoid process (avulsion fracture, type I) are uncommon but are thought to be stable in most cases. They can be treated by using a hard cervical collar with or without preceding cervical traction or by immobilizing the patient in a halo vest.

Fractures of the neck (type II) and fractures at the junction of the odontoid process and the axis body (type III) are more common (accounting for 65% to 80% and 20% to 35% of odontoid fractures, respectively). Management of type II fractures depends on the degree to which the dens is displaced: fractures with more than 5 mm of displacement are typically managed surgically, whereas fractures with less than 5 mm of displacement can be treated nonsurgically with a halo vest or a semirigid orthosis (e.g., a sterno-occipito-mandibular immobilizer [SOMI] brace).⁶⁰ The management of type II fractures also depends on the age and general medical condition of the pa-

tient. Halo-vest immobilization is associated with a significantly increased risk of pulmonary complications and death in elderly patients and thus should be used with caution in this population. Surgical stabilization and fusion is recommended for type II fractures in patients older than 50 years.⁶⁰

The type IIa subcategory of odontoid fracture warrants special mention. These fractures have either anterior or posterior chip-fracture fragments at the base of the dens and are considered unstable. They are often widely displaced and have a nonunion rate of 75% to 85% with halo-vest immobilization. Accordingly, surgical management is recommended. The integrity of the transverse ligament should be evaluated in patients with type II injuries; fixation with an odontoid screw is contraindicated, and C1-C2 fixation should be performed instead.

Most type III odontoid fractures will fuse with rigid external mobilization (i.e., either cervical traction followed by placement in a rigid cervical collar or placement in a halo vest). Again, more than 5 mm of displacement is an indication for surgical stabilization.⁶⁰

Traumatic spondylolisthesis, or hangman's fracture, accounts for approximately 20% of C2 fractures. Injury usually results from axial compression in combination with hyperextension of the occipito-atlanto-axial complex on the lower spine, resulting in bilateral fracture of the pars interarticularis. Fractures affecting the ring of the axis without C2-C3 angulation are stable and can be treated with immobilization in a Philadelphia collar or a SOMI brace. Halo-vest immobilization is recommended in unreliable patients or patients with both C1 and C2 fractures. The average healing time is 12 weeks. Fractures with angulation, subluxation, or C2-C3 locked facets are treated with halo-vest immobilization if they are adequately reducible and with surgical intervention if they are nonreducible, are associated with disruption of the C2-C3 disk space, or are subject to recurrent subluxation.^{47,60}

Approximately 80% of all fractures of the lower cervical spine are produced by indirect forces. The vertebra most commonly involved is C5, and dislocations are most frequent at the C5-C6 level. The following injury mechanisms are observed: flexion and distraction (approximately 40% of cases), flexion and compression (22%), vertical compression (8%), extension and compression (24%), extension and distraction (6%), and lateral flexion (3%).

Flexion and distraction injuries usually result from a blow to the occiput from below. The initial disruption is within the posterior ligamentous complex, leading to facet dislocation and an abnormally large divergence of the spinous processes. Unilateral facet dislocation and facet interlocking result when a rotatory component is involved. Bilateral facet dislocation with anterior translation of the superior vertebra results from severe hyperflexion; the translation is usually at least 50% in such cases. Cord and root involvement vary with the degree of subluxation and translation: 50% of patients with unilateral facet dislocation present with moderate cord and root injury, and 90% of patients with bilateral facet dislocation and a full translation of the vertebral body have a neurologic deficit (most often a complete cord lesion). Teardrop fractures (characterized by a bone chip just beyond the anterior inferior edge of the vertebral body) result from severe hyperflexion injury, and the fractured vertebra is usually displaced posteriorly on the vertebra below; these patients are often quadriplegic.

Flexion and compression injuries, usually observed at the C4-C5 and C5-C6 levels, typically result from a blow to the back of the head. The effect on the anterior vertebral body varies from a moderate rounding or loss of anterior height to a wedge shape with an oblique fracture from the anterior surface to the inferior subchondral plate. Approximately 50% of patients with the latter type of injury have a neurologic deficit. More severe injuries are

accompanied by translation of the inferior posterior margin of the vertebral body into the neural canal. About 75% of patients have neurologic involvement. Translations of more than 3 mm result in a complete spinal cord lesion in most cases.

Extension and compression injuries are usually caused by a blow to the forehead and result in fractures of the posterior complex. About 40% of patients with unilateral vertebral arch fractures (articular process, pedicle, or lamina) have a neurologic deficit (most often a radiculopathy). Bilaminar fractures are accompanied by a complete cord lesion in 40% of cases. Bilateral vertebral arch fractures with complete anterior translation of the vertebral body present with radiculopathy (30% of cases), central cord syndrome (30%), or an incomplete cord lesion (30%). In one series, no complete cord lesions were observed with this type of injury.⁶¹

Treatment of injuries to the lower cervical spine has not been standardized. As a general rule, severe ligamentous involvement and severe vertical compression call for surgical intervention. Severely comminuted vertebral body fractures may also necessitate surgery because of the high risk of progressive kyphosis. Isolated spinous process fractures and unilateral lamina and pedicle fractures are usually managed conservatively with placement in a rigid cervical collar. If there is a fracture through the transverse foramen above C6, the vertebral artery should be evaluated for dissection by means of magnetic resonance angiography (MRA), CT angiography, or catheter angiography.⁴⁵ Surgical intervention should be carefully considered, especially in young trauma victims. In a series from 1988, 87% of patients with distractive flexion injury and 88% of those with compressive flexion injury healed with halo-vest immobilization.⁶²

Thoracolumbar spine Approximately 64% of fractures of the spine occur at the T12-L1 junction, and 70% of these fractures are unaccompanied by immediate neurologic injury. Evaluation according to Denis's three-column principle [see Figure 7] is useful for determining whether a fracture is stable, though the precise definition of stability remains controversial.⁶³ Fractures of the thoracic spine are more stable because of support from the surrounding rib cage and the strong costovertebral ligaments. When two of the three columns are affected, the fracture is considered unstable, and surgical intervention is generally required.

The four major types of thoracolumbar spine injuries are compression fractures, burst fractures, seat-belt fractures (Chance fractures), and fracture-dislocations. These four types of fracture involve the anterior, middle, and posterior columns of the spine in different ways [see Table 4]. Transverse process fractures are rarely unstable and are typically managed conservatively with analgesics or muscle relaxants.

Minimal to moderate compression fractures (< 50% loss of height or < 30° of angulation) with an intact posterior column can be treated with analgesics and bed rest. Ambulation should be started early, and depending on the degree of kyphosis, external immobilization (with a thoracolumbar orthosis or a Boston brace) may or may not be indicated. Severe compression injuries should be treated with external immobilization in extension. If the loss of anterior height of the vertebral body exceeds 50%, there is an increased risk of progressive kyphosis; evaluation with follow-up radiographs is indicated. Occasionally, surgical intervention is required. An anterior injury is considered unstable if it involves more than three adjacent elements or if height loss in a single element exceeds 50% with more than 30° of angulation.⁶⁴

Burst fractures are considered unstable even if there is no initial neurologic deficit. Early ambulation should be avoided because

the axial loading may result in progressive collapse or angulation, with concomitant neurologic damage. Indications for the surgical treatment of burst fractures are as follows⁶⁴:

1. Loss of more than 50% of body height.
2. Retropulsed bony fragments narrowing the canal by more than 50%.
3. Kyphotic angulation of 25° or more.

A Chance fracture is a horizontal fracture through all three columns. It occurs most commonly in the lower lumbar spine and is a highly unstable injury. Chance fractures are now less frequent

than they once were because of the widespread use of shoulder belts in addition to lap belts, which prevents upper torso flexion during deceleration. Chance fractures are treated with surgical stabilization, and decompression and correction of spinal alignment may be required as well.⁶⁴

Fracture-dislocations, also known as fracture subluxations, are three-column injuries that usually involve disruption of the ligamentous structures or the disk space. Dural lacerations and neurologic injury are common with such injuries. Fracture-dislocations are considered unstable and are treated with surgical decompression and stabilization.

Discussion

Pathophysiology

HEAD INJURY

Cerebral Metabolism

At 1,200 to 1,400 g, the brain accounts for only 2% to 3% of total body weight and does not do any mechanical work; yet it receives 15% to 20% of all cardiac output to meet its high metabolic demands. Of the total energy generated, 50% is used for interneuronal communication and the generation, release, and reuptake of neurotransmitters (synaptic activity); 25% is used for

maintenance and restoration of ion gradients across the cell membrane; and the remaining 25% is used for molecular transport, biosynthesis, and other, as yet unidentified, processes.

Cell metabolism involves the consumption of adenosine triphosphate (ATP) during work and the ensuing consumption of metabolic substrates to resynthesize ATP from adenosine diphosphate (ADP). ATP is generated both in the cytosol (via glycolysis) and in the mitochondria (via oxidative phosphorylation). Glucose is the sole energy substrate, unless there is ketosis, and 95% of the energy requirement of the normal brain comes from aerobic conversion of glucose to water and CO₂. ATP generation is highly efficient. Glycolysis and subsequent oxidative phosphorylation result in the generation of 38 molecules of ATP for each molecule of glucose:

In the absence of oxygen, anaerobic glycolysis can proceed, but energy production is much less efficient. Two molecules of ATP and two molecules of lactate are generated for each molecule of glucose:

Regulation of Blood Flow

Because the reserves of glucose and glycogen within the astrocytes of the brain are limited and there is no significant storage capacity for oxygen, the brain depends on blood to supply the oxygen and glucose it requires. More specifically, substrate availability is determined by its concentration in blood, flow volume, and the rate of passage across the blood-brain barrier.

Under normal circumstances and with certain physiologic alterations, an adequate supply of substrates can be maintained by regulation of CBF. CBF increases with vasodilatation and decreases with vasoconstriction. Caliber changes take place mainly in cerebral resistance vessels (i.e., arterioles with a diameter of 300 μm down to 15 μm).^{65,66} Control of CBF by influencing vessel caliber is commonly referred to as autoregulation of blood flow.

Metabolic autoregulation CBF is functionally coupled to cerebral metabolism, changing proportionally with increasing or decreasing regional or global metabolic demand. Thus, the brain precisely matches local CBF to local metabolic needs. Because 95% of the energy in the normal brain is generated by oxidative metabolism of glucose, CMRO₂ is considered to be a sensitive measure of cerebral metabolism. The relation between CBF and metabolism is expressed in the Fick equation:

$$\text{CMRO}_2 = \text{CBF} \times \text{A-VDO}_2$$

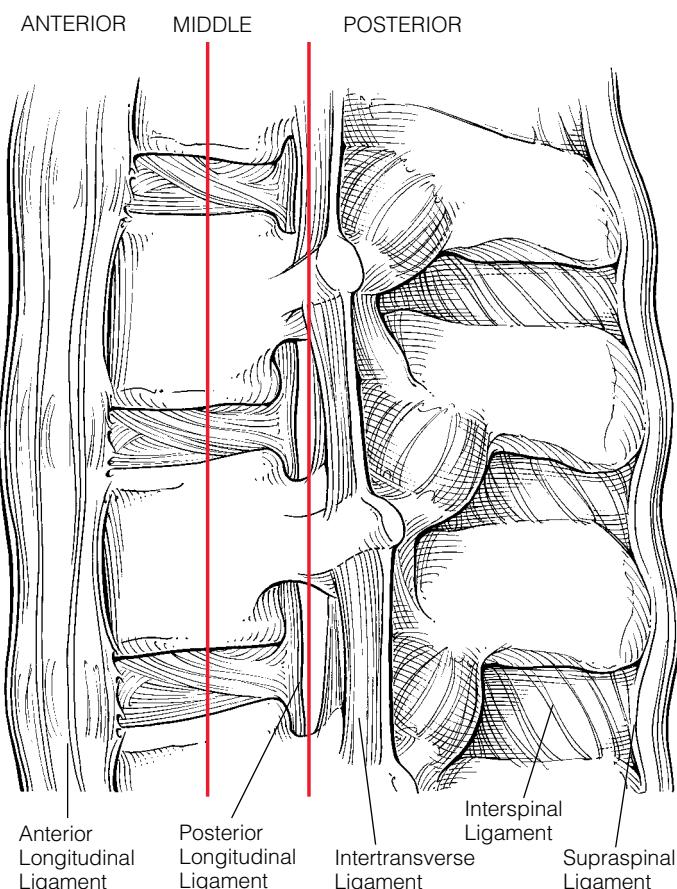

Figure 7 Illustrated is the three-column concept for assessment of spinal stability. If two or more columns are destroyed or non-functional, instability is likely.

Table 4 Column Failure in the Four Types of Major Thoracolumbar Spinal Injury⁶³

Fracture Type	Anterior Column	Middle Column	Posterior Column
Compression	Compression	Intact	Intact, or distraction if severe
Burst	Compression	Compression	Intact
Seat belt	Intact or mild compression of 10%–20% of anterior vertebral body	Distraction	Distraction
Fracture-dislocation	Compression, rotation, shear	Distraction, rotation, shear	Distraction, rotation, shear

CMRO₂, expressed in milliliters per 100 g of brain tissue, is normally about 3.2 ml/100 g/min in awake adults. The average CBF value for mixed cortical flow is 53 ml/100 g/min in a healthy adult. A-VDO₂, a measure of cerebral oxygen extraction, can be calculated by subtracting the oxygen content of jugular venous blood (6.7 ml/dl) from that of arterial blood (13 ml/dl), resulting in a value of 6.3 ml/dl; this value can then be corrected for hemoglobin content according to the formula discussed earlier [see Head Injury, ICU Management, *above*]. Under conditions of increasing metabolic demand (increased CMRO₂), such as seizures or fever, CBF increases proportionally, thus keeping A-VDO₂ constant. With decreasing metabolism (anesthesia, deep coma), CBF decreases.

Pressure autoregulation Another important physiologic property of the cerebral circulation is maintenance of a constant supply of substrates at the level set by metabolism. According to Poiseuille's equation,

$$CBF = k \frac{CPP \times d^4}{(8 \times l \times v)}$$

in which k is a constant of proportionality, d is vessel diameter, l is vessel length, and v is blood viscosity, changes in CPP (e.g., arterial hypotension or increases in ICP) are followed by changes in CBF, unless diameter regulation (pressure autoregulation) takes place.⁶⁷ In humans, the limits of pressure autoregulation range from 40 to 150 mm Hg of CPP.

Viscosity autoregulation In accordance with Poiseuille's equation, CBF can vary with changes in the viscosity of blood. Blood viscosity changes with variations in hematocrit, γ-globulin, and fibrinogen components of plasma protein. Increased viscosity would increase cerebrovascular resistance ($8 \times l \times v / d^4$). By means of diameter adjustment (viscosity autoregulation), cerebrovascular resistance is decreased and CBF can be kept constant.⁶⁸

CO₂ reactivity Vascular caliber and cerebral blood flow are also responsive to changes in P_aCO₂. Cerebral blood flow changes 2% to 3% for each mm Hg change in P_aCO₂ within the range of 20 to 60 mm Hg. Hypercarbia (hypoventilation) results in vasodilatation and higher CBF, and hypocarbia (hyperventilation) results in vasoconstriction and lower CBF. Autoregulation is a compensatory or adaptive response adjusting CBF to metabolism; with CO₂ variation, vessel caliber changes and CBF follow passively. The vessels respond not to changes in P_aCO₂ but to the pH in the perivascular space. CO₂ can cross the blood-brain barrier freely, thus changing the pH, but over 20 to 24 hours, with a con-

stant new level of P_aCO₂, the pH in blood and in the perivascular space returns to baseline, and the diameter of the cerebral blood vessels also returns to baseline.⁶⁹ With CO₂ reactivity, changes in CBF are compensated for by changes in A-VDO₂, so that a constant supply of substrates is maintained at the level set by metabolism (CMRO₂). A constant A-VDO₂ is a common feature of metabolic, pressure, and viscosity autoregulation; because CBF is tuned to metabolism, A-VDO₂ can be kept constant.

Cerebral Circulation and Metabolism after Severe Head Injury

Arterial hypoxia and hypotension It is known from eyewitness reports of head injury and experimental studies immediately after the impact that arterial hypotension and interruption of normal respiration, sometimes with a period of prolonged apnea, are common findings. In the days after a head injury, there are many occasions and opportunities for hypoxic and hypotensive insults. Studies have identified hypotension (systolic BP < 90 mm Hg) and hypoxia (P_aO₂ < 60 mm Hg) as major determinants of poor outcome.^{9,19,70}

The effect of hypotension on the brain depends on the status of autoregulation. If autoregulation is defective, decreased BP leads directly and linearly to a reduction in CBF. If autoregulation is intact, arterial hypotension can lead to a considerable increase in ICP, which interferes with CBF by decreasing perfusion pressure.

Elevated ICP According to the Monro-Kellie doctrine,^{71,72} ICP is governed by three factors within the confines of the skull: brain parenchyma plus cytotoxic edema; CSF plus vasogenic edema; and CBV. When the volume in one compartment increases, ICP increases unless there is a compensatory decrease in volume in the other compartments. The relation between intracranial volume and ICP is expressed in the pressure-volume index (PVI).⁷³ PVI is defined by the volume that must be added to or withdrawn from the craniospinal axis to raise or decrease ICP 10-fold:

$$PVI = \frac{\Delta V}{\log ICP_i / ICP_o}$$

where ΔV is the change in volume, ICP_o is ICP before the volume change, and ICP_i is ICP after the volume change. PVI is thus a measure for the compliance (ΔV/ΔP) or tightness of the brain. Under normal circumstances, PVI is 26 ± 4 ml; 26 ml of volume will raise ICP from 1 to 10 mm Hg, but the same volume will also raise ICP from 10 to 100 mm Hg. Conversely, a change in volume of only 6.4 ml is necessary to increase ICP from 10 mm Hg (normal) to the treatment threshold of 20 mm Hg. Thus, small changes in volume have a relatively large effect on ICP. PVI values as low as 5 ml have been reported in patients with head injuries.

Apart from mass lesions, ICP typically increases after severe head injury because of cerebral edema. Initial compensation is by displacement of CSF from the cranium, which is visualized in a CT scan of the head as small ventricles and basal cisterns. Subsequent compensation would be by a decrease in CBV, which can be accomplished by means of vasoconstriction.

Relation between vessel diameter, CBV, and ICP The total diameter of the cerebrovascular bed determines CBV. Cerebral veins contain most of the total blood volume, but their diameter and thus their volume are relatively constant. Approximately 20 ml of blood (i.e., one third of total CBV) is located in the cerebral resistance vessels (which range in diameter from 300 μm down to 15 μm).⁶⁹ Because most autoregulatory and CO_2 -dependent variations in diameter take place in these vessels, CBV is determined mainly by their diameter. Typically, the diameter ranges from 80% to 160% of baseline, resulting in volume changes between 64% and 256% of baseline. With a baseline value of 20 ml in the resistance vessels, CBV will range from 13 ml (maximal vasoconstriction) to 51 ml (maximal vasodilatation). Given a PVI of 26, change from maximal vasoconstriction to maximal vasodilatation will be accompanied by an almost 29-fold change in ICP.

CBV, ICP, and CBF CBF and CBV are governed by vascular diameter. Thus, depending on other parameters influencing CBF (such as mean arterial BP, ICP, and blood viscosity), changes in vascular caliber also affect CBF.

Hypocarbia reduces ICP by means of vasoconstriction, consequently improving CPP. However, net CBF is decreased because in Poiseuille's equation, vessel diameter is carried to the fourth power. A randomized clinical trial has shown that preventive hyperventilation retards clinical improvement after severe head injury, perhaps through reduction of CBF to ischemic levels.⁷⁴ However, its rapid effect on ICP is a great advantage in cases of acute neurologic deterioration (e.g., in the presence of an expanding mass lesion before evacuation can take place) and should be reserved for these situations.

There are two methods of reducing ICP by means of vasoconstriction without affecting CBF. The first is to reduce blood viscosity. As can be deduced from Poiseuille's equation, decreasing the blood viscosity will, by itself, lead to vasoconstriction, provided that viscosity autoregulation is intact. With impaired autoregulation, decreased viscosity will result in an increase in CBF but no decrease in ICP. However, this effect can be used to maintain CBF under vasoconstriction with hypocarbia. The effect of mannitol on ICP is thought to be mediated in part by lowering blood viscosity.^{75,76}

The second method of reducing ICP without affecting CBF is to increase CPP, which can be done by raising blood pressure. Again, with intact autoregulation, an increase in CPP will lead to vasoconstriction, with net CBF remaining constant. With impaired autoregulation, CBF will follow CPP passively, and maintenance of normal BP may be indicated in these cases. More important, however, is the avoidance of hypotension under these circumstances; the effect of CPP therapy may be attributable in part simply to prevention of hypotension.^{28,77}

Cerebral ischemia Cerebral ischemia, defined as CBF that is inadequate to meet the metabolic demands of the brain, is an important mechanism of secondary injury in patients with severe head injury, and the adequacy of CBF has been associated with neurologic outcome. In autopsy findings from patients dying after severe head injury, histologic damage indicative of cerebral ische-

Table 5 Changes in CBF, CBV, ICP, and A-VDO₂ Associated with Primary Reduction of Selected Variables⁸¹

Variable Reduced	CBF	CBV (ICP)	A-VDO ₂
CMRO ₂	↓	↓	—
CPP (autoregulation intact)	—	↑	—
CPP (autoregulation defective)	↓	↓	↑
Blood viscosity (autoregulation intact)	—	↓	—
Blood viscosity (autoregulation defective)	↑	—	↓
P _a CO ₂	↓	↓	↑
Conductance vessel diameter (vasospasm above ischemia threshold)	↓	↑	↑

A-VDO₂—arteriovenous oxygen content difference CBF—cerebral blood flow
CBV—cerebral blood volume CMRO₂—cerebral metabolic rate of oxygen CPP—cerebral perfusion pressure ICP—intracranial pressure P_aCO₂—arterial carbon dioxide tension

mia was seen in 80% of cases.⁷⁸ One group of investigators found that ischemia (CBF < 18 ml/dl with abnormally high A-VDO₂ values) occurred in 20% to 33% of patients with severe head injuries within 4 to 12 hours of injury and that the ischemia was associated with a poor prognosis.⁷⁹ Of the intracranial lesions, acute subdural hematoma and diffuse cerebral swelling were most often associated with ischemia.

The relation between cerebral metabolism and CBF is expressed in the Fick equation [see Metabolic Autoregulation, above]. The normal brain tends to keep A-VDO₂ constant and to react to changes in metabolism by adjusting blood flow. When CBF decreases in response to metabolism (as with hyperventilation or decreasing CPP with impaired autoregulation), oxygen supply is maintained by increasing oxygen extraction (i.e., A-VDO₂ increases). A rising A-VDO₂ is thus a sensitive marker of insufficient cerebral perfusion. However, the extent to which oxygen extraction can be increased is limited, and this limit is reached when A-VDO₂ is doubled (13.2 ml/dl). Consequently, any further reduction in CBF results in neuronal dysfunction (i.e., CMRO₂ decreases). Because 50% of the energy is used for synaptic activity, a reversible and functional loss is usually observed first. Further decline, however, will result in ion pump failure, loss of membrane integrity, consequent cell swelling (cytotoxic edema), and cell death (irreversible infarction). The occurrence of irreversible infarction depends on both the level and the duration of ischemia. When CBF falls to approximately 18 ml/100 g/min for more than 4 hours, it reaches the threshold for irreversible infarction.⁸⁰

Maintenance or improvement of CBF is thus essential to the treatment of severe head injury, and A-VDO₂ is a sensitive marker of the adequacy of therapy. When therapeutic measures fail to sustain CBF, CMRO₂ can be decreased to reinstate the match between CBF and metabolism. CNS suppression can be achieved by administering hypnotic agents (e.g., barbiturates or propofol) or inducing hypothermia. Decreasing cell metabolism will result in reduced production of CO₂, lactic acid, or both and (with blood vessels almost always remaining responsive to perivascular pH changes) in vasoconstriction accompanied by reductions in both CBF and ICP. The relations between CMRO₂, CBF, CBV, CPP, and A-VDO₂ are complicated. An overview is available elsewhere [see Table 5].⁸¹

Altered cerebral metabolism Anaerobic metabolism of glucose to the end product lactate is characteristic of cerebral hy-

poxia/ischemia.⁸² Increased lactate production, hyperglycolysis, and low tissue glucose levels have been observed after severe head injury, suggesting an increased turnover of glucose by the anaerobic glycolytic pathway. Increased lactate levels have also been found in the presence of preserved CBF, suggesting impairment not only of oxygen delivery but also of oxidative metabolism (i.e., of mitochondrial function).^{83,84} Data from animal and human models indicate that mitochondrial function is impaired after severe head injury, which may explain the poor outcomes despite adequate CBF levels; ATP generation by anaerobic glycolysis is usually insufficient to maintain the metabolic activity of the brain.⁸⁵⁻⁸⁷ In part, however, such poor outcomes may be attributable to the effects of lactate production (acidosis), because high lactate and hydrogen ion levels interfere with the functional recovery of tissue.

SPINAL CORD INJURY

Spinal cord injury is often viewed as an all-or-nothing event that is irreversible from the moment of injury. By this view, spinal cord injury is classified as either incomplete or complete. This dichotomy is not absolute, however, because some functional recovery occurs even after severe spinal cord injury. NASCIS II revealed that patients with so-called complete loss of neurologic function recovered, on average, 8% of the function they had lost, and patients with an incomplete injury recovered 59%.⁸⁸

An injury classified as complete does not necessarily involve loss of all connections. Several studies have demonstrated that many patients with a clinically complete lesion show evidence of residual connections.⁸⁹ A certain number of intact connections is probably necessary for functional recovery. The determinants of functional outcome are complex, however, and probably include not only the extent of axonal loss but also the level of dysfunction of the surviving axons and the plasticity of the spinal cord.

Animal studies have shown that a small number of axons may be sufficient to support functional recovery.⁹⁰⁻⁹² Animals recover evoked potentials and the ability to walk with as few as 10% of their spinal axons. Nerve sprouting, one of the mechanisms of plasticity, allows a few nerves to carry out the function of many. Finally, animal studies have also shown that many of the axons

surviving traumatic injury are dysfunctional and that many of these axons have lost part or all of their myelin sheath, which is the structural component that improves the reliability and speed of conduction. 4-Aminopyridine, an axon-excitatory drug used for the treatment of multiple sclerosis, has significantly improved conduction in animals and humans with spinal cord injury.⁹³ Unfortunately, the drug must be given continuously to support axon function, and this is not feasible in humans because of its side effects (seizures, tachycardia, and hyperthermia).

Injury initiates complex responses in the body and the spinal cord. Ischemia is a prominent feature of events occurring after spinal cord injury.^{94,95} Within 2 hours of a spinal cord injury, there is a significant reduction in spinal cord blood flow. It is unclear whether this reduction is mechanically or biochemically induced. Like the brain, the spinal cord possesses autoregulatory capacity (pressure autoregulation). When this autoregulation is impaired, blood flow becomes dependent on systemic blood pressure. In a patient with multiple injuries or vasogenic spinal shock (a lesion above T5) complicating the spinal cord injury, severe systemic hypotension may exacerbate the effects of spinal cord injury.

Edema, another prominent feature of spinal cord injury, tends to develop first at the injured site, subsequently spreading to adjacent and sometimes distant segments. The relation between spreading edema and potential worsening of neurologic function is poorly understood. The inflammatory response to injury is mounted in part to scavenge cellular debris and repair tissue. This response is accompanied, however, by the release of toxic substances, which cause further tissue damage, or secondary injury. Processes resulting in secondary injury involve generation of free radicals, excessive calcium influx and excitotoxicity, the release of eicosanoids and cytokines, and programmed cell death.

Some evidence from experimental studies of spinal cord injury suggests that macrophages may play a key role in CNS repair. Administration of stimulated macrophages to the CNS, where the number of macrophages is limited and their activity restricted in comparison with other tissues, has led to partial motor recovery in a completely transected spinal cord in adult rats.⁹⁶ Clinical trials have been initiated to evaluate this approach further.

3 INJURIES TO THE FACE AND JAW

Seth Thaller, M.D., and F. William Blaisdell, M.D.

Assessment and Management of Maxillofacial Injuries

Tremendous progress has been made in the management of patients with facial injuries. Reconstructive surgeons are treating an increasing number of challenging facial injuries because of excellent advances in the transportation of trauma victims and the regionalization of care in trauma centers. Although severe facial injuries are often associated with devastating cosmetic and functional defects, reconstructive surgeons are achieving better long-term surgical results and are able to repair certain injuries that were once considered nonreconstructible by employing craniofacial surgical techniques developed through the pioneering efforts of Dr. Paul Tessier, of Paris. These techniques include widespread subperiosteal exposure, rigid internal fixation with miniature plates and screws, and widespread primary bone grafting.

Initial Survey

Maxillofacial injuries are secondary to either blunt or penetrating trauma. Motor vehicle accidents remain the most common cause of facial injuries characterized by bony comminution and distraction. However, penetrating injuries, such as knife wounds, can cause extensive soft tissue injuries to skin and underlying nerves, blood vessels, parotid structures, and other structures of the upper aerodigestive system. Gunshot wounds can cause devastating injuries that necessitate extensive flap reconstruction to provide satisfactory soft tissue coverage of the underlying bone.

On initial assessment, the physician must always pay special attention to correcting the most life-threatening problems, including an obstructed airway, bleeding, and shock [see 7:1 Life-Threatening Trauma, 8:3 Shock, and 1:4 Bleeding and Transfusion]. Patients with facial injuries often have multisystem involvement; priorities in the evaluation and treatment of associated significant injuries are discussed elsewhere.

After establishing that the patient is stable, the examiner should quickly make note of lacerations and contusions, extensive bony disruptions, loss of vision, malocclusion, trismus, and bleeding.

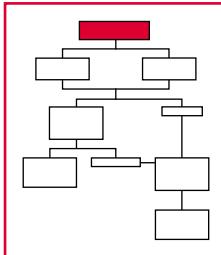

In the evaluation of facial injuries, a quick analysis of occlusion provides extremely important diagnostic information that serves as the foundation for future fracture repair. Angle's clas-

sification of malocclusion, which is more than 100 years old, remains one of the most commonly used systems. The maxillomandibular relation is determined by the position of the mesiobuccal cusp of the maxillary first molar in relation to the buccal groove of the mandibular first molar. Angle's class I, or neutroclusion, exists when the permanent maxillary first molar is ideally positioned—that is, the buccal cusp of the maxillary first molar and the mesiobuccal groove of the mandibular first molar occlude, resulting in a normal anteroposterior relation of the maxillary and mandibular dentition. Angle's class II, or distoclusion, exists when the maxillary first molar is mesial (i.e., toward the midline) to the corresponding mandibular first molar. Angle's class III, or mesioclusion, exists when the mandibular first molar is mesial to the maxillary first molar.

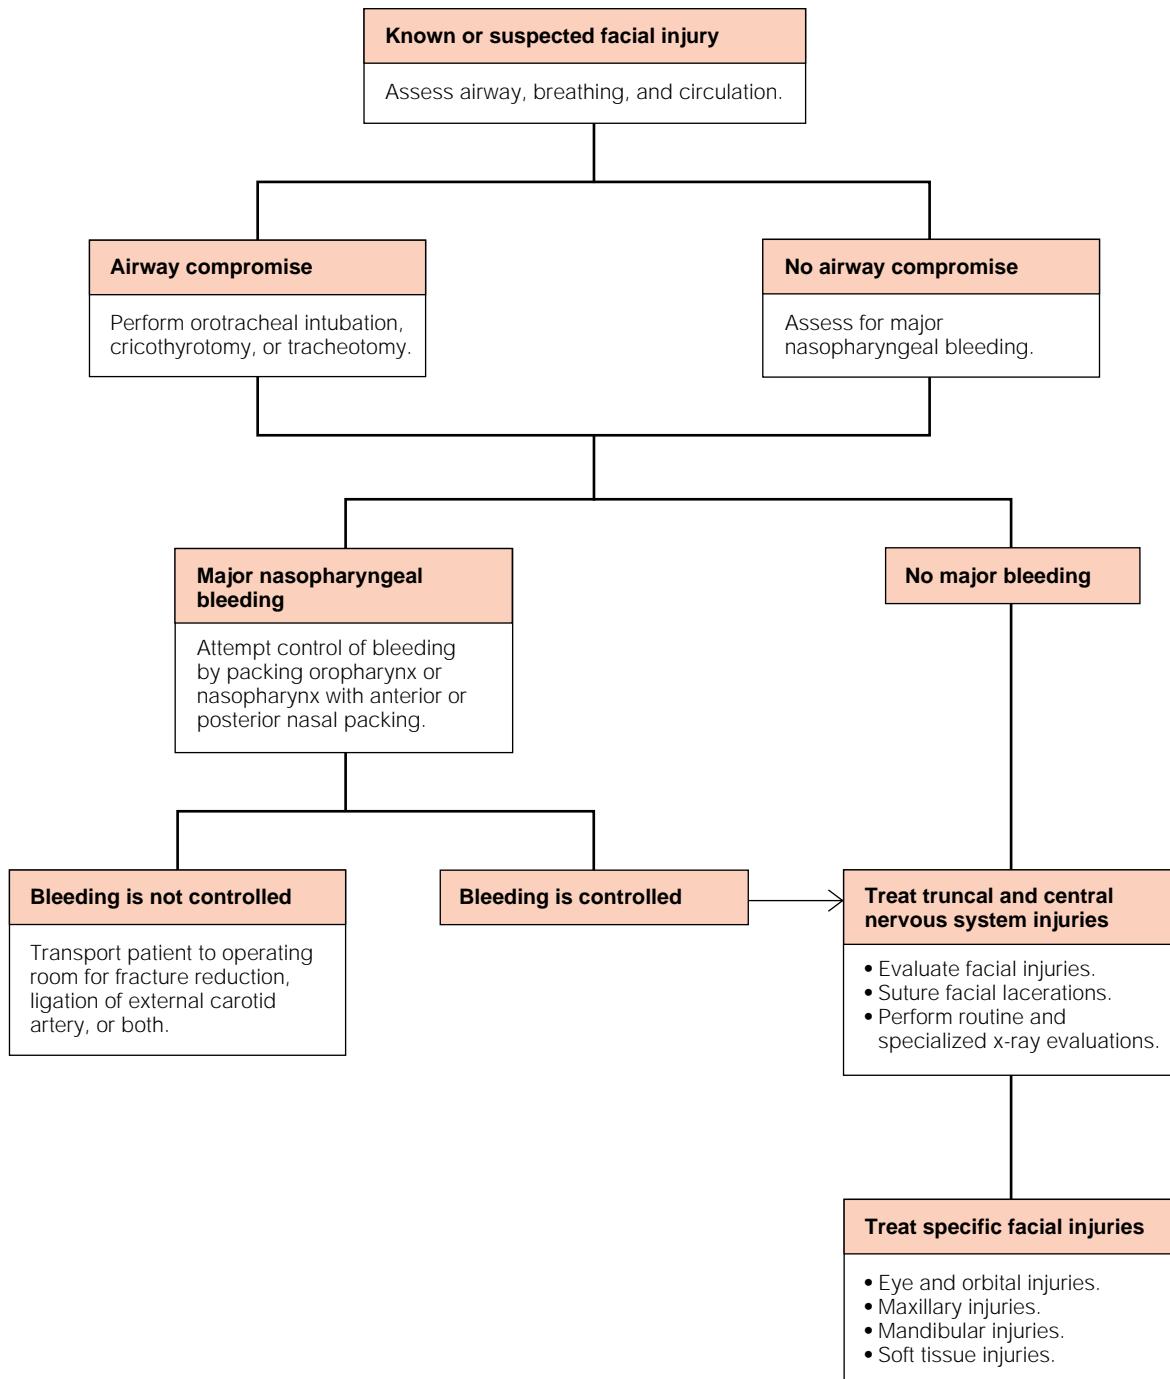

AIRWAY ASSESSMENT

Facial bone fractures, bleeding, loose dentition, debris, and laryngeal injuries can contribute to airway compromise. Accordingly, whenever there is any evidence of maxillofacial injuries, it is essential to monitor the airway status carefully. If the patient is conscious, alert, and breathing at a rate of less than 20 respirations/min, without excessive airway secretions or excessive hemorrhage, it can be assumed that the patient has an adequate airway.

In a comatose patient with compromised vital reflexes (i.e., gag, cough, and swallow), an endotracheal tube must be inserted immediately to prevent aspiration. In the presence of nasopharyngeal bleeding, major maxillofacial injuries, or cerebrospinal fluid leakage, nasal intubation should be avoided because of the potential for intracranial contamination. If there is a possible fracture of the cribriform plate, either an orotracheal tube should be placed or a cricothyrotomy should be performed. In an agitated or restless patient, only a single attempt should be made at inserting an endotracheal or nasotracheal tube; if the attempt is unsuccessful, an emergency cricothyrotomy should be performed [see 7:1 Life-Threatening Trauma]. In slightly more elective circumstances, a deliberate tracheotomy may be the optimal means of ensuring an adequate airway. Cricothyrotomy and tracheotomy must never be taken lightly, because they can lead to significant complications. In addition, because newer treatment modalities using rigid fixation decrease the time required for extensive maxillo-

Assessment and Management of Maxillofacial Injuries

mandibular fixation, more conservative methods of airway control are often indicated.

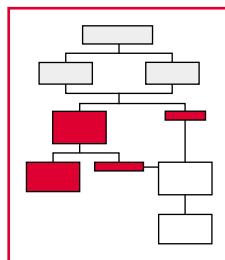

If the respiratory rate is higher than 25/min or if there is evidence that the airway is obstructed or compromised, the patient should be carefully monitored. When the respiratory rate increases to 30/min or higher, an immediate assessment of arterial blood gases should be made under close observation. A respiratory rate higher than 35/min is an indication for both intubation and respiratory support unless the cause of the rapid rate can be identified and immediately reversed.

MAXILLOFACIAL BLEEDING

Once the airway has been satisfactorily stabilized, the next priority is to manage maxillofacial bleeding. There is a misconception that patients do not bleed profusely from facial injuries and that facial bleeding can be controlled easily.¹ Unfortunately, this is not necessarily always the case. In addition, because facial injuries themselves can be so striking, associated significant hemorrhage can often be overlooked or underestimated. Firm compression with moist sponges will temporarily stop most arterial and venous bleeding. Careful application of digital pressure or definitive ligation of the bleeding point can often control external bleeding. These procedures are best performed in the operating room, with the patient under general anesthesia.

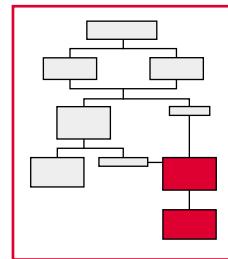

If the source of hemorrhage is in the depths of a narrow laceration, bleeding can be controlled temporarily by packing. Blind clamping or suture ligation can damage important underlying facial structures, particularly branches of the facial nerve; therefore, such procedures must be avoided. Insertion of an anterior pack moistened with 1:10,000 epinephrine may be used to control nasal bleeding. However, persistent nasopharyngeal hemorrhage will necessitate either placement of a posterior pack or ligation of the internal maxillary artery or the external carotid artery.

In major maxillofacial injuries with extensive pharyngeal bleeding, immediate airway access is mandatory, either with an endotracheal tube or by cricothyrotomy. Once airway control has been achieved, the patient should be brought to the operating room for reduction of gross bony injuries, which will often stop uncontrollable hemorrhage. In those rare instances when maxillofacial injuries are associated with serious and uncontrollable hemorrhage, it may be necessary to obtain access to the external carotid artery for ligation of the major trunk or a branch if either is the source of bleeding [see 7:4 Injuries to the Neck].

Definitive Evaluation

When there is no associated airway compromise, facial injuries are a lower priority than potential thoracic, abdominal, or head injuries.

In fact, in the absence of airway compromise and severe hemorrhage, definitive diagnostic evaluation and management of maxillofacial injuries can be delayed until the more life-threatening injuries have been stabilized and treated.

EXAMINATION

Like any other anatomic region, the face must be examined in an orderly fashion, with careful attention paid to gross asymmetry, paralysis, weakness, eye movements, occlusal discrepancies, and ecchymosis. Areas of hypesthesia or anesthesia should be noted. Special attention should be directed toward bimanual palpation of bony prominences within the craniofacial region to look for crepitus, tenderness, irregularities, and step-offs. Palpation should start with the frontal bones and lateral and inferior orbital rims.

The zygomatic arch should be palpated for evidence of depression, and the region of the malar eminence should be evaluated for recession [see Figures 1 through 4]. Fracture of the

Figure 1 Broken nose.

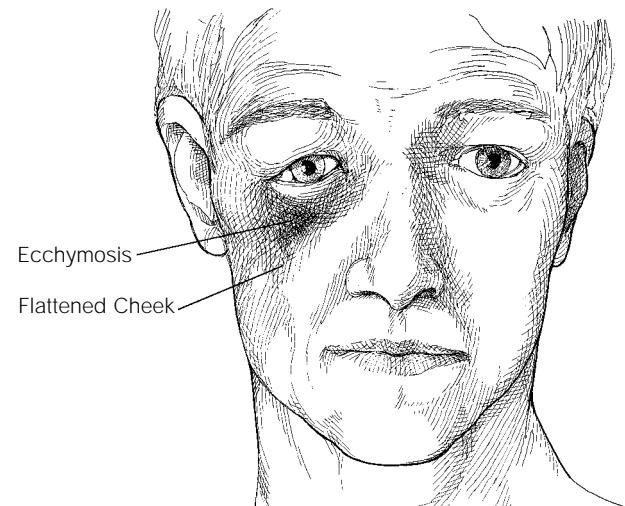

Figure 2 Fractured zygoma.

Figure 3 Infraorbital fracture.

zygomatic complex is often identified with an inferiorly displaced lateral canthus, paresthesias of the infraorbital nerve, visual impairment, displacement of the globe, or trismus secondary to impingement of the zygomatic arch on the coronoid process or temporal muscle.

Orbital evaluation is key to the assessment of facial injuries. The nasolacrimal duct should be inspected, and the distance between the medial canthi should be measured for the presence of telecanthus. (The normal intercanthal distance in the average adult is less than 35 mm.) Pupils should be checked for reactivity, and extraocular muscle motion should be assessed. Diplopia secondary to extraocular muscle entrapment should be determined. The position of the globe should also be assessed; orbital floor fractures may cause enophthalmos and severe swelling, and a blow-in type fracture may result in exophthalmos. A visual acuity test must be performed before any surgical intervention for correction of facial fractures. An ophthalmologic consultation is essential if there is any evidence of ocular damage, such as lens displacement, hyphema, retinal detachment, acute visual impairment, or global disruption.

Next, the nose should be gently palpated. Any depression, abnormal motion, or deviation of the nasal bones and cartilages should be noted. The nasal cavity should be examined specifically for the presence of septal deviation, septal hematoma, or leakage of cerebrospinal fluid. A septal hematoma can be ruled out by aspiration with an 18-gauge or 20-gauge needle and syringe; if bleeding is present, an incision and drainage and placement of a drain are necessary. If left untreated, a septal hematoma may lead to the development of a saddle-nose deformity. Flattening of the face, or dish-face deformity, is characteristic of midfacial fractures.

Mobility of the maxilla is determined by placing one hand over the bridge of the nose while the other grasps the palate and upper dentition and moves the maxilla anteriorly and posteriorly, checking for separation of the midfacial structures. The mandible should be palpated carefully with both hands to locate any intraoral mucosal lacerations or lesions. Bimanual

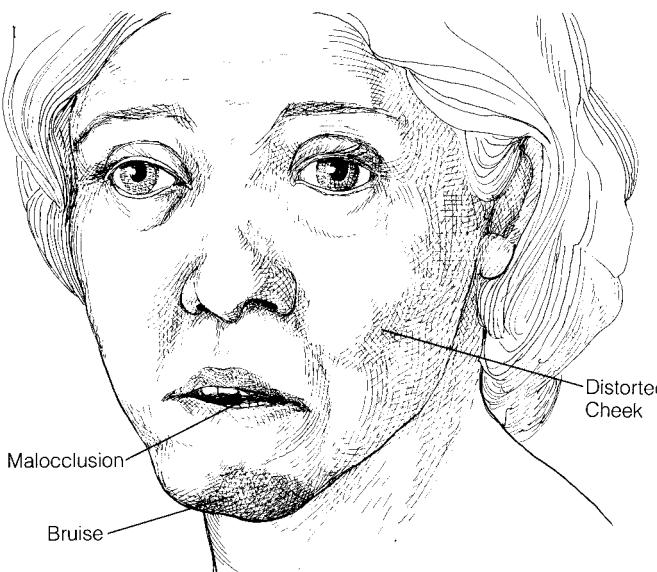

Figure 4 Fractured mandible.

palpation of the mandible is accomplished by placing the thumbs over the molar occlusal surfaces and the index fingers externally over the inferior border of the mandible and torquing the bone to check for movement. Any missing or mobile teeth must be recorded. The floor of the mouth should also be examined with bimanual palpation.

The ears should be examined for evidence of lacerations or contusions of the external auditory canal that may be caused by condylar neck fractures. A simple diagnostic method is to insert the fingertip into the external auditory canal on one side; if no movement can be determined with mandibular excursion, a diagnosis of condylar fracture can be made.

FACIAL X-RAYS

A spectrum of available radiologic modalities plays a significant role in the diagnosis and treatment of facial injuries. Appropriate studies are mandatory. In addition, x-rays provide an excellent permanent record for medicolegal purposes. The initial x-rays of patients in the emergency room (the first level for assessment and clarification of maxillofacial injuries) should be performed using conventional films and should consist of a cervical spine series (with all the cervical vertebrae adequately visualized), skull x-rays, and facial x-rays, including the anteroposterior, lateral, Waters, Towne, submentovertex, panorex, and mandibular views. More definitive x-rays can be obtained later for complete evaluation of specific injuries. The Caldwell view defines the orbital walls and the frontal sinus structures. The Waters view is important for determining the bony continuity of the orbit, nose, zygoma, and lateral portion of the maxilla. The lateral skull view is helpful for evaluation of frontal sinus fractures. Oblique views of the orbit are excellent for demonstrating the apex and the medial, lateral, and orbital walls.

The lateral oblique and modified Towne views are used to evaluate the mandible. The lateral oblique is the most common and useful view and provides evaluation of the body, angle of the body, and the ascending ramus. A posteroanterior view is helpful in assessing the symphyseal and body regions as well as

the condylar and coronoid processes. Panoramic x-rays are the best screening views for assessing mandibular fractures, especially within the condyles. Associated injuries to the dentition and supporting structures may necessitate dental spot films for more specific information.

OTHER STUDIES

Computed tomographic scanning can be of great value in diagnosing the more complex traumatic injuries, such as craniomaxillofacial injuries and associated central nervous system injuries. Computed tomography is used to evaluate most critically injured patients with craniocerebral trauma, and the studies can easily be extended to include the patient's facial skeleton with little additional risk. Both 3 mm axial and coronal CT cuts of the facial skeleton should be obtained, especially for examination of the orbit. A lateral oblique scan through the midportion of the globe provides additional information regarding the bony architecture of the orbit. This information can be reformatted, and three-dimensional reconstructions can be made for further evaluation. Magnetic resonance imaging is proving to be of benefit in assessing both bony and soft tissue injuries. Arteriography may be needed to evaluate the source of a hemorrhage or to rule out major vascular injuries.

Treatment of Soft Tissue Injuries

Soft tissue injuries are most often the result of penetrating trauma but can also be the result of blunt trauma [see Treatment of Maxillofacial Fractures, below]. Any patients who need general anesthesia, such as a child or a patient with extensive complex lacerations involving deeper structures, should be treated in the operating room after appropriate evaluation of their overall status. Soft tissue injuries can involve nerves, parotid ducts, lacrimal ducts, and other critical facial structures. Abrasions must be thoroughly cleaned, and lacerations should be irrigated with normal saline and conservatively debrided as necessary. With deeply embedded foreign material, debridement and irrigation must be particularly meticulous and extensive to prevent residual cosmetic deformities. Dermabrasion is especially good for large involved areas. Most facial lacerations can be closed primarily with standard suturing procedures [see 1:7 Acute Wound Care]. Antibiotic coverage is left to individual preferences; however, 24 hours of prophylactic perioperative antibiotic coverage with a cephalosporin is strongly recommended. The examiner must always consider the possibility of underlying injuries, and careful palpation and visualization of important underlying structures should be part of the definitive wound evaluation and treatment.

Local anesthetic agents used in the head and neck region should always contain epinephrine for hemostasis. To decrease pain and discomfort, the local anesthetic should be administered through the margins of the wound rather than through the surrounding skin. Regional nerve blocks are preferred for suture closure of lacerations involving the forehead, cheeks, lips, and chin. The forehead can be blocked by local infiltration of the supraorbital nerve, which is located just superior to the eyebrow. The upper lip, side of the nose, and adjacent skin can be blocked by anesthetizing the infraorbital nerve. Injection of the mental nerve, located between the first and second bicuspid teeth, will anesthetize the lower lip and surrounding chin. Regional blocks also provide the advantage of minimizing tis-

sue damage to already traumatized skin and lead to less scar formation.

NERVE INJURIES

The facial nerve is the nerve most vulnerable to maxillofacial trauma, and its function must be thoroughly evaluated before the administration of any local anesthetic. In addition, facial nerve injuries result in the most serious functional disabilities and aesthetic defects. Sensory nerves, such as the infraorbital and supraorbital nerves, can also be involved in traumatic injuries; however, the associated hypesthesia causes only minimal long-term disability.

Whenever the posterior half of the parotid gland suffers a deep laceration, it should be assumed that a major branch of the facial nerve has been divided, and the face should be carefully examined. If there is a clean, sharp division of one of the five major trunks or of the proximal main nerve trunk, it can be repaired immediately with microanastomotic techniques. If there is substantial nerve loss, the nerve ends should be identified and appropriately tagged for future nerve grafting. If a nerve laceration occurs anterior to the region of the lateral canthus, nerve repair is generally unnecessary because there is sufficient crossover from the opposite side. Peripheral branch injury is manifest by inability to raise the eyebrow (frontal branch), inability to close the eyelids (malar), smoothness of the cheek (infraorbital), inability to smile (buccal), and inability to frown (marginal mandibular).

PAROTID DUCT INJURIES

The parotid duct is located between the parotid gland and the oral mucosa, opening opposite the second upper molar. Any deep laceration of the anterior parotid gland can damage this duct. If there is a possibility that the parotid duct is injured, the orifice of Stensen's duct should be probed. Should the probe enter the wound, division of the duct is verified. The proximal cut end of the duct can be located by expressing saliva from the gland. A catheter should then be passed through Stensen's duct and through the area of laceration, and the duct should be repaired over the catheter [see Figure 5].

LACRIMAL DUCT INJURIES

Whenever there is a laceration involving the medial canthal region, a lacrimal duct injury should be assumed. Acute reconstruction of the lacrimal duct is controversial. If both ends of the duct can be easily discerned, the severed ends should be realigned, splinted internally, and repaired. This procedure is best accomplished over a fine Silastic rod. Dissection to locate the residual parts of the duct should be delicate and meticulous, because traumatic dissection can aggravate the injury and result in further permanent damage.

SCALP INJURIES

When scalp injuries are repaired, extensive shaving is unnecessary. Scalp injuries can be associated with profuse bleeding because of the scalp's extensive vascular supply. To obtain adequate control of hemorrhage from the wound margins, closure can be achieved in a single layer with a running, locking 3-0 chromic suture on a large cutting needle. Associated underlying skull fractures are always a possibility, and the skull should be palpated and inspected through any full-thickness scalp wound.

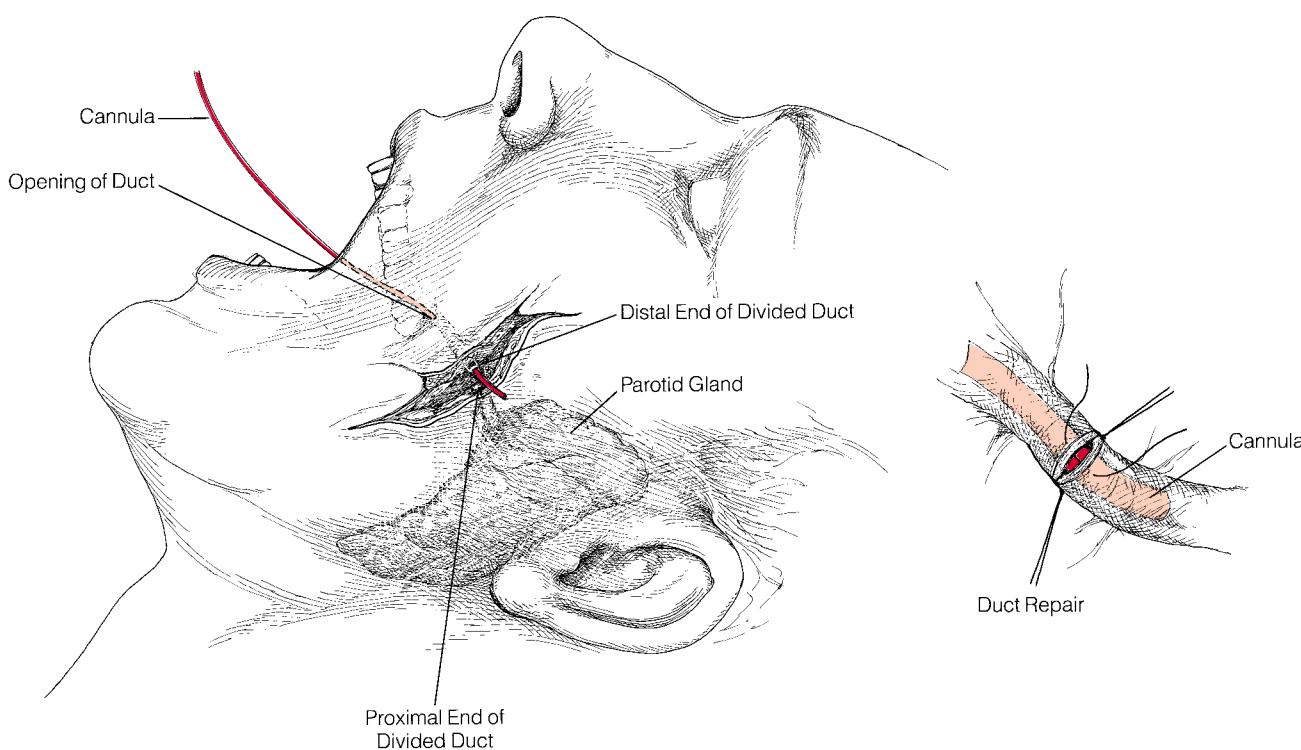

Figure 5 Injuries to the parotid duct are repaired by passing a catheter through Stensen's duct and through the area of laceration and then repairing the parotid duct over the catheter.

EYELID INJURIES

If the patient reports excessive eye pain, the initial examiner must always first rule out an associated ocular injury. In addition, when faced with through-and-through lid lacerations, the examiner must perform a very careful eye examination. Lacerations of the eyelid should be meticulously repaired by approximation of the margins of the lid defect, followed by closure of the laceration in three layers. The conjunctiva may be left unsutured if good apposition can be obtained by closing the tarsal plate and the pretarsal muscles that occupy the middle layer, which is preferably closed with fine absorbable sutures. Fine nonabsorbable skin sutures are employed to close the final layer. All skin sutures should be removed within 48 hours. When there is extensive tissue loss, it may be necessary to use plastic techniques to mobilize sufficient conjunctiva for closure.

EYEBROW INJURIES

For optimal cosmetic results, the eyebrows should be closed meticulously in layers with careful alignment of the eyebrow margins. Lacerations passing through the eyebrow should not be shaved; leaving them intact facilitates good plastic closure. Because the hairs of the eyebrow run obliquely to the surface of the skin, any incision for debridement should follow the line of the eyebrows to avoid further loss of hair.

EXTERNAL-EAR INJURIES

If avulsions of the ear are properly repaired, the chances are good that they will heal because of the highly vascular pedicle. Circulation is maintained if even a small pedicle is present.

Repair of ear wounds should be done in three layers by using fine nonabsorbable sutures to approximate the cartilage and the skin. If the ear is completely detached, the cartilage should be preserved within a subcutaneous pocket in the mastoid region for future reconstruction.

Hematomas can occur secondary to the shearing of the vascular mucoperichondrium from the underlying cartilage. These must be evacuated early, and a conforming pressure dressing should be placed to maintain the normal ear contour.

NASAL INJURIES

Through-and-through lacerations of the nose and near-avulsion injuries are cosmetic problems. Because the nose is extremely vascular, repair of these injuries should be especially meticulous and done in layers. The cartilage and skin should be aligned with fine nonabsorbable interrupted sutures. Absorbable sutures should be employed for repair of the mucosa. Key cosmetic points (i.e., epidermal-mucosal junctions, nasal fold junctions, or critical angles in jagged lacerations) should be sutured first to ensure that no deformity results.

LIP INJURIES

If the margin of the lip has been divided, the vermillion border should be carefully identified and tattooed, and the first sutures should be placed to approximate this critical margin. A common problem in the treatment of lip injuries is that it may become more difficult to identify landmarks when they are obliterated by local anesthetic injections or associated edema.

Treatment of Maxillofacial Fractures

Management of maxillofacial fractures can be extremely challenging. The common maxillofacial fractures include nasal, mandibular, orbital, zygomatic complex, sinus (e.g., maxillary, sphenoid, ethmoid, and frontal), and maxillary fractures (e.g., Le Fort I, II, or III). Management of these fractures often requires sophisticated specialty treatment involving plastic surgeons, ophthalmologists, neurosurgeons, otolaryngologists, or a combination of these.²⁻⁷

FRONTAL SINUS FRACTURES

The frontal sinus region is prone to injury because of its prominent location and relatively thin anterior bony wall.^{8,9} Injuries to the frontal sinus area require comprehensive treatment, often with a team approach. The key to treatment lies in determining the status of the nasofrontal ducts.^{10,11} Patients with such injuries also require careful, regular, long-term follow-up care because potentially life-threatening complications, such as meningitis, osteomyelitis, and mucopyocele, may develop.¹²⁻¹⁵

NASAL AND NASO-ORBITO-ETHMOIDAL FRACTURES

The nasal bone is the most commonly fractured facial bone.¹⁶ Before any treatment is embarked on, it is always helpful to have the patient provide a preinjury photo of himself or herself so that it can be determined whether the nasal deformity is from the acute episode.¹⁷ If a patient is seen almost immediately after injury and the associated swelling and ecchymosis are minimal, closed reduction can be performed at once. Nasal bone fractures can be reduced simply by inserting a scalpel handle or large hemostat into the nostril; the fracture segments can then be elevated and relocated. Usually, the nasal cavity is packed with petroleum jelly gauze to maintain alignment of the fracture and nasal septum, and a malleable splint is taped over the nose to provide counterpressure and assist in maintaining alignment. Packing is removed within 48 hours. However, treatment is generally not urgent and, depending on the individual situation, may be delayed for 7 to 10 days.

Naso-orbito-ethmoidal fractures generally occur secondary to direct force applied over the nasal bridge, resulting in posterior displacement of bony structures and involvement of the medial canthus, lacrimal duct, canaliculi, and sac.¹⁸ Repair of naso-orbito-ethmoidal fractures can be extremely challenging because of the number of important structures involved and their extensive comminution.¹⁹ Satisfactory surgical management should be conducted through a coronal approach, thereby permitting precise three-dimensional reduction and stabilization and extensive primary bone grafting for replacement augmentation.²⁰ If there is associated CSF rhinorrhea, neurosurgical assistance should be obtained and early fracture reduction done.

ORBITAL FRACTURES

Orbital fractures can occur as isolated events or as a component of more extensive injuries. Orbital fractures, such as lacrimal duct lacerations and injuries to the globe, require highly specialized management with the aid of an ophthalmologist. Naso-orbital fractures with telecanthus should be treated with open reduction and fixation, as should all displaced fractures of the orbital rim and floor.^{21,22}

ZYGOMATIC FRACTURES

The zygoma is a tetrapod structure that forms the malar prominence and the inferior and lateral aspects of the orbit. Fractures of the zygomatic complex should be repaired to prevent the development of serious aesthetic and functional deformities. Satisfactory stabilization requires three-point fixation achieved through incisions placed within the regions of the upper and lower lids and the upper buccal sulcus.²³

MAXILLARY FRACTURES

In 1901, maxillary fractures were classified by René Le Fort into three types.²⁴ Although the Le Fort classification system remains entrenched in the literature and serves as a basis for both communication and description, it is rare that patients exhibit pure Le Fort fracture patterns. Instead, trauma sur-

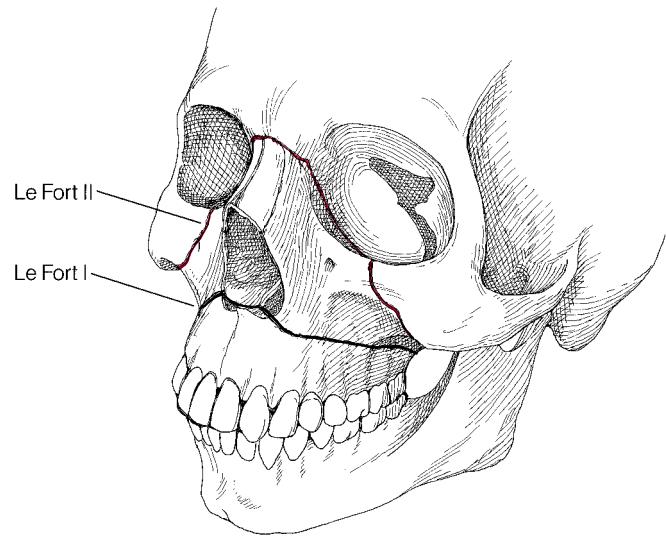

Figure 6 Le Fort I fractures (black line) affect the upper jaw alone. In Le Fort II fractures (red line), the upper jaw and the central portion of the face are separated from the skull.

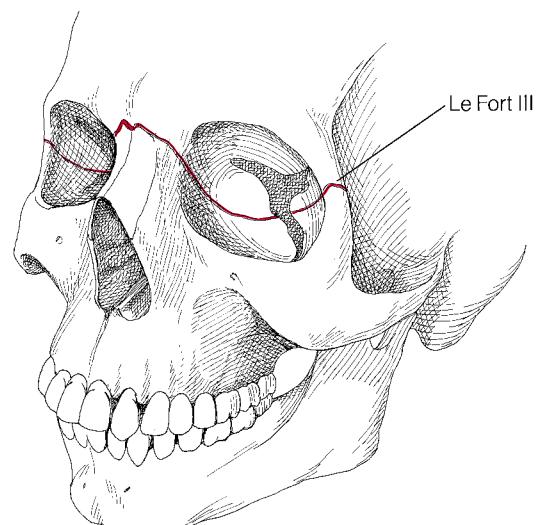

Figure 7 In Le Fort III fractures, all of the facial bones are separated from the skull.

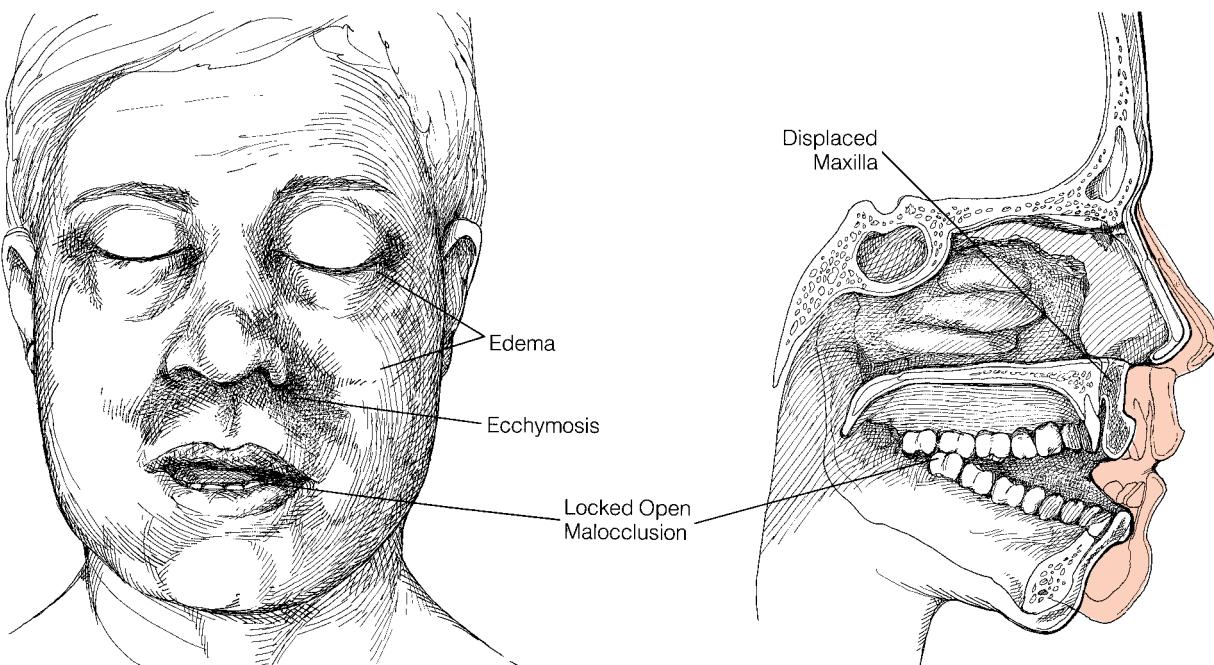

Figure 8 Findings in patients with Le Fort III maxillary fractures immediately after injury, before obliterative edema develops.

geons are generally challenged by severe bony comminution and distraction.

Le Fort I, or lower maxillary fractures, are the simplest type of maxillary fracture, consisting of horizontal detachment of the tooth-bearing segment of the maxilla at the level of the nasal floor [see Figure 6]. Le Fort II, or central or pyramidal fractures, pass through the central portion of the face, which includes the right and left maxillae, the medial aspect of the antra, the infraorbital rim, the orbital floor, and the nasal bones. Le Fort III, or craniofacial disjunction, is characterized by complete separation of all facial structures from the cranium [see Figures 7 and 8]. Le Fort III fractures pass through the upper portions of the orbits as well as through both zygomas.

All Le Fort fractures require highly specialized treatment that involves the use of craniofacial techniques, consisting of exploration and visualization of the entire fracture pattern, precise reduction, and rigid stabilization of bony segments.

MANDIBULAR FRACTURES

Diagnosis of mandibular fractures can usually be made on physical examination. Common findings include malocclusion, intraoral lacerations, and mobility at the fracture site. Radiographs are useful for planning treatment. Fractures of the mandible rarely involve the midline or symphyseal region. Most often, fractures will pass through areas of weakness, including the parasymphysis region and the angle or neck of the condyle [see Figure 9]. The fracture pattern is usually determined by the site and mechanism of injury. Because of the mandible's architectural arrangement, more than one half of mandibular fractures involve multiple sites.

Mandibular fractures are not an emergency, but early defin-

itive treatment results in a decreased number of complications. Preinjury occlusal relations remain the keystone to treatment. Mandibular fractures can be repaired by closed reduction with maxillomandibular fixation or by open reduction and fixation with wire osteosynthesis. However, newer techniques with rigid internal fixation with miniature plates and screws have attained widespread popularity because of increased patient comfort.²⁵⁻³¹ In cooperative patients, a nondisplaced fracture can sometimes be handled conservatively with a dental soft diet and serial x-rays.

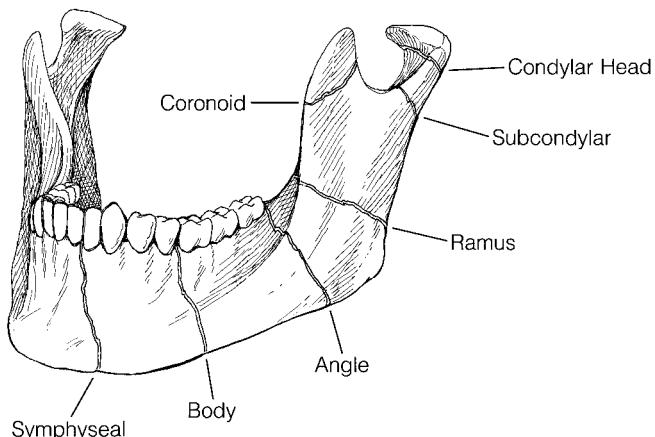

Figure 9 Mandibular fractures.

Discussion

Because the face is so thoroughly exposed, it is one of the most frequently injured areas of the body. Facial injuries can occur under a variety of circumstances, such as automobile accidents, altercations, or falls; more specifically, these injuries can be the results of bites, fires, explosions, lacerations, and contact with sharp or blunt objects. In automobile accidents, shards of glass may penetrate the wound, and these shards may not be radiopaque. If abrasions are present, note should be made of the abrading agent, whether it be grease, particles of dirt, gravel from a highway, or other contaminants. Underlying bony injury may or may not be obvious near the wounds. Because such injuries can expose the patient to tetanus or other anaerobic infections, antitetanic agents should be administered as part of the treatment regimen [see *I:7 Acute Wound Care*]. If treatment is delayed for any reason, a systemic prophylactic antibiotic should be administered. Minor lacerations of the face caused by domestic assaults or household accidents can be adequately treated in the emergency department under local anesthesia [see *I:7 Acute Wound Care*]. Lacerations that are contaminated are often best treated in the operating room with the patient under general anesthesia.

Only as much hair should be removed as is necessary for adequate assessment of the wound or for effective suturing. Eyebrows are best left unshaved to facilitate cosmetic repair. Local anesthesia should be induced, and abrasions should be scrubbed with a stiff brush until every particle of dirt is removed. If the dirt is deeply embedded, some tissue may have to be excised; this step can often be accomplished through the use of a fine curette or the point of a No. 11 blade. If dirt is not removed initially, it may be extremely difficult to remove later, and permanent tattooing may result.

Any dead or devitalized tissue should be excised, but there is no place for radical debridement of facial wounds. Tissue can survive on small pedicles. Full-thickness skin loss can be replaced with a free graft, which provides a better cosmetic match than a split-thickness skin graft [see *3:7 Surface Reconstruction Procedures*]. If the wound is so ragged that it cannot be approximated, careful squaring of the edges may be advisable to facilitate a cosmetic closure. Dead or devitalized subcutaneous tissue should be removed conservatively.

Most facial wounds can be closed by simple suturing. Although the deadline for closure of wounds to other sites is usually 6 to 8 hours, facial wounds, unless heavily contaminated, can be closed as long as 24 hours after injury, particularly if meticulous attention is paid to procedural details. Such details include irrigation of the wound, removal of all foreign bodies, excision of devitalized tissue, and accurate approximation of tis-

sue, with minimal dead space and no tension.

If the wound cannot be closed within the first 24 hours, delayed primary closure may be undertaken after 48 hours. In this event, the patient should be given systemic antibiotics, and the wound should be kept moist and protected as much as possible in the interval before closure. For best cosmetic results, the wound should be closed in multiple layers.

Sutures made of fine monofilament nylon, such as 6-0, are ideal for approximating the skin because they are nonreactive. The sutures should be applied loosely so that they do not strangulate tissue.

Key anatomic points should be identified and tattooed, mucosal edges should be approximated, and irregular margins of the skin should be excised and squared to provide the best possible fit. Margins of damaged structures, such as the nose or the ear, should be defined, and the critical margins should be determined and approximated initially. While the wound is being closed, all dead space in the wound should be obliterated and the edges everted. If the needle is passed through the skin at right angles, the edges of the skin will abut and eversion will occur. If, however, the needle is passed through the skin edge obliquely, inversion will result, and healing will be compromised. Subcutaneous or subcuticular sutures should be placed in such a way as to allow the skin edges to be approximated with minimal tension. If this procedure is done, through-and-through sutures can be removed in 3 days, and no marks will be left on the skin.

Any skin defects that require closure should be closed by grafting. No facial wound should be allowed to heal by granulation, because this would lead to excessive scarring. Instead, a temporary cover in the form of a skin graft should be provided to minimize scar formation; any deformity that results from the graft can be repaired at a later date [see *3:7 Surface Reconstruction Procedures*].

The more complex of the maxillofacial fractures, such as major maxillary fractures, orbital fractures, malar fractures, and mandibular fractures [see *Treatment of Maxillofacial Fractures, above*], must be treated with specialty techniques; therefore, corresponding specialty consultation must be sought. However, in treating these fractures and soft tissue injuries [see *Treatment of Soft Tissue Injuries, above*], the priorities are to ensure adequacy of the airway and to control immediate bleeding. Once these aims have been achieved, none of the defects described, except for facial lacerations, require emergency treatment; they can be repaired days to even months later, if necessary, without jeopardizing a good cosmetic result.

4 INJURIES TO THE NECK

David H. Wisner, M.D., F.A.C.S., and Robert C. Jacoby, M.D., F.A.C.S.

Assessment and Management of Neck Injuries

Injuries to the neck can be secondary to both blunt and penetrating trauma. Occasionally, blunt trauma to the neck causes injury to the airway, the carotid artery system, or the vertebral artery system. Blunt airway injuries are sometimes surgical emergencies; the approach to these injuries is similar to that of penetrating injuries [see Airway Compromise and Isolated Laryngotracheal Injuries, below]. Blunt arterial injuries are almost always discovered by angiography and are usually treated nonoperatively [see Discussion, Screening Criteria for and Recommended Management of Blunt Cervical Arterial Injuries, below]. In the rare instance of a patient who undergoes operative treatment for a blunt injury to carotid or vertebral arteries, the operative and postoperative principles for penetrating arterial injuries should be applied [see Injuries to the Carotid Arteries, Jugular Veins, Pharynx, and Esophagus, below].

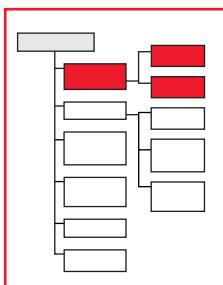

Patients with penetrating wounds of the neck can be loosely categorized into the following six groups according to the location and nature of the wound:

1. Patients with emergency or impending airway compromise.
2. Patients with an isolated injury to the larynx or trachea.
3. Patients with suspected or known injuries to the carotid arteries, jugular veins, pharynx, or esophagus.
4. Patients with wounds at the base of the neck (particularly when intrathoracic injury is suspected).
5. Patients with known injury to the vertebral arteries.
6. Patients with obviously superficial wounds of the neck.

Division of patients into these groups, though somewhat arbitrary, helps in choosing an incision and determining the initial operative priorities at exploration.

Airway Compromise

Some patients will present with emergency or impending airway compromise. The initial priority should be to ensure an adequate airway. In some patients, this requires orotracheal intubation. In other patients, a surgical airway must be created by means of either cricothyrotomy (in emergency cases) or tracheotomy (in less extreme cases). Nasotracheal intubation is not advisable in most trauma settings.

CRICOHYROTOMY

In true emergency situations, a cricothyrotomy should be done. The landmarks of the superior (notched) and inferior borders of the thyroid and the cricoid cartilage should be palpated. For this task, it is helpful to stand on the patient's right side (for a right-

handed surgeon) and to stabilize the cartilaginous framework by holding the thyroid cartilage in place with the left hand. A transverse incision should be made at the level of the cricothyroid membrane and developed rapidly through the subcutaneous tissue [see 7:1 Life-Threatening Trauma]. As with any transversely oriented incision of the anterior neck, the anterior jugular veins are at risk for injury. If such injury occurs, the damaged veins are best controlled with suture ligation after an airway is obtained. In true emergency circumstances when the exact site of injury is unknown, a vertical rather than transverse incision should be used to allow access to as much of the anterior surface of the airway as possible and to decrease the chance of injury to the anterior jugular veins.

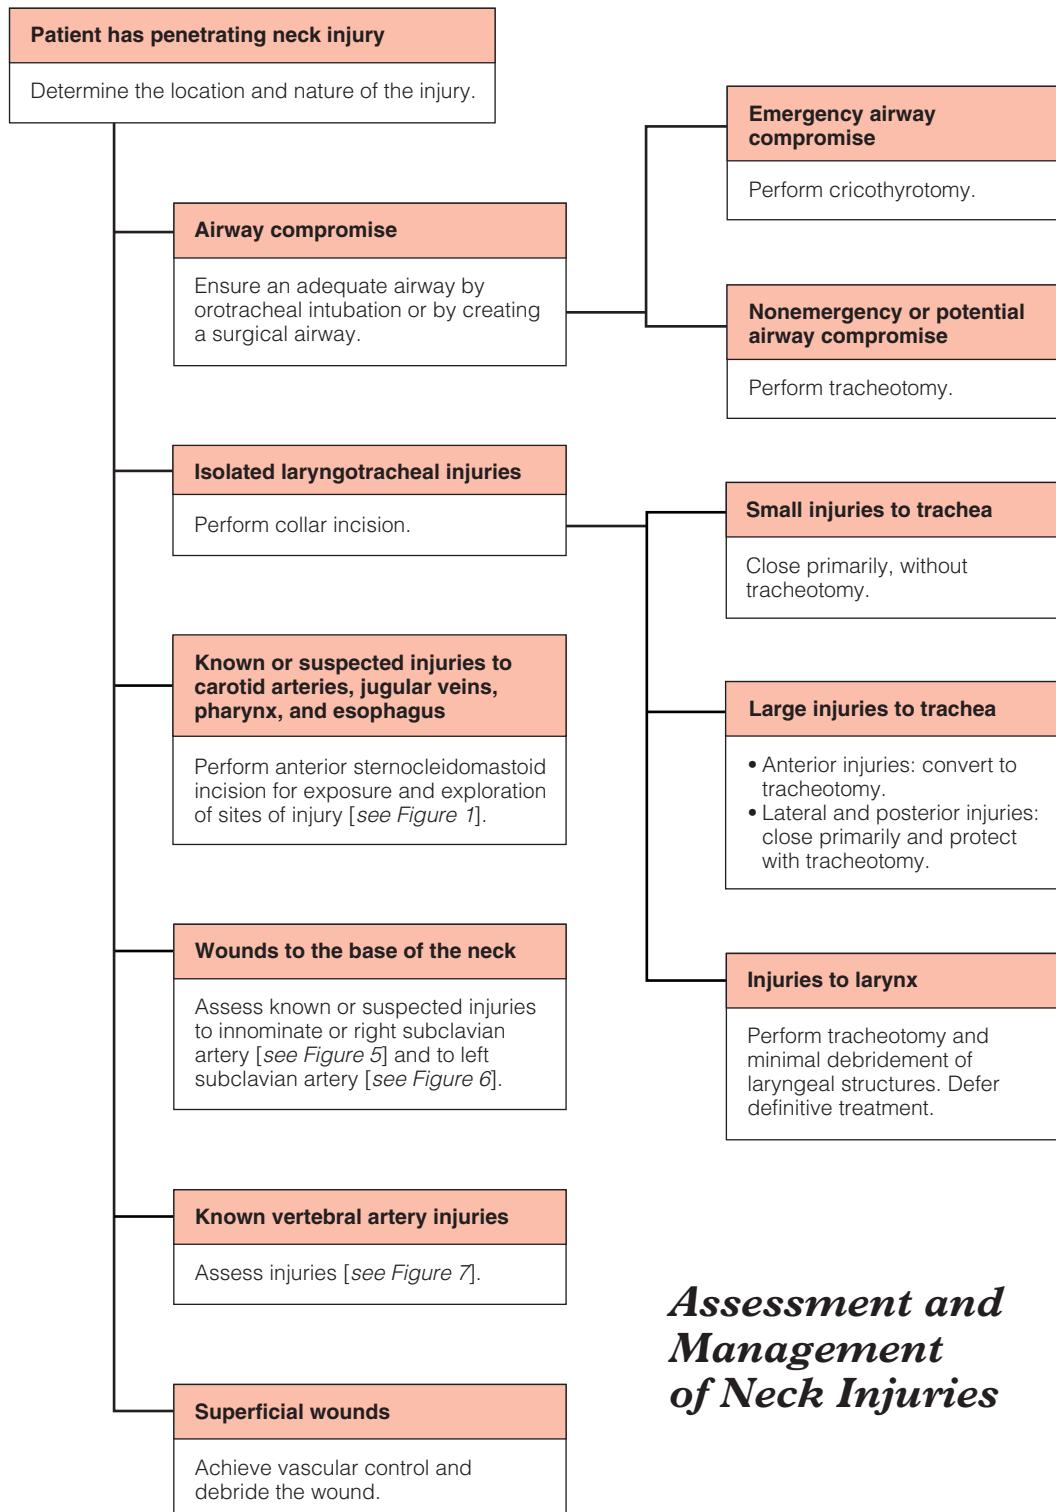

After the skin and the subcutaneous tissue have been divided, an incision should be made through the cricothyroid membrane. This is most rapidly done with a No. 11 knife blade. It is important to avoid pushing the knife blade too far and causing injury to the posterior wall of the airway or to the posteriorly located hypopharynx and esophagus. After the incision has been made, the opening should be enlarged by placing the knife handle in the incision and twisting it 90°. At this point, an indwelling endotracheal airway should be placed and secured. In most adults, a No. 6 airway is the largest that can be inserted; a No. 4 or larger airway is adequate for initial placement. Any incisional bleeding from the anterior jugular veins or other vessels should be controlled. Cricothyrotomies should be converted to tracheotomies within 48 to 72 hours as long as the patient's general condition permits [see Discussion, Conversion of Cricothyrotomy to Tracheotomy, below].

TRACHEOTOMY

In some instances, airway compromise may not be extreme but a surgical airway may still be necessary for safety or subsequent management of a laryngeal injury. In such circumstances, a tracheotomy rather than a cricothyrotomy should be done, because cricothyrotomy is more likely than tracheotomy to make definitive treatment more difficult.

The initial approach for emergency tracheotomy is similar to that for cricothyrotomy, the difference being that a so-called collar incision is made at a point one to two fingerbreadths inferior to the level of the cricothyroid membrane. The incision should be wide enough to provide rapid exposure and should extend as far as the anterior border of the sternocleidomastoid bilaterally. Anteriorly located injuries at the level of the cricoid or the trachea may already have a hole in the airway. In such cases, if the need for a surgical airway is immediate, the wound should be enlarged and used as a route of access to the airway.

On rare occasions, the injury is in the distal cervical or proximal intrathoracic trachea. In such circumstances, access to the trachea may not be possible through a cervical incision alone. Median sternotomy and lateral retraction of the innominate artery and the left internal carotid artery allow exposure of the anterior surface of the trachea at the thoracic inlet. Right thoracotomy provides access to the more distal intrathoracic trachea.

Assessment and Management of Neck Injuries

Isolated Laryngotracheal Injuries

Most commonly, the presence of an isolated laryngotracheal injury is not recognized preoperatively. On occasion, however, isolated injuries to the larynx and trachea are recognized preoperatively on the basis of a suspicious history and the results of diagnostic studies, such as laryngoscopy and bronchoscopy.

Injuries to the larynx that result in airway compromise should be treated initially with a collar incision for the creation of a surgical airway [see Airway Compromise, Tracheotomy, *above*]; however, definitive treatment should be deferred. Minimal debridement of laryngeal structures should be carried out during the initial operative procedure. Injuries to the larynx should be handled on a semielective basis by otolaryngologists with expertise in laryngeal repair and reconstruction. Further investigation of the larynx, including laryngeal x-rays, laryngoscopy, and computed tomography, may be necessary.

Small injuries of the trachea can be repaired primarily without tracheotomy. Absorbable 3-0 or 4-0 sutures should be placed transversely, if possible, and should include tracheal rings above and below the site of injury. Large anterior defects should be converted to a tracheotomy, whereas defects to the lateral or posterior aspects of the trachea should be closed primarily and protected with a tracheotomy. Tension can be relieved from a repair by mobilizing the trachea proximally and distally. During this mobilization, the recurrent laryngeal nerves are subject to injury if the dissection is carried into the tracheoesophageal groove. Laryngotracheal injuries do not require routine drainage unless there is an associated injury to the pharynx or esophagus [see Injuries to the Carotid Arteries, Jugular Veins, Pharynx, and Esophagus, *below*].

If a large segment of trachea has been destroyed, primary anastomosis can be accomplished for defects up to five or six tracheal rings in length. Anastomosis requires mobilization of the intrathoracic trachea inferiorly and the laryngeal complex superiorly and is best done electively.^{1,2}

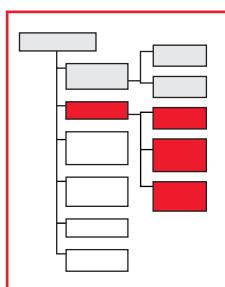

Patients with laryngeal injuries should be watched carefully in the postoperative period for signs of mediastinitis, which may result from persistent airway leak or a missed pharyngoesophageal injury. The chest x-ray should also be checked for pneumomediastinum as a sign of continued airway leakage, particularly in patients who remain on positive pressure ventilation.

Injuries to the Carotid Arteries, Jugular Veins, Pharynx, and Esophagus

Probably the most common situation in penetrating cervical trauma is the patient with underlying structural injuries, the precise location and nature of which are unknown. An anterior sternocleidomastoid incision provides good access to most of the vital structures in the neck and can be done relatively rapidly.

STERNOCLIDEOMASTOID INCISION

If the location of underlying neck injuries is either unknown or confirmed by preoperative studies to be in the carotid arteries, the jugular veins, the pharynx, or the esophagus, an incision along the anterior border of the sternocleidomastoid muscle should be used [see Figure 1]. The sternocleidomastoid incision is particularly

important in patients with a true emergency condition, such as external bleeding, a focal neurologic deficit, coma, or an expanding neck hematoma. When bilateral exploration is necessary, separate sternocleidomastoid incisions should be done.

An anterior sternocleidomastoid incision has several important advantages [see Figure 2]. For example, it can be lengthened to provide more extensive proximal or distal exposure. If a superior extension to below the earlobe is necessary, the incision should be curved posteriorly to avoid injury to the marginal mandibular branch of the facial nerve. Another advantage of the sternocleidomastoid incision is that it provides exposure of the carotid sheath, the pharynx, and the cervical esophagus.

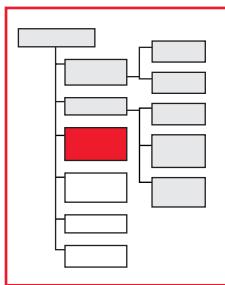

Operative Technique

The patient is placed in the supine position, with the head turned away from the side of exploration and the neck extended. In this regard, it is helpful to clear the cervical spine before operation if possible. If both sides of the neck are to be explored, the head is left in the midposition, facing up. The entire neck and the appropriate side of the face and head are prepared. The anterior chest is also included in the preparation in case a median sternotomy is necessary for proximal control [see Exploration and Exposure, Arteries and Veins, *below*]. The patient is draped so that the lateral neck is left as the primary field while the chest is kept easily accessible. The lateral chin and the tip of the earlobe are also kept in the field to provide landmarks. If the possibility exists that the injury is to the distal subclavian artery or the axillary artery, the patient's arm should be draped in a way that allows it to be manipulated.

The skin incision is carried through the dermis and the platysma. After the platysma is divided in the direction of the incision, the investing fascia overlying the anterior border of the sternocleidomastoid muscle is incised, and the muscle is retracted laterally and posteriorly to expose the carotid sheath. It is often necessary to divide a venous branch that connects the external jugular vein posterolaterally to the anterior jugular vein anteromedially. This vein lies in a plane immediately deep to the platysma.

Exploration and Exposure

When possible, proximal and distal control should be obtained before exploration of a carotid artery injury. In practice, obtaining proximal control before entering a perivascular hematoma is all that is absolutely necessary. If necessary, distal bleeding can be controlled with digital pressure while the dissection of the injured vessel is completed. Although it is often difficult to obtain control before addressing the area of injury, proximal and distal control of the vessel should be obtained at some point before any attempts at definitive repair. For injuries near the carotid bifurcation, it is necessary to control the common, internal, and external carotid arteries, as well as the proximal branches of the external carotid artery.

Arteries and veins The initial exploration should attempt to rule out arterial or venous injury, unless an overt airway injury is present and requires immediate attention [see Airway Compromise, *above*]. The location of the carotid artery can then be confirmed by the presence of a pulse. It is often necessary to retract the jugular vein posterolaterally to provide adequate arterial exposure [see Figure 3]. During dissection of the carotid sheath and retraction of the jugular vein, care must be taken to keep from injuring the associated vagus nerve. Jugular vein retraction is facilitated by division of the facial vein, which is superficial to the carotid bifurcation. The severed ends of the facial vein should be suture-ligated to ensure that the ties will not come off with

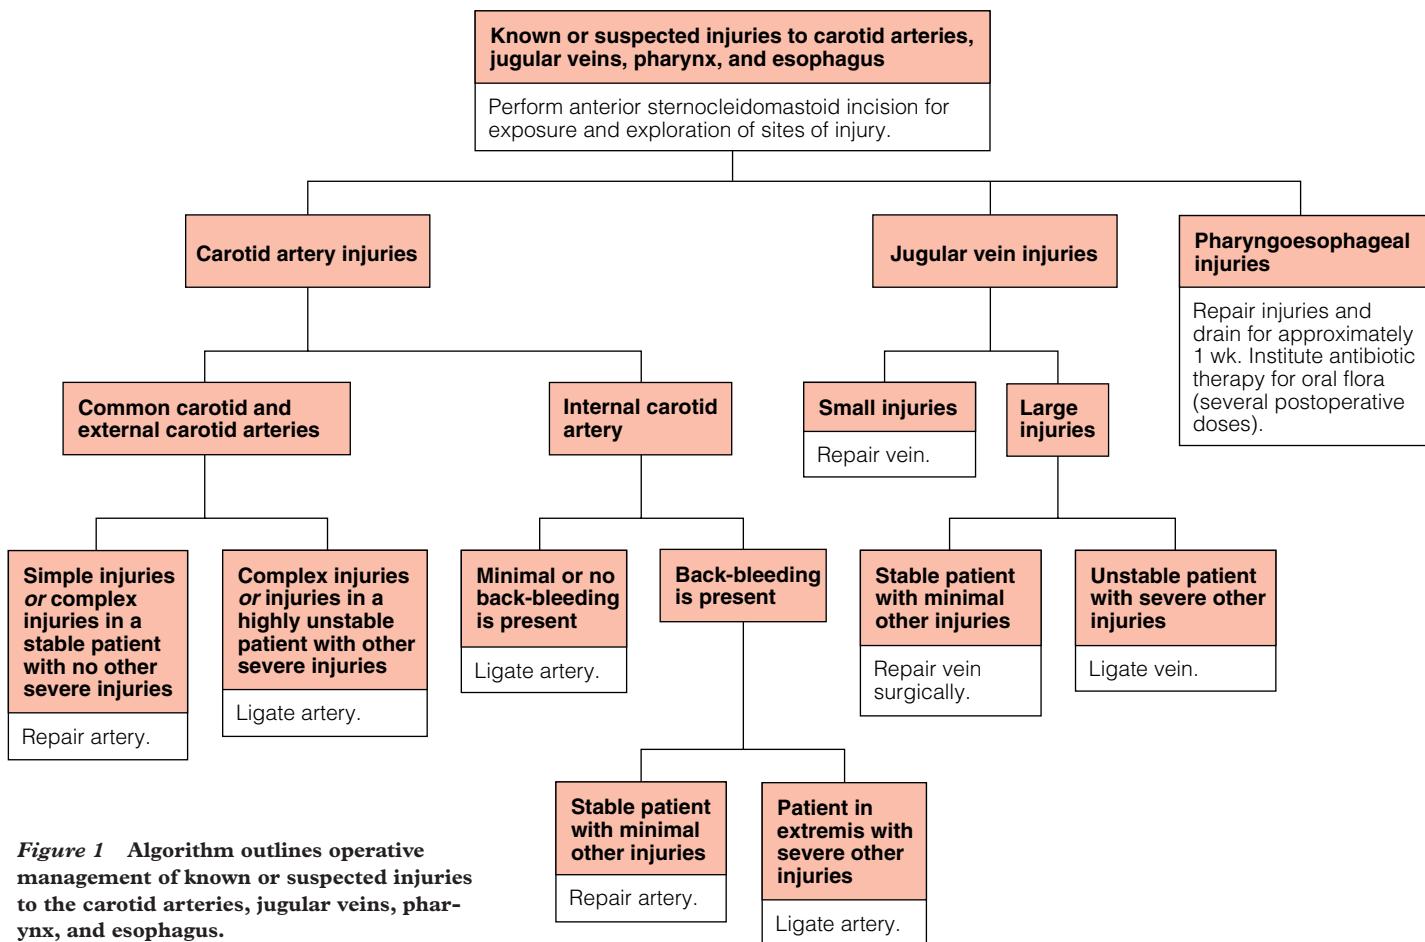

Figure 1 Algorithm outlines operative management of known or suspected injuries to the carotid arteries, jugular veins, pharynx, and esophagus.

increased intravenous pressure in the postoperative period—for example, secondary to a cough or a Valsalva maneuver.

Exposure of the proximal common carotid artery at the base of the neck is easier after division of the omohyoid muscle at the point where its superior and inferior bellies are joined. Division of the omohyoid muscle results in minimal functional deficit postoperatively. For proximal control of the common carotid artery, it may be necessary to enter the chest via median sternotomy. To minimize blood loss, the decision to do a sternotomy should be made without undue delay. Control of the proximal right common carotid artery via this route is relatively easy and is accomplished by first obtaining control of the innominate artery and then dissecting distally. Proximal control of the left common carotid artery via median sternotomy is more difficult, because its origin from the aortic arch is more posterior than the origin of the innominate artery.

Exposure of the distal internal carotid artery can be very difficult, particularly if there is an injury in that location. As dissection is carried distally on the internal carotid artery, a number of important structures should be identified and protected [see Figure 4]. The hypoglossal nerve is usually encountered within several centimeters of the carotid bifurcation and should be dissected free of the internal carotid and retracted upward. This is facilitated by division of the occipital artery, which crosses superficial to the hypoglossal nerve on its course from the external carotid artery toward the occiput. It is also helpful to divide the ansa cervicalis branches that run inferiorly from the hypoglossal nerve to supply the muscles of the neck. Injury to the hypoglossal nerve results in impaired motor function of the tongue and can lead to dysarthria

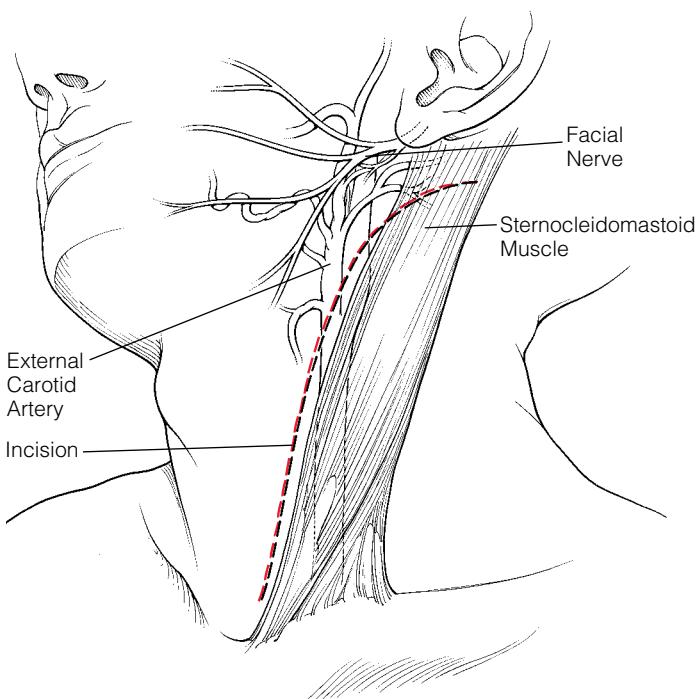

Figure 2 In general, exposure of structures in the anterior areas of the neck is best done through an incision oriented along the anterior border of the sternocleidomastoid muscle.

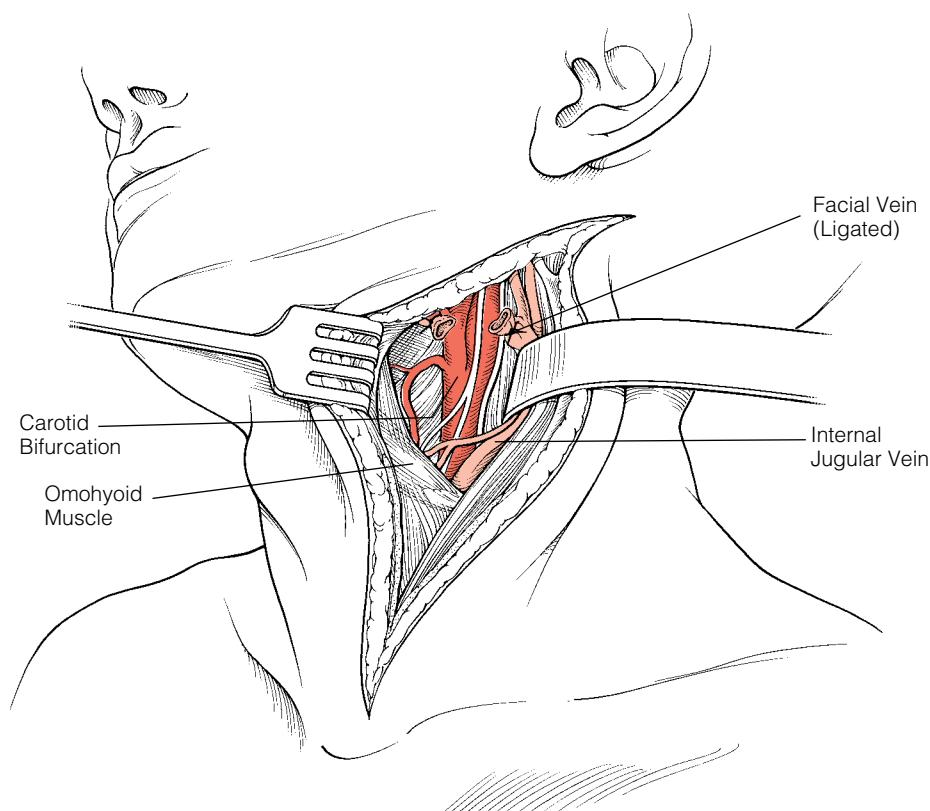

Figure 3 After a plane along the anterior border of the sternocleidomastoid muscle has been developed, dissection is carried down to the level of the carotid sheath. Suture ligation of the facial vein facilitates this dissection. Lateral retraction of the internal jugular vein improves exposure of the carotid bifurcation.

and dysphagia. Injury to or sectioning of the ansa cervicalis causes little or no morbidity.

Further distal exposure of the internal carotid artery may require unilateral mandibular subluxation or division of the ascending ramus of the mandible.³ Such maneuvers are somewhat easier when the patient is nasotracheally intubated. They increase the size of the small area immediately behind the condyle and allow easier division of the stylohyoid ligament and the styloglossus and stylopharyngeus muscles. These three structures can be divided together adjacent to their common origin at the styloid process. If this is done, care should be taken to preserve the facial nerve, which lies superficial to these muscles and must be dissected free of the muscles before they are divided. The underlying glossopharyngeal nerve, which lies deep to these muscles and superficial to the internal carotid artery, should also be protected by dissecting it free of the muscles before their division. Injury to the facial nerve results in loss of function of the muscles of facial expression. If the glossopharyngeal nerve is injured, loss of motor and sensory supply to parts of the tongue and pharynx increases the risk of aspiration.

Once the muscles originating from the styloid process have been divided, the styloid process itself can be resected to gain a further short distance of distal exposure. In very rare instances, it may prove useful to remove portions of the mastoid bone to provide even more distal exposure of the internal carotid artery as it enters the carotid canal. This can generally be accomplished via a cervical incision. For more distal lesions, it is necessary to place a posterolateral scalp incision, reflect a medially based scalp flap, and divide the ipsilateral external auditory canal. This approach results in better exposure of the mastoid process and allows exposure of

the intrapetrous portion of the internal carotid after removal of the overlying bone of the mastoid with a high-speed bone drill.

Pharynx and esophagus The oropharynx, hypopharynx, and cervical esophagus are exposed via the same anterior sternocleidomastoid incision used for arterial and venous injuries. If the patient has a known right-side injury, the incision should be made in the right neck. If the injury is on the patient's left side or if the exact site of injury is unknown, the exposure should be made from the left because the cervical esophagus is located slightly to the left of the midline. After the initial incision, the contents of the carotid sheath are retracted laterally to expose the lateral aspects of the pharynx and the esophagus. This maneuver is made easier if the anesthesiologist places a large colored esophageal dilator through the mouth. The dilator makes identification of the otherwise flat esophagus easier, and the colored tubing of the dilator can sometimes be seen through defects in the esophageal wall.⁴

Sometimes, a pharyngoesophageal injury is suspected but cannot be confirmed preoperatively. In such cases—especially when the injury is more than 1 or 2 hours old—salivary amylase may be present in the wound, giving the surgeon's gloves a greasy feel. The presence of salivary amylase can be a valuable clue to the existence of an otherwise unknown occult injury.

CAROTID ARTERY INJURIES

During dissection of the external carotid artery, the branches should be identified. They can be ligated if necessary but should be preserved if possible (this usually depends on whether they can be temporarily occluded with vessel loops, a looped suture, or

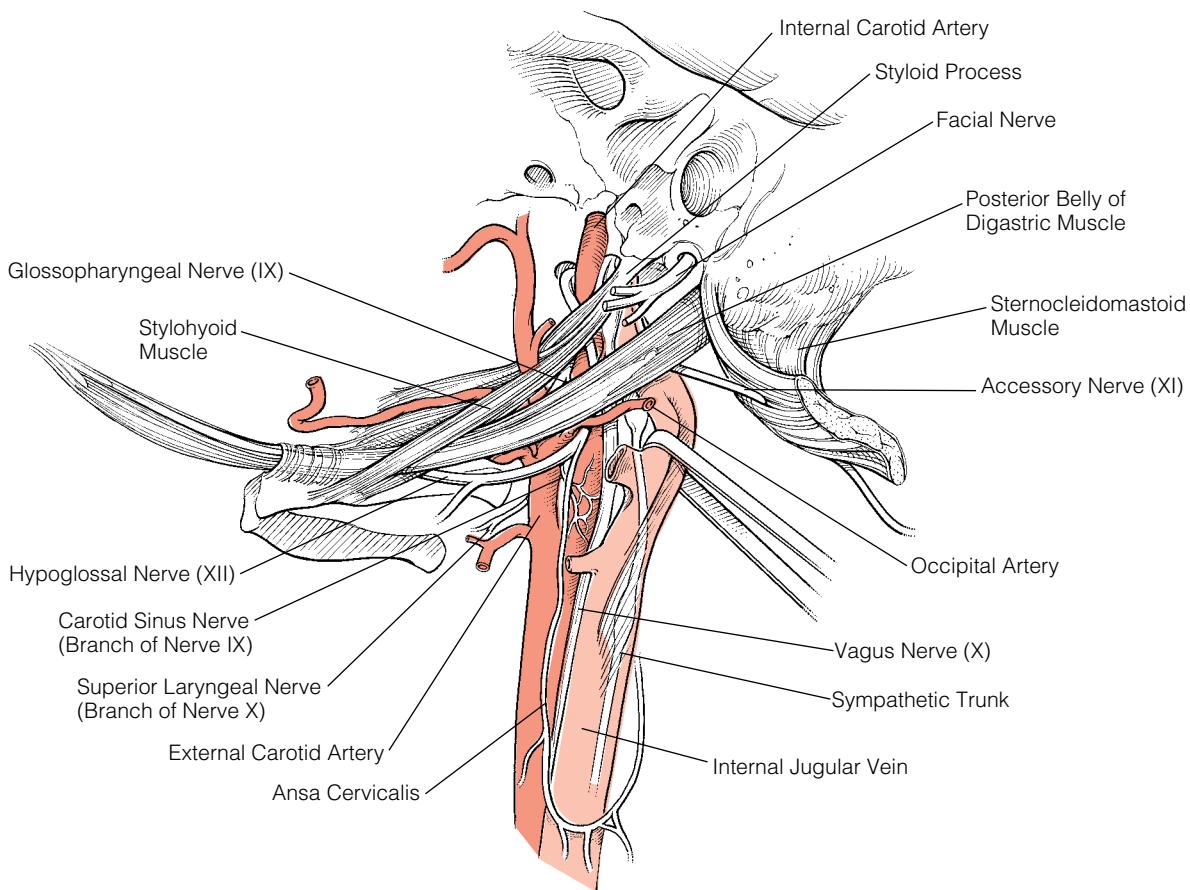

Figure 4 During distal dissection of the internal and external carotid arteries, a number of important structures are encountered, including the hypoglossal nerve and the occipital artery.

clips). During dissection around the common and internal carotid arteries, care should be taken to avoid cutting or clamping the posterolaterally located vagus nerve; the recurrent laryngeal nerve runs with the vagus nerve at this level, and damage to the laryngeal nerve can lead to paralysis of the ipsilateral vocal cord.

For wounds of the distal internal carotid artery, distal control may be a problem, particularly in the presence of vigorous ongoing bleeding, in which case a 3 to 5 French Fogarty balloon catheter should be placed through the area of injury or through a proximal arteriotomy. The catheter should be advanced distally, and the balloon should be inflated to provide a dry field for arterial repair. Repair can be done around the catheter; the balloon is deflated near the conclusion of the repair, and the catheter is removed before the final several sutures are tied.

If associated injuries allow, a 5,000 to 10,000 unit bolus of heparin should be given before any of the arteries in the neck are occluded. Because they have no branches, the common and internal carotid arteries can be safely mobilized for some distance from the injury to ensure a tension-free repair.

Management of common or external carotid artery injuries is governed by the extent of injury and the overall status of the patient. Small, simple injuries should be repaired. Complex injuries should be repaired in stable patients and ligated in patients with severe hemodynamic instability or major associated injuries.

Initial management of injuries to the internal carotid artery depends on a determination of the amount of back-bleeding from the artery distal to the site of injury.^{5,6} If back-bleeding is minimal or absent, the artery should be ligated. If significant back-bleeding is present, the overall status of the patient and the nature of the

associated injuries should be taken into account [see Discussion, Repair versus Ligation of Carotid Arteries, below]. If the patient is hemodynamically stable and has minimal or moderate associated injuries, the internal carotid artery should be repaired. If the patient is hemodynamically unstable or has devastating associated injuries, the internal carotid artery should be ligated even when back-bleeding is present.

If a carotid artery injury involves minimal loss of vascular wall, primary repair is straightforward and can be done with either a continuous or an interrupted technique; interrupted sutures will not purse-string the vessel. In younger patients who are still growing, interrupted sutures should be used to prevent later stenosis. As in elective vascular surgery, nonabsorbable sutures should be used; the carotid arteries generally require a 5-0, 6-0, or 7-0 monofilament suture, depending on the location of the injury and the type of suture material employed.

Defects longer than 1 to 2 cm should not be repaired primarily, because this will place excessive tension on the repair. For large defects limited to one surface of the vessel, a patch repair should be done. Either a venous patch or a synthetic patch can be used; when available, a venous patch is preferred for better long-term patency and to avoid placing a foreign body in a potentially contaminated wound. Saphenous vein from the groin is preferable for patches because of its durability; a saphenous vein from the ankle is easiest to harvest when time is of the essence. Although the jugular vein is in the operative field and can be easily harvested, it is better not to interfere with venous outflow in a neck in which the arterial inflow is to undergo repair; in addition, the jugular vein is very thin and difficult to handle.

For repairs near the carotid bifurcation, an alternative to venous patches and synthetic patches is the use of the proximal external carotid artery. This approach is especially appropriate when the origin of the external carotid artery is itself involved in the area of injury. If the injury is to the proximal internal carotid artery and the origin of the external carotid artery is free of injury, it is better to leave the external carotid artery patent and to use a venous patch or a synthetic patch instead; if the repair fails, the external carotid artery provides collateral distribution to the internal carotid artery via the ophthalmic artery.

Repair of circumferential loss of the common or internal carotid arteries is difficult. In this circumstance, if the defect is too long for primary anastomosis and the patient's general and neurologic condition permits, an interposition graft is indicated. As with patch grafts, though either venous or synthetic material can be used, saphenous vein from the groin is generally the donor material of first choice because of its strength. The saphenous vein from the groin is also well suited for reconstruction of the common carotid artery.

Completion angiography should be done after interposition graft placements and complex repairs of the common or internal carotid arteries. In general, patients with carotid artery injuries should be admitted postoperatively to an intensive care unit. ICU observation need not be prolonged but should be continued for at least 12 to 24 hours postoperatively. In the early postoperative period, the patient should be observed for bleeding or for the development of a neck hematoma; large postoperative hematomas may compromise the airway. If a tense hematoma develops postoperatively, the neck should be reexplored. Acute changes in the neurologic examination are a potential sign of thrombosis or embolism from the site of injury and should prompt further investigation or reexploration.

Labile blood pressure—particularly in patients with extensive dissection around the carotid bifurcation—is another potential postoperative problem. It is related to manipulation of the carotid body, and control may require pharmacologic intervention. Labile blood pressure is usually self-limiting and disappears over the first 1 to 3 days after operation, but it is another reason why patients with carotid artery repairs should be monitored initially in the ICU.

Antibiotics should be administered to cover common skin flora and should generally be continued only for one or two postoperative doses.

JUGULAR VEIN INJURIES

Any of the veins in the neck can be ligated when necessary. An exception to this rule is the rare instance when both internal jugular veins have been injured, in which case an attempt should be made to repair one of the veins, if possible. Even in such cases, however, bilateral internal jugular ligation, if necessary, is usually tolerated. It is particularly important to use suture ligatures rather than simple ligatures on the cut ends of the internal jugular vein.

If the injury to the internal jugular is simple, the vein should be repaired. Large jugular vein injuries should be repaired only if the patient's general condition and associated injuries allow; if the patient is hemodynamically unstable or has severe associated injuries, large jugular vein injuries should be treated with ligation.

It is not always necessary to encircle the jugular vein completely both proximal and distal to the site of injury; pressure with a finger or a sponge stick sometimes suffices to control bleeding while simple lateral venorrhaphy is done. In the case of more elaborate repairs, it is better either to encircle and occlude the proximal and distal vein or to place a side-biting vascular clamp for control during repair. Nonabsorbable 4-0 or 5-0 sutures should be used.

PHARYNGOESOPHAGEAL INJURIES

Injuries to the pharynx and the esophagus may be repaired in either one or two layers with either 3-0 or 4-0 absorbable sutures. Attempts should be made to repair nearly all injuries, even when they are severe or their discovery is delayed. In extreme cases of very large injuries or very delayed operative intervention, it may be necessary simply to drain the neck widely and turn the injury into a cervical esophagostomy. Esophageal diversion with distal esophageal ligation is rarely necessary in patients with isolated cervical esophageal injuries, except when the injury is very low in the neck or in the thoracic esophagus.

Pharyngoesophageal injuries should be drained; either closed or Penrose drainage can be used. The drains should be left in place for approximately 1 week, at which time a radiographic contrast study should be obtained to determine whether the repair is competent. If the contrast study is negative for extravasation and the patient's general status permits, feeding can begin. If the feedings are well tolerated, the drains can be removed.

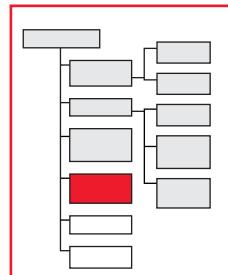

Patients with pharyngoesophageal injuries should receive several postoperative doses of antibiotics appropriate for oral flora. If the repair is inadequate or breaks down, the resultant fistula often heals with nonoperative management, provided that drainage is adequate. A high index of suspicion for mediastinitis should be maintained; the prevertebral space provides a ready route of access from the pharynx and the cervical esophagus into the mediastinum. Missed or inadequately drained injuries may result in profound infection and a septic response.

Wounds at the Base of the Neck

Patients with wounds at the base of the neck should be identified early—particularly when an intrathoracic injury is suspected—so that the appropriate incision and operative approach can be undertaken.

A median sternotomy should be done for unstable patients with injuries at the base of the right neck or patients in whom the superior mediastinum is the most likely site of injury and the most likely arterial injuries are to either the innominate artery or the right subclavian artery [see Figure 5]. Exposure of injuries to the proximal left subclavian artery is extremely difficult via sternotomy because of the artery's posterior location; in patients with such injuries, a left thoracotomy is needed [see Figure 6]. If it appears likely that a left thoracotomy will be necessary, it is helpful to bump up the patient's left hip and shoulder to position the left chest 20° to 30° anteriorly. The head is turned to the right, and the left arm is prepared as far as the elbow and draped so as to allow it free movement. Moving the arm is helpful when proximal exposure and control are obtained through the chest and distal exposure and control are obtained through a supraclavicular incision. It also allows improved exposure of the axillary artery if necessary.

In stable patients with angiographically diagnosed injuries to either subclavian artery, a supraclavicular approach alone can be used, thereby eliminating the need for initial entry into the chest. Because proximal control may not be feasible via this limited incision, the patient should still be positioned, prepared, and draped so that sternotomy or thoracotomy is possible. If the injury is on the right side of the neck and proximal control is not possible, a median sternotomy should be done. If the injury is on the left side of the neck and proximal control is not possible, a left thoracotomy should be performed.

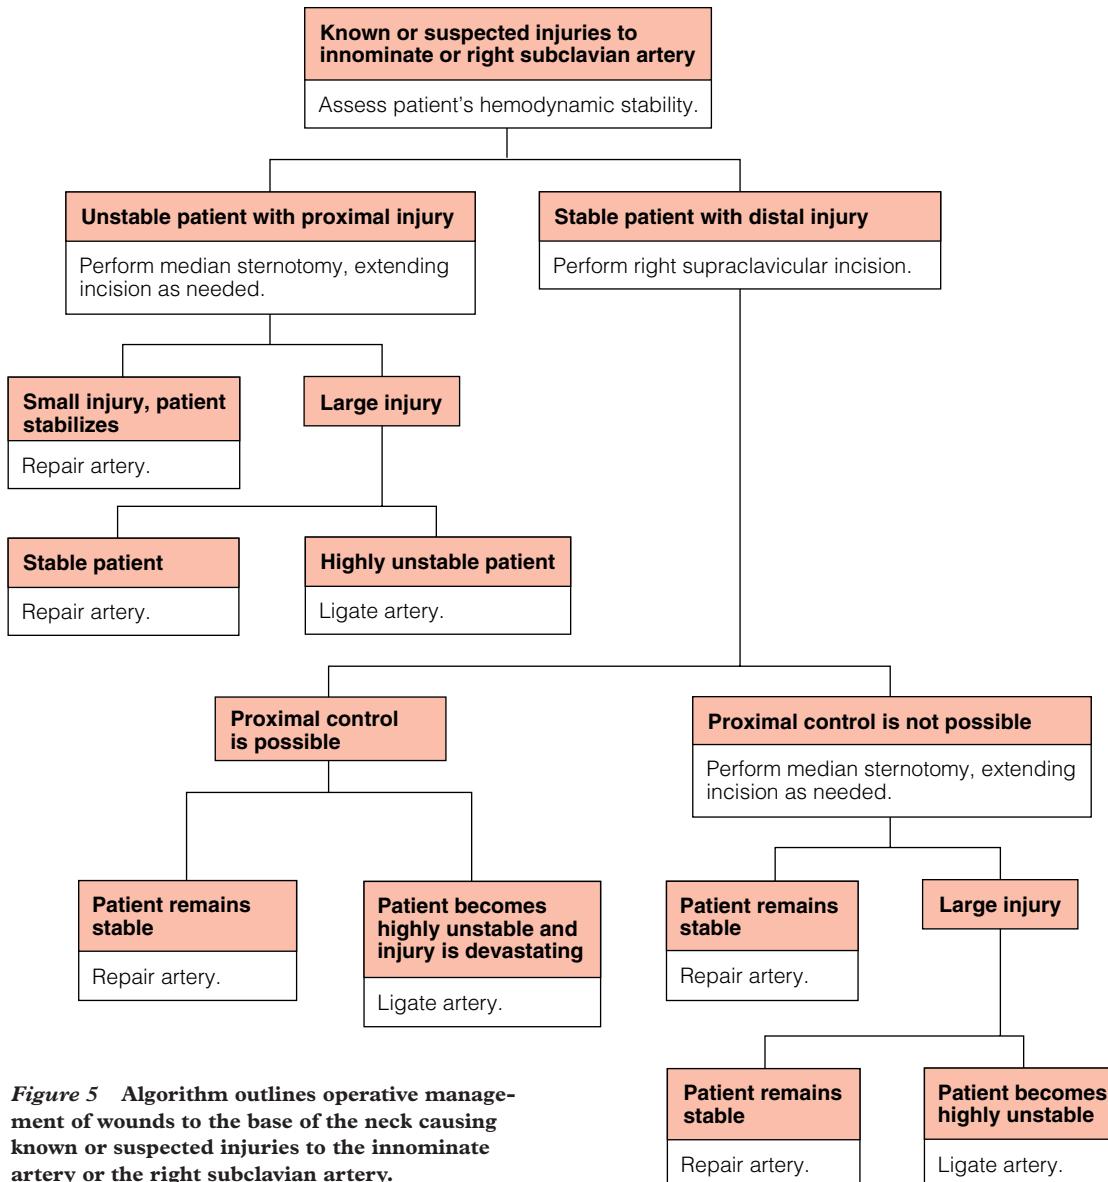

Figure 5 Algorithm outlines operative management of wounds to the base of the neck causing known or suspected injuries to the innominate artery or the right subclavian artery.

If a median sternotomy has been done for exposure of an innominate artery or right subclavian artery injury, it may prove necessary to extend the incision into the right neck to obtain adequate distal control and exposure. Either a right supraclavicular or an anterior sternocleidomastoid extension can be used. Although both are easily accomplished, the anterior sternocleidomastoid extension is the more versatile of the two. If a left thoracotomy is done for proximal control and exposure of the left subclavian artery, the distal subclavian artery should be exposed via a left supraclavicular incision. Improved exposure of the left subclavian artery at the thoracic outlet can be obtained either by resecting the medial one third to one half of the left clavicle or by making a so-called trapdoor incision. The trapdoor incision consists of a superior sternotomy and connection of the medial aspects of the thoracotomy and supraclavicular incisions. We find the trapdoor approach limited and cumbersome and strongly prefer clavicular resection. Medial clavicular resection is accomplished by encircling the midclavicle in the subperiosteal plane via the supraclavicular incision. A Gigli wire saw is passed around the clavicle, and the clavicle is divided. The medial aspect of the divided bone is then grasped with a bone hook or a Kocher clamp, and the dissection is

carried medially in the subperiosteal plane to the sternoclavicular joint, which is disarticulated.⁷ If necessary, this dissection and resection can be accomplished in a matter of a few minutes.

After adequate exposure and control of innominate or subclavian artery injuries have been obtained, further management is determined by the nature of the injury and the status of the patient. Small injuries should always be repaired. Large injuries are not often seen, because they are usually incompatible with survival to a point where medical attention is available. Nonetheless, such injuries do occur, and their management is influenced by the status of the patient. Attempts at repair should be made for most such injuries, but in highly unstable patients, the artery should be ligated. However, arterial ligation is sometimes associated with severe morbidity and should therefore be avoided if possible.

The wall of the subclavian artery is thin, and extra care should be taken in dissecting around it. Primary repair should be done with either interrupted or continuous nonabsorbable 4-0 or 5-0 sutures, laterally placed. Because of its location and the large number of branches, the subclavian artery is difficult to mobilize extensively. None of the branches are vital, however, and all can be divided as necessary to gain mobility. The origin of the vertebral

artery should be preserved if possible, because in rare instances, ligation of the artery can lead to cerebral ischemia. Even with division of arterial branches, only short segments of the subclavian artery can be removed without the need for an interposition graft to prevent an anastomosis under tension. The saphenous vein is usually too small to be used as a graft, even when it is harvested from the groin. Accordingly, a synthetic graft is usually the better choice. Infections in this location are rare, even when the graft is placed in a contaminated field.⁸

Complex injuries of the innominate and subclavian veins should be treated with suture ligation, particularly when the patient has severe associated injuries. Simple injuries can be treated with lateral venorrhaphy. Depending on the circumstances, formal control of the proximal and distal vein can first be obtained, or pressure can be applied proximally and distally to provide for a bloodless field during repair. Another alternative for control of bleeding during venous repair is the use of a side-biting vascular clamp.

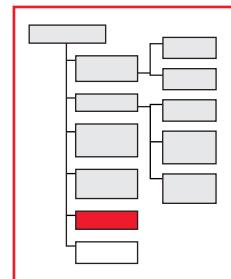

Some patients with injuries to the subclavian artery or the subclavian vein require dissection of the supraclavicular area. The supraclavicular fat pad contains a large number of lymph nodes and lymphatic channels, and dissection of the fat pad can result in considerable weeping of lymphatic fluid; these wounds should therefore be drained. Either a closed or an open drain can be used, and the drain should be brought out through a separate stab wound near the incision. After a left-side procedure, persistent milky drainage via either drains or the wound suggests injury to the thoracic duct and may necessitate repeat operative intervention if it persists.

Elevation or paralysis of the hemidiaphragm ipsilateral to the

side of dissection can indicate injury to the phrenic nerve, which courses in the field of dissection on the anterior surface of the anterior scalene muscle.

Known Vertebral Artery Injuries

On occasion, patients who present with penetrating cervical wounds and are hemodynamically and neurologically stable are demonstrated on angiographic workup to have an injury to the vertebral artery. In rarer instances, the location of an injury in the posterior triangle of the neck and the presence of ongoing hemorrhage may also indicate the high likelihood of an injury to the distal vertebral artery [see Figure 7].

Most vertebral artery injuries occur in stable patients and are discovered on angiography. Because operative attempts at ligation are associated with blood loss that can be problematic, an alternative approach utilizing angiographic embolization has been developed.⁹ In most cases of injury to the distal vertebral artery, the angiographic approach is preferred if available [see Discussion, Angiographic Embolization of Distal Vertebral Artery Injuries, below]. If angiographic expertise is not available and the patient is stable enough for transfer, it is preferable to send the patient to a center with angiographic embolization capability if at all possible. In urgent circumstances, an angiographic approach is not practical, and a direct surgical approach is necessary.¹⁰

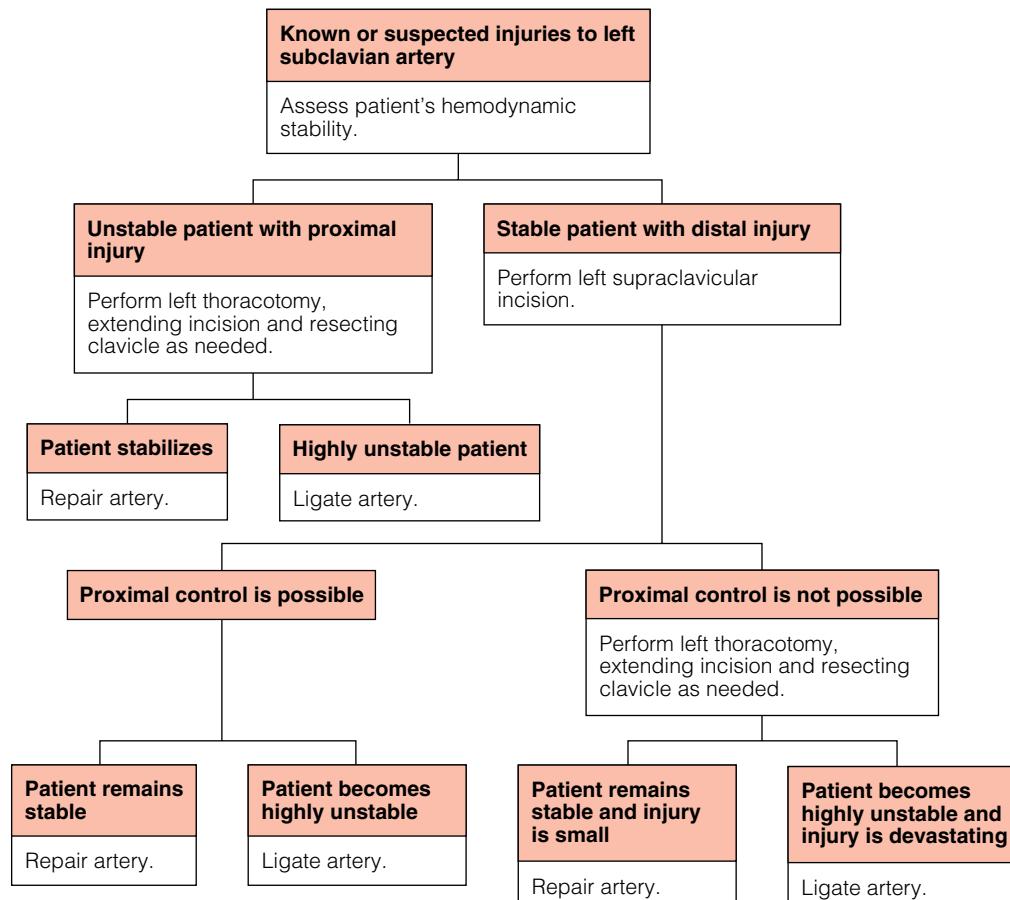

Figure 6 Algorithm outlines operative management of wounds to the base of the neck causing known or suspected injuries to the left subclavian artery.

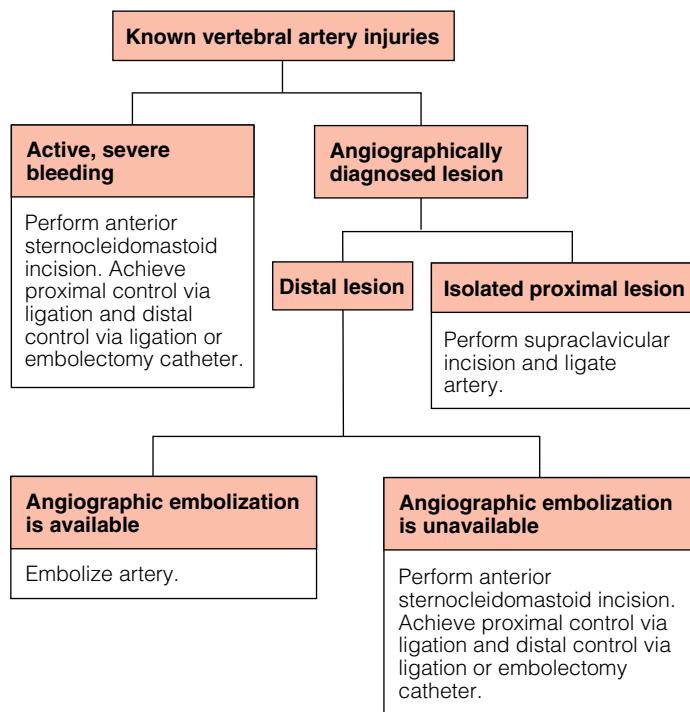

Figure 7 Algorithm outlines management of known injuries to the vertebral artery, which are most often discovered by angiography.

EXPOSURE AND EXPLORATION

In the rare case of a patient who presents with active, severe bleeding and in whom the most likely source of bleeding is the distal vertebral artery, surgical exposure of the vertebral artery is necessary. Such exposure is reviewed more fully elsewhere.¹¹ Initial exposure should be obtained via an anterior sternocleidomastoid incision [see Injuries to the Carotid Arteries, Jugular Veins, Pharynx, and Esophagus, above]. This approach can be used for exposure of both the proximal and the distal vertebral artery. The incision is developed down to the level of the carotid sheath. The lateral margin of the internal jugular vein is developed sharply, and the internal jugular vein and the other contents of the sheath are retracted medially. After retraction of the carotid sheath, the plane just superficial to the prevertebral muscles is encountered. The ganglia of the cervical sympathetic chain are located here and should be protected, though this is not always possible in emergency circumstances. The anterior longitudinal ligament, located deep in the medial aspect of the wound, is incised longitudinally. The ligament, the underlying periosteum, and the overlying longus colli and longissimus capitis are mobilized anterolaterally with a periosteal elevator [see Figure 8]. The elevation is carried laterally along the lateral margin of the bodies of the cervical vertebrae and along the anterior aspect of the transverse processes of the cervical vertebrae. To avoid injury to the laterally and posteriorly placed cervical nerve roots, the dissection should not be extended laterally beyond the tips of the transverse processes.

After the anterior aspects of the transverse processes of the cervical vertebrae have been exposed, they can be removed with a small rongeur. This should be done distal to the area of injury only; proximal ligation of the vertebral artery can be done in its more easily exposed proximal portion. Although the vertebral artery is also accessible in the spaces between the transverse processes, there are a number of venous branches in these regions, and it is therefore safer to approach the artery within the confines of the bony foramina.

The third and most distal portion of the vertebral artery is most easily approached between the atlas and the axis. The segment of the artery between the transverse processes of these two vertebrae is longer and more exposed than the segments between the other cervical vertebrae and is therefore, in theory, somewhat easier to expose. In practice, rapid exposure of this portion of the vertebral artery is very difficult, particularly in an actively bleeding patient. As with exposures to the second portion of the vertebral artery, lesions requiring this exposure are best treated with angiographic embolization. If angiographic expertise is available, it may prove wisest to pack the wound as a temporizing measure and then take the patient for embolization. If angiographic embolization is not an option, a surgical approach may be necessary.

The standard anterior sternocleidomastoid incision is used but is carried superiorly with a curved extension to a point just below the tip of the ear. Once the plane is developed along the anterior border, the sternocleidomastoid muscle is divided near its origin at the mastoid process. The spinal accessory nerve, which enters the sternocleidomastoid 2 to 3 cm below the tip of the mastoid, is dissected free of the muscle and mobilized anteriorly. After division of the sternocleidomastoid muscle and anterior retraction of the spinal accessory nerve, the transverse process of the atlas is palpable and the prevertebral fascia is visible in the depths of the wound. The fascia is incised in a line with the spinal accessory nerve, and the laterally placed levator scapulae and splenius cervicis are divided as close to the transverse process of the atlas as possible [see Figure 9]. The anterior ramus of the nerve root of C2 is closely associated with the anterior edge of the levator scapulae and should be protected. After division of the levator scapulae and the splenius cervicis, the distal vertebral artery is visible in the medial aspect of the wound. Venous branches associated with the

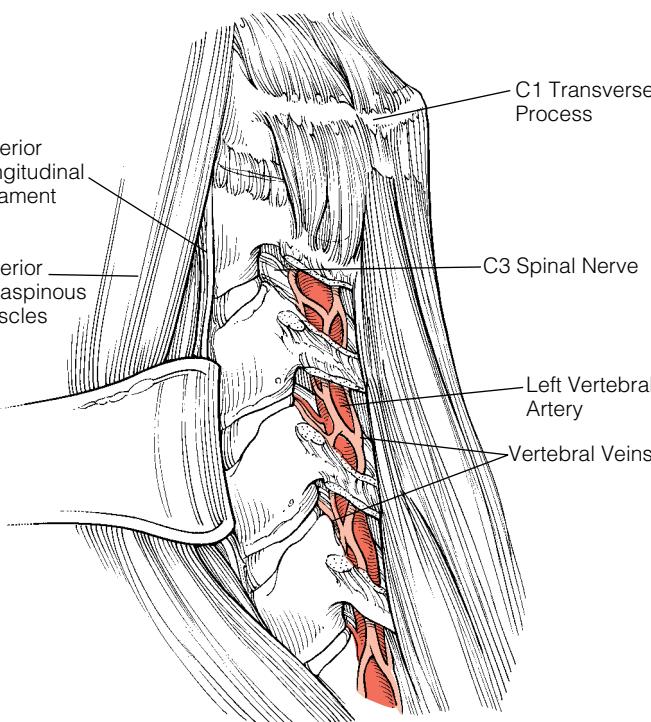

Figure 8 Throughout most of their course, the vertebral artery and the vertebral veins are surrounded by the transverse processes of the cervical vertebrae. Exposure of this portion of the vertebral artery is best done with anterior and lateral mobilization of the longus colli and the longissimus capitis.

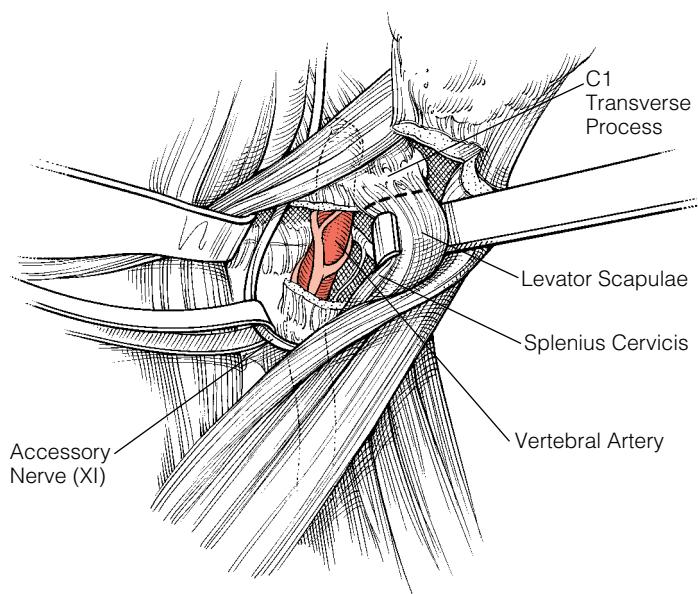

Figure 9 Exposure of the distal vertebral artery is done via an incision along the anterior border of the sternocleidomastoid muscle. The sternocleidomastoid muscle is then divided near its origin at the mastoid process. The spinal accessory nerve is mobilized anteriorly. The vertebral artery is accessible after division of the levator scapulae and the splenius cervicis.

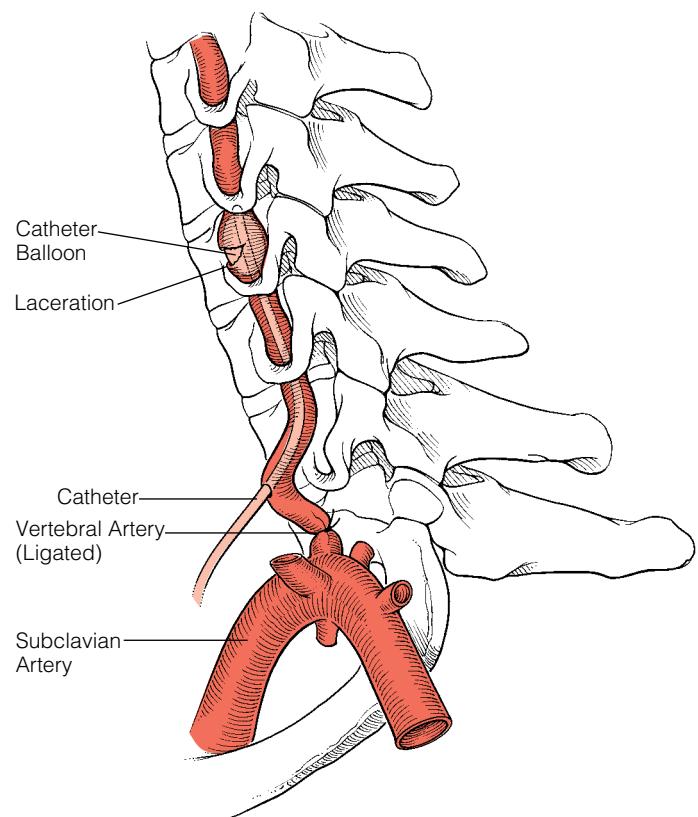

Figure 10 Bleeding from vertebral artery injuries located within the transverse process of the cervical vertebrae can sometimes be controlled by exposing the proximal vertebral artery at the base of the neck, passing a thrombectomy catheter distally, and inflating the balloon at the site of injury.

vertebral artery are most likely to be located near the transverse processes; therefore, ligation should be preferentially directed to the middle of the interspace between the transverse processes.

Exposure of the proximal vertebral artery at the base of the neck can also be achieved via an incision along the anterior border of the sternocleidomastoid muscle. Initial exposure is identical to that used for exposure of the carotid arteries [see Injuries to the Carotid Arteries, Jugular Veins, Pharynx, and Esophagus, above]. At the level of the carotid sheath, however, dissection is carried lateral to the internal jugular vein, which is retracted medially to expose the supraclavicular fat pad. The proximal vertebral artery can then be controlled after dissection deep to the fat pad, as described for the supraclavicular approach to isolated proximal vertebral artery injuries (see below).

TREATMENT

As opposed to injuries of the carotid arteries, in which either repair or ligation is an option, injuries to the vertebral arteries should always be treated with interruption of flow by surgical or other means. Proximal ligation should usually be done at the origin of the vertebral artery because the approach to the artery at this point is easier than the approaches to the more distal segments. The artery should be suture-ligated as close to its origin as possible so as not to create a thrombogenic blind pouch off the subclavian artery. Distal ligation can be accomplished by first exposing the artery (see above) and then ligating with ligatures, suture ligatures, or surgical clips. The use of clips minimizes dissection around the artery, which, in turn, decreases the likelihood of further injury to surrounding veins.

In emergency circumstances, a useful technique is to approach the proximal artery surgically at the base of the neck and pass a thrombectomy catheter distally to the site of injury [see Figure 10]. First, the proximal vertebral artery is exposed and ligated at its origin. Next, the thrombectomy catheter is passed distally via an arteriotomy. The catheter balloon is then inflated, and the wound is checked to determine whether bleeding has been controlled. If bleeding has been controlled, the distal end of the catheter is left in place, and the proximal end is brought out through the wound. The catheter is left in situ for approximately 48 hours, at which time the balloon is deflated and the wound is again checked for bleeding. If there is no bleeding for 4 to 6 hours, the catheter can be withdrawn. Use of a thrombectomy catheter can also serve as a bridge to angiographic embolization. If the thrombectomy catheter technique is unsuccessful, a direct surgical approach to the second or third portion of the artery is necessary. A potential disadvantage of a surgical approach, however, is that proximal ligation of the vertebral artery precludes angiographic embolization except via the contralateral vertebral artery. Embolization via the contralateral vertebral artery is extremely difficult and may result in ischemia or uncontrolled embolization.

If the injury is shown by preoperative angiography to be confined to the first portion of the vertebral artery, both proximal and distal ligation may be possible via a supraclavicular incision [see Figure 11]. The patient is positioned with the head turned away from the side of the injury, and the chest and ipsilateral neck are prepared and draped. Preparation and draping include the chest so that a left thoracotomy can be done later if necessary for proximal control of the left subclavian artery. In such cases, it is helpful to bump the patient up on the left so that an anterolateral thoracotomy incision can be carried further posteriorly.

The supraclavicular incision is made approximately one fingerbreadth superior to the clavicle and is extended medially to the

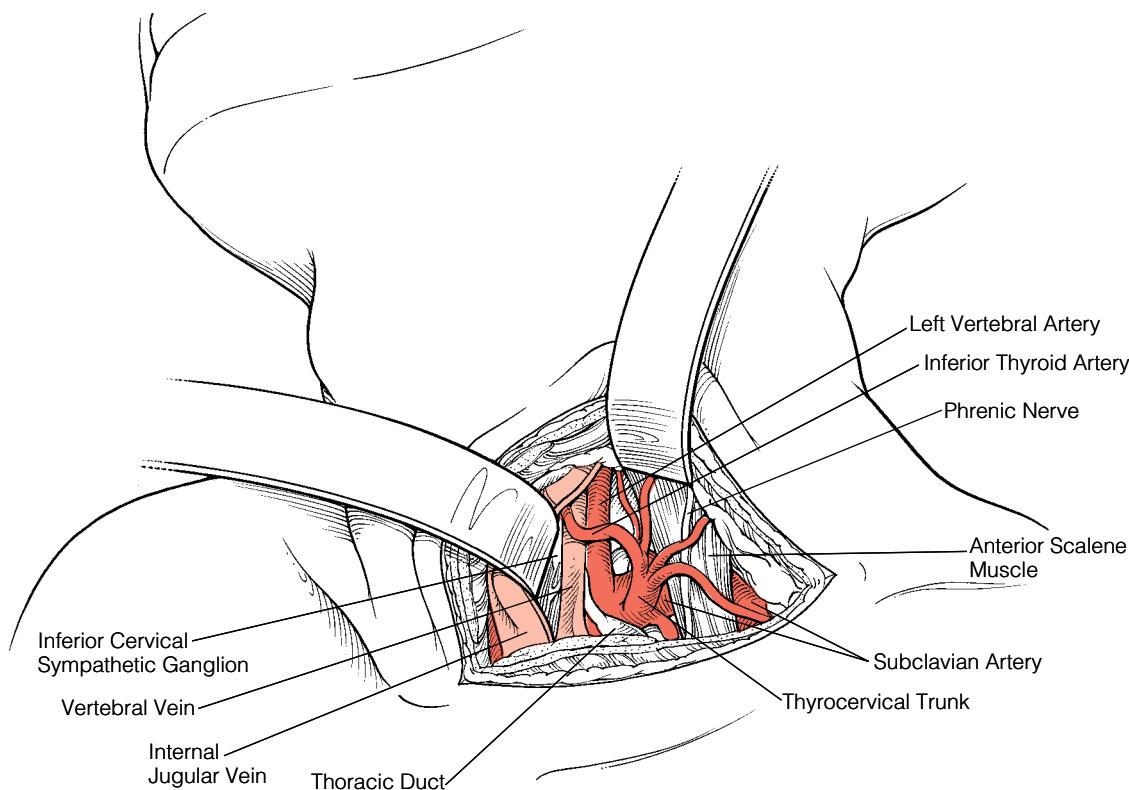

Figure 11 The proximal vertebral artery can be approached via a supraclavicular incision. Dissection of the supraclavicular fat pad reveals the underlying vertebral artery where it diverges from the subclavian artery. During dissection, care should be taken to avoid injuring the phrenic nerve.

midpoint of the sternocleidomastoid insertion and laterally to the juncture of the middle and lateral thirds of the clavicle. The skin, the subcutaneous tissue, and the platysma are incised. The external jugular vein, if in the operating field, is suture-ligated. The clavicular head of the sternocleidomastoid muscle is encountered next, and its lateral aspect is divided with the electrocautery at its insertion on the clavicle. The muscle is then retracted superiorly and medially. In the plane deep to the sternocleidomastoid muscle, the omohyoid muscle is divided in its middle tendinous portion with the electrocautery.

At a level just deep to the sternocleidomastoid and omohyoid muscles, the carotid sheath is encountered in the medial aspect of the wound. The lateral border of the internal jugular vein is dissected free of adjacent tissue and retracted medially. If the operation is on the left, the thoracic duct may be found in the medial portion of the wound. The thoracic duct is easily injured with retraction and should be divided and ligated if it is in the way.

Just lateral to the internal jugular vein at the same depth is the supraclavicular fat pad, which is dissected from the supraclavicular fossa in which it lies. Exposure is further enhanced by dissection and division of the anterior scalene muscle. The phrenic nerve, which is closely applied to the anterior surface of the anterior scalene muscle, is dissected free of the underlying muscle and retracted out of the field with a vessel loop. The anterior scalene muscle is then divided with the electrocautery. During dissection of the supraclavicular fat pad, it may be necessary to divide branches of the thyrocervical and costocervical trunks. The most prominent of these branches is the inferior thyroid artery, which stems from the thyrocervical trunk and courses medially toward the thyroid.

After the supraclavicular fat pad has been dissected, the proximal portion of the vertebral artery is reached. The vertebral vein, which usually lies slightly superficial and medial to the vertebral artery, is divided and suture-ligated to provide better exposure. Care should be taken not to retract the vertebral vein too vigorously before suture ligation so that this vessel is not avulsed from the subclavian vein. At the depth of the vertebral artery, the white, cordlike elements of the brachial plexus are often visible in the superolateral aspect of the wound. If possible, traction should not be placed on the brachial plexus, and use of the electrocautery around the plexus should be minimized. After exposure, the proximal vertebral artery is ligated both proximal and distal to the site of injury. No attempts at repairing the injury should be made.

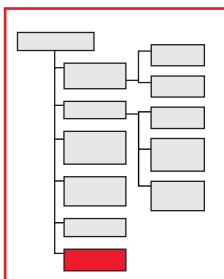

The use of angiographic embolization, the preferred treatment of angiographically diagnosed injuries of the distal vertebral artery, depends on the availability of equipment for and expertise with the procedure [see Discussion, Angiographic Embolization of Distal Vertebral Artery Injuries, below]. Stable patients who have angiographically documented injuries to the distal vertebral artery should be transferred to the closest center with cerebral embolization capability. If angiographic embolization is not available, exposure and ligation should be carried out as described (see above).

In cases where angiographic embolization of the vertebral artery has been employed, a postprocedure angiogram should be done several days to weeks after the procedure to ensure that the artery remains occluded and that no arteriovenous fistula has developed between the injured vertebral artery and the surrounding venous plexus. Duplex scanning has also been used to a limited extent for

follow-up screening. It can serve as an alternative to angiography, but its sensitivity relative to that of angiography remains to be established.

Superficial Wounds

Some wounds are obviously superficial on initial physical examination. Most com-

monly, these wounds are slash wounds caused by a knife or other sharp object rather than true stab wounds. Rapid exposure and vascular control are sometimes easily accomplished through these wounds. In such circumstances, the surgical procedure consists of debridement of the neck wound, and deep dissection is not necessary. If greater access and control are needed to rule out further injuries or for definitive repair, a standard anterior sternocleidomastoid incision should be done [see Injuries to the Carotid Arteries, Jugular Veins, Pharynx, and Esophagus, above].

Discussion

Screening Criteria for and Recommended Management of Blunt Cervical Arterial Injuries

Blunt injuries to cervical arteries, though relatively rare, can be difficult to diagnose and can lead to devastating complications (e.g., stroke and bleeding). Most such injuries result from stretching of the vessels as a consequence of hyperextension of the neck. Motor vehicle collision is the most common mechanism of this sort of stretch injury; chiropractic manipulation and rhythmic flexion and extension of the neck ("head banging") are less common mechanisms.^{12,13} Injury may also be caused by direct trauma to the artery or by fracture fragments. Arterial stretching leads to endothelial tearing with subsequent intimal flaps, dissections, or emboli.

The true incidence of blunt cervical vascular injury is unknown. Figures as high as 1.55% of all blunt trauma patients have been reported,^{14,15} as have figures an order of magnitude lower. Because many patients with pathologic changes on screening tests are asymptomatic before diagnosis and remain asymptomatic after diagnosis, the reported incidences are likely to depend heavily on the screening criteria used.¹⁶⁻²¹

Many recommendations have been made regarding screening criteria for blunt cervical arterial injuries. Performing four-vessel cervical angiography on all blunt trauma patients would identify nearly all cervical arterial injuries, but the logistical considerations, expense, and potential risks associated with this approach make it unfeasible. When aggressive screening with broad criteria is employed, approximately 3% to 5% of blunt trauma patients undergo workup and approximately 30% of the workups reveal an injury.¹⁴ Even with early and aggressive screening, about a quarter of patients exhibit neurologic signs and symptoms before workup.¹⁶

Some of the published screening criteria are uncommon and thus, if present, are probably reasonable triggers for diagnostic imaging studies. Such uncommon criteria include arterial bleeding from the ears, nose, or mouth; an expanding cervical hematoma; a cervical bruit in a patient younger than 50 years; evidence of cerebral infarction on CT scanning; Horner syndrome; and basilar skull fracture involving the carotid canal. Other published screening criteria are somewhat more difficult to apply, being either quite common or highly subjective. These more difficult criteria include neurologic symptoms not explained by CT findings; an injury mechanism consistent with severe cervical hyperextension, hyperrotation, or hyperflexion, especially if associated with a displaced facial fracture or complex mandible fracture; closed head injury consistent with diffuse axonal injury of the brain; a near-hanging resulting in cerebral anoxia; seat-belt abrasion or other soft tissue injury to the anterior neck; and cervical vertebral body fracture or distraction injury (isolated spinous process fracture excluded).^{22,23}

Four-vessel angiography remains the gold standard for imaging the cervical vasculature. Duplex ultrasonography has not proved sensitive enough for diagnosis of blunt cervical arterial injury, in large part because so many of the lesions are located high in the neck, where accurate ultrasonography is difficult.¹⁸ Magnetic resonance angiography (MRA) also lacks the sensitivity needed to screen trauma patients for blunt cervical arterial injury. MRA imaging relies on signal subtraction related to flow and thus may miss lesions such as pseudoaneurysms, in which flow is diminished. CT angiography has been applied with increasing frequency in attempts to make this diagnosis, with mixed results. Helical CT scanners capable of fewer than 16 slices per rotation probably lack the sensitivity to make a reliable diagnosis, but small series using more sophisticated CT scanners have reported promising results.²⁴ Large series evaluating current CT angiography technology are lacking at present. CT angiography is particularly attractive in that it is noninvasive, it can be performed relatively rapidly, and it can be done in the course of CT scanning of the head and other parts of the body. Improvements in CT technology and increased use of CT instead of angiography for screening may make widespread radiographic screening for blunt carotid injury much simpler and easier.

Biffl and associates developed a grading scale for blunt cervical arterial injury based on the arteriographic appearance of the lesion.²⁵ On this scale, grade I and II lesions show less than 25% and greater than 25% luminal narrowing, respectively; grade III lesions are pseudoaneurysms; grade IV lesions demonstrate thrombosis; and grade V lesions are transections with extravasation. Grade I to III lesions may progress to a higher grade. Follow-up imaging should be performed 7 to 10 days after diagnosis.

Treatment of blunt cervical arterial injury depends on the location and grade of the lesion. Grade I injuries, regardless of location, are best treated with anticoagulation.²⁵ The intimal defect leaves the patient at risk for thromboembolism, and anticoagulation protects against subsequent stroke. Grade II lesions extending to a location that is inaccessible to traditional surgical approaches should also be treated with anticoagulation. Carotid artery pseudoaneurysms (grade III lesions) located at the base of the skull (the usual location) should be treated initially with anticoagulation, then followed up with delayed imaging studies to check for enlargement. Pseudoaneurysms that are enlarged should probably be treated with stenting, though to date, experience with stenting at this location for this indication has been relatively limited. Stenting may also be indicated for lesions that progress and threaten to limit flow despite full anticoagulation, as well as for high grade V lesions.²⁶ Good results have been obtained with anticoagulation in patients with grade IV injuries.²⁵ Accessible grade II to V lesions, though rare, should be repaired operatively by

means of traditional surgical approaches.

Blunt vertebral artery injuries should be treated nonoperatively for the most part, and the threshold for employing transcatheter embolization should be low. As with carotid artery injuries, small lesions can be treated with anticoagulation. Larger and more distal lesions should be treated with occlusion of the artery by means of interventional radiologic techniques.

The best choice of anticoagulation remains unclear. There is some indication that the use of heparin positively affects patient outcome, but the evidence is not particularly strong.^{19,21} The partial thromboplastin time (PTT) should be monitored and maintained within an arbitrary range of 40 to 60 seconds. Patients with a contraindication to heparin therapy (e.g., an intracranial lesion at risk for hemorrhage) can be managed with aspirin. Patients managed with heparin and those managed with aspirin have similar stroke rates; however, the number of patients treated with either drug in published reports is relatively small, and the evidence that anticoagulation of any kind makes a difference is relatively sparse. The safety and efficacy of other antiplatelet treatments are unknown. The optimal duration of treatment is unknown as well, though it appears that 3 to 6 months is adequate in most cases.²¹ Therapy may be discontinued when repeat imaging shows that the injury has resolved.

Zones of the Neck and Mandatory versus Selective Neck Exploration for Penetrating Cervical Injuries

One approach to managing penetrating cervical injuries is to categorize them on the basis of their location in the neck. In this schema, the neck is divided into three distinct zones [see Figure 12], and management is determined by the zone in which the patient happens to have wounds in the skin. The idea is that hemodynamically stable patients without any obvious sign of vascular injury (e.g., pulsatile bleeding from the wound, an expanding hematoma, a bruit, or a neurologic deficit) who have wounds to the base of the neck or the upper neck (zones I and III) may have injuries that are problematic with respect to proximal or distal vascular control and thus may require incisions other than the standard sternocleidomastoid approach. Accordingly, these patients undergo imaging studies and endoscopy to rule out injuries to the vasculature or the aerodigestive tract. If the study results are negative for injuries that call for operative repair, the patients are simply observed. Patients with zone II injuries, on the other hand, presumably have underlying injuries to either the vasculature or the aerodigestive tract that are easily accessible via a sternocleidomastoid incision; such patients therefore undergo neck exploration if the wound has violated the platysma.

The concept of mandatory exploration of patients with zone II injuries, though time honored, has a number of problems. Division of the neck into three distinct areas results in extremely small zones I and III, and even zone II, in the middle of the neck, is not very long in most patients. As a result, determining that a given wound is clearly in only one of the zones is often very difficult. Description of a wound as being on the border of zones I and II or on the border of zones II and III is a common and confusing occurrence. Moreover, the location of the skin wound is not a reliable guide to the locations of injuries to underlying structures. This is most obviously true of gunshot wounds, in which the path of the missile is clearly as important as the location of the skin wound. It is also true of knife wounds: a blade that enters the skin in zone II can easily injure structures in zones I or III, depending on the direction in which the knife was thrust after it entered the skin.

A more logical approach to the initial management of penetrat-

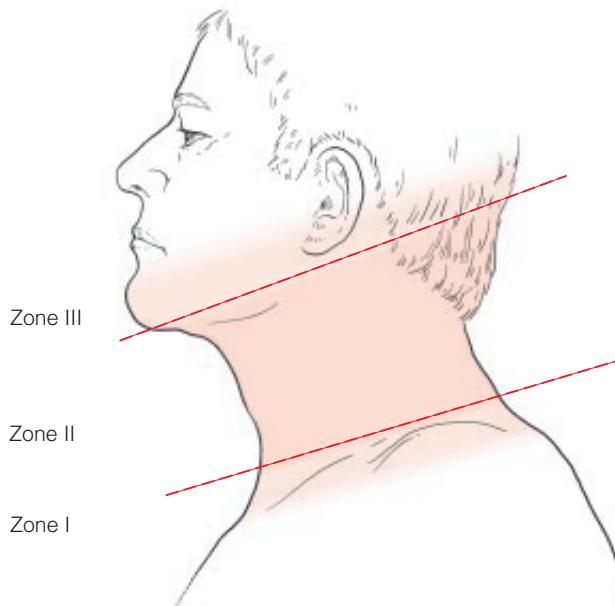

Figure 12 Depicted is the traditional division of the neck into three separate zones. This division has been used as a basis for decision-making with respect to penetrating cervical injuries.

ing neck trauma starts by determining the depth of the wound. If the wound did not violate the platysma, injury to major underlying structures can be ruled out. If the wound clearly violated the platysma or its depth cannot be determined, further investigation is warranted. If the patient has any obvious signs of underlying vascular injury, the neck should be explored via the standard sternocleidomastoid incision, and the exploration should be expanded as necessary to obtain proximal or distal control. If the patient is stable and has no obvious signs of underlying vascular injury, a nonoperative workup should be obtained regardless of the location of the skin wound.

Conventional angiography is the gold standard for ruling out vascular injury, but it is somewhat invasive and can be time consuming and resource intensive. As experience with CT in this setting accumulates, this modality is becoming an increasingly valuable imaging adjunct.^{27,28} CT can be quite helpful in determining the course that a knife or bullet takes within the neck and detecting the presence of vascular or aerodigestive injury. If CT defines a knife or bullet tract that is clearly remote from major vascular or aerodigestive structures, no further workup is needed. If CT clearly shows an injury that should be repaired, exploration of the neck is indicated. If CT can neither establish nor rule out the presence of vascular or aerodigestive injury, further directed imaging or endoscopic studies should be done. This selective approach reduces the rate of negative neck explorations and decreases the need for invasive, lengthy, and expensive diagnostic modalities.

Repair versus Ligation of Carotid Arteries

Simple injuries to the external carotid artery should be repaired, whereas complex injuries should be ligated.

Injuries to the common carotid artery and the internal carotid artery are more problematic. If the injury is simple and there is no suggestion that flow in the vessel has been interrupted, repair should always be undertaken. An example of such an injury is a simple stab wound of part of the circumference of the artery with an associated pseudoaneurysm and good distal flow. In this cir-

cumstance, lateral repair can be done quickly and easily with a short cross-clamp time. After proximal and distal control of the vessel is obtained, a check should be made for back-bleeding. If the back-bleeding from the distal circulation is brisk, as it usually is, repair can be done safely.

If an injury to the common carotid artery or the internal carotid artery has interrupted flow in the vessel, repair creates a theoretical disadvantage. Interruption of flow may lead to focal brain ischemia and partial disruption of the blood-brain barrier. Sudden restoration of blood flow may cause hemorrhage in the area of the ischemia and worsen the extent of brain injury; an anemic, or white, infarct of the brain may be converted to a hemorrhagic, or red, infarct. Whether this pathophysiology is important after traumatic injury is unclear and controversial.

Deciding whether to repair or ligate when flow has been interrupted is often difficult.^{5,6} One approach is to base the decision on the patient's preoperative neurologic status. If there is no neurologic deficit, it is presumed that there are no areas of brain ischemia and that repair is safe. Conversely, a focal neurologic deficit is presumed to be related to ischemia, and in such cases, the risk of worsening the patient's neurologic status with restoration of blood flow is increased. Even though this approach is rational, it is not applicable in cases in which a detailed neurologic examination before surgery is not possible. Furthermore, this approach may be applicable only to patients in coma or with severe neurologic deficits. There are indications that milder neurologic deficits respond favorably to revascularization.

Yet another approach is to gauge the appropriateness of repair according to the nature of the injury itself. In this approach, large, complicated injuries requiring involved and lengthy procedures for repair are ligated, whereas simple injuries requiring only simple and quick repairs are repaired. Similarly, repair is not indicated in patients with severe or multiple associated injuries. There is also a difference between the management of injuries of the common carotid artery and management of injuries of the internal carotid artery. Common carotid injuries are more accessible and easier to repair, and repair is generally associated with a good outcome. Continued antegrade flow in the internal carotid artery is more likely after injury to the common carotid artery than after injury to the internal carotid artery because of the possibility of collateral flow via the external carotid artery.

A reasonable way to deal with repair dilemmas is to make the decision on the basis of distal back-bleeding. Interruption of blood flow to the brain is tolerated only for a short time, and restoration of flow is unlikely to be accomplished quickly enough to improve outcome. It is therefore logical to base the decision about revascularization on the state of back-bleeding from the internal carotid artery. If back-bleeding is brisk, the patient is presumed to have good collateral flow, and the chances that there is an area of ischemia are low. Repair rather than ligation is safe in such circumstances. If internal carotid artery back-bleeding is minimal or absent, an ischemic infarct is more likely and restitution of arterial inflow is more dangerous. A corollary to this reasoning is that if back-bleeding is poor, a clot distal to the area of injury may be present, and return of flow with repair may dislodge the clot distally.

Nonoperative Management and Stenting of Carotid Artery Injuries

Some minimal penetrating injuries to the vasculature of the extremities (e.g., small pseudoaneurysms and endothelial injuries) need not be repaired if they do not compromise distal flow, and they usually heal over time without sequelae. It has been hypothe-

sized that minimal injuries to the carotid vasculature can be approached in a similar fashion. The consequences of distal embolization or pseudoaneurysm rupture in the carotid circulation make such an approach somewhat risky.^{29,30} Increasing experience with nonoperative management of minor blunt injuries to the cerebral vasculature supports the relative safety of this approach, particularly if the patient can safely undergo anticoagulation to prevent subsequent thromboembolic complications.³¹ Experience with nonoperative management of penetrating injuries is more limited, however. Penetrating mechanisms are more likely than blunt mechanisms to involve a full-thickness injury to the vessel, and the presence of a full-thickness injury makes anticoagulation riskier. Furthermore, the apparent degree of vessel injury from penetrating trauma on angiography is often significantly less than the actual degree of injury as seen at exploration. Nonoperative management is currently supported for minor blunt injuries, ideally in conjunction with anticoagulation. Until more experience with nonoperative management of penetrating injuries is reported in the literature, accessible penetrating injuries should be repaired surgically.

There is increasing support for treatment of carotid artery injuries with intraluminal stenting.³²⁻³⁴ This approach is now commonly used for aneurysms of the thoracic and abdominal aorta, as well as for more distal peripheral vascular lesions. On rare occasions, it has also been applied to the management of traumatic injuries to the thoracic aorta and selected injuries to the peripheral and visceral vasculature. Not surprisingly, stenting has also been used for the management of carotid artery injuries, particularly injuries to the distal internal carotid artery that are not easily approached surgically. Overall, stents are most frequently used in situations where arterial lesions are not surgically accessible or when anticoagulation is contraindicated. The technical success rates have been good in these settings, and there is accumulating (albeit still limited) evidence to suggest that stents in the carotid circulation remain patent for prolonged periods and are not associated with a high thromboembolic complication rate.^{25,35-38} Large pseudoaneurysms in inaccessible areas of the distal carotid circulation usually do not heal with time and, when persistent, may reasonably be treated with stenting.²⁵

Angiographic Embolization of Distal Vertebral Artery Injuries

Most patients with vertebral artery injuries are stable and experience no external bleeding, and the injury is discovered by angiography. A number of such lesions have been successfully treated with angiographic embolization. Given the difficulties of surgical exposure, lesions of the distal vertebral artery should be treated angiographically when the patient's general condition permits and when the necessary expertise is available. If the patient is bleeding profusely, such an approach is not possible and a rapid surgical approach is indicated, with ligation of the proximal vertebral artery and an attempt at thrombectomy catheter control or packing of the wound until an angiographic approach can be attempted. If this is unsuccessful, the lesion should be approached directly [see Known Vertebral Artery Injuries, above].

If a patient with a distal vertebral artery lesion is stable—particularly when the lesion is otherwise silent and has been detected angiographically—an attempt should be made at angiographic embolization if the necessary expertise is available. If the patient is stable, transfer to the nearest center with cerebral angiographic embolization capability is appropriate. Embolization is done via the ipsilateral proximal vertebral artery. Detachable balloons or coils can be used.

Conversion of Cricothyrotomy to Tracheotomy

Cricothyrotomy is typically reserved for life-threatening airway compromise when the need for a rapid surgical airway is paramount [see Airway Compromise, above, and 6:1 Trauma Resuscitation]. Tracheotomy is preferred if time and a lesser degree of urgency permit. Similarly, in the postoperative period, tracheotomy is preferred to cricothyrotomy. The traditional view, initially promulgated by Chevalier Jackson in 1921, is that cricothyrotomy is more likely than tracheotomy to result in airway stricture or damage to more proximal structures in the larynx. On the basis of this rationale, cricothyrotomies are converted to tracheotomies on a semiselective basis within 24 to 48 hours of admission if the patient's general condition permits.^{39,40}

The evidence supporting a policy of routine conversion is mixed. Several series document a low but increased incidence of complications to the larynx and trachea from prolonged maintenance of cricothyrotomies. Even though the incidence is low, the complications can be severe and may necessitate extensive recon-

structive procedures. Conversely, studies of cardiac patients undergoing routine cricothyrotomy do not demonstrate a significant increase in the incidence of airway complications. Cricothyrotomy is sometimes favored over tracheotomy in these patients because of concerns about the proximity of tracheotomy wounds to the patient's sternotomy incision. The results of studies of routine cardiac patients may be different from results of studies showing an increase in complications after cricothyrotomy, in that the cardiac patients were intubated for shorter periods.

There have been no studies documenting a high incidence of complications in trauma patients who have undergone emergency cricothyrotomy and have remained intubated via the cricothyrotomy for longer than 2 or 3 days. Because complications are potentially so devastating, however, emergency cricothyrotomies should be converted to tracheotomies within 1 to 2 days after admission in stable patients. In a stable patient, the risks of conversion are minimal, and conversion is justified to avoid the possibility of future complications.

5 INJURIES TO THE CHEST

Edward H. Kincaid, M.D., and J. Wayne Meredith, M.D., F.A.C.S.

Most persons who experience torso trauma, whether blunt or penetrating, sustain some degree of associated injury to the chest. Thoracic injuries are a primary or contributing cause of death in nearly half of all cases of torso trauma.¹ Fortunately, many thoracic injuries can be treated effectively, and often definitively, by relatively simple maneuvers that can be learned and performed by most physicians involved in early trauma care. Approximately one in six patients, however, has life-threatening injuries that necessitate urgent operative repair. These extremes in injury severity are unique to the chest and require a correspondingly broad range of knowledge and skills on the part of the treating surgeon.

Initial Evaluation and Management

PRIMARY SURVEY

Initial evaluation and treatment of patients with thoracic injuries are guided by the same principles and priorities as initial evaluation and treatment of patients with other injuries. Evaluation begins with an organized and rapid primary survey aimed at recognizing and treating immediately life-threatening problems.

The first priority is to ensure an adequate airway. An airway often can be established by clearing any blood or debris from the oropharynx and pulling the mandible or the tongue forward. Severely injured patients commonly require nasotracheal or orotracheal intubation, and some, especially those with severe maxillofacial trauma, require cricothyroidotomy or tracheostomy.

The second priority is to ensure adequate ventilation. If the patient is not breathing, he or she must be intubated promptly. If ventilation is inadequate because of open or tension pneumothorax, these problems should be addressed at this stage of care.

The next priority is control of external hemorrhage and restoration of circulation. External hemorrhage is best controlled by direct pressure. Inadequate perfusion generally results from either hypovolemia or pump (i.e., cardiac) problems. Hypovolemia from hemorrhage often must be treated operatively as part of the resuscitative effort. Pump problems are signaled by distended neck veins and are caused by one of four conditions: (1) tension pneumothorax, (2) pericardial tamponade, (3) coronary air embolism, or (4) cardiac contusion or myocardial infarction (MI). These conditions are discussed in detail elsewhere (see below). At this early stage of treatment, they should be addressed sufficiently to ensure adequate perfusion.

In most blunt trauma patients, urgent treatment of thoracic injury is accomplished during the primary survey because the most common blunt chest injuries can be controlled with endotracheal intubation or tube thoracostomy. In this setting, thoracotomy is indicated for cardiac tamponade, a massive hemothorax, or uncontrolled massive air leaks. Neither pulmonary nor cardiac contusions should delay diagnosis or definitive treatment of extrathoracic injuries resulting from blunt trauma.

TUBE THORACOSTOMY: INDICATIONS AND TECHNIQUE

During initial resuscitation, chest tube placement can be both therapeutic and diagnostic. The two most common indications for tube placement in this setting are pneumothorax and hemothorax; however, signs and symptoms of these conditions may not be readily apparent. In addition, when the patient is in shock, the surgeon often cannot afford to take the time to differentiate between various possible causative conditions. Because tube thoracostomy is quick, relatively safe, and simple, it should be liberally used for patients in extremis.

Tension pneumothorax, the most common and easily treated immediately life-threatening thoracic injury, results when blunt or penetrating trauma disrupts the respiratory system and allows air to escape from the lung parenchyma or the tracheobronchial tree into the pleural space, thereby increasing intrathoracic pressure. This increased pressure is transmitted to all the cardiac chambers and retards venous return to the heart, resulting in hypotension. The classic signs of tension pneumothorax—decreased breath sounds, tympany on the ipsilateral side, tracheal shift, and distended neck veins—commonly are absent or are incompletely manifested in a busy emergency department. The diagnosis is often suggested by the presence of shock accompanied by evidence of adequate venous filling on physical examination and recognition of asymmetric motion of the two sides of the chest. Treatment of suspected tension pneumothorax should not be delayed in patients with hemodynamic compromise.

Chest tube placement in the trauma setting is a straightforward procedure. The chest is prepared and draped in a sterile fashion. A local anesthetic (e.g., 1% lidocaine) is not required in unconscious patients but should be used in alert patients. On the midaxillary line in approximately the fifth interspace, a scalpel is used to make a 2 to 3 cm incision, oriented in the direction of the interspace, through all layers of the skin and subcutaneous tissue. A finger or a blunt clamp is inserted to penetrate the intercostal muscles and the parietal pleura. The wound is explored with the index finger (in adults) or the fifth finger (in children) to ensure that the pleural space has been entered and allow local exploration of the chest cavity.

In adults, a 36 French chest tube is then inserted and directed posteriorly and towards the apex for optimally effective drainage of air and blood. The desired tube position is best achieved through appropriate orientation of the skin incision relative to the entrance into the chest cavity: the straight line between these two points defines the direction of the tube once it is in the chest. The tube is then attached to 20 cm of suction with a water seal and a collection chamber. Visual inspection of air passing through the water seal yields an estimate of the size of the air leak—an important consideration with suspected airway injuries.

Collection chambers for hemothoraces should be of the same design. Those associated with autotransfusion devices (e.g., cell

savers) have immense theoretical potential for rapid retrieval and processing of shed blood. In practice, however, their utility is limited. For example, with a small to moderate-sized hemothorax (< 1,000 ml), the red-cell yield of an autotransfusion device would be small and not worth the associated time and expense. With a large hemothorax, the most important goal of therapy is control of bleeding, and arranging for autotransfusion could delay or hinder the achievement of this goal. In addition, products of autotransfusion may contain harmful cytokines, damaged cells, and debris, while lacking platelets and other important proteins and coagulation factors.²

Antibiotic prophylaxis after tube thoracostomy is controversial.³ Most clinicians, however, would recommend use of a first-generation cephalosporin for 24 hours, ideally starting before the initial tube placement.

After the primary survey, less dramatic pneumothoraces may be recognized on diagnostic images, along with hemothoraces, on various imaging studies. Treatment of occult pneumothoraces (i.e., those seen only on computed tomography) deserves special mention. In general, patients with occult pneumothoraces who require positive pressure ventilation, those who are hypotensive or have respiratory distress of any etiology, and those who have associated complex injuries or hemothorax should be treated with tube thoracostomy. One group, however, has questioned the need for tube thoracostomy in patients requiring positive pressure ventilation on the basis of findings from a small number of patients.⁴ Patients with occult pneumothoraces who are treated without tube thoracostomy should be observed for at least 24 hours.

Retained Hemothorax and Empyema

In treating a hemothorax with tube thoracostomy, the goal is complete removal of blood. Complications such as atelectasis and empyema after chest trauma are clearly related to the presence of residual blood, fluid, and air, as can occur secondary to improper positioning of the tube (i.e., within a fissure), obstruction of the tube, or blood clot or loculated fluid within the chest.

A persistent or clotted hemothorax is suggested by the presence of a persistent opacification in the pleural space in a patient with a known previous hemothorax. This radiodensity can be confused with adjacent pulmonary contusion or atelectasis; chest CT confirms the diagnosis. Because retained blood serves as a nidus for infection and empyema,⁵ aggressive attempts at removal are justified. Occasionally, removal can be accomplished by placing more chest tubes, but often, an operative approach is needed. Video-assisted thoracic surgery (VATS) [see 4:7 *Video-Assisted Thoracic Surgery*] may be useful for managing small, clotted hemothoraces and free-flowing blood in patients who can tolerate single-lung ventilation⁶; however, VATS tends to limit the surgeon's ability to control bleeding and perform definitive repair of injuries. In patients who have ongoing bleeding or large, clotted hemothoraces, posterolateral thoracotomy is generally required.

Empyema thoracis is a relatively common complication after chest trauma, occurring in 5% to 10% of patients.^{7,8} Possible causes include retained hemothorax, pneumonia with parapneumonic effusion, persistent foreign body, ruptured pulmonary abscess, bronchopleural fistula, esophageal leakage, and tracking through the intact or injured diaphragm from an abdominal source. Empyema may be difficult to diagnose and must be differentiated from pleural thickening, pulmonary contusion, and an uninfected effusion. Chest CT with intravenous contrast usually demonstrates a fluid collection with loculations or an enhancing rim. Such findings, coupled with a clinical scenario of low-grade sepsis or failure to

thrive, are diagnostic. Analysis and culture of fluid obtained at thoracocentesis or chest tube placement typically confirms the diagnosis, but the fluid may be sterile if the patient is already receiving antibiotics.

Antibiotic therapy, either broad-spectrum or specifically directed against cultured organisms (usually gram-positive pathogens), is certainly an important component of therapy for empyema thoracis, but the primary goal is removal of the infection while the fluid is still thin. When this goal is met, a more modest therapeutic procedure can be performed, there is less risk that a restrictive pulmonary peel will develop, and the injured patient recovers faster overall. In the early stages, tube thoracostomy may suffice for treatment; however, if the infected pleural process cannot be completely evacuated via chest tube because of thicker fluid, loculations, or pleural adhesions, a formal thoracotomy with decortication is generally required.

Decortication should not be undertaken in the face of severe sepsis. Instead, antibiotics and chest drainage (via tube thoracostomy, CT-directed catheter placement, or open rib resection) should be employed until sepsis is controlled. In cases of early empyema, VATS has been successfully used for lysis of adhesions and removal of fluid.^{9,10} Because of the limited capacity for performing pleurectomy with this procedure, VATS should not be used when thick peel or a trapped lung is present. In adult patients with posttraumatic empyema, there is no proven role for intrapleural fibrinolytic therapy.

EMERGENCY DEPARTMENT THORACOTOMY

ED thoracotomy is a drastic step in the treatment of the injured patient. If possible, the patient should be stabilized and transported to the operating room, where better facilities are available for definitive care.

ED thoracotomy is best reserved for patients who arrive at the ED and deteriorate rapidly and those who have undergone cardiac arrest just before arrival. The results are dismal when it is performed in patients who have undergone cardiac arrest some time before arrival and have required cardiopulmonary resuscitation for more than a few minutes. Blunt trauma victims who have sustained cardiopulmonary arrest at the scene of injury should not be subjected to thoracotomy, either at the scene or in the ED.¹¹ Similarly, patients who are found at emergency thoracotomy to have no cardiac activity have a dismal prognosis, as do those who do not respond to improvement of systolic blood pressure after aortic occlusion. Overall, the survival rate for patients undergoing ED thoracotomy for blunt trauma is lower than 10%. The reported survival rate for patients undergoing ED thoracotomy for penetrating trauma ranges from 16% to 57%,¹¹⁻¹³ and that for patients with cardiac wounds ranges from 57% to 72%.¹¹⁻¹³

The technique of ED thoracotomy is straightforward. An antiseptic solution may be splashed on the chest, but skin preparation is not required. An incision is made from the sternal border to the midaxillary line in the fourth intercostal space. A chest retractor is inserted and opened widely. The costochondral junctions of the fifth, the fourth, and sometimes the third rib are divided quickly with the scalpel to provide exposure. Attention is directed first to the injury. If there is exsanguination from a great vessel, the hemorrhage is controlled with pressure. If air embolism is the cause of the arrest, the hilum is clamped and air evacuated from the aorta. Otherwise, the pericardium is opened anterior and parallel to the phrenic nerve. The hemopericardium is evacuated, the cardiac injury is controlled with digital pressure, and a temporary repair is performed.

After the cause of the arrest has been addressed, the descending thoracic aorta is occluded with a vascular clamp or digital pressure and intrathoracic cardiac compression is initiated. The patient's intravascular volume is restored, and electrolyte imbalances are corrected. If the patient can be saved, he or she is transported to the OR for definitive repair and closure.

SECONDARY SURVEY AND DEFINITIVE DIAGNOSIS

The secondary survey should focus on more subtle evidence of injury that may be detected on physical examination and chest x-ray. Simple rib fractures are clinically relevant when associated with pain and are better diagnosed by palpation than by most imaging studies. Pneumothorax and hemothorax often go undetected during the primary survey but are common findings later in the workup.

Echocardiography can be an important adjunct for assessing proximity wounds to the heart or evaluating a new murmur. Because of continuing improvements in CT scanning technology, this modality is increasingly being used in the evaluation of the widened mediastinum.¹⁴ Indeed, CT angiography is now routinely employed for definitive diagnosis of aortic injuries, rendering standard angiography unnecessary in most cases.¹⁵

Operative Considerations

INDICATIONS FOR OPERATIVE MANAGEMENT

Indications for operative treatment of thoracic injuries fall into five broad categories: (1) hemorrhage, (2) major airway disruption, (3) cardiac and vascular injuries, (4) esophageal disruption, and (5) diaphragmatic disruption. The extent and location of hemorrhage can sometimes be determined from open wounds but are more often established after chest tube insertion. If 1,500 mL of blood or more is obtained initially or ongoing bleeding at a rate of 300 mL/hr or higher for 3 hours is noted, thoracotomy is indicated.¹⁶ Massive air leakage and the presence of gastric or esophageal contents in the chest tube effluent also necessitate surgical intervention. The severity of an air leak can be estimated by examining the amount of air traversing the water seal chamber. Intermittent bubbling signifies a small leak, whereas a continuous stream of bubbles signifies a large leak. A continuous leak seen in conjunction with inability to expand the lung completely or with inadequate tidal volumes is considered a massive air leak. In stable patients with no evidence of bleeding, specific diagnostic measures may be performed to evaluate the thoracic viscera. The likelihood of associated intra-abdominal injuries must not be overlooked.

CHOICE OF INCISION

The choice of thoracic incision obviously depends on many factors, including the indication for operation, the urgency of the situation, the presence of associated injuries, the mechanism of injury, and the results of preoperative studies. For injuries that are suspected or diagnosed preoperatively, the approach to the affected thoracic structure is relatively straightforward [see Table 1]. For exploratory surgery, the choice of incision should depend on the mechanism, the instrument, the location (of the entire injury, not just the entry site), and the symptoms. Stab wounds generally have a lower potential for deep penetration than missile injuries do.

A median sternotomy is one of the more versatile thoracic incisions. It can be opened and closed more quickly than a thoracotomy, is associated with less postoperative pain, and may be less likely to result in contamination of the dependent hemithorax. In gen-

Table 1 Surgical Approaches for Traumatic Injuries to Thoracic Structures

Site of Injury	Incision

0—site inaccessible

eral, a median sternotomy provides the best exposure of the right-side cardiac chambers, the ascending aorta, the aortic arch, and the arch vessels (excluding the left subclavian artery), and it provides adequate exposure of both lungs and both hemidiaphragms. In the setting of exploratory surgery, a median sternotomy is the best incision for mantle stab wounds and some precordial gunshot wounds whose trajectory can be reliably determined. Its main limitation is that it does not provide exposure of the posterior mediastinal structures.

For exploration of lateral stab or gunshot wounds, a posterolateral thoracotomy on the side of the injury is the incision of choice. Besides being the best incision for exploratory purposes, the fifth interspace thoracotomy is the most versatile approach to ipsilateral pulmonary and mediastinal pathologic states. Exposure can be markedly enhanced by removal of the fifth rib, which yields an incision that is as long as the rib itself and extends as high as the fourth interspace and as low as the sixth interspace. In general, it

is unwise to perform an exploratory thoracotomy below the fourth interspace or above the sixth.

A transverse anterior thoracotomy (clamshell incision) is occasionally useful for undetermined or transmediastinal injuries in urgent situations. When exposure of both hemithoraces is required in nonurgent situations, both staged bilateral posterolateral thoracotomies and median sternotomy provide better exposure; one or the other is therefore preferred.

The role of VATS in the trauma setting continues to evolve. In acute situations, VATS is useful for ruling out diaphragm injury and may be preferable to laparoscopy insofar as it is less likely to cause tension pneumothorax. VATS may also have a role to play in the management of persistent intercostal or internal mammary artery bleeding, but this application demands some degree of experience with thoracoscopic surgery. Later after injury, VATS can be employed for evacuation of retained hemothorax and for management of the early stages of empyema.

DAMAGE CONTROL TACTICS

Whereas the concept of damage control is critically important in abdominal trauma, it is less important in thoracic trauma. Although serious bleeding from most thoracic structures is unlikely to be controlled with packing, severe coagulopathy occasionally prevents definitive repair and necessitates abbreviation of surgery and temporary closure of the chest by suturing or stapling the skin incision only.¹⁷ The two most common locations of injury in these scenarios are the lung and the chest wall.

Hemorrhage from lung lacerations in patients with metabolic exhaustion generally should not be treated with formal anatomic resection: stapled wedge resection, tractotomy, or simple suture repair is more appropriate. In patients with persistent chest wall bleeding that is not associated with a major vessel, treatment with lung reexpansion for local tamponade and correction of coagulopathy usually suffices. In rare circumstances, complex esophageal injuries may be associated with extensive loss of tissue, necessitating rapid exclusion and proximal diversion. In most patients with any chance of survival, however, the surgeon should attempt primary closure of the injury, buttressing the repair with autologous tissue, and employing wide drainage. Even with large defects, this approach has a surprisingly high rate of ultimate success.

ANESTHETIC CONCERN

Airway management can be extremely complex in patients with thoracic injuries, especially when tracheobronchial injury is involved. Whenever operative management is required for a thoracic trauma patient, operative planning should begin with a discussion with the anesthesiology team about airway issues.

In general, double-lumen and bronchial-blocker endotracheal tubes, which allow better exposure by partially or completely deflating a selected lung, should be strongly considered for any thoracic operation. For any given patient, the improved exposure achievable with such tubes must be weighed against the disadvantages—namely, the additional time needed for placement and the requirement that single-lung ventilation be tolerable from a cardiopulmonary standpoint. Hemodynamic stability, therefore, is usually a prerequisite for the use of these devices. The extent of the advantage gained with lung isolation must also be considered. For example, surgery on the mediastinum or the hilum is greatly facilitated by lung deflation, whereas surgery on the chest wall is not. If necessary, these tubes can often be placed in the ED.

If, at presentation, a patient with an otherwise adequate airway has signs of airway injury (e.g., a massive air leak, subcutaneous

air, or hemoptysis), further evaluation with bronchoscopy in the OR is indicated before a decision is made to replace the existing adequate airway. In the absence of massive air leakage, bronchial tearing, or hemorrhage into one mainstem bronchus, a double-lumen tube should be advanced into the left mainstem bronchus. Otherwise, the tube should be placed so as to protect the uninjured side.

When a patient with a double-lumen tube in place requires continued intubation after operation, the tube generally must be replaced with a standard endotracheal tube or a tracheostomy because an adequate pulmonary toilet cannot be performed through a double-lumen tube. In contrast, a bronchial-blocker tube may be left in place after surgery because a suction catheter can be passed down it. A disadvantage of the bronchial-blocker tube, however, is that intraoperative lung isolation may be less complete than that obtained with a double-lumen tube.

When a patient requiring a thoracic operation presents with an inadequate airway, specific airway management depends on the nature of the injuries. Most of these patients can be intubated in the standard fashion. If intubation is unsuccessful, however, cricothyroidotomy should be attempted without delay. In cases of tracheal transection, the distal segment must be controlled quickly through a neck incision and selectively intubated through the wound. In cases of known or suspected thoracic airway injuries, an endotracheal tube should be inserted over a bronchoscope past the injury or into an uninjured mainstem bronchus.

Intraoperative management of the airway in patients with complex tracheobronchial injuries can be challenging and is discussed in detail elsewhere [see Tracheobronchial Injuries, below]. Injuries to the thoracic trachea may necessitate placement of temporary tubes within the operative field to provide ventilation [see Figure 1]. After repair of a tracheobronchial injury, the patient should be extubated if at all possible to prevent stress on the repair.

The locations of arterial catheters should be considered as well. In general, radial arterial lines should be placed in the extremity opposite the side of the intended thoracotomy and not (obviously) in vessels distal to anticipated cross-clamps. Placement of an epidural catheter for postoperative pain management [see 1:5 Postoperative Pain] should also be considered in patients undergoing nonurgent thoracotomy.

Control of body temperature is critical for both operative and nonoperative management. Most thoracic trauma patients are hypothermic and require a warm OR, warm I.V. fluids, and warming blankets. Occasionally, controlled hypothermia is a useful adjunct to procedures involving the thoracic aorta when spinal cord injury and paraplegia are risks. For patients with severe coagulopathy and a core temperature lower than 33.5° C, extracorporeal warming can be lifesaving. This procedure involves placement of a 21 French femoral venous cannula and a 17 French internal jugular cannula and use of a centrifugal pump and a heat exchanger. Heparin is not necessary.

Chest Wall Injuries

BLUNT

The greatest significance of certain chest wall injuries is their frequent association with other, more life-threatening injuries. These so-called sentinel injuries include first rib fractures, scapular fractures, sternal fractures, bilateral rib fractures, and lower rib fractures.

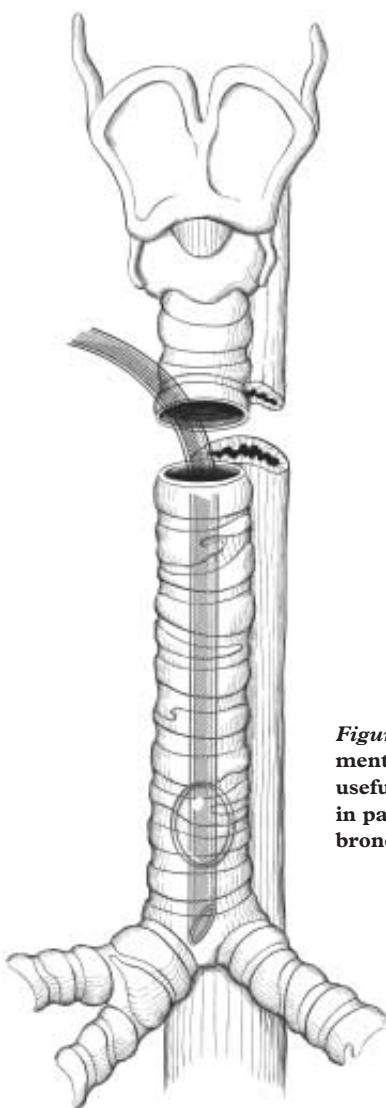

Figure 1 Intraoperative placement of an endotracheal tube is useful for airway management in patients with tracheobronchial injuries.

Simple Rib Fractures

Rib fractures are the most common chest wall injuries resulting from blunt trauma. The main pathophysiologic consequences of rib fractures are pain, splinting, and prevention of adequate cough. The diagnosis should be suspected if pain or splinting occurs on deep inspiration, and it is confirmed by careful physical examination, consisting of anterior-posterior and lateral-lateral manual compression. If an alert patient feels no pain when these maneuvers are done, clinically significant rib fractures can be excluded. Although rib fractures are often identified on routine chest radiographs, they are more likely to be undetectable except on rib-detail films, which are rarely indicated. A variant of rib fracture that falls into the same physiologic category is costochondral or costosternal separation. This condition is usually detected during physical examination but is not seen on routine chest radiographs.

Management Isolated rib fractures can usually be adequately treated by giving oral analgesics and encouraging good pulmonary toilet. We mention chest wall strapping, taping, and bracing only to condemn these practices. Binding devices generally restrict tidal volume and thus promote rather than prevent atelectasis and pulmonary complications. Treatment of multiple rib fractures, costochondral separation, and costosternal separation is described more fully elsewhere [see Flail Chest, below].

Special mention should be made of rib fractures in the elderly. The mortality associated with rib fractures is twice as high in patients older than 65 years as in younger patients, and the relative increase in the incidence of pneumonia in older patients is even higher, even after the increased comorbidity is taken into account.^{18,19}

Sternal Fractures

The vast majority of sternal fractures result from motor vehicle accidents and are associated with the use of three-point restraints. Isolated sternal fractures in this setting are relatively benign, having a low incidence of associated cardiac, great vessel, and pulmonary injuries. Sternal fractures in unrestrained occupants and victims of crush injuries, however, are commonly associated with underlying visceral injuries, which must be excluded.²⁰

The diagnosis of sternal fracture is based on the presence of severe pain, often associated with instability on sternal palpation. In many cases, physical examination can clarify the nature of the fracture. Sternal fractures are almost invariably transverse, with the majority occurring at the sternomanubrial joint or in the mid-body of the sternum. They may be characterized as simple (two fragments) or comminuted (multiple fragments), as displaced or aligned, or as stable or unstable. The fragments of an unstable fracture move substantially with activity.

Management Initial management of sternal fracture is directed toward resuscitation and identification or exclusion of other life-threatening injuries. In patients with isolated sternal fractures, a normal electrocardiogram and a normal chest radiograph suggest that associated serious injuries are unlikely. If the pain is controlled with oral analgesics, these fractures can usually be managed on an outpatient basis. Displaced fractures may be reduced by the simple (albeit painful) maneuver of having the patient simultaneously raise his or her head and legs from the bed. Such a position requires contraction of the rectus abdominis, which distracts the caudad segment inferiorly, and the sternocleidomastoid muscles, which retract the cephalad segments superiorly. The physician can then depress the anterior segment and allow the patient to relax. This measure often suffices for alleviation of subsequent pain and sometimes constitutes adequate long-term treatment.

The vast majority of sternal fractures heal with nonoperative management. Those that are unstable or are displaced by more than 1 cm of overlap are more likely to exhibit malunion or nonunion and subsequent chronic pain; they should be treated with open reduction and internal fixation. Occasionally, a patient with a clinically stable, minimally displaced sternal fracture associated with lower extremity injuries who requires crutches for ambulation experiences such disabling sternal pain during ambulation that fracture repair is necessary.

Sternal fractures may be repaired with either of two operative techniques. In both, the sternum is approached via either a vertical midline incision or a sweeping transverse inframammary incision similar to that used for repair of pectus excavatum. The fracture is exposed, and the ends are mobilized and fixed with either reconstruction plates or No. 6 sternal wires. Reconstruction plates provide a more stable and less painful fixation, and they can be used in the management of comminuted and crush fractures. Wire repair is unsatisfactory in patients with comminuted or crush fractures and in many patients requiring crutches for ambulation. Both wire fixation and plate fixation are well tolerated and, in fact, greatly appreciated by properly selected patients.

Flail Chest

Flail chest is the most serious of the blunt chest wall injuries. It is common after any form of blunt thoracic trauma, and though it may occur as an isolated finding, it is usually associated with other significant injuries.²¹ Flail chest represents a disruption of the stability and normal respiratory mechanics of the rib cage. It involves fractures of adjacent ribs, each of which is fractured in two or more places, so that a panel of chest wall moves independently of, and in the opposite direction to, the remainder of the chest. When it occurs in conjunction with separation of the costochondral or costosternal joints, the sternum can also be part of the flail segment, and the condition is termed a sternal flail chest.

The following are the three components of the pathophysiology of flail chest:

1. Alteration of chest wall mechanics. The paradoxical motion of a large flail segment occasionally impairs the patient's ability to achieve an adequate tidal volume or an effective cough.
2. Underlying pulmonary contusion. In the vast majority of serious flail chest injuries, this is the most significant physiologic aberration. In the contused portion of the lung, there is extravasation and accumulation of blood and fluid in the alveolar air space, which results in sufficient shunting to produce hypoxemia.
3. Pain. The extreme pain of multiple rib fractures leads to profound splinting and diminution of tidal volume and prevents adequate coughing and pulmonary toilet in most alert patients. The combination of depressed tidal volume and inadequate coughing leads to hypoventilation, atelectasis, and often pneumonia.

The diagnosis is typically suspected on the basis of the presence of numerous adjacent rib fractures on a chest radiograph, but it can be conclusively confirmed only by the presence of a paradoxical motion observed in the involved segment in a spontaneously breathing patient. A flail segment may be overlooked in a patient undergoing positive pressure ventilation because there may be no paradoxical motion without inspiratory effort. Therefore, in an intubated patient, the diagnosis must be sought through careful examination and palpation of the rib cage for instability.

Management Proper management of flail chest hinges on the recognition that the injury is not a static condition but, rather, an evolving process. Frequent reevaluation and timely, appropriate intervention are essential. During the initial assessment, the patency of the airway and the adequacy of ventilation must be established or confirmed. Immediate intubation is rarely required for patients with isolated flail chest injuries. When early intubation is indicated, it is usually for associated injuries, most commonly to the central nervous system.

In virtually all awake and alert patients, management without intubation should be attempted. To this end, early and aggressive pain management is essential. Pain cannot be eliminated entirely, but it usually can be diminished sufficiently to allow an adequate tidal volume and a forceful cough. Oral analgesics rarely suffice for patients with even a small flail segment; stronger agents are required for all but the most stoic of patients. Parenteral narcotics are effective, especially when administered in a patient-controlled analgesia (PCA) device. Intercostal nerve blocks occasionally provide dramatic pain relief, but only for short periods. If the patient is encouraged to cough vigorously during pain relief, intermittent nerve blocks may be helpful, despite the inherent risk of pneumothorax.

The mainstay of pain control in patients with flail chest is thoracic epidural anesthesia, in which a solution containing 0.002% to 0.005% morphine sulfate and 0.075% to 0.2% bupivacaine is infused through a small catheter in the thoracic epidural space at a constant rate of 0.15 to 0.75 mg morphine/hr. At this low dosage, bupivacaine acts synergistically with morphine and does not exert a local anesthetic effect on the spinal cord; in addition, it generally does not give rise to the respiratory depression frequently observed with systemic narcotics. Epidural anesthesia provides immediate comfort, dramatically improves vital capacity and tidal volume, and, most important, enables the patient to produce a forceful cough.²²

The most common serious adverse effect of epidural anesthesia is transient hypotension at the time of insertion. This complication can be prevented by providing adequate volume resuscitation before creating the chemical sympathectomy. Urinary retention occurs in 30% to 50% of cases; in practical terms, this means that most flail chest patients should not have their urinary catheters removed until the epidural analgesics are no longer required. Patients who have head injuries and are thus at risk for increased intracranial pressure should not undergo epidural catheterization, because an unintentional dural puncture could alter cerebrospinal pressure sufficiently to induce or contribute to cerebral herniation. Relative contraindications to epidural catheter placement include spine fractures and infection; however, fever may be a relative indication if it is thought to be secondary to splinting with atelectasis or pneumonia.

The decision-making process for management of flail chest should begin with assessment of the patient's ability to cough [see Figure 2]. If the patient is able to clear tracheal secretions—that is, actually cough them up into the oropharynx—then observation in an acute care setting, in conjunction with small, infrequent doses of narcotics, is appropriate. If the patient has no cough or has a very truncated cough that moves secretions but does not propel them into the oropharynx, an aggressive program to promote pulmonary toilet, including chest physiotherapy and postural drainage, should be instituted. If a sufficiently vigorous cough cannot be achieved and there is no specific contraindication, an epidural catheter is inserted and the patient followed closely with frequent physical examinations in the intensive care unit. Ambulation is encouraged, and frequent coughing is required.

There is no role for antibiotic prophylaxis in the management of flail chest or pulmonary contusion. Pneumonia is common in this setting, occurring in 25% to 50% of flail chest victims, but prophylactic antibiotics do not reduce the incidence of this complication: they simply shift the spectrum of offending organisms to favor drug-resistant bacteria and fungi. Routine administration of steroids also has no role in the treatment of flail chest.

Given adequate pulmonary toilet, many flail chest victims can avoid intubation.²³ However, any patient with flail chest who demonstrates further deterioration of pulmonary function and who becomes hypoxic or hypercarbic should undergo mechanical ventilation aimed at (1) ensuring a tidal volume adequate for establishing normal chest wall excursion and (2) maintaining a respiratory rate adequate for achieving normocarbia. Hypoxia is managed by increasing the fraction of inspired oxygen (F_1O_2) and applying sufficient positive end-expiratory pressure to achieve adequate oxygenation (usually defined as arterial oxygen saturation greater than 90%) with nontoxic levels of F_1O_2 .

A few patients with severe disruption of chest wall mechanics as a result of flail chest continue to require positive pressure ventilation even though adequate pain control has been achieved and the pulmonary contusions are beginning to resolve. Some of them

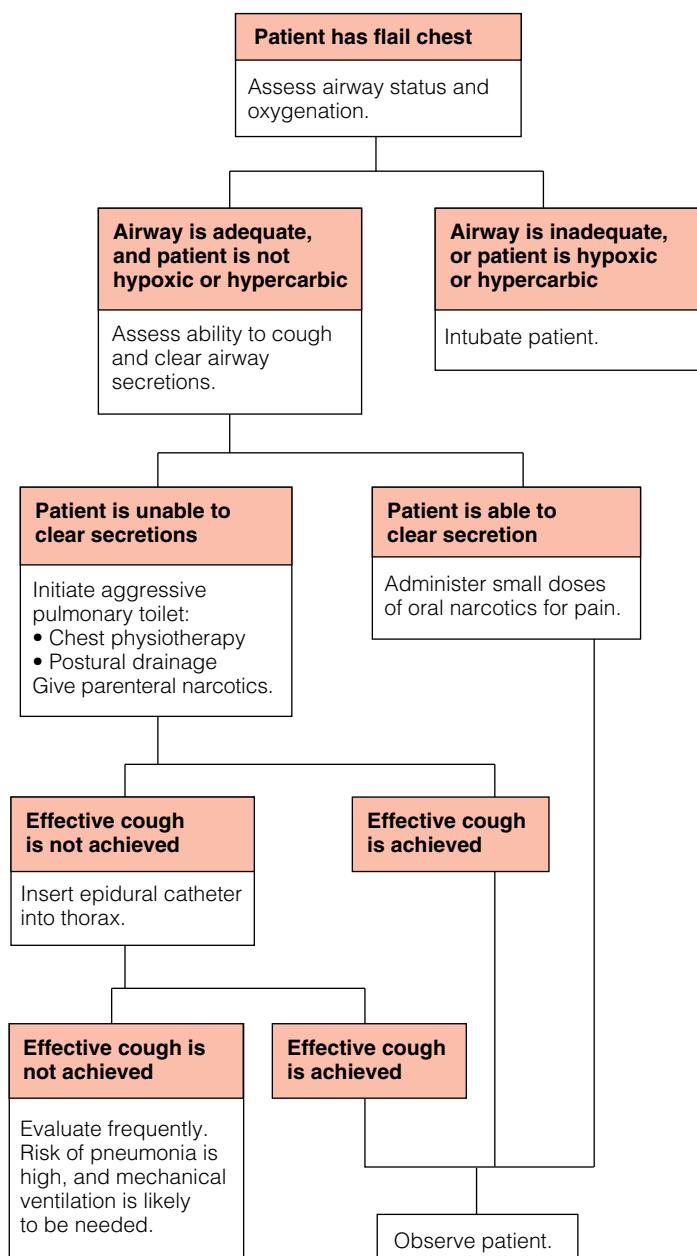

Figure 2 Algorithm illustrates approach to management of flail chest.

may benefit from internal fixation of the multiple rib fractures, which restores chest wall stability and eliminates much of the fracture-related pain. In this procedure, the fractured ribs are exposed and a small orthopedic plate is affixed so as to stabilize the ribs and obtain compression osteosynthesis of each fracture site. To date, internal fixation of rib fractures has not been widely studied in the United States, but reports involving a few carefully selected patients suggest that it can provide excellent pain relief. It has also been shown to improve tidal volume and pulmonary mechanics and reduce time spent on the ventilator.^{24,25}

PENETRATING

In most cases of penetrating thoracic trauma, the injury to the chest wall is vastly overshadowed by the injury, or potential for injury, to the intrathoracic structures. The notable exceptions to this general rule are hemorrhage and open chest wounds.

Hemorrhage

Stab wounds and low-caliber gunshot wounds to the anterior chest are common in urban areas. Such injuries often can be managed with tube thoracostomy or observation alone, once serious injury to intrathoracic organs has been excluded. Indications for urgent thoracotomy are discussed elsewhere [see Operative Considerations, Indications for Operative Management, above].

In patients with persistent hemorrhage from chest tubes who require thoracotomy, the most common source of the bleeding is a lacerated internal mammary or intercostal artery. Attempts to control bleeding from these vessels nonoperatively usually fail. Angiography to localize the bleeding vessel is unnecessary and delays definitive care: coupled with embolization of the lacerated vessel, it is more time-consuming than surgical intervention and does not address associated injuries and hemothorax.

Penetrating wounds to the midportion of the pectoral muscle occur with surprising frequency, possibly as a result of an assailant's erroneous conception of the location of the heart. Such injuries often lacerate the pectoral branch of the thoracoacromial artery, which courses along the posterior surface of the pectoral muscle. Control of this troublesome bleeding is extremely difficult to achieve if exploration is attempted directly through an extension of the entrance wound, but it is a straightforward and simple matter if exploration is attempted through an oblique wound along the lateral pectoral margin after entry into the subpectoral plane.

Open Chest Wounds

The diagnosis of an open chest wound is usually obvious, and their treatment depends on the size of the wound and the size of the chest wall defect. Most small open pneumothoraces can be managed initially with occlusive dressings, but there is usually an underlying pulmonary injury with air leakage, which necessitates early tube thoracostomy to prevent tension pneumothorax. Once the patient's condition is stable, the wound can be debrided and closed. Occasionally, primary skin closure must be delayed.

Larger chest wall defects pose a challenging therapeutic problem. Such wounds usually result from high-velocity missiles or shotguns fired at close range. Initial management is directed toward restoration of respiratory mechanics with early intubation and mechanical ventilation.

The next priority is to address any underlying intrathoracic injuries, which may range from mild pulmonary contusion to massive hemorrhage in conjunction with severe lung or hollow viscus injury. When associated intrathoracic injuries are present, the first step in the closure of the defect is to select an appropriate operative approach. Although the primary objective in this situation is to provide excellent exposure for repair of what may be life-threatening injuries, whenever possible, the thoracotomy should be performed in such a way as to preserve the blood supply and muscle mass of the chest wall adjacent to the defect.

After definitive repair of intrathoracic injuries and debridement of devitalized chest wall tissue, the next step is to plan the closure. Such planning requires a degree of familiarity with current and developing techniques and an understanding of pleural drainage, respiratory mechanics, and techniques of tissue transfer. Collaboration with plastic and thoracic surgeons is often helpful. Most chest wall defects can be closed with viable autogenous tissue, usually through rotation of local myocutaneous or myofascial flaps of the pectoral muscle, the latissimus dorsi, or the rectus abdominis.

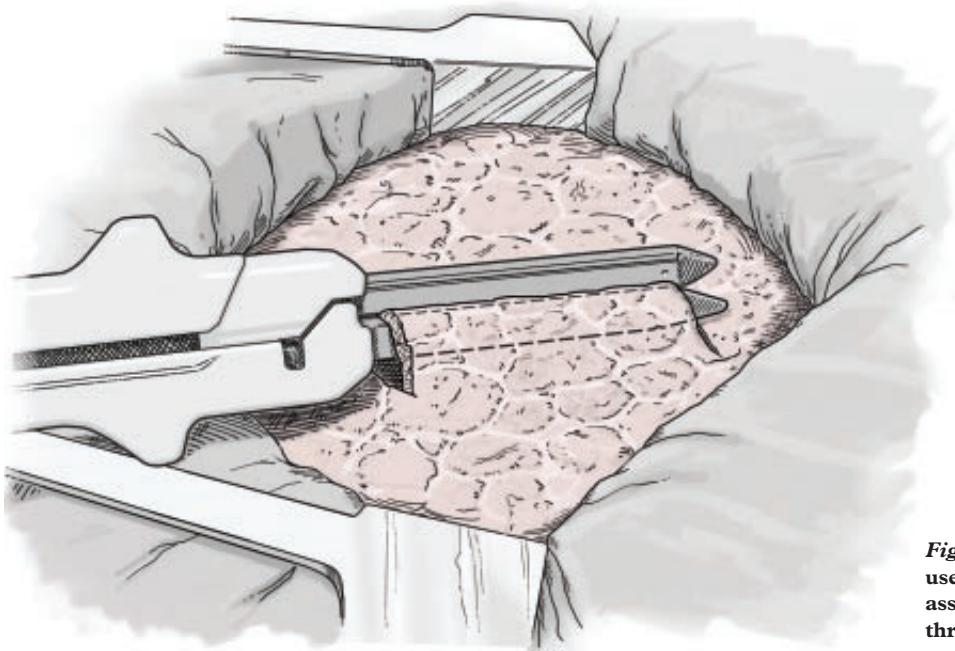

Figure 3 Pulmonary tractotomy is useful for controlling hemorrhage associated with deep through-and-through injuries to the lungs.

Pulmonary Injuries

Because of their size, the lungs are commonly injured in cases of thoracic trauma. Mortality from pulmonary lacerations is directly proportional to the amount of blood lost. A 1,500 ml hemothorax, regardless of causative mechanism, should always prompt exploration.

LACERATIONS

Bleeding pulmonary lacerations can be oversewn, resected, or explored via pulmonary tractotomy. Bleeding from small or shallow lacerations can be controlled with an over-and-over repair using a continuous monofilament suture. Bleeding from deeper lacerations is controlled with resection or tractotomy. Most pulmonary resections for trauma should be stapled, nonanatomic resections. Mortality is proportional to the amount of lung tissue resected: with suture repair alone, mortality is 9%; with tractotomy, 13%; with wedge resection, 30%; with lobectomy, 43%; and with pneumonectomy, 50%.^{26,27}

Tractotomy is especially useful for deep through-and-through injuries. In this technique, the injury tract is opened with a linear stapler [see Figure 3] or between two aortic clamps. If clamps are used, the cut lung edges are oversewn and the tract left open. Tractotomy exposes bleeding vessels and air leaks inside the tract and permits selective ligation. Occasionally, it exposes an injury to a major vascular or airway structure that must be treated with a formal resection. Because of the risk of exanguination or excessive devitalization of lung tissue, tractotomy is not indicated when the injury traverses the hilum or when the entire thickness of a lobe will be cut.

Central lung injuries often cause massive hemorrhage. In addition, they may be sources of pulmonary venous air emboli when both a major pulmonary vein and a large airway are disrupted. A common scenario involves an intubated patient on positive pressure ventilation who exhibits sudden deterioration of CNS and cardiac status. Emergency thoracotomy must be performed and the pulmonary hilum clamped. The diagnosis is confirmed by visualizing air in the epicardial coronary arteries. Aspiration of air from the left-side cardiac chambers and elevation of central blood pressure are also useful maneuvers. Most central lung injuries are associated with extensive parenchymal injury in gravely ill patients.

Selective repair of hilar structures is usually impractical in this setting, and lobectomy or pneumonectomy is the salvage procedure of choice.

CONTUSIONS

Pulmonary contusions are bruises to the lung that usually are caused by blunt trauma to the chest but sometimes result from penetrating injury by high-velocity weapons. The contused segment of the lung has a profound ventilation-perfusion mismatch, which produces an intrapulmonary right-to-left shunt and hypoxia. The bruise also may serve later as a source of sepsis. The diagnosis is usually evident on initial chest x-ray or CT, but the bruise often is not fully developed until 12 to 24 hours after injury.

Most pulmonary contusions that are not complicated by excessive attempts at resuscitation or by superinfection resolve over 3 to 5 days. Cardiovascular and, if necessary, ventilatory support must be provided. In general, pulmonary contusion is treated in much the same fashion as flail chest. Patients with rib fractures and painful chest wall excursions must be given sufficient analgesic support to allow them to produce a cough forceful enough to maintain pulmonary toilet. Intubated patients should undergo suctioning frequently. Patients with pulmonary contusions who require substantial volume resuscitation should be considered for pulmonary arterial catheter monitoring. Steroids are not indicated, because they have no effect on the development or resolution of the contusion and because they set the stage for subsequent infection. Diuretics and prophylactic antibiotics are also unnecessary.

Tracheobronchial Injuries

Although tracheobronchial injuries are often lethal, a high index of suspicion for the existence of the injury, a timely diagnosis, and appropriate intervention can improve the chances of a successful outcome. The reported incidence of tracheobronchial injury in blunt chest trauma patients ranges from 0.2% to 8%.²⁸⁻³⁰ More than 80% of tracheobronchial ruptures occur within 2.5 cm of the carina. Mainstem bronchi are injured in 86% of patients and distal bronchi in only 9.3%, whereas complex injuries are seen in 8%.

Knowledge of the anatomy of the trachea and the bronchial tree facilitates safe exposure and repair of these structures. The trachea is a tubular structure 10 to 13 cm long, with half of its length in the neck and half in the thorax. The anterior two thirds of the trachea is protected by 18 to 22 U-shaped cartilages. The posterior wall of the trachea is membranous and in intimate contact with the esophagus. The recurrent laryngeal nerve lies adjacent to the esophagus and the trachea in the tracheoesophageal groove. At the level of the fourth thoracic vertebra, the trachea ends and the mainstem bronchi originate. The blood supply to the trachea is segmental and approaches the trachea laterally.

When dissecting and mobilizing the trachea, one should avoid the lateral pedicles and mobilize only one tracheal ring circumferentially so as to maintain an adequate vascular supply. One may resect a substantial length of the trachea (as much as 4 or 5 cm, or half) and still achieve a safe primary anastomosis. Because the trachea is in contact with the esophagus along its entire posterior length and is surrounded by vital structures (e.g., lungs, heart, and great vessels), associated injuries are common and often fatal.

Intrathoracic injury to the tracheobronchial tree is more commonly the result of blunt trauma but may also be caused by bullet wounds. Blunt trauma may injure the trachea and the bronchi via several mechanisms, including direct blows, shear stress, and burst injury. Shear forces on the trachea cause damage at its relatively fixed points—namely, the cricoid and the carina. Burst injury along the tracheobronchial tree often results in rapid anteroposterior compression of the thorax. This compression causes a simultaneous expansion in the lateral thoracic diameter, and the negative intrapleural pressure stretches the lungs laterally along with the chest wall, thereby placing traction on the carina. When the plasticity of the tracheobronchial tree is exceeded, the lungs are pulled apart and the bronchi avulsed. Closure of the glottis before impact may convert the trachea into a rigid tube with increased intratracheal pressure, and as a consequence, the impact may cause a linear tear or blowout of the membranous portion of the trachea or a complex disruption of the trachea and the bronchi. Given the protected nature of these structures, a high degree of energy transfer is usually required to injure them.

Various clinical presentations result after injury to the tracheobronchial tree, generally depending on the severity and the location of the injury. In the neck, airway involvement may create severe respiratory distress that causes death before emergency care can be given. Alternatively, patients with cervical tracheal injuries may present with stridor and severe respiratory distress or with hoarseness, hemoptysis, or cervical subcutaneous emphysema.

The presentation of thoracic tracheobronchial injury depends on whether the injury is confined to the mediastinum or communicates with the pleural space. Thoracic tracheobronchial injuries confined to the mediastinum usually present with a massive pneumomediastinum. Pneumopericardium is occasionally described, but this description is usually mistaken, because air in the pericardial sac is in fact rare. What is actually seen is air in the plane just external to the pericardium, between it and the pleura. Injuries that do extend into the pleural space usually create an ipsilateral pneumothorax that may or may not be under tension. A pneumothorax that persists despite adequate placement of a thoracostomy tube and that leaks air continuously is suggestive of tracheobronchial injury and bronchopleural fistula. Dyspnea may actually worsen after insertion of the chest tube because of the loss of total volume via the tube. Several radiographic clues to possible airway injury may be observed with endotracheal intubation, such

as abnormal migration of the tube tip and distention of the endotracheal tube balloon beyond the normal tracheal diameter.

In only 30% of cases is a definitive diagnosis of tracheobronchial injury made within 24 hours. More often, the diagnosis is made late, when pulmonary collapse and sepsis occur. As many as 10% of tracheobronchial tears give rise to no initial clinical or radiologic signs and are not recognized until months later, after stricture occurs. Immediate intubation of patients with multisystem trauma can mask laryngeal or high cervical tracheal injuries and thereby delay the diagnosis. After tracheobronchial transection, the peri-bronchial connective tissues sometimes remain intact and allow continued ventilation of the distal lung, in much the same way that perfusion is maintained after traumatic aortic transection. If unrecognized, this injury heals with scarring and granulation tissue and occasionally creates bronchial obstruction.

Concomitant injury is the rule rather than the exception, but the patterns of associated injury vary widely. Major vascular, cardiac, pulmonary, esophageal, bony thoracic, and neurologic injuries are common in tracheobronchial trauma and reflect the site, magnitude, and mechanism of the trauma. The mechanism of injury may alert the examiner to search for specific associated injuries. For example, transcervical and transmediastinal penetrating injuries pose a particular danger to the structures they traverse. The esophagus is the organ most frequently injured in conjunction with tracheal trauma.³¹

The diagnosis is typically suspected on the basis of the clinical history and the characteristic signs and symptoms [see Figure 4]. The advent of spiral CT has led to renewed interest in the use of this modality to evaluate tracheobronchial injury; however, there is, at present, no evidence that CT is adequate to exclude such injury and render diagnostic bronchoscopy unnecessary. Indications for bronchoscopy in this setting include a large pneumomediastinum, a refractory pneumothorax, a large air leak, persistent atelectasis, and possibly marked subcutaneous emphysema.³¹ Bronchoscopy is the most reliable means of establishing the diagnosis and determining the site, nature, and extent of the tracheobronchial disruption.

Both rigid and flexible bronchoscopy have been employed in this setting; neither has been conclusively shown to be superior to the other. Rigid bronchoscopy must be performed with the patient under general anesthesia, and it requires a stable ligamentous and bony cervical spine. On the other hand, it permits direct visualization and has the ability to provide ventilation. Flexible bronchoscopy may be performed without general anesthesia and allows controlled insertion of a nasal or orotracheal tube while maintaining cervical stabilization; this maneuver may help prevent the need for emergency tracheostomy and the potential associated morbidity. At the same time, the entire larynx and trachea can be visualized with a flexible bronchoscope, as can the major lobar bronchi.

Whichever type of scope is used, the signs and symptoms should be correlated with the endoscopic findings. The most critical determinant seems to be the endoscopist's level of experience and comfort with the procedure. An experienced bronchoscopist can perform either technique with a high degree of sensitivity, specificity, and accuracy.²⁹ Often, the lesions are missed initially, or their severity is underestimated, or they evolve into more obvious or severe lesions. For this reason, bronchoscopy should be liberally repeated as needed.

MANAGEMENT

With tracheobronchial injuries, as with all injuries, airway management is the first priority in treatment. If the patient is maintaining his or her own airway and is adequately ventilated, a cau-

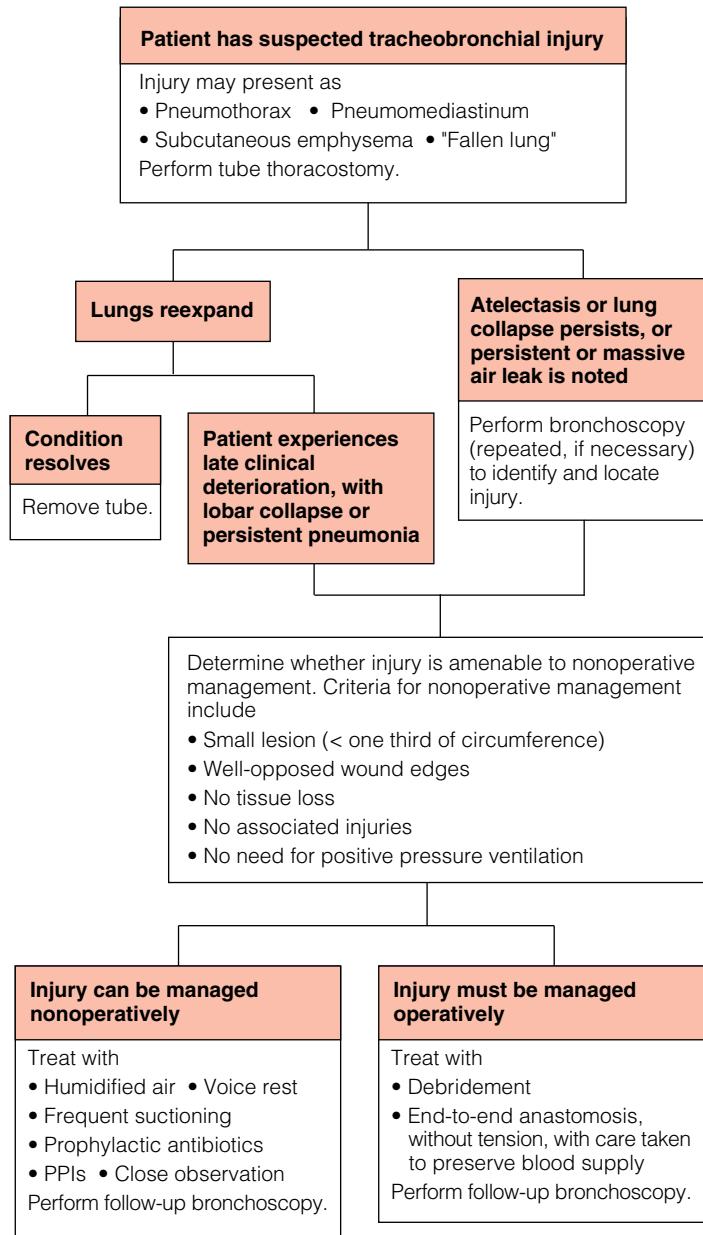

Figure 4 Algorithm illustrates approach to management of suspected tracheobronchial injury.

tious noninterventional approach is probably the best initial choice until further diagnostic workup is performed or other life-threatening injuries are stabilized. Careless handling or mishandling of the airway (e.g., inadvertently placing an endotracheal tube through a transected or ruptured airway and into soft tissue) can be disastrous and may compound the injury. ED tracheostomies are difficult and may be dangerous, to say the least.

How best to secure an airway in a patient with neck trauma and possible tracheal injury is a matter of debate. With blind endotracheal intubation, the path of the tube distal to the larynx is unknown, and it is possible to lose the lumen or create a false passage. With intubation over a flexible bronchoscope, the tube can be visualized as it passes beyond the site of injury, and some of the dangers of blind intubation are thereby mitigated; however, some degree of sedation is usually required, and if the patient is oversedated, the airway that was being spontaneously protected may be

lost. Paralytic medications should generally be avoided in this setting, for the same reason. Furthermore, bronchoscopy requires a level of expertise that is not always immediately available in an emergency situation. Urgent tracheostomy or cricothyrotomy, performed in the OR, is advocated by many as the safest and surest way of obtaining airway control. If the trachea is completely transected, the distal trachea can usually be found in the superior mediastinum and grasped for insertion of a cuffed tube. Early tracheostomy may prevent the damage often caused by these hurried, blind attempts at emergency airway control, but inevitably, a number of these tracheostomies will prove to have been unnecessary. The approach taken to airway control must vary with the resources and expertise available at each institution. One must also keep in mind that even after the airway is secured, it may still be possible to exacerbate the injury by means of aggressive ventilation with high airway pressures. Tube thoracostomies should be appropriately placed at this time and connected to suction, even though dyspnea may worsen.

Once the airway is controlled, there is time for orderly identification of concurrent injuries, esophagoscopy, laryngoscopy, arteriography, transport to definitive care areas, and, if necessary, celiotomy.

Nonoperative

On occasion, asymptomatic tracheobronchial tears are found incidentally in the course of bronchoscopy or other imaging procedures. Nonoperative management is reserved for highly selected patients with unsuspected small injuries of this type. Lesions suitable for observation must involve less than one third of the circumference of the tracheobronchial tree. For patients to be candidates for nonoperative care, their lungs should be fully reexpanded with tube thoracostomy, and any air leaks should stop soon after insertion of the tube. There must be no associated injuries and no need for positive pressure ventilation. Prophylactic antibiotics, humidified oxygen, voice rest, frequent suctioning, and close observation for sepsis and airway obstruction are required.

Small penetrating wounds with well-opposed edges and no evidence of loss or devitalization of tracheal tissue may be effectively treated with temporary endotracheal intubation.³² The cuff of the endotracheal tube should be inflated below the level of injury and left undisturbed for 24 to 48 hours while the wound seals. If a conservatively managed patient's clinical condition deteriorates, bronchoscopy should be liberally repeated. Even small tears may produce substantial amounts of granulation tissue upon healing, which may necessitate late endobronchial excision.

Operative

Like emergency airway management, intraoperative airway management requires close coordination with the anesthesiologist. After the airway is initially secured, manipulation during the repair creates additional challenges. A sterile anesthesia circuit and tube must be available to pass off the table once control of the airway at the level of transection has been regained and the peritracheal connective tissue has been disrupted or entered for repair. If orotracheal intubation is performed, either a single-lumen or a double-lumen endotracheal tube may be used. For proximal levels of rupture, a long single-lumen tube may be passed beyond the area of injury [see Figure 1]; for distal injuries, the tube may be advanced into the contralateral mainstem bronchus for single-lung ventilation. Intubation over a flexible bronchoscope improves the safety and diagnostic capability of the procedure.

If a tracheostomy is performed, it should be placed two to three rings caudal to any high tracheal or laryngeal injuries and should

be brought out through an incision separate from the surgical repair wound. Tracheostomy proximal to an injury is probably not necessary to protect the suture lines after repair of the thoracic trachea or a major bronchus, and its prophylactic use is discouraged for distal tracheobronchial injuries. Routine use of tracheostomy may result in various complications, including pneumonia, mediastinitis, wound infection, laryngeal and tracheal stenosis, and postoperative dysphonia.

In especially difficult cases, in which airway management is unsatisfactory or the repair is complex, cardiopulmonary bypass or venovenous extracorporeal membrane oxygenation (ECMO) may be instituted. Both of these techniques require systemic anticoagulation, and their potential risks and benefits in multiply injured patients remain to be determined.

Once the repair is complete, the endotracheal tube ideally should be removed immediately after the operation. Occasionally, there is a need for ongoing positive pressure ventilation, which may require the surgeon to employ sophisticated techniques of critical care and ventilation, such as positioning of the endotracheal tube distal to the repair, dual-lung ventilation, high-frequency jet ventilation, and ECMO. Every effort must be made to improve lung compliance by providing good pulmonary toilet, appropriate fluid management, and aggressive treatment of pneumonia.

Intrathoracic tracheal, right bronchial, and proximal left main-stem bronchus injuries are best repaired through a right posterolateral thoracotomy at the fourth or fifth intercostal space because this approach avoids the heart and the aortic arch. Complex or bilateral injuries are also approached through the right chest, for the same reason. Distal left bronchial injuries more than 3 cm from the carina are approached through a left posterolateral thoracotomy in the fifth intercostal space.

Optimal repair includes adequate debridement of devitalized tissue (including cartilage) and primary end-to-end anastomosis of the clean tracheal or bronchial ends. The anastomosis can be accomplished without tension by mobilizing the structures anteriorly and posteriorly, thereby preserving the lateral blood supply.

Tension may also be released with cervical flexion, which can be maintained postoperatively by securing the chin to the chest with a suture. Many investigators recommend performing the anastomosis with interrupted absorbable sutures; however, a continuous absorbable monofilament suture also offers a secure repair, is more readily visible during construction of the anastomosis, and eliminates knots within the tracheal lumen.

The membranous portion may be repaired without tension and then brought together as repair of the cartilaginous portion is begun. Sutures may be placed around or through the cartilage but, in either case, must ensure approximation of mucosa to mucosa. Tying the suture knots on the outside of the lumen also helps prevent suture granulomata and subsequent stricture. To prevent subsequent leakage and fistula formation, the suture line should be reinforced with a patch of pericardium or a vascularized pedicle from the pleura, an intercostal muscle, a strap muscle, or the omentum to protect the repair and assist bronchial healing.

For early repairs, the pleura is too flimsy to be suitable as reinforcement. A vascularized pedicle of intercostal muscle offers both better protection and added healing potential. For this reason, the intercostal muscle should routinely be preserved during thoracotomy, along with the corresponding vein, artery, and nerve. This is accomplished by entering the chest through the bed of the rib; the rib itself may be either preserved or sacrificed. An incision is made directly over the rib, and the periosteum is stripped off. At the superior border of the rib, the incision is carried through the posterior layer of the periosteum to enter the pleural space. The intercostal muscle is then divided from the ribs above and below and used as a flap to be wrapped around and tacked to the trachea. In this manner, viable tissue is placed between the repair and the surrounding vital structures, and the blood supply in the area of the repair is increased, thus facilitating healing [see Figure 5].

If diagnosis is delayed, repair should proceed as soon as the diagnosis is made or as soon as is practical after treatment of other life-threatening injuries. Regardless of the length of the delay, recon-

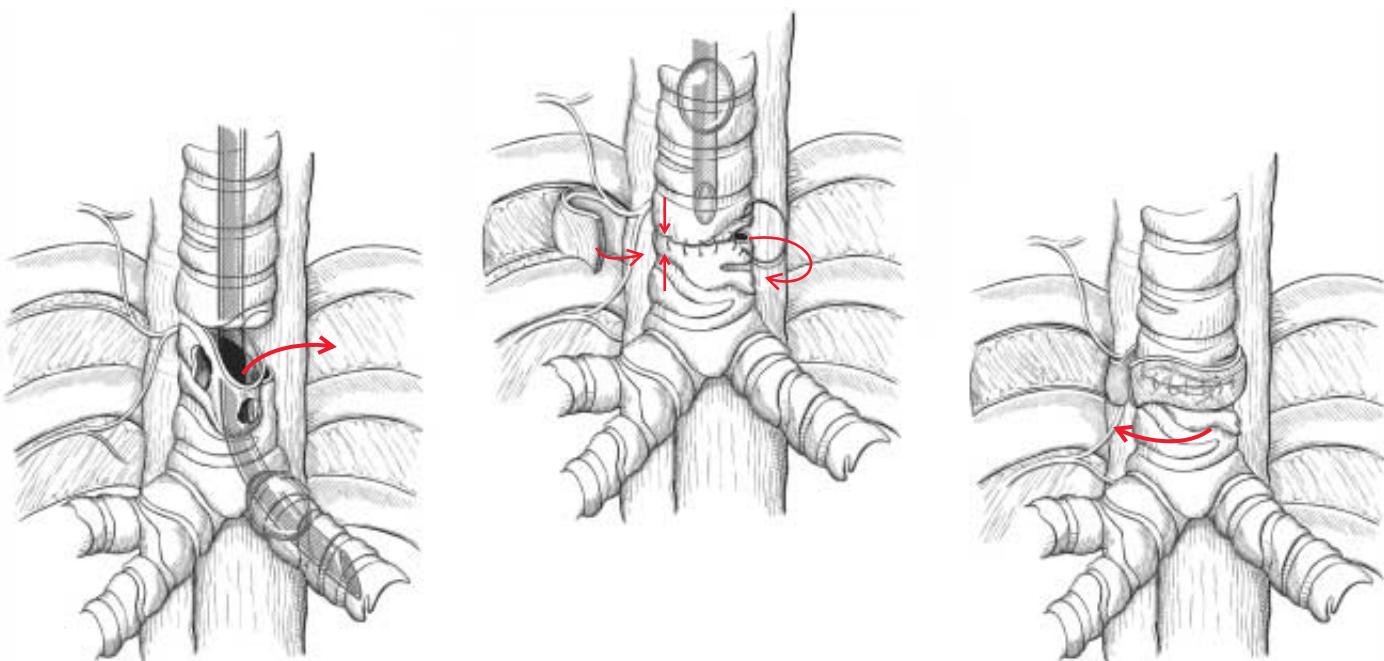

Figure 5 Tracheal injury may be repaired by means of segmental resection, with the suture line buttressed with an intercostal muscle flap.

struction of the tracheobronchial tree should be attempted if there is no distal suppuration. Total bronchial disruption often leads to complete occlusion and sterile atelectasis and may be amenable to repair years later. The stenotic segment is resected and repaired in much the same manner as an acute injury or a benign stenosis would be. Incomplete bronchial obstruction ultimately leads to suppuration and irreversible pulmonary parenchymal destruction. Bronchography and sputum culture are useful for determining whether pulmonary resection (pneumonectomy or lobectomy) is necessary for salvage. On occasion, bronchial sleeve resection, lobectomy, or pneumonectomy is urgently required for more extensive or distal injuries to lobar or segmental bronchi.

Although bronchial rupture can be treated successfully in either the acute or the delayed phase, early diagnosis and treatment minimize the risk of infection and resection and shorten hospital stay.

Esophageal Injuries

Injury to the esophagus, though relatively rare, poses particular problems for the treating physician because of the complexity of the presentation, the workup, and the treatment options. Despite diagnostic and therapeutic advances, the morbidity and mortality associated with esophageal injury remain high. Diagnosis and management of esophageal injuries evoke strong, and widely varying, opinions from surgeons. Preoperative evaluation is still a subject of debate, as is the question of mandatory surgical exploration versus selective nonoperative management. Currently, most esophageal injuries are iatrogenic or endoluminal; however, we will concentrate here on injuries specifically related to external trauma—namely, penetrating injury and blunt esophageal rupture.

Whereas the cervical esophagus is relatively unprotected from external trauma, the thoracic esophagus, being surrounded by the bony thorax, is well protected. The esophagus lies in close proximity to the heart, the great vessels, and the entire membranous portion of the trachea. Consequently, simultaneous injury to several of these intrathoracic organs is common, which greatly increases associated morbidity and mortality. The esophagus has no serosal covering; rather, it is entirely surrounded by loose areolar connective tissue, which makes suture placement less secure and increases the overall difficulty of surgical repair. The planes of the paraesophageal and prevertebral spaces communicate freely with the mediastinum. As a result, spillage from the esophagus readily tracks into the mediastinum, leading to mediastinitis, causing sepsis, and accounting for much of the increased morbidity and mortality seen with delayed diagnosis and treatment of esophageal injuries.

The exact incidence of injury of the esophagus caused by external trauma is unknown, but such injury accounts for fewer than 1% of injuries for which patients are admitted to hospitals. Most esophageal injuries result from penetrating trauma. If surgical exploration is performed for all penetrating cervical wounds that violate the platysma, the esophagus is found to be injured approximately 12% of the time. Penetrating intrathoracic esophageal injuries are less common, however, occurring in about 0.7% of all penetrating chest wounds.³³ Blunt esophageal trauma is relatively uncommon; it may develop when the organ suffers a direct blow or when increased intraluminal pressure against a closed glottis causes a burst-type injury.

Intrathoracic esophageal injuries tend to occur just proximal to the esophagogastric junction on the left side, where the esophagus is less well protected. The injury is thought to be the result of increased transmission of intra-abdominal pressure to the stomach, as is seen in postemetic esophageal rupture (Boerhaave syndrome). Gastric contents are widely and violently expelled into the

Table 2 Diagnostic Measures for Evaluating Suspected Esophageal Injuries

Diagnostic Measure	Sensitivity (%)	Specificity (%)	Accuracy (%)
Assessment of clinical signs and symptoms	80	64	72
Contrast esophagography	80–100	94–100	90–95
Rigid esophagoscopy	67–100	89–95	86–94
Flexible esophagoscopy	67–100	67–100	82–97

mediastinum, sepsis ensues, and the resulting mortality is high.

Between 60% and 80% of esophageal injuries give rise to clinical signs or symptoms, the sensitivity and specificity of which depend on the location of the injury, the size of the perforation, the degree of contamination, the length of time elapsed after injury, and the presence of associated injury. Odynophagia, dysphagia, hematemesis, oropharyngeal blood, cervical crepitus, pain and tenderness in the neck or chest, resistance to passive motion, dyspnea, hoarseness, bleeding, cough, and stridor are commonly noted. Fever, subcutaneous emphysema, abdominal tenderness, and mediastinal crunching sounds (Hamman sign) may be observed. Pain is the most common presenting symptom (71% of patients), followed by fever (51%), dyspnea (24%), and crepitus (22%).³⁴

Overall, the signs and symptoms associated with esophageal injury are fairly nonspecific, and a high index of suspicion must be maintained to make the diagnosis. As noted (see above), concomitant injuries to structures surrounding the esophagus are common. Of these, tracheal and vascular injuries are most frequently seen, occurring in as many as two thirds of victims. The associated injuries also determine the symptoms seen in patients with esophageal trauma, the course the diagnostic evaluation takes, and the treatment options considered.

Evaluation of potential penetrating trauma to the esophagus is based on the trajectory and path of the missile. For penetrating injuries near the organ, it is necessary to prove that the esophagus is uninjured. Generally, this is done in one of two ways: (1) surgical exploration demonstrates a missile path inconsistent with esophageal injury, or (2) direct examination of the esophagus reveals no injury. If neither option is feasible, proof is obtained through diagnostic testing. Plain x-rays, CT scans, and contrast esophagograms have all been used for this purpose, with varying sensitivity and specificity [see Table 2]. Endoscopy may add to the diagnosis, but the results depend on the operator's technique and experience, and there is a risk that it may exacerbate an esophageal tear or further injure an unstable cervical spine.

In an otherwise asymptomatic patient who is awake, alert, and able to cooperate, a simple contrast swallow is usually sufficient to exclude injury. Injuries resulting from low-velocity projectiles and stab wounds do not cause large tissue defects; for these injuries, barium gives superior anatomic detail and is the agent of choice. Injuries from large-caliber or high-velocity projectiles usually cause more damage, and thus, the contrast agent tends to spread more widely throughout the mediastinum during a diagnostic swallow. If contrast studies are indicated in this setting, a water-soluble agent may be used first. Such agents cause pulmonary damage when aspirated, however, and should not be used if tracheoesophageal fistula is suspected.

For patients who are going to the OR for another reason (e.g., vascular repair or laparotomy), it may be most expedient to perform esophagoscopy simultaneously with the operation. If the entire esophagus is well visualized and no injury is identified, no further evaluation is required. If the study is suboptimal for any reason, or if the possibility of an injury persists, a contrast study should be done as soon as the patient's condition permits.

Regardless of the diagnostic studies obtained, evaluation must be carried out expeditiously. Significant delays in management can increase the incidence of esophageal injury-related morbidity by as much as a factor of two.³⁵

In cases of blunt trauma, determining when further study is needed is a vexing task. In general, whenever a patient has pneumomediastinum that is extensive or is associated with any of the symptoms of esophageal injury (e.g., odynophagia or blood in the esophagus), the esophagus should be evaluated. Simple pneumomediastinum rarely warrants evaluation of the esophagus. Injury to

the thoracic esophagus from blunt trauma is so extremely unusual, compared with the other causes of simple pneumomediastinum,³⁶ that evaluation for esophageal injury is necessary only in the presence of other suggestive findings, such as pleural effusion, free air, and mediastinitis. In the absence of these suggestive signs and symptoms, pneumomediastinum associated with blunt trauma is much more likely to be from a distal small airway disruption or from a bronchial injury, the evaluation of which should take precedence over evaluation of the esophagus. When esophageal or major airway injury has been ruled out, pneumomediastinum should be treated with observation alone. Chest tubes should be placed only if there is an associated hemothorax or pneumothorax.

MANAGEMENT

Although injuries to the thoracic esophagus caused by external trauma are less common than those to the cervical esophagus, they are more likely to be fatal.^{33,37} Trauma to the thoracic esoph-

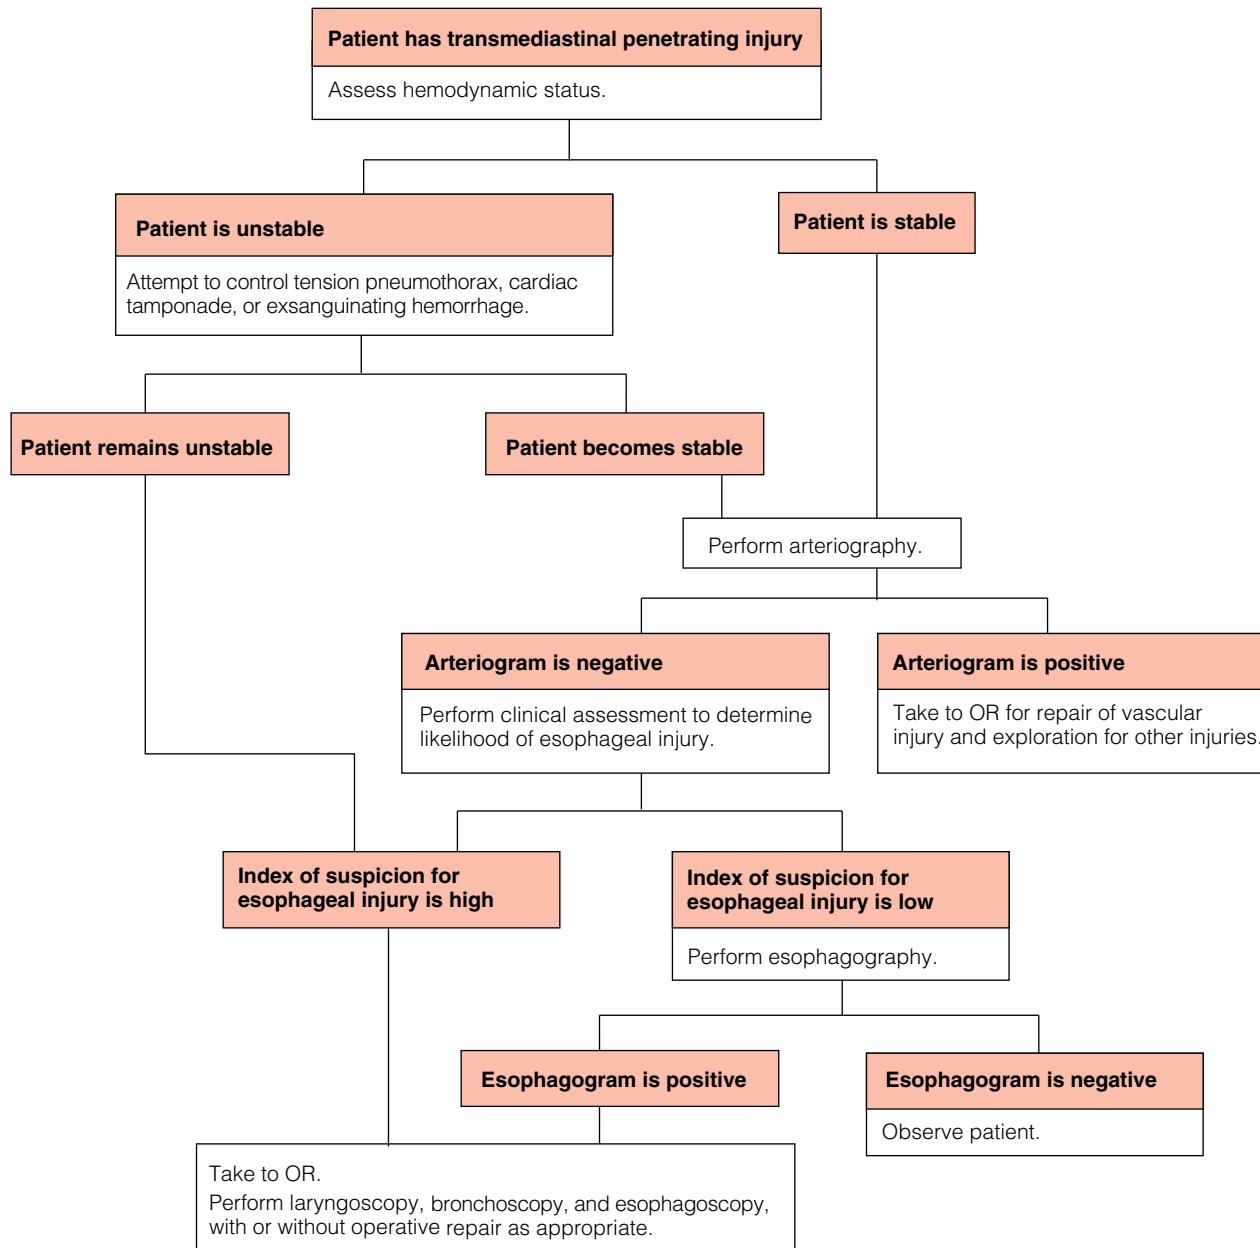

Figure 6 Algorithm illustrates approach to management of transmediastinal penetrating injury.

agus is almost exclusively caused by gunshot wounds; the location of the organ within the chest protects it from most stab wounds. Care of any associated injuries to surrounding structures (e.g., major airways and blood vessels) takes precedence in the management scheme; thus, by necessity, diagnosis and definitive therapy of intrathoracic esophageal injuries are often delayed.

Guidelines have been formulated for the evaluation of transmediastinal penetrating wounds [see *Figure 6*]. The signs and symptoms of thoracic esophageal injury, besides being nonspecific, often take several hours to develop. As with injuries to all other areas of the esophagus, delays in diagnosis and therapy result in a longer duration of contamination and a higher incidence of mediastinitis, sepsis, and death.

Injuries to the distal third of the thoracic esophagus are most easily approached via the left chest. More proximal injuries are best approached through the right chest or via a combination of chest and cervical incisions. The incision should be made so as to facilitate subsequent buttressing of the repair (e.g., with a pedicle from an intercostal muscle or the latissimus dorsi).

Surgical repair entails local debridement, wide drainage, primary repair of the perforation, and buttressing of the repair with a viable muscle flap. Primary repair can usually be accomplished when the perforation is operated on within 24 hours of occurrence. Many investigators recommend two-layer repair of esophageal injuries; however, a secure single-layer repair performed with a continuous absorbable monofilament suture (e.g., 3-0 polydioxanone) allows excellent visualization of each bite and good mucosa-to-mucosa approximation. There is no evidence that adding a second layer adds any strength or security to the anastomosis. A number of different tissue flaps—free pericardium, pleura, intercostal muscle, diaphragm, rhomboid muscle, lung, and gastric fundus (as in a Thal patch)—have all been used, with varying success. Each of these flaps has its own set of advantages, but the use of any of them (if viable) will yield an improved anastomotic outcome.

Depending on the interval before exploration, the severity of the injury, the degree of contamination, and the extent of the local inflammatory response, primary repair may not be feasible. If this is the case, there are several techniques that may be employed, including esophageal diversion, total esophageal exclusion, esophagectomy, and T tube drainage. Most of the experience with these delayed repairs has been acquired in patients who have perforations caused by instrumentation or by emetogenic esophageal rupture, neither of which is entirely analogous to the injuries seen with external trauma.

In general, even late-presenting esophageal perforations should be treated with an attempt at primary repair with autologous tissue coverage. During the workup and surgical management, esophageal patency must be ascertained. Primary esophageal lesions (e.g., strictures) must be corrected, or the repair is likely to fail. In the absence of distal obstruction, almost all late-presenting esophageal perforations heal after primary repair and tissue flap coverage. Generally speaking, techniques such as esophageal exclusion, diversion, and resection should be needed only when perforation occurs in the setting of a primary esophageal pathologic condition (e.g., cancer); esophageal perforation in this setting is rarely managed by trauma surgeons.

Complications

Complications seen after esophageal repair include esophageal leakage and fistula, wound infection, mediastinitis, empyema, sepsis, and pneumonia. Long-term complications (e.g., esophageal stricture) also occur, but they are more common after iatrogenic

perforation of an already diseased esophagus. Risk factors associated with an increased complication rate include shock, the need for urgent tracheostomy, and associated injuries (especially tracheal disruption and paralysis from spinal cord injuries).

Esophageal anastomotic leakage is the most common complication associated with repair of perforations, occurring in 10% to 28% of repairs.³⁸ The causes are primarily technical and include inadequate debridement, devascularization, closure under tension, and the presence of associated infection. As many as 50% of these leaks are asymptomatic; in this setting, they are usually associated with prompt flow of oral contrast back into the esophageal or gastric lumen. Continued abstinence from oral intake, supplemental parenteral nutrition, and antibiotic therapy usually suffice for successful treatment.

In patients who have sepsis and esophageal leakage after repair of an esophageal perforation caused by external trauma, treatment should focus on wide local drainage and creation of a controlled fistula, which is usually best accomplished by resecting a segment of a rib posteriorly at the level of the perforation, then packing the wound open. Because there is usually no underlying esophageal or gastric pathologic condition and no forceful distribution of mediastinal contamination, these fistulas generally heal well without resection, diversion, or replacement of the esophagus. Most of these patients also benefit from feeding jejunostomy tubes; healing time is generally measured in weeks.

Thoracic Duct Injuries

Chylothorax after blunt or penetrating chest trauma is rare: only case reports and small case series are found in the literature. Much of the management of this condition is extrapolated from management of iatrogenic thoracic duct injuries, which are much more common. Most patients with traumatic chylothorax show evidence of other axial injuries to the chest, especially spine fractures.³⁹ The diagnosis is made by finding chylomicrons and high levels of triglycerides in a typically large pleural effusion of milky appearance. Drainage of as much as 1,000 ml/day is not unusual and results in severe nutritional and immunologic derangements, which are the main causes of the high mortality associated with this condition.

MANAGEMENT

Treatment usually begins with limiting oral intake of short- and long-chain triglycerides, which cause increased flow of chyle. Diets high in medium-chain triglycerides must often be given enterally because they are not palatable. Some clinicians recommend instituting total parenteral nutrition with complete abstinence from oral intake. Administration of octreotide may also help decrease chyle production.⁴⁰ These modalities, in conjunction with adequate pleural drainage and lung expansion, are successful in approximately 50% of cases after 2 to 6 weeks.

Operative strategies for managing thoracic duct injuries are generally undertaken only after conservative measures fail. Preoperatively, patients are fed cream, with or without dyes such as Sudan black, to increase chyle flow and enhance visualization of the site of injury. The thoracic duct is then ligated above and below the injury; this may be performed by means of VATS on the hemithorax ipsilateral to the effusion.⁴¹ Fibrin glue and talc pleurodesis may be used as adjuncts to ligation. Because there are usually multiple areas of injury and because the thoracic duct is friable by nature, surgical treatment is not always successful. Continued nutritional management and reoperation may be required.

Cardiac Injuries

The incidence of cardiac trauma continues to rise as a consequence of growing urban violence, improved detection of cardiac injuries, and an increase in the percentage of patients with such injuries who arrive at trauma centers alive. Improved prehospital transport, along with the continuing evolution of diagnostic, surgical, and anesthetic techniques, has contributed to an increase in overall survival in this population. Although the overall mortality associated with cardiac trauma remains high, survival rates of 50% to 95% are not uncommon in patients who arrive at the hospital with vital signs.⁴²⁻⁴⁵

PENETRATING

Patients with penetrating cardiac injuries generally present in one of three ways. In approximately 20% of patients, the injury is clinically silent, at least initially, and is subsequently diagnosed at operation or on diagnostic imaging. In approximately 50%, there is evidence of pericardial tamponade, including one or more of the signs in Beck's triad (hypotension, distended neck veins, and muffled heart sounds). In the remaining patients, hemorrhagic shock develops after free bleeding from an atrial or ventricular wound into one or both hemithoraces.

Diagnosis of penetrating injuries to the heart often requires a high index of suspicion. The locations of entrance and exit wounds, the trajectory and path of the wounding object, and the locations of any retained missiles on radiographs are helpful in predicting heart injuries. Proximity wounds to the heart are defined as those that penetrate the chest wall in the area bounded superiorly by the clavicles, laterally by the midclavicular lines, and inferiorly by the costal margins. Any crossing of the anterior mediastinum by a missile or an instrument is also considered a proximity wound. Because cardiac injuries are present in 15% to 20% of patients who present with proximity wounds, these injuries must be definitively excluded.

Physical examination is often unreliable in detecting pericardial tamponade. It is rare for all three signs in Beck's triad to be found; in fact, only about half of patients with tamponade show even two of the three. Moreover, detection of muffled heart sounds and distended neck veins amid the commotion typical of the trauma bay can be extremely difficult, especially when (as is often the case) the patient is agitated or intoxicated. Accordingly, whenever tamponade is suspected, additional diagnostic modalities should be employed.

As more surgeons become familiar with the use of ultrasonography in the trauma setting, two-dimensional surface echocardiography is gaining acceptance as a means of diagnosing cardiac injuries. When performed by appropriately trained surgeons, this modality detects blood within the pericardial sac with a sensitivity of 96% to 100% and a specificity of 100%—results essentially equivalent to those achieved with a pericardial window.⁴⁶ When the requisite equipment is readily available, this test can be performed in approximately 2 minutes. It is of vital importance that the trauma surgeon who is attending to the patient perform and interpret the test: the results will be available sooner, the clinical correlation will be more accurate, and the information obtained will be more rapidly applied to treatment decisions. The main limitations of two-dimensional surface echocardiography are the high cost of the equipment and the specialized training required.

Although cardiac ultrasonography has many advantages, the subxiphoid pericardial window remains the gold standard for diagnosis of cardiac injury. For otherwise stable patients with proximity wounds or suggestive signs and symptoms, a pericardial

window should be considered when ultrasonographic findings are equivocal or when ultrasonography is unavailable. This procedure is usually performed in the OR with the patient under general anesthesia, often in combination with abdominal exploration.

A subxiphoid pericardial window is performed through a 10 cm vertical midline incision that is made over the xiphoid, slightly favoring the epigastrium. The xiphoid is grasped with a clamp and dissected away from the abdominal fascia and the diaphragmatic fibers, and the substernal plane is accessed. As the inferior portion of the sternum is being elevated, the prepericardial adipose tissue is dissected to provide exposure of the acute margin of the pericardium. The pericardium is then retracted inferiorly into the wound and incised sharply. The presence of blood or clot within the pericardial sac indicates a positive result, necessitating immediate repair of the injury. A pericardial window can also be accomplished during thoracoscopy of the left hemithorax [see 4:7 Video-Assisted Thoracic Surgery], and examination of the pericardium can be performed, though less reliably, during laparoscopy via a trans-diaphragmatic view.

Some authorities advocate using pericardiocentesis to detect cardiac injuries, especially where rapid access to the OR, trauma surgeons, and anesthesiologists is not available. Drawbacks to this approach include the high rate of false positives and false negatives and the potential for iatrogenic cardiac injuries. Furthermore, pericardiocentesis is of limited use in treating tamponade because blood within the pericardial sac often is clotted and is not amenable to removal through a needle.

Management

Treatment of penetrating cardiac wounds depends on the urgency of the presentation. In patients who are in shock from suspected cardiac injuries, the distinction between the two most likely causes, pericardial tamponade and free hemorrhage, is important. If the patient exhibits distended neck veins and the characteristic plethoric, dusky facial expression, chest tubes should immediately be placed bilaterally. If shock does not then resolve, the diagnosis of tamponade should be made and a pericardial window performed, either in the ED with local or no anesthesia or in the OR as described (see above). If there is a suspicion of free hemorrhage into one or both hemithoraces, which can usually be detected by means of physical examination and chest x-ray, the patient should be transported to the OR for definitive treatment. In patients who are in extremis from either causative condition or who go into cardiac arrest in the ED, an emergency left anterior thoracotomy should be performed.

In planning the surgical approach to the repair of cardiac injuries, the location of the entrance and exit wounds, the path of the wounding object, the type of wound created, the associated signs and symptoms, and the level of suspicion for other thoracic visceral injuries are important considerations. A median sternotomy is a logical extension of a subxiphoid pericardial window and provides access to all four chambers of the heart. It is appropriate for most precordial stab wounds and some low-caliber gunshot wounds. Its main limitations are that it does not allow repair or cross-clamping of the descending aorta or examination or repair of the esophagus and bronchi and that it provides limited exposure of the lower lobes of the lungs and the hemidiaphragms. A left thoracotomy is appropriate for patients who may require cross-clamping of the thoracic aorta and for those with suspected cardiac injuries in conjunction with other complex thoracic visceral injuries. Only occasionally is a right thoracotomy required; this incision generally does not provide adequate exposure of the heart.

Atrial wounds are generally amenable to early control by finger pressure or by exclusion with a vascular clamp and simple over-sewing. Right or left ventricular free wall injuries away from the coronary arteries may be treated by applying digital pressure over the entrance wound for hemostasis, then placing horizontal mattress sutures under the wound, reinforced with an epicardial continuous suture along the site of injury. All left ventricular wounds should be repaired with felt-pledged or pericardial-pledged sutures. Many right ventricular stab wounds can be closed primarily without pledges if the sutures are tied accurately.

Injuries near coronary arteries must be closed without the coronary artery being incorporated within the suture. This can be accomplished by placing horizontal mattress sutures lateral and deep to the coronary artery across the cardiac laceration. If the sutures are tied with careful attention to the function of the myocardium distal to the injury and equally careful attention to the electrocardiogram, the laceration can be closed without coronary artery occlusion and subsequent ischemia.

An alternative method of repair of cardiac lacerations employs a skin stapler, which is effective in controlling hemorrhage from stab injuries and low-velocity gunshot wounds.⁴⁷ The stapler can be used on all chambers of the heart, and in some instances, staple repair can be quicker than suture repair.

With all penetrating cardiac wounds, it is important to recognize the possibility of associated intracardiac injuries. The surgeon should palpate the heart along the pulmonary outflow tract for a thrill that would indicate a traumatic ventricular septal defect. This diagnosis can be confirmed by performing co-oximetry on a sample of blood aspirated from the pulmonary artery and the right atrium and demonstrating a step-up. Digital palpation through atrial wounds should be routinely employed to identify atrioventricular valvular insufficiency or, occasionally, an atrial septal defect. Intraoperative surface echocardiography and transesophageal echocardiography are also excellent at diagnosing intracardiac injuries, but they are not readily available in the urgent trauma setting.

Postoperatively, all patients with cardiac wounds should receive a thorough cardiovascular examination aimed at detecting murmurs or evidence of cardiac failure and should undergo echocardiography if either of these is detected. Repair of intracardiac lesions usually can wait until the patient's condition is stable and cardiac catheterization has been performed, though some patients experience such profound heart failure that immediate operative repair, with cardiopulmonary bypass, must be performed.

BLUNT

Blunt cardiac injuries range from disruption of myocardium, septa, or valvular structures to cardiac contusion. Both cardiac disruption (also known as cardiorrhexia) and cardiac contusion are common; the former is seen most often in patients who die at the scene, the latter in those who survive to reach the hospital.

Blunt cardiac injury typically involves a direct blow to the chest, usually sustained in a motor vehicle collision or a fall. Cardiac injuries generally are associated with sternal or rib fractures, though they may occur in the absence of any chest wall fracture; however, sternal fractures do not predict the presence of blunt cardiac injury. The most common location of blunt cardiac injury is the anterior heart, which consists primarily of the right ventricle. A blow that causes the sternum to exert a direct impact on the myocardium may result in direct injury to myocardial cells, sometimes leading to cell death, mechanical dysfunction, or dysrhythmias.

The diagnosis of myocardial contusion is elusive. Many tests have been proposed, but none have proved definitive, except for

direct visualization of the heart at surgery or autopsy. For practical purposes, the clinically significant sequelae of myocardial contusion are myocardial dysrhythmias and pump failure. Both of these sequelae must be treated, regardless of whether the diagnosis of blunt cardiac injury can be made. Guidelines have been proposed that may facilitate the workup of this condition.⁴⁸

As an initial test, a 12-lead ECG should be obtained whenever blunt cardiac injury is suspected. If the ECG is normal, no further workup is required. If there is an ECG abnormality that does not necessitate treatment (e.g., nonspecific ST-T wave changes), the patient should undergo monitored observation for 12 hours, then be discharged if there are no dysrhythmias and the ECG is normal at that time. If there is a more serious ECG abnormality (e.g., dysrhythmia, ST-segment elevation, or heart block), the patient should undergo observation for at least 24 to 48 hours and may require further testing and treatment, depending on the sequelae of the abnormality. In patients with hemodynamic instability and suspected blunt cardiac injury, echocardiography should be performed promptly. There is no role for cardiac enzyme analysis or cardiac troponin assay in this setting. The latter test may detect myocardial injury, but this information does not complement ECG and echocardiographic findings and has no clinical utility. Similarly, there is no role for nuclear medicine studies.

Management

Pump failure associated with cardiac contusion is usually the result of right heart failure, in that most hemodynamically significant cardiac contusions are caused by injury to the anterior right ventricular free wall. Treatment of right heart failure from cardiac contusion consists of inotropic support and reduction of right ventricular afterload. Dysrhythmias secondary to cardiac contusion are treated in the same manner as dysrhythmias of any other etiology.

The commonly repeated adage that cardiac contusion should be treated similarly to MI is incorrect. Therapy for MI is based on the premises that the patient is likely to have concomitant coronary artery disease and that increased myocardial oxygen demand may result in extension of the evolving infarct or the creation of an additional infarct. However, most young trauma patients have normal coronary arteries, and increased myocardial oxygen demand is unlikely to extend cardiac contusion unless the heart sustains an additional blow. Generally, the goal in resuscitation of injured patients is to increase systemic oxygen delivery, which may increase cardiac work. In addition, unlike patients with MI, patients with myocardial contusion appear not to be at increased risk for cardiac complications from general anesthesia and surgery.

In the rare patient with cardiorrhexia who presents to the hospital with signs of life, the most common injury is right atrial perforation. Other lesions seen in patients with vital signs, in order of decreasing incidence, are left atrial perforation, right ventricular perforation, atrial septal perforation, ventricular septal perforation, coronary artery thrombosis, and valvular insufficiency (most commonly involving the tricuspid and mitral valves).⁴²⁻⁴⁵ Patients with cardiac rupture generally present with signs of pericardial tamponade and require rapid decompression. Placement of an intra-aortic balloon pump is often an effective temporizing measure while preparations are made for definitive repair.

Patients with blunt cardiac trauma who lose vital signs in the field or who go into cardiac arrest before arrival at the hospital generally should not be subjected to ED thoracotomy, because virtually none of these patients can be saved. Patients admitted with vital signs after suffering blunt cardiac rupture, however, have

about a 50% chance of survival, and much of the mortality in these patients is attributable to associated injuries.

Blunt Aortic Injuries

Traumatic rupture of the aorta may account for as many as 10% to 15% of all traffic fatalities, and the majority of such injuries are fatal at the scene. Of those who survive the initial injury, 50% die in the first 24 hours and 90% die within the first month if the aorta is not repaired. Traumatic disruption of the thoracic aorta results from rapid deceleration and is produced by a shearing effect caused by differences in the mobility of the aorta above and below a point where the vessel is fixed. Most thoracic aortic disruptions in survivors occur at the aortic isthmus just distal to the origin of the left subclavian artery, where the aorta is fixed to a significant degree by the ligamentum arteriosum. Autopsy series reveal that as many as 40% of aortic injuries in nonsurvivors are not located at the isthmus, and the injuries tend to be complex.⁴⁹

Suspicion of an aortic injury is most often triggered by abnormal findings on a chest x-ray in a patient with a high-speed mechanism of injury and multiple other injuries. Most patients show no signs or symptoms on physical examination, but some complain of interscapular pain or hoarseness, and some exhibit a difference in blood pressure or pulse fullness between the upper and lower extremities or between the right and left upper extremities. Accordingly, the diagnosis is usually made radiographically, often beginning with the recognition of mediastinal hemorrhage on a screening chest x-ray.

Numerous radiographic signs of a torn thoracic aorta have been described, all of which are manifestations of hemorrhage within the mediastinum that alters or obliterates the shadows seen on a normal chest radiograph. Mediastinal widening is the most frequent indicator of mediastinal hematoma from a torn thoracic aorta. Other important signs are obscuration of the detail of the contour of the aortic knob, opacification of the aortopulmonary window, depression of the left mainstem bronchus, apical cap, deviation of the nasogastric tube, and displacement of the esophagus to the right. These signs may be present in any combination or may be entirely absent.

Currently, high-speed CT scanning with I.V. contrast is being liberally used for diagnosis of thoracic vascular injuries. Appropriately, this modality is employed in virtually all patients with abnormal chest x-rays and in many patients with normal x-rays whose injury mechanisms include a high degree of energy transfer. CT findings that are diagnostic of aortic injury include mediastinal hematoma, periaortic hematoma, intraluminal irregularity (intimal flap), acute coarctation, and abnormal aortic contour [see Figure 7]. Depending on the experience of the interpreting clinician, aortography may be eliminated in most of these patients before surgical repair; the sensitivity and specificity of CT in this setting approach 100%.^{15,50,51} Aortography should continue to be used for equivocal cases or cases in which spiral CT is not available.

MANAGEMENT

Essentially all aortic injuries associated with mediastinal hematomas should be repaired. The timing of repair, however, is less urgent than the timing of certain associated maneuvers that must be done, such as attainment of an adequate airway, control of external or cavitary hemorrhage, and evacuation of intracranial mass lesions. In general, if there is active bleeding from a blunt

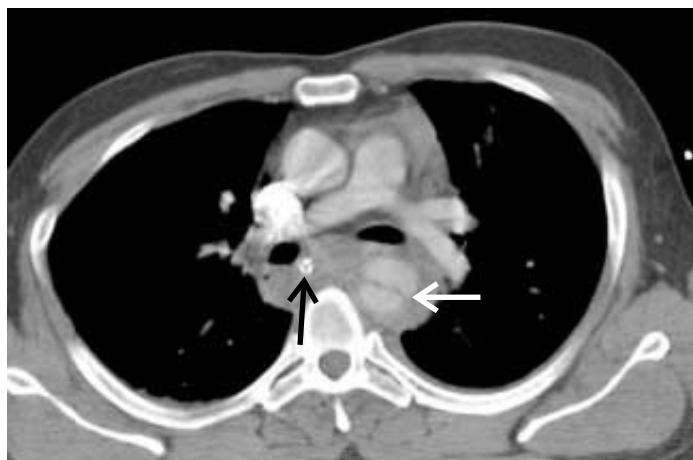

Figure 7 Shown is an injury to the descending thoracic aorta (white arrow). A nasogastric tube can be seen in the esophagus, which is deviated to the right (black arrow).

aortic injury, it will be massive; lesser amounts of bleeding from a chest tube often derive from associated injuries. If intra-abdominal bleeding is present, laparotomy is indicated before repair of the torn thoracic aorta and before aortography. Similarly, in patients with intracranial hemorrhage that necessitates operative evacuation, craniotomy should take precedence over repair of the torn thoracic aorta.

While one is temporizing, stringent efforts must be made to prevent hypertension and reduce shear forces across the injury, ideally by means of I.V. beta blockade. Esmolol, because of its short half-life, is the best agent to use in these patients, who are at risk for sudden hypovolemic episodes of hypotension. The goals of medical therapy are a heart rate lower than 100 beats/min and a systolic blood pressure of approximately 100 mm Hg (in young and middle-aged patients) or 110 to 120 mm Hg (in elderly patients).¹⁵ Nitroprusside may have to be given to achieve these goals, but it should not be used until after adequate beta blockade is achieved, because it can increase intravascular shear forces when used alone. During pharmacologic treatment of aortic injuries, pulmonary arterial catheter monitoring is essential to prevent deleterious reductions in cardiac output and mixed venous oxygen saturation. With careful delayed operative management of aortic injuries, the risk of rupture is low but is not completely eliminated.^{15,52}

Traditional repair techniques include exposure of the aorta and arch through a left thoracotomy and direct repair or interposition graft placement. Although excellent results have been obtained with so-called clamp-and-sew techniques, most guidelines recommend use of some form of distal aortic perfusion (e.g., left atrial-distal aortic bypass or partial cardiopulmonary bypass with femoral cannulation). Systemic heparinization is required for cardiopulmonary bypass and has been shown to be safe with respect to hemorrhagic complications.^{53,54} The aortic arch is clamped between the common carotid and left subclavian arteries after these vessels and the distal aorta have been controlled. An interposition graft is required for most of these injuries, though 15% to 20% can be treated with suture repair alone. With distal aortic perfusion, the risk of paraplegia is approximately 5% and is independent of clamp time; without distal aortic perfusion, ischemic times longer than 30 minutes are associated with an exponential rise in the incidence of spinal cord injury.

Another potential advantage to using cardiopulmonary bypass is the ability to institute deep hypothermic circulatory arrest if needed. This technique involves cooling to a core temperature lower than 20° C to induce cardiac standstill, turning off the pump, and operating on the unclamped aorta in a relatively dry field. Circulatory arrest can be safely maintained in this setting for approximately 30 to 45 min. This technique may be useful for patients who have previously undergone thoracic aortic surgery or who have complex tears involving the arch.

An evolving modality for the treatment of aortic injury is endovascular stent grafting. The rationale for the insertion of a stent graft in this population is that the aorta above and below the injury is usually normal, which is not the case in the atherosclerotic population. Early results with this method of treatment are encouraging and are in fact superior to those obtained with endovascular repair of aortic aneurysms and dissections.⁵⁵ If longer-term follow-up continues to report acceptable outcomes, stent grafts will probably become standard therapy for uncomplicated aortic injuries.

Great Vessel Injuries

Except for tears in the descending aorta, injuries to the thoracic great vessels, by any mechanism, are rarely seen in clinical practice; the best descriptions come from wartime and autopsy series. Indeed, postmortem studies reveal that patients with nonisthmus aortic and great vessel injuries rarely reach the hospital alive.⁵⁶ As many as 14% of patients have multiple great vessel injuries. Diagnosis and management of these injuries covers a wide spectrum of possibilities, depending on mechanism of injury, presenting features, and associated injuries.

PENETRATING

Penetrating thoracic great vessel injuries are usually obvious. The presence of an entrance wound at the base of the neck or in the chest should alert the clinician to this possibility. If the patient is in shock, urgent operation is required. If the patient's condition stabilizes with resuscitation, an arteriogram should be performed to localize the injury.

Management

Exposure is most often obtained via a median sternotomy, with or without neck extension as needed for innominate, right subclavian, or carotid arterial injuries [see Table 1]. Exposure of the left subclavian artery can be more difficult, even through a sternotomy with a trap-door extension. For isolated injuries to the proximal subclavian artery, a fourth-interspace left posterolateral thoracotomy is most useful. For injuries to the middle and distal thirds, supraclavicular incisions or deltopectoral incisions—or, occasionally, a combination thereof—are appropriate, provided that inflow control can be achieved. When inflow control may not be achievable, as in cases involving injury at the thoracic outlet or the presence of a large hematoma, endovascular control of the proximal subclavian artery by means of a balloon catheter placed percutaneously through the femoral artery may be necessary. There are also case reports describing total endovascular management of subclavian injuries through stent-graft placement.⁵⁷ This technique may be valuable for unstable patients who are already undergoing arteriography and for patients with multiple high-priority injuries.

Most penetrating wounds of the middle and distal segments of the great vessels are amenable to lateral repair or end-to-end anastomosis; injuries involving greater tissue destruction, for which grafts might be indicated, usually prove fatal before the patient arrives at the hospital. The subclavian artery is a notable exception to this general rule because the lack of elastic fibers in its tunica media makes it extremely friable. End-to-end anastomosis of an injured subclavian artery under any tension is doomed to failure. Accordingly, many subclavian injuries should be repaired with an interposition graft. Proximal injuries to the great vessels are best repaired by exclusion and bypass grafting with prosthetic material from the ascending aorta. Because bleeding is usually active, there is rarely enough time to arrange for cardiopulmonary bypass. In any case, cardiopulmonary bypass generally is not needed, except for rare cases of associated ascending or aortic arch injury.

BLUNT

Blunt injuries of the great vessels are typically the result of high speed and rapid deceleration. In postmortem examinations, pedestrians struck by motor vehicles have the highest rate of great vessel injuries. Patients with such injuries are rarely seen in the ED with signs of life.⁵⁶ Superior mediastinal hematoma is the most common finding during workup; its presence is an indication for further imaging with spiral CT or angiography. Besides vessel laceration with hematoma, presentations of blunt thoracic great vessel injury include dissection and thrombosis, which may be asymptomatic if localized to the proximal segments. Central neurologic injury may also be present, especially with carotid dissection. Associated stretch injury of the brachial plexus or the cervical nerve roots is common with subclavian artery injuries.

Management

Once the diagnosis is made, virtually all great vessel injuries should be treated surgically, with the possible exception of small intimal defects that are found incidentally. Surgery is contraindicated, however, if neurologic injury is present, the injury is deemed unsurvivable, or a common carotid dissection has extended into the distal internal carotid artery. As with blunt aortic injuries, the timing of surgery should be tailored to the treatment priorities mandated by the associated injuries. When time permits, proximal lesions are best managed with cardiopulmonary bypass and hypothermic circulatory arrest. Arranging for these techniques is mandatory with injuries involving the ascending aorta and the arch.

Mediastinal blood seen on chest CT probably more often derives from mediastinal venous injuries than from arterial injuries. These isolated venous injuries need not be repaired unless they are associated with cardiac tamponade or massive hemorrhage into a pleural space, both of which are uncommon. An exception is injury to the intrapericardial vena cavae, which is usually associated with tamponade. These injuries are caused by tearing of the mobile heart against the relatively fixed veins, particularly the inferior vena cava. In most cases, they can be repaired primarily. Associated venous injuries are commonly encountered during exploration for great vessel arterial injury. If possible, they should be treated with lateral repair or patch venorrhaphy with pericardium or saphenous vein. However, ligation of these veins sometimes proves necessary and is generally well tolerated.

Injuries to the Liver

ASSESSMENT

The initial step in the management of penetrating abdominal injuries and of blunt abdominal injuries in cases when nonoperative treatment is contraindicated or has failed is exploratory laparotomy [see 7:9 *Operative Exposure of Abdominal Injuries and Closure of the Abdomen*].

Visualization of the right hemiliver [see Figure 1] is hindered by the posterior attachments and by the right lower costal margin. Exposure of the right hemiliver is facilitated by elevating the right costal margin with a large Richardson retractor. Further exposure can be achieved with mobilization, which requires division of the right triangular and coronary ligaments [see Figure 2]. In dividing the superior coronary ligament, care must be taken not to injure the lateral wall of the right hepatic vein; in dividing the inferior coronary ligament, care must be taken not to injure the right

adrenal gland (which is vulnerable because it lies directly beneath the peritoneal reflection) or the retrohepatic vena cava. When the ligaments have been divided, the right hemiliver can be rotated medially into the surgical field. Mobilization of the left hemiliver poses no unusual problems other than the risk of injury to the left hepatic vein, the left inferior phrenic vein, and the retrohepatic vena cava.

If optimal exposure of the junction of the hepatic veins and the retrohepatic vena cava is necessary, the midline abdominal incision can be extended by means of a median sternotomy. The pericardium and the diaphragm can then be divided toward the center of the inferior vena cava. This combination of incisions provides superb exposure of the hepatic veins and the retrohepatic vena cava while avoiding injury to the phrenic nerves.

Hepatic injuries are classified according to the grading system developed by the American Association for the Surgery of Trauma Committee on Organ Injury Scaling [see Table 1 and Figure 3].¹ The

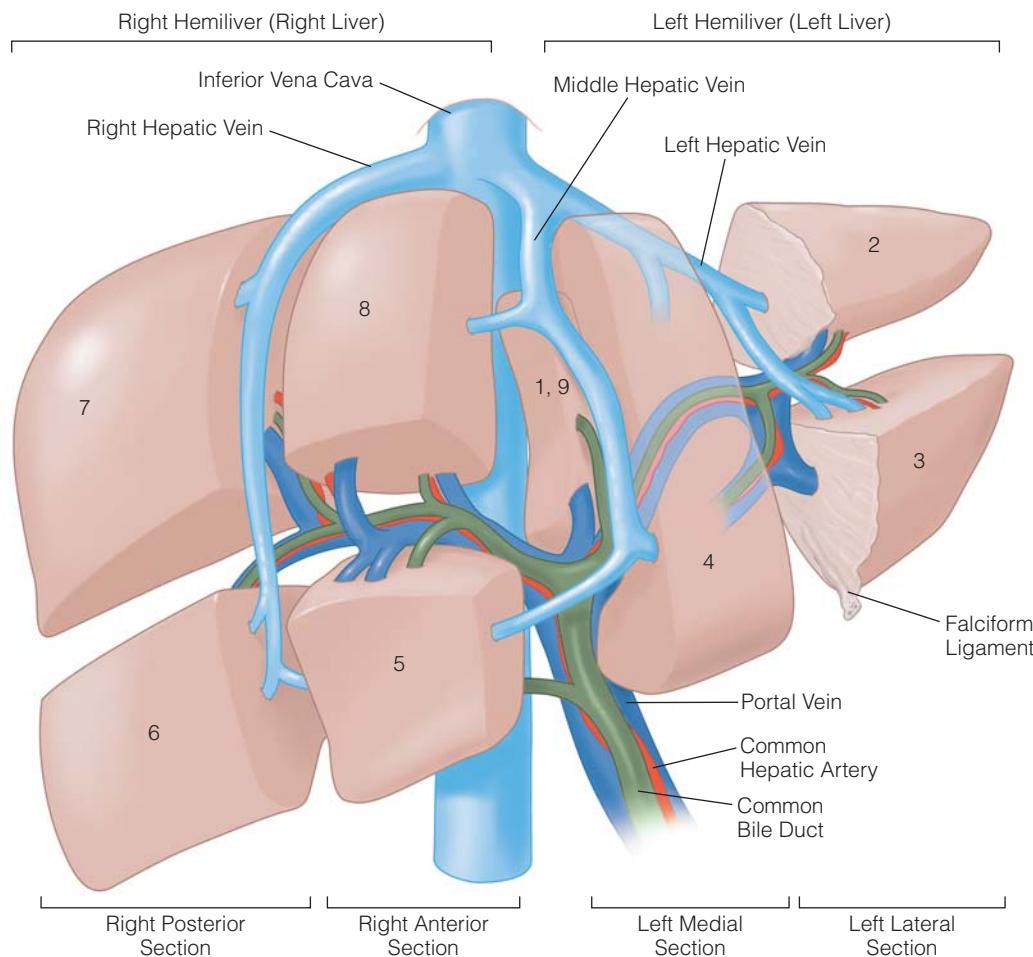

Figure 1 Shown are the anatomic divisions of the liver.

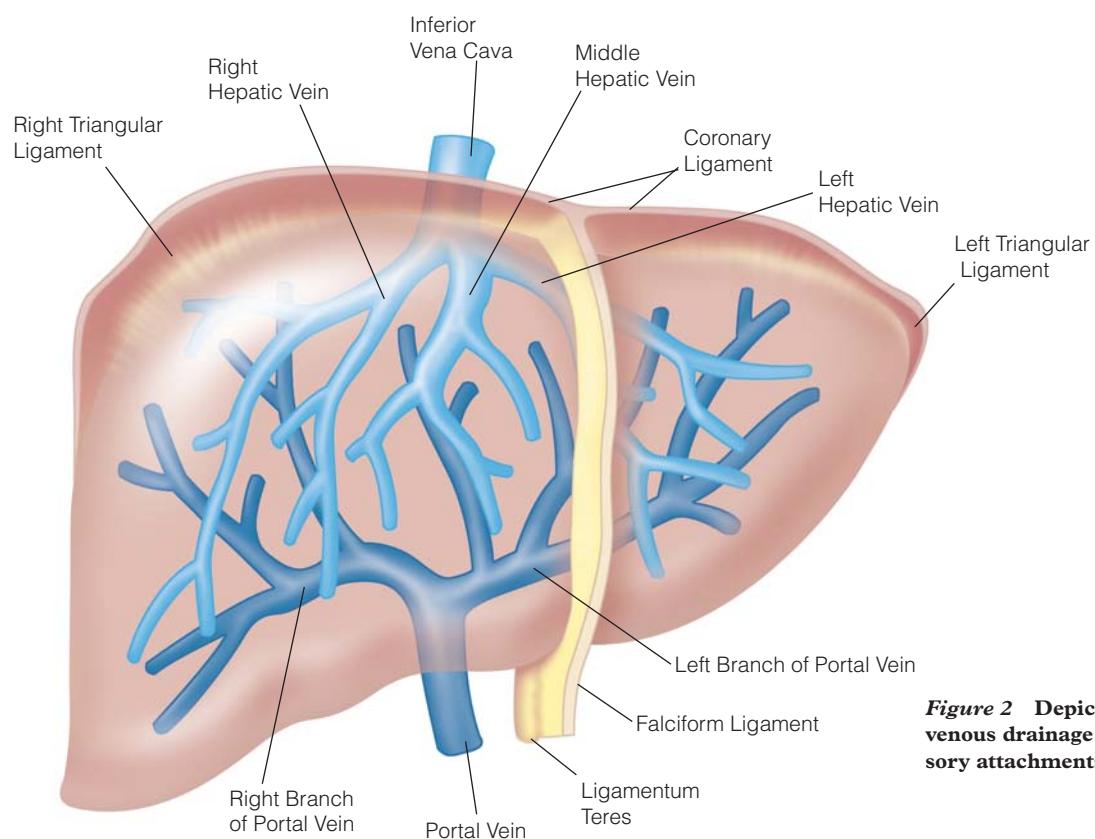

Figure 2 Depicted are the venous drainage and suspensory attachments of the liver.

grading scale ranges from I to VI, with I representing superficial lacerations and small subcapsular hematomas and VI representing avulsion of the liver from the vena cava. Isolated injuries that are not extensive (grades I to III) often require little or no treatment; however, extensive parenchymal injuries and those involving the juxtahepatic veins (grades IV and V) may require complex maneuvers for successful treatment, and hepatic avulsion (grade VI) is lethal.

Clamping of the hepatic pedicle—the Pringle maneuver—is helpful for evaluating grade IV and V hepatic injuries [see Figure 4]. This maneuver allows one to distinguish between hemorrhage from branches of the hepatic artery or the portal vein, which ceases when the clamp is applied, and hemorrhage from the hepatic veins or the retrohepatic vena cava, which does not. When performing the Pringle maneuver, we prefer to tear open the lesser omentum manually and place the clamp from the patient's left side while guiding the posterior blade of the clamp through the foramen of Winslow with the aid of the left index finger. The advantages of this approach are the avoidance of injury to the structures within the hepatic pedicle, the assurance that the clamp will be properly placed the first time, and the inclusion of a replacing or accessory left hepatic artery between the blades of the clamp.

MANAGEMENT OF INJURIES

Techniques for Temporary Control of Hemorrhage

Temporary control of hemorrhage is essential for two reasons. First, during treatment of a major hepatic injury, ongoing hemorrhage may pose an immediate threat to the patient's life, and temporary control gives the anesthesiologist time to restore the circulating volume before further blood loss occurs. Second, multiple bleeding sites are common with both blunt and penetrating tra-

ma, and if the liver is not the highest priority, temporary control of hepatic bleeding allows repair of other injuries without unnecessary blood loss. The most useful techniques for the temporary control of hepatic hemorrhage are manual compression, perihepatic packing, and the Pringle maneuver.

Periodic manual compression with the addition of laparotomy pads is useful in the treatment of complex hepatic injuries to provide time for resuscitation [see Figure 5].²⁻⁴ Hands and pads should be positioned to realign the liver in its normal anatomic position. Perihepatic packing with carefully placed laparotomy pads is capable of controlling hemorrhage from almost all hepatic injuries.⁵⁻⁹ The right costal margin is elevated, and the pads are strategically placed over and around the bleeding site [see Figure 6]. Additional pads may be placed between the liver and the diaphragm and between the liver and the anterior chest wall until the bleeding has been controlled. Ten to 15 pads may be required to control the hemorrhage from an extensive right lobar injury. Packing is not as effective for injuries to the left hemiliver, because with the abdomen open, there is insufficient abdominal and thoracic wall anterior to the left hemiliver to provide adequate compression. Fortunately, hemorrhage from the left hemiliver can be controlled by dividing the left triangular and coronary ligaments and compressing the hemiliver between the hands. Two complications may be encountered with the packing of hepatic injuries. First, tight packing compresses the inferior vena cava, decreases venous return, and reduces left ventricular filling; hypovolemic patients may not tolerate the resultant decrease in cardiac output. Second, perihepatic packing forces the right diaphragm superiorly and impairs its motion; this may lead to increased airway pressures and decreased tidal volume. Careful consideration of the patient's condition is necessary to determine whether the risk of these complications outweighs the risk of additional blood loss.

The Pringle maneuver is often used as an adjunct to packing

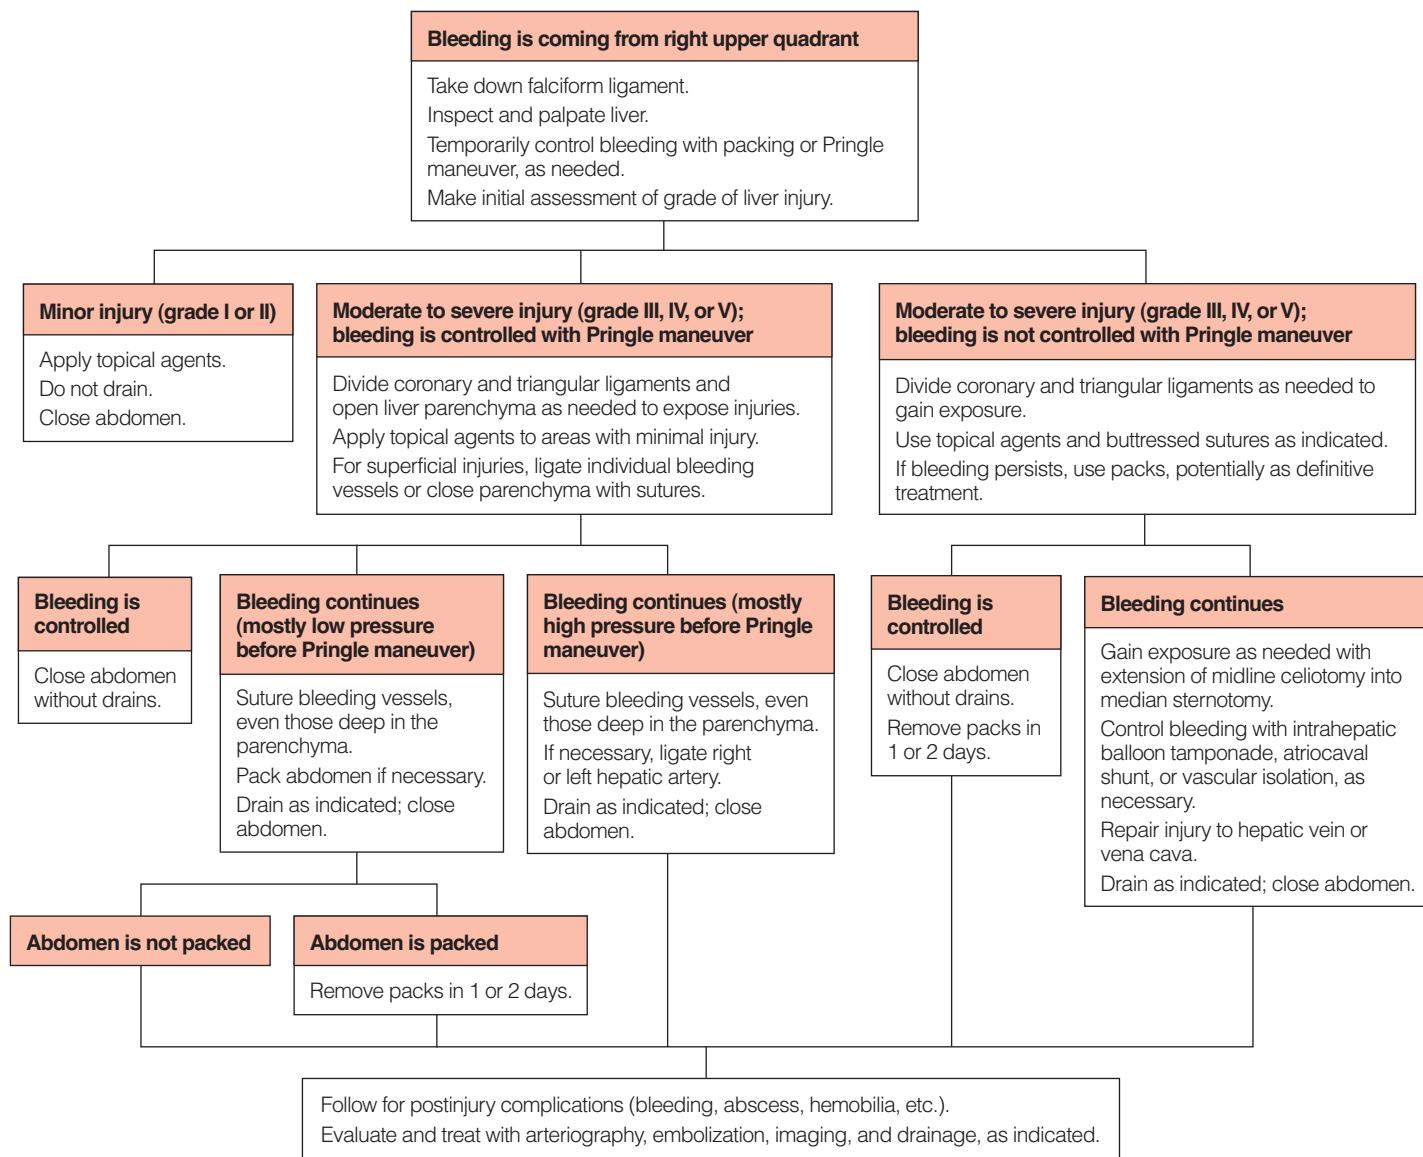

Table 1 AAST Organ Injury Scales for Liver, Biliary Tract, Diaphragm, and Spleen

Injured Structure	AAST Grade	Characteristics of Injury	AIS-90 Score
Liver*	I	Hematoma: subcapsular, nonexpanding, < 10% surface area Laceration: capsular tear, nonbleeding, < 1 cm parenchymal depth	2 2
	II	Hematoma: subcapsular, nonexpanding, 10%–50% surface area; intraparenchymal, nonexpanding, < 10 cm in diameter Laceration: capsular tear, active bleeding, 1–3 cm parenchymal depth, < 10 cm in length	2 2
	III	Hematoma: subcapsular, > 50% surface area, expanding; ruptured subcapsular hematoma with active bleeding; intraparenchymal, > 10 cm or expanding Laceration: > 3 cm parenchymal depth	3 3
	IV	Hematoma: ruptured intraparenchymal hematoma with active bleeding Laceration: parenchymal disruption involving 25%–75% of hepatic lobe or 1–3 Couinaud's segments within a single lobe	4 4
	V	Laceration: parenchymal disruption involving > 75% of hepatic lobe or > 3 Couinaud's segments within a single lobe Vascular: juxtahepatic venous injuries (i.e., injuries to retrohepatic vena cava or central major hepatic veins)	5 5
	VI	Vascular: hepatic avulsion	5
Extrahepatic biliary tree*	I	Gallbladder contusion/hematoma Portal triad contusion	2 2
	II	Partial gallbladder avulsion from liver bed; cystic duct intact Laceration or perforation of gallbladder	2 2
	III	Complete gallbladder avulsion from liver bed Cystic duct laceration	3 3
	IV	Partial or complete right or left hepatic duct laceration Partial common hepatic duct or common bile duct laceration (< 50%)	3 3
	V	> 50% transection of common hepatic duct or common bile duct Combined right and left hepatic duct injuries Intraduodenal or intrapancreatic bile duct injuries	3–4 3–4 3–4
Diaphragm†	I	Contusion	2
	II	Laceration < 2 cm	3
	III	Laceration 2–10 cm	3
	IV	Laceration > 10 cm, with tissue loss < 25 cm ²	3
	V	Laceration with tissue loss > 25 cm ²	3
Spleen*	I	Hematoma: subcapsular, nonexpanding, < 10% surface area Laceration: capsular tear, nonbleeding, < 1 cm parenchymal depth	2 2
	II	Hematoma: subcapsular, nonexpanding, 10%–50% surface area; intraparenchymal, nonexpanding, < 5 cm in diameter Laceration: capsular tear, active bleeding, 1–3 cm parenchymal depth, not involving a trabecular vessel	2 2
	III	Hematoma: subcapsular, > 50% surface area or expanding; ruptured subcapsular hematoma with active bleeding; intraparenchymal, > 5 cm or expanding Laceration: > 3 cm parenchymal depth or involving trabecular vessels	3 3
	IV	Hematoma: ruptured intraparenchymal hematoma with active bleeding Laceration: laceration involving segmental or hilar vessels producing major devascularization (> 25% of spleen)	4 4
	V	Laceration: completely shattered spleen Vascular: hilar vascular injury that devascularizes spleen	5 5

†Advance one grade for bilateral injuries, up to grade III.

AAST—American Association for the Surgery of Trauma

**Figure 3** Shown is an algorithm for the treatment of hepatic injuries.

for the temporary control of hemorrhage.³ Over the years, the length of time for which surgeons believe a Pringle maneuver can be maintained without causing irreversible ischemic damage to the liver has increased. Several authors have documented the maintenance of a Pringle maneuver for longer than 1 hour in patients with complex injuries, without appreciable hepatic damage.^{4,10} When a life-threatening hepatic injury is encountered on entry into the abdomen, the Pringle maneuver should be performed immediately and perihepatic packs placed. Persistent bleeding in the face of effective inflow occlusion implies that either the retrohepatic vena cava or hepatic vein has been injured. Perihepatic packing is more likely to control bleeding from the retrohepatic vena cava.

Another technique for temporary control of hepatic hemorrhage is the application of a tourniquet or a liver clamp.¹¹ Once the bleeding hemiliver is mobilized, a 2.5 cm Penrose drain is wrapped around the liver near the anatomic division between the left hemiliver and the right. The drain is stretched until hemorrhage ceases, and tension is maintained by clamping the drain. Unfortunately, tourniquets are difficult to use: they tend to slip off

or tear through the parenchyma if placed over an injured area. An alternative is the use of a liver clamp; however, the application of such devices is hindered by the variability in the size and shape of the liver. We have not had consistent success with either of these methods.

Juxtahepatic venous injuries are technically challenging, difficult to control with packing, and often lethal. Complex procedures may be required for temporary control of these large veins. Of these procedures, the most important are hepatic vascular isolation with clamps, placement of the atricaval shunt, and use of the Moore-Pilcher balloon.

Hepatic vascular isolation is accomplished by executing a Pringle maneuver, clamping the aorta at the diaphragm, and clamping the suprarenal and suprahepatic vena cava.¹² In patients scheduled for elective procedures, this technique has enjoyed nearly uniform success, but in trauma patients, the results have been disappointing. The relative ineffectiveness of hepatic vascular isolation with clamps in this setting is presumably due to the inability of a patient in shock to tolerate an acute reduction in left ventricular filling pressure; on occasion, sudden death has occurred

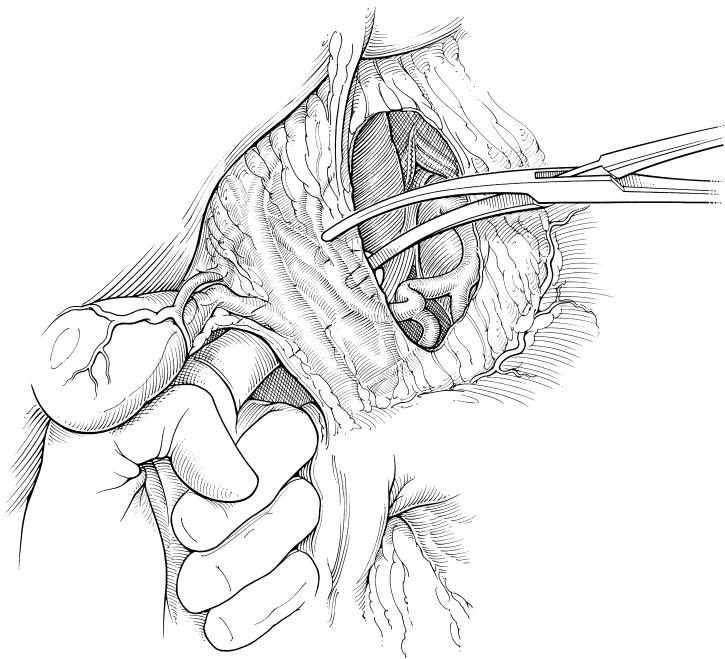

Figure 4 The Pringle maneuver controls arterial and portal vein hemorrhage from the liver. Any hemorrhage that continues must come from the hepatic veins.

on placement of the venous clamps.¹³ If, however, a trauma patient requiring hepatic vascular isolation has been maintained in a relatively normal physiologic condition, it is reasonable to consider this method.

An alternative approach to exposure of the retrohepatic vena cava and the hepatic veins has been developed in which vascular isolation of the liver is achieved by means of clamping and the suprahepatic vena cava is divided between vascular clamps [see Figure 7].¹⁴ The liver and the suprahepatic vena cava are then

Figure 5 Manual compression of large hepatic injuries temporarily controls blood loss in hypovolemic patients until the circulating blood volume can be restored.

rotated anteriorly to provide direct access to the posterior aspect of the retrohepatic vena cava. Anterior injuries of the large veins are repaired through an incision in the posterior aspect of the retrohepatic vena cava.

The atriocaval shunt was designed to achieve hepatic vascular isolation while still permitting some venous blood from below the diaphragm to flow through the shunt into the right atrium.⁴ After a few early successes, the initial enthusiasm for the atriocaval shunt declined as high mortalities associated with its use began to be reported.¹⁵⁻²⁰ Surgeons' lack of familiarity with the technique; the manipulation of a cold, acidotic heart; and poor patient selection have all contributed to the poor overall results.¹³ A variation on the original atriocaval shunt has been described in which a 9 mm endotracheal tube is substituted for the usual large chest tube [see Figure 8].²¹ The balloon of the endotracheal tube makes it unnecessary to surround the suprarenal vena cava with an umbilical tape. This minor change eliminates one of the most difficult maneuvers required for the original shunt procedure: because hemorrhage must be controlled by posterior pressure on the liver during the insertion of the shunt, access to the suprarenal vena cava is severely restricted, and thus, surrounding this vessel with an umbilical tape is almost impossible. A side hole must be cut in the tube to allow blood to enter the right atrium. Care must be taken to avoid damage to the integral inflation channel for the balloon.

An alternative to the atriocaval shunt is the Moore-Pilcher balloon.²¹ This device is inserted through the femoral vein and advanced into the retrohepatic vena cava. When the balloon is properly positioned and inflated, it occludes the hepatic veins and the vena cava, thus achieving vascular isolation. The catheter itself is hollow, and appropriately placed holes below the balloon permit

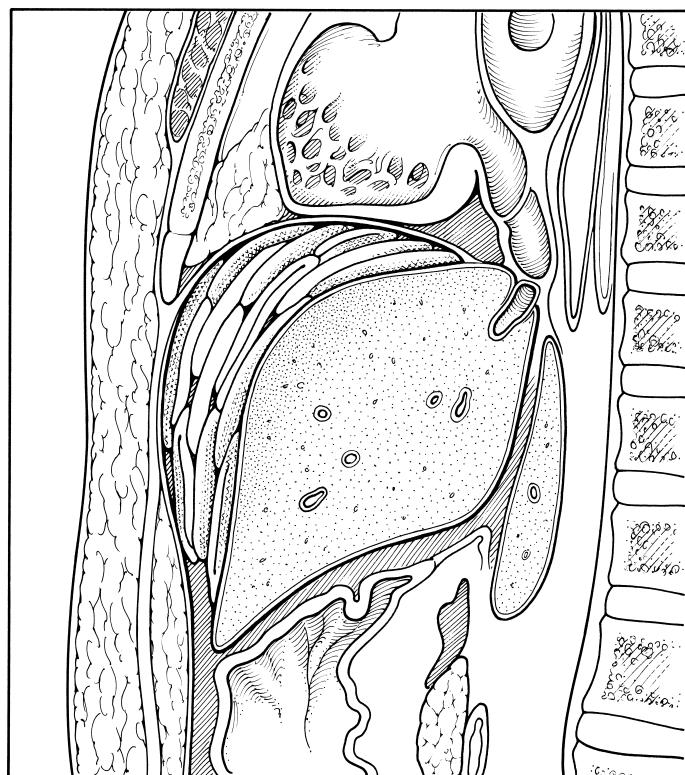

Figure 6 Perihepatic packing is often effective in managing extensive parenchymal injuries. It has also been successfully employed for grade V juxtahepatic venous injuries.

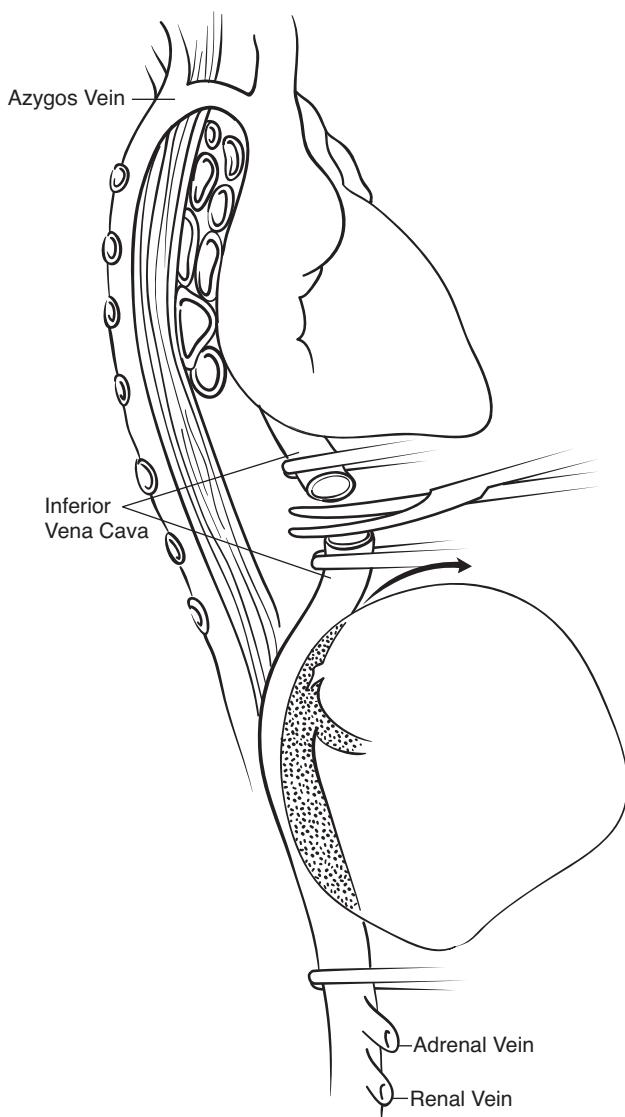

Figure 7 With hepatic vascular isolation accomplished, the suprahepatic vena cava is divided between clamps, and the liver and the suprahepatic vena cava are rotated anteriorly to afford access to the posterior aspect of the retrohepatic vena cava.

blood to flow into the right atrium, in much the same way as the atriocaval shunt. At present, the survival rate for patients with juxtahepatic venous injuries who are treated with this device is similar to that for patients treated with the atriocaval shunt.¹⁸

Surgeons who attempt hepatic vascular isolation should be aware that none of these techniques provide complete hemostasis. Drainage from the right adrenal vein and the inferior phrenic veins and persistent hepatopetal flow resulting from unrecognized replacing or accessory left hepatic arteries contribute to this problem. The relatively small volume of blood that continues to flow after vascular isolation is readily removed by means of suction.

An adjunct to vascular isolation with clamps is venovenous bypass. This technique provides vascular decompression for the small bowel and maintains high cardiac filling pressures, which are often necessary. Venovenous bypass is accomplished by placing a catheter in the inferior vena cava via the femoral vein and a second catheter in the superior mesenteric vein [see Figure 9].²² A centrifugal pump withdraws blood from these veins and pumps it into the superior vena cava through a third catheter placed in the internal jugular vein.

Techniques for Definitive Management of Injuries

Techniques available for the definitive management of hepatic injuries range from manual compression to hepatic transplantation. Grade I or II lacerations of the hepatic parenchyma can generally be controlled with manual compression. If these injuries do not respond to manual compression, they can often be controlled with topical hemostatic measures.

The simplest of these measures is electrocautery, which can often control small bleeding vessels near the surface of the liver (though the machine's power output may have to be increased). Bleeding from raw surfaces of the liver that does not respond to the electrocautery may respond to the argon beam coagulator. This device imparts less heat to the surrounding hepatic tissue and creates a more consistent eschar, which enhances hemostasis. Also useful in similar situations is micro-crystalline collagen in the powdered form. The powder is placed on a clean 10 × 10 cm sponge and applied directly to the oozing surface, with pressure maintained on the sponge for 5 to 10 minutes. Thrombin can also be applied topically to minor bleeding injuries by saturating either a gelatin foam sponge or a microcrystalline collagen pad and pressing it to the bleeding site.

In previous years, there was interest in the use of "bathtub" fi-

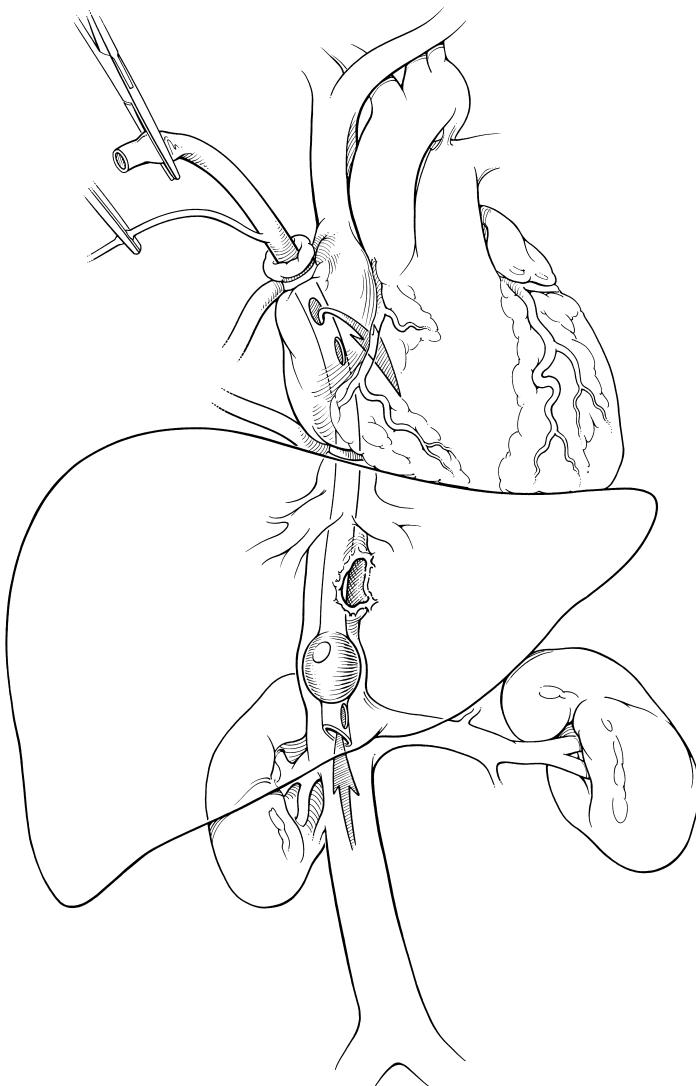

Figure 8 Shown is a method of achieving hepatic vascular isolation with a 9 mm endotracheal tube.

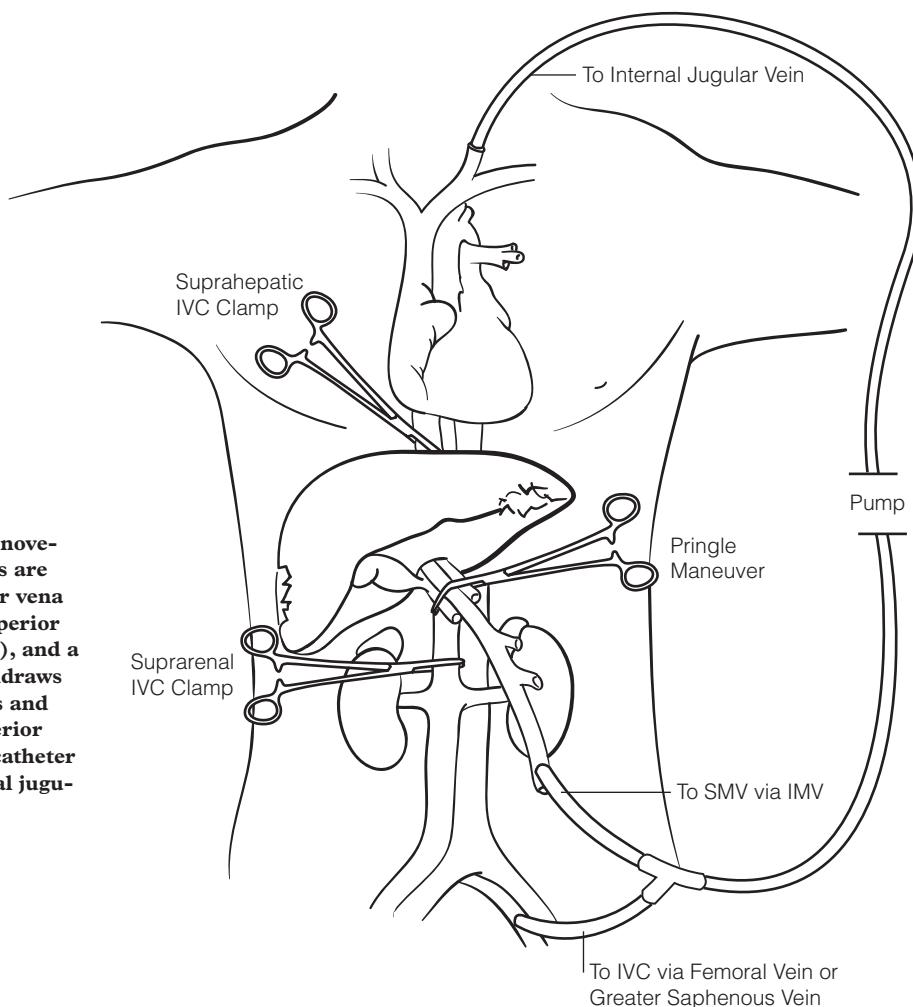

Figure 9 Shown is venovenous bypass. Catheters are placed into the inferior vena cava (IVC) and the superior mesenteric vein (SMV), and a centrifugal pump withdraws blood from these veins and pumps it into the superior vena cava via a third catheter placed into the internal jugular vein.

brin glue (made by mixing concentrated human fibrinogen with a solution containing bovine thrombin and calcium) to treat hepatic lacerations.^{23,24} This substance has now been rendered obsolete by the commercial availability of numerous glues and sealants [see Table 2].

Another relatively new hemostatic adjunct that can be highly useful in the setting of hepatic injury is recombinant activated factor VII (NovoSeven; Novo Nordisk, Copenhagen), which works by promoting coagulation at the lacerated edges of blood vessels. Many trauma surgeons have personally witnessed the abrupt cessation of hemorrhage when factor VII has been administered after other materials have failed. Although this agent seems at times to have an almost magical effect, it does not always work, and it is extremely expensive; furthermore, the only prospective study to date that addressed the use of factor VII in trauma patients reported only a modest decrease in total blood use and failed to demonstrate a survival advantage.²⁵ For these reasons, many institutions, including ours (University of Colorado Health Sciences Center), have created protocols for the use of factor VII. At our institution, for factor VII to be used, (1) the patient must be salvageable; (2) the patient must have received at least 10 units of packed red blood cells (PRBCs) plus clotting factors; (3) surgical control of hemorrhage must be achieved; and (4) the patient must still be experiencing diffuse hemorrhage. The usual dose is 60 to 90 µg/kg, which may be repeated once. It should be kept in mind that factor VII is not a substitute for fresh frozen plasma and platelets and that adequate amounts of fibrin and platelets must be present for it to work.

Although some grade III and IV lacerations respond to topical measures, many do not. In these instances, one option is to suture the hepatic parenchyma. Although this hemostatic technique has been maligned as a cause of hepatic necrosis, it still is frequently used.^{3,4,10,17,26,27} Suturing of the hepatic parenchyma is often employed to control persistently bleeding lacerations less than 3 cm in depth; it is also an appropriate alternative for deeper lacerations if the patient cannot tolerate the further hemorrhage associated with hepatotomy and selective ligation. If, however, the capsule of the liver has been stripped away by the injury, this technique is far less effective.

The preferred suture material is 0 or 2-0 chromic catgut attached to a large, blunt-tipped, curved needle; the large diameter prevents the suture from pulling through Glisson's capsule. For shallow lacerations, a simple continuous suture may be used to approximate the edges of the laceration. For deeper lacerations, interrupted horizontal mattress sutures may be placed parallel to the edges. When tying sutures, one may be sure that adequate tension has been achieved when hemorrhage ceases or the liver blanches around the suture.

Most sources of venous hemorrhage can be managed with parenchymal sutures. Even injuries to the retrohepatic vena cava and the hepatic veins have been successfully tamponaded by closing the hepatic parenchyma over the bleeding vessels.^{13,28} Venous hemorrhage caused by penetrating wounds traversing the central portion of the liver may be managed by closing the entrance and exit wounds with interrupted horizontal mattress sutures.

Table 2 Characteristics of Selected Commercially Available Tissue Glues and Sealants

	Tisseele VH*	FloSeal*	CoSeal*	BioGlue†
Contents	Human fibrinogen and thrombin; calcium chloride; bovine aprotinin	Bovine gelatin and thrombin	Polyethylene glycol	Glutaraldehyde; bovine albumin
Method of absorption (time)	Fibrinolysis (10–14 days)	Cell-mediated inflammation (6 wk)	Hydrolysis (30 days)	Not absorbed
Physical properties	Flexible and elastic	Granular; conforms to irregular surfaces	Clear hydrogel; flexible and elastic	Ridged and inelastic
Preparation time	7–15 min	1–2 min	1–2 min	1–2 min
General applications	Tissue sealing and adherence; hemostasis in venous oozing	Hemostasis in wet fields up to arterial pressure	Tissue sealing in dry fields	Tissue sealing in dry fields
Specific applications	Venous oozing; sealing of staple lines; decortication; pleurodesis	Active bleeding	Sealing of small vessels and synthetic grafts; prevention of adhesion in pediatric cardiac surgical patients; sealing of large vessels	Sealing of large vessels
Means of application	Cannula; spray; minimally invasive surgery	Cannula; minimally invasive surgery; 8 cm or 10 cm bulb tip	Flexible cannula; spray; minimally invasive surgery	Cannula
Limiting factors	Arterial pressure	Does not seal	Wet field	Wet field, nerves
Set times	3 min	2 min	1 min	30 sec
Stability	4 hr	2 hr	2 hr	—

Although this measure may lead to the formation of intrahepatic hematomas that may then become infected, the risk is reasonable compared with the risks posed by an intracaval shunt or a deep hepatotomy. Still, suturing of the hepatic parenchyma is not always successful in controlling hemorrhage, particularly hemorrhage from the larger branches of the hepatic artery. If it fails, one must acknowledge the failure promptly and remove the sutures so that the wound can be explored.

Hepatotomy with selective ligation of bleeding vessels is an important technique that is usually reserved for deep or transhepatic penetrating wounds. Most authorities prefer it to parenchymal suturing^{3,4,10,29,30}; some even favor it over placement of an atrio caval shunt for exposure and repair of juxtahepatic venous injuries.²⁰ The finger-fracture technique is used to extend the length and depth of a laceration or a missile tract until the bleeding vessels can be identified and controlled [see Figure 10]. It should be remembered that considerable blood loss may be incurred with the division of viable hepatic tissue in the pursuit of bleeding from deep penetrating wounds. As an alternative to finger fracture, we have begun to use the LigaSure vessel sealing system (Valleylab, Boulder, Colorado) and have observed significant decreases in blood loss with this device.

An adjunct to parenchymal suturing or hepatotomy is the use of the omentum to fill large defects in the liver and to buttress hepatic sutures. The rationale for this use of the omentum is that it provides an excellent source for macrophages and fills a potential dead space with viable tissue.³¹ In addition, the omentum can provide a little extra support for parenchymal sutures, often enough to prevent them from cutting through Glisson's capsule.

Hepatic arterial ligation may be appropriate for patients with arterial hemorrhage from deep within the liver³²; however, it plays only a limited role in the overall treatment of hepatic injuries,

because it does not stop hemorrhage from the portal and hepatic venous systems.³³ Its primary role is in the management of deep injuries when application of the Pringle maneuver results in the cessation of arterial hemorrhage. If the bleeding from the wound stops once the left or right hepatic artery is isolated and clamped, hepatic arterial ligation is a reasonable alternative to deep hepatotomy. Generally, ligation of the right or left hepatic artery is well tolerated; however, ligation of the proper hepatic artery (distal to the origin of the gastroduodenal artery) may produce hepatic necrosis.

An alternative to suturing the entrance and exit wounds of a transhepatic penetrating injury or to performing an extensive hepatotomy is the use of an intrahepatic balloon.³⁴ These devices are hand-crafted by the surgeon in the operating room. One method of fashioning such a device is to tie a 2.5 cm Penrose drain to a hollow catheter [see Figure 11]. The balloon is then inserted into the bleeding wound and inflated with a soluble contrast agent. If the hemorrhage is controlled, a stopcock or clamp is used to occlude the catheter and maintain the inflation. (It should be noted that the balloon catheter may not be able to generate sufficient intraparenchymal pressure to tamponade major arterial hemorrhage.) The balloon is left in the abdomen and removed at a subsequent operation after 24 to 48 hours. The hemorrhage may recur when the balloon is deflated.

Resectional debridement is indicated for peripheral portions of nonviable hepatic parenchyma. Except in rare circumstances, the amount of tissue removed should not exceed 25% of the liver. Resectional debridement is performed by means of the finger-fracture technique and is appropriate for selected patients with grade III to grade V lacerations. Because additional blood loss occurs during removal of nonviable tissue, this procedure should be reserved for patients who are in sound physiologic condition and can tolerate additional blood loss.

Figure 10 Hepatotomy with selective ligation is an important technique for controlling hemorrhage from deep (usually penetrating) lacerations. This technique includes finger fracture to extend the length and depth of the wound until vessels or ducts are encountered and controlled.

Perihepatic packing is the most significant advance in the treatment of hepatic injuries to occur in the past 25 years. The practice of packing hepatic injuries is not a new one, but the concepts and techniques associated with it have changed. In the past, liver lacerations were packed with yards of gauze, and one end of the gauze strip was brought out of the abdomen through a separate stab wound³⁵; the remainder of the gauze was then teased out of the wound over a period of days. Unfortunately, this approach often led to abdominal infection and failed to control the hemorrhage, and as a result, it eventually fell from favor. The current approach is not to place packing material in the laceration itself but rather to place it over and around the injury to compress the wound by compressing the liver between the anterior chest wall, the diaphragm, and the retroperitoneum.⁵⁻⁹ The abdomen is closed, and the patient is taken to the surgical intensive care unit for resuscitation and correction of metabolic derangements. Within 24 hours, the patient is returned to the OR for removal of the packs. Perihepatic packing is indicated for grade IV and V lacerations and for less severe injuries in patients who have a coagulopathy caused by associated injuries.

A technique that may be attempted if packing fails is to wrap the injured portion of the liver with a fine porous material (e.g., polyglycolic acid mesh) after the injured hemiliver has been mobilized.^{36,37} Using a continuous suture or a linear stapler, the surgeon constructs a tight-fitting stocking that encloses the injured hemiliver. Blood clots beneath the mesh, which results in tamponade of the hepatic injury. Although this technique is intuitively attractive, to date it has achieved only limited success.

The final alternative for patients with extensive injuries to one hemiliver is anatomic hepatic resection. In elective circumstances, anatomic hemihepatectomies can be performed with excellent

results; however, in the setting of trauma, the mortality associated with this procedure exceeds 50% in most series.^{26,27,29,38-40} Consequently, hepatic resection is rarely performed in trauma patients, having been largely replaced by perihepatic packing, resectional debridement, and hepatotomy with selective ligation. Nonetheless, there are two circumstances in which anatomic resection may still be a reasonable choice. The first is prompt resection in patients with extensive injuries of the left lateral section of the liver; because hemorrhage from the left hemiliver is easily controlled with bimanual compression, the risk of uncontrolled blood loss is not as high as it is with left or right anatomic hemihepatectomies. The second is delayed anatomic hemihepatectomy in patients whose hemorrhage has been controlled but whose left or right hemiliver is nonviable as a result of ligation or thrombosis of essential blood vessels. Because of the large mass of necrotic liver tissue, there is a high risk of subsequent infection or persistent hyperinflammation, setting the stage for the multiple organ dysfunction syndrome (MODS). The necrotic hemiliver should be removed as soon as the patient's condition permits.

Hepatic transplantation has been successful in several trauma patients with devastating hepatic injuries who required total hepatectomy.⁴¹⁻⁴⁴ In each of these five patients, the mean anhepatic period was approximately 24 hours. All five survived the transplantation, though two died of disseminated viral infections within 2 months of the procedure. Two others were alive and well 16 and 17 months after the procedure; no follow-up was reported for the fifth patient. Hepatic transplantation represents the ultimate expression of aggressive trauma care. All other injuries must be well delineated (particularly injuries to the CNS), and the patient must have an excellent chance of survival aside from the hepatic injury. High cost and limited availability of donors restrict the performance of hepatic transplantation for trauma, but it seems probable that this procedure will continue to be performed in extraordinary circumstances.

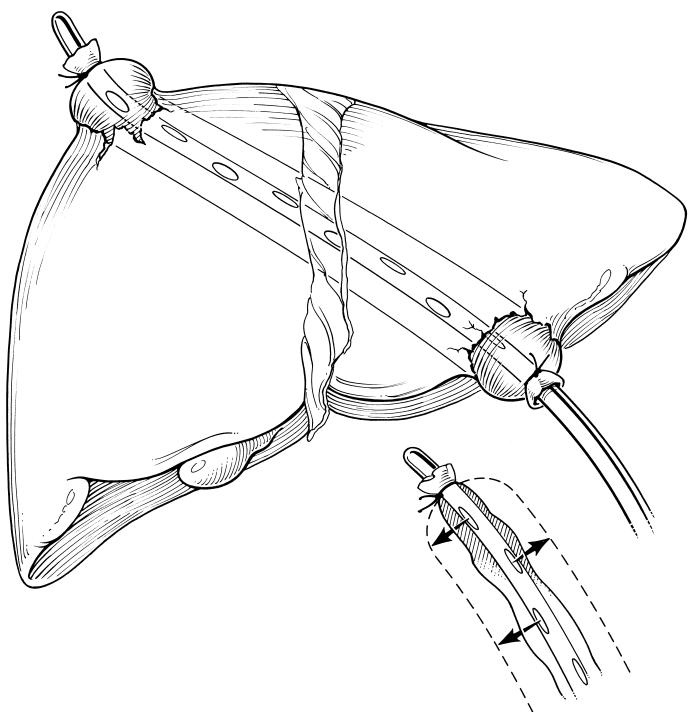

Figure 11 A handmade balloon from a Robinson catheter and a Penrose drain may effectively control hemorrhage from a trans-hepatic penetrating wound.

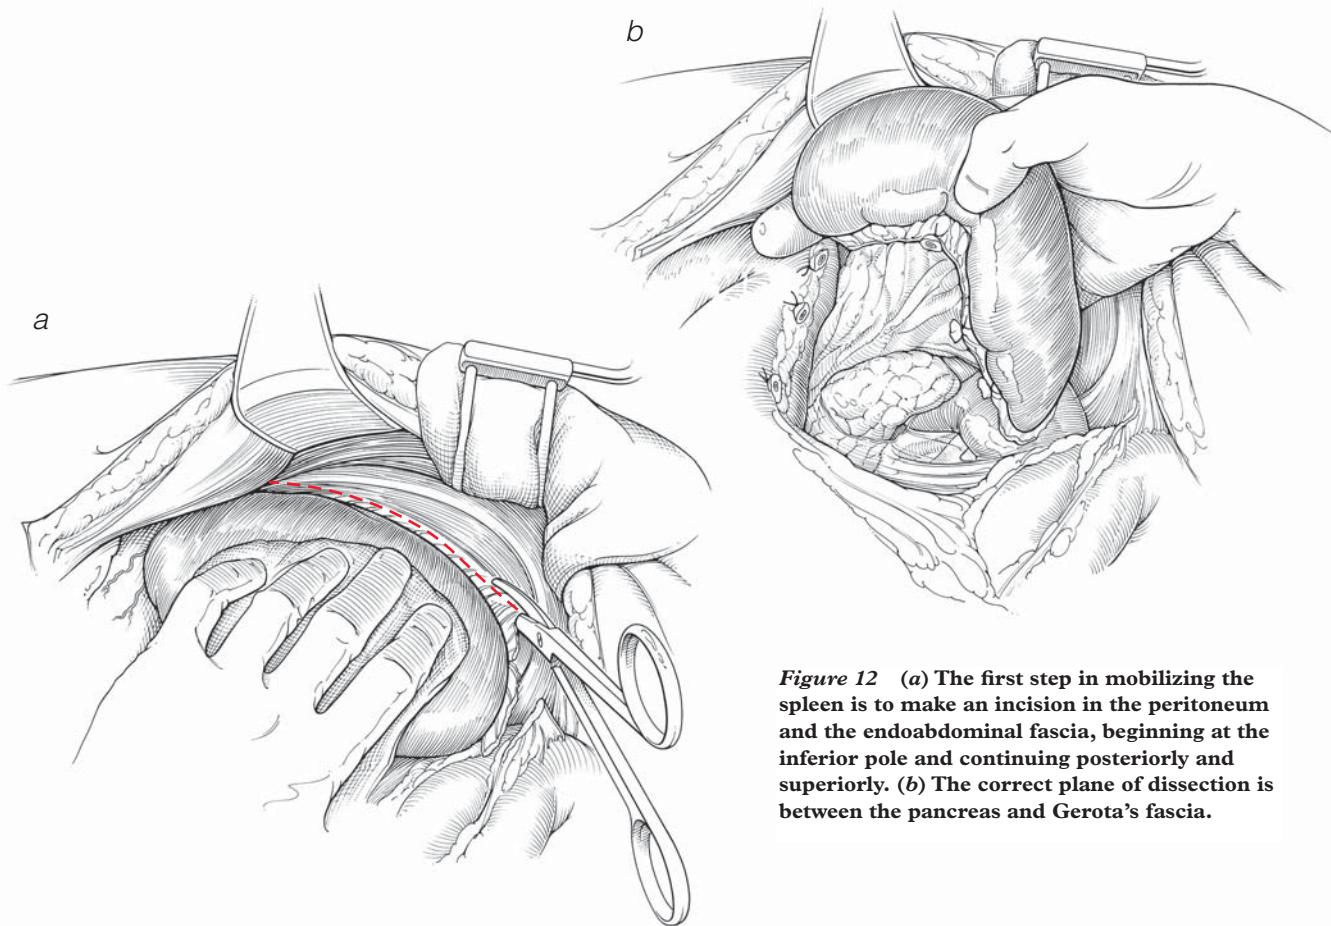

Figure 12 (a) The first step in mobilizing the spleen is to make an incision in the peritoneum and the endoabdominal fascia, beginning at the inferior pole and continuing posteriorly and superiorly. (b) The correct plane of dissection is between the pancreas and Gerota's fascia.

Subcapsular Hematoma

An uncommon but troublesome hepatic injury is subcapsular hematoma, which arises when the parenchyma of the liver is disrupted by blunt trauma but Glisson's capsule remains intact. Subcapsular hematomas range in severity from minor blisters on the surface of the liver to ruptured central hematomas accompanied by severe hemorrhage [see Table 1]. They may be recognized either at the time of the operation or in the course of CT scanning.

Regardless of how the lesion is diagnosed, subsequent decision making is often difficult. If a grade I or II subcapsular hematoma—that is, a hematoma involving less than 50% of the surface of the liver that is not expanding and is not ruptured—is discovered during an exploratory laparotomy, it should be left alone. If the hematoma is explored, hepatotomy with selective ligation may be required to control bleeding vessels. Even if hepatotomy with ligation is effective, one must still contend with diffuse hemorrhage from the large denuded surface, and packing may also be required. A hematoma that is expanding during operation (grade III) may have to be explored. Such lesions are often the result of uncontrolled arterial hemorrhage, and packing alone may not be successful. An alternative strategy is to pack the liver to control venous hemorrhage, close the abdomen, and transport the patient to the interventional radiology suite for hepatic arteriography and embolization of the bleeding vessels. Ruptured grades III and IV hematomas are treated with exploration and selective ligation, with or without packing.

Perihepatic Drainage

For years, all hepatic injuries were drained via Penrose drains brought out laterally or through the bed of the resected 12th rib;

recently, the use of large sump drains and closed suction drains has become increasingly popular. Several prospective and retrospective studies have demonstrated that the use of either Penrose or sump drains carries a higher risk of intra-abdominal infection than the use of either closed suction drains or no drains at all.⁴⁵⁻⁴⁷ It is clear that if drains are to be used, closed suction devices are preferred. What remains unclear, however, is whether closed suction drains are better or worse than no drains, particularly in view of the advent of percutaneous catheter drainage. Patients who are initially treated with perihepatic packing may also require drainage; however, drainage is not indicated at the initial procedure, given that the patient will be returned to the OR within the next 48 hours.

MORTALITY AND COMPLICATIONS

Overall mortality for patients with hepatic injuries is approximately 10%. The most common cause of death is exsanguination, followed by MODS and intracranial injury. Three generalizations may be made regarding the risk of death and complications: (1) both increase in proportion to the injury grade and to the complexity of repair; (2) hepatic injuries caused by blunt trauma carry a higher mortality than those caused by penetrating trauma; and (3) infectious complications occur more often with penetrating trauma.⁴⁸

Postoperative hemorrhage occurs in a small percentage of patients with hepatic injuries. The source may be either a coagulopathy or a missed vascular injury (usually to an artery). In most instances of persistent postoperative hemorrhage, the patient is best served by being returned to the OR. Arteriography with embolization may be considered in selected patients. If coagula-

tion studies indicate that a coagulopathy is the likely cause of postoperative hemorrhage, there is little to be gained by reoperation until the coagulopathy is corrected.

Perihepatic infections occur in fewer than 5% of patients with significant hepatic injuries. They develop more often in patients with penetrating injuries than in patients with blunt injuries, presumably because of the greater frequency of enteric contamination. An elevated temperature and a higher than normal white blood cell count after postoperative day 3 or 4 should prompt a search for intra-abdominal infection. In the absence of pneumonia, an infected line, or urinary tract infection, an abdominal CT scan with intravenous and upper gastrointestinal contrast should be obtained. Many perihepatic infections can be treated with CT-guided drainage; however, infected hematomas and infected necrotic liver tissue cannot be expected to respond to percutaneous drainage. Right 12th rib resection remains an excellent approach for posterior infections and provides superior drainage in refractory cases.

Bilomas are loculated collections of bile that may or may not be infected. If a biloma is infected, it is essentially an abscess and should be treated as such; if it is sterile, it will eventually be resorbed. Biliary ascites is caused by disruption of a major bile duct. Reoperation after the establishment of appropriate drainage is the prudent course. Even if the source of the leaking bile can be identified, primary repair of the injured duct is unlikely to be successful. It is best to wait until a firm fistulous communication is established with adequate drainage.

Biliary fistulas occur in approximately 3% of patients with major hepatic injuries.⁴⁰ They are usually of little consequence and generally close without specific treatment. In rare instances, a fistulous communication with intrathoracic structures forms in patients with associated diaphragmatic injuries, resulting in a bronchobiliary or pleurobiliary fistula. Because of the pressure differential between the biliary tract and the thoracic cavity, most of these fistulas must be closed operatively; however, we know of one pleurobiliary fistula that closed spontaneously after endoscopic sphincterotomy and stent placement.

Hemorrhage from hepatic injuries is often treated without identifying and controlling each bleeding vessel individually, and arterial pseudoaneurysms may develop as a consequence. As the pseudoaneurysm enlarges, it may rupture into the parenchyma of the liver, into a bile duct, or into an adjacent branch of the portal vein. Rupture into a bile duct results in hemobilia, which is characterized by intermittent episodes of right upper quadrant pain, upper GI hemorrhage, and jaundice; rupture into a portal vein may result in portal vein hypertension with bleeding varices. Both of these complications are exceedingly rare and are best managed with hepatic arteriography and embolization.

Injuries to the Bile Ducts and Gallbladder

Injuries to the extrahepatic bile ducts [see Table 1] can be caused by either penetrating or blunt trauma; however, they are rare in either case.⁴⁹⁻⁵³

The diagnosis is usually made by noting the accumulation of bile in the upper quadrant during laparotomy for treatment of associated injuries. Treatment of common bile duct (CBD) injuries after external trauma is complicated by the small size and thin wall of the normal duct, which render primary repair almost impossible except when the laceration is small and there is no tissue loss. When there is tissue loss or the laceration is larger than 25% to 50% of the diameter of the duct, the best treatment option is a Roux-en-Y choledochojejunostomy [see 5:22 Procedures for Benign

and Malignant Biliary Tract Disease].⁵⁴⁻⁵⁷ Treatment of injuries to the left or right hepatic duct is even more difficult—so much so that we question whether repair should even be attempted under emergency conditions. If only one hepatic duct is injured, a reasonable approach is to ligate it and deal with any infections or atrophy of the hemiliver rather than to attempt repair.⁵⁸ If both ducts are injured, each should be intubated with a small catheter brought through the abdominal wall. Once the patient has recovered sufficiently, delayed repair is performed under elective conditions. Injuries to the intrapancreatic portion of the CBD are treated by dividing the duct at the superior border of the pancreas, ligating the distal portion, and performing a Roux-en-Y choledochojejunostomy.

The Roux-en-Y choledochojejunostomy is done in a single layer with interrupted 5-0 absorbable monofilament sutures. To prevent ischemia and possible stricture, no circumferential dissection of the duct is performed. A round patch of approximately the same diameter as the CBD is removed from the seromuscular layer of the small bowel, but the mucosa and submucosa are only perforated, not resected. The posterior row of sutures is placed first, with full-thickness bites taken through both the duct and the small bowel. The anterior row is then completed. Finally, three or four 3-0 polypropylene sutures are placed to secure the small bowel around the anastomosis to the connective tissue of the porta hepatis. The only purpose for these sutures is to spare the fragile anastomosis any potential tension. No T tubes or stents are employed. Closed suction drainage is added in the case of injuries to the intrapancreatic portion of the duct or at the surgeon's discretion.

Injuries to the gallbladder [see Table 1] are treated by means of either lateral repair with absorbable sutures or cholecystectomy [see 5:21 Cholecystectomy and Common Bile Duct Exploration]; the decision between the two approaches depends on which is easier in a given situation. Cholecystostomy is rarely, if ever, indicated.

Injuries to the Spleen

Splenic injuries [see Table 1] are treated operatively by means of splenic repair (splenorrhaphy), partial splenectomy, or resection, depending on the extent of the injury and the condition of the patient.^{57,58} The continued enthusiasm for nonoperative management of splenic injuries is driven, in part, by concern about the rare but often fatal complication known as overwhelming postsplenectomy infection (OPSI). OPSI is caused by encapsulated bacteria (e.g., *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*) and is very resistant to treatment: mortality may exceed 50%. OPSI occurs most often in young children and immunocompromised adults and is uncommon in otherwise healthy adults. For this reason, splenic salvage is attempted more vigorously in pediatric patients than in adult ones [see Discussion, Nonoperative Management of Blunt Hepatic and Splenic Injuries, below].

To ensure safe removal or repair, the spleen should be mobilized to the point where it can be brought to the surface of the abdominal wall without tension. To this end, the soft tissue attachments between the spleen and the splenic flexure of the colon must be divided. Next, an incision is made in the peritoneum and the endoabdominal fascia, beginning at the inferior pole, 1 to 2 cm lateral to the posterior peritoneal reflection of the spleen, and continuing posteriorly and superiorly until the esophagus is encountered [see Figure 12a]. Care must be taken not to pull on the spleen, so that it will not tear at the posterior peritoneal reflection, causing significant hemorrhage. Instead, the spleen should be rotated counterclockwise, with posterior pressure applied to expose the

peritoneal reflection. It is often helpful to rotate the operating table 20° to the patient's right so that the weight of the abdominal viscera facilitates their retraction. A plane is thus established between the spleen and pancreas and Gerota's fascia that can be extended to the aorta [see Figure 12b]. With this step, mobilization is complete, and the spleen can be repaired or removed without any need to struggle to achieve adequate exposure.

Splenectomy [see 5:25 *Splenectomy*] is the usual treatment for hilar injuries or a pulverized splenic parenchyma. It is also indicated for lesser splenic injuries in patients who have multiple abdominal injuries and a coagulopathy, and it is frequently necessary in patients in whom splenic salvage attempts have failed. Partial splenectomy is suitable for patients in whom only a portion of the spleen (usually the superior or inferior half) has been destroyed. Once the damaged portion has been removed, the same methods used to control hemorrhage from hepatic parenchyma can be used to control hemorrhage from splenic parenchyma [see Figure 13]. When horizontal mattress sutures are placed across a raw edge, gentle compression of the parenchyma by an assistant facilitates hemostasis; when the sutures are tied and compression is released, the spleen will expand slightly and tighten the sutures further. Drains are never used after completion of the repair or resection.

If splenectomy is performed, vaccines effective against the encapsulated bacteria are administered. The pneumococcal vaccine is routinely given, and vaccines effective against *H. influenzae* and *N. meningitidis* should also be given if available.

Injuries to the Diaphragm

In cases of blunt trauma to the diaphragm, the injury is on the left side 75% of the time, presumably because the liver diffuses some of the energy on the right side. With both blunt and penetrating injuries [see Table 1], the diagnosis is suggested by an abnormality of the diaphragmatic shadow on chest x-ray. Many of these abnormalities are subtle, particularly with penetrating injuries, and further diagnostic evaluation may be warranted. The typical injury from blunt trauma is a tear in the central tendon; often, the tear is quite large. Regardless of the cause, acute injuries are repaired

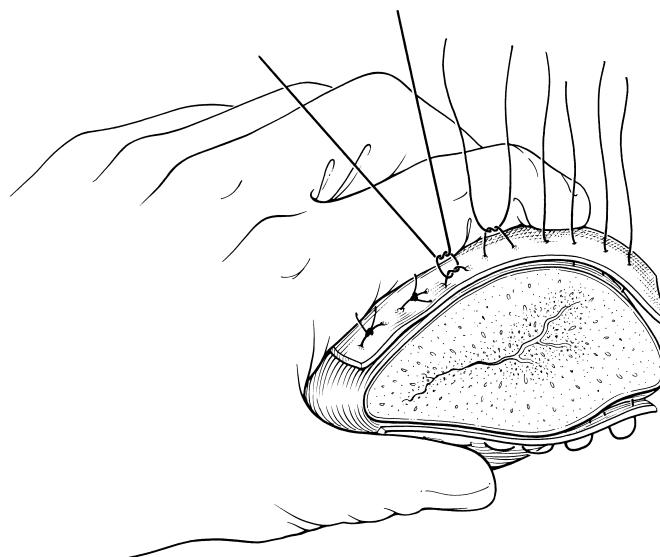

Figure 13 Methods for controlling hemorrhage from the splenic parenchyma are similar to those for controlling hemorrhage from the hepatic parenchyma. Shown are interrupted mattress sutures across a raw edge of the spleen.

through an abdominal incision. Because of the concave shape of the diaphragm and the overlying anterior ribs, anterior diaphragmatic injuries may be difficult to suture. Repair is greatly facilitated by using a long Allis clamp to grasp part of the injury and evert the diaphragm. Lacerations are repaired with continuous No. 1 monofilament nonabsorbable sutures. Occasionally, with large avulsions or gunshot wounds accompanied by extensive tissue loss, polypropylene mesh is required to bridge the defect.

The explosive growth of laparoscopic procedures has led to the application of this technology for both diagnostic and therapeutic purposes in trauma patients. In a number of patients with low anterior thoracic stab wounds who otherwise were not candidates for a laparotomy, small diaphragmatic lacerations have been identified and repaired with laparoscopy and stapling.

Discussion

Nonoperative Treatment of Blunt Hepatic and Splenic Injury

Only a few years ago, blunt and penetrating hepatic and splenic injuries were managed in a similar fashion on the basis of a positive diagnostic peritoneal lavage or the probability of peritoneal penetration: a laparotomy was performed, and the injured organs were identified and treated. Currently, although penetrating abdominal injuries are still treated in the same way, nearly all children and 50% to 80% of adults with blunt hepatic and splenic injuries are treated without laparotomy.⁵⁹⁻⁶⁸ This remarkable change was made possible by the development of the high-speed helical CT scanner, the replacement of diagnostic peritoneal lavage by ultrasonography, and the growth of interventional radiology.

The diagnosis of blunt abdominal trauma is suspected on the basis of the mechanism of injury and the presence of associated injuries (e.g., right or left lower rib fractures). Ultrasonographic examination of the abdomen may reveal a fluid stripe in

Morrison's pouch, the left upper quadrant, or the pelvis, which suggests a hemoperitoneum. This observation prompts a CT scan of the abdomen, which establishes the presence or absence of injuries to the liver or the spleen and, to some degree, serves as a means of grading the severity of organ injury. Patients may be observed either in the SICU or on the ward, depending on the apparent severity of the parenchymal injury on the CT scan, the presence and extent of any associated injuries, and the overall hemodynamic status.^{69,70}

The primary requirement for nonoperative therapy is hemodynamic stability.⁶³⁻⁷² To confirm stability, frequent assessment of vital signs and monitoring of the hematocrit are necessary. Continued hemorrhage occurs in 1% to 4% of patients.^{65,66,68-73} Hypotension may develop, usually within the first 24 hours after hepatic injury but sometimes several days later, especially when splenic injury is present.^{71,72} It is often an indication that operative intervention is necessary. A persistently falling hematocrit should be treated with PRBC transfusions. If the hematocrit con-

tinues to fall after two or three units of PRBCs, embolization of the liver in the interventional radiology suite should be considered.⁶⁶ Overall, nonoperative treatment obviates laparotomy in more than 95% of cases.⁵⁹⁻⁶⁵

Out of concern over the risk of delayed hemorrhage or other complications, follow-up CT scans have often been recommended; unfortunately, there is no consensus as to when or even whether they should be obtained. Given that patients with grade I or II hepatic or splenic injuries rarely show progression of the lesion or other complications on routine follow-up CT scans, it is reasonable to omit such scans if patients' hematocrits remain stable and they are otherwise well. Patients with more extensive injuries often have a less predictable course, and CT scanning may be necessary to evaluate possible complications. Routine scanning before discharge, however, is unwarranted. On the other hand, patients who participate in vigorous or contact sports should have CT documentation of virtually complete healing before resuming those activities.

A more convenient and less expensive alternative to follow-up CT scanning is ultrasonographic monitoring of lesions. Ultrasonographic monitoring is particularly useful for following up splenic injuries; however, it may not be useful for following up hepatic injuries, because the technology currently available is incapable of reliably imaging the entire liver.

Other complications of nonoperative therapy for blunt hepatic and splenic injuries occur in 2% to 5% of patients; these include

missed abdominal injuries, parenchymal infarction, infection, and bile leakage (a complication associated solely with hepatic injuries).^{59,62-64} Aseptic infarcts, infected hematomas, and bile collections are suspected on the basis of a clinical picture suggestive of infection and confirmed by CT-guided aspiration. Aseptic infarction usually does not necessitate operative intervention. Fluid collections are drained, with the method depending on the viscosity of the fluid: CT-guided drainage may be effective in treating thin collections, but operative intervention is required for thicker collections, those with solid components, and those for which percutaneous drainage was attempted without success. Extrahepatic bile collections should be treated with percutaneous drainage under CT guidance. Most biliary fistulas close spontaneously; endoscopic stent placement may hasten closure in recalcitrant cases.⁷⁴ Intrahepatic collections of blood and bile are managed expectantly. Complete absorption of large intrahepatic collections may take several months. If a collection becomes infected, CT-guided aspiration is performed and drainage obtained as described.

Missed enteric and retroperitoneal injuries are another cause of failed nonoperative treatment. Such injuries are present in 1% to 4% of patients in whom nonoperative treatment is attempted.^{59,61-64} High-quality images and expert interpretation minimize the number of missed injuries on CT scans but cannot eliminate them entirely. Therefore, patients must be watched carefully for the development of peritoneal irritation and other signs of intraabdominal pathology.

7 INJURIES TO THE STOMACH, SMALL BOWEL, COLON, AND RECTUM

Jordan A. Weinberg, M.D., F.R.C.S.C., and Timothy C. Fabian, M.D., F.A.C.S

Hollow viscus injury is most commonly the result of penetrating abdominal trauma. It is relatively infrequent in the setting of blunt trauma: in one multi-institutional analysis, only 1.2% of blunt trauma admissions were associated with a hollow viscus injury.¹ Initial resuscitation of the patient with abdominal trauma is described in detail elsewhere [see 7:1 *Initial Management of Life-Threatening Trauma*]. The diagnosis of hollow viscus injury remains a challenge in abdominal trauma patients, and subsequent evaluation is determined by the mechanism of injury. Regardless of the specific injury mechanism, however, the principles of operative management are the same.

Determination of Need for Operation

BLUNT TRAUMA

Hollow viscus injury after blunt trauma, though uncommon, can have serious consequences if the diagnosis is missed or delayed. In a multi-institutional study of 198 patients with blunt small bowel injury, delay of as little as 8 hours in making the diagnosis resulted in increased morbidity and mortality.² Mortality increased in parallel with time to operative intervention (< 8 hours to operation, 2% mortality; 8 to 16 hours, 9%; 16 to 25 hours, 17%; > 24 hours, 31%), as did the complication rate.

Particular consideration should be given to lap- and shoulder-restraint injuries, which may be associated with an increased risk of hollow viscus injury. The so-called seat-belt sign (i.e., ecchymosis of the abdominal wall secondary to the compressive force of the lap belt) is associated with a more than doubled relative risk of small bowel injury.³ Flexion-distraction fractures of the spine (Chance fractures) are also associated with lap-belt use, and the presence of such fractures should raise the index of suspicion for associated hollow viscus injury.

Clinical examination often indicates the need for exploratory laparotomy. Abdominal tenderness after blunt torso trauma is frequently associated with significant intra-abdominal pathology, but the reliability of the examination may be compromised by distracting chest or long bone injury, closed head injury, spinal cord injury, or intoxication. In such scenarios, additional diagnostic tests are necessary.

Ultrasonography is routinely performed early in the evaluation of blunt abdominal trauma. It is highly specific and moderately sensitive in identifying intra-abdominal fluid, the presence of which in a hemodynamically unstable patient is an indication for laparotomy (in that it strongly suggests the presence of significant intra-abdominal hemorrhage).⁴ Ultrasonography does not, however, reliably distinguish solid-organ injury from hollow viscus injury—a distinction that is critical for determining subsequent management (i.e., operative versus nonoperative) in a hemodynamically stable patient. Diagnostic peritoneal lavage (DPL) may help differentiate one type of injury from the other (see below).

Helical (spiral) computed tomography is currently the imaging modality of choice in stable patients who have undergone blunt abdominal trauma. Our experience indicates that it is useful for identifying blunt hollow viscus injury. In a review of over 8,000 CT scans performed to evaluate cases of blunt abdominal trauma, we found that the number of abnormal radiologic findings suggesting blunt injury to the bowel, the mesentery, or both [see Table 1] was correlated with the true presence of injury.⁵ A CT scan demonstrating a solitary abnormality was associated with a true positive rate of 36%, whereas a scan demonstrating more than one abnormality was associated with a true positive rate of 83%. Unexplained intraperitoneal fluid (i.e., fluid appearing in the absence of solid-organ injury) was the most common radiographic finding associated with blunt bowel or mesenteric injury, but it often proved to be a false positive finding [see Table 1].

On the basis of this experience, we developed an algorithm for the evaluation of blunt hollow viscus injury in patients with unreliable clinical examination results [see Figure 1]. If CT scanning demonstrates no suspicious findings, the patient is observed. No further diagnostic workup of hollow viscus injury is performed, and the duration of the observation period depends on the reliability of the clinical examination. It is worth noting that the 2003 multi-institutional review of 2,457 cases carried out by the Eastern Association for the Surgery of Trauma (EAST) reported a 13% incidence of blunt small bowel injury in patients with an initial negative CT scan. These results indicate that caution should be exercised in dismissing the presence of hollow viscus injury on the basis of a negative scan.³ This concern is echoed by our own insti-

Table 1 Incidence of Findings Suggestive of Blunt Mesenteric and Bowel Injury in True Positive and False Positive CT Scans⁶

Finding	Incidence	
	True Positive CT Scans (%)	False Positive CT Scans (%)
Unexplained intraperitoneal fluid	74	79
Pneumoperitoneum	28	2
Bowel wall thickening	30	8
Mesenteric fat stranding	9	4
Mesenteric hematoma	19	19
Extravasation of luminal content	4	0
Extravasation of vascular content	9	0

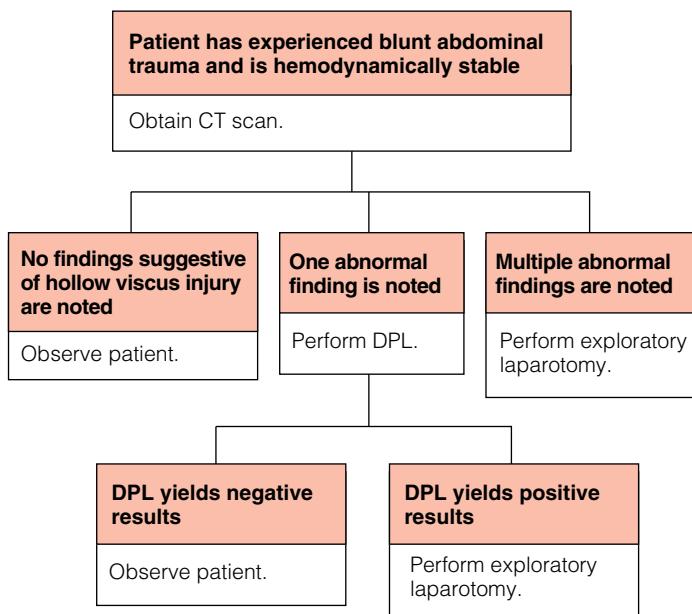

Figure 1 Algorithm outlines the evaluation of blunt injury to a hollow viscus.

tutorial experience, in which the incidence of injury in patients with an initial negative CT scan was 12%.⁵

If CT demonstrates a solitary suspicious finding, DPL is performed for further evaluation. If DPL yields positive results (white blood cell [WBC] count > 500 cells/mm³, alkaline phosphatase level > 10 IU/L, or amylase level > 20 IU/L), exploratory laparotomy is performed. It must be kept in mind, however, that DPL results may be falsely negative or equivocal in the early period after trauma.⁶ This phenomenon may be attributable to a time lag between the intestinal perforation and the subsequent development of intraperitoneal leukocytosis. If a high degree of suspicion of hollow viscus injury remains even after a negative DPL result, DPL may be repeated. Alternatively, exploratory laparotomy may be performed. The choice between the two options is largely based on the individual surgeon's clinical judgment.

If CT demonstrates multiple abnormalities, DPL is omitted from the workup and exploratory laparotomy is performed.

PENETRATING TRAUMA

Gunshot Wounds

Gunshot wounds to the abdomen generally necessitate exploratory laparotomy, given the high incidence of intra-abdominal injury. The exception to this rule is the case of a tangential wound that is believed to be traversing the soft tissues of the abdominal wall without entering the peritoneal cavity. In this scenario, we usually perform laparoscopy to look for peritoneal penetration. If the peritoneum has been violated, a laparotomy is done to permit systematic evaluation of the peritoneal cavity. If the peritoneum has not been violated, the operation may be terminated and the patient discharged after recovery from anesthesia, provided that there are no other extra-abdominal injuries necessitating hospital admission.

Stab Wounds

Stab wounds to the abdomen are associated with a lower incidence of intra-abdominal injury than gunshot wounds are. Accordingly, there has been a shift toward selective management

algorithms that rely on diagnostic tests, serial abdominal examination, or some combination of the two. When the peritoneum has obviously been penetrated (as with omental or bowel evisceration), we perform a laparotomy to evaluate the entire peritoneal cavity for organ injury. When it is unclear whether the peritoneum has been penetrated, we proceed with a definitive evaluation to rule out peritoneal violation. Anterior wounds (i.e., those anterior to the midaxillary line) are evaluated for fascial penetration by means of local wound exploration. In the emergency department (ED), with sterile technique and local anesthesia, the wound is sharply extended to allow retraction of the subcutaneous tissue and visualization of the anterior fascia. If fascial penetration is evident, laparoscopy is performed in the operating room to look for peritoneal penetration; if peritoneal penetration is confirmed, a laparotomy is then done. In cooperative patients who have no history of abdominal surgery, it is often possible to perform diagnostic laparoscopy with local anesthesia in the ED by establishing pneumoperitoneum through a 5 mm trocar (e.g., Optiview; Ethicon Endo-Surgery, Cincinnati, Ohio) and maintaining a relatively low (7 mm Hg) intra-abdominal pressure to allow visualization of the peritoneum while maintaining patient comfort.

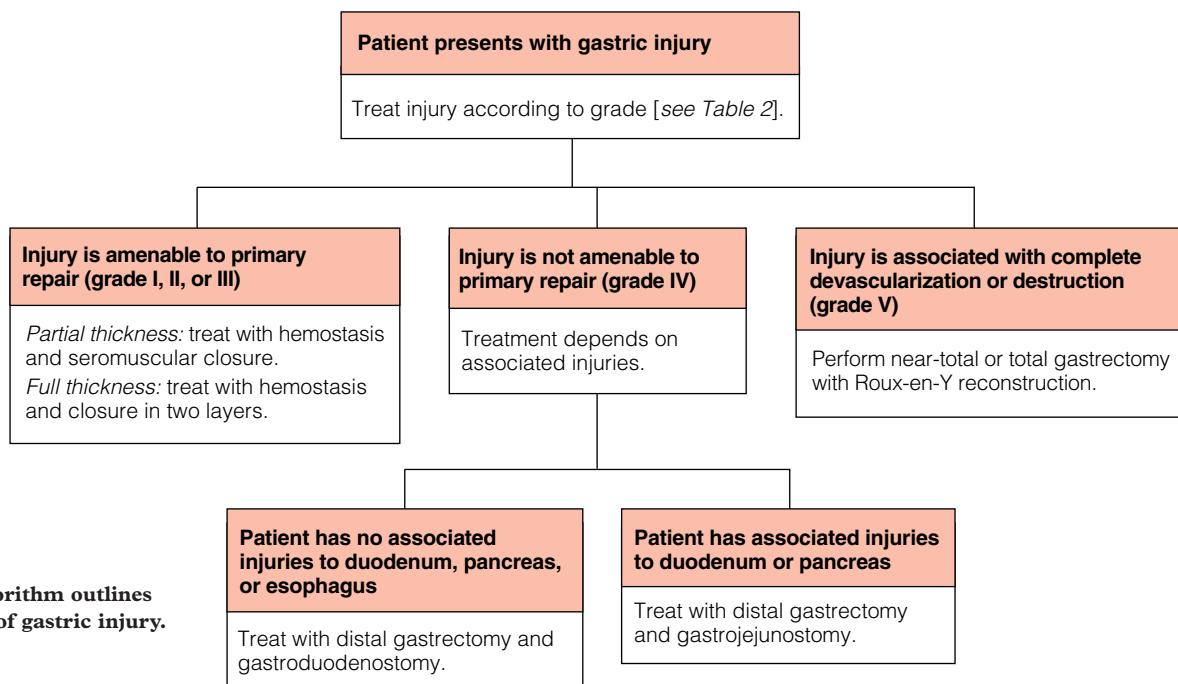

Several centers have reported favorable experiences with expectant management of anterior stab wounds.^{7,8} Patients without evidence of peritonitis are admitted and monitored with serial physical examinations. As noted (see above), we prefer to determine the presence of peritoneal penetration at the time of presentation. The rationale for this approach is to avoid any delay in diagnosis of hollow viscus injury and to allow early discharge of patients with no peritoneal violation. Various centers have described both DPL and CT criteria for excluding peritoneal penetration.^{9,10}

Wounds to the lower back or the flank (posterior to the midaxillary line), which carry a lower risk of intra-abdominal injury, are evaluated with CT, augmented by intravenous, oral, and rectal contrast studies. CT scanning has proved to be a reliable means not only of identifying posterior intraperitoneal violation but also of evaluating injury to retroperitoneal structures.¹¹

Operative Management of Injuries at Specific Sites

When hollow viscus injury is suspected, antibiotics with broad-spectrum aerobic and anaerobic coverage should be administered before the skin incision. If injury is confirmed, the antibiotics should be continued for a 24-hour period. The EAST Practice Management Guidelines Workgroup has reviewed the available evidence regarding perioperative antibiotic use in the trauma setting.¹² Data from prospective studies clearly indicate that prolonging antibiotic administration beyond 24 hours provides no additional protection against surgical site infection (SSI).

Abdominal exploration is generally performed through a midline incision that is sufficiently extensive to permit evaluation of the entire peritoneal cavity. Once initial control of any significant bleeding has been obtained, the next step is to control any contamination from spilled GI contents. Babcock clamps are useful for temporarily controlling contamination from bowel perforations without causing injury to the bowel wall. Inspection commences in a systematic fashion, with any holes in the bowel controlled as they are found. In the setting of penetrating injury, when an odd number of hollow viscus perforations are encountered, a diligent search for an additional perforation is essential. An odd number of perforations implies that one of the wounds is tangential (or that the projectile is intraluminal); this is a diagnosis of exclusion.

INJURIES TO THE STOMACH

Intraoperative evaluation of the stomach begins with full visualization of the anterior gastric surface from the pylorus to the esophagogastric junction. Proximal exposure is facilitated by incising the triangular ligament and retracting the left lateral section of the liver to the patient's right. The posterior aspect of the stomach is assessed by opening the gastrocolic ligament, which provides access to the lesser sac. Care must be taken to avoid injuring the vascular arcade of the greater curvature. While the stomach is elevated superiorly, the transverse colon is retracted inferiorly to expose the posterior gastric wall. Frequently, light adhesions between the posterior gastric wall and the retroperitoneum overlying the pancreas must be freed to provide full exposure. Alternatively, the greater omentum may be detached from its avascular attachment to the transverse colon to afford access to the lesser sac. Care must be taken to avoid placing excess tension on the greater curvature of the stomach and the short gastric vessels so as not to cause iatrogenic injury to the spleen. The greater and lesser curvatures should be closely inspected because the omental attachments may obscure an underlying gastric wound. Such inspection is particularly important in the setting of a small-caliber missile wound: the perforation can be remarkably small, and the serosal tissue damage in such cases is often subtle.

Treatment of a gastric injury is dictated by its severity [see Figure 2], which is classified according to the grading system developed by the American Association for the Surgery of Trauma (AAST) [see Table 2]. Intramural hematomas (grade I) are managed by means of unroofing and evacuation, followed by seromuscular closure with interrupted sutures. The great majority of gastric perforations are amenable to primary repair (grades II and III). In view of the propensity of the richly vascularized gastric wall to bleed at the site of injury, a two-layer technique is recommended to achieve adequate hemostasis. When the wound involves the pylorus, conversion to pyloroplasty to prevent stenosis is often beneficial. Suture repair of wounds at the cardioesophageal junction is reinforced by gastric fundoplication.

Some extensive wounds are not amenable to primary repair (grades IV and V). Such injuries include significant tissue loss or

gastric devascularization and often are associated with major vascular injury as a consequence of the proximity of the major vessels and the force necessary to cause such a significant injury. Patients with grade IV or V injuries often do not survive long enough to undergo laparotomy, and consequently, these extensive gastric wounds are rarely encountered. Grade IV injuries can usually be managed by means of a partial gastrectomy. Restoration of gastric outflow is accomplished with either a gastroduodenostomy or a gastrojejunostomy; the choice is dictated by the extent of the resection and the presence or absence of an associated duodenal or pancreatic injury. In the exceedingly rare event of complete gastric devascularization or destruction, a total gastrectomy is required; we have yet to encounter such a situation. Occasionally, reconstruction of intestinal continuity after resection should not be performed at the initial operation. Such a damage-control approach is indicated in the presence of the triad of acidosis, hypothermia, and coagulopathy.

In fasting patients, the stomach harbors low numbers of bacteria because of its low pH. In trauma victims, however, who, it seems, often arrive with full stomachs, a more neutral pH and a higher bacterial count can be expected. If a gastric perforation with significant contamination is encountered, secondary or delayed primary skin closure should be performed in view of the increased risk of SSI; this is particularly true when significant hemorrhage or associated injury is present, in which case the rate of intra-abdominal abscess formation may be as high as 24%.¹³

INJURIES TO THE SMALL INTESTINE

Injury to the small intestine is evaluated intraoperatively by “running the bowel”: the small bowel and its mesentery are inspected in a systematic and comprehensive fashion from the ligament of Treitz caudad to the ileocecal valve. As active mesenteric bleeding is encountered, it is controlled by isolation and individual ligation of the bleeding vessels rather than by mass ligation of the mesentery, which may produce ischemia. Likewise, as bowel perforations are found, temporary control measures are rapidly initiated in an effort to prevent excessive or ongoing soiling. Once all bowel injuries are accounted for, the decision must be made

Table 2 AAST Organ Injury Scales for Stomach, Small Intestine, Colon, and Rectum

Injured Structure	AAST Grade*	Characteristics of Injury	AIS-90 Score
Stomach	I	Intramural hematoma < 3 cm; partial-thickness laceration	2
	II	Intramural hematoma ≥ 3 cm; small (< 3 cm) laceration	2
	III	Large (> 3 cm) laceration	3
	IV	Large laceration involving vessels on greater or lesser curvature	3
	V	Extensive (> 50%) rupture; stomach devascularized	4
Small bowel	I	Contusion or hematoma without devascularization; partial-thickness laceration	2
	II	Small (< 50% of circumference) laceration	3
	III	Large (≥ 50% of circumference) laceration without transection	3
	IV	Transection	4
	V	Transection with segmental tissue loss; devascularized segment	4
Colon	I	Contusion or hematoma; partial-thickness laceration	2
	II	Small (< 50% of circumference) laceration	3
	III	Large (≥ 50% of circumference) laceration	3
	IV	Transection	4
	V	Transection with tissue loss; devascularized segment	4
Rectosigmoid and rectum	I	Contusion or hematoma; partial-thickness laceration	2
	II	Small (< 50% of circumference) laceration	3
	III	Large (≥ 50% of circumference) laceration	4
	IV	Full-thickness laceration with perineal extension	5
	V	Devascularized segment	5

*Advance one grade for multiple injuries, up to grade III.

AIS-90—Abbreviated Injury Score, 1990 version AAST—American Association for the Surgery of Trauma

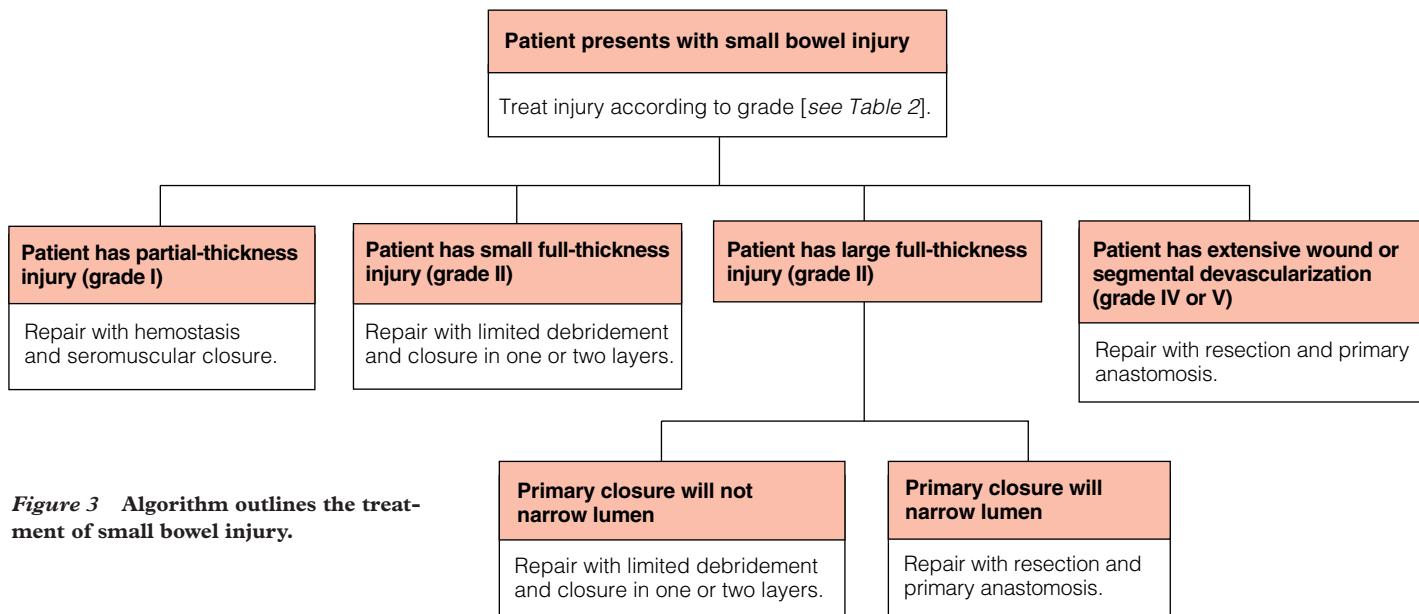

whether to perform primary repair, resection of the injured segment, or some combination of the two. Primary repair of multiple injuries preserves bowel length and is generally preferred. At the discretion of the operating surgeon, resection of a segment containing multiple injuries may be performed to expedite the operation, provided that the amount of bowel to be resected is small enough that its loss would have only a negligible effect on digestive function.

Management of each individual wound is determined by its severity according to the AAST grading system [see *Figure 3* and *Table 2*]. Small partial-thickness injuries (grade I) are managed by reapproximating the seromuscular layers with interrupted sutures. Small full-thickness wounds (grade II) are repaired with limited debridement and closure. Closure is performed in either one or two layers (we prefer a single-layer closure), and transverse closure is preferred to avoid luminal narrowing. Larger full-thickness wounds (grade III) may be repaired primarily if luminal narrowing can be avoided; otherwise, resection and anastomosis should be performed. Extensive wounds and wounds associated with devascularization (grades IV and V) are treated with resection and anastomosis. When mesenteric injury is encountered in the absence of bowel injury, the associated bowel must be closely assessed for evidence of vascular compromise. If the bowel appears viable, the rent in the mesentery should be reapproximated after bleeding is controlled to prevent an internal hernia. If there is evi-

dence of vascular compromise, bowel resection and anastomosis are indicated.

Determination of intestinal viability begins with assessment of the bowel's appearance. Adjunctive measures, such as the use of a handheld Doppler device or fluorescein infusion with Wood lamp illumination, may facilitate assessment of perfusion in segments where viability is questionable. We generally prefer to use a handheld Doppler device because it is easy to use and is available at short notice in the OR. A probe applied directly to the antimesenteric side of the bowel wall effectively detects the presence of arterial flow, which reliably demonstrates viability.

Small bowel anastomoses are usually handsewn in one or two layers, though stapling devices may also be employed [see *5:29 Intestinal Anastomosis*]. The choice of technique depends largely on surgeon preference. One multicenter retrospective study suggested that in the setting of trauma, stapled anastomoses had a higher complication rate than sutured anastomoses did¹⁴: overall, 13% of stapled anastomoses were associated with an intra-abdominal postoperative complication, compared with 5% of sutured anastomoses. Because this study did not separate small intestinal anastomoses from colonic anastomoses, it is unclear to what extent the results apply specifically to small bowel anastomoses. It is likely, however, that bowel edema contributes to staple line failure. If bowel edema is evident or anticipated, it may be prudent to perform a sutured anastomosis.

INJURIES TO THE COLON

In World War II, colostomy was mandatory for penetrating colon trauma because of the significant morbidity associated with anastomotic suture line dehiscence.¹⁵ In the ensuing years, experience with primary repair of penetrating colonic injuries in civilian settings suggested that primary repair could be performed safely and perhaps, in select cases, with less morbidity than colostomy.^{16,17} This suggestion was confirmed in the late 1970s by a randomized, prospective study that demonstrated significantly lower rates of intra-abdominal infection in patients treated with primary repair than in those treated with colostomy.¹⁸ In that early trial, high-risk patients (i.e., those with shock, hemorrhage, associated injuries, delayed presentation, significant peritoneal soiling, destructive wounds of the colon, or loss of abdominal wall integrity) were excluded from randomization and treated with colostomy. Currently, there is less concern for such risk factors, and primary repair is gaining wider acceptance.¹⁹

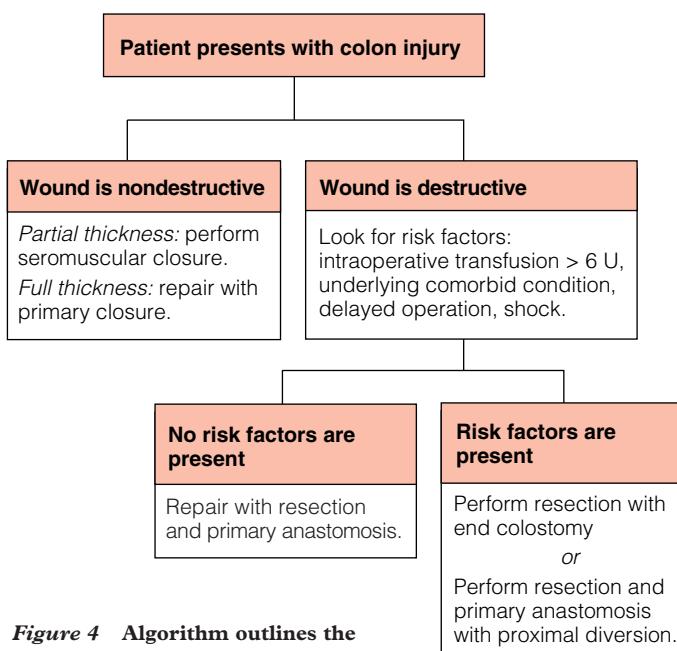

To direct management decisions, it is helpful to categorize penetrating colonic injuries as either nondestructive or destructive [*see Figure 4*].^{20,21} Although blunt colonic injuries are considerably less common, we manage them in a similar fashion.

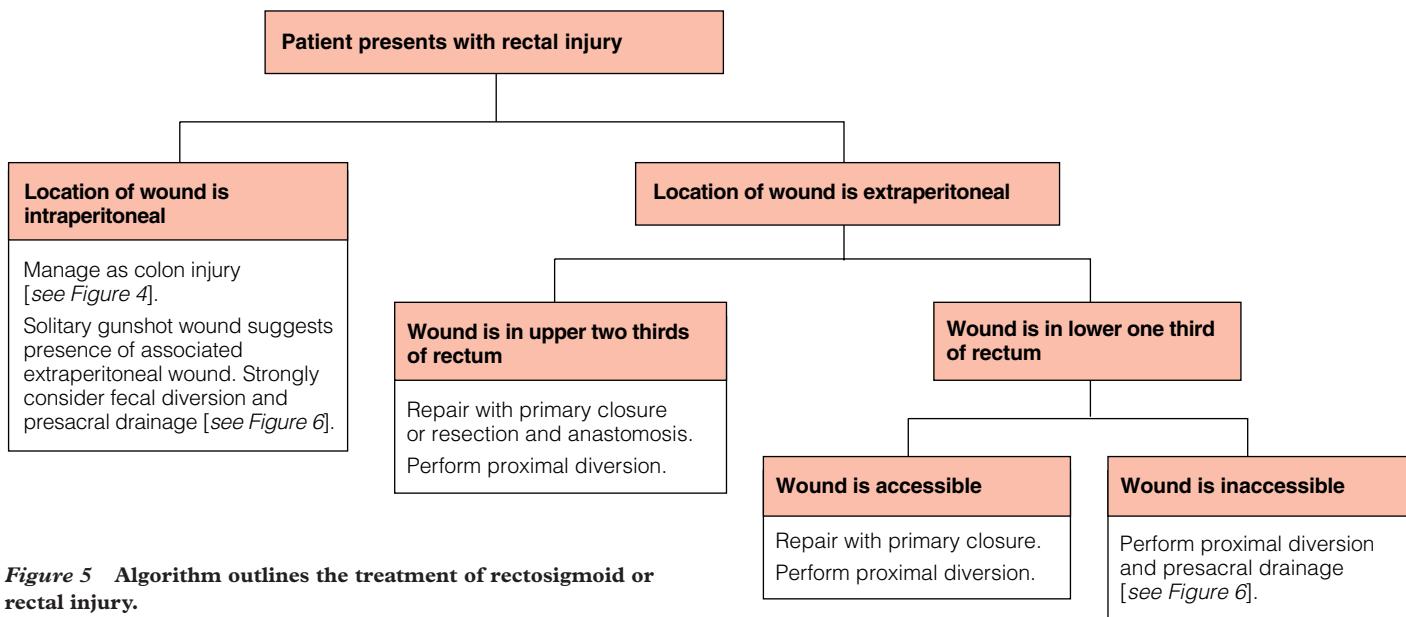

Nondestructive colonic injuries are defined as wounds that involve less than 50% of the bowel wall without devascularization. Such wounds account for approximately 80% of colon wounds and are amenable to primary suture repair with limited amounts of debridement. Sufficient data have been accumulated over the past 30 years to support primary repair as standard treatment for nondestructive colon wounds in the absence of peritonitis, regardless of associated injuries or comorbid conditions. Evaluation of the available prospective and retrospective data indicates that the suture line failure rate for primary repair is approximately 1%, which is less than the rate generally reported for elective colon and rectal surgery. Mortality associated with suture line failure in this setting is uncommon. The favorable morbidity and mortality profiles, along with the inherent benefits of avoiding colostomy, support primary repair as standard therapy for nondestructive wounds. Partial-thickness lacerations (grade I) are repaired with inverting seromuscular sutures. Full-thickness lacerations (grade II) may be closed in one or two layers.

Destructive colonic injuries are defined as wounds that com-

pletely transect the colon (grade IV) or involve tissue loss and devascularized segments (grade V). Optimal management of such wounds is less certain than optimal management of nondestructive wounds. Data from randomized and prospective trials demonstrate that resection and primary anastomosis can be performed safely.²²⁻²⁵ It should be kept in mind, however, that these results are derived from a relatively small number of reported cases. The retrospective data indicate a higher incidence of suture line failure and a significant incidence of associated mortality, suggesting that resection and primary anastomosis may not be the optimal treatment for all colonic wounds.²⁰

A 1994 report from our institution (University of Tennessee) concluded that patients with destructive colonic injuries who had comorbid medical conditions or transfusion requirements greater

than 6 units of blood were at significantly higher risk for suture line breakdown when the wounds were managed with resection and primary anastomosis.²⁶ Other reported risk factors that may direct the surgeon toward fecal diversion include a Penetrating Abdominal Trauma Index (PATI) score greater than 25, shock, and a delayed operation.²⁷ It is our practice to manage these patients as high-risk patients and perform fecal diversion. Diversion may be accomplished by means of either loop colostomy (with an open or closed distal stoma) or end colostomy (with a mucous fistula or closure of the rectal stump) [see 5:30 *Intestinal Stomas*]. The diversion technique is dictated both by surgeon preference and by the nature of the colonic injury. In most civilian clinical practices, destructive wounds account for approximately 20% of all colon wounds encountered. Between 50% and 75% of destructive wounds do not have risk factors that prompt diversion. Thus, the overall diversion rate ranges from 5% to 10%. In our experience over the past several years, 90% to 95% of all colon wounds have been managed with primary repair or resection and anastomosis.

The potential risk of postoperative SSI associated with colonic injury should be considered at the time of initial laparotomy. Retained bullets or other projectiles that have penetrated the colon or rectum may act as nidi for abscess formation and should be removed when it is technically feasible to do so. Approximately 10% of these retained missiles result in soft tissue infection or osteomyelitis.²⁸ Delayed primary or secondary skin closure is recommended.

If colostomy is performed, it will eventually have to be closed in most cases. The mortality associated with colostomy closure is low, but the reported morbidity has varied considerably, ranging from 5% to 25% in single-institution studies.²⁹⁻³¹ We typically perform closure 2 to 3 months after hospital discharge to allow time for the resolution of the dense inflammatory adhesions that may form after laparotomy. Before closure, a contrast enema is obtained to confirm that no distal strictures or fistulas are present. Some surgeons maintain that early closure (within 2 weeks) is as safe as the traditional late closure (3 months), with a shorter operating time and less intraoperative blood loss, and suggest that it may also allow colostomy closure during the patient's initial hospitalization.³² To date, however, this practice has not garnered wide enthusiasm.

Occasionally, blunt abdominal trauma associated with lap-belt

use results in a large deserosalization injury to the cecum and ascending colon or to the sigmoid colon. In such cases, the serosa may be reapproximated with interrupted silk sutures in an accordion-type fashion, provided that the lumen is not significantly compromised by the imbrication of the submucosa. It is likely that subclinical luminal narrowing occurs frequently after such repairs, of which we rarely see sequelae. If significant luminal narrowing is anticipated or the serosal disruption is extensive enough to preclude reapproximation, resection of the injured segment with primary anastomosis is indicated.

INJURIES TO THE RECTUM

Recognition of rectal injuries requires diagnostic vigilance. All patients with a penetrating wound to the pelvis, perineum, buttock, or upper thigh should be evaluated for rectal injury. Digital examination for the presence of rectal blood is mandatory, but the absence of blood does not definitively rule out injury. Rigid proctoscopy should be performed whenever there is any suspicion of rectal injury.

It is our practice to classify rectal injuries according to anatomic criteria, which then dictate management [see Figure 5].³³ The anterior and lateral sidewalls of the upper two thirds of the rectum are serosalized; injuries in this region are classified as intraperitoneal and are managed in the same manner as colonic injuries [see Figure 4]. The upper two thirds of the rectum posteriorly and the lower one third of the rectum circumferentially are not serosalized; injuries in these regions are classified as extraperitoneal.

Extraperitoneal wounds in the upper two thirds are usually amenable to exploration and suture repair. Fecal diversion is also performed as an adjunctive measure and may be accomplished with either loop or end colostomy [see 5:30 *Intestinal Stomas*]. In select cases in which the wound is primarily intraperitoneal with minimal extraperitoneal involvement, diversion may be omitted.

Extraperitoneal wounds to the lower third of the rectum are usually explored and repaired, provided that the wound is easily accessible without risk to the associated neurovascular and genitourinary structures. Fecal diversion is recommended. Wounds that are difficult to reach are not explored and instead are managed with proximal fecal diversion and presacral drainage. Presacral drainage is performed with the patient in the lithotomy position

[see Figure 6]. A curvilinear incision is made in the skin between the coccyx and the anus, and blunt dissection is employed to gain entry into the presacral space. Generally, we place one or two Penrose drains into this space and gradually withdraw them between postoperative days 5 and 7.

Whether presacral drainage is necessary is controversial. There is published prospective evidence to suggest that presacral drainage does not lessen morbidity³⁴; however, this study did not make a distinction between accessible and inaccessible extraperitoneal wounds. Our view is that for inaccessible extraperitoneal wounds, presacral drainage is required to prevent retroperitoneal abscess formation, which results from fecal contamination of a relatively closed space and can produce significant morbidity in the form of retroperitoneal infection that may also track downward into the thighs. Accessible extraperitoneal wounds that are explored and repaired become effectively intraperitonealized; thus, presacral drainage is not required for these injuries.

As emphasized (see above), a tangential gunshot wound is a diagnosis of exclusion. This point is of particular importance when the wound involves the rectum, because mobilization and visualization may be limited by a narrow pelvis, a fat-laden mesorectum,

and, in many cases, a patient who is unstable as a result of associated injuries. Although a solitary proximal rectal gunshot wound may truly be tangential (or the projectile may be intraluminal), an associated distal extraperitoneal wound is often present. After primary repair of the proximal wound, fecal diversion and presacral drainage should be performed, as with inaccessible extraperitoneal rectal injuries.

Distal rectal washout was initially advocated on the basis of experience gained during the Vietnam War.³⁵ In the majority of civilian studies since then, however, distal rectal washout has had no significant effect on morbidity.^{33,36-38} It may be useful in cases of severe wound contamination or fecal impaction, but in general, it does not seem to be an important adjunct to the management of rectal injuries. Typically, distal rectal washout involves lavage of the rectum distal to the injury with 3 to 6 L of irrigant via an irrigation tube placed into the distal limb of a loop colostomy. The irrigant may be normal saline, a genitourinary irrigant, or an antiseptic solution. Digital rectal dilatation is performed to facilitate drainage of the irrigant. Care should be taken to protect the midline wound with a polyethylene or similar barrier to reduce the risk of wound contamination during the washout.

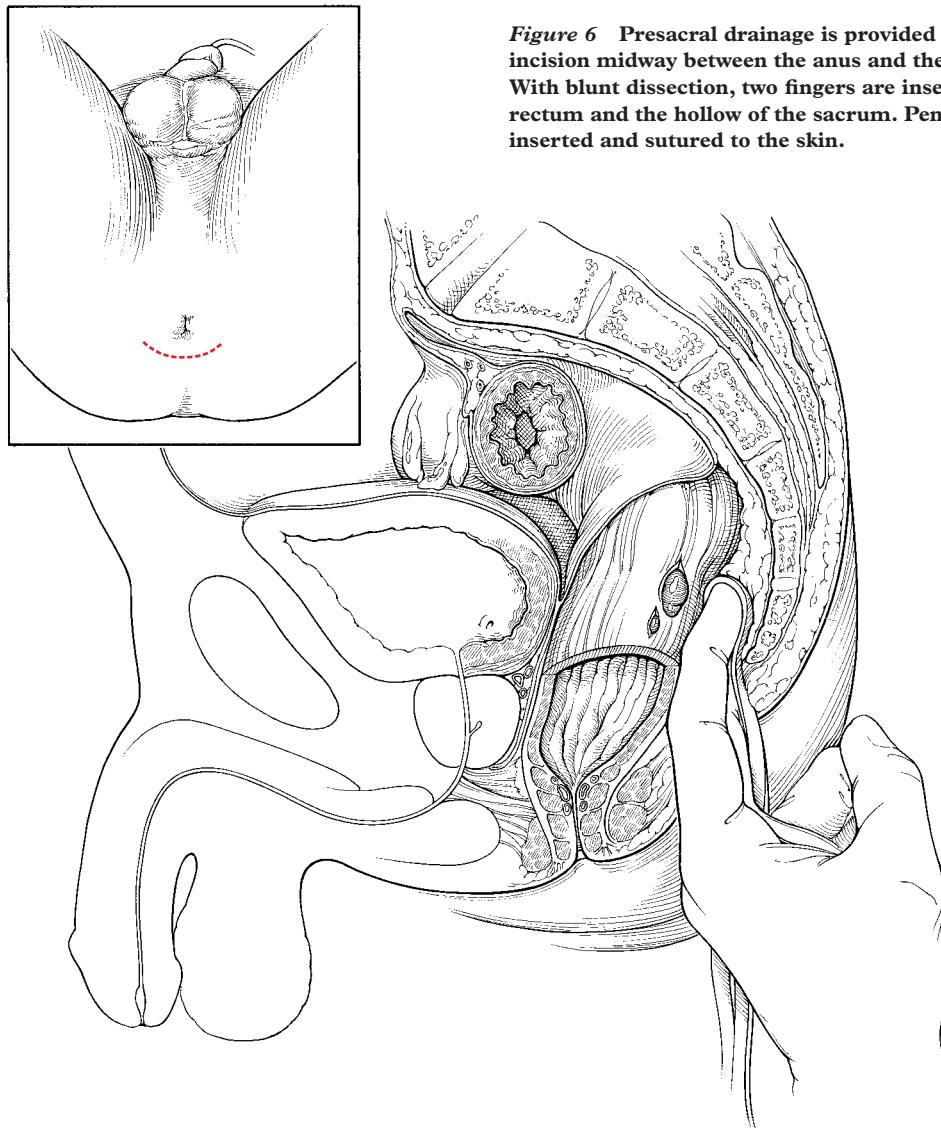

Figure 6 Presacral drainage is provided through a curved incision midway between the anus and the tip of the coccyx. With blunt dissection, two fingers are inserted between the rectum and the hollow of the sacrum. Penrose drains are inserted and sutured to the skin.

8 INJURIES TO THE PANCREAS AND DUODENUM

Gregory J. Jurkovich, M.D., F.A.C.S.

Pancreatic and duodenal injuries continue to challenge trauma surgeons. The relative rarity of these unforgiving injuries, the difficulty of diagnosing them in a timely manner, and the high morbidity and mortality associated with them justify the anxiety they evoke. Because of the deep, central, and retroperitoneal location of the pancreas and much of the duodenum, trauma to these organs is infrequent; however, this relatively protected anatomic location also is the reason for the diagnostic difficulty and contributes to the high morbidity and mortality. Mortality for pancreatic trauma ranges from 9% to 34%. Duodenal injuries are similarly lethal, with mortality ranging from 6% to 25%. Complications after duodenal or pancreatic injuries are alarmingly frequent, occurring in 30% to 60% of patients.^{1,2} If these injuries are recognized early, treatment is straightforward, and morbidity and mortality are low; if they are recognized late, they typically follow a protracted, difficult clinical course, often ending in a devastating outcome.

Injuries to the Pancreas

DIAGNOSIS

The two most important determinants of outcome after pancreatic injury are (1) the status of the main pancreatic duct and (2) the time interval between initial trauma and definitive management of a duct injury. These determinants were probably first recognized and emphasized in 1962 by Baker and associates.³ Two subsequent reviews of pancreatic trauma cases at the University of Louisville confirmed the importance of determining pancreatic duct status. The first found that resection of distal duct injuries, as opposed to drainage alone, significantly lowered postoperative morbidity and mortality.⁴ The second confirmed this observation by noting that pancreatic resection distal to the site of duct injury caused mortality at the University to decrease from 19% to 3%.⁵ Experience at my institution (University of Washington School of Medicine) supported this finding, in that accurate determination of the status of the pancreatic duct with intraoperative pancreatography was found to reduce the complication rate from 55% to 15%.⁶

Unfortunately, the cross-sectional body-imaging techniques currently employed in multiply injured patients (e.g., abdominal computed tomography) are not sensitive enough for accurate assessment of duct status, and operation for direct inspection carries its own morbidity. Thus, the main challenge in addressing potential pancreatic trauma is to make an early determination of whether or not a pancreatic duct injury has occurred.

Which diagnostic techniques are most useful in a patient with a possible pancreatic injury depends on the mechanism of injury, the presence or absence of other indications for early laparotomy, and the time that has elapsed since the initial abdominal insult occurred. If the patient has a clear indication for laparotomy, there is little or no need for preoperative evaluation directed at identifying a possible pancreatic injury, because the diagnosis of such injury must be made intraoperatively. If, however, the patient does

not require immediate laparotomy for hemorrhage or bowel perforation, establishing the presence of pancreatic injury is a considerable challenge, made more difficult by the knowledge that a missed pancreatic duct injury has dire consequences for the patient.⁷⁻¹⁰

There are isolated reports of patients with complete duct transection who remain asymptomatic for weeks, months, or even years after the initial injury.^{5,7,8,11} More commonly, however, patients with pancreatic duct injuries that were initially missed manifest an abdominal crisis within a few days after the injury.¹²⁻¹⁴ The reasons why physical signs and symptoms may not develop promptly are related to the retroperitoneal location of the pancreas, the inactivity of pancreatic enzymes after an isolated injury, and the decreased secretion of pancreatic fluid after trauma. Early identification of a subtle pancreatic injury therefore depends on a high index of suspicion, a carefully planned approach, and close observation.

A high index of suspicion is warranted in any patient who has sustained a direct high-energy blow to the epigastrium—for example, from a crushed steering wheel (in an adult) or a bicycle or tricycle handlebar (in a child).^{15,16} The energy of impact causes the retroperitoneal structures to be crushed against the spine, and the pancreas is typically transected at this point. The presence of soft tissue contusion in the upper abdomen or disruption of the lower ribs or costal cartilages should suggest possible pancreatic injury. Epigastric pain that is out of proportion to the abdominal examination findings is often another clue to a retroperitoneal injury.

Although the highest concentration of amylase in the human body is in the pancreas, hyperamylasemia is not a reliable indicator of pancreatic trauma. In one series, only 8% of hyperamylasemic patients with blunt abdominal trauma had pancreatic duct injuries.¹⁷ As many as 40% of patients with pancreatic injuries may initially have normal serum amylase levels.^{18,19} In addition, there is evidence that isolated brain injury can cause elevated amylase²⁰ or lipase levels²¹ through a central mechanism that remains to be clarified. Nonetheless, the presence of hyperamylasemia should raise the index of suspicion for pancreatic injury. The time between pancreatic duct injury and serum amylase determination may be critical. In a report of 73 patients with documented blunt injury to the pancreas, serum amylase levels were elevated in 61 patients (84%) and normal in 12 (16%).²² Patients with elevated serum amylase levels were assayed 7 ± 1.5 hours after injury, whereas those with normal levels were assayed 1.3 ± 0.2 hours after injury. The investigators concluded that determination of serum amylase levels within 3 hours after injury did not yield diagnostic results.

Review of the available data suggests that the sensitivity of serum amylase level determination in detecting blunt pancreatic trauma ranges from 48% to 85% and that the specificity ranges from 0% to 81%.¹ The negative predictive value of the serum amylase level after blunt trauma is about 95%.^{18,19,23} The sensitivity and the positive predictive value may be increased if the serum amylase level is obtained more than 3 hours after injury. The conclusion to be drawn is that 95% of blunt abdominal trauma patients with normal amylase levels will not have a pancreatic injury.

An elevated amylase level in serum or peritoneal lavage effluent does not necessarily confirm the presence of a pancreatic injury, but it does mandate further evaluation.

Blunt abdominal trauma patients with hyperamylasemia in whom the results of abdominal examination are reliable and benign are carefully observed, and the amylase level is measured again after several hours. Persistent elevation of serum amylase levels or the development of abdominal symptoms is an indication for further evaluation, which may include abdominal CT, endoscopic retrograde cholangiopancreatography (ERCP), or surgical exploration. If the abdominal examination initially yields equivocal or unreliable results in a hemodynamically stable patient with hyperamylasemia, a dual-contrast (i.e., intravenous and oral) abdominal CT scan should be done as part of the initial evaluation. If abdominal symptoms subsequently develop or the amylase level does not return to normal, directed evaluation of the pancreas by means of repeat abdominal CT, ERCP, or surgical exploration is warranted.

Overall, abdominal CT is reported to be 70% to 80% sensitive and specific for diagnosing pancreatic injury, though its accuracy is largely dependent on the experience of the interpreter, the quality of the scanner, and the time elapsed since injury.^{24–26} Characteristic CT findings associated with pancreatic injury include direct visualization of a parenchymal fracture, an intrapancreatic hematoma, fluid in the lesser sac, fluid separating the splenic vein and the pancreatic body, a thickened left anterior renal fascia, and a retroperitoneal hematoma or fluid collection. These findings often are subtle and rarely are all present in one patient.²⁷ If the patient is examined immediately after injury, some of the CT signs of pancreatic injury may not yet be apparent, which may be part of the explanation for the false negative CT scans reported in as many as 40% of patients with significant pancreatic injuries.²⁸ This possibility is not sufficient grounds for delaying CT evaluation, but it is an argument for repeating CT if symptoms persist.

ERCP has no role in the acute evaluation of hemodynamically unstable patients, but numerous reports over the past decade have indicated that it can be useful in the diagnosis and management of pancreatic trauma. Currently, ERCP is the best available modality for imaging the pancreatic duct and its divisions, but it usually involves anesthesia, and it is not readily or widely available. For the most part, ERCP has been used in the setting of a late or missed diagnosis of pancreatic duct injury, occasionally with transductal stenting to manage the injury, particularly in children.^{29–33} Appropriate application of ERCP is an evolving issue that will continue to foster investigations, but any application will continue to be based on the principle of timely diagnosis, recognition, and management of pancreatic duct injury.^{4,34} If ERCP is done early and shows intact pancreatic ducts (including the secondary and tertiary radicles) without any extravasation, nonoperative therapy is permissible if no associated injuries are present.³⁵ The difficulties in this management scheme are determining which patients should undergo ERCP and getting the ERCP accomplished promptly.^{36,37}

Magnetic resonance imaging has emerged as a potentially valuable technique for evaluation of the pancreatic duct.^{38,39} Although to date, magnetic resonance pancreatography (MRP) has primarily been employed in elective settings, it has also been employed as a noninvasive alternative method of determining the status of the main pancreatic duct in patients with pancreatic injuries. Early reports suggest that MRP is unreliable early after injury but is useful for delayed diagnosis and management.¹⁰ Further study of its sensitivity and specificity in this setting appears warranted.

Intraoperative Evaluation

Careful inspection of the pancreas and classification of injuries [see Management, Classification of Pancreatic Injuries, below] are often complicated by the extent and severity of associated injuries and occasionally hindered by the reluctance of the surgeon to mobilize retroperitoneal structures. Clues suggesting pancreatic injury include the injury mechanisms described (see above), the presence of an upper abdominal wall contusion or abrasion, and concomitant lower thoracic spine fractures. The presence of an upper abdominal central retroperitoneal hematoma, edema around the pancreatic gland and the lesser sac, and retroperitoneal bile staining mandate thorough pancreatic inspection.

Inspection of the pancreas requires complete exposure of the gland. First, the lesser sac is opened through the gastrocolic ligament just outside the gastroepiploic vessels. This exposure is carried far to the patient's left, fully opening the lesser sac and freeing the transverse colon. The transverse colon is then retracted downward and the stomach upward and anteriorly [see Figure 1]. Frequently, there are a few adhesions between the posterior stomach and the anterior surface of the pancreas that must be incised. Next, a complete Kocher maneuver is performed to provide adequate visualization of the pancreatic head and the uncinate process. In addition, mobilization of the hepatic flexure of the colon (a frequently overlooked maneuver) greatly facilitates visualization and bimanual examination of the head and neck of the pancreas. Inspection of the pancreatic tail requires exposure of the splenic hilum. If the injury involves the tail, the peritoneal attachments lateral to the spleen and colon are divided, and the colon, the spleen, and the body and tail of the pancreas are then mobilized forward and medially by creating a plane between the kidney and the pancreas with blunt finger dissection. This maneuver permits bimanual palpation of the pancreas and inspection of its posterior surface.

Injuries to the major pancreatic duct occur in perhaps 15% to 20% of cases of pancreatic trauma. At my institution, of 193 patients with pancreatic injuries managed over a period of 15 years, only 27 (14%) had grade III injuries, and 10 (5%) had grade IV or V injuries.² Studies from the 1970s and 1980s observed that penetrating trauma was more likely to cause pancreatic duct injury than blunt trauma was,^{40,41} but subsequent reviews did not confirm these observations.^{2,42}

The majority of pancreatic duct injuries, regardless of mechanism, can be diagnosed through careful inspection of the injury tract after adequate exposure. All penetrating wounds should be traced from the entry point through the surrounding tissue to the exit point or the end of the tract. If the pancreas was damaged by a knife or a bullet, it is necessary to determine the integrity of the major pancreatic duct. With most penetrating wounds to the margins of the gland, the pancreas can be inspected directly and duct integrity confirmed. With penetrating wounds to the head, neck, or central portion of the pancreas, however, further evaluation is often required. Occasionally, intravenous injection of 1 to 2 µg of cholecystokinin pancreozymin (CCK-PZ) may stimulate pancreatic secretions enough to allow an otherwise unrecognized major pancreatic duct injury to be identified. The remaining few injuries may necessitate the use of more elaborate investigative techniques, including intraoperative pancreatography (see below).

Minor blunt contusions or lacerations of the pancreatic substance usually do not necessitate further evaluation of the pancreatic duct and can be effectively managed with closed suction drainage. The presence of an intact pancreatic capsule, however, does not necessarily rule out complete division of the pancreatic

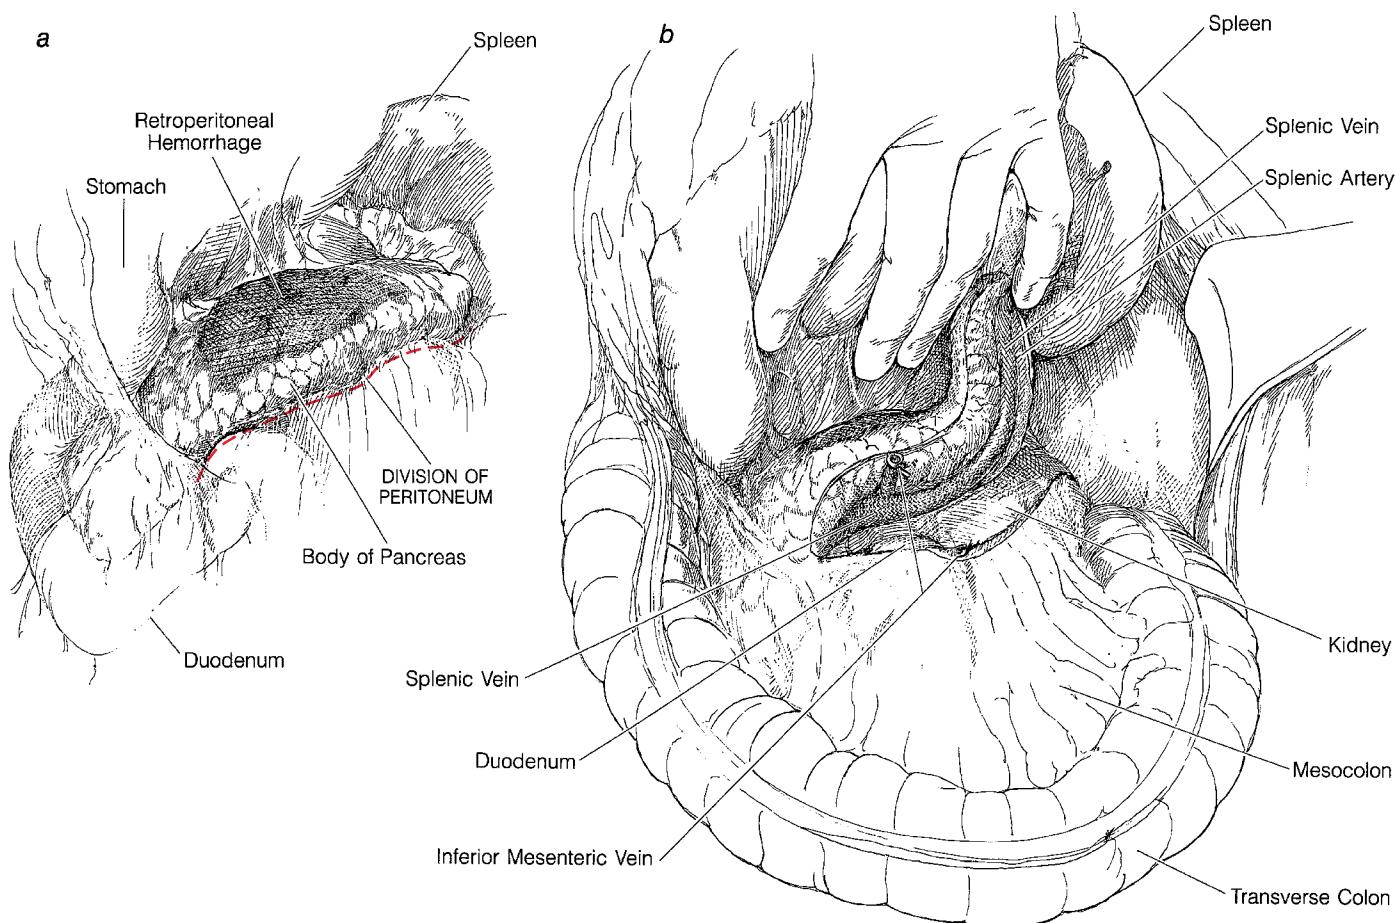

Figure 1 Illustrated is the appearance of a contusion to the body of the pancreas overlying the vertebral column, as seen from the lesser sac (a). The pancreas is mobilized to determine whether a fracture is present and to assess the likelihood of a duct injury. This exposure is best accomplished by dissecting along the inferior border of the gland, dividing the inferior mesenteric vein if necessary, and reflecting the pancreas superiorly (b).

duct, and on rare occasions, a blunt impact on the pancreas can result in transection of the major duct without complete transection of the gland.⁵ Under these circumstances, establishing the status of the major duct system is an essential step in determining therapy and in anticipating late morbidity and mortality. In one study, routine performance of intraoperative pancreategraphy when proximal pancreatic duct injury was suspected reduced postoperative morbidity from 55% to 15%.⁶

Intraoperative imaging of the pancreatic duct can be performed with ERCP, direct open ampillary cannulation, or needle cholangiopancreatography. Intraoperative ERCP is cumbersome and often difficult to coordinate during an emergency operation, but it has been used in this setting.⁴³ Duodenotomy and direct ampillary cannulation—or even transection of the tail of the pancreas and distal duct cannulation—have been employed in the past, but as a consequence of advances in perioperative imaging, improvements in exposure and direct visualization of the pancreas, and effective use of wide closed suction drainage and postoperative ERCP, these very invasive diagnostic methods of imaging the pancreatic duct have largely been abandoned.⁴⁴ Needle cholangiopancreatography remains a useful intraoperative adjunct in the evaluation of the pancreatic duct. This technique involves cannulating the gallbladder with an 18-gauge angiocatheter and injecting 30 to 75 ml of three-quarter-strength water-

soluble contrast material under fluoroscopic guidance. It typically yields clear images of the biliary tree, and in one study, it successfully visualized the pancreatic duct in 64% of the patients (7/11).² Contracture of the sphincter of Oddi from I.V. morphine administration may enhance the likelihood of pancreatic duct visualization. A cholecystectomy is not necessary after this procedure.

MANAGEMENT

Classification of Pancreatic Injuries

Classification of pancreatic injuries is based on the status of the pancreatic duct and the site of injury relative to the neck of the pancreas. Several different classification systems have been devised to catalogue pancreatic injuries.^{39,44,45} At present, the most widely used system is the one devised by the American Association for the Surgery of Trauma (AAST) [see Table 1], which addresses the key issues of parenchymal disruption and major pancreatic duct status by focusing on the anatomic location of the injury for the more severe (grade III to V) injuries.⁴⁶

The management alternatives for proximal pancreatic duct injuries differ from those for distal duct and parenchymal injuries [see Figure 2]. For parenchymal contusions or lacerations with minimal or no parenchymal tissue loss and no duct injury (grade I or II), the only treatment required is external drainage. For combined

Table 1 AAST Organ Injury Scales for Pancreas and Duodenum

Injured Structure	AAST Grade*	Characteristics of Injury	AIS-90 Score
Pancreas	I	Small hematoma without duct injury; superficial laceration without duct injury	2
	II	Large hematoma without duct injury or tissue loss; major laceration without duct injury or tissue loss	2; 3
	III	Distal transection or parenchymal laceration with duct injury	3
	IV	Proximal [†] transection or parenchymal laceration involving ampulla	4
	V	Massive disruption of pancreatic head	5
Duodenum	I	Single-segment hematoma; partial-thickness laceration without perforation	2; 3
	II	Multiple-segment hematoma; small (< 50% of circumference) laceration	2; 4
	III	Large laceration (50%–75% of circumference of segment D2 or 50%–100% of circumference of segment D1, D3, or D4)	4
	IV	Very large (75%–100%) laceration of segment D2; rupture of ampulla or distal CBD	5
	V	Massive duodenopancreatic injury; devascularization of duodenum	5

*Advance one grade for multiple injuries, up to grade III.

[†]Proximal pancreas is to the patient's right of the superior mesenteric vein.

AAST—American Association for the Surgery of Trauma AIS-90—Abbreviated Injury Score, 1990 version CBD—common bile duct

duodenal and pancreatic head injuries that include the major duct or the ampulla, the required treatment is a combined pancreatico-duodenectomy (Whipple procedure). The difficult decisions in managing pancreatic trauma involve patients with parenchymal disruption and major duct injury. By focusing on the anatomic location of duct and parenchymal injury (proximal versus distal), the AAST classification provides a useful management guide.

Grades I and II: Contusions and Lacerations without Duct Injury

Minor pancreatic contusions, hematomas, and capsular lacerations (grade I) account for about 50% of all pancreatic injuries; lacerations of the pancreatic parenchyma without major duct disruption or tissue loss (grade II) account for an additional 25%. These injuries are treated with hemostasis and adequate external drainage.⁴⁷ No attempt should be made to repair capsular lacerations, because closure may result in a pancreatic pseudocyst, whereas a controlled pancreatic fistula is usually self-limiting. Soft closed suction drains (Jackson–Pratt) are preferred to Penrose drains or sump drains because intra-abdominal abscess formation is less likely, effluent is more reliably collected, and the skin excoriation at the exit site is significantly less with closed suction drains.^{15,48,49} Drains are removed when the amylase concentrations in the drains are lower than the serum concentration, which generally occurs within 24 to 48 hours. An international consensus group has defined pancreatic fistula as the persistence of any measurable volume of drain output on or after postoperative day 3 with an amylase content higher than three times the serum amylase content.⁵⁰ This group has also defined three grades of pancreatic fistula complications [see Complications, below]. Drains are generally left in situ until there is no evidence of pancreatic leakage.

Nutrition should be provided via the oral or gastric route as soon as possible. In patients with severe pancreatic injuries, however, prolonged gastric ileus or pancreatic complications may preclude standard gastric feeding. Because most tube-feeding formulas are high in fat and increase pancreatic effluent volume and amylase concentration, elemental diets, which have a lower fat content and a higher pH and tend to be less stimulating to the pancreas, are preferred.^{51,52}

Creation of a needle-catheter jejunostomy or a small-feeding-tube jejunostomy at the time of the initial celiotomy should be considered for all patients with grade III to V pancreatic injuries. This measure allows early postoperative enteral nutrition and avoids committing patients who cannot tolerate oral or gastric feedings to total parenteral nutrition (TPN). Surgically placed feeding tubes are, however, associated with some degree of morbidity. In a study from my institution, feeding jejunostomies had a major complication rate of 4% in severely injured patients.⁵³ Needle-catheter jejunostomies were associated with fewer complications than Witzel-tube jejunostomies—hence my preference for the smaller-caliber feeding tube.

Grade III: Distal Transection or Distal Parenchymal Injury with Duct Disruption

The anatomic distinction between the proximal and the distal pancreas is generally defined by the superior mesenteric vessels passing behind the pancreas at the junction of the pancreatic head and body. In the gland itself, there is no true anatomic distinction between the head, the body, and the tail, but dividing the organ into these three parts is useful for estimating residual pancreatic endocrine and exocrine function. A 1994 study found that a distal pancreatic resection at the portal vein removed an average of 56% of the gland by weight (range, 36% to 69%).⁵⁴ Because most blunt-trauma pancreatic injuries occur at the spine, which is just to the patient's left of the portal vein as it crosses behind the pancreas, a distal pancreatectomy in this circumstance involves resecting, on average, 56% of the gland. A resection at the common bile duct (CBD), on the other hand, removes an average of 89% of the gland (range, 64% to 95%). Although there have been reports of normal endocrine and exocrine function after a 90% pancreatectomy, every possible effort should be made to leave at least 20% of the pancreatic tissue in situ to minimize postoperative complications.^{55,56}

Distal parenchymal transection, particularly if it involves disruption of the main pancreatic duct, is best treated by means of distal pancreatectomy [see Figure 3]. If there is any concern regarding the status of the remaining proximal main pancreatic duct, intraoperative pancreatography should be performed through the open end of the proximal duct. If the remaining proximal duct is

normal, the transected duct should be identified and closed with a direct U stitch ligature using nonabsorbable monofilament suture material.⁵⁷ The parenchyma may be closed with a large (4.8 mm) TA-55 stapler^{57,58}; however, I find that this crushes the residual pancreas excessively, and I prefer to place mattress sutures through the full thickness of the pancreatic gland from the anterior to the posterior capsule to minimize leakage from the transected parenchyma. Although most surgeons prefer nonabsorbable suture material for pancreatic stump closure, one report found that complication rates were lower when absorbable polyglycolic acid sutures were employed.³⁴ A small omental patch may be used to buttress the surface, and a drain should be left near the transection line.

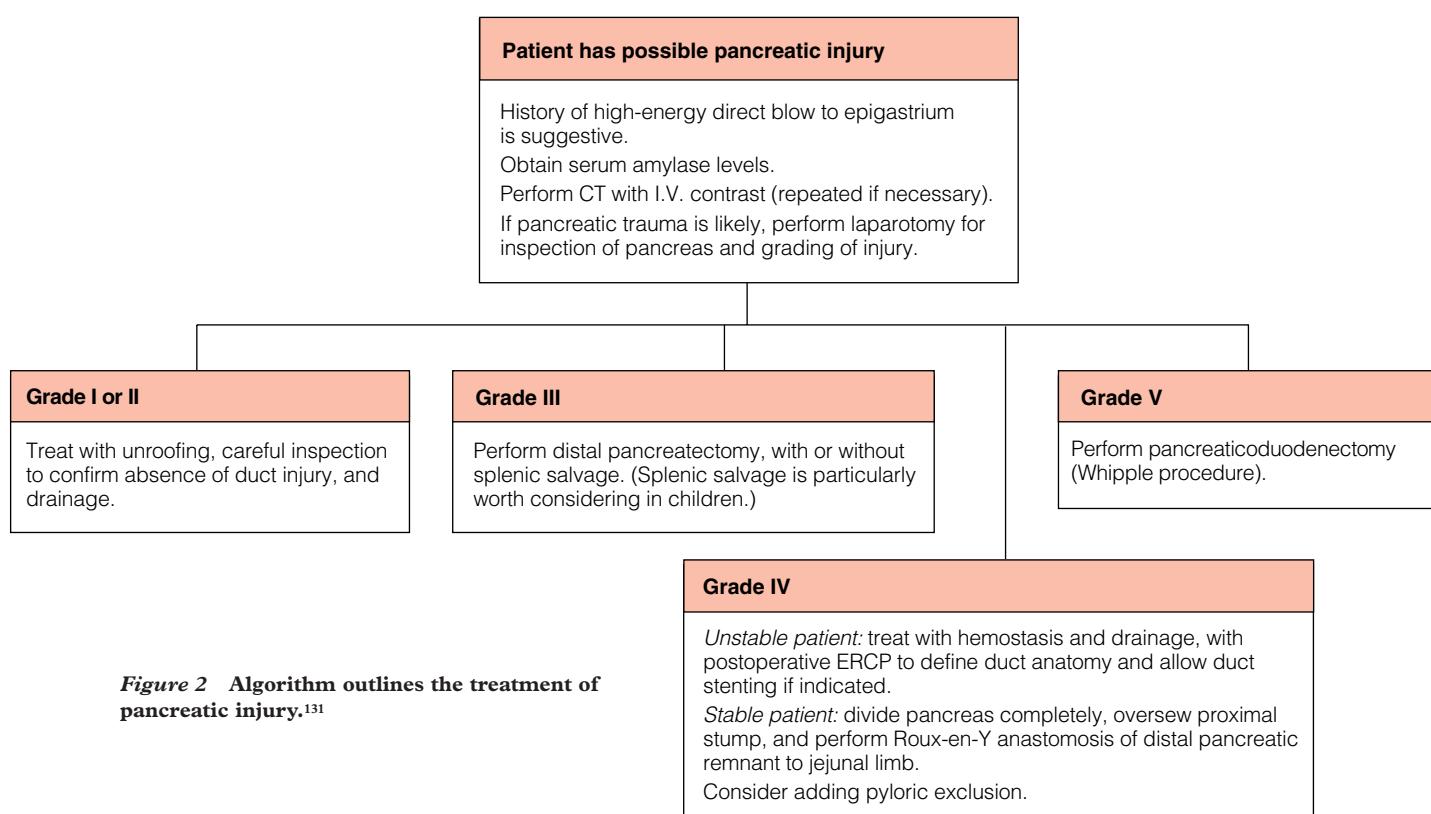

Concerns about the possibility of overwhelming postsplenectomy infection (OPSI) and subphrenic abscess formation after splenectomy have prompted several authors to consider distal pancreatectomy without splenectomy. The technical challenge in pancreatectomy with splenic salvage is how to isolate the pancreatic branch vessels off the splenic vein and artery and ligate them without causing injury to the splenic hilum and thrombosis of the splenic vein. Generous mobilization of the entire pancreatic gland and the spleen is a prerequisite. On average, there are 22 tributaries of the splenic vein and seven branches of the splenic artery that must be ligated.⁵⁹ One report suggested that this maneuver would increase operating time by an average of 50 minutes (range, 37 to 80 minutes).⁶⁰ Another reported splenic salvage in 21 (64%) of the 33 patients who underwent distal pancreatic resection.¹³ The increased operating time and the potential blood loss associated with pancreatectomy without splenectomy must be balanced against the slight risk of OPSI. In my view, the balance favors splenic salvage only when the patient is hemodynamically stable and normothermic and when the pancreatic injury is isolated or occurs with only minor associated injuries.

Grade IV: Proximal Transection or Parenchymal Injury with Probable Duct Disruption

Injuries to the pancreatic head represent the most challenging management dilemmas. The key steps in immediate management, in order of importance, are (1) to control bleeding, (2) to halt contamination, and (3) to define the anatomy of the injury. Only when these steps have been carried out is effective management possible.

In particular, it is essential that the surgeon define the anatomy of the pancreatic duct in patients who have sustained proximal pancreatic injuries. This can usually be accomplished through local inspection and exploration of the defect to determine the status of the duct.⁶¹ If local exploration fails to determine the status of the main pancreatic duct, intraoperative pancreatography (see above) is strongly recommended. The only exception to this approach involves hemodynamically unstable patients with hypothermia, acidosis, and coagulopathy, for whom simple damage-control surgery is advised.

Some experienced surgeons have expressed reservations about making a duodenotomy to perform pancreatography. In many cases (64%, according to experience at my institution), needle cholangiopancreatography can image the pancreatic duct along with the distal CBD.² If this technique proves unsuccessful, the best approach consists of wide external drainage with several closed suction drains in conjunction with planned early postoperative ERCP or MRP. If postoperative ERCP confirms the presence of major proximal pancreatic duct injury, pancreatic duct stenting may be considered as an alternative to near-total pancreatectomy. A growing body of experience suggests that pancreatic duct stenting is a promising approach^{30,32,33}; however, at least one report has found it to yield discouraging results, citing long-term stricture development and acute sepsis as particular problems.¹⁰

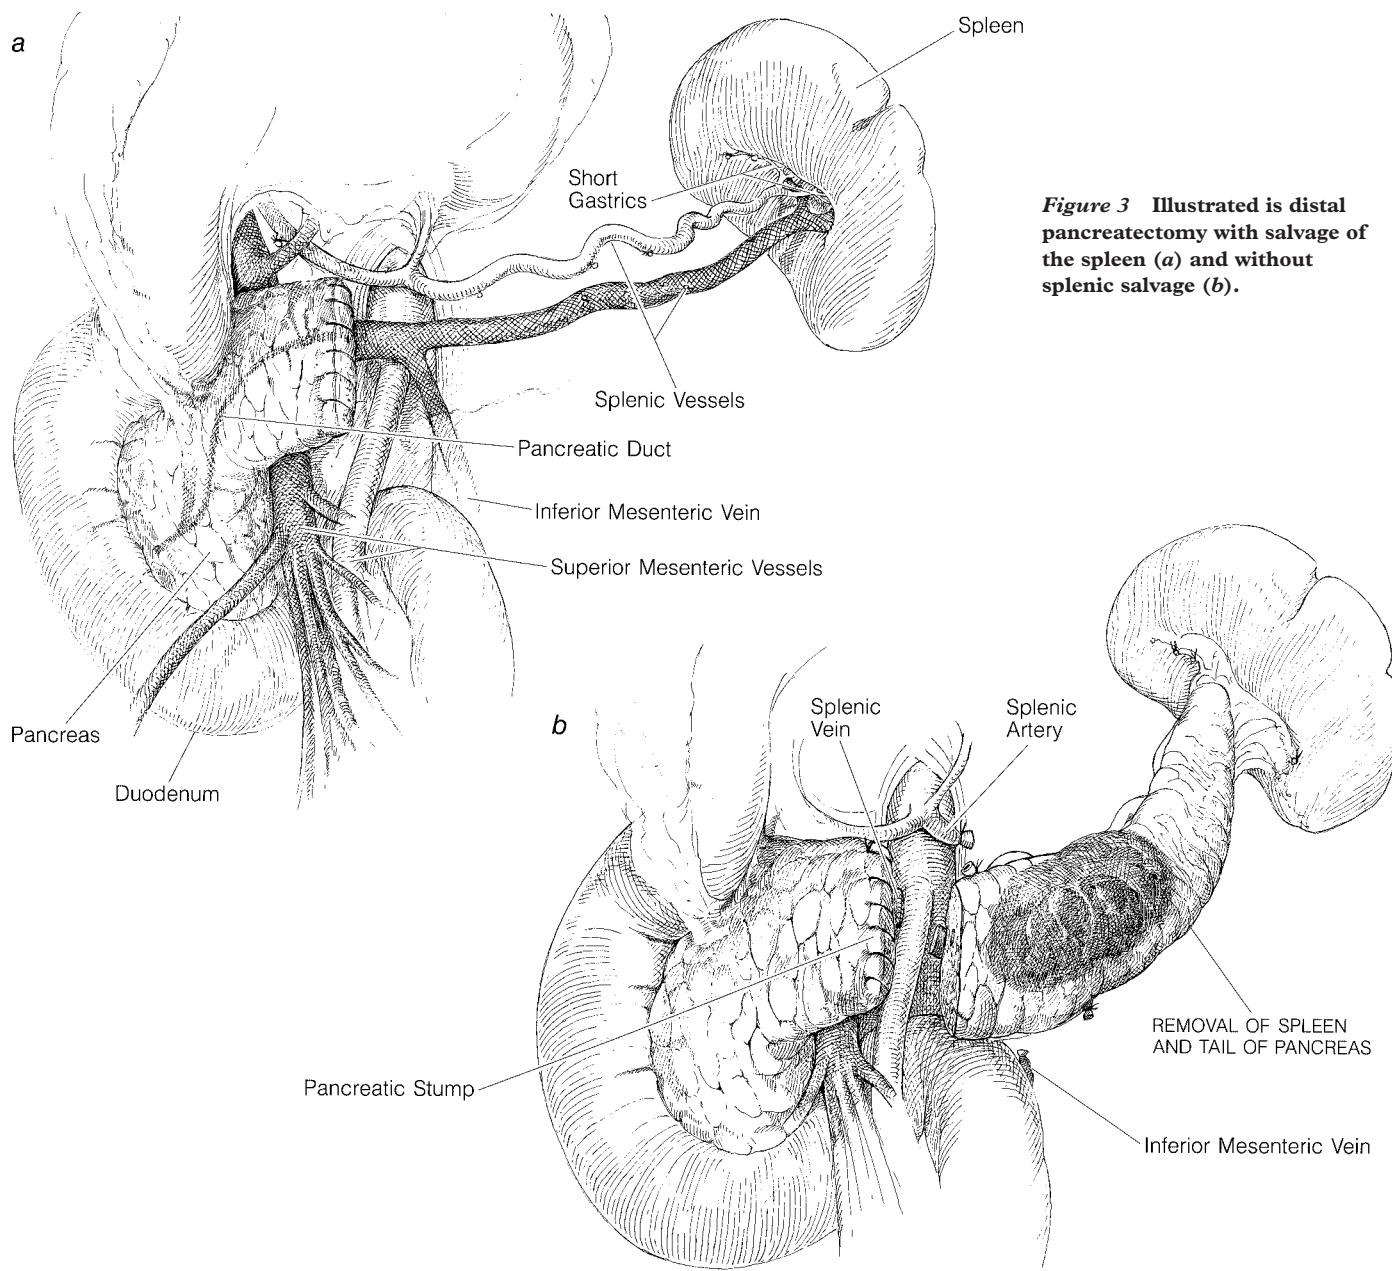

Figure 3 Illustrated is distal pancreatectomy with salvage of the spleen (a) and without splenic salvage (b).

If the proximal pancreatic duct is injured but the ampulla and the duodenum are spared (a rare scenario), two options are available. The first option is extended distal pancreatectomy, resulting in subtotal removal of the gland. The proximal residual gland should drain into the duodenum in a normal fashion if the duct is intact. Wide external drainage of the residual pancreatic duct surface must be provided. I do not add pyloric exclusion or duodenal defunctionalization or diverticularization [see Combined Pancreatico-Duodenal Injuries, below] to this procedure, though others advocate the use of such techniques in this circumstance.^{51,61} If it appears that the residual proximal pancreatic tissue may be inadequate to provide endocrine or exocrine function, the second option may be applied, which is to preserve the pancreatic tail distal to the injury by performing a Roux-en-Y pancreaticojejunostomy [see Figure 4]. This technique involves division of the pancreas at the site of injury, debridement of injured parenchyma, secure closure of the proximal duct and the parenchyma, and anastomosis of the open end of the divided distal pancreas to the Roux-en-Y jejunal limb.

A review of 399 patients with pancreatic injuries from four separate published reports revealed that only two (0.5%) patients underwent Roux-en-Y drainage of the distal segment of a transected pancreatic gland.^{13,34,62,63} A report from the University of Tennessee at Memphis is compelling for its findings regarding the effectiveness of drainage alone, without extended pancreatectomy, particularly for proximal pancreatic gland injuries in which the duct status is unclear.¹³ A total of 37 patients with proximal pancreatic duct injuries were managed with closed suction drainage alone, and the fistula and abscess rate was a modest 13.5%. Because pancreatography was not performed in these patients, the status of the pancreatic duct was not defined. Thus, it remains unclear whether this technique is truly effective in the presence of a major pancreatic duct injury.

In cases of incomplete pancreatic parenchymal transection, some surgeons have employed an end-to-side jejunopancreatic anastomosis. This technique is not recommended, because of the difficulty of ensuring the integrity of the anastomosis and because

of the potential for a high-output pancreatic fistula resulting from the posterior pancreatic wound. A report from Emory University illustrated the high complication rate associated with this dated technique: of the seven patients in whom the technique was used (out of a total of 283 patients), five (71%) had fistulas and three (43%) died.⁴⁹

Again, provisions should be made for early enteral nutritional support in all patients with major pancreatic duct injuries. A measure of foresight in placing a jejunal feeding tube at the time of the initial celiotomy will be amply rewarded by the institution of a simplified and advantageous enteral nutrition regimen.⁶⁴ Elemental or short-chain polypeptide feeding formulas are particularly useful in this situation. These formulas may be delivered via a needle-catheter jejunostomy, which is the approach I prefer.^{52,53}

Combined Pancreatic-Duodenal Injuries

Severe combined injuries to the pancreatic head and the duodenum are, fortunately, rare. In one study, only 48 (3%) of 1,404 patients with pancreatic duct injuries reported between 1981 and 1990 underwent pancreaticoduodenectomy.⁶⁵ These combined injuries are most commonly caused by penetrating trauma and occur in association with multiple other intra-abdominal injuries. In fact, the associated injuries are the primary cause of mortality, a fact that again underscores the importance of hemorrhage control and contamination control in dealing with pancreatic or duo-

denal injury. Most of the immediate mortality in patients with combined pancreatic and duodenal injuries is attributable to major vascular injury in the vicinity of the head of the pancreas. Provided that immediate control of hemorrhage and adequate resuscitation can be achieved, the Whipple procedure [see 5:24 *Pancreatic Procedures*] remains the preferred option in the select group of patients who have unreconstructable injuries to the ampulla or the proximal pancreatic duct or who have massive destruction of both the duodenum and the pancreatic head. In these patients, pancreaticoduodenectomy is essentially the completion of surgical debridement of devitalized tissue. For patients with hemodynamic instability, hypothermia, coagulopathy, and acidosis, a staged operative approach (i.e., damage-control surgery) is advocated. First, hemorrhage is controlled; next, bowel and bacterial contamination are managed; and finally, the anatomy of the injury is identified. The patient is then resuscitated in the ICU and returned to the operating room for definitive reconstruction and anastomoses when stabilized (generally, 24 to 48 hours later).

Because of the large number of possible combinations of injuries to the pancreas and the duodenum, no single therapeutic approach is appropriate for all patients. In a review of 129 cases of combined pancreatic-duodenal injuries, 24% of the patients were treated with simple repair and drainage, 50% underwent repair and pyloric exclusion, and only 10% required a Whipple procedure.⁶¹ The best treatment option for a given patient is determined

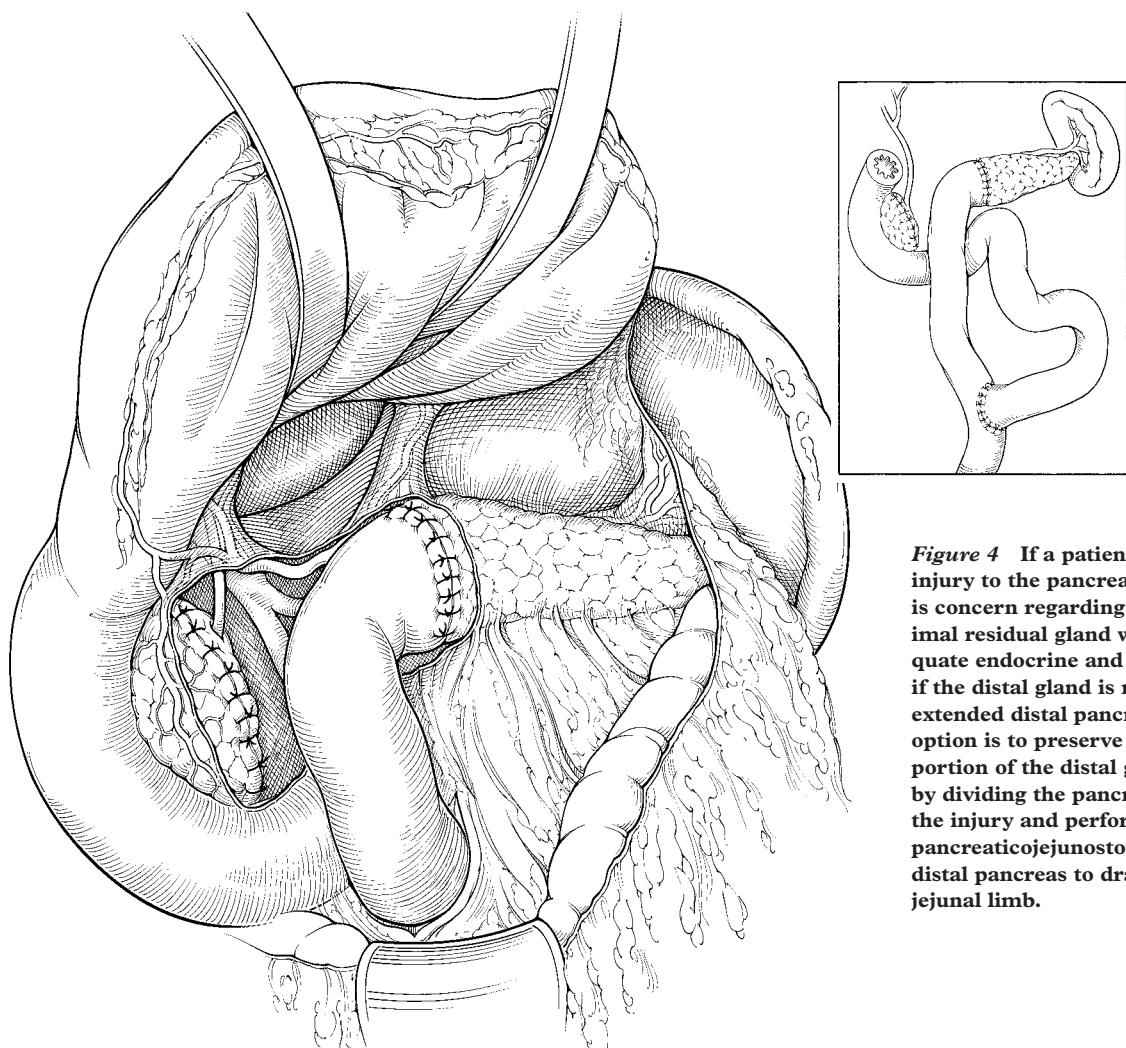

Figure 4 If a patient has a grade IV injury to the pancreatic head and there is concern regarding whether the proximal residual gland would have adequate endocrine and exocrine function if the distal gland is resected in an extended distal pancreatectomy, an option is to preserve the uninjured portion of the distal gland. This is done by dividing the pancreas at the site of the injury and performing a Roux-en-Y pancreaticojejunostomy to allow the distal pancreas to drain into the jejunal limb.

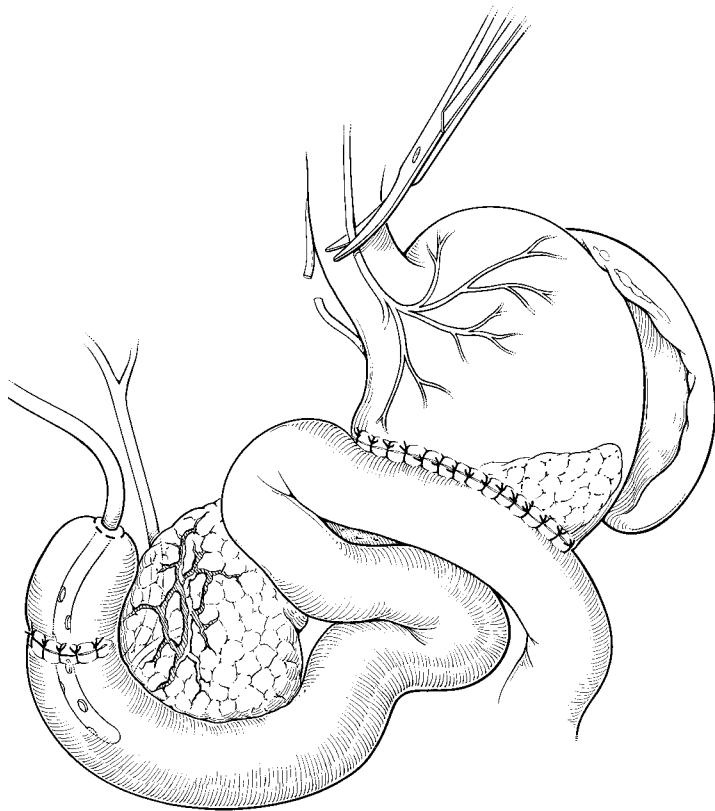

Figure 5 Duodenal diverticularization consists of antrectomy with gastrojejunostomy, tube duodenostomy, vagotomy, and peripancreatic drainage.

by the integrity of the distal CBD and the ampulla, as well as by the severity of the duodenal injury. For this reason, every patient with a combined pancreatic-duodenal injury should undergo cholangiography, pancreatography, and evaluation of the ampulla. If the CBD and the ampulla are intact (as they are in the majority of cases), the duodenum may be closed primarily and the pancreatic duct injury treated as described (see above). If the status of the pancreatic duct cannot be determined intraoperatively, wide external drainage of the pancreatic head with closed suction drains, rather than total pancreatectomy, should be performed, followed by early postoperative ERCP or MRP.

In cases of severe injury to the duodenum, it may be advisable to divert gastric contents away from the duodenal repair. One technique for accomplishing this diversion is duodenal diverticulization, which employs primary closure of the duodenal wound, antrectomy, vagotomy, end-to-side gastrojejunostomy, drainage of the CBD with a T tube, and lateral tube duodenostomy [see Figure 5]. The goals are (1) complete diversion of both gastric and biliary contents away from the duodenal injury, (2) provision of enteral nutrition via the gastrojejunostomy, and (3) conversion of a potential uncontrolled lateral duodenal fistula to a controlled fistula.

A less formidable and less destructive alternative technique for diversion of gastric contents is pyloric exclusion, which does not employ antrectomy, biliary diversion, or vagotomy [see Figure 6].^{51,66-68} This procedure is performed through a gastrotomy and involves grasping the pylorus with a Babcock clamp, suturing the pylorus closed with absorbable size 0 polyglycolic acid or polyglyconate, and constructing a loop gastrojejunostomy. Gastric flow is then diverted away from the duodenum for several weeks while the duodenal and pancreatic duct injuries heal. After a period of 2

weeks to 2 months, the pylorus opens and the gastrojejunostomy functionally closes. One group has described a technical method of controlling the release of the pyloric exclusion knot and thereby timing the opening of the pyloric occlusion.⁶⁹ Marginal ulceration at the gastrojejunostomy site has been reported in 5% to 33% of patients in whom a vagotomy was not performed.^{67,68,70,71} Pyloric exclusion is generally reserved for severe combined pancreatic head and duodenal injuries for which a Whipple procedure is not required. Few surgeons advocate pyloric exclusion for isolated pancreatic duct injuries.

In patients who have sustained massive injuries of the proximal duodenum and the head of the pancreas, destruction of the ampulla and the proximal pancreatic duct or the distal CBD may preclude reconstruction. In addition, because the head of the pancreas and the duodenum share an arterial supply, it is essentially impossible to resect one structure entirely without making the other ischemic. In this situation, a pancreaticoduodenectomy [see 5:24 Pancreatic Procedures] is required. Between 1961 and 1994, 184 Whipple procedures for trauma were reported; there were 26 operative deaths and 39 delayed deaths, for a 65% overall survival rate.⁶⁵ Subsequent experience, however, suggests that with appropriate selection criteria, pancreaticoduodenectomy for trauma can be performed with morbidity and mortality comparable to those of pancreaticoduodenectomy for cancer.⁷²⁻⁷⁴

Nonoperative Management in Children

Major pancreatic duct injury is rare in children, occurring in only 0.12% of children with blunt abdominal trauma.⁷⁵ Most pediatric pancreatic injuries are grade I or II injuries, which do not

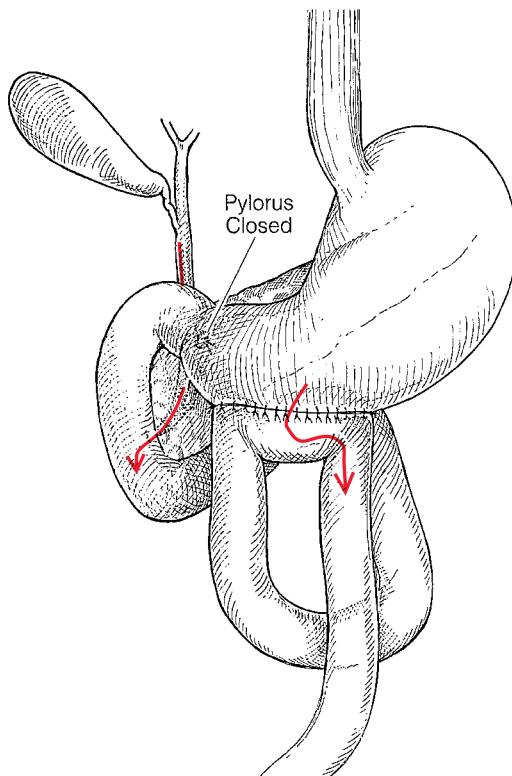

Figure 6 Pyloric exclusion consists of closure of the pylorus from within the stomach, followed by gastrojejunostomy. The procedure eliminates discharge of gastric acid into the duodenum, thus minimizing the stimulation of pancreatic secretion and reducing morbidity if there is breakdown of a repair.

involve major pancreatic duct injury. Accordingly, several authors have advocated managing all blunt pediatric pancreatic injuries nonoperatively with bowel rest, serial abdominal CT scans to watch for pseudocyst formation, and percutaneous drainage as required.⁷⁶⁻⁷⁹ However, this approach is generally associated with a high morbidity and a prolonged hospital course and therefore may not be justified, given the good recovery reported after distal pancreatectomy with splenic salvage.⁸⁰ Pseudocysts develop in 40% to 100% of children with major duct injury,^{78,81,82} and recurrent episodes of pancreatitis may arise long after the time of injury.^{16,83} ERCP with proximal stenting of duct injuries may be a useful adjunct to care in these patients, but it requires a skilled pediatric endoscopist.

A report from Toronto detailed the management of 35 children with pancreatic trauma over a 10-year period.⁷⁸ In 23, the injury was diagnosed early (< 24 hours), whereas in the remaining 12, the diagnosis was initially missed. In all, 28 of the 35 were managed nonoperatively. A subsequent report provided a more detailed examination of 10 patients from this group who had pancreatic duct transections.⁷⁹ Pseudocysts developed in 44% and were managed in all cases with percutaneous drainage. Atrophy of the distal pancreatic remnant developed in 75%, but there was no evidence of endocrine or exocrine dysfunction. A report from Japan found that pseudocysts developed in five out of five children with pancreatic duct injuries that were managed nonoperatively.⁸² The data suggest that pediatric pancreatic injuries can be successfully managed nonoperatively but also that there is a high incidence of pseudocyst formation necessitating further hospitalization and interventions and that atrophy of the distal remnant is common. Several pediatric surgeons have argued for the benefits of distal pancreatectomy in terms of shortening hospital stay and minimizing intervention.^{29,80,84}

Nonoperative management of adults with blunt pancreatic injuries has been less well studied. In one report, patients with grade I and II injuries (confirmed by laparotomy) had a higher morbidity with external drainage than with exploration without drainage.⁸⁵ Selection bias might have affected these results, however, in that less severe injuries might not have been drained. Proponents of nonoperative management of grade I and II injuries have advocated early ERCP to identify the presence of any pancreatic duct injuries that would necessitate surgical intervention.^{86,87} Proximal stenting of the pancreatic duct has been successful in isolated case reports of duct injuries in adults.³³ Further study is indicated before any recommendations can be made regarding nonoperative management of pancreatic duct injury in adults. For the present, I continue to advocate operative management for known or suspected pancreatic duct injury.

COMPLICATIONS

The complication rate after pancreatic injury remains uncomfortably high. Between 20% and 40% of patients who undergo surgical intervention for a pancreatic duct injury have a complicated postoperative course, and the rate is even higher if both the pancreatic head and the duodenum were injured.¹ The risk of complications is directly and independently related to the injury grade on the AAST scale and to the presence or absence of an associated bowel injury.² Although most of the complications of pancreatic duct injury are either self-limiting or treatable, there is a significant risk of sepsis and multiple organ dysfunction syndrome (MODS), which are responsible for nearly 30% of deaths resulting from pancreatic trauma. In some series, as many as one half of the postoperative complications could have been prevent-

ed by careful inspection of the pancreas and accurate determination of the status of the main pancreatic duct.⁹

Fistula

Postoperative pancreatic fistula has been defined as any measurable drain output with an amylase level higher than three times the serum level.⁵⁰ It is the most common complication after pancreatic duct injury, occurring in 7% to 20% of patients (and in 26% to 35% of patients with combined pancreatic-duodenal injury).^{2,13,40,88,89} Direct suture closure of the main pancreatic duct may help minimize this complication; fibrin sealants appear to be ineffective.⁹⁰

The vast majority of pancreatic fistulas are minor (drain output < 200 ml/day) and spontaneously resolve within 2 weeks after injury, given adequate external drainage. In a multicenter review of distal pancreatectomy for trauma, the postoperative fistula rate was 14% (10/71), and fistulas closed spontaneously in 89% (8/9) of survivors within 6 to 54 days.⁶³ Extirpation of a residual pancreatic sequestrum was required to facilitate fistula closure in one patient. By way of comparison, a subsequent study reported a 3.3% fistula rate after elective distal pancreatectomy for chronic pancreatitis.⁵⁵

High-output fistulas (drain output > 700 ml/day) are rare. Generally, either more extended external drainage or surgical intervention is required for resolution. If a high-output fistula does not progressively decrease in volume or persists for longer than 10 days, ERCP is indicated to help establish the cause of the persistent fistula and guide further therapy. Nutritional support must be provided throughout this period. At this point, as noted [*see Management, Grade IV: Proximal Transection or Parenchymal Injury with Probable Duct Disruption, above*], the surgeon's foresight in placing a feeding jejunostomy at the time of the initial trauma laparotomy is rewarded. Elemental feeding formulas cause less pancreatic stimulation than standard enteral formulas and should therefore be tried before the patient is committed to TPN.⁵² The somatostatin analogue octreotide acetate has shown promise in treating prolonged high-output pancreatic fistulas but only when any infection has been eradicated and when pancreatic duct obstruction or stricture is absent.⁹¹

The use of octreotide as an adjuvant to standard fistula management probably reduces fistula output, but whether it hastens fistula closure remains to be proved.⁹² Somatostatin analogues do appear to prevent postoperative complications and fistula formation in patients undergoing elective pancreatic resection. However, nonrandomized studies addressing the efficacy of somatostatin analogues in pancreatic trauma patients have yielded conflicting results.^{93,94} Moreover, in the trials demonstrating reductions in postoperative complications with octreotide use in elective pancreatic resection, octreotide administration was initiated in the preoperative period—a time frame that is not applicable to the trauma setting. The octreotide dosage typically starts at 50 µg subcutaneously every 12 hours but may rise as high as 1,000 µg/day. Although octreotide has been included in TPN solutions, this practice remains controversial and is not recommended by the 1997 package insert, because of the formation of glycosyl octreotide conjugates that may reduce the efficacy of the agent.⁹⁵ The major potential side effects are unpredictable changes in serum glucose levels, pain at the injection site, and various nonspecific GI complaints.

Abscess

The incidence of abscess formation after pancreatic trauma ranges from 10% to 25%, depending on the number and type of

associated injuries present. Early operative or percutaneous decompression or evacuation is critical, though even with these measures, the mortality in this group of patients remains about 25%.^{61,96} In most cases, the abscesses are subfascial or peripancreatic; true pancreatic abscesses are unusual and generally result from inadequate debridement of dead tissue or inadequate initial drainage.^{40,63,89,97} True pancreatic abscesses often are not amenable or responsive to percutaneous drainage and must be treated with prompt surgical debridement and drainage. Percutaneous decompression may be helpful in distinguishing abscesses from pseudocysts (see below).

Pancreatitis

Transient abdominal pain and a rise in the serum amylase concentration, signaling pancreatitis, may be anticipated in 8% to 18% of postoperative patients.^{5,63,98} This type of pancreatitis is treated with nasogastric decompression, bowel rest, and nutritional support and can be expected to resolve spontaneously. A much less common but far more deadly complication is hemorrhagic pancreatitis. The first sign of this complication may be bloody pancreatic drainage or a fall in the serum hemoglobin concentration, with the patient rapidly becoming desperately ill. It is fortunate that this complication occurs in fewer than 2% of operative pancreatic trauma patients: mortality may approach 80%, and there is no effective treatment.^{40,56}

Secondary Hemorrhage

Postoperative hemorrhage necessitating blood transfusion may occur in 5% to 10% of pancreatic trauma patients, particularly when external drainage after pancreatic debridement was inadequate or when intra-abdominal infection has developed.^{98,99} Generally, reoperation is required to control secondary hemorrhage, though angiographic embolization may be an effective alternative.

Pseudocysts

Blunt pancreatic injuries that were missed or were intentionally managed nonoperatively often result in the formation of a pseudocyst; in one report, 22 pseudocysts developed in 42 blunt pancreatic trauma patients managed nonoperatively.⁸ The status of the pancreatic duct is the key determinant of how a pancreatic pseudocyst is treated. If the pancreatic duct is intact, percutaneous drainage of the pseudocyst is likely to be effective. If the pseudocyst is secondary to major disruption of the duct, however, percutaneous drainage will not provide definitive therapy but will convert the pseudocyst to a chronic fistula. ERCP should therefore precede any attempt at percutaneous drainage. If pancreatic duct stenosis or injury is demonstrated, the treatment options are (1) reexploration and partial resection of the gland, (2) internal Roux-en-Y drainage of the distal gland, and (3) endoscopic transpapillary stenting of the pancreatic duct.³² There is some evidence to suggest that surgical decompression will be required if the pseudocyst is larger than 10 cm.⁸²

Exocrine and Endocrine Insufficiency

Exocrine and endocrine insufficiency are unusual after pancreatic trauma. Animal and human studies suggest that a residuum as small as 10% to 20% of the normal pancreatic tissue mass is adequate for pancreatic function.⁶ The implication is that any resection distal to the mesenteric vessels should leave an adequate amount of functioning pancreatic tissue. In a multicenter study of 74 cases of distal pancreatic resection, only one case of endocrine

deficiency (diet-controlled hyperglycemia after 80% pancreatectomy) was documented, and no instances of exocrine insufficiency were observed.⁶³ In another study, no cases of pancreatic insufficiency were reported after resection of as much as 90% of the pancreas.⁸⁸ By way of contrast, patients with chronic pancreatitis who undergo distal pancreatectomy have an incidence of diabetes ranging from 15% (with 0% to 33% of the gland resected) to 64% (with 50% to 75% of the gland resected).⁵⁵

Injuries to the Duodenum

Duodenal injuries are uncommon. A 6-year statewide review in Pennsylvania found the incidence of blunt duodenal injury to be only 0.2% (206 of 103,864 trauma registry entries), and only 30 of the patients had full-thickness duodenal injuries.¹⁰⁰ About 75% of the patients in published reports of duodenal injury sustained penetrating rather than blunt trauma; however, this figure may primarily reflect the experience of urban trauma centers.¹⁰¹ Blunt duodenal injuries are the result of a direct blow to the epigastrium, which in adults is usually the result of a steering-wheel injury to an unrestrained driver and in children is usually the result of a direct blow from a bicycle handlebar or similar device. It is well known that the insidious nature of many blunt duodenal injuries makes the initial diagnosis difficult unless a high index of suspicion is maintained. Nevertheless, delays in the diagnosis of duodenal trauma continue to plague trauma surgeons and seriously compromise patient care.¹⁰²

DIAGNOSIS

The radiologic signs of duodenal injury on the initial plain abdominal or upright chest radiograph are often quite subtle. Mild spine scoliosis or obliteration of the right psoas muscle may be visible, in addition to retroperitoneal air, which is often difficult to distinguish from the overlying transverse colon. An early suspicion of retroperitoneal duodenal rupture is best confirmed or excluded by means of either an abdominal CT scan, with both oral and I.V. contrast, or an upper GI series, first with a water-soluble contrast agent and then with barium if the initial examination yields negative results. The findings must be interpreted with a high index of suspicion for injury, and any uncertainty in interpretation is adequate justification for operative exploration.

Even with careful examination, false negative results are known to occur.¹⁰³ In one study of the accuracy of CT in diagnosing duodenal and other small bowel injuries, only 10 (59%) of 17 scans were prospectively (i.e., preoperatively) interpreted as suggestive of bowel injury, but 15 (88%) of 17 were suggestive when evaluated retrospectively.¹⁰⁴ The investigators emphasized that using CT to diagnose blunt bowel rupture requires careful inspection and technique to detect the often subtle findings. Abdominal CT findings suggestive of duodenal injury may be difficult to confirm with duodenography.¹⁰⁵ In a series of 96 patients with CT findings suggestive of duodenal injury, duodenography had a sensitivity of 54% and a specificity of 98%. For injuries necessitating operative repair, the sensitivity was only 25%, with a 25% false negative rate. In another study, 83% of patients in whom diagnosis of blunt duodenal injury was delayed had subtle CT findings (e.g., pneumoperitoneum, unexplained fluid, and unusual bowel morphology) that were dismissed.¹⁰⁶ The authors emphasized the point that subtle findings of duodenal injury on abdominal CT should be an indication for laparotomy.

Diagnostic peritoneal lavage (DPL) is unreliable in detecting isolated duodenal and other retroperitoneal injuries. Nevertheless,

Table 2 Factors Determining Severity of Duodenal Injury¹⁰⁸

Factor	Degree of Injury	
	Mild	Severe
Means of Injury	Stab	Blunt force or missile
Size of Injury	≤ 75% of circumference	> 75% of circumference
Location of injury in duodenum	D3, D4	D1, D2
Interval between injury and repair	≤ 24 hr	> 24 hr
Adjacent injury to CBD	Absent	Present

it is often helpful, in that approximately 40% of patients with a duodenal injury have associated intra-abdominal injuries that will result in a positive DPL result. The presence of amylase or bile in the lavage effluent is a more specific indicator of possible duodenal injury. Serum amylase levels are nondiagnostic as well, but if they are found to be elevated, additional investigation (via CT or celiotomy) for possible pancreatic or duodenal injury is warranted. At celiotomy, the presence of any central upper abdominal retroperitoneal hematoma, bile staining, or air mandates visualization and thorough examination of the duodenum. The technical details of exposure of the entire duodenum and pancreas are well described elsewhere.¹⁰⁷

MANAGEMENT

Classification of Duodenal Injury

Treatment of duodenal trauma is determined by the severity of the injury and the likelihood of postrepair complications. Approximately 70% to 80% of duodenal wounds can safely be repaired primarily; approximately 20% to 30% call for more complex procedures. A 1980 review of 247 patients treated for duodenal trauma catalogued factors that determined whether a duodenal wound could be primarily repaired.¹⁰⁸ In the 228 patients who survived longer than 72 hours, the overall duodenal fistula rate was 7%, and the mortality was 10.5%. The investigators identified five factors that, in their view, correlated most significantly with the severity of duodenal injury and subsequent morbidity and mortality [see Table 2]. To these five factors should be added a sixth—namely, the presence of a pancreatic injury, which is a significant predictor of late morbidity and mortality. These factors, both individually and in different combinations, have been used to develop a variety of duodenal injury classification systems. One such system is simply to divide injuries into two categories, mild and severe. In the study already mentioned,¹⁰⁸ the investigators reported a 0% mortality and a 2% duodenal fistula rate in patients with mild duodenal trauma, compared with a 6% mortality and a 10% fistula rate in those with severe duodenal trauma. In general, primary repair is satisfactory for mild duodenal injuries without associated pancreatic injuries. More complex treatment strategies may be required for more severe duodenal injuries.

A more contemporary classification system is that developed by the AAST, in which duodenal injuries are graded from I to V in order of increasing severity [see Table 1 and Figure 7].⁴⁶ In a multicenter review of 164 duodenal trauma patients to whom the AAST classification scheme was applied, there were 38 grade I, 70 grade II, 48 grade III, 4 grade IV, and 4 grade V injuries. Primary repair was the sole treatment in 71% (117) of all cases.¹⁰⁹ Ninety of the 108 patients with grade I or II injuries underwent either pri-

mary duodenal repair or no duodenal procedure at all. Twenty-six of the 56 patients with grade III to V injuries were treated with more complex duodenal treatment strategies, including pyloric exclusion, duodenoduodenostomy, duodenojejunostomy, and pancreaticoduodenectomy.

Duodenal Hematoma

Duodenal hematoma is generally considered a consequence of childhood play or child abuse. In one report, 50% of cases of duodenal hematoma in children were attributable to child abuse.¹¹⁰ However, this condition can occur in adults as well. Nearly one third of patients present with obstruction of insidious onset at least 48 hours after injury, presumably resulting from a fluid shift into the hyperosmotic duodenal hematoma. Generally speaking, duodenal hematoma is a nonsurgical injury, in that the best results are obtained with conservative or nonsurgical management.¹¹¹ It may be diagnosed by means of either contrast-enhanced CT or an upper GI study. The initial contrast examination should be done with a water-soluble agent (e.g., meglumine diatrizoate), followed by a barium study to provide the greater detail needed for detection of the so-called coiled-spring or stacked-coin sign. This finding is characteristic of intramural duodenal hematoma, but it is present in only about one quarter of patients with hematomas.

Although initial treatment is nonoperative, care must be taken to exclude associated injuries, with particular attention paid to the potential for pancreatic injuries, which occur in 20% of patients.¹¹¹ Continuous nasogastric suction should be employed and TPN initiated. If signs of obstruction do not spontaneously abate, the patient should be reevaluated with upper GI contrast studies at 5- to 7-day intervals. Ultrasonography may also be employed to follow a resolving duodenal hematoma.¹¹² Percutaneous drainage of an unresolving duodenal hematoma has been reported,^{113,114} but the usual recommendation is to perform operative exploration and evacuation of the hematoma after 2 weeks of conservative therapy to rule out stricture, duodenal perforation, or injury to the head of the pancreas as factors that might be contributing to the obstruction.¹¹⁵ In a review of six cases of duodenal and jejunal hematoma resulting from blunt trauma, the hematomas resolved with nonoperative management in five cases; the average hospital stay was 16 days (range, 10 to 23 days), and the average duration of TPN was 9 days (range, 4 to 16 days). In the sixth case, upper GI series showed evidence of complete bowel obstruction, which failed to resolve after 18 days of conservative management. Laparotomy revealed jejunal and colonic strictures with fibrosis, which were successfully resected.¹¹⁶

If a duodenal hematoma is incidentally found at celiotomy, a thorough inspection must be done to exclude perforation. Inspection necessitates an extended Kocher maneuver, which usu-

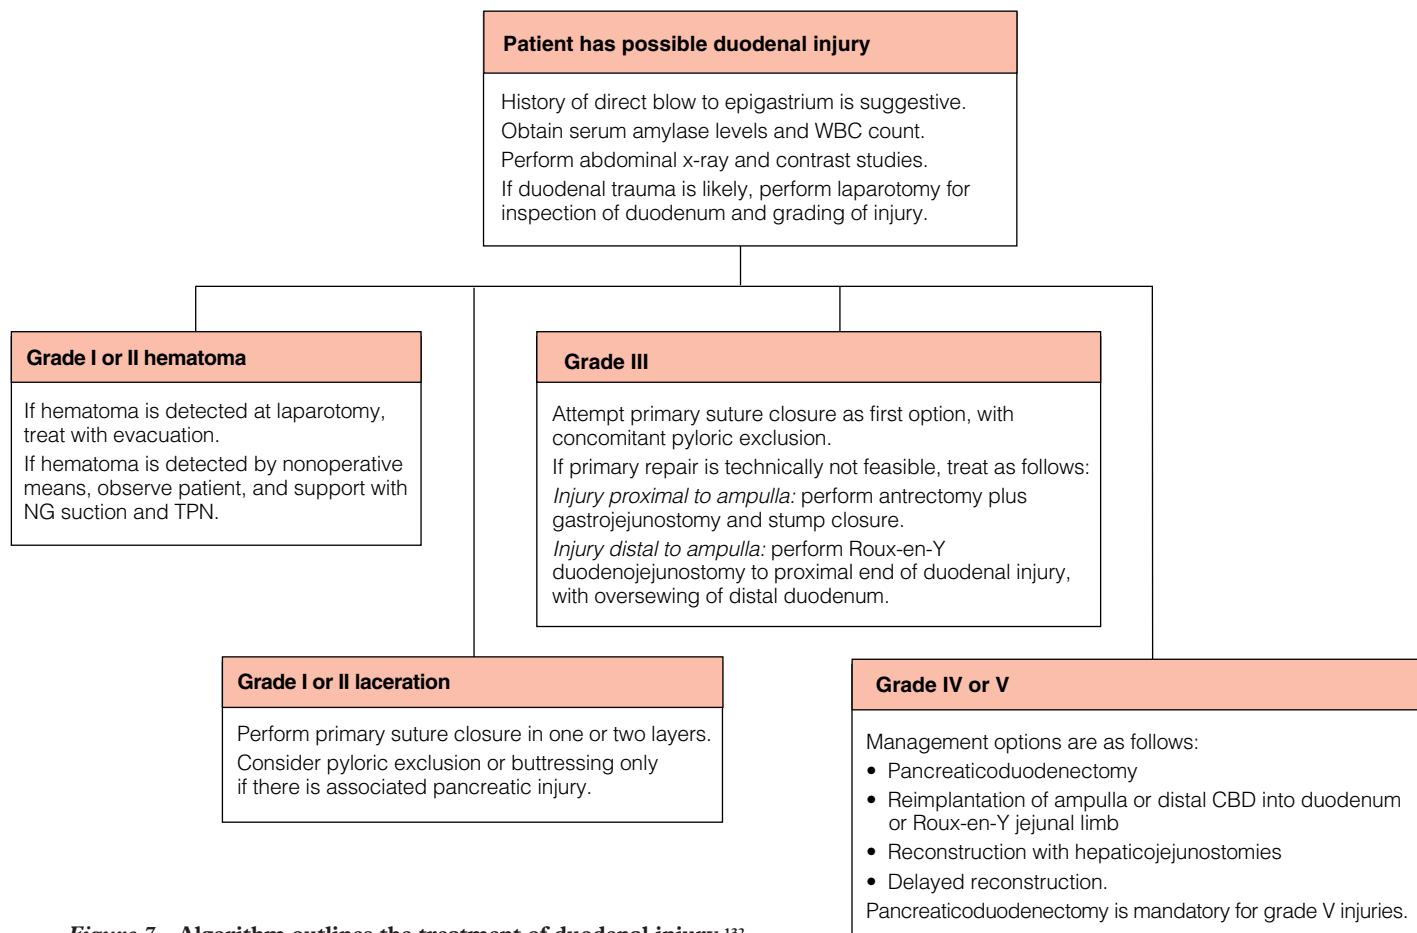

Figure 7 Algorithm outlines the treatment of duodenal injury.¹³²

ally successfully drains the subserosal hematoma. It is unclear whether the serosa of the duodenum should intentionally be incised along its extent to evacuate the hematoma or whether doing so would actually increase the likelihood of turning a partial duodenal wall tear into a complete perforation. Because an extended period of gastric decompression will probably be required, a feeding jejunostomy should be placed.

Duodenal Laceration and Transection

For complete transection of the duodenum, primary repair is appropriate if there is little tissue loss, if the ampulla is not involved, and if the mucosal edges can be debrided and closed without tension. If adequate mobilization for a tension-free repair is impossible or if the injury is very near the ampulla and mobilization might result in injury to the CBD, the most reasonable option is a Roux-en-Y jejunal limb anastomosis to the proximal duodenal injury with oversewing of the distal injury. Mucosal jejunal patch repair is rarely, if ever, employed; it was not used in any of the 164 patients in the multicenter trial previously cited,¹⁰⁹ in which only five patients (3%) underwent repair with duodenoduodenostomy or duodenojejunostomy. Pancreaticoduodenectomy is only required for duodenal injuries if there is uncontrollable pancreatic hemorrhage or if duodenal injuries exist in combination with distal CBD or pancreatic duct injuries.

Several techniques may be applied to help protect a tenuous duodenal repair. One option is buttressing the repair with omentum (my preference) or a serosal patch from a loop of jejunum. This approach seems intuitively logical, though its benefits are unproven.^{117,118} Another option is diversion of gastric contents,

most commonly accomplished by means of pyloric exclusion [see Figure 6].⁶⁸ This technique, probably first described by Summers in 1904 as an adjunct to the treatment of duodenal wounds,¹¹⁹ is less disruptive than true duodenal diverticularization [see Figure 5].^{66,120} To date, no prospective, randomized trial has proved that gastric diversion is truly beneficial in the setting of duodenal trauma, but several reports have supported the use of pyloric exclusion and gastrojejunostomy in cases of severe duodenal injury^{71,121} or in cases of delayed diagnosis of injury.⁶⁷ Potential benefits notwithstanding, the additional operating time and the extra anastomosis required with gastric diversion suggest that this approach should be employed with a good deal of selectivity. Marginal ulceration is a well-described complication of gastric diversion and has prompted some surgeons to add truncal vagotomy to the procedure. Most surgeons, however, do not perform vagotomy with gastric diversion, because nearly all of the pyloric closures open within a few weeks, regardless of the type of suture material used, and the occasional marginal ulcer can be medically managed in the interim.

An alternative or addition to gastric diversion is duodenal decompression via retrograde jejunostomy. In a study of 237 patients with a variety of duodenal injuries treated by means of retrograde jejunostomy tube drainage, the fistula rate was lower than 0.5%, whereas the incidence of duodenal complications was 19.3% when decompression was not performed.¹²² Retrograde duodenal drainage is preferred to lateral duodenostomy. Direct drainage with a tube through the suture line results in a high (23%) rate of dehiscence or fistula. In a 1984 review of the literature on penetrating duodenal trauma and tube duodenostomy,¹²³ there was an overall mortality of 19.4% and a fistula rate of

11.8% when decompression was not performed, compared with a 9% mortality and a 2.3% fistula rate when it was. The authors concluded that tube drainage should be performed either via the stomach or via a retrograde jejunostomy, noting that these methods were associated with a lower fistula rate and a lower overall mortality than lateral tube duodenostomy was. Nonetheless, there has been no prospective, randomized analysis of the efficacy of tube duodenal drainage techniques, and not all surgeons support the use of decompression in this setting.

Mortality directly related to the duodenal injury is the result of duodenal dehiscence, uncontrolled sepsis, and subsequent MODS. Given the known lethal nature of duodenal dehiscence and duodenal fistula, the operating surgeon may well be strongly tempted to add pyloric exclusion, anastomosis buttressing, and duodenostomy to the repair of grade III or IV duodenal injuries. Concomitant pancreatic injury should be included as a high-risk confounder that might warrant the addition of pyloric exclusion to the duodenal repair. In a report of 40 patients with penetrating duodenal injuries, 14 patients had combined pancreatic-duodenal wounds. Five of these 14 were treated with primary duodenal repair alone, and two of the five had duodenal leaks. Three of the 14 underwent pyloric exclusion in addition to primary repair, and none of them had duodenal leaks.¹²⁴

DETERMINANTS OF OUTCOME

Large series published toward the end of the 20th century documented an average mortality of 18% in patients with duodenal injuries, but the mortalities cited in individual reports showed great variability, ranging from 6% to 29%.^{1,71,117,125} Mortality directly related to duodenal injury is much lower—generally, 2% to 5%—and is primarily the result of complications, dehiscence, sepsis, and MODS.^{42,108,109,117,121,122,126,127} Morbidity after duodenal injury ranges from 30% to 63%; however, in only about one third of cases is morbidity directly related to the duodenal injury itself.^{108,117,125} To a large extent, the variability in morbidity and mortality statistics can be explained by differences in the mechanism of injury, the nature and severity of associated injuries (if present), and the time between initial injury and diagnosis. For example, a review of 100 consecutive penetrating duodenal injuries documented a mortality of 25%,¹¹⁷ compared with a mortality of 12% to 14% for blunt injuries.^{102,108}

Early death from a duodenal injury, particularly a penetrating injury, is usually attributable to exsanguination from associated vascular, hepatic, or splenic trauma.^{4,128} The proximity of the duodenum to other vital structures and the high-energy transfer mechanisms involved make isolated duodenal injuries uncommon, though certainly not unheard of. Most late deaths from duodenal trauma are attributable to infection and MODS. In as many as one third of patients who survive the first 48 hours after duodenal injury, a complication related to the injury eventually develops. Common complications include anastomotic breakdown, fistula, intra-abdominal abscess, pneumonia, bloodstream infection, and organ failure. Late deaths typically occur from 1 to 2 weeks or more after the initial duodenal injury; about one third of them are directly attributable to the injury itself.^{108,125}

The length of time between injury and definitive treatment has a substantial effect on the development of late complications and subsequent mortality. In one study, 10 patients were identified in whom the diagnosis of duodenal injury was delayed for more than 24 hours; four of the 10 died, and three of the 10 had duodenal fistulas.¹²⁹ In a classic report from 1975, the remarkable importance (and frequency) of delays in the diagnosis of duodenal injury was strikingly demonstrated.¹³⁰ Diagnosis was delayed by more than 12 hours in 53% of the patients in this report and by more than 24 hours in 28%. In patients whose diagnosis was delayed for more than 24 hours, mortality was 40%; in those who underwent surgery within 24 hours of injury, mortality was 11%. These observations were subsequently confirmed by other studies. In one study, two of the four blunt duodenal trauma patients with delayed diagnoses died, and the other two had duodenal fistulas.¹⁰⁸ In another study, 100% of the deaths directly attributable to duodenal injury occurred in patients with delayed diagnoses.¹⁰²

The implication of these observations is that the first priority in managing duodenal trauma, as in managing pancreatic trauma, should be control of hemorrhage. The second priority should be limiting bacterial contamination from associated colon or other bowel injury, with the aim of preventing late infections. As a rule, if a duodenal injury has occurred, it will be apparent intraoperatively; thus, the next priority should be a diligent search for potential pancreatic injury, with an emphasis on assessing the status of the pancreatic duct.^{1,6}

9 OPERATIVE EXPOSURE OF ABDOMINAL INJURIES AND CLOSURE OF THE ABDOMEN

Erwin R. Thal, M.D., F.A.C.S., and Terence O'Keeffe, M.B., Ch.B., F.R.C.S.Ed.

Over the past two decades, the advent of nonoperative management techniques for many solid-organ injuries has led to a significant shift in the care of patients who have sustained abdominal trauma. The ever-improving accuracy of diagnostic modalities (computed tomography in particular) has also contributed to this shift.^{1–4} Today, fewer patients require operative intervention for treatment of abdominal injuries. Those who do require such intervention make up a select group who continue to pose a significant challenge to surgeons. In our view, these patients are best managed by following a standardized operative approach, the aim of which is to diagnose, prioritize, and treat the injuries in an expeditious fashion so that the patient is not kept in the operating room any longer than necessary [see *Figure 1*]. Such an approach optimizes patient care by minimizing the risk of missed injuries and ensuring a rapid and efficient response by the members of the surgical team. Naturally, every patient's care should be individualized as necessary. In general, however, a standardized operative approach, complemented by a solid knowledge of a variety of exposures and techniques, should allow the surgeon to deal with virtually any abdominal injury. In this chapter, we outline our recommended approach to operative intervention in patients with abdominal trauma.

Patient Preparation

The key to success in this setting is advance preparation aimed at covering all eventualities. Such preparation involves both the environment and the patient. The room should be warmed to ensure that the patient does not lose too much heat and become hypothermic. The instruments should be open on the back table, and specific instruments should be available when specific injuries are anticipated (e.g., a vascular set should be available when a vascular injury is suspected). A sufficient number of laparotomy pads should be on hand, and a retracting device with which the surgical team is familiar should be employed. Cell saver systems and rapid infusion systems can be useful adjuncts; if desired and available, they should be requested in advance.⁵

Patient preparation begins with the insertion of a nasogastric or orogastric tube and a Foley catheter. Invasive monitoring lines may have to be placed, and resuscitation should continue as the patient is being prepared. A broad-spectrum antibiotic should be administered intravenously before the initial incision is made. When the patient is correctly positioned on the operating table, skin preparation should extend from the sternal notch superiorly to include the anterior thorax. Thus, no further preparation will be required if a thoracic injury is identified or vascular control in the thorax is necessary. Thoracostomy, if required, can also be performed without the drapes being changed. Inferiorly, skin preparation should extend to the upper anterior thighs so that the proximal saphenous veins are available if a vascular reconstruction is required and so that distal vascular control can be achieved without undue delay.

All areas of the body that are not included in the skin preparation should be covered so as to prevent excessive heat loss, and warming devices should be placed if available. Sterile draping should be placed so as to allow access to all potential injuries. If the patient is in extremis and in danger of expiring, however, patient preparation should be limited to a rapid skin cleansing and surgery should commence immediately.

Incision and Initial Exploration

CHOICE OF INCISION

A midline celiotomy is the incision of choice. Its advantages are that it allows rapid and easy access to the abdominal cavity, with good exposure of the majority of the intra-abdominal organs and structures, and that it can be extended into a median sternotomy if necessary. Its main disadvantage is that it may not provide adequate exposure of injuries in the deep recesses of the upper quadrants.

Patients with previous midline incisions pose a challenge to the surgeon. If at all possible, an attempt should be made to enter the abdomen above or below the previous incision, in an area less likely to have adhesions. If this is not possible, an alternative incision, such as a chevron (bilateral subcostal) incision, should be considered. A chevron incision provides entry into the abdomen while avoiding any viscera that are adherent to the undersurface of the previous laparotomy scar. However, this incision takes more time, does not provide ideal exposure, and is associated with a higher morbidity; accordingly, it should be considered only when the circumstances are dire. Paramedian, subcostal, retroperitoneal, and flank incisions are not recommended, for much the same reasons.

INITIAL EXPLORATION

Once the peritoneal cavity has been entered, initial exploration proceeds in an orderly fashion so as to minimize hemorrhage and contamination, prevent iatrogenic injury, and facilitate the expeditious identification of injuries. The intestines are eviscerated, and gross blood is rapidly evacuated. Laparotomy pads are then rapidly placed in all four quadrants to pack the abdomen; the right upper quadrant is packed first, then the left upper quadrant, and finally the lower two quadrants. Care should be taken not to tear the falciform ligament or the fibrous capsule of the liver during this maneuver. Blood pressure may drop when the abdomen is decompressed. Anesthesia should be given the opportunity to catch up with resuscitation efforts at this point.

Once hemodynamic stability has been achieved, the intraperitoneal portion of the exploration is begun. In cases of blunt trauma, the temporary packs (except for those around the solid viscera) may now be carefully removed and any remaining blood evacuated. In cases of penetrating trauma, it is often easier initially to address the site of ongoing hemorrhage via a direct approach. Vascular injuries are controlled manually until proximal and distal

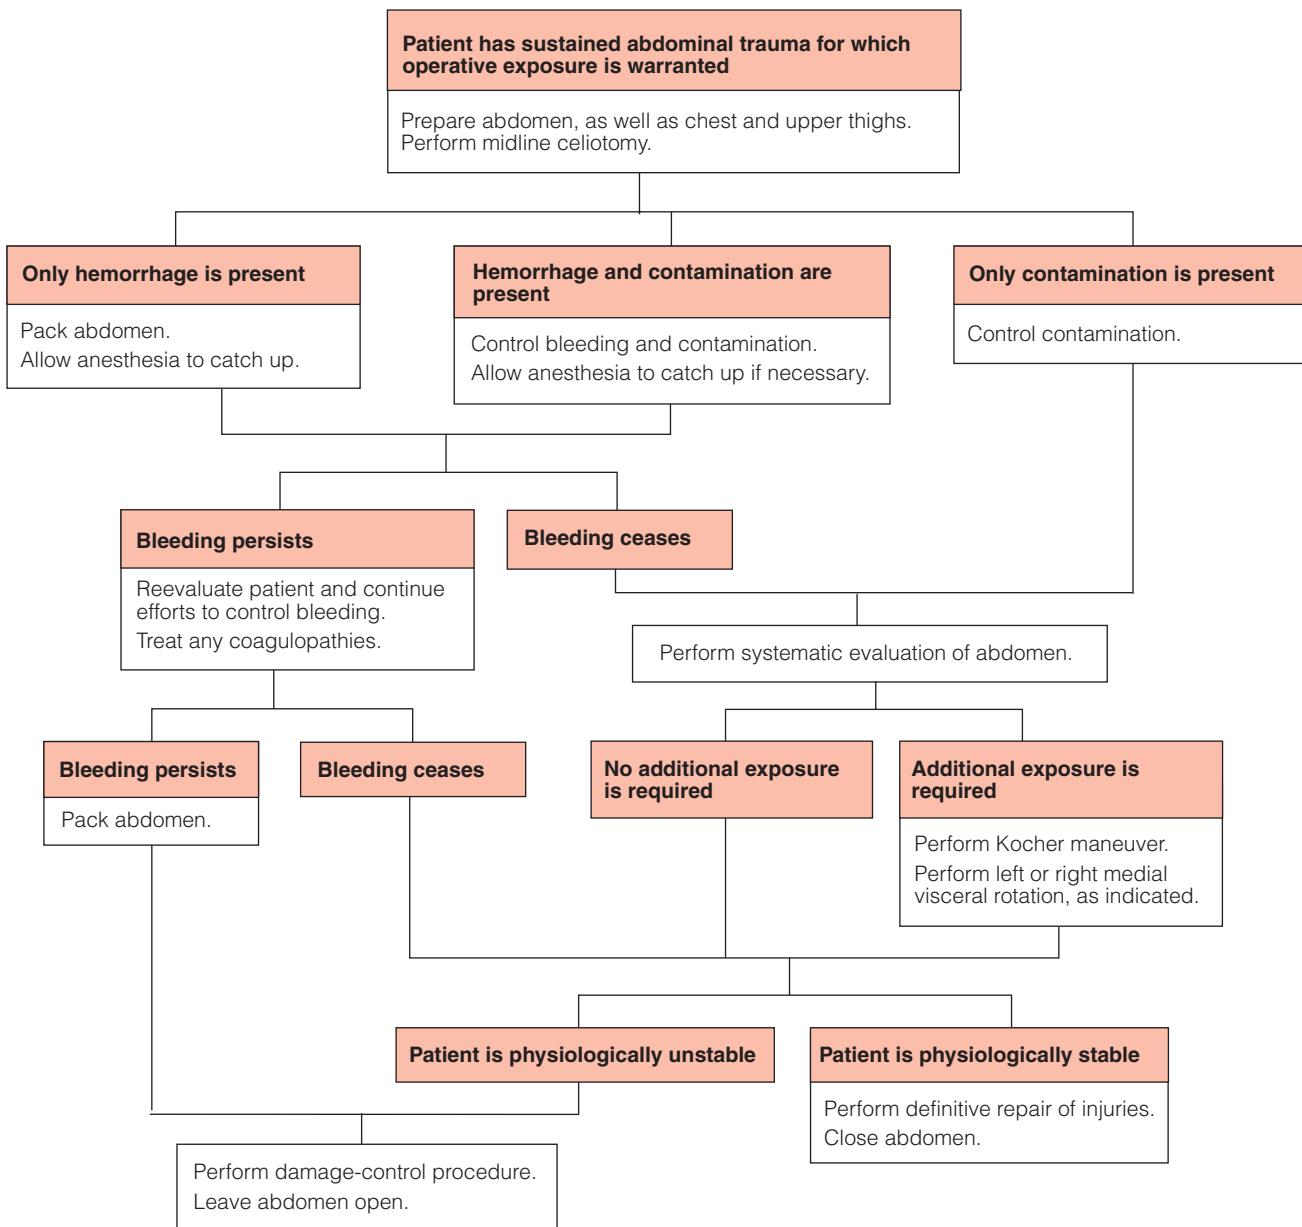

Figure 1 Algorithm outlines the approach to initial operative exposure in abdominal trauma patients.

control can be achieved. Mesenteric bleeding sites are clamped. Solid organs are initially packed as for blunt trauma, then treated with directed repair. In either scenario, bleeding that remains uncontrolled by packing requires immediate attention.

The enteric viscera are then examined in an orderly fashion. The anterior aspect of the stomach is inspected from the esophagogastric junction down to the pylorus. If an injury is present or is strongly suspected on the basis of the mechanism of injury or the presence of a hematoma or soiling, the posterior aspect of the stomach is examined by opening the gastrocolic omentum; this measure also permits examination of the anterior surface of the body of the pancreas. The exploration then continues distally along the course of the GI tract. If duodenal or pancreatic injury is a possibility, the duodenum is mobilized fully by means of a Kocher maneuver. The duodenojejunal junction at the ligament of Treitz is then inspected, and the small intestine is inspected all the way to the ileocecal valve. Both sides of the small intestine must

be examined, and particular care must be taken not to miss an injury at the mesenteric border. Careful consideration should also be given to the possibility of mesenteric vascular injuries, which may be manifested as mesenteric hematomas.

Next, the colon is inspected from the cecum to the rectum. If injuries are present or missile tracts are noted in proximity to a portion of the ascending or descending colon, the retroperitoneal portion of the colon is inspected by incising the white line of Toldt (the retroperitoneal reflection) so as to allow access to the posterior surface of the colon. Finally, the laparotomy pads around the solid organs are removed, one organ at a time, to permit inspection for hemorrhage or injury.

Once the peritoneal survey is complete, the retroperitoneum is inspected for potential injuries. Retroperitoneal hematomas are classified on an anatomic basis: zone 1 is the central area, bounded laterally by the kidneys and extending from the diaphragmatic hiatus to the bifurcation of the vena cava and the aorta; zone 2

comprises the lateral area of the retroperitoneum, from the kidneys laterally to the paracolic gutters; and zone 3 is the pelvic portion [see Figure 2]. Whether exploration is warranted for a retroperitoneal hematoma depends on the mechanism of injury and the location of the hematoma [see Priorities in Management, Repair of Retroperitoneal Injuries, below, and 7:10 Injuries to the Great Vessels of the Abdomen]. A careful evaluation is performed to identify possible occult injuries to organs (e.g., the pancreas, the duodenum, the retroperitoneal colon, the kidneys, and vascular structures).

The initial exploration concludes with a brief pelvic survey aimed at excluding injuries to the rectum or the distal urogenital tract (including the bladder). At the end of the operation, this initial inspection should be repeated, following the same sequence, to confirm that no injuries have been missed.

Operative Exposure

To expose the various organs that may be injured in patients who have sustained abdominal trauma, the surgeon must be familiar with a number of different techniques. In what follows, we detail the operative exposures that enable the surgeon to perform

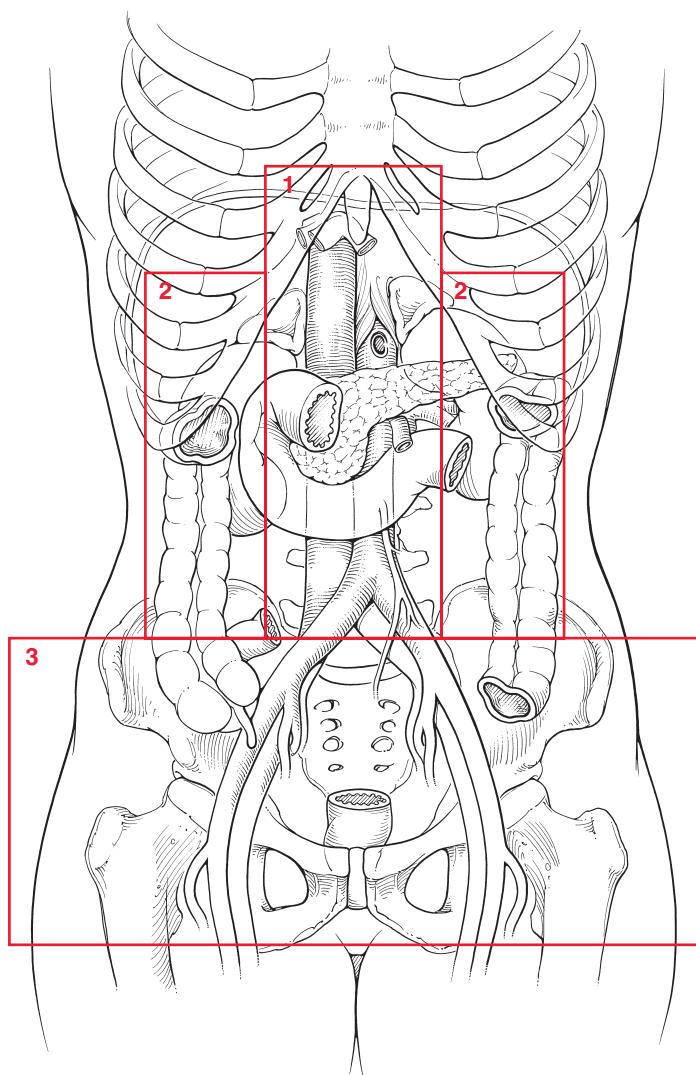

Figure 2 Shown are the anatomic zones of the retroperitoneum: zone 1 (central), zone 2 (flank), and zone 3 (pelvic).

the necessary repairs. The repairs themselves are described in greater detail elsewhere [see 7:6 Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm; 7:7 Injuries to the Stomach, Small Bowel, Colon, and Rectum; 7:8 Injuries to the Pancreas and Duodenum; 7:10 Injuries to the Great Vessels of the Abdomen; and 7:11 Injuries to the Urogenital Tract].

AORTA AND BRANCHES

Control of the aorta can be gained at several different levels, depending on the site of injury. The supraceliac aorta can be exposed by incising the gastrohepatic ligament, retracting the left hemiliver laterally and cephalad, and retracting the stomach caudally. The esophagus and periesophageal fat pad are then mobilized laterally to permit identification of the abdominal aorta at the diaphragmatic hiatus, at which point the aorta can be encircled, clamped, or compressed. This exposure allows control of the aorta, but it is inadequate in terms of providing vascular access for definitive repair. Better exposure of the supraceliac aorta and its branches can be obtained by means of a left medial visceral rotation [see Figure 3]. To perform this maneuver, the splenorenal ligament is mobilized with a combination of sharp and blunt dissection. The left peritoneal reflection is incised from the splenocolic flexure down the paracolic gutter to the level of the distal sigmoid colon. The left-side viscera are then gently mobilized to the midline (mostly with blunt dissection) in a plane anterior to Gerota's fascia. This technique allows exploration of the entire length of the abdominal aorta, the origin of the celiac axis, the origin of the superior mesenteric artery, the left iliac system, and the origin of the right common iliac artery. In addition, it facilitates control of the left renal vascular pedicle before exploration of a left-side zone 2 retroperitoneal hematoma. Alternatively, a variation on the standard left medial visceral rotation (the Mattox maneuver⁶) may be employed, in which the left kidney is also included in the organs that are rotated (the plane being anterior only to the muscles of the posterior abdominal wall). This variant may afford better access to the origin of the left renal artery.

If the injury is more distal, the aorta may be approached in a transperitoneal fashion. The small intestine is retracted to the right, the transverse colon is retracted cephalad, and the descending colon is retracted laterally. The peritoneum is then incised directly over the aorta, and the third and fourth portions of the duodenum are mobilized cephalad. The proximal limit of this dissection extends to the left renal vein, which may be divided if necessary to provide more cephalad access to the aorta. If ligation of the left renal vein is called for, it should be done at a point where the gonadal vein will be left intact to drain the kidney. A more limited dissection may suffice to expose the distal infrarenal aorta. Depending on the injury, distal control may or may not be required. Control may be achieved at the level of the distal infrarenal aorta, above the bifurcation.

Once again, if the patient is in extremis, formal dissection may be curtailed and proximal control achieved either by manually compressing the aorta against the spine at the level of the esophagogastric junction or by using an aortic occluder [see 7:10 Injuries to the Great Vessels of the Abdomen].

VENA CAVA AND BRANCHES

Access to the suprahepatic inferior vena cava can be gained only by either incising the central tendon of the diaphragm or by performing a median sternotomy and opening the pericardium. The infrahepatic inferior vena cava is exposed by performing a right medial visceral rotation (the Cattell-Braasch maneuver) [see Figure

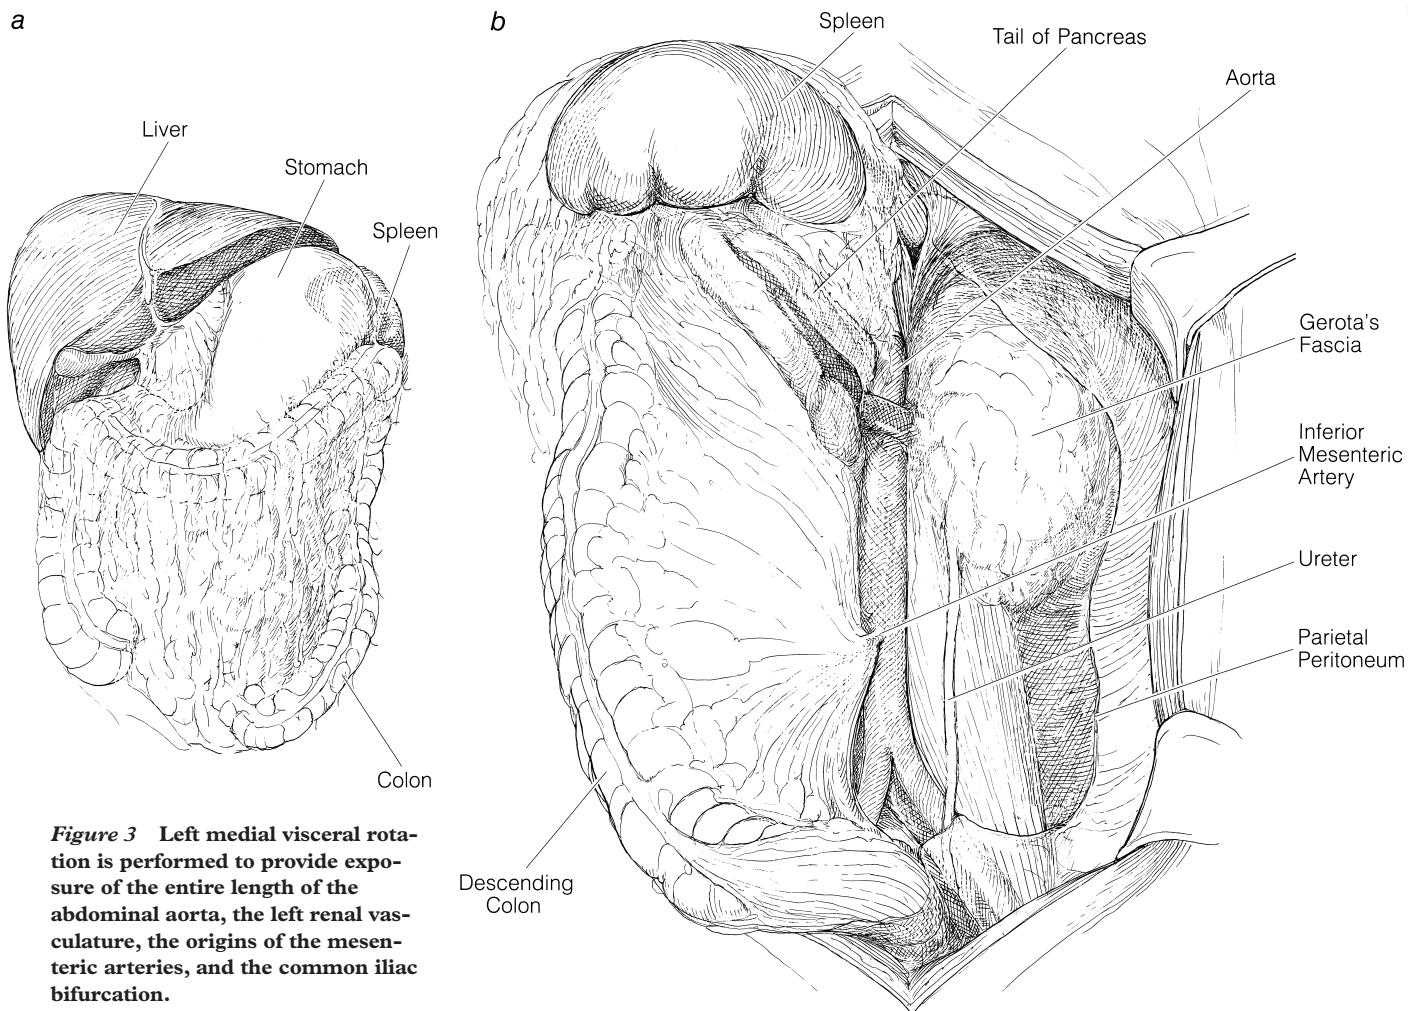

Figure 3 Left medial visceral rotation is performed to provide exposure of the entire length of the abdominal aorta, the left renal vasculature, the origins of the mesenteric arteries, and the common iliac bifurcation.

4]. The right colon is mobilized by taking down the hepatic flexure and then incising the right peritoneal reflection along the paracolic gutter. The colon is once again reflected medially toward the aorta in a plane anterior to Gerota's fascia with careful blunt dissection. If additional exposure is necessary, the inferior margin of the peritoneal incision may be extended to the root of the mesentery—and even beyond, if the inferior mesenteric vein is sacrificed. This exposure permits visualization of both the aorta below the origin of the superior mesenteric artery and the vena cava below the third portion of the duodenum. Exposure of the portion of the vena cava directly below the liver alone can be achieved by performing a Kocher maneuver [see Figure 5] with medial mobilization of the duodenum and the head of the pancreas.

LIVER

Mobilization of the liver begins with division of the round ligament (ligamentum teres), followed by takedown of the falciform ligament (to prevent iatrogenic trauma to the liver capsule during exposure and identification of other intraperitoneal injuries). This mobilization may be extended as far cephalad as is necessary. Further mobilization can be achieved by incising the left triangular ligament, with care taken not to injure the suprahepatic inferior vena cava at the diaphragmatic hiatus during the dissection. When visualization of the right hemiliver is required, the falciform ligament should be incised to its most superior extent, and the right triangular ligament should then be carefully divided. This

step is challenging and may have to be performed partly by palpation, with care taken not to injure the inferior vena cava, the hepatic veins, or the phrenic vessels [see 7:6 *Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm*].

SPLEEN

The spleen can be mobilized into the midline by dividing the phrenicosplenic and splenorenal ligaments with a mixture of sharp and blunt dissection. In cases where the spleen has been injured by blunt trauma, these ligaments often are already disrupted, and this disruption facilitates the dissection. The splenocolic ligament often contains sizeable blood vessels that must be controlled, and the gastrosplenic ligament contains the short gastric arteries. Once the spleen is mobilized into the midline, control of the vascular pedicle can be achieved, the splenic injury can be assessed, and splenorrhaphy or splenectomy can be performed as appropriate [see 7:6 *Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm* and 5:25 *Splenectomy*].

PANCREAS

Intraoperative evidence of a central hematoma, peripancreatic edema, or bile staining in the retroperitoneum or the lesser sac raises the possibility of pancreatic injury. The contents of the lesser sac can be visualized by performing a direct inspection through the gastrohepatic ligament or by dividing the ligament. Alternatively, access can be gained by dividing and ligating two or three gas-

troepiploic arcades of the gastrocolic ligament. If it proves necessary to explore the pancreas, the stomach is separated from the transverse colon by completing the division of the gastrocolic ligament, and a Kocher maneuver is performed to reflect all portions of the duodenum medially, along with the head of the pancreas. The peritoneum lateral to the duodenum is incised, and careful blunt dissection is employed to mobilize the duodenal loop from the common bile duct superiorly to the superior mesenteric vein inferiorly. This mobilization allows inspection of the anterior and posterior surfaces of the head of the pancreas, as well as the uncinate process. If injury to the body or tail of the pancreas is suspected, the splenorenal and splenocolic ligaments are incised. At this point, the spleen and then the pancreas can be mobilized medially to a position near the level of the superior mesenteric vessels, and the anterior and posterior aspects of the body and tail of the pancreas can be examined [see 7:8 *Injuries to the Pancreas and Duodenum*].

KIDNEYS

Operative exposure of the kidneys starts with either a left or a right medial visceral rotation, depending on which kidney is involved. The renal vascular pedicle should be controlled before any hematoma in Gerota's fascia is opened [see 7:11 *Injuries to the Urogenital Tract*]. Repair of the kidney may be facilitated by mobilizing the organ out of Gerota's fascia and retracting it medially.

DUODENUM, BILIARY TRACT, AND SMALL INTESTINE

Exposure of the posterior surface of the duodenum is achieved by means of a Kocher maneuver [see *Pancreas, above*, and *Figure 5*]. This technique is also used when injury to the distal extrahepatic biliary system is suspected. The proximal extrahepatic biliary tree is visualized by using a Kocher maneuver in conjunction with local exploration of the porta hepatis. In patients with injuries to the distal duodenum or the proximal jejunum, division of the ligament of Treitz may also be necessary for accurate identification of the site of injury. Because of the mobility of the small intestine, injuries to this structure generally are readily identified and repaired without additional mobilization.

COLON AND RECTUM

Evidence of staining, pneumatosis, or hematoma in proximity to a portion of the ascending or descending colon, particularly in the setting of related injuries or missile tracts, should prompt a full evaluation of the colon. Because the colon is a partially retroperitoneal structure, the retroperitoneal reflection must be incised to allow inspection of the posterior surface of the colon. Sometimes, rectal injuries are not accessible via an intraperitoneal approach; in this situation, consideration should be given to a diverting colostomy and presacral drainage [see 7:7 *Injuries to the Stomach, Small Bowel, Colon, and Rectum*].^{7,8}

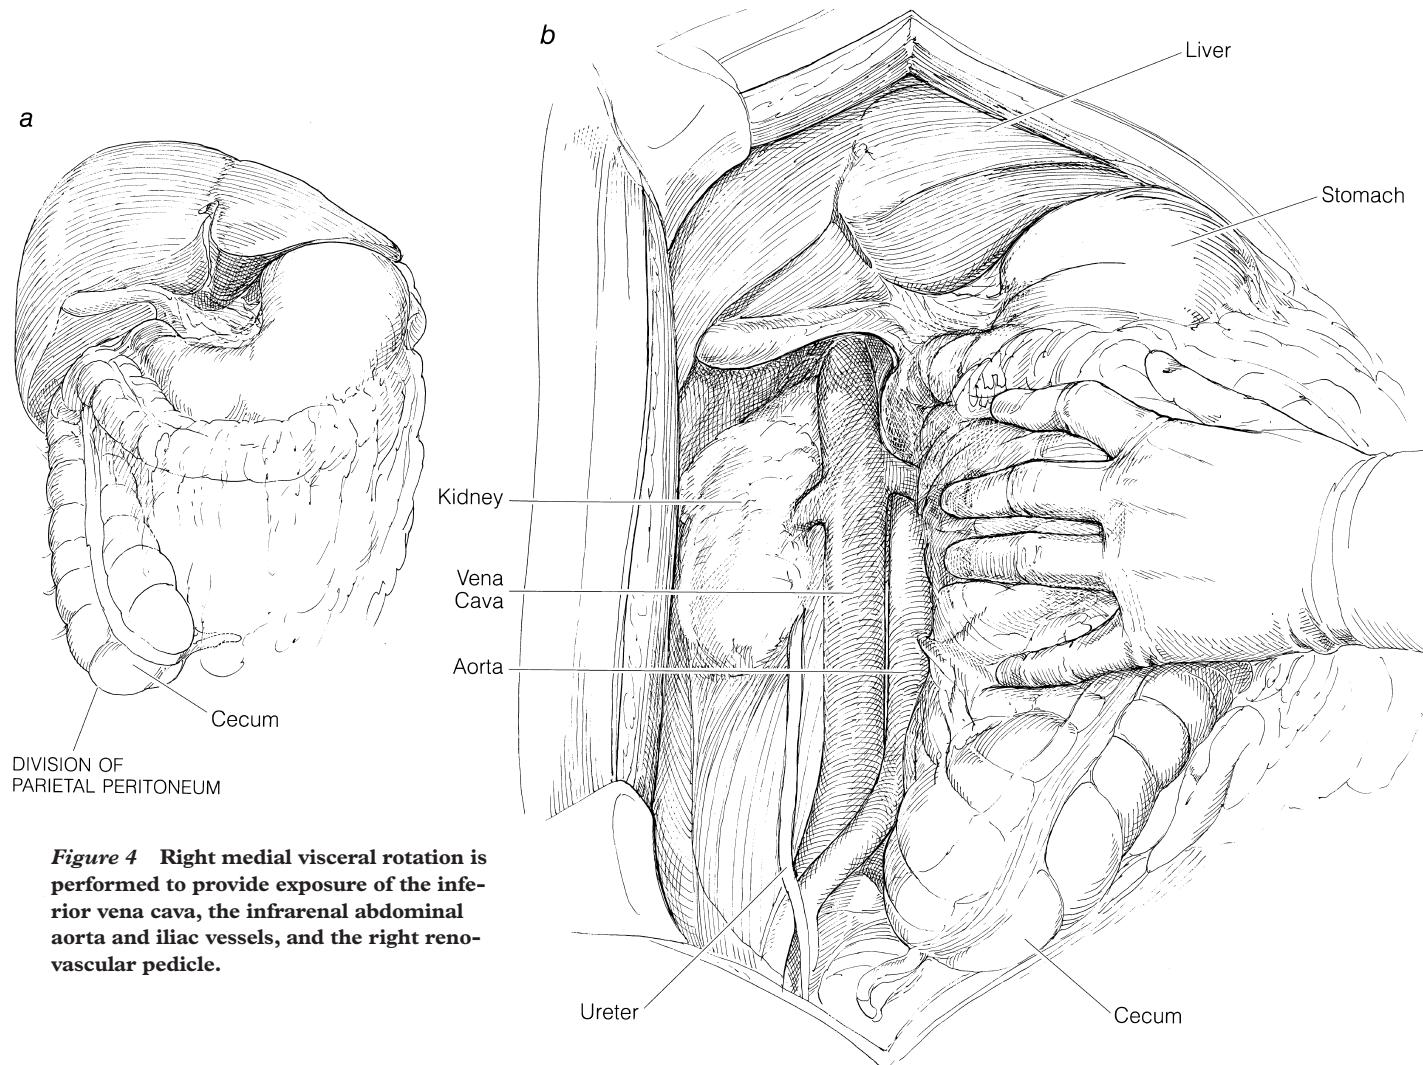

Figure 4 Right medial visceral rotation is performed to provide exposure of the inferior vena cava, the infrarenal abdominal aorta and iliac vessels, and the right renal vascular pedicle.

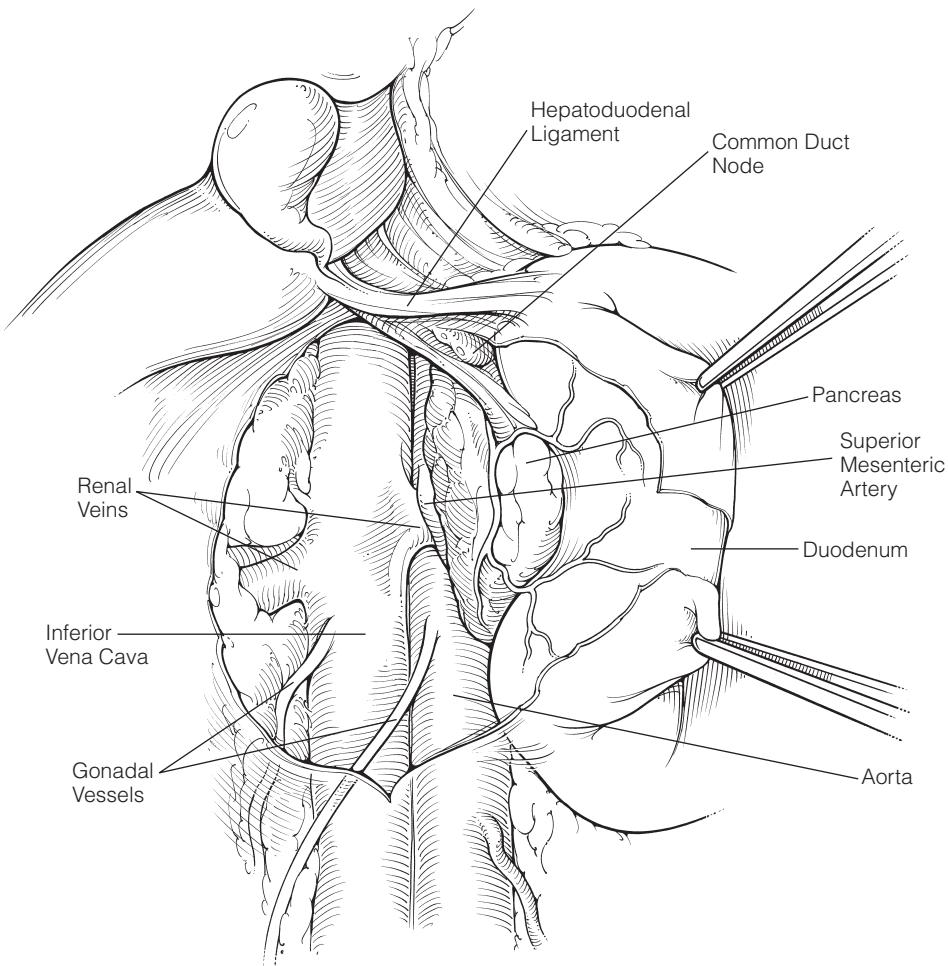

Figure 5 The Kocher maneuver reflects the duodenum and the pancreatic head from the retroperitoneum, allowing access to the infrarenal inferior vena cava as well as to the distal common bile duct, the duodenum, and the pancreatic head.

Priorities in Management

CONTROL OF HEMORRHAGE

In the event that the patient remains hemodynamically unstable because of persistent uncontrolled hemorrhage, the primary focus of the initial exploration is control of bleeding. As noted (see above), the approach to hemorrhage control differs depending on whether the patient sustained blunt trauma or penetrating trauma. In cases of blunt trauma with bleeding from a solid organ, the first thing that should be done is to attempt repeat packing of the specific bleeding site with a sufficient number of laparotomy pads. This is an important skill to master and can be effective as a temporizing measure until either more definitive vascular control can be achieved or coagulopathy can be corrected. In cases of penetrating trauma, bleeding is more effectively managed by means of either vascular control just proximal and distal to the site of injury or direct control at the bleeding site.

When significant hemorrhage is anticipated, control of the injured vessel should be obtained by the operative techniques discussed previously [see Operative Exposure, above]. Given the possibility of exsanguinating hemorrhage, the surgeon must be prepared to gain proximal aortic control at the diaphragmatic hiatus or even within the chest via a left lateral thoracotomy. For immediate control, the aorta can be manually compressed at the hiatus; a padded Richardson retractor, an aortic compressor, or an assistant's hand can then take over this function to allow the surgeon to continue the exploration. If a need for prolonged proximal aortic control is anticipated, an atraumatic aortic vascular clamp should

be placed. Injuries to the proximal abdominal aorta often necessitate that the vessel be controlled in the chest to permit repair.

In patients who have sustained parenchymal injuries to solid viscera, control of the vascular inflow is crucial as both a diagnostic and a therapeutic maneuver. Gaining control of the splenic hilum effectively arrests further splenic hemorrhage. Similarly, use of the Pringle maneuver [see 7:6 *Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm*] to control the vessels in the porta hepatis (the hepatic artery and the portal vein) helps determine the source of perihepatic hemorrhage. This maneuver is initially performed by digitally compressing the portal structures; if digital compression causes the hemorrhage to diminish, the surgeon's hand is replaced with an atraumatic vascular clamp or a Rumel tourniquet. Although the Pringle maneuver can be maintained for at least 30 to 45 minutes without causing permanent liver damage, the clamp or tourniquet should be removed as soon as is feasible. In the vast majority of cases of liver trauma—aside from those involving an injury to the retrohepatic vena cava—the use of the Pringle maneuver, combined with perihepatic packing, should arrest hemorrhage.

In patients who have sustained injuries to the retrohepatic vena cava, it may be necessary to gain vascular control by performing hepatic exclusion before definitive repair can be attempted [see 7:6 *Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm*]. Hepatic exclusion may be achieved by means of either atricaval shunting (which is rarely if ever used^{9,10}) or occlusion of the inferior vena cava both above and below the liver. The latter may lead to significant hemodynamic instability, particularly in volume-depleted

patients; however, it may reasonably be considered in patients whose volume status is adequate. Complete hepatic exclusion involves both (1) atriocaval shunting or clamping of both the infrahepatic and the suprahepatic inferior vena cava and (2) control of hepatic arterial and portal venous inflow.¹¹ In general, injuries to the retrohepatic vena cava are best dealt with by means of damage-control procedures.

Hepatic parenchymal hemorrhage can be challenging, and any of a number of techniques may be used to control it, depending on the location, type, and degree of bleeding. These techniques range from simple electrocauteration and parenchymal suturing to argon beam cauterization, direct vessel ligation, hepatotomy, and even resection [see 7:6 *Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm*.]^{12,13} In difficult cases, it may be advisable to perform an abbreviated laparotomy, pack the liver extensively, and transport the patient to the angiography suite, where selective embolization can be performed; the patient can then be transported to the ICU, undergo warming, and have any coagulopathy corrected before returning to the OR to have the packs removed.

Mesenteric bleeding can usually be controlled with manual compression of the vessel followed by suture ligation. Retroperitoneal hematomas are often harbingers of vascular injury, and proximal and distal vascular control should be obtained before exploration is initiated [see 7:10 *Injuries to the Great Vessels of the Abdomen*]. Typically, bleeding from injured hollow viscera is minor and can be controlled by repairing the injury; on occasion, however, temporary hemostatic suturing or stapling may be required.

CONTROL OF CONTAMINATION

Once hemorrhage has been controlled, the next priority is to control contamination. All gross spillage should be removed from the abdomen with suction and laparotomy pads, and further contamination should be prevented by temporarily closing small enterotomies with Babcock clamps (or, alternatively, with a continuous suture or skin staples). When multiple enterotomies are present, suture closure is preferred (to ensure that multiple clamps are not present in the operative field). If the injuries are in close proximity, the preferred method of controlling intestinal spillage is to apply atraumatic bowel clamps at both the proximal and the distal end of the injury site. Alternatively, if the injured segment will have to be resected, rapid control of further spillage can be obtained by firing a GI stapler at each end of the injured segment.

REPAIR OF VASCULAR INJURIES

Once intestinal contamination has been dealt with, the next priority is definitive vascular repair [see 7:10 *Injuries to the Great Vessels of the Abdomen*]. If proximal and distal control of the injured vessel has not already been obtained, it is obtained at this point. The extent of the vascular injury is determined, dead or devitalized tissue is carefully debrided, and vessel continuity is reestablished if possible. If the injury is not amenable to primary repair and the vessel cannot be ligated, autogenous tissue should be obtained (usually from the proximal greater saphenous vein) and used for either patch angioplasty or interposition grafting. If no suitable autogenous venous tissue is available, synthetic material may be considered as an alternative vascular conduit. For aortic or iliac arterial injuries, primary ligation with subsequent extra-anatomic bypass is an acceptable alternative. In cases in which an abbreviated laparotomy is necessary, vascular shunting may serve as a substitute for definitive repair until hypothermia, coagulopathy, and acidosis are corrected.

REPAIR OF DAMAGED OR DEVITALIZED BOWEL

Once vascular injuries have been addressed, the next priority is to repair any enteric injuries [see 7:7 *Injuries to the Stomach, Small Bowel, Colon, and Rectum*]. Because the stomach is a large and well-vascularized organ, gastric injuries are usually amenable to primary repair. Injuries to the small intestine that involve less than 50% of bowel circumference after debridement of devitalized edges can be repaired with either a single-layer or a two-layer closure; single-layer closure, being less likely to compromise the lumen of the bowel, is generally preferred. In cases involving multiple enterotomies in close proximity or a large area of devitalized tissue, a segmental enterectomy with primary anastomosis is preferable. The anastomosis may be either hand-sewn or stapled; the latter tends to be more expeditious but less cost-effective.

Solitary injuries to the colon that do not necessitate resection after debridement and are not associated with multiple transfusions or significant gross contamination are managed by means of primary closure. Large or multiple injuries to the right colon are best managed with a right hemicolectomy followed by an immediate ileocolic anastomosis. Similar injuries to the left colon are generally treated with resection and proximal diversion. The distal limb may be exteriorized as a mucous fistula, or, if inadequate bowel length renders diversion impossible, a Hartmann procedure may be performed.¹⁴⁻¹⁶

REPAIR OF RETROPERITONEAL INJURIES

Once all injuries within the peritoneal cavity have been addressed, the next priority is to inspect the retroperitoneum once more, paying particular attention to the possibility of hematoma expansion. The decision whether to explore a retroperitoneal hematoma is based on the mechanism of injury and on the zone in which the injury is located. All zone 1 hematomas should be explored regardless of the injury mechanism: they signal possible aortic, vena caval, duodenal, or pancreatic injury. Zone 2 and 3 hematomas should be explored in cases of penetrating trauma but not, as a rule, in cases of blunt trauma (with the exception of expanding zone 2 hematomas).

Before a retroperitoneal hematoma is opened, proximal vascular control should be obtained so that hemorrhage will be minimized once the effect of the tamponade has been lost. Injuries to retroperitoneal organs (e.g., the kidneys, the pancreas, and the adrenal glands) are treated by means of debridement or resection, with drainage as indicated. Vascular injuries are repaired as discussed previously [see Repair of Vascular Injuries, above, and 7:10 *Injuries to the Great Vessels of the Abdomen*].

Closure

GENERAL TECHNIQUE

Once the abdominal exploration has been completed, the abdomen is copiously irrigated with an isotonic crystalloid solution. The closure method employed is typically determined on the basis of five main considerations: (1) the degree of blood loss, (2) the volume of resuscitation fluid received, (3) the degree of contamination, (4) the patient's perceived nutritional status, and (5) the patient's hemodynamic stability. In cases that necessitate an abbreviated or damage-control procedure, the speed with which the closure can be performed may be the most important factor. Provided that the risk of subsequent abdominal compartment syndrome (ACS) is considered to be low, every effort should be made to close the fascia. Fascial closure is usually accomplished with a continu-

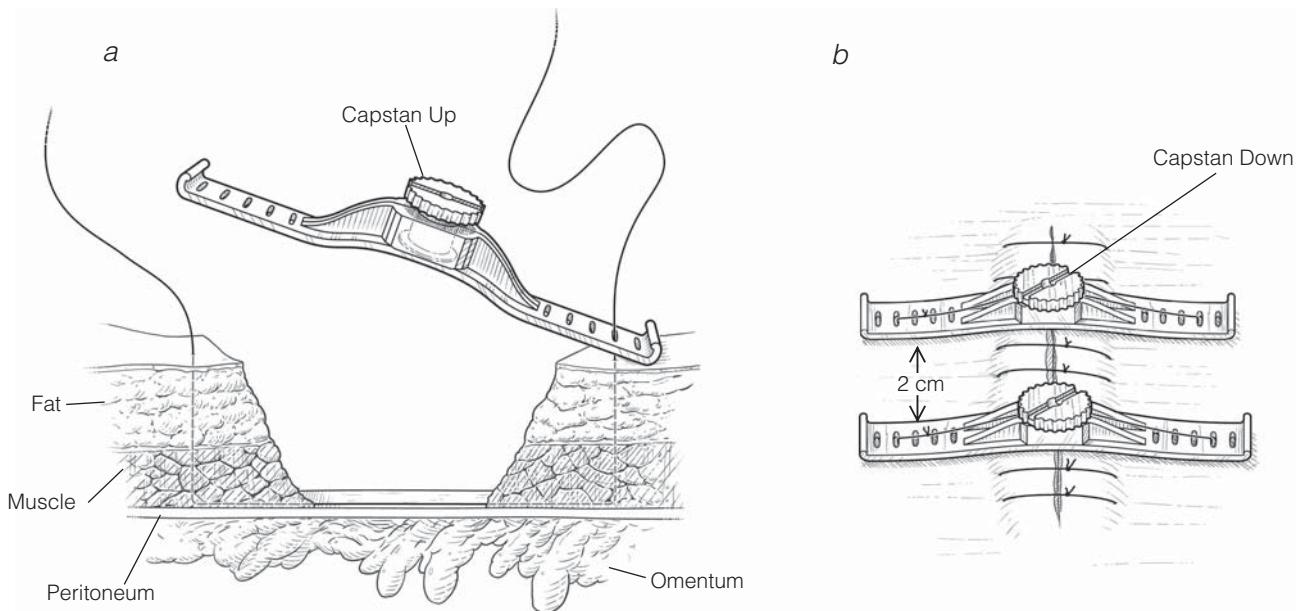

Figure 6 Retention sutures may be used to bolster fascial closure in wounds at high risk for breakdown. (a) Sutures are placed in the subfascial plane. (b) The defect is approximated, and the sutures are tied over skin bridges.

ous absorbable or nonabsorbable monofilament suture, though it may also be accomplished with interrupted sutures. The rate of fascial dehiscence is essentially the same for the two techniques; however, the extent of dehiscence is more limited when closure is done with interrupted sutures.^{17,18} With either technique, it is important not to place excessive tension on the fascial tissues.

In cases where there is a specific reason to be concerned about possible dehiscence (e.g., in patients who are malnourished or obese or are receiving steroid therapy), large monofilament sutures may be placed at intervals within the standard closure to serve as retention sutures. They may be tied over bolsters created from a red rubber catheter or over plastic skin bridges [see Figure 6]. If rapid closure is required, the abdomen may be closed with four or five retention sutures of this type that are placed through the abdominal wall and just above the peritoneum. These sutures must be checked daily and should be loosened if there is evidence that they are cutting through the abdominal skin as a consequence of edema creating increased tension on the wound.

SKIN CLOSURE

If the patient has minor injuries without evidence of enteric contamination, the skin may be closed primarily. Stapled closure is most expeditious, but suture closure is also acceptable. A degree of clinical judgment is required in assessing a wound's suitability for closure. If the skin is closed primarily, it should be inspected daily, and the wound should be opened without delay if there is concern about subsequent infection. Alternatively, primary delayed closure may be performed by leaving the wound open, packed with moist gauze. If the wound shows no evidence of infection when examined after 3 to 5 days, it may be closed with Steri-Strips or with interrupted sutures that are placed (without being tied) during the original operation. If intraperitoneal contamination has occurred, either primary delayed closure should be performed or the wound should be packed and left to heal by secondary intention.

ABBREVIATED OR DAMAGE-CONTROL LAPAROTOMY

If a patient remains unstable after surgical bleeding and contamination have been controlled or is cold and coagulopathic, an

abbreviated or damage-control procedure is indicated. It may be necessary to perform a rapid abdominal closure—with the proviso that further exploration, as well as definitive repair of injuries that have been temporarily controlled, will be required. The decision to perform a damage-control procedure should be made at an early stage, before the so-called lethal triad (hypothermia, acidosis and coagulopathy) has had time to develop. Damage control has undoubtedly led to improved survival for trauma patients, but it has also led to an increase in the number of patients whose abdomens are left open.¹⁹

TEMPORARY ABDOMINAL CLOSURE

When a damage-control procedure is required, it is often most expedient to perform a rapid temporary abdominal closure, then to transport the patient to the intensive care unit. This measure may also be necessary in patients whose abdomens cannot be closed because of intestinal and organ edema caused by intraoperative fluid resuscitation. The simplest form of temporary abdominal closure is the use of towel clips to close only the skin [see Figure 7], in conjunction with the application of a bioocclusive dressing to control fluid loss and contamination. This closure, however, leaves the patient still at risk for subsequent ACS.

The first temporary abdominal dressing described was the so-called Bogotá bag—that is, an empty intravenous fluid bag that was cut in half and sewn to the wound edges. This dressing can still be used in circumstances where no other equipment is available. The so-called vacuum pack technique involves the placement of a sterile plastic drape over the bowel contents and under the fascia, followed by insertion of two or more suction drains, over which sterile towels or open laparotomy pads may be placed. To minimize heat loss and insensible fluid loss, an adherent bioocclusive dressing is placed over the entire dressing and the abdominal wall, with the drains attached to suction. Several commercial devices are now available that can be used to facilitate temporary closure of the open abdomen; these include the VAC Abdominal Dressing System (Kinetic Concepts Inc., San Antonio, Texas) and the Wittmann Patch (Star Surgical, Burlington, Wisconsin).^{20,21}

MANAGEMENT OF THE OPEN ABDOMEN

Once the patient's physiologic status has stabilized, he or she should be returned to the OR for reexploration and definitive repair of any remaining injuries [see *Figure 8*], preferably within 48 hours after the first operation. At this juncture, the abdomen should be assessed for the feasibility of closure. In some patients, the fascial edges cannot be approximated, because of edema; in others, reapproximation may cause a significant rise in intra-abdominal pressure, as evidenced by a rise in pulmonary inspiratory pressures. These patients are at risk for ACS, and their abdomens should be left open.

At this point, if temporary abdominal coverage continues to be required, a temporary abdominal dressing should be placed that attempts to prevent fascial retraction and the associated increased risk of nonclosure of the abdomen. Options include dynamic retention sutures, the Suture Tension Adjustment Reel (STAR) (WoundTEK, Inc., Newport, Rhode Island), the Wittmann Patch, nonabsorbable mesh, fascial zippers, and the VAC Abdominal Dressing System.²⁰⁻²⁵ Once the dressing is placed, it should be

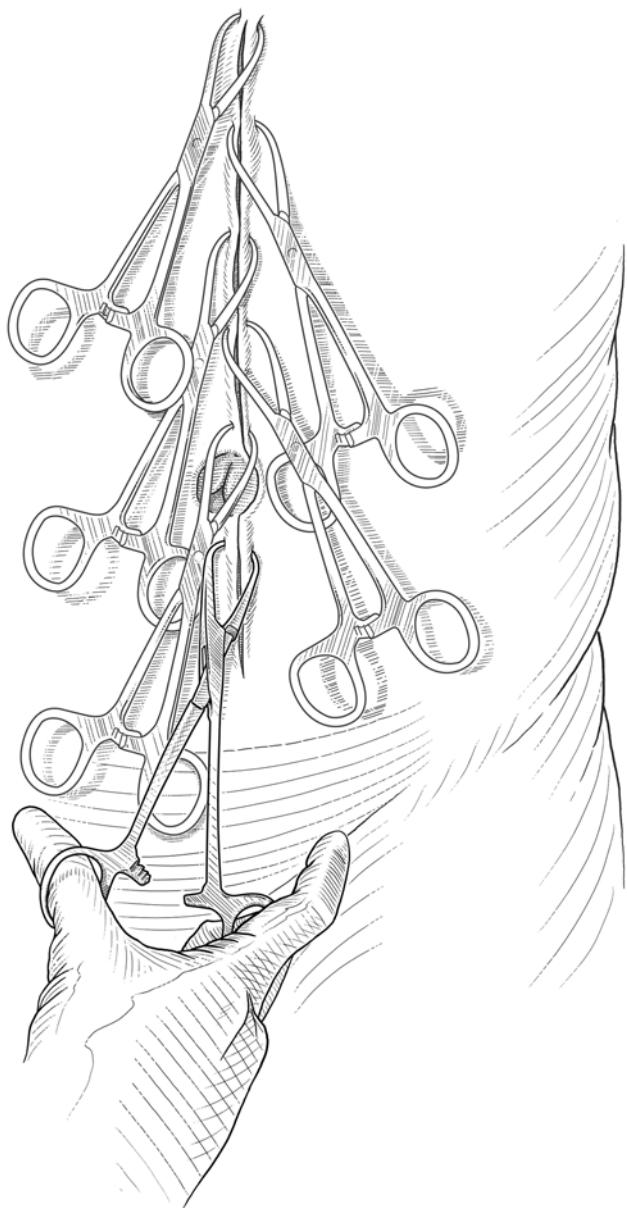

Figure 7 Shown is a “quick out” closure with surgical towel clips.

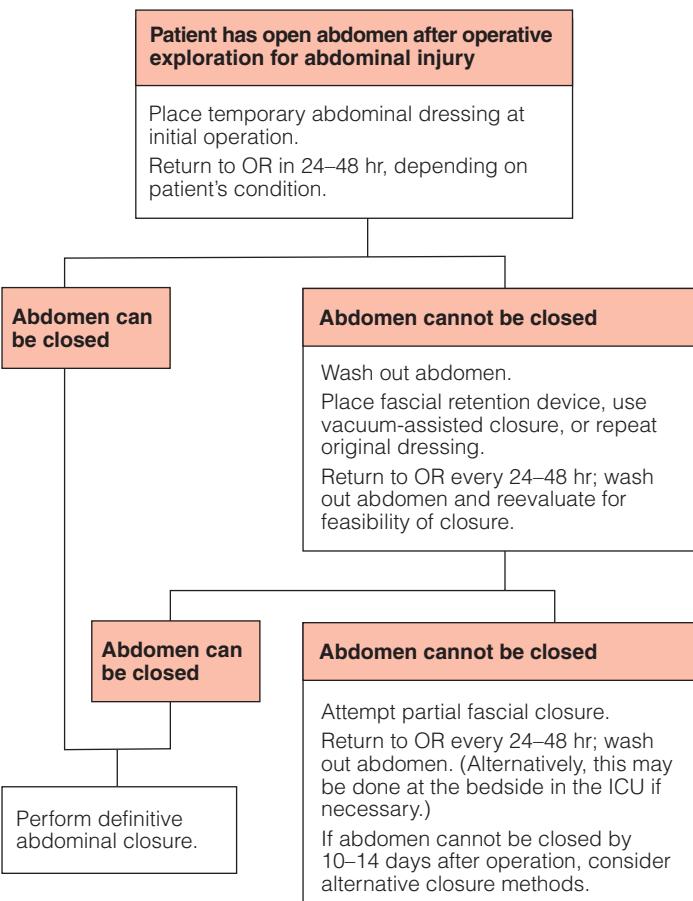

Figure 8 Algorithm outlines the approach to the open abdomen in a patient with abdominal injuries.

examined every 24 to 48 hours, depending on the degree of contamination; this is often best done in the OR, but it may also be done in the ICU if the patient remains unstable. At every subsequent procedure, the fascia should be assessed for the possibility of closure. Partial closure of the incision (i.e., closure of the cephalad and caudad portions) should be considered, even if full closure cannot be accomplished. In approximately 50% of patients, closure of the fascia is not possible; however, there is some evidence to suggest that this figure may be lowered by employing some of the devices now commercially available.^{20,26,27}

ABDOMINAL COMPARTMENT SYNDROME

Patients who undergo fascial closure are at risk for ACS as a consequence of ongoing resuscitation efforts and associated bowel and organ edema. ACS is defined as intra-abdominal hypertension greater than 25 mm Hg in conjunction with dysfunction of one or more organ systems (e.g., pulmonary, renal, or cardiac).^{28,29} Intra-abdominal pressure is determined indirectly by measuring bladder pressure. Bladder pressure can be measured by using an arterial transducer at the level of the symphysis pubis that is connected to the urinary catheter after 30 to 50 ml of sterile water has been introduced. Alternatively, an idea of the intra-abdominal pressure can be gained by raising the Foley tubing above the bed after instillation of the water, then measuring the column.³⁰ A rising trend in pressure can be as significant as a single elevated measurement. Patients who have undergone a long operation, have been the object of vigorous resuscitation efforts, or who have sustained mul-

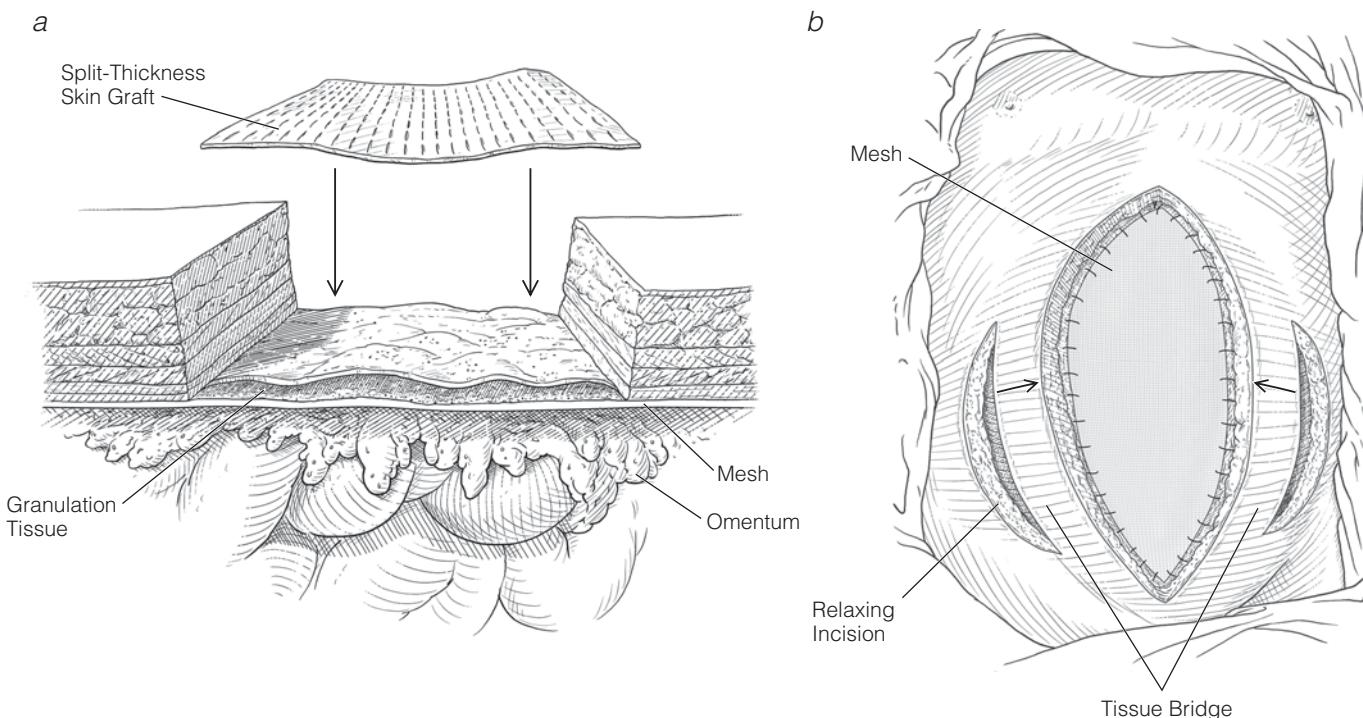

Figure 9 Mesh may be used for temporary or permanent abdominal closure in patients at risk for increased abdominal pressure. (a) Mesh is sutured into the fascial plane, then covered with a split-thickness skin graft. (b) The abdominal defect is closed with mesh.

tiple injuries should be monitored closely for the development of ACS. If the diagnostic criteria for ACS are met, prompt abdominal decompression is indicated. On occasion, this measure may have to be carried out at the bedside in the ICU.

Occasionally, ACS develops in patients who have a temporary abdominal dressing in place (so-called tertiary ACS). Accordingly, it is mandatory to continue to monitor intra-abdominal pressure in these patients.²⁹

CLOSURE OF THE OPEN ABDOMEN

It is important to close the abdomen as early as possible: an open abdomen carries an increased risk of desiccation of the intestines and subsequent fistula formation. In certain patients, however, despite aggressive efforts to close the fascia, it proves impossible to accomplish primary closure, even after many days and repeated procedures. There are several techniques that may be employed to obtain final closure in this situation.

The simplest method is to allow granulation tissue to form over the omentum and the exposed intestines and later, when there is a good clean granulation bed with no evidence of infection, to place a split-thickness skin graft. Alternatively, a piece of absorbable mesh may be placed; this helps facilitate dressing changes, provides a modicum of protection to the intestines, and serves to control evisceration [see Figure 9]. A skin graft can then be placed in the same fashion, once a granulation bed has developed.

Another option is to employ relaxing incisions, either to allow a skin-only closure or to allow the skin to be closed over absorbable mesh. Open skin wounds should be left open to heal by secondary intention. Unfortunately, the use of relaxing incisions will not prevent the formation of large ventral hernias, which will have to be repaired at a later date.

Abdominal fascial defects may also be closed with sheets of nonincorporable synthetic material (e.g., Gore-Tex; W. L. Gore and Associates, Inc., Newark, Delaware). The advantages of these nonabsorbable materials are that they do not react with tissue and that they are associated with a low incidence of complications (e.g., fistula formation). The disadvantages are that they are expensive and that they must ultimately be removed unless the skin can be closed over them to prevent contamination.

Another option for achieving primary closure of the abdomen is component separation of the rectus sheath. The external oblique aponeurosis is incised and mobilized, along with the rectus sheath, to bring the fascia to the midline. Defects as wide as 14 to 20 cm can be bridged in this fashion, but recurrent hernia rates remain high.³¹

Several biosynthetic materials are now available to be used for bridging abdominal fascial defects. One such material is Surgisis (Cook Biotech Inc., West Lafayette, Indiana), a porcine submucosal matrix that can provide scaffolding for the ingrowth of fibrous tissue while supporting abdominal contents and permitting skin closure.³² Another is AlloDerm (LifeCell Corp., Branchburg, New Jersey), a denatured human cadaveric product that can be used in a similar fashion to replace denuded fascia or to bridge the fascial gap in cases where primary closure cannot be accomplished.^{33,34} At present, long-term follow-up data are lacking for both products, and their use is further limited by their very high cost.

Morbidity is very high in these patients; subsequent complications range from prolonged ventilator dependence to enteric fistulas to massive ventral hernias.^{35,36} Major ventral hernias represent a significant technical challenge and should not be repaired until the patient's recovery from injury is complete and his or her nutritional and general status has returned to normal. This may take as long as 12 months from the time of the initial trauma.

10 INJURIES TO THE GREAT VESSELS OF THE ABDOMEN

David V. Feliciano, M.D., F.A.C.S.

In patients who have injuries to the great vessels of the abdomen, the findings on physical examination generally depend on whether a contained hematoma or active hemorrhage is present.¹ In the case of contained hematomas around the vascular injury in the retroperitoneum, the base of the mesentery, or the hepatoduodenal ligament, the patient often has only modest hypotension in transit or on arrival at the emergency center; the hypotension can be temporarily reversed by the infusion of fluids and may not recur until the hematoma is opened at the time of laparotomy. This is usually the situation when an abdominal venous injury is present. In the case of active intraperitoneal hemorrhage, the patient typically has significant hypotension and may have a distended abdomen on arrival. Another physical finding that is occasionally noted in association with an injury to the common or external iliac artery is intermittent or complete loss of a pulse in the ipsilateral femoral artery; this finding in a patient with a transpelvic gunshot wound is pathognomonic of an injury to the iliac artery.

Injuries to the great vessels of the abdomen are caused by penetrating wounds in 90% to 95% of cases; accordingly, they are often accompanied by injuries to multiple intra-abdominal organs, including those in the gastrointestinal tract.²⁻⁵ The general principles governing the sequencing of repairs of injuries to the great vessels and the GI tract are outlined elsewhere [see 7:9 *Operative Exposure of Abdominal Injuries and Closure of the Abdomen*].

A hematoma [see Figures 1 and 2] or hemorrhage associated with an injury to a great vessel of the abdomen occurs in one of

the three zones of the retroperitoneum or in the portal-retrohepatic area of the right upper quadrant [see 7:9 *Operative Exposure of Abdominal Injuries and Closure of the Abdomen*]. The magnitude of injury is usually described according to the Abdominal Vascular Organ Injury Scale, devised in 1992 by the American Association for the Surgery of Trauma [see Table 1].⁶

Injuries in Zone 1

SUPRAMESOCOLIC

It is helpful to divide midline retroperitoneal hematomas into those that are supramesocolic and those that are inframesocolic.¹ Hematoma or hemorrhage in the midline supramesocolic area of zone 1 is cause to suspect the presence of an injury to the suprarenal aorta, the celiac axis, the proximal superior mesenteric artery, or the proximal renal artery.

When a hematoma is present in the midline supramesocolic area, one usually has time to perform left medial visceral rotation [see Figure 3 and 7:9 *Operative Exposure of Abdominal Injuries and Closure of the Abdomen*.^{7,8} The advantage of this technique is that it allows visualization of the entire abdominal aorta, from the aortic hiatus of the diaphragm to the common iliac arteries [see Figure 4]. Obvious disadvantages include the 4 to 5 minutes required to complete the maneuver when the surgeon is inexperienced; the risk of damage to the spleen, the left kidney, or the

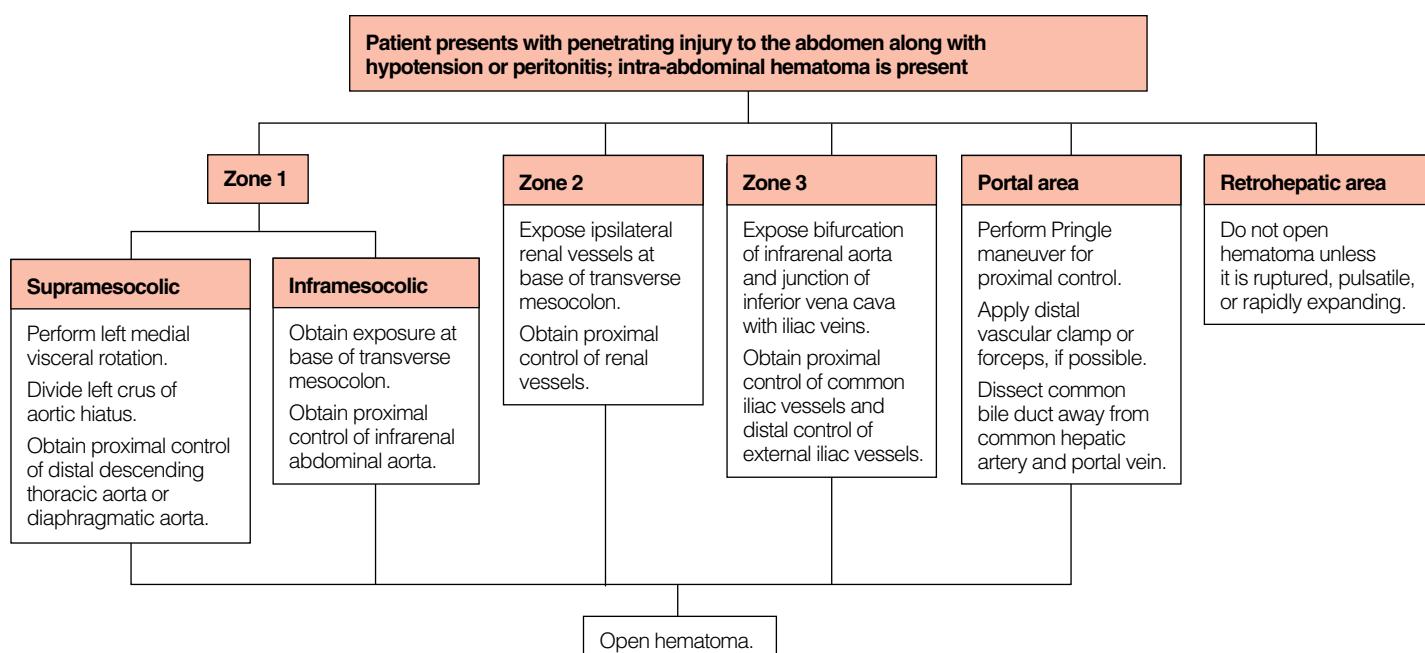

Figure 1 Algorithm illustrates management of intra-abdominal hematoma found at operation after penetrating trauma.

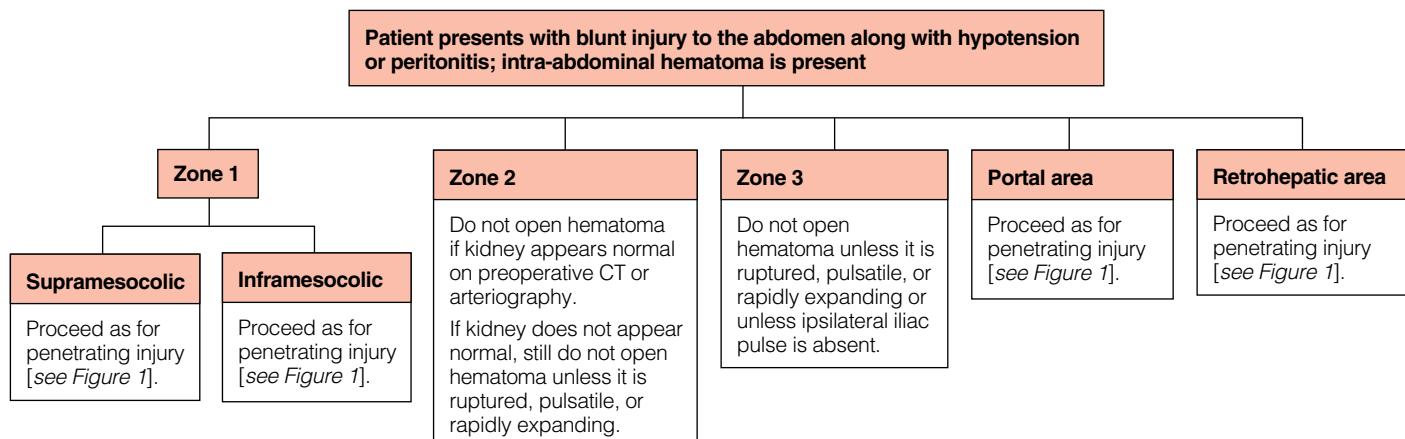

Figure 2 Algorithm illustrates management of intra-abdominal hematoma found at operation after blunt trauma.

posterior left renal artery as the maneuver is performed; and the anatomic distortion that results when the left kidney and the left renal artery are rotated anteriorly. When the hematoma is near the aortic hiatus of the diaphragm, it may be advisable to leave the left kidney in its fossa, thereby eliminating potential damage

to the structure as well as the distortion resulting from rotation. Because of the density of the celiac ganglia and nerve plexus and the lymphatic vessels surrounding the upper abdominal aorta, this portion of the aorta is difficult to visualize even when left medial visceral rotation has been performed. It is frequently help-

Table 1 AAST Abdominal Vascular Organ Injury Scale

Grade	Characteristics of Injury	OIS Grade	ICD-9	AIS-90
I	Unnamed superior mesenteric artery or superior mesenteric vein branches	I	902.20/902.39	NS
	Unnamed inferior mesenteric artery or inferior mesenteric vein branches	I	902.27/902.32	NS
	Phrenic artery or vein	I	902.89	NS
	Lumbar artery or vein	I	902.89	NS
	Gonadal artery or vein	I	902.89	NS
	Ovarian artery or vein	I	902.81/902.82	NS
II	Other unnamed small arterial or venous structures requiring ligation	I	902.90	NS
	Right, left, or common hepatic artery	II	902.22	3
	Splenic artery or vein	II	902.23/902.34	3
	Right or left gastric arteries	II	902.21	3
	Gastroduodenal artery	II	902.24	3
	Inferior mesenteric artery, trunk, or inferior mesenteric vein, trunk	II	902.27/902.32	3
III*	Primary named branches of mesenteric artery (e.g., ileocolic artery) or mesenteric vein	II	902.26/902.31	3
	Other named abdominal vessels requiring ligation or repair	II	902.89	3
	Superior mesenteric vein, trunk	III	902.31	3
	Renal artery or vein	III	902.41/902.42	3
	Iliac artery or vein	III	902.53/902.54	3
IV†	Hypogastric artery or vein	III	902.51/902.52	3
	Vena cava, infrarenal	III	902.10	3
	Superior mesenteric artery, trunk	IV	902.25	3
	Celiac axis, proper	IV	902.24	3
V†	Vena cava, suprarenal and infrahepatic	IV	902.10	3
	Aorta, infrarenal	IV	902.00	4
	Portal vein	V	902.33	3
	Extraparenchymal hepatic vein	V	902.11	3 (hepatic vein) 5 (liver + veins)
	Vena cava, retrohepatic or suprahepatic	V	902.19	5
	Aorta, suprarenal and subdiaphragmatic	V	902.00	4

Note: This classification is applicable to extraparenchymal vascular injuries. If the vessel injury is within 2 cm of the parenchyma of a specific organ, one should refer to the injury scale for that organ.

*Increase grade by I if there are multiple injuries involving > 50% of vessel circumference.

†Reduce grade by I if laceration is < 25% of vessel circumference.

AAST—American Association for the Surgery of Trauma AIS—Abbreviated Injury Scale ICD—International Classification of Diseases

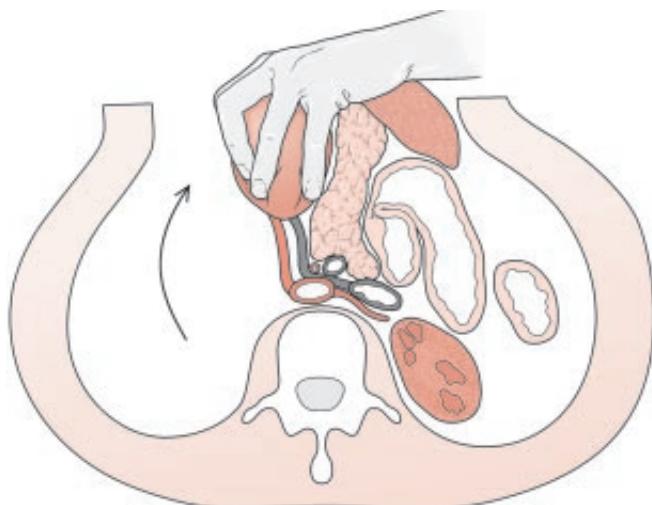

Figure 3 Left medial visceral rotation is performed by means of sharp and blunt dissection with elevation of the left colon, the left kidney, the spleen, the tail of the pancreas, and the gastric fundus.

ful to transect the left crus of the aortic hiatus in the diaphragm at the 2 o'clock position to allow exposure of the distal descending thoracic aorta above the hiatus. Visualization of this portion of the vessel is much easier to achieve than visualization of the diaphragmatic or visceral abdominal aorta below, and an aortic cross-clamp can be applied much more quickly at this level.

Active hemorrhage from the midline supramesocolic area is controlled temporarily by packing with laparotomy pads or using an aortic compression device [see Figure 5].^{9,10} A definitive approach is to divide the lesser omentum manually, retract the stomach and esophagus to the left, and manually dissect in the area just below the aortic hiatus of the diaphragm to obtain rapid exposure of the supraceliac abdominal aorta.¹¹ An aortic cross-clamp can then be applied. Distal control of the upper abdominal aorta is difficult to obtain because of the presence of the anteriorly located celiac axis and superior mesenteric artery. In young trauma patients who are

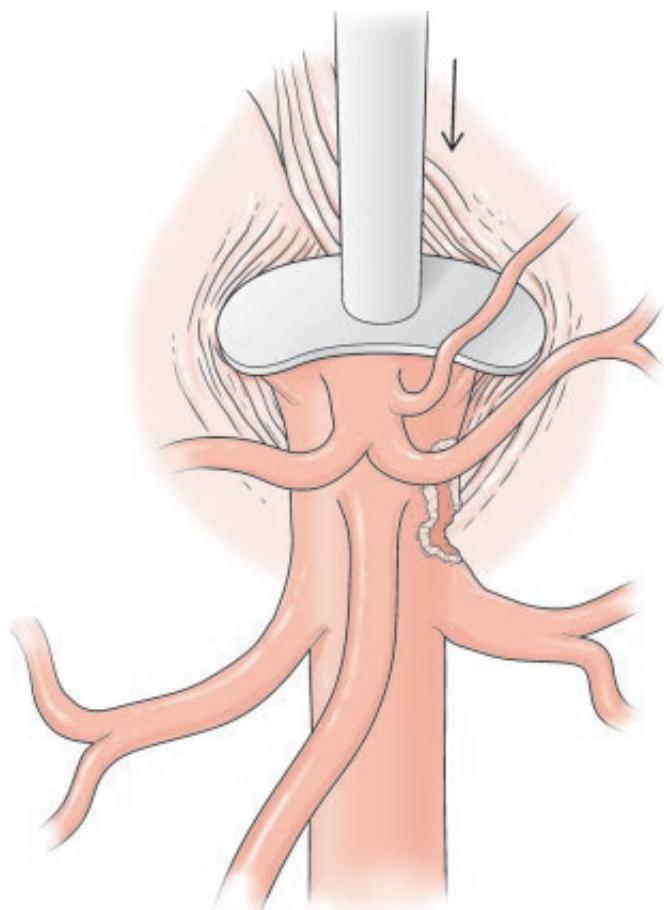

Figure 5 An aortic compression device is used to control hemorrhage from the visceral portion of the abdominal aorta.

Figure 4 Shown is an autopsy view of the supraceliac aorta and the celiac axis, the proximal superior mesenteric artery, and the medially rotated left renal artery after removal of lymphatic and nerve tissue.

otherwise healthy, ligation and division of the celiac axis allow easier application of the distal aortic clamp and better exposure of the supraceliac area for subsequent vascular repair.¹²

Small penetrating wounds to the supraceliac abdominal aorta are repaired with a continuous 3-0 or 4-0 polypropylene suture. If two small perforations are adjacent to each other, they can be connected and the defect closed in a transverse fashion. If closure of a perforation would result in significant narrowing of the aorta or if a portion of the aortic wall is missing, patch aortoplasty with polytetrafluoroethylene (PTFE) is indicated. On rare occasions, in patients with extensive injuries to the diaphragmatic or supraceliac aorta, resection of the area of injury and insertion of a vascular conduit are indicated. Even though many of these patients have associated gastric, enteric, or colonic injuries, the most appropriate prosthesis with such a life-threatening injury is a 12 mm or 14 mm Dacron or PTFE graft [see Figure 6].¹³ Provided that vigorous intraoperative irrigation is performed after repair of GI tract perforations, that proper graft coverage is ensured, and that perioperative antibiotics are appropriately employed, it is extraordinarily rare for a prosthesis inserted in the healthy aorta of a young trauma patient to become infected.

The aortic prosthesis is sewn in place with a continuous 3-0 or 4-0 polypropylene suture. Both ends of the aorta are flushed before the distal anastomosis is completed, and the distal aortic cross-clamp is removed before the final knot is tied to eliminate air from the system. The proximal aortic cross-clamp is removed very slowly as the anesthesiologist rapidly infuses fluids and intra-

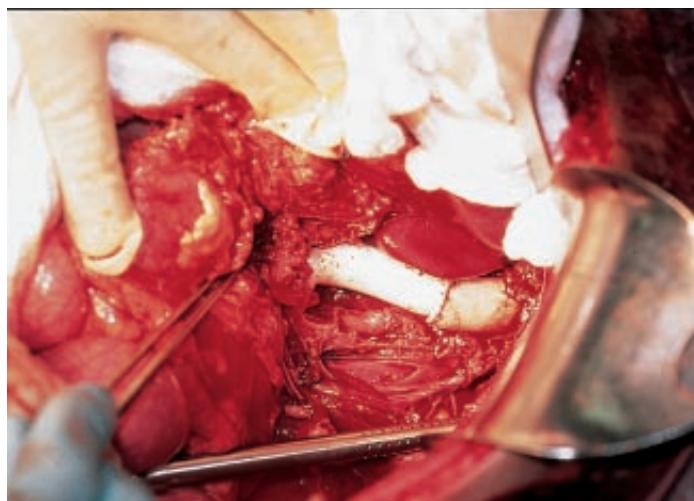

Figure 6 A 22-year-old man with a gunshot wound to the right upper quadrant had injuries to the prepyloric area of the stomach and to the supraceliac abdominal aorta. The aortic injury was managed by means of segmental resection and replacement with a 16 mm polytetrafluoroethylene (PTFE) graft. The patient went home 46 days after injury.

venous bicarbonate to reverse so-called washout acidosis from the previously ischemic lower extremities. The retroperitoneum is then irrigated with an antibiotic solution and closed over the graft in a watertight fashion with an absorbable suture.

Cross-clamping of the diaphragmatic or supraceliac abdominal aorta in a patient with hemorrhagic shock results in severe ischemia of the legs. Restoration of flow through the repaired abdominal aorta may then cause a reperfusion injury in addition to the ischemic edema that develops in the muscle compartments below the knee. In a patient who is hemodynamically stable after repair of the suprarenal abdominal aorta and other injuries, measurement of compartmental pressures below the knees should be performed before the patient is moved from the operating room. Pressures in the range of 30 to 35 mm Hg are likely to rise in the intensive care unit; accordingly, at many centers, bilateral below-the-knee two-incision four-compartment fasciotomies would be performed in this situation.

The survival rate in patients with injuries to the suprarenal abdominal aorta had been 30% to 35% but was lower than 10% in one 2001 review.^{4,13}

Injuries to branches of the celiac axis are often difficult to repair because of the amount of dissection required to remove the dense neural and lymphatic tissue in this area. Because most patients have excellent collateral flow in the upper abdomen, major injuries to either the left gastric or the proximal splenic artery generally should be ligated. Because the common hepatic artery may have a larger diameter than either of these two arteries, an injury to this vessel can occasionally be repaired by means of lateral arteriorrhaphy, an end-to-end anastomosis, or the insertion of a saphenous vein graft. One should not worry about ligating the common hepatic artery proximal to the origin of the gastroduodenal artery: there is extensive collateral flow to the liver from the midgut. When the entire celiac axis is injured, it is best to ligate all three vessels and forgo any attempt at repair.

Injuries to the superior mesenteric artery are managed according to the anatomic level of the perforation or thrombosis.¹⁴ On rare occasions, in patients with injuries beneath the neck of the pancreas, one may have to transect the pancreas to obtain proximal control.

Another option is to perform left medial visceral rotation (see above) and apply a clamp directly to the origin of the superior mesenteric artery. Injuries to the superior mesenteric artery in this area or just beyond the base of the mesocolon are often associated with injuries to the pancreas. The potential for a postoperative leak from the injured pancreas near the arterial repair has led numerous authors to suggest that any extensive injury to the artery at this location should be ligated [see *Figure 7*].

Because of the intense vasoconstriction of the distal superior mesenteric artery in patients who have sustained exsanguinating hemorrhage from more proximal injuries treated with ligation, the collateral flow from the foregut and hindgut is often inadequate to maintain the viability of the organs in the distal midgut, especially the cecum and the ascending colon. Therefore, it is safest to place a saphenous vein or PTFE graft on the distal infrarenal aorta, away from the pancreatic injury and any other upper abdominal injuries.¹⁵ Such a graft can be tailored to reach the side or the anterior aspect of the superior mesenteric artery, or it can be attached to the transected distal superior mesenteric artery in an end-to-end fashion without significant tension [see *Figure 8*]. Soft tissue must be approximated over the aortic suture line of the graft to prevent the development of an aortoenteric fistula in the postoperative period.

In patients with severe shock from exsanguination caused by a complex injury to the superior mesenteric artery, damage-control laparotomy is indicated [see *Damage-Control Laparotomy, below*]: the injured area should be resected and a temporary intraluminal Argyle, Javid, or Pruitt-Inahara shunt inserted to maintain flow to the midgut during resuscitation in the surgical intensive care unit.¹⁶

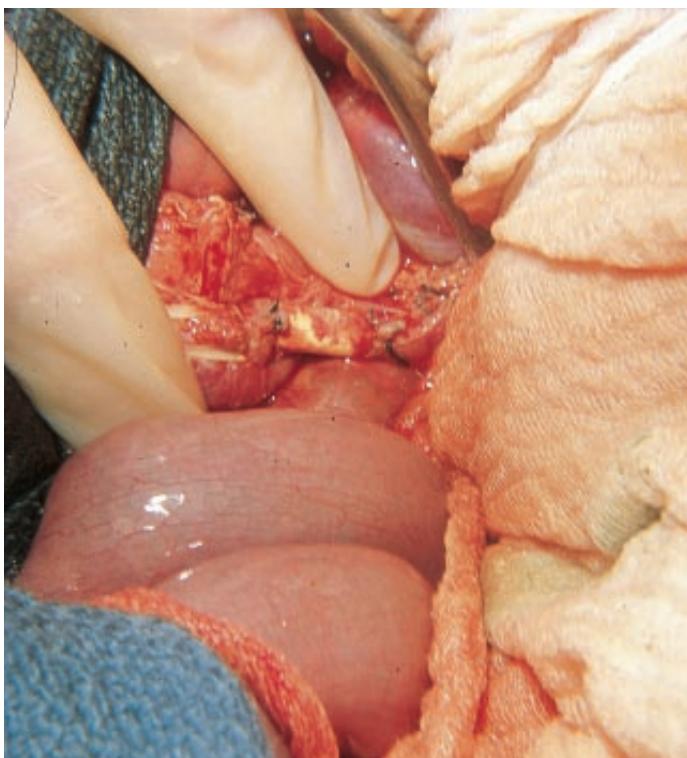

Figure 7 An 18-year-old man experienced a gunshot wound to the head of the pancreas and the proximal superior mesenteric artery. A Whipple procedure was performed, and a 6 mm PTFE graft was placed in the artery. The artery-graft suture line dehisced secondary to a pancreatic leak on day 30 after injury, and the patient died on day 42.

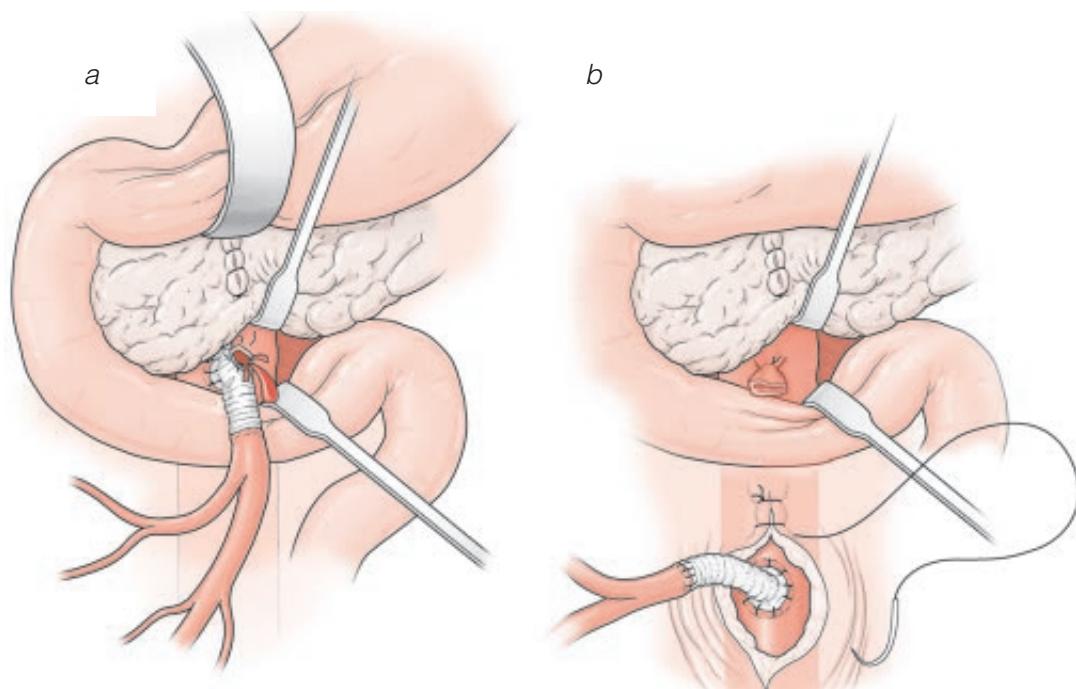

Figure 8 (a) When complex grafting procedures to the superior mesenteric artery are necessary, it may be dangerous to place the proximal suture line near an associated pancreatic injury. (b) The proximal suture line should be on the lower aorta, away from the upper abdominal injuries, and should be covered with retroperitoneal tissue.

When ligation is indicated for more distal injuries to the superior mesenteric artery, segments of the ileum or even the right colon may have to be resected because of ischemia.

The survival rate in patients with penetrating injuries to the superior mesenteric artery is approximately 50% to 55% overall [see Table 2] but only 20% to 25% when any form of repair more complex than lateral arteriorrhaphy is necessary.^{1-4,15,17}

An injury to the proximal renal artery may also be present under a supramesocolic hematoma or bleeding area. When active hemorrhage is present, control of the supraceliac abdominal aorta in or just below the aortic hiatus must be obtained. When only a hematoma or a known thrombosis of the proximal renal artery is present, proximal vascular control can be obtained by elevating the transverse mesocolon and dissecting the vessel from the lateral aspect of the abdominal aorta. Options for repair of either the proximal or the distal renal artery are described elsewhere [see Injuries in Zone 2, below].

The superior mesenteric vein is the other great vessel of the abdomen that may be injured in the supramesocolic or retromesocolic area of the midline retroperitoneum. Because of the overlying pancreas, the proximity of the uncinate process, and the close association of this vessel with the superior mesenteric artery, repair of the superior mesenteric vein is quite difficult. As with injuries to the superior mesenteric artery (see above), one may have to transect the neck of the pancreas between noncrushing vascular or intestinal clamps to gain access to a perforation of the superior mesenteric vein. An injury to this vein below the inferior border of the pancreas can be managed by compressing it manually between one's fingers as an assistant places a continuous 5-0 polypropylene suture to complete the repair. When a penetrating injury to the vein has a posterior component, one must ligate multiple collateral vessels entering the vein in this area to achieve proper visualization.

There is excellent evidence that young trauma patients tolerate ligation of the superior mesenteric vein well when vigorous postoperative fluid resuscitation is performed to reverse the peripheral hypovolemia that results from splanchnic hypervolemia.^{18,19} Typically, ligation is followed almost immediately by swelling of the midgut and discoloration suggestive of impending ischemia. In such cases, temporary coverage of the midgut with a silo, followed by early reoperation, may be necessary to reassure the operating surgeon that the ischemia has not become permanent.

The survival rate in patients with injuries to the superior mesenteric vein ranges from 36% to 71%, depending on whether other vascular injuries are present [see Table 3].^{1-4,18}

INFRAAMESOCOLIC

The lower area of the midline retroperitoneum in zone 1 is known as the midline inframesocolic area. Injuries to either the infrarenal abdominal aorta or the inferior vena cava occur in this area.

An injury to the inframesocolic abdominal aorta that is under a hematoma is controlled by performing the same maneuvers used to gain proximal control of an infrarenal abdominal aortic aneurysm. The infrarenal abdominal aorta is exposed by pulling the transverse mesocolon up toward the patient's head, eviscerating the small bowel to the right side of the abdomen, and opening the midline retroperitoneum until the left renal vein is exposed. A proximal aortic cross-clamp is then placed immediately inferior to this vessel [see Figure 9]. When the entire inframesocolic area is distorted by the presence of a large pulsatile hematoma, the inexperienced trauma surgeon should remember that the hole in the infrarenal abdominal aorta is under the highest point of the hematoma (the so-called Mt. Everest phenomenon). When there is active hemorrhage from this area, rapid proximal control is obtained in the same fashion or, if necessary because of the need

Table 2 Survival after Injuries to Arteries in the Abdomen

Injured Artery	Asensio et al ² (2000)		Davis et al ³ (2001)*	Tyburski et al ⁴ (2001)
	Isolated Injury	With Other Arterial Injury		
Abdominal aorta as a whole	21.7% (10/46)	17.6% (3/17)	39.1% (25/64)	21.1% (15/71)
Pararenal to diaphragm	—	—	—	8.3% (3/36)
Infrarenal	—	—	—	34.2% (12/35)
Superior mesenteric artery	52.4% (11/21)	28.6% (2/7)	53.3% (8/15)	48.8% (20/41)
Renal artery	62.5% (5/8)	33.3% (2/6)	56.2% (9/16)	73.7% (14/19)
Iliac artery				
Common	—	—	55.5% (5/9)	44.7% (17/38)
External	—	—	65.2% (30/46)	62.5% (20/32)

*Excludes patients who exsanguinated before repair or ligation.

to apply compression, by dividing the lesser omentum and applying the cross-clamp just below the aortic hiatus of the diaphragm. Distal control of the infrarenal abdominal aorta is obtained by dividing the midline retroperitoneum down to the aortic bifurcation, taking care to avoid the origin of the inferior mesenteric artery on the left side.

Injuries to the infrarenal aorta are repaired by means of lateral aortorrhaphy, patch aortoplasty, an end-to-end anastomosis, or insertion of a Dacron or PTFE graft. Much as with injuries to the suprarenal abdominal aorta in young trauma patients, it is rarely possible to place a tube graft larger than 12 or 14 mm. Because the retroperitoneal tissue is often thin at this location in young patients, an important adjunctive measure after the aortic repair is to mobilize the gastrocolic omentum, flip it into the lesser sac superiorly, and then bring it down over the infrarenal aortic graft through a hole in the left transverse mesocolon. An alternative is to mobilize the gastrocolic omentum away from the right side of the colon and then swing the mobilized tissue into the left lateral gutter just below the ligament of Treitz to cover the graft. With either technique, it is mandatory to suture the viable omental pedicle superior to the aortic suture line to prevent a postoperative aortoduodenal fistula.^{20,21}

The survival rate in patients with injuries to the infrarenal abdominal aorta had been approximately 45% but was 34% in a 2001 review [see Table 2].¹⁻⁴

Injury to the inferior vena cava below the liver should be suspected when the aorta is found to be intact underneath an inframesocolic hematoma, when such a hematoma appears to be more extensive on the right side of the abdomen than on the left, or when there is active hemorrhage coming through the base of the mesentery of the ascending colon or the hepatic flexure. It is certainly possible to visualize the inferior vena cava through the midline retroperitoneal exposure just described (see above); however, most surgeons are more comfortable with visualizing the vessel by mobilizing the right half of the colon and the C loop of the duodenum.¹ With this right medial visceral rotation maneuver, the right kidney is left in situ unless there is an associated injury to the posterior aspect of the right renal vein, to the suprarenal vena cava, or to the right kidney itself. Right medial visceral rotation, in conjunction with the Kocher maneuver, permits visualization of the entire vena caval system from the confluence of the iliac veins to the suprarenal vena cava below the liver [see 7.9 *Operative Exposure of Abdominal Injuries and Closure of the Abdomen*]. Local exposure of the iliac vein–vena cava junction in the lower abdomen and of the renal vein–vena cava junction in the upper abdomen is appropriate before completion of right medial visceral rotation. This measure allows rapid application of proximal and distal vascular clamps on the inferior vena cava in the event that exsanguinating hemorrhage results when the caval injury is exposed.

Table 3 Survival after Injuries to Veins in the Abdomen

Injured Vein	Asensio et al ² (2000)		Davis et al ³ (2001)*	Tyburski et al ⁴ (2001)
	Isolated Injury	With Other Venous Injury		
Inferior vena cava as a whole	29.3% (12/41) [†]	22.2% (8/36) [†]	56% (47/84)	43% (61/142)
Pararenal to diaphragm	—	—	—	40.3% (31/77)
Infrarenal	—	—	—	46.2% (30/65)
Superior mesenteric vein	47.4% (9/19)	35.7% (5/14)	71.4% (15/21)	56.3% (18/32)
Renal vein	—	44.1% (15/34)	70% (21/30)	68.8% (22/32)
Iliac vein (all)	62.2% (23/37)	33.3% (5/15)	—	—
Common	—	—	81% (17/21)	49% (24/49)
External	—	—	74.5% (41/55)	66.7% (16/24)

*Excludes patients who exsanguinated before repair or ligation.

[†]Excludes retrohepatic vena cava.

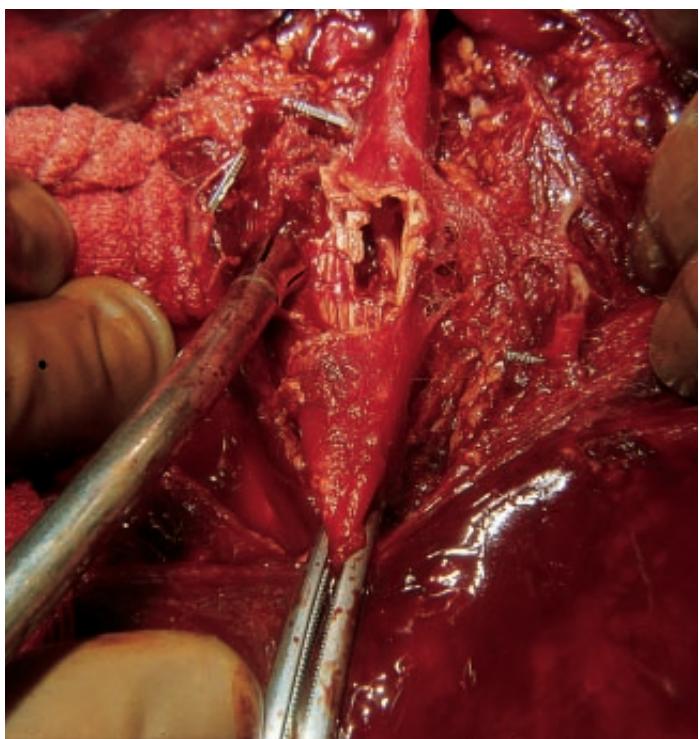

Figure 9 Shown is a gunshot wound to the infrarenal abdominal aorta viewed through standard infrramesocolic exposure. Patient's head is at the bottom of the photograph.

For proper exposure of a hole in a large vein such as the inferior vena cava, the loose retroperitoneal fatty tissue must be dissected away from the wall of the vessel. Active hemorrhage coming from the anterior surface of the inferior vena cava is best controlled by applying a Satinsky vascular clamp. If it is difficult to apply this clamp, one should try grasping the area of the perforation with a pair of vascular forceps or several Judd-Allis clamps; this step may facilitate safe application of the Satinsky clamp.²² When the perforation in the inferior vena cava is more lateral or posterior, it is often helpful to compress the vessel proximally and distally around the perforation, using gauze sponges placed in straight sponge sticks. On occasion, an extensive injury to the inferior vena cava can be controlled only by completely occluding the entire inferior vena cava with large DeBakey aortic cross-clamps. This maneuver interrupts much of the venous return to the right side of the heart and is poorly tolerated by hypotensive patients unless the infrarenal abdominal aorta is cross-clamped simultaneously.

There are two anatomic areas in which vascular control of an injury to the inferior vena cava below the liver is difficult to obtain: (1) the confluence of the common iliac veins and (2) the junction of the renal veins with the inferior vena cava. One interesting approach to an injury to the inferior vena cava at the confluence of the iliac veins is temporary division of the overlying right common iliac artery, coupled with mobilization of the aortic bifurcation to the patient's left.²³ This approach yields a better view of the common iliac veins and the proximal inferior vena cava and makes repair considerably easier than it would be if the aortic bifurcation were left in place. Once the vein is repaired, the right common iliac artery is reconstituted via an end-to-end anastomosis. The usual approach to injuries to the inferior vena cava at its junction with the renal veins involves clamp or sponge-stick compression of the infrarenal and suprarenal vena cava, as

well as control of both renal veins with Silastic loops to facilitate the direct application of angled vascular clamps. As noted, medial mobilization of the right kidney may permit the application of a partial occlusion clamp across the inferior vena cava at its junction with the right renal vein as an alternative approach to an injury in this area. Another useful technique for controlling hemorrhage from the inferior vena cava at any location is to insert a 5 ml or 30 ml Foley balloon catheter into the caval laceration and then inflate it in the lumen.^{24,25} Once the bleeding is controlled, vascular clamps are positioned around the perforation, and the balloon catheter is removed before repair of the vessel.

Anterior perforations of the inferior vena cava are managed by means of transverse repair with a continuous 4-0 or 5-0 polypropylene suture. Much has been written about visualizing posterior perforations by extending anterior perforations, but in my experience, opportunities to apply this approach have been rare. It is often easier to roll the vena cava to one side to complete a continuous suture repair of a posterior perforation. When both anterior and posterior perforations have been repaired, there is usually a significant degree of narrowing of the inferior vena cava, which may lead to slow postoperative occlusion. If the patient's condition is unstable and a coagulopathy has developed, no further attempt should be made to revise the repair. If the patient is stable, there may be some justification for applying a large PTFE patch to prevent this postoperative occlusion [see Figure 10].

Ligation of the infrarenal inferior vena cava is appropriate for young patients who are exsanguinating and in whom a complex repair of the vessel would be necessary. After the damage-control abdominal procedure has been completed and a silo has been used to cover the midgut, it is, once again, worthwhile to measure the compartmental pressures below the knees before the patient is moved from the OR. Below-the-knee two-incision four-compartment fasciotomies are performed when pressures exceed 30 to 35 mm Hg. Three-compartment fasciotomies in the thighs have proved necessary in some surviving patients after caval liga-

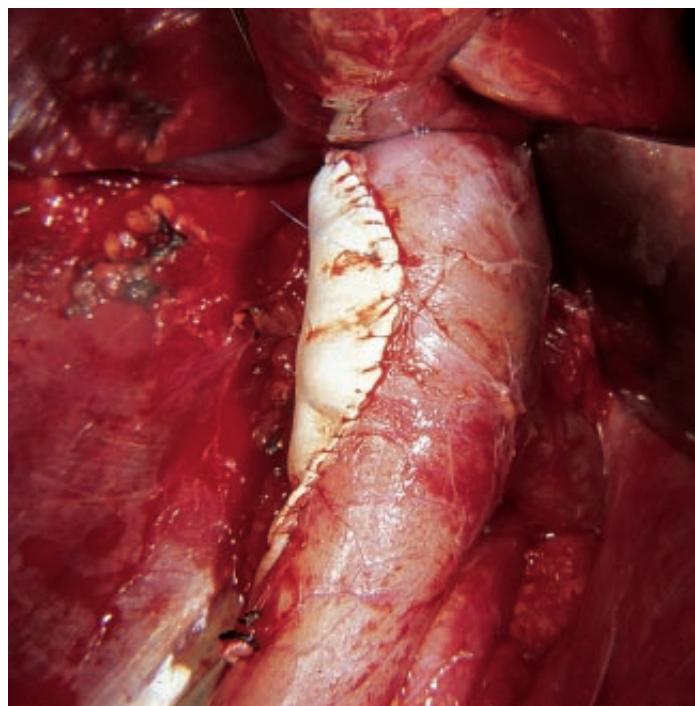

Figure 10 Shown is PTFE patch repair of an injury to the infrarenal inferior vena cava.

Figure 11 A right perirenal hematoma was not opened at operation, because preoperative abdominal CT documented a reasonably intact kidney.

tion. Patients who have undergone ligation of the infrarenal inferior vena cava require vigorous resuscitation with crystalloid solutions in the postoperative period; in addition, both lower extremities should be wrapped with elastic compression wraps and elevated for 5 to 7 days after operation. Patients who have some residual edema during the later stages of hospitalization despite the elastic compression wraps should be fitted with full-length custom-made support hose. Ligation of the suprarenal inferior vena cava is occasionally necessary when the patient has an extensive injury at this location and appears to be in an irreversible shock state during operation.²⁶ If the patient's condition improves during a brief period of resuscitation in the SICU, reoperation and reconstruction with an externally supported PTFE graft are usually necessary to prevent renal failure.

The survival rate in patients with injuries to the inferior vena cava depends on the location of the injury; in the past, it ranged from 60% for the suprarenal vena cava to 78% for the infrarenal vena cava but decreased to approximately 33% to 56% if injuries to the retrohepatic vena cava were included. Current studies indicate survival rates of 22% to 56% for inferior vena cava injuries taken as a whole.^{1-3,26-28} A 2001 review reported survival rates of 46.1% for the infrarenal inferior vena cava and 40.3% for more superior injuries.⁴

Injuries in Zone 2

Hematoma or hemorrhage in zone 2 is cause to suspect the presence of injury to the renal artery, the renal vein, or the kidney.

In patients who have sustained blunt abdominal trauma but in whom preoperative intravenous pyelography, renal arteriography, or abdominal CT confirms that a reasonably intact kidney is present, there is no justification for opening a perirenal hematoma if one is found at a subsequent operation [see Figure 11].²⁹

In highly selected stable patients with penetrating wounds to the flank, there are some data to justify performing preoperative CT. On occasion, documentation of an isolated minor renal injury in the absence of peritoneal findings on physical examination makes it possible to manage such patients nonoperatively.²⁹ In all other patients with penetrating wounds, when a perirenal hematoma is found during initial exploration, the hematoma should be unroofed and the wound tract explored. If the hematoma is not rapidly expanding and there is no active hemorrhage from the perirenal area,

one may control the ipsilateral renal artery with a Silastic loop in the midline of the retroperitoneum at the base of the mesocolon [see Figure 12].^{30,31} Control of the left renal vein can be obtained at the same location; however, control of the proximal right renal vein requires mobilization of the C loop of the duodenum and dissection of the vena cava at its junction with this vessel.

If there is active hemorrhage from the kidney through Gerota's fascia or from the retroperitoneum overlying the renal vessels, no central renal vascular control is necessary. In such a situation, the retroperitoneum lateral to the injured kidney should be opened, and the kidney should be manually elevated directly into the abdominal incision. A large vascular clamp should then be applied directly to the hilar vessels of the elevated kidney to control any further bleeding until a decision is reached on repair versus nephrectomy.

Occasionally, a small perforation of the renal artery can be repaired by lateral arteriorrhaphy or resection with an end-to-end anastomosis.³² Interposition grafting and replacement of the renal artery with either the hepatic artery (on the right) or the splenic artery (on the left) have been used on rare occasions, but such approaches ordinarily are not indicated unless the injured kidney is the only one the patient has. In patients who have sustained multiple intra-abdominal injuries from penetrating wounds or have undergone a long period of ischemia while other injuries were being repaired, nephrectomy is the appropriate choice for a major renovascular injury, provided that intraoperative palpation has confirmed the presence of a normal contralateral kidney.

The role of renal revascularization in patients who have intimal tears in the renal arteries as a result of deceleration-type trauma remains controversial. If a circumferential intimal tear is noted on preoperative arteriography but flow to the kidney is preserved, the decision whether to repair the artery depends on whether laparotomy is necessary for other injuries and whether the opportunity for anticoagulation is available. If there are no other significant injuries and flow to the kidney is preserved despite the presence of an intimal tear, anticoagulation and a repeat isotope renogram within the first several days may be justified. An alternative approach involves insertion of an endovascular stent in the renal

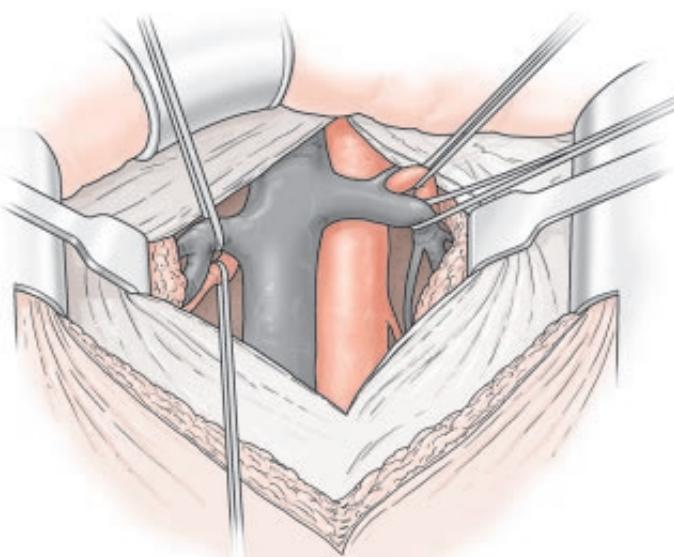

Figure 12 Midline looping of respective renal vessels is performed before entry into any perirenal hematoma.

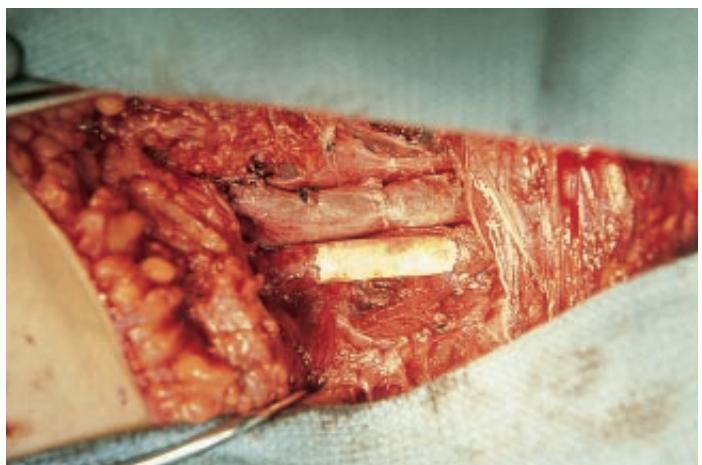

Figure 13 A 24-year-old man experienced a gunshot wound to the left external iliac artery and vein. The arterial injury was repaired with segmental resection and insertion of an 8 mm PTFE graft; the venous injury was repaired with segmental resection and an end-to-end anastomosis.

artery, followed by a period of anticoagulation.³³ If occlusion of the proximal renal artery from blunt deceleration-type trauma is documented, the critical factor for renal salvage is the time from occlusion to revascularization. Renal artery occlusion from deceleration-type trauma that is detected within 6 hours of injury may be treated with immediate operation, resection of the area of intimal damage, and an end-to-end anastomosis performed by an experienced vascular trauma team. Given proper exposure and medial mobilization of the kidney, this operation is not technically difficult in a young trauma patient whose renal artery is otherwise normal. In a 1998 review, fewer than 20% of kidneys revascularized in this manner regained any significant degree of function.³⁴ Hypertension develops in 40% to 45% of patients who undergo observation only after thrombosis is detected.

The survival rate in patients with isolated injuries to the renal arteries ranges from 56% to 74% [see Table 2].^{1,3,4}

Many patients with penetrating wounds to the renal veins are quite stable as a result of the retroperitoneal tamponade described earlier (see above). Once vascular control is obtained with the direct application of clamps, lateral venorrhaphy is the preferred tech-

nique of repair. If ligation of the right renal vein is necessary to control hemorrhage, nephrectomy should be performed, either at initial laparotomy or at reoperation after a damage-control laparotomy; the medial left renal vein may be ligated as long as the left adrenal and gonadal veins are intact. It should be noted, however, that in some series, more postoperative renal complications were noted when this maneuver was used on the left side.³⁵

The survival rate in patients with isolated injuries to the renal veins is approximately 70% [see Table 3].^{1,3,4}

Injuries in Zone 3

Hematoma or hemorrhage in either lateral pelvic area is suggestive of injury to the iliac artery or the iliac vein. When lateral pelvic hematoma or hemorrhage is noted after penetrating trauma, compression with a laparotomy pad or the fingers should be maintained as proximal and distal vascular control is obtained. The proximal common iliac arteries are exposed by eviscerating the small bowel to the right and dividing the midline retroperitoneum over the aortic bifurcation. In young trauma patients, the common iliac artery usually is not adherent to the common iliac vein, and Silastic loops can be passed rapidly around these vessels to provide proximal vascular control. Distal vascular control is most easily obtained where the external iliac artery and vein come out of the pelvis proximal to the inguinal ligament. Even with proximal and distal control of the common or the external iliac artery and vein, there is often continued back-bleeding from the internal iliac artery. Such bleeding is controlled by elevating the Silastic loops on the proximal and distal iliac artery and then either clamping or looping the internal iliac artery, which is the only major branch vessel that descends into the pelvis.

For transpelvic bilateral iliac vascular injuries resulting from a penetrating wound, a technique of total pelvic vascular isolation has been described. Proximally, the abdominal aorta and the inferior vena cava are cross-clamped just above their bifurcations, and distally, both the external iliac artery and the external iliac vein are cross-clamped, with one clamp on each side of the distal pelvis. Back-bleeding from the internal iliac vessels is minimal with this approach.

Ligation of either the common or the external iliac artery in a hypotensive trauma patient leads to a 40% to 50% amputation rate in the postoperative period; consequently, injuries to these vessels should be repaired if at all possible. The standard options for repair—lateral arteriorrhaphy, completion of a partial transection with an end-to-end anastomosis, and resection of the injured area with insertion of a conduit—are feasible in most situations [see Figure 13].³⁶ On rare occasions, it may be preferable either to mobilize the ipsilateral internal iliac artery to serve as a replacement for the external iliac artery or to transpose one iliac artery to the side of the contralateral iliac artery.³⁷ When a patient is in severe shock from exsanguination caused by a complex injury to the common or the external iliac artery, damage control laparotomy [see Damage Control Laparotomy, below] is indicated.³⁸ The injured area should be resected and a temporary intraluminal Argyle, Javid, or Pruitt-Inahara shunt inserted to maintain flow to the ipsilateral lower extremity during resuscitation in the SICU.¹

One unique problem associated with repair of the common or the external iliac artery is the choice of technique when significant enteric or fecal contamination is present in the pelvis. In such cases, there is a substantial risk of postoperative pelvic cellulitis, a pelvic abscess, or both, which may lead to blowout of any type of repair. When extensive contamination is present, it is appropriate to divide

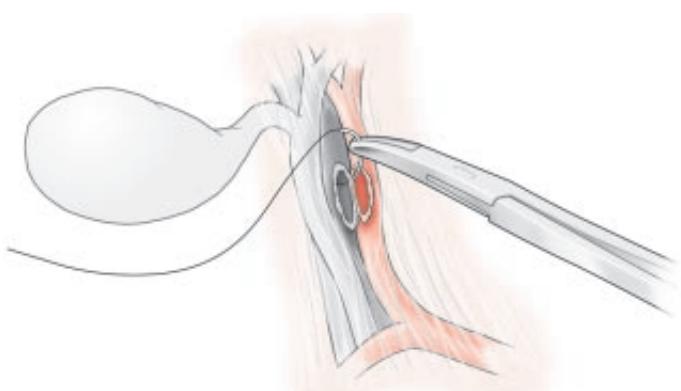

Figure 14 Failure to properly dissect out the structures in the porta hepatis after a penetrating wound led to the creation of an iatrogenic hepatic artery–portal vein fistula, which was corrected after the arrival of the attending surgeon.

the common or external iliac artery above the level of injury, close the injury with a double row of continuous 4-0 or 5-0 polypropylene sutures, and bury the stump underneath uninjured retroperitoneum. If a stable patient has obvious ischemia of the ipsilateral lower extremity at the completion of this proximal ligation, one may perform an extra-anatomic femorofemoral crossover bypass with an 8 mm externally supported PTFE graft to restore arterial flow to the extremity.¹ If the patient is unstable, one should take several minutes to perform an ipsilateral four-compartment below-knee fasciotomy; this step will counteract the ischemic edema that inevitably leads to a compartment syndrome and compromises the early survival of the leg. After adequate resuscitation in the SICU, the patient should be returned to the OR for the femorofemoral graft within 4 to 6 hours.

Injuries to the internal iliac arteries are usually ligated even if they occur bilaterally, because young trauma patients typically have extensive collateral flow through the pelvis.

The survival rate in patients with isolated injuries to the external iliac artery exceeds 80% when tamponade is present. If the injury is large and free bleeding has occurred preoperatively, however, the survival rate is only 45%. Current studies report overall survival rates of approximately 45% to 55% for injuries to the common iliac artery and 62% to 65% for injuries to the external iliac artery [see Table 2].^{1,3,4,39}

Hemorrhage from injuries to the iliac veins can usually be controlled by means of compression with either sponge sticks or the fingers. As noted, division of the right common iliac artery may be necessary for proper visualization of an injury to the right common iliac vein. Similarly, ligation and division of the internal iliac artery on the side of the pelvis yield improved exposure of an injury to an ipsilateral internal iliac vein.⁴⁰

Injuries to the common or the external iliac vein are best treated by means of lateral venorrhaphy with continuous 4-0 or 5-0 polypropylene sutures. Significant narrowing often results, and a number of reports have demonstrated occlusion on postoperative venography. For patients with narrowing or occlusion, as well as for those in whom ligation was necessary to control exsanguinating hemorrhage, the use of elastic compression wraps and elevation for the first 5 to 7 days after operation is mandatory.⁴¹

In some centers, once the patient's perioperative coagulopathy has resolved, anticoagulation with a low-molecular-weight heparin is initiated to prevent progression or migration of a venous thrombus. The patient is then discharged on a regimen of oral warfarin sodium, and serial measurement of the international normalized ratio (INR) is continued for 3 months.

The survival rate in patients with injuries to the iliac veins ranges from 33% to 81%, depending on whether associated vascular injuries are present [see Table 3].^{1-4,38,42}

Injuries in the Porta Hepatis or Retrohepatic Area

PORTA HEPATIS

Hematoma or hemorrhage in the area of the portal triad in the right upper quadrant is cause to suspect the presence of injury to the portal vein or the hepatic artery or of vascular injury combined with an injury to the common bile duct.

If a hematoma is present, the proximal hepatoduodenal ligament should be occluded with a vascular clamp (the Pringle maneuver [see 7:6 *Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm*]) before the hematoma is entered.⁴³ If the hematoma is centrally located in the porta, one may also be able to apply an angled vascular clamp to the distal end of the portal structures at their entrance into the liver.

If hemorrhage is occurring, compression of the bleeding vessels with the fingers should suffice until the vascular clamp is in place. Once proximal and distal vascular control is obtained, the three structures in the hepatoduodenal ligament must be dissected out very carefully because of the danger of blindly placing sutures in proximity to the common bile duct [see Figure 14].

Injuries to the hepatic artery in this location are occasionally amenable to lateral repair, though ligation without reconstruction is ordinarily well tolerated because of the extensive collateral arterial flow to the liver.⁴⁴⁻⁴⁷ If an associated hepatic injury calls for extensive suturing or debridement, ligation of the common hepatic artery or artery to the injured lobe will certainly lead to increased postoperative necrosis of the hepatic repair. Moreover, ligation of the common hepatic artery, the right or left hepatic artery supplying the injured lobe, and the portal vein branch to that lobe will lead to necrosis of the lobe and will necessitate hepatectomy. Finally, ligation of the right hepatic artery to control hemorrhage should be followed by cholecystectomy.

Because of the large size of the portal vein and its posterior position in the hepatoduodenal ligament, injuries to this vessel are particularly lethal. Once the Pringle maneuver has been performed, mobilization of the common bile duct to the left and of the cystic duct superiorly, coupled with an extensive Kocher maneuver, allows excellent visualization of any injury to this vein above the superior border of the pancreas. When the perforation extends underneath the neck of the pancreas, it may be necessary to have an assistant compress the superior mesenteric vein below the pancreas and then to divide the pancreas between noncrushing intestinal clamps to obtain exposure of the junction of the superior mesenteric vein and the splenic vein.

The preferred technique for repairing an injury to the portal vein is lateral venorrhaphy with continuous 4-0 or 5-0 polypropylene sutures.^{48,49} Complex repairs that have been successful on rare occasions include end-to-end anastomosis, interposition grafting with externally supported PTFE, transposition of the splenic vein, and a venovenous shunt from the superior mesenteric vein to the distal portal vein or the inferior vena cava. Such vigorous attempts at restoration of blood flow are not justified in patients who are in severe hypovolemic shock, for whom ligation of the portal vein is more appropriate. In addition, if a portosystemic shunt is performed in such a patient, hepatic encephalopathy will result because hepatofugal flow will be present in the rerouted or bypassed portal vein. As with ligation of the superior mesenteric vein, it is necessary to infuse tremendous amounts of crystalloids to reverse the transient peripheral hypovolemia that occurs secondary to the splanchnic hypovolemia resulting from ligation of the portal vein.^{18,19,49}

Since the early 1980s, the survival rate in patients with injuries to the portal vein has been approximately 50%.^{1,3,48,49}

RETROHEPATIC AREA

Retrohepatic hematoma or hemorrhage is cause to suspect the presence of injury to the retrohepatic vena cava, a hepatic vein, or a right renal blood vessel. In addition, hemorrhage in this area may signal injury to the overlying liver [see 7:6 *Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm*].

If there is a hematoma that is not expanding or ruptured and clearly has no association with the right perirenal area, a tamponaded injury to the retrohepatic vena cava or a hepatic vein is present. Perihepatic packing around the right lobe of the liver for 24 to 48 hours has been shown to prevent further expansion and should be considered.

If hemorrhage is occurring that does not appear to be coming from the overlying liver, the right lobe of the liver should be com-

pressed posteriorly to tamponade the caval perforation. The Pringle maneuver is then applied, and the surgical and nursing team, the anesthesiologist, and the blood bank are notified. Once the proper instruments and banked blood are in the OR, the overlying injured hepatic lobe or the lobe closest to the presumed site of injury is mobilized by dividing the triangular and coronary ligaments and then lifted out of the subdiaphragmatic area.⁵⁰ On occasion, an obvious perforation of the retrohepatic or suprahepatic vena cava or an obvious area where a hepatic vein was avulsed from the vena cava may be grasped with a forceps or a series of Judd-Allis clamps; a Satinsky clamp may then be applied.⁴ Because of the copious bleeding that occurs as the liver is lifted and the hole in the vena cava sought, the anesthesiologist should start blood transfusions as the lobe is being mobilized.

If the retrohepatic hemorrhage is not controlled after one or two direct attempts, another technique must be tried. The most common choice is the insertion of a 36 French chest tube or a 9 mm endotracheal tube as an atricaval shunt [see 7.9 Operative Exposure of Abdominal Injuries and Closure of the Abdomen and 7.6 Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm].⁵¹ The shunt can reduce bleeding by 40% to 60%, but vigorous hemorrhage persists until full control of the perforation is obtained with clamps or sutures. An alternative approach is to isolate the liver and the vena cava by cross-clamping the supraceliac aorta, the porta hepatis, the suprarenal inferior vena cava, and the intraperitoneal inferior vena cava.⁵² Because profoundly hypovolemic patients usually cannot tolerate cross-clamping of the inferior vena cava, this approach is rarely employed. Some experienced hepatic surgeons have successfully used extensive hepatotomy to expose and repair the retrohepatic vena cava.⁵³

The retrohepatic vena cava is repaired with continuous 4-0 or 5-0 polypropylene sutures. When the atricaval shunt is removed from the heart after the vessel has been repaired, the right atrial appendage is ligated with a 2-0 silk tie.

The survival rate in patients not in cardiac arrest who undergo atricaval shunting and repair of the retrohepatic vena cava has ranged from 33% to 50%.^{51,52}

Damage-Control Laparotomy

Patients with injuries to the great vessels of the abdomen are ideal candidates for damage-control laparotomy⁵⁴: they are uniformly hypothermic, acidotic, and coagulopathic on completion of the vascular repair, and a prolonged operation would lead to their demise. In such patients, packing of minor or moderate injuries to solid organs, packing of the retroperitoneum, stapling and rapid resection of multiple injuries to the GI tract, and consideration of diffuse intra-abdominal packing are all appropriate, as is silo coverage of the open abdomen, in which a temporary silo made from a urologic irrigation bag is sewn to the skin edges with a continuous 2-0 polypropylene or nylon suture.

The patient is then rapidly moved to the SICU for further resuscitation. Priorities in the SICU include rapid restoration of normal body temperature, reversal of shock, infusion of intravenous bicarbonate to correct a persistent pH lower than 7.2, and administration of fresh frozen plasma, platelets, and cryoprecipitate when indicated. It is usually possible to return the patient to the OR for removal of clot and packs, reconstruction of the GI tract, irrigation, and reapplication of silo coverage or application of a vacuum-assisted closure device within 48 to 72 hours.^{55,56}

When massive distention of the midgut persists after 7 days of intensive care and use of the vacuum-assisted closure device (15% to 25% of patients), the safest approach is to convert the patient to an open abdomen (i.e., without closure of the midline incision) and cover the midgut with a double-thickness layer of absorbable mesh. With proper nutritional support and occasional use of Dakin solution to minimize bacterial contamination of the absorbable mesh, most patients are ready for the application of a split-thickness skin graft to the eviscerated midgut within 3 to 4 weeks of the original operation for an injury to a great vessel.

Complications

Besides those already mentioned, major complications associated with repair of injuries to the great vessels in the abdomen include thrombosis, dehiscence of the suture line, and infection. Because of the risk of occlusion of repairs in small vasoconstricted vessels (e.g., the superior mesenteric artery), it may be worthwhile to perform a second-look operation within 12 to 24 hours if the patient's metabolic state suggests that ischemia of the midgut is present. Early correction of an arterial thrombosis in the superior mesenteric artery may permit salvage of the midgut.

As noted [see Injuries in Zone 1, above], dehiscence of an end-to-end anastomosis or a vascular conduit inserted in the proximal superior mesenteric artery when there is an injury to the adjacent pancreas may be prevented or the incidence lowered by inserting a distal aorta–superior mesenteric artery bypass graft. To prevent adjacent loops of small bowel from adhering to the vascular suture lines, both lines should be covered with soft tissue (retroperitoneal tissue for the aortic suture line and mesenteric tissue for the superior mesenteric arterial suture line). Also as noted [see Injuries in Zone 3, above], when an extensive injury to either the common or the external iliac artery occurs in the presence of significant enteric or fecal contamination in the pelvis, ligation and extra-anatomic bypass may be necessary.

On occasion, vascular-enteric fistulas occur after repair of the anterior aorta or the insertion of grafts in either the abdominal aorta or the superior mesenteric artery.⁶ In my experience, such fistulas all occur at suture lines; hence, once again, proper coverage of suture lines with soft tissue should eliminate or lower the incidence of this complication.^{20,57}

11 INJURIES TO THE UROGENITAL TRACT

Hunter Wessells, M.D., F.A.C.S.

The World Health Organization (WHO) predicts a dramatic worldwide rise in the burden of disease caused by road traffic accidents and war.¹ This rise will directly influence the incidence of urogenital trauma, in that motor vehicle crashes (MVCs) and firearm injuries are responsible for the overwhelming majority of major renal and pelvic injuries.² In one population-based study, the percentage of trauma patients in the United States who had renal injuries was 1.2% (incidence, 4.9 per 100,000 population).³ Thus, in 1 year, some 14,000 patients with renal injuries are hospitalized nationwide. Approximately 45,000 pelvic fractures occur each year in the United States, 15% to 25% of which are associated with urologic injury. Urogenital injuries, though rarely fatal, can cause profound long-term morbidity and permanently impair quality of life.

Blood in the urine is the hallmark of injury to the urogenital system; however, as an isolated indicator, it is not specific for injury location or severity. In penetrating abdominal trauma, hematuria is a signal that the kidneys, the ureters, and the bladder must be evaluated. Urethral and genital injuries are suspected only in the setting of wounds to the pelvis, the perineum, or the buttocks. When hematuria occurs in association with blunt trauma, the entire urogenital system must be evaluated: the forces associated with high-speed MVCs and falls can cause injuries to both the upper and the lower regions of the urogenital tract.

In what follows, each of the major urogenital organs is treated separately. New imaging modalities and a growing emphasis on nonoperative management of upper and lower urinary tract injuries have dramatically changed the field of urologic trauma. Concomitant injury to both the upper and the lower urinary tract is rare, but extra vigilance must be maintained to detect such injury when it does occur. Evaluation and management of trauma to the female reproductive organs requires special expertise, particularly when the patient is the victim of a sexual assault.

Injuries to the Kidneys

INITIAL EVALUATION

The most reliable sign of injury to the kidney is hematuria [*see Figure 1*], except in patients with renal artery thrombosis or pedicle avulsion, who may have no blood in their urine. However, the degree of hematuria correlates poorly with the severity of renal injury,⁴ and as a result, criteria for imaging in these patients must take into account both the mechanism of injury and the probability of severe kidney injury.⁵ Accordingly, a Consensus Statement from a Renal Trauma Subcommittee convened by the WHO proposed guidelines for imaging renal injuries [*see Table 1*.⁶ As with all guidelines, exceptions exist. A high degree of suspicion for renal trauma is required for patients who do not meet the hematuria criteria for imaging but who have experienced a fall from a height, have sustained a direct blow to the flank, or have other indicators (e.g., persistent flank pain or severe associated injuries).

Computed tomography is the first-line imaging modality for all

cases of suspected renal trauma in hemodynamically normal and stable patients. A standard examination includes helical (spiral) CT with a portal venous phase (from the diaphragm to the ischial tuberosities) to visualize active arterial bleeding [*see Figure 2a*], followed after 10 minutes by delayed images (from the kidneys to the ischial tuberosities) to identify urinary contrast extravasation [*see Figure 2b*]. CT should not be used as the primary evaluation method in hemodynamically unstable patients: other diagnostic tests, such as diagnostic peritoneal lavage (DPL) or ultrasonography, should be performed before renal imaging with CT.

The American Association for the Surgery of Trauma (AAST) Organ Injury Scale is used to classify blunt and penetrating renal injuries and corresponds closely to the appearance of the kidney on CT [*see Figure 3 and Table 2*.⁷]

MANAGEMENT

Differences in the management of blunt and penetrating renal trauma are a result of the greater instability of the patient after penetrating trauma and the higher likelihood of severe renal injuries after firearm and stab wounds.

Nonoperative

Increasing numbers of renal injuries are being managed nonoperatively. The accuracy and rapidity of helical CT, combined with the improvements achieved in resuscitation methods, have reduced the number of renal explorations performed.⁸ Currently, one half of all penetrating renal injuries and fewer than 5% of blunt injuries necessitate operative management.³ All grade I and II renal injuries, regardless of the mechanism of injury, can be managed with observation alone because the risk of delayed bleeding is extremely low. Most grade III and IV injuries, including those with devitalized parenchymal fragments and urinary extravasation, can be managed nonoperatively with close monitoring, serial hematocrit measurement, and repeat imaging in selected cases. Active arterial bleeding, in the absence of other associated injuries, can be treated with emergency arteriography and angioembolization.

Thrombosis of the renal artery or its branches is treated expectantly unless the contralateral kidney is absent or injured, in which case emergency revascularization is indicated. Treatment with modalities such as endoluminal stenting and thrombolytic therapy is a promising but still experimental approach.⁹⁻¹¹

Operative

The only absolute indications for renal exploration are pedicle avulsion, pulsatile or expanding hematoma, and hemodynamic instability resulting from renal injury.⁶ Shattered kidneys (grade V) and renal vascular injuries (grades IV and V) call for immediate renal exploration and, usually, nephrectomy [*see Figure 4*.^{12,13} In patients who require laparotomy for associated injuries, renal exploration and reconstruction of grade III and IV injuries may reduce the likelihood of delayed complications. Thus, exploration of suspected kidney injuries (as determined by previous imaging or on-table evaluation) in patients undergoing laparotomy for major

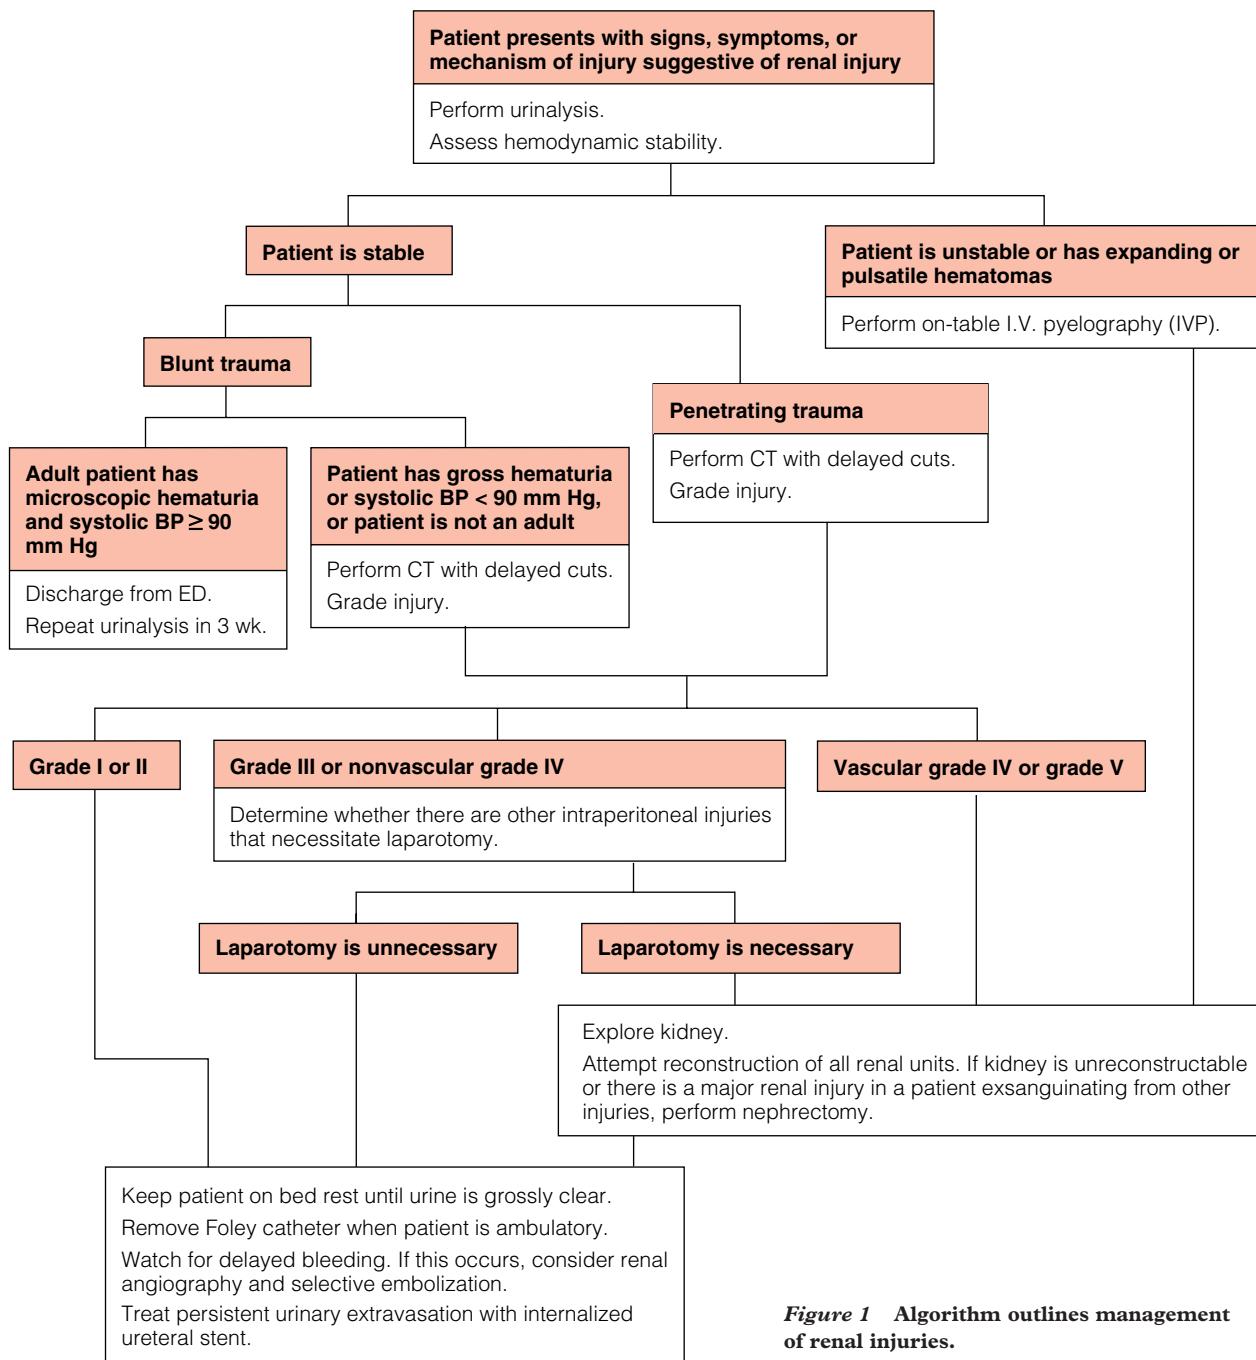

Figure 1 Algorithm outlines management of renal injuries.

splenic or bowel injury should be attempted by surgeons experienced in repairing an injured kidney. In reality, the success of nonoperative management for most grade III and IV injuries means that operative intervention in cases of blunt trauma is typically limited to patients with the most severe renal injuries, in whom conservative management fails either because of bleeding or because of ongoing urinary extravasation despite ureteral stenting.¹⁴

A significant number of patients with a penetrating injury and a minority of those with blunt trauma require immediate laparotomy before radiographic evaluation.¹⁵ Hematuria should alert the surgeon to the possibility of renal injury, and the presence of a perinephric hematoma visible through the mesocolon should prompt further evaluation. If a major renal injury is suspected on the basis of the size of the hematoma or an abnormal intraoperative intravenous pyelogram (IVP), exploration is indicated.

Intraoperative IVP (so-called one-shot IVP) is indicated when exploration of a kidney is planned and no preoperative imaging is available. The main purpose of a one-shot IVP in this setting is to confirm the presence of a contralateral functioning kidney; a potential benefit is the ability to rule out major injury. The plain abdominal film is obtained 10 minutes after injection of a 150 ml bolus of iodinated contrast material. If the injured kidney is adequately imaged and found to be normal, exploration may be omitted¹⁶; otherwise, the kidney should be explored. In critically ill patients with multiple associated injuries, renal exploration is indicated only if a pulsatile or expanding hematoma is present, in which case expeditious nephrectomy is necessary. If exploration is not done, staging with CT should be completed once the patient is stable; angiembolization and percutaneous drainage can be used to manage bleeding and urinary extravasation, respectively.¹⁷⁻¹⁹

Table 1 Criteria for Imaging of Renal Injuries

Type of Trauma	Criteria for Imaging
Blunt	Gross hematuria (visibly blood-tinged urine) Adult with microhematuria (defined as $\geq 1 +$ RBC on dipstick or > 3 RBC/hpf) with a period of hypotension (systolic BP < 90 mm Hg) Child (< 15 yr) with > 50 RBC/hpf
Penetrating	Stable patient with any degree of hematuria and injury near urinary tract

The priorities of operative management for grade III, IV, and V injuries are hemorrhage control and definitive repair of the collecting system. A midline transabdominal incision permits exploration of the kidneys and provides optimal access to the renal hilum. After intraperitoneal sources of bleeding have been controlled, preliminary isolation of the renal artery and vein should be achieved before Gerota's fascia is opened. There is some controversy regarding the value of early vascular control, with one randomized controlled trial showing no benefit from early isolation of the vessels in cases of renal gunshot wounds²⁰; however, the weight of the remaining evidence suggests that this technique is still valuable if renal reconstruction is the goal of exploration.^{6,21,22} Isolation of the renal vessels is accomplished by opening the posterior peritoneum medial to the inferior mesenteric vein or by reflecting the ipsilateral colon (provided that the perinephric hematoma is left undisturbed).

Once vessel loops have been placed around the renal artery and vein, Gerota's fascia is opened. If massive bleeding occurs when the hematoma is entered, Rumel tourniquets or vascular clamps are applied to occlude the renal artery. If this maneuver does not stop the bleeding, one should suspect a venous injury and occlude the renal vein as well. Surface cooling of the kidney is not advocated, because of time constraints and concerns about possibly exacerbating hypothermia. Total exposure of the kidney by means of sharp and blunt dissection facilitates identification of injury to the parenchyma, the renal pedicle, or the collecting system. The renal capsule should not be pulled off the parenchyma: doing so would complicate subsequent repair.

Renal reconstruction includes sharp debridement of all devitalized tissue, achievement of hemostasis, closure of the collecting system, coverage of the defect, and drainage [see Figure 5]. Renal salvage should be possible in nearly 90% of grade III and IV injuries. Nephrectomy is reserved for destroyed kidneys that cannot be reconstructed or for cases of serious renal injury associated with other life-threatening injuries (e.g., vascular or hepatic trauma) in which taking the time required for attempted renal repair would jeopardize the life of the patient.^{3,23}

A number of sophisticated products are available for enhancing surgical hemostasis and reducing the need for tedious ligation of individual small arterioles on the parenchymal surface. Such products include a hemostatic bandage applied directly to the cut surface of the kidney,²⁴ polyethylene glycol-based hydrogels, fibrin glue, and a gelatin matrix–thrombin tissue sealant (FloSeal; Baxter International, Inc., Deerfield, Illinois).^{25–28} To date, none of these products have been evaluated in the setting of blunt renal injuries, but results in elective partial nephrectomy models are encouraging.

Once hemostasis is satisfactory, the collecting system is scrutinized for evidence of injury. If the extent of the injury is unclear, 2 to 3 ml of methylene blue is directly injected into the renal pelvis while the ureter is occluded with a vessel loop to identify any openings in the collecting system. Open calyces or infundibula are closed with 4-0 absorbable sutures. Often, the renal capsule can be used to cover exposed renal parenchyma and provide additional hemostasis. The defect in the parenchyma can be filled with folded absorbable gelatin sponges as the capsule is closed over the bolsters. If the capsule has been destroyed, coverage may be obtained with an omental or perinephric fat flap tacked down over the defect, a patch constructed from polyglycolic acid or peritoneum, or an entire sac of polyglycolic acid wrapped around the kidney, with the parenchymal edges kept well apposed.²⁹

At the end of the procedure, the kidney is returned to its location within Gerota's fascia, which is not reapproximated. Closed-suction drainage of the renal fossa is recommended only after repair of the collecting system; internalized stents are reserved for complex injuries (e.g., large lacerations of the renal pelvis or the ureteropelvic junction [UPJ]).

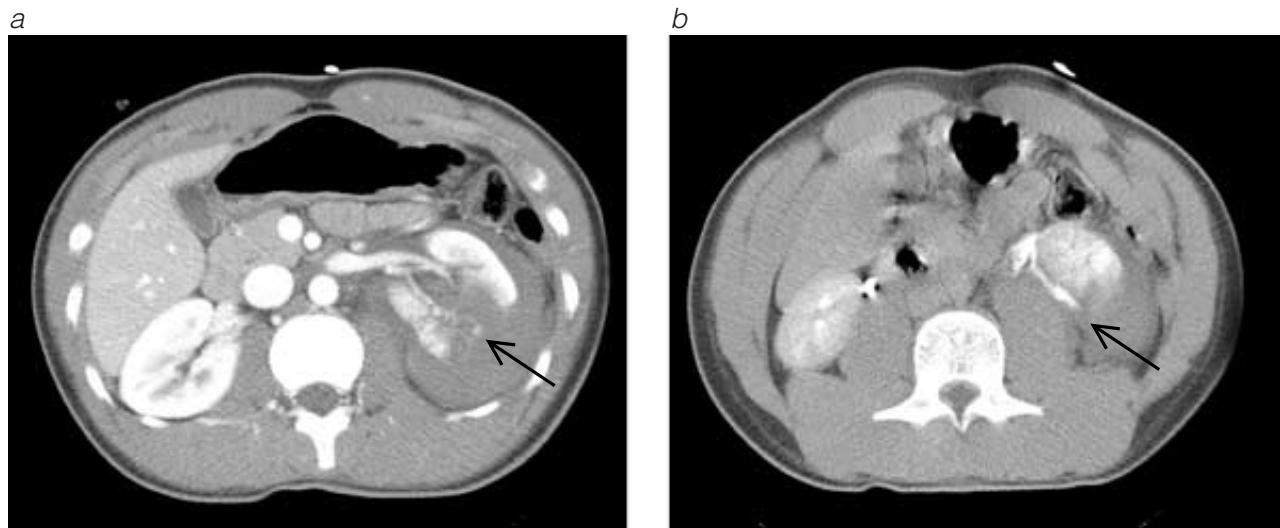

Figure 2 Shown are (a) a deep laceration with vascular contrast extravasation (arrow) and (b) a deep laceration with urinary contrast extravasation (arrow).

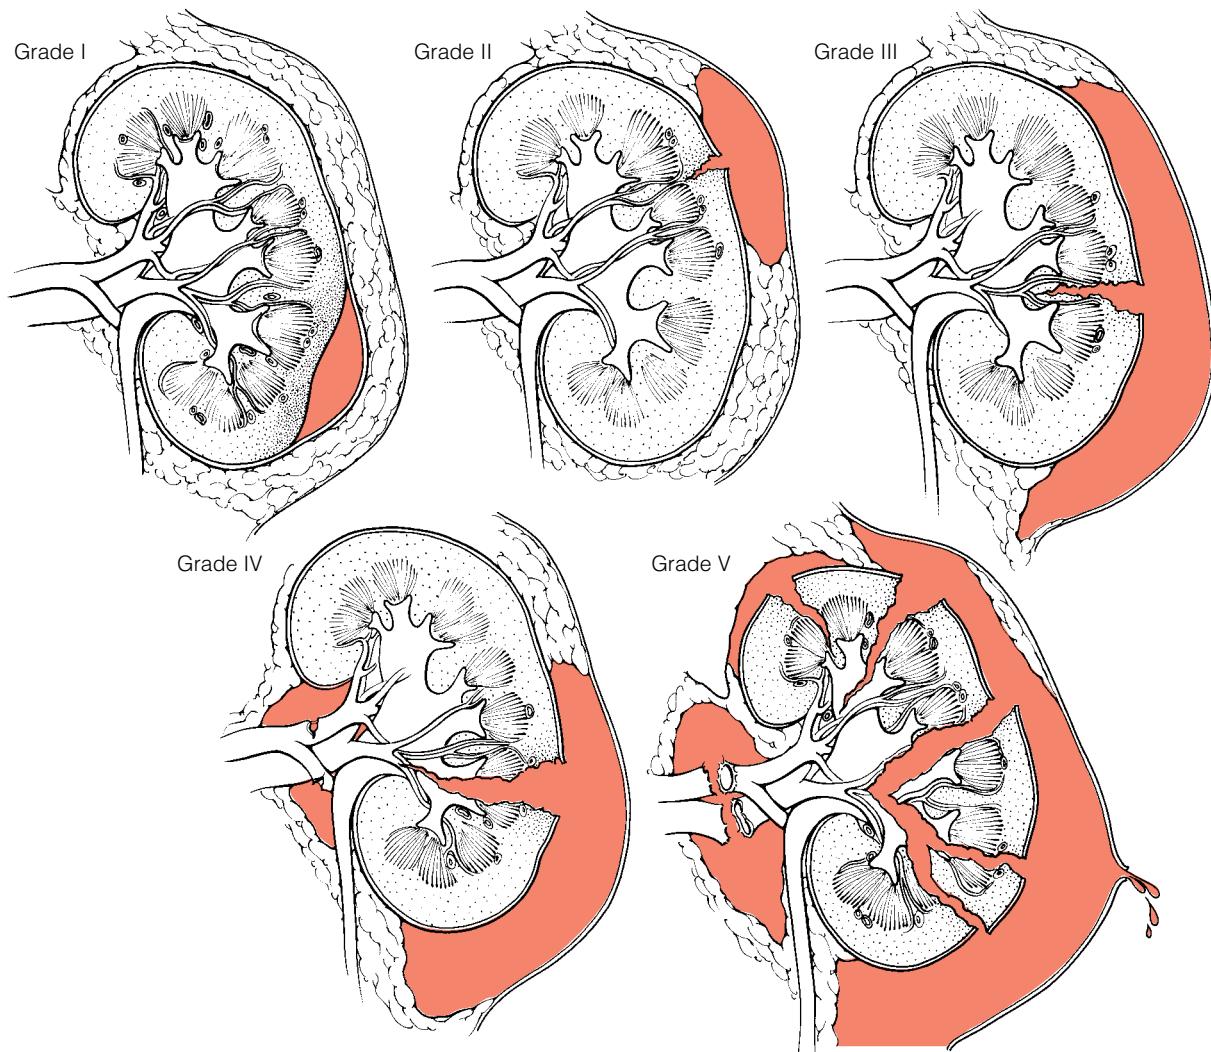

Figure 3 Illustrated is the AAST classification of renal injuries into grades I through V.

Postintervention Care

Management of patients after operative or nonoperative intervention for renal trauma depends to a large extent on the presence and severity of associated injuries. The most significant urologic complications are urinary leakage, urinoma formation, and delayed bleeding.

After nonoperative management Bed rest is prescribed until the urine becomes grossly clear. Drainage of the bladder with a Foley catheter is necessary only until other injuries are stable and the patient can void spontaneously. For grade IV injuries with large amounts of urinary extravasation, follow-up imaging 48 to 72 hours after the initial scan is recommended to evaluate the degree of ongoing extravasation. CT is recommended, though in children, protocols that reduce the radiation exposure should be used. If at 72 hours the amount of extravasation has not decreased from that seen on the initial scan, stenting is indicated. Cystoscopy and internal double J stenting allow successful treatment of the small percentage of cases in which the injury does not close spontaneously.³⁰ When a double J stent is used to manage persistent extravasation, the urinary bladder should be decompressed with a Foley catheter.

Parenchymal fragmentation and arterial thrombosis cause ischemia and often delay resolution of urinary leakage.³¹ Nevertheless, internal stenting almost invariably suffices, though

resolution of extravasation can take weeks to months. Ultrasonography is useful for following such collections and for reducing the patient's radiation exposure. For small uninfected collections adjacent to the kidney, no intervention is needed. If a perinephric fluid collection is large enough to compress the ureter or becomes infected, additional percutaneous drainage is indicated [see Figure 6]. The drain fluid is tested for creatinine, and if the findings are consistent with a urine leak, the drain is left in place until the collection resolves and leakage can no longer be demonstrated on contrast imaging.

Delayed bleeding is a rare but serious complication of nonoperative management of major lacerations.³² Pseudoaneurysm formation is the most common cause of delayed bleeding [see Figure 7].³³ Gross hematuria usually, but not invariably, accompanies the bleeding. If it is seen in conjunction with hypotension or a decreasing hematocrit, urgent angiography is the best initial approach; selective embolization is an effective treatment that renders exploration unnecessary in most instances.

After operative management Retroperitoneal drains are removed within 48 hours after renal exploration unless the creatinine concentration in the drained fluid is higher than that in the serum. Persistent urinary leakage is best evaluated by means of repeat CT with delayed cuts. As with nonoperative management,

Table 2 AAST Organ Injury Scales for Urinary Tract

Injured Structure	AAST Grade	Characteristics of Injury	AIS-90 Score
Kidney*	I	Contusion with microscopic or gross hematuria, urologic studies normal; nonexpanding subcapsular hematoma without parenchymal laceration	2; 2
	II	Nonexpanding perirenal hematoma confined to renal retroperitoneum; laceration < 1.0 cm parenchymal depth of renal cortex without urinary extravasation	2; 2
	III	Laceration > 1.0 cm parenchymal depth of renal cortex without collecting system rupture or urinary extravasation	3
	IV	Parenchymal laceration extending through renal cortex, medulla, and collecting system; injury to main renal artery or vein with contained hemorrhage	4; 4
	V	Completely shattered kidney; avulsion of renal hilum that devascularizes kidney	5; 5
Ureter*	I	Contusion or hematoma without devascularization	2
	II	< 50% transection	2
	III	≥ 50% transection	3
	IV	Complete transection with < 2 cm devascularization	3
	V	Avulsion with > 2 cm devascularization	3
Bladder†	I	Contusion, intramural hematoma; partial-thickness laceration	2; 3
	II	Extraperitoneal bladder wall laceration < 2 cm	4
	III	Extraperitoneal bladder wall laceration > 2 cm or intraperitoneal bladder wall laceration < 2 cm	4
	IV	Intraperitoneal bladder wall laceration > 2 cm	4
	V	Intraperitoneal or extraperitoneal bladder wall laceration extending into bladder neck or ureteral orifice (trigone)	4
Urethra*	I	Contusion with blood at urethral meatus and normal urethrography	2
	II	Stretch injury with elongation of urethra but without extravasation of urethrography contrast material	2
	III	Partial disruption with extravasation of urethrography contrast material at injury site with visualization in the bladder	2
	IV	Complete disruption with < 2 cm urethral separation and extravasation of urethrography contrast material at injury site without visualization in the bladder	3
	V	Complete transection with ≥ 2 cm urethral separation or extension into the prostate or vagina	4

†Advance one grade for multiple injuries, up to grade III.

AAST—American Association for the Surgery of Trauma AIS-90—Abbreviated Injury Score, 1990 version

internal stenting and percutaneous drainage are the mainstays of treatment for leaks and urinomas, respectively. Postoperative hemorrhage is rare if the injured parenchyma has been adequately debrided and repaired. Angiographic evaluation with embolization is the best approach for postoperative renal bleeding.

Functional imaging Postoperative nuclear imaging is recommended in patients with grade IV and V injuries involving significant parenchymal loss or vascular injury.³⁴ The goal is to identify patients with significant loss of functioning renal tissue who are at potential risk for chronic renal insufficiency. Patients whose level of residual function in the injured kidney, as determined by radionuclide scintigraphy, is less than 25% should be considered as having a solitary kidney. This information is useful in counseling patients who participate in high-risk sports activities (e.g., skydiving, motocross, and hang gliding). The optimal timing of post-

operative nuclear imaging has not been determined, but by 3 months, the hematoma and inflammation related to the injury usually have resolved.

Hypertension is a rare late complication of renal reconstruction, usually renin-mediated and deriving from an ischemic segment of renal parenchyma. Occasionally, angiography delineates the ischemic segment of the kidney, and excision of the nonperfused segment or complete nephrectomy may be required.

Injuries to the Ureters

INITIAL EVALUATION

Ureteral trauma [see Table 2] is rare, accounting for fewer than 1% of genitourinary injuries. Furthermore, the absence of physical signs of injury makes diagnosis difficult, and a delayed presen-

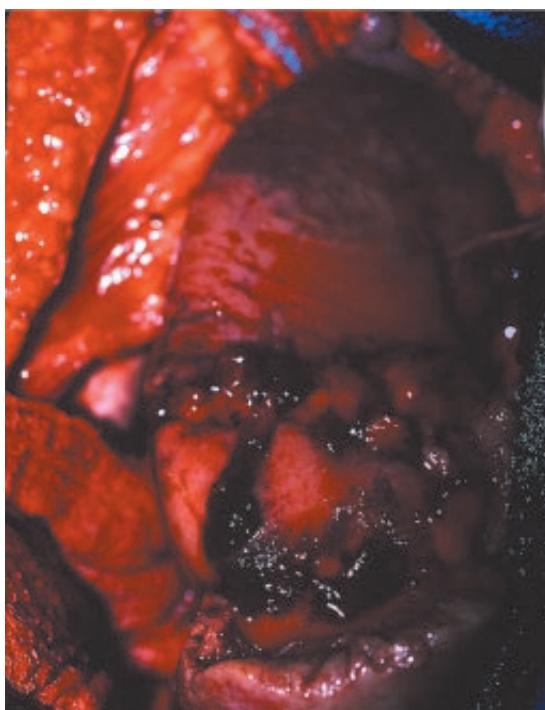

Figure 4 Shown is the intraoperative appearance of a shattered, ischemic, nonviable kidney that was removed (grade V injury).

tation is not uncommon. Gross or microscopic hematuria may be absent in 25% to 70% of patients with ureteral injuries, and as many as one half of all ureteral injuries resulting from blunt trauma are not recognized immediately. A high index of suspicion and a high degree of vigilance are necessary if the diagnosis is to be made early enough to prevent late consequences such as urinoma, sepsis, and nephrectomy.³⁵⁻³⁷

The mechanism of injury has a particular bearing on the diagnosis and management of ureteral injury. Overall, penetrating wounds are the predominant cause of these injuries. CT with delayed cuts should be performed when ureteral injury is suspected and the patient is stable. Imaging is of variable usefulness in the detection of ureteral injuries, but extravasation of the contrast agent is diagnostic.³⁸ Only 10% to 20% of ureteral injuries are caused by blunt trauma, and within this category, MVCs predominate.³⁵ In children, ureteral injury at the UPJ often occurs after severe deceleration.³⁹ Children's ureters are particularly prone to injury at this location because the hyperextensibility of their spines can result in ureteral avulsion at the UPJ.^{37,38,40}

MANAGEMENT

All injuries to the ureter should be repaired surgically [see Figure 8] unless a delay in diagnosis has resulted in an abscess or a urinoma [see Figure 9]. If an abscess or a urinoma is present, drainage by means of percutaneous nephrostomy, coupled with ureteral stenting, allows infection and inflammation to resolve before definitive management; in this setting, an operative approach is likely to result in nephrectomy.

Ureteral Exploration

In stable patients, blunt ureteral injuries are typically identified by preoperative radiographic studies, which allow directed exploration and repair (see below). With penetrating trauma, ureteral injury may not be suspected until the time of laparotomy, when a

hematoma is found near the kidney or ureter. Direct inspection of the entire trajectory of the offending agent requires particular vigilance for direct injury to or contusions of the ureter. Injection of indigo carmine into the collecting system identifies extravasation. Direct injection saves time and ensures that injuries are not missed as a result of low urine output from shock or renal injury. One study found that all penetrating ureteral injuries were detected at laparotomy without previous imaging.³⁶

Reconstruction and Repair

Ureteral injuries should undergo surgical reconstruction as soon as they are recognized unless associated injuries prevent such a strategy. For example, gunshot injuries to the iliac vessels or the ureters may necessitate heroic vascular reconstruction. Ligation of the ureter with subsequent nephrostomy tube drainage or exteriorization of a ureteral stent allows elective reconstruction months later. Percutaneous and endoscopic approaches can also be used to establish urinary drainage if ureteral exploration is not feasible.

Reconstructive steps in ureter repair include debridement of devitalized tissue, creation of a spatulated tension-free anastomosis, watertight mucosal approximation, stenting, coverage of the repair with vascularized tissue when feasible, and appropriate drainage.⁴¹ Stab wounds generally cause less tissue damage than gunshot wounds and are more easily repaired; partial transections may be closed primarily.

Upper ureter Disruption or transection of the upper ureter or the UPJ is repaired by means of debridement and primary anastomosis of the renal pelvis and the ureter. Mobilization of the ureter is limited to ensure that the blood supply is not compromised. Interrupted 5-0 or 6-0 absorbable sutures are preferred, and a double J ureteral stent or a nephrostomy tube is inserted before completion of the anastomosis.
