Biomarkers have the potential to predict the risk of progression to cancer in patients with BE. The Early Detection Research Network, established by the National Cancer Institute, has defined five phases of biomarker development and validation analogous to phases of drug development.<sup>111</sup> To become a useful screening/risk-stratification tool, biomarkers must pass through each phase of research, starting at identification and culminating in an understanding of the impact of screening/surveillance on reducing the burden of disease in the population. Phase 1 involves identification of a biomarker (exploratory phase) followed by development of a clinical assay (phase 2). Phases 3 and 4 entail validation in retrospective and prospective studies, respectively.

**TABLE 25.2 Current Status of Biomarkers for Diagnosis, Risk Stratification, and Prediction of Response to Therapy**

Biomarker	Current Status
Trefoil factor 3 (TFF3)	<ul style="list-style-type: none"> <li>• Phase 4 study showed significant promise for diagnosis</li> </ul>
FISH	<ul style="list-style-type: none"> <li>• Phase 3 and 4 studies showed promise for risk stratification, potential candidates studied alone or in combination [8q24 (C-MYC), 8p21 (p16), 17q12 (HER2), 17p13.1 (p53), 20q13, and ZNF217]</li> <li>• Phase 3 and 4 studies showed p16 loss and multiple gains to hold promise for prediction of response to therapy</li> </ul>
DNA content abnormalities/aneuploidy	<ul style="list-style-type: none"> <li>• Useful for risk stratification, possibly a late biomarker</li> <li>• Somatic gene diversity can be quantified</li> </ul>
Methylation	<ul style="list-style-type: none"> <li>• Phase 2 studies show promise for diagnosis given the different methylation signatures between squamous and BE tissues (potential candidates – p16, RUNX3, MGMT, SFRP1, TIMP3, and CDH13 among others)</li> <li>• No dominant marker for risk stratification based on phase 3 and 4 studies</li> </ul>
MicroRNA	<ul style="list-style-type: none"> <li>• Phase 2 studies show promise for diagnosis (miRNAs – 192, -215, -194, -205, and -203 different between squamous and BE tissue)</li> <li>• No dominant miRNA for risk stratification</li> </ul>
p53	<ul style="list-style-type: none"> <li>• Only biomarker recommended to clarify histologic diagnosis of dysplasia</li> <li>• p53 mutational analysis feasible on cytologic specimens</li> <li>• Phase 4 data support use of p53 analysis for risk stratification</li> <li>• Not a predictor for response to therapy in a phase study</li> </ul>
Clonal diversity	<ul style="list-style-type: none"> <li>• Phase 2 studies suggest predictive ability</li> </ul>
Proliferation markers	<ul style="list-style-type: none"> <li>• Limited utility for risk stratification</li> </ul>

BE, Barrett's esophagus; FISH, fluorescent in-situ hybridization.

From Bansal A, Fitzgerald RC: Biomarkers in Barrett's esophagus: role in diagnosis, risk stratification, and prediction of response to therapy. *Gastroenterol Clin North Am* 44(2):373-390, 2015.

This is followed by phase 5 studies that evaluate the impact of a biomarker on the population disease burden and primary outcomes, such as costs and mortality rates.<sup>112</sup> Although many biomarkers have been identified and evaluated in phase 3 and a few in phase 4 studies, none have progressed through and been validated in a phase 5 trial. Several biomarkers have been studied to improve the current risk stratification approach and identification of patients at the highest risk for progression. These include detection of DNA content abnormalities (aneuploidy or increased 4N fraction), mutation or loss of heterozygosity of the p53 and p16 genes, chromosomal abnormalities, and methylation-based biomarkers among others (Table 25.2).<sup>112-118</sup> The use of biomarkers in clinical practice has been limited by a lack of prospective data, differences in reproducibility of results, cost, and complexity of testing; current US guidelines recommend against the use of individual or a panel of biomarkers.<sup>119</sup> An ideal biomarker or panel of biomarkers needs to be validated in prospective trials, be inexpensive, easily administered and accessible, and highly accurate in risk stratification (superior to the current gold

standard of dysplasia grade on histology). The goal of identifying such a biomarker or panel of biomarkers ready for clinical application remains elusive.

### Risk Stratification and Prediction Tools

**Clinical and endoscopic predictors of progression.** Advanced age and increasing length of the BE segment are known predictors for the presence and progression of BE to HGD/EAC.<sup>71,118–122</sup> A multicenter study that included 1175 patients with nondysplastic BE showed that the risk of progression to HGD/EAC increased with an increase in BE segment length (28% increase in risk for every 1-cm increase in BE length,  $p = 0.01$ ). After adjusting for confounding variables, BE length was a significant predictor of progression with an odds ratio (OR) of 1.2 (95% CI 1.1–1.3).<sup>122</sup> Similarly, another prospective study of 713 patients with BE showed that for every 1 cm increase in BE length segment, the relative risk of progression to HGD/EAC was 1.11 (95% CI 1.01–1.2).<sup>123</sup> Presence of visible endoscopic lesions is a predictor for prevalent HGD/EAC and a risk factor for progression to EAC.<sup>123–126</sup>

**Dysplasia and risk of progression.** Currently, despite all the advances in the field of molecular markers to predict progression to EAC in patients with BE, dysplasia is used as the standard marker of progression risk. The progression of BE to EAC is believed to occur in a probabilistic manner through recognizable histologic steps of intestinal metaplasia, LGD, (HGD, intramucosal cancer, and finally, invasive EAC. Several contemporary studies have demonstrated a low rate of progression to EAC in patients with nondysplastic BE, and this estimate ranges from 0.1% to 0.3% per year.<sup>70,121,127</sup> Results from a multicenter study demonstrated that persistence of nondysplastic BE identifies patients who are at low risk for development of EAC.<sup>128</sup> These findings need to be reproduced in other larger cohorts before lengthening or discontinuation of surveillance can be recommended in patients with persistent nondysplastic BE. Variable rates of progression of LGD to endpoints of HGD/EAC and EAC alone have been reported with progression rates ranging from 0.4% to 13.4% per year.<sup>70,126,128–141</sup> These variable rates stem from inclusion of a relatively small number of patients with LGD in the vast majority of the studies, lack of expert or central pathology panel review which limited reliability of LGD diagnosis, variability in pathologic diagnosis of LGD, analyses not distinguishing prevalent from incident dysplasia, referral and selection bias, and limited endoscopic follow-up data, especially for survival analyses.<sup>142,143</sup> A systematic review and meta-analysis that included 24 studies with 2694 LGD patients reported a pooled annual incidence rate of 1.73% (95% CI 0.99%–2.47%) for the endpoint of HGD/EAC and 0.54% (95% CI 0.32%–0.76%) for EAC.<sup>144</sup> However, substantial heterogeneity in the results was a major limitation of this study. A noteworthy feature, as demonstrated in several studies, in the natural history data of LGD patients, is the phenomenon of regression where follow-up endoscopic biopsies after an initial diagnosis of LGD do not demonstrate LGD and the diagnosis is downgraded to nondysplastic BE.<sup>126,144,145,146</sup> The potential reasons for this phenomenon include interobserver variability among pathologists, sampling errors, misdiagnosis, removal of the dysplastic focus by biopsies, and perhaps even true regression of the dysplastic area. The diagnosis of HGD is associated with a high yearly rate of progression to EAC (approximately 7% based on a meta-analysis) making this an actionable diagnosis.<sup>147</sup> Two randomized controlled trials have reported even higher rates of progression to EAC in BE patients with HGD.<sup>148,149</sup>

**Predictors of progression in patients with low-grade dysplasia.** Review of pathology slides by an expert GI pathologist has been shown to "purify" the group of LGD patients by downgrading the vast majority of cases to nondysplastic BE. Studies have demonstrated that individuals with confirmed LGD (defined by confirmation of diagnosis by an expert GI pathologist or panel) are at a higher risk of progression to EAC and HGD/EAC.<sup>148,150,151</sup> In addition, patients with LGD confirmed by multiple pathologists instead of a single pathologist diagnosis may be associated with a higher risk of progression to HGD/EAC.<sup>151,152</sup> Persistent LGD (defined by the presence of LGD on two consecutive endoscopies) has also been identified as a risk factor for progression, or as a risk factor for failure to regress subsequently. A 2017 study showed that the number of pathologists confirming the diagnosis of LGD (OR 47.14, 95% CI 13.1–169.7 when all three pathologists agreed) and persistent LGD (OR 9.28, CI 4.39–19.64 for individual pathologists) were predictors associated with progression of LGD.<sup>153</sup> Similarly, another Dutch study showed a statistically significant difference in the rates of progression to HGD/EAC between cases with and without confirmed LGD (confirmed incidence rate: 5.18 [95% CI 3.63–7.19]/100 person-years vs. 1.85 [95% CI 1.52–2.22]/100 person-years,  $p < 0.001$ ). Persistent LGD was the only independent risk factor for the development of HGD/EAC (hazard ratio [HR] 3.5, 95% CI 1.48–8.28).<sup>154</sup> Aside from pathologist confirmation of LGD and persistent LGD, no other factor appears to be reproducibly associated with progression.

**Prediction models.** There is growing interest in the development of risk-prediction models to identify patients with BE at risk for the development of HGD/EAC. Models described have incorporated demographic and clinical factors such as age, sex, smoking status, body mass index, waist:hip ratio, frequency of GERD, frequency of use of acid suppressive medications, and nonsteroidal antiinflammatory drugs (NSAIDs), along with endoscopic findings such as BE length, presence of nodularity in combination with histology, and relevant biomarkers.<sup>116,125,130</sup> Currently available models need to be validated prior to clinical application. Until clinically applicable biomarkers are available, there is significant interest in validating models that incorporate clinical, endoscopic, and histologic factors in risk stratification.

## MANAGEMENT

### Medical Therapy

Because BE has the most severe pathophysiologic abnormalities of GERD, PPIs are the cornerstone of medical therapy for BE. Studies show that PPIs consistently result in symptom relief and heal esophagitis in patients with BE.<sup>155–159</sup> However, even at high doses, PPIs result in either no regression of the Barrett's segment or modest regression that is of uncertain clinical importance.<sup>160–162</sup> PPIs typically increase squamous islands in the Barrett's segment, but biopsy specimens taken from such islands often show underlying intestinal metaplasia.<sup>163</sup>

Alleviation of reflux symptoms in BE is not equivalent to normalization of esophageal acid exposure, despite the use of high-dose PPI therapy. Persistent abnormal acid exposure is encountered in approximately 25% of patients with BE despite use of twice-daily PPIs.<sup>164,165</sup> The importance of complete control of esophageal acid exposure in patients with BE is unknown. A 2014 meta-analysis found that PPI use was associated with a reduction in the risk of EAC and/or HGD (OR 0.29; 95% CI

0.12–0.79).<sup>168</sup> Furthermore, longer duration of PPI use (> 2–3 years) was associated with a greater protective effect.

### Antireflux Surgery

Antireflux surgery effectively alleviates GERD symptoms in patients with BE. The LOTUS randomized controlled trial that compared laparoscopic antireflux surgery to esomeprazole found that the outcome of laparoscopic antireflux surgery was similar in GERD patients with and without BE and comparable to use of esomeprazole for symptom control and quality of life measures, although antireflux surgery afforded better intraesophageal acid control.<sup>167</sup> The indications for surgery in patients with BE are the same as the indications for GERD patients without BE.

It has long been hypothesized that antireflux surgery provides protection from progression of BE to EAC. However, two randomized clinical trials found no attenuation of the risk for developing EAC in BE patients treated surgically compared with patients treated medically.<sup>168,169</sup> However a 2016 meta-analysis of surgical versus medical therapy of BE found that in a subgroup of four studies published after 2000, antireflux surgery was associated with a decreased risk of developing EAC when compared to medical therapy.<sup>170</sup> The best available evidence suggests that antireflux surgery has outcomes equivalent to medical therapy for symptom control in BE and surgery should not be chosen solely as an intervention to decrease cancer risk in BE patients.

### Chemoprevention

Chemoprevention is a pharmacologic intervention for either the prevention of cancer or the treatment of identifiable precancerous lesions. Various chemoprevention agents have been proposed for patients with BE, including PPIs, NSAIDs, aspirin, lyophilized black raspberries, antioxidants, green tea, retinoids, ursodeoxycholic acid, statins, and curcumin.

Multiple observational studies suggest that NSAIDs, including aspirin, may play a protective role against BE by inhibiting the cyclooxygenase 1 and 2 enzymes, which regulate PGE<sub>2</sub> production. A 2012 pooled analysis of six population-based studies in the Barrett's and Esophageal Adenocarcinoma Consortium (BEACON) group examined the association between NSAID use and risk of EAC and found that when compared to nonusers, NSAID users had a reduced risk of EAC, and almost identical effects were seen for both aspirin and nonaspirin NSAIDs.<sup>171</sup> Furthermore, higher frequency and longer duration use were associated with a decreased risk of cancer in this study. A 2014 meta-analysis of nine observational studies likewise found that both aspirin and NSAIDs were associated with a decreased risk of HGD/EAC in BE patients.<sup>172</sup> Despite the consistent evidence from observational studies, limited clinical trial data are available to address this issue. A single clinical trial has examined the effect of celecoxib at a dose of 200 mg twice daily given for 48 weeks in patients with LGD/HGD on change in proportion of biopsy samples with dysplasia between patients treated with celecoxib compared to those treated with a placebo.<sup>173</sup> No differences were found between the two groups. A clinical trial of esomeprazole in conjunction with low and high dose aspirin found that only high dose aspirin (325 mg daily) was able to decrease mucosal PGE<sub>2</sub> content in mucosal biopsies from BE patients.<sup>174</sup> The results of a large randomized clinical trial in the United Kingdom (ASPECT) are awaited to see if chemoprevention with aspirin in conjunction with a PPI is a useful clinical strategy in BE patients. Currently, it is premature to use aspirin or NSAIDs for chemoprevention in BE patients.

### BOX 25.2 Relevant Quality Indicators Pertinent to the Diagnosis, Surveillance and Medical Management of Barrett's Esophagus

- For patients in whom Barrett's esophagus (BE) is being considered, the squamocolumnar junction, the gastroesophageal junction, and the location of the diaphragmatic hiatus (if there is a hiatal hernia present) should be recorded on each endoscopy
- If BE is suspected on an endoscopy, the endoscopist should document the extent of suspected BE using a standardized grading system (Prague criteria)
- Inspection of the BE segment should be performed using high-definition white light endoscopy
- Biopsies should be obtained in patients with suspected BE
- The normal-appearing and normally located squamocolumnar junction should not be biopsied
- In a patient with BE undergoing surveillance endoscopy, systematic biopsies should be obtained from every 1 to 2 cm in a four-quadrant fashion throughout the extent of the Barrett's segment
- In a patient with BE undergoing surveillance endoscopy, biopsies from any visible lesion should be obtained and processed separately from the systematic biopsies
- The diagnosis of dysplasia should be confirmed by an expert GI pathologist
- If surveillance biopsies in a patient with BE show no evidence of dysplasia, surveillance endoscopy should be recommended in no sooner than 3 to 5 years

Statins, a class of drugs well known for cholesterol lowering effects, also have antiproliferative, proapoptotic, antiangiogenesis, and immunomodulatory effects which could provide chemoprevention potential in BE.<sup>175</sup> A systematic review and meta-analysis of five studies of Barrett's patients demonstrated a 43% reduction in the risk of progressing to the combined endpoints of HGD/adenocarcinoma after adjustment for potential confounders.<sup>175</sup> Taken together, these data suggest the potential for statins in chemoprevention of BE, but this has not yet been addressed in clinical trials.

### QUALITY INDICATORS IN DIAGNOSIS AND MANAGEMENT

The recent shift from volume-based to value-based practice in the United States and variability in quality of care have provided the impetus for defining quality indicators in the diagnosis and management of patients with BE. The quality of health care delivered can be measured by comparing the performance of an individual or a group of individuals with an ideal or benchmark, and nonadherence to a quality indicator reflects suboptimal care. Three recent documents have addressed this important issue.<sup>26,57A,177</sup> Relevant quality indicators pertinent to this chapter are highlighted in Box 25.2. Adherence to these quality indicators has the potential to improve quality of care, reduce variability in health care, and ultimately improve patient outcomes.

## INTRODUCTION AND EPIDEMIOLOGY

Esophageal cancer is the eighth most common cancer and the sixth leading cause of cancer death in the world. There are two major histologic subtypes of esophageal cancer: adenocarcinoma and squamous cell cancer. Globally, more than 400,000 deaths were estimated attributable to esophageal cancer in 2012.<sup>1</sup> There is considerable geographic variability in the incidence of esophageal cancer, with the majority of cases (80%) occurring in less-developed parts of the world.<sup>1</sup> Based on recent incidence data, nearly 17,000 new cases of esophageal cancer will be diagnosed in the United States in 2016 (13,460 cases in men and 3,450 cases in women), and there will be 15,690 esophageal cancer-related deaths.<sup>2</sup> On the other hand, more than 290,000 new esophageal cancer diagnoses and more than 218,000 esophageal cancer deaths were estimated in China in 2011.<sup>3</sup>

Overall survival rates for esophageal cancer are poor, with highest mortality rates observed in regions with highest disease incidence, including Eastern Asia, Southern Africa, and Eastern Africa<sup>1</sup> (Fig. 26.1). Even within regions there is substantial geographic heterogeneity in the incidence of disease. Data published nearly four decades ago from the Caspian Cancer Registry, originating from the Caspian Littoral region on the rim of the Caspian Sea, reported annual age-adjusted incidence rates ranging from a low of 20.1 cases per 100,000 population in subregions of lowest incidence to a high of 165.5 cases per 100,000 population in subregions of highest incidence.<sup>4</sup>

Of the two major histologic subtypes of esophageal cancer, the majority of diagnosed cases worldwide are classified as esophageal squamous cell carcinoma (ESCC). A unique trend in Western countries, including the United States, has been a dramatic increase in the incidence of esophageal adenocarcinoma over the past several decades, to the extent that proportionally the majority of esophageal cancers diagnosed currently in the United States are adenocarcinoma rather than ESCC.<sup>5</sup>

Nonetheless, due to the significant morbidity of ESCC, the potential for prevention through early detection and treatment of ESCC and precursor lesions, and the nuances of endoscopic diagnosis of ESCC (with particular attention to the role of chromoendoscopy), understanding and implementing an evidence-based approach to screening for ESCC is essential for health care providers, and particularly the practicing gastrointestinal endoscopist.

### Risk Factors for ESCC and Unique Populations at Risk

Common to the pathogenesis of many types of neoplasia, development of ESCC is often a consequence of the interplay between nonmodifiable (genetic) and modifiable (environmental) risk factors for disease.

Worldwide, ESCC incidence rates are more than twofold higher for men than for women.<sup>1</sup> In many countries, including relatively lower-incidence countries in the developed world, alcohol and tobacco use are major risk factors for ESCC. For instance, in a case control study of African-American men in an urban location, the relative risk of esophageal cancer associated with alcohol consumption was 6.4 (95% confidence interval [CI] 2.5–16.4) and the relative risk associated with tobacco use (not controlling for alcohol consumption) was 1.9 (95% CI 1.0–3.0).<sup>6</sup> In this study, consumption of hard liquor was associated with a higher risk of esophageal cancer than beer or wine consumption.<sup>6</sup> In addition, the race-specific incidence of ESCC among US men with exposure to alcohol and tobacco is highest among African-American men compared to other racial and ethnic groups.<sup>7</sup>

The combined effects of alcohol and tobacco are synergistic. In a case control study from Italy, with individuals who were nonsmokers and with moderate weekly alcohol consumption as the reference standard, odds ratios for development of esophageal cancer were 2.6 (95% CI 4–29) for nonsmokers with very heavy alcohol consumption, 8.4 (95% CI 16–41) for heavy smokers with moderate alcohol consumption, and 21.8 (95% CI 6–15)

**Abstract**

Esophageal squamous cell cancer (ESCC) is one of the most common cancers worldwide. There is considerable geographic variability in the prevalence of ESCC. The high mortality rates observed for ESCC reflect the fact that most patients diagnosed with ESCC have advanced disease at the time of diagnosis. The goal of ESCC screening is to prevent cancer-related death by detecting ESCC and precursor lesions when in an early, asymptomatic stage, thereby permitting the opportunity for curative intervention. Both endoscopic and nonendoscopic techniques for ESCC screening have been developed and investigated, and these techniques and supporting data will be discussed in this chapter.

**FIG 26.1 A,** Esophageal cancer incidence in men (2012 data). **B,** Esophageal cancer mortality in men (2012 data). (From International Agency for Health Research on Cancer; World Health Organization: GLOBOCAN 2012: estimated cancer incidence, mortality and prevalence worldwide in 2012. 2015. Available at [globocan.iarc.fr](http://globocan.iarc.fr). Accessed February 1, 2017.)

for heavy smokers with very heavy alcohol consumption.<sup>9</sup> Even in higher-incidence regions for ESCC, such as China, smoking has been implicated as a significant risk factor for esophageal cancer as tobacco consumption has increased across the population.<sup>10</sup> And in a case control study from Uganda, the age- and gender-adjusted percentage of cases of ESCC attributable to alcohol and smoking was 13%.<sup>11</sup> Smokeless tobacco use has also been implicated as a risk factor for ESCC. In a study on the

global burden of disease, smokeless tobacco use was implicated as the cause of more than 24,000 deaths worldwide due to ESCC, with the majority of these deaths (> 20,000) occurring in Southeast Asia.<sup>12</sup>

Consumption of alcohol and/or tobacco can significantly influence host factors contributing to baseline ESCC risk. For instance, an increased risk of ESCC has been reported in individuals with a family history of esophageal cancer, yet this

risk increases substantially for individuals with a family history of esophageal cancer and who are also current smokers and heavy drinkers.<sup>12</sup> In addition, whereas the incidence of ESCC is higher in men than in women, an increasing prevalence of female smokers in the United States can result in comparable incidence between women and men smokers in smoking-related cancers, including ESCC.<sup>13</sup>

Throughout the world, dietary and nutritional factors have been implicated in the pathogenesis of ESCC. Multiple studies have suggested that populations with low dietary intake of fruits and vegetables are at increased risk for ESCC.<sup>14,15</sup> Micronutrient deficiencies including zinc<sup>16</sup> and selenium<sup>17</sup> may also be associated with increased risk for ESCC. Dietary folate consumption was reported to be inversely associated with risk for ESCC in a European population with high alcohol consumption.<sup>18</sup> On a population health scale, alterations in nutritional habits represent an opportunity to modify ESCC risk. Long-term decline in ESCC mortality in China has been attributed to changes in diet.<sup>19</sup>

Other specific environmental exposures reported to be associated with ESCC risk include exposure to polycyclic aromatic hydrocarbons from not only tobacco smoke but sources including indoor coal stoves<sup>20</sup> and the Brazilian beverage maté,<sup>21</sup> hot tea consumption (in a northern Iranian region),<sup>22</sup> poor oral hygiene,<sup>23,24</sup> and infection with certain serotypes of human papillomavirus infection.<sup>25,26</sup>

Unique populations of patients with comorbid illness are at increased risk for ESCC and may be candidates for targeted screening programs. The rare genetic condition tylosis, characterized by cutaneous hyperkeratosis associated with a chromosome 17 abnormality, is associated with a high cumulative lifetime risk of ESCC.<sup>27</sup> Current American Society for Gastrointestinal Endoscopy (ASGE) guidelines recommend screening for ESCC among patients with tylosis beginning at age 30 and repeated at 1 to 3 year intervals thereafter.<sup>28</sup> Targeted screening for ESCC is also recommended in patients who have sustained caustic esophageal injury, typically following lye ingestion, beginning 10 to 20 years after exposure and repeated at 2 to 3 year intervals.<sup>28</sup>

Other populations at increased risk for ESCC include patients with upper aerodigestive (head and neck) squamous cell cancers, among whom high rates of synchronous and metachronous ESCC have been reported,<sup>29,30</sup> as well as patients with achalasia.<sup>31,32</sup> However, current ASGE guidelines recommend against screening in patients with upper aerodigestive cancers or achalasia due to a lack of sufficient evidence to suggest that screening confers a benefit with respect to early cancer detection or survival.<sup>28</sup>

## RATIONALE FOR POPULATION SCREENING FOR ESCC

The high mortality rates observed for ESCC<sup>1</sup> reflect the fact that most patients diagnosed with ESCC have advanced disease at the time of diagnosis. The development of luminal obstruction sufficient to cause the cardinal symptom of dysphagia is typically indicative of the presence of invasive carcinoma. A rationale for implementation of a screening program aimed at early cancer detection and, ultimately, improved cancer-specific prognosis and survival must be interpreted in this context. In general, several criteria must be fulfilled for a screening test to be recommended for routine clinical practice:

1. Screening should enable early detection of an unrecognized (asymptomatic) disease or precursor lesion which, if left undetected and untreated, has the potential to progress and result in significant morbidity and/or burden of suffering.
2. The test utilized for screening should be accurate, cost-effective, safe, and acceptable to both clinicians and patients undergoing screening.
3. Effective and acceptable treatment options should be available for patients found to have disease as a result of the screening examination.

Each of these criteria can be examined with respect to ESCC.

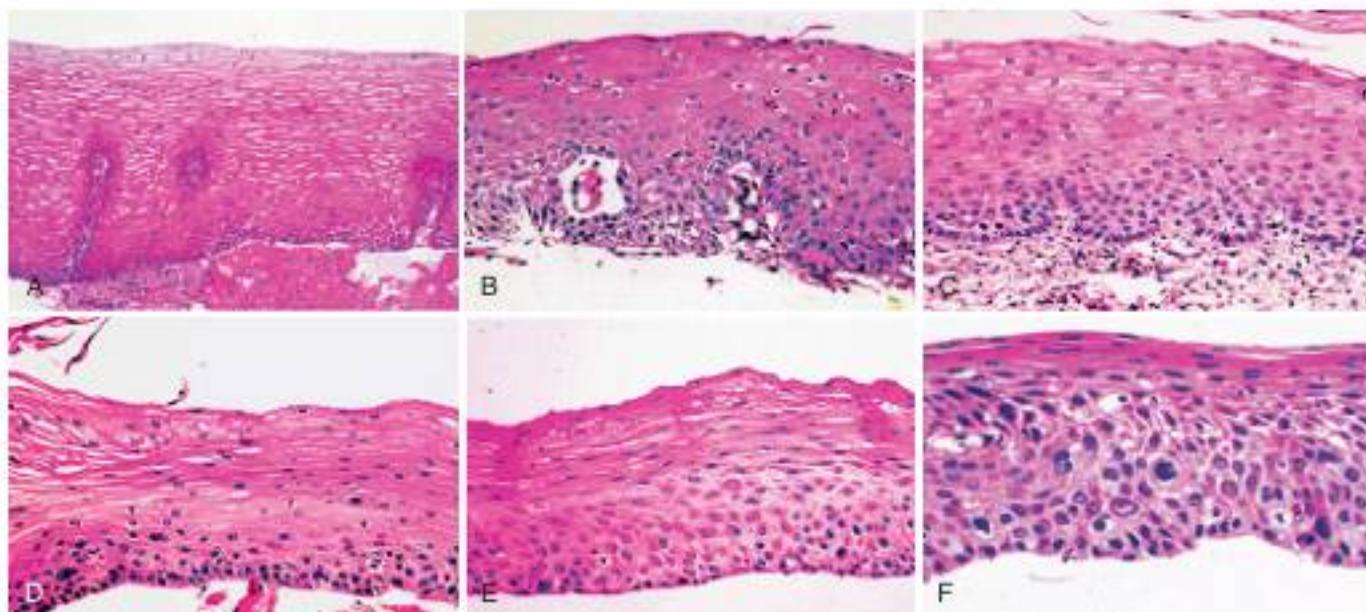

### Precursors of ESCC

Squamous dysplasia has been recognized as a precursor lesion to ESCC (Fig. 26.2). Squamous dysplasia can be detected in a substantial proportion of patients in regions with high prevalence of ESCC. A study in Linzhou, China, subjecting more than 700 adult volunteers to screening upper endoscopy, detected a 32% prevalence of squamous dysplasia.<sup>33</sup> Risk factors for squamous dysplasia in this study mirrored risk factors for ESCC.<sup>33</sup> A 2016 prospective study in a high-risk region of Kenya detected a 14% prevalence of squamous dysplasia; the prevalence was greater than 20% in men older than age 50 and women older than age 60.<sup>34</sup>

Risk of progression from dysplasia to ESCC can be stratified according to grades of dysplasia. In a cohort of Chinese individuals diagnosed with squamous dysplasia and followed for 13.5 years, ESCC developed in 17%.<sup>33</sup> Relative risk (RR) of progression was lowest for patients with dysplasia classified as mild at baseline study entry (RR 2.9, 95% CI 1.6–5.20), intermediate for patients with moderate dysplasia (RR 9.8, 95% CI 5.3–18.3), and highest for patients with severe dysplasia (RR 28.3, 95% CI 15.3–52.3) or carcinoma in situ (RR 34.4, 95% CI 16.6–71.4).<sup>33</sup>

Histopathologic grading of dysplasia associated with esophageal intestinal metaplasia (Barrett's esophagus), the major precursor lesion for esophageal adenocarcinoma, is subjective and notoriously fraught with high rates of interobserver variability.<sup>35</sup> There are no data available to estimate either the interobserver or intraobserver variability in grading of esophageal squamous dysplasia. In the esophageal adenocarcinoma context, when histopathologic assessment of Barrett's esophagus suggests the presence of dysplasia, the standard practice recommendation is to obtain additional review from a second expert pathologist for confirmation of the diagnosis of dysplasia. No equivalent recommendation exists with respect to the diagnosis of squamous dysplasia, nor would such a practice be feasible in a resource-limited setting. A potential further confounder in the assessment and grading of dysplasia is inconsistency in descriptive terminology, with World Health Organization guidelines, for instance, preferring the term *intraneoplastic neoplasia* (classified as either low grade or high grade) over dysplasia.<sup>37</sup>

Novel tissue biomarkers may, in the future, facilitate detection, diagnosis, and risk stratification for ESCC and precursor lesions. For instance, a recent screen of candidate genes found overexpression of two genes (TNFAIP3 and CHN1) with differential overexpression in squamous dysplasia and ESCC compared to normal esophagus.<sup>38</sup> On the other hand, cytologic assessment of DNA ploidy and p53 loss of heterozygosity appears to offer no additional benefit to endoscopically obtained biopsies in detection of ESCC.<sup>39</sup> Absent further validation and rigorous assessment of the performance characteristics of novel tissue biomarkers, at this time the presence of squamous dysplasia remains the only clinically relevant and accepted precursor lesion for ESCC capable of predicting future cancer risk and a target

**FIG 26.2** Histologic categories used in endoscopic studies in Linxian, China. **A**, Normal. **B**, Esophagitis. The epithelium is infiltrated by polymorphonuclear leukocytes. **C**, Basal cell hyperplasia. The basal zone is greater than 15% of the epithelial thickness, without cellular atypia. **D**, Mild squamous dysplasia. There is cellular atypia, confined to the lower third of the epithelium. **E**, Moderate squamous dysplasia. There is cellular atypia involving the lower two-thirds of the epithelium. **F**, Severe squamous dysplasia. The cellular atypia involves all thirds of the epithelium, without invasion of the lamina propria.

for potential intervention during screening and surveillance examinations.

### Endoscopic Screening

Upper gastrointestinal endoscopy has emerged in the United States and much of the developed world as the primary test for screening for foregut malignancy. The capabilities of endoscopy for this purpose have been progressively influenced by generational technological advantages, as flexible endoscopes have evolved from fiber optics, to high definition white light imaging, to platforms capable of offering real-time image modification and enhancement.

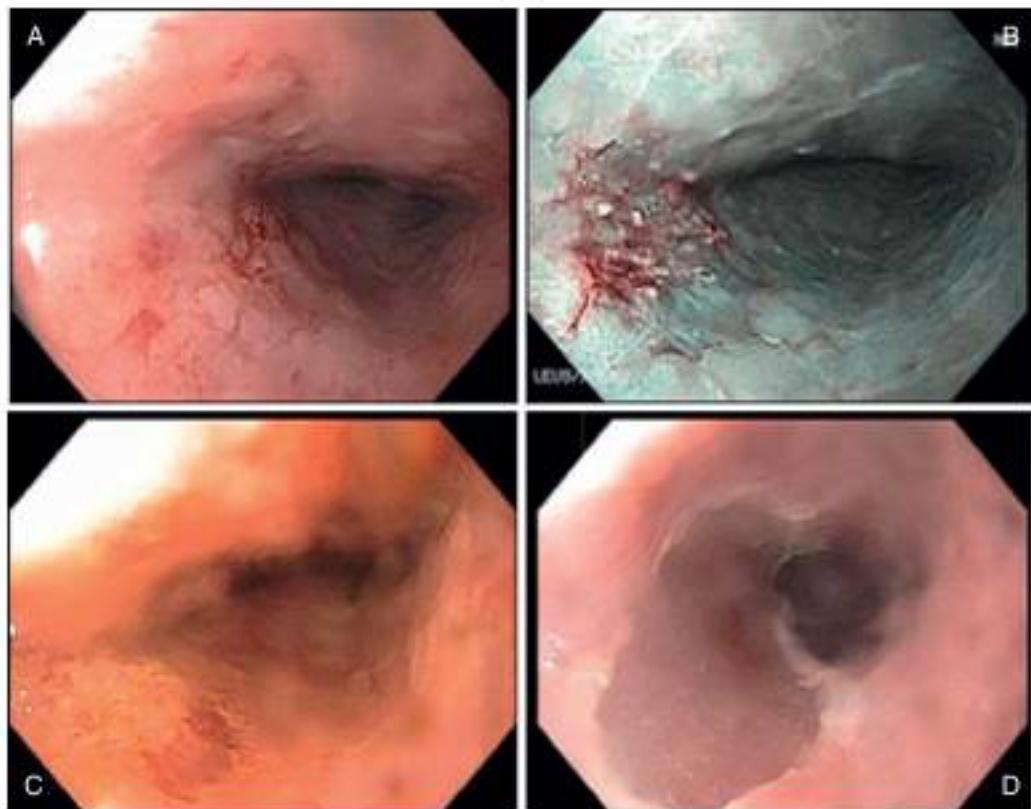

ESCC has a predilection for the upper and mid esophagus, which should be inspected carefully during both endoscopic intubation and withdrawal from the esophagus. Early-stage ESCC may be detectable on careful white light inspection as a focal endoscopic abnormality such as a nodule or superficial ulceration (Figs. 26.3 and 26.4A). Variants of ESCC such as verrucous carcinoma may have a uniquely identifiable morphology (Video 26.1).

In many instances, however, detection of early ESCC and precursors lesions may prove elusive. Chromoendoscopy has therefore played a fundamental role in endoscopic screening for ESCC. The principle of chromoendoscopy consists of topical application of a liquid substance, typically a vital dye, to elicit subtle mucosal morphology and abnormalities. In ESCC screening, the agent of choice for endoscopic screening has been Lugol's iodine solution. Iodine binds to glycogen, a substance that is present in squamous epithelial cells throughout the body. Normal squamous epithelial cells will have a characteristic brown ("stained") appearance following topical application of Lugol's iodine. In contrast, atypical squamous cells, including areas

containing dysplasia or cancer, contain less glycogen, have less cellular uptake of iodine, and therefore exhibit a characteristic "unstained" appearance on inspection following application of Lugol's iodine (see Figs. 26.3 and 26.4C; Video 26.2).

The practice of chromoendoscopy for detection of neoplasia using Lugol's iodine is not unique to the esophagus, and was initially described for evaluation of the cervix.<sup>40</sup> Reports describing use of Lugol's iodine for esophageal examination emerged in the late 1960s and early 1970s.<sup>41–43</sup> Since that time, an extensive and robust experience with use of Lugol's iodine for diagnosis of ESCC has been reported. Misumi and colleagues reported the use of this technique in 1990 for detection of 17 lesions in a Japanese cohort with ESCC. Endoscopic inspection was initially performed using conventional (white light) endoscopy. After administration of mucolytics, 20 mL of 1.5% Lugol solution was applied under direct visualization. The iodine solution was aspirated through the scope 30 to 60 seconds later, followed by irrigation with 40 to 60 mL of water prior to endoscopic inspection. Whereas only 14 of 17 lesions were detected using white light endoscopy, all 17 lesions were detected following application of Lugol's iodine. Moreover, the size and margin of the lesions as estimated by Lugol's chromoendoscopy correlated reliably with the histopathologic assessment of the size of the lesion, an important consideration if an endoscopic resection is to be entertained with the goal of achieving an R0 resection<sup>44</sup> (see Chapter 27).

Also in 1990, Shiozaki and colleagues reported the results of endoscopic examination of the esophagus, first with conventional endoscopy, and then with chromoendoscopy following application of Lugol's iodine, in 178 patients with known head and neck cancer but no esophageal symptoms. Unstained lesions were identified in 69 patients. Biopsy of unstained lesions detected

**FIG 26.3** Esophageal squamous cell carcinoma as identified by **A**, high-definition white light, **B**, narrow band imaging, **C**, chromoendoscopy with Lugol's iodine, and **D**, following mucosal resection.

13 cancerous lesions in 9 patients (5% of the cohort) and squamous dysplasia in 22 patients (12% of the cohort); the remainder of the unstained lesions demonstrated pathology consistent with either inflammation or what was described as parakeratosis. The majority of ESCC lesions detected by chromoendoscopy were undetectable by conventional endoscopy or esophagram.<sup>45</sup>

In a 1998 study reported by Dawsey and colleagues, 225 patients with known esophageal dysplasia or cancer detected initially by nonendoscopic cytologic evaluation underwent endoscopy, including chromoendoscopy following application of a 1.2% Lugol's solution. The sensitivity of endoscopy for detection of high-grade dysplasia or cancer without Lugol's chromoendoscopy was 62%; the sensitivity for detection of high-grade dysplasia or cancer by identification of unstained lesions on Lugol's chromoendoscopy was 96%. All cases of invasive cancer were detected by conventional endoscopy; however, 55% of cases of moderate dysplasia and 23% of cases of severe dysplasia would have been missed without chromoendoscopy.<sup>46</sup>

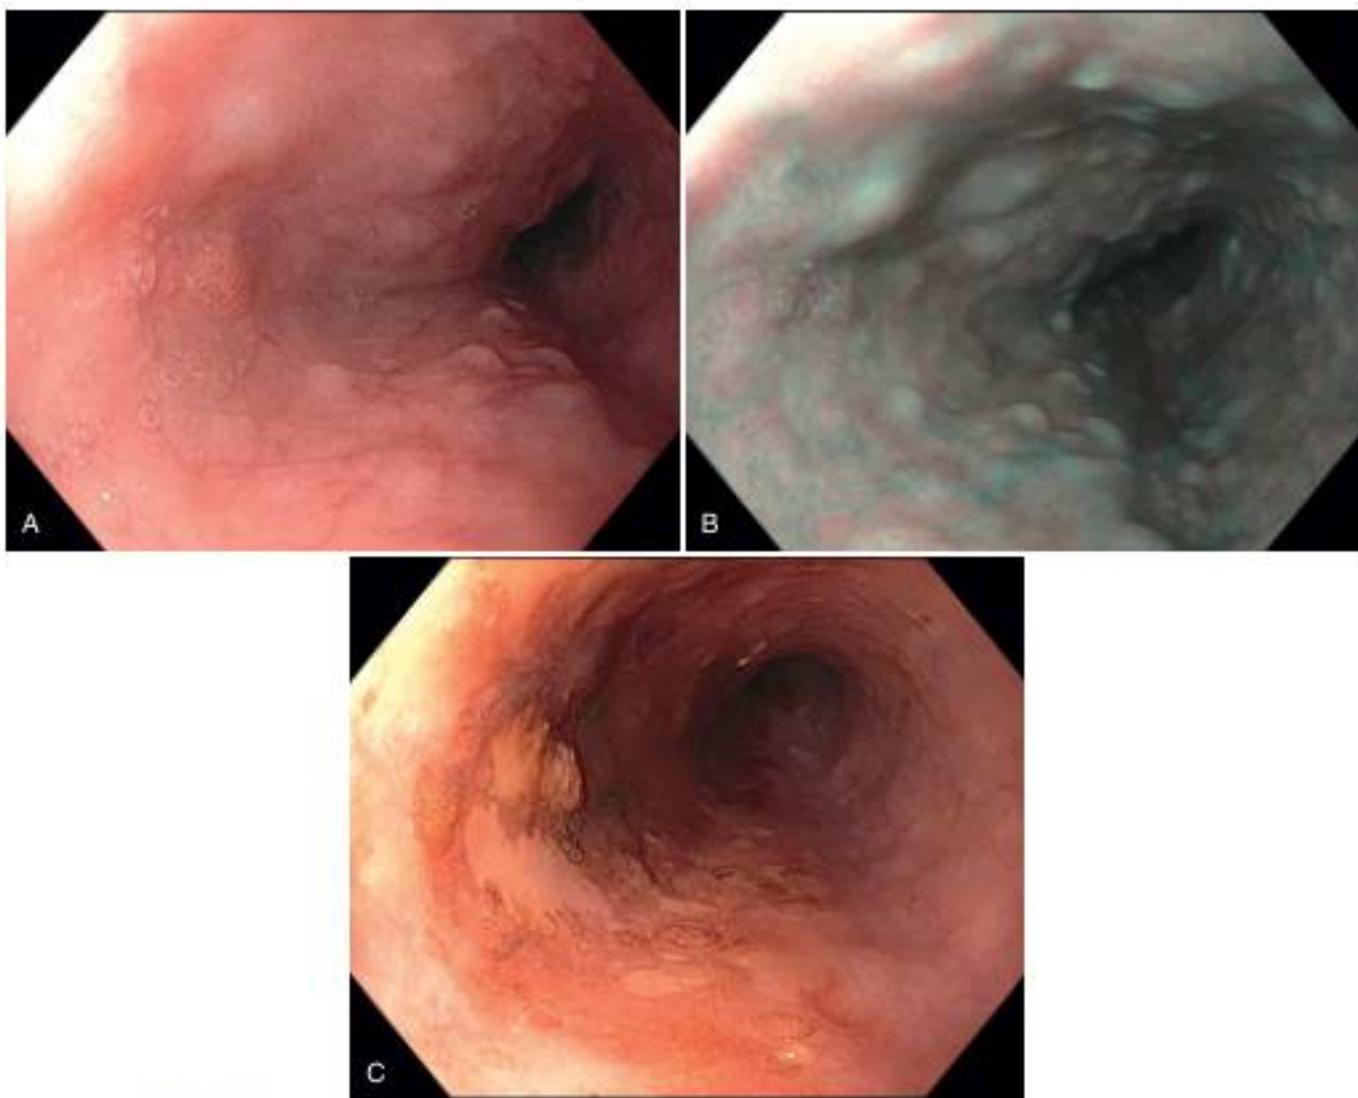

Practical aspects of Lugol's use include appropriate dilution to the desired concentration, followed by application under direct visualization using a spray catheter or cannula. Potential adverse events include postprocedure chest discomfort,<sup>47</sup> allergic reaction,<sup>48</sup> and esophagitis.<sup>49</sup>

Additional agents that have been utilized for chromoendoscopic detection of ESCC include toluidine blue. In series of 18 patients with head and neck cancer reported by Hix et al (1987), esophagoscopy following toluidine blue staining detected esophageal cancer in 17% of subjects.<sup>50</sup> In a larger series of 103 patients

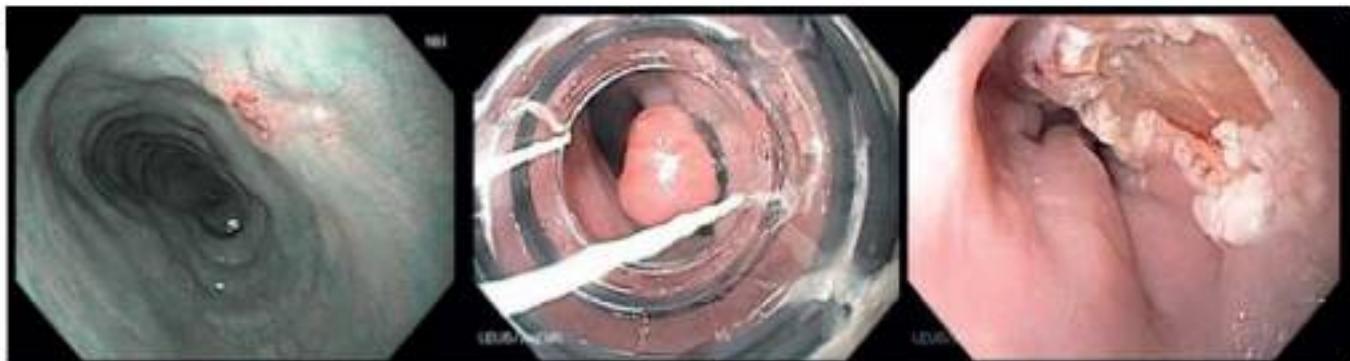

with head and neck cancer, vital staining with 1% toluidine blue resulted in detection of two neoplastic lesions not detected by standard endoscopy.<sup>51</sup>

Advances in endoscopic technology have provided the opportunity for increasingly accurate endoscopic detection and diagnosis of mucosal pathology, potentially including ESCC. Many modern endoscope processors are equipped with proprietary technologies capable of image modification/enhancement to assist in endoscopic detection of mucosal pathology. One such technology is narrow band imaging (NBI) (Olympus, Tokyo, Japan), which filters white light to two wavelengths (450 nm and 514 nm) specific for hemoglobin absorption. The rationale behind this image enhancement is that accentuation of the mucosal vasculature will allow detection of unique vascular morphology present in neoplastic lesions (see Figs. 26.3, 26.4B, 26.5).

Multiple early studies designed to assess the ability of NBI to detect ESCC used the combination of NBI with magnification endoscopy capabilities. White light endoscopy and NBI were compared head to head in a multicenter randomized controlled trial. Three hundred and twenty patients with histologically confirmed ESCC were randomized to undergo either white light endoscopy followed by NBI or NBI followed by white light endoscopy. In addition, the imaging platform utilized for the study enabled 80 $\times$  optical magnification. Fifty-five percent of ESCC were detected by primary white light endoscopy, whereas 97% of lesions were detected by primary NBI. Forty-eight lesions were detected by NBI only (and not white light); one lesion was detected by white light only (and not NBI). Overall procedure

**FIG 26.4** Esophageal squamous cell carcinoma visualized with **A**, high definition white light imaging, **B**, narrow band imaging, and **C**, Lugol's chromoendoscopy.

**FIG 26.5** Esophageal squamous cell carcinoma identified by narrow band imaging and treated with mucosal resection using a band ligator device.

time was longer for primary NBI versus primary white light examinations (135 seconds vs. 95 seconds,  $p < 0.001$ ).<sup>32</sup>

In a study by Takenaka et al (2009) comparing NBI with chromoendoscopy, 142 patients with head and neck cancer underwent NBI endoscopy (with magnification) followed by

Lugol chromoendoscopy. Twenty-one lesions were detected in 16 patients with NBI. All lesions were subsequently evaluated by Lugol chromoendoscopy; 20 of 21 lesions measured greater than 5 mm in diameter and were biopsied. Histopathology confirmed ESCC in 4 lesions, high-grade intraepithelial neoplasia

in 11 lesions, and low-grade intraepithelial neoplasia in 4 lesions. Lugol chromoendoscopy detected four additional lesions in patients with NBI findings, two of which proved to be low-grade intraepithelial neoplasia. With histopathology as the gold standard, the sensitivity of endoscopy for detection of ESCC was 91% using NBI versus 100% using Lugol chromoendoscopy. Performance characteristics of NBI were superior to Lugol's chromoendoscopy with respect to specificity (95% vs. 85%,  $p < 0.001$ ) and overall accuracy (95% vs. 86%,  $p < 0.01$ ).<sup>53</sup>

In a prospective study of NBI without magnification endoscopy, 202 patients deemed at high risk for ESCC underwent endoscopy with white light, followed by NBI inspection, then followed by chromoendoscopy. Biopsies were obtained following complete endoscopic inspection. In analysis using propensity score matching, the accuracy and specificity of NBI were superior to chromoendoscopy, whereas the sensitivity of NBI and chromoendoscopy were comparable.<sup>54</sup>

Additional enhanced endoscopy techniques that have been investigated for the detection of ESCC include autofluorescence imaging (AFI).<sup>55,56</sup> Whereas at least one study reported acceptable test performance characteristics (sensitivity 97% and specificity 95%),<sup>55</sup> large-scale validation of AFI for ESCC screening has not been performed, and this technology is not in routine clinical use at this time.

### Disruptive and Nonendoscopic Screening Techniques

Potential disadvantages of endoscopic screening as currently practiced include: 1) the invasive nature of endoscopic examination and need for administration of procedural sedation; 2) potential for adverse events as a consequence of endoscopic examination and/or procedural sedation; 3) direct costs to the health care system, chiefly in the form of physician and facility reimbursement; and 4) indirect costs incurred via missed work time (by patient and driver/chaperone) on the date of endoscopic examination. Additionally, whereas endoscopy may be viewed by health care providers as a minimally invasive, low-risk procedure, patient willingness to undergo endoscopy as an "acceptable" screening test may be limited. In a high-risk region for ESCC in Iran, only 18% of adult individuals contacted by phone for a screening program agreed to a clinic visit and only 16% underwent endoscopy.<sup>57</sup>

An option for addressing some of these disadvantages would include unsedated endoscopy, which would conceivably allow the patient to return to work following an office-based examination and eliminate the need for a chaperone. In a study of patients undergoing inspection for upper aerodigestive cancers, including the esophagus, using a standard endoscope under topical pharyngeal anesthesia and given the choice of either propofol sedation or no sedation, 123 patients opted for no sedation. The examination was reported as acceptable by 68% (84/123) of unsedated patients; however a complete (pharyngeal) examination was achieved in only 60% (74/123). ESCC was detected in 21% (26/123) of the no sedation group compared to 19% (25/132) of the propofol group.<sup>58</sup>

An alternative to standard peroral esophagoscopy is performance of unsedated transnasal endoscopy using a narrow-caliber endoscope. In a study of 248 patients with established head and neck cancer, unsedated transnasal endoscopy was performed to evaluate for synchronous esophageal neoplasia. Topical nasal decongestive and oropharyngeal anesthesia was administered. Complete esophageal examination was achieved in 244 out of 248 subjects, and esophageal lesions were detected in 46%

(111/244), including 36 patients with ESCC and 23 patients with squamous dysplasia.<sup>59</sup>

Wireless capsule endoscopy for ESCC screening has been described in at least one study, in which esophageal examination with a swallowed pill camera was followed by upper gastrointestinal endoscopy including Lugol chromoendoscopy. Compared to lesions detected by Lugol chromoendoscopy as the gold standard, the sensitivity of capsule endoscopy for the detection of dysplasia or cancer was less than 50%.<sup>60</sup>

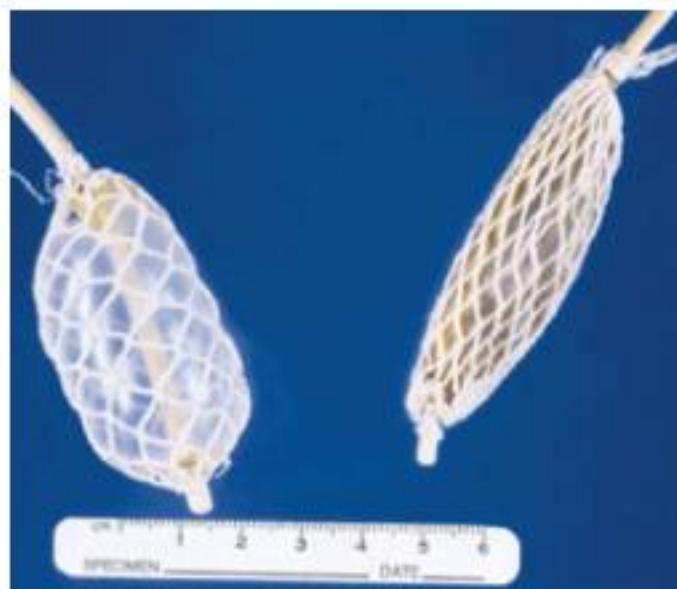

Yet, whereas endoscopy may be considered as the standard and reflexive screening test in the developed world, there are well-established means for ESCC screening with nonendoscopic, peroral cytologic sampling. The general principle of this technique involves asking the patient to swallow a tethered cellular acquisition device, which can then be withdrawn from the stomach and through the esophagus, with the goal of cytologic sampling of the esophageal mucosa.

Several iterations of balloon-based cytologic sampling devices have been developed and used for ESCC screening (Figs. 26.6 and 26.7). A tethered, uninflated balloon is swallowed and then inflated with a small volume (20–30 mL) of air before being withdrawn from the stomach. The balloon is covered with a cotton mesh, and some versions also allow for aspiration of samples through the lumen of the catheter. In a study of more than 12,000 subjects in Linxian, China, balloon-based cytologic screening detected cancer in 2% and dysplasia in more than a quarter of subjects.<sup>61</sup> Among more than 10,000 subjects without cancer at initial screening, 747 incident cancers and 322 cancer-related deaths were identified during 7.5 years of subsequent follow-up. Relative risk of cancer correlated with grade/severity of cytologic dysplasia at baseline.<sup>62</sup>

The other principal category of devices utilized for non-endoscopic cytologic screening for ESCC consists of sponge-based brush biopsy devices (see Fig. 26.6). These devices are enclosed in a gelatin capsule which dissolves in the stomach within a few minutes following ingestion, thereby permitting expansion of the sponge. In a study using an esophageal brush biopsy capsule for screening of subjects in southern Africa, satisfactory specimens were obtained from 96% of subjects screened. Subjects were allocated to subgroups deemed as low-risk, intermediate-risk,

**FIG 26.6** Sponge and balloon cytologic samplers used in Japan and China.

**FIG 26.7** Balloon cytologic samplers. (From Roth MJ, Liu SF, Dawsey SM, et al: Cytologic detection of esophageal squamous cell carcinoma and precursor lesions using balloon and sponge samplers in asymptomatic adults in Linxian, China. *Cancer* 80(11):2047–2059, 1997.)

or high-risk, respectively, for esophageal cancer based on geographic location. Among subjects in the high-risk location, this screening technique detected cancer in 2% of subjects; dysplasia was detected in 9% of subjects older than age 35.<sup>61</sup> In a study of 334 subjects with previously treated upper aerodigestive tract malignancy, brush biopsy capsule screening had a sensitivity of 89% and specificity of 91% for detection of recurrent malignancy during a 3-year follow-up period; approximately one-third of malignancies were esophageal, while the remainder were oropharyngeal.<sup>62</sup> In a 2014 study, more than 300 subjects in Iran underwent screening with a new iteration of a sponge-based device. The sensitivity for detection of high-grade squamous dysplasia was 100% and the specificity was 100%. Addition of p53 immunohistochemistry to cytology resulted in a diagnostic accuracy of 100% for detection of high-grade dysplasia. Ninety-three percent of subjects reported the sponge examination as “acceptable” on a 6-point visual analog scale.<sup>63</sup>

Balloon-based and sponge-based cytologic sampling devices were compared head-to-head, followed by standard endoscopy with Lugol chromoendoscopy, in a study of asymptomatic, previously unscreened individuals in Linxian, China. The order of nonendoscopic cytologic sampling (balloon vs. sponge) was randomized. A complete examination was achieved in 99% of 625 subjects using the balloon and in 86% of 538 subjects using the sponge. Thirty-one percent of subjects reported preference for the balloon technique, 43% reported preference for the sponge, and 26% reported no preference. Adequate squamous cells for analysis were obtained in 99% of 434 cases using the balloon and 86% of 378 cases using the sponge.<sup>64</sup> The comparative yield for detection of squamous dysplasia/ESCC by these two techniques is depicted in Table 26.1.

Four hundred and fifty-nine subjects then underwent standard endoscopy with Lugol chromoendoscopy and biopsy, following administration of topical oropharyngeal anesthesia but no other

**TABLE 26.1 Detection of Esophageal Squamous Neoplasia by Cytologic and Endoscopic Sampling**

	Balloon Cytology (%) N = 434	Sponge Cytology (%) N = 378
LGSIL	42 (10)	23 (6)
HGSIL	5 (1)	0
Suspicious for carcinoma	4 (1)	3 (1)
Carcinoma	7 (2)	0

LGSIL, low-grade squamous intraepithelial lesion; HGSIL, high-grade squamous intraepithelial lesion.

Data from Roth MJ, Liu SF, Dawsey SM, et al: Cytologic detection of esophageal squamous cell carcinoma and precursor lesions using balloon and sponge samplers in asymptomatic adults in Linxian, China. *Cancer* 80(11):2047–2059, 1997.

sedation. Endoscopy with biopsy detected pathology in nearly a third of subjects: mild squamous dysplasia in 12% (52/459), moderate dysplasia in 10% (45/459), severe dysplasia in 6% (26/459), and ESCC in 4% (16/459).<sup>64</sup> With endoscopic diagnosis as the comparative standard, the sensitivity of nonendoscopic cytologic sampling for detection of ESCC was 44% using the balloon and 18% using the sponge, and the sensitivity for detection of the combined diagnoses of dysplasia and/or ESCC was 47% using the balloon and 24% using the sponge. Specificity for detection of cancer was 99% using the balloon and 100% using the sponge; specificity for detection of dysplasia or cancer was 81% using the balloon and 92% using the sponge.<sup>64</sup>

### Endoscopic Treatment of Superficial ESCC

The final criteria for implementation of a screening program is the requirement that effective and acceptable treatment options should be available for patients found to have disease as a consequence of screening examination. Esophageal malignancy, when detected at an asymptomatic or otherwise advanced stage, is associated with a poor prognosis. Treatment regimens may be multimodal and entail systemic chemotherapy, radiation therapy, and/or surgical esophagectomy (if therapeutic intent is curative rather than palliative).

The endoscopic techniques of endoscopic mucosal resection (EMR) (see Fig. 26.5) and endoscopic submucosal dissection (ESD) have revolutionized treatment for superficial gastrointestinal tract neoplasia, including esophageal neoplasia. The ability to offer EMR/ESD techniques provides a strong rationale for early detection of ESCC with the goal of endoscopic therapy for durable disease remission/cure. These techniques are described in detail elsewhere in this textbook (see Chapter 27).

### SUMMARY OF CURRENT RATIONALE FOR SCREENING: EFFECTIVENESS AND COST-EFFECTIVENESS

Individuals at high risk for ESCC can be identified based on factors including residence in a high-risk geographic location and health-associated factors including alcohol and tobacco use. Squamous dysplasia is a precursor lesion to ESCC, and both squamous dysplasia and ESCC can be detected at an asymptomatic stage by nonendoscopic cytologic or endoscopic

screening. Endoscopic biopsy, particularly following Lugol chromoendoscopy, is highly accurate for detection of dysplasia/ESCC. Individuals detected with esophageal neoplasia as a consequence of screening at an early, asymptomatic stage may be candidates for endoscopic, esophagus-preserving therapy with minimal associated morbidity.

It must be recognized that the detection of dysplasia and even ESCC is, to some degree, a surrogate endpoint. Each of the criteria requisite for the justification of an ESCC screening program can be supported by data. Ultimately, however, the metric by which an ESCC screening program should be judged is the extent to which a program aimed at early detection and prevention reduces ESCC-associated mortality. For instance, relatively recent data reported 10-year follow-up data of 3,319 patients from fourteen villages in a high-risk area of China who underwent one time screening endoscopy. Patients found to have lesions amenable to endoscopic intervention were treated with endoscopic resection and/or fulguration; treatment for invasive/advanced disease included surgery and systemic therapy when appropriate. Comparison was made to a control group of 23,733 subjects who did not undergo endoscopic screening. Cumulative incidence of ESCC was 4.17% in the screening group compared to 5.92% in the control group. Mortality due to ESCC was 3.35% in the screening group compared to 5.05% in the control group. The adjusted hazard ratio for ESCC mortality was 0.51 in the screening group.<sup>20</sup>

Whereas the effectiveness of a program is one measure, cost may be an equally important measure within the constraints of any given health system, particularly in a region or setting that may be resource-limited. Formal cost-utility analysis (often referred to as cost-effectiveness analysis) is a technique in which a mathematical model is created to allow a simulated patient to transition between varying health and disease states. A "utility" score can be used to assign a relative value for any given health or disease state, with reference values ranging from 1 for perfect health and 0 for death. Actual or estimated costs can be assigned to interventions (such as screening tests or treatments) that affect the likelihood of transitioning between health and disease states or for the costs associated with treatment of various health states. For instance, costs for management of esophageal cancer are generally high and are dominated by costs of surgery and chemotherapy.<sup>21</sup> At final analysis, for any given intervention an incremental cost effectiveness ratio (ICER) can be calculated; for instance, in a typical cost-effectiveness analysis the ICER is reported as dollars spent for quality adjusted life year saved (\$/QALY). Based on this calculation, a screening test might be deemed acceptable from a societal standpoint if the ICER is below an accepted willingness to pay threshold (WTP), usually \$50,000–\$100,000/QALY in the United States. Other commonly performed health interventions (mammogram for breast cancer screening, colonoscopy for colorectal cancer screening, etc.) fulfill this criterion as their ICER is below the accepted WTP.

Numerous cost-effectiveness analyses have been published to examine the rationale for endoscopic prevention of esophageal adenocarcinoma in the United States and Western populations via screening endoscopy among patients with gastroesophageal reflux disease and surveillance endoscopy among patients with established Barrett's esophagus. Similar analysis of ESCC screening is limited.

General population screening for ESCC via endoscopy cannot be justified in a region of low prevalence. One study estimated that the prevalence rate of ESCC in the United States would

have to increase 1948% from current levels to justify endoscopic screening at a WTP of less than \$50,000/QALY.<sup>22</sup> On the other hand, the cost utility calculation for ESCC screening in a highly endemic area may be much more favorable. It has been suggested that 100 adults in a high-risk region of China could undergo endoscopic screening with Lugol chromoendoscopy and biopsy at a cost equivalent to the cost of treating one patient with advanced stage cancer.<sup>23</sup>

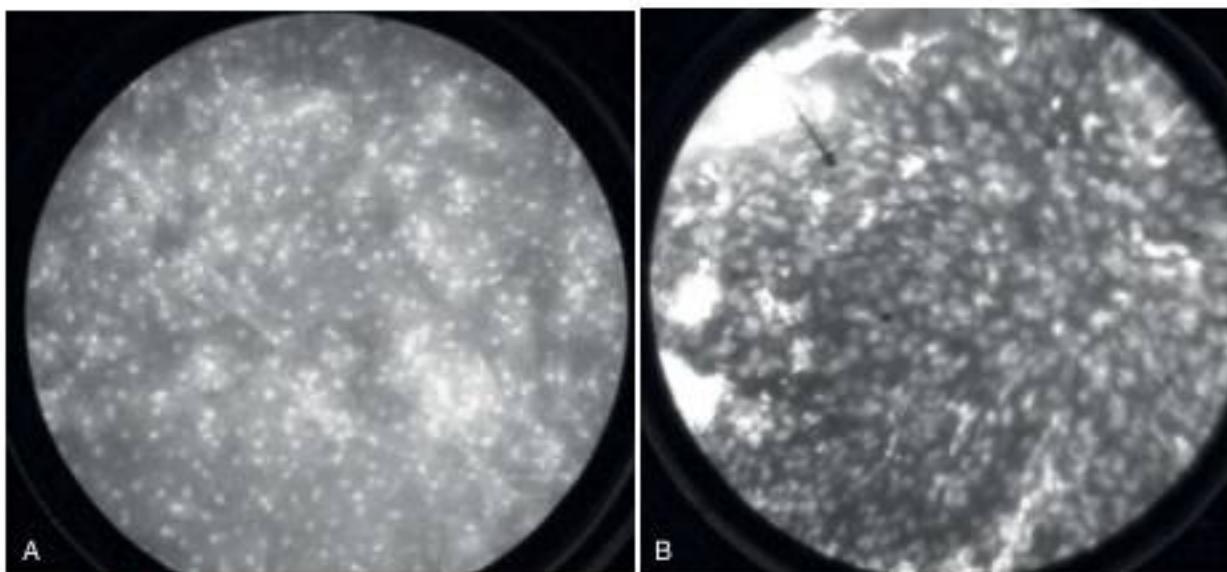

Disruptive technologies that offer new mechanisms for screening can be assessed by cost-utility analysis. As an example, emerging endoscopic technologies with "optical biopsy" capabilities offer the promise of real-time histopathologic assessment, and potential cost savings by reducing the number of unnecessary biopsies, or conceivably even by allowing the endoscopist to proceed immediately from diagnostic assessment to therapeutic intervention in a single endoscopy session. High-resolution microendoscopy (HRME) technology used as an adjunct to Lugol's chromoendoscopy may improve the diagnostic accuracy for detection of squamous neoplasia<sup>24</sup> (Fig. 26.8), and cost-effectiveness analysis has demonstrated that incorporation of HRME into an endoscopic screening program for a high-risk population could be cost-effective at an ICER of \$8173/QALY.<sup>25</sup>

Additional technologies that offer the promise of optical biopsy include confocal laser endomicroscopy (Fig. 26.9). In this technique, fluorescein is administered intravenously. Following cellular uptake of fluorescein, the esophageal mucosa is examined with a specially equipped endoscope or accessory probe, permitting evaluation of cellular and capillary architecture as histopathologic correlates. Whereas the ability of this technique to discriminate between normal mucosa and early ESCC has been reported,<sup>26,27</sup> and the learning curve and interobserver variability appear reasonable,<sup>28</sup> formal cost-utility analysis has not been reported.

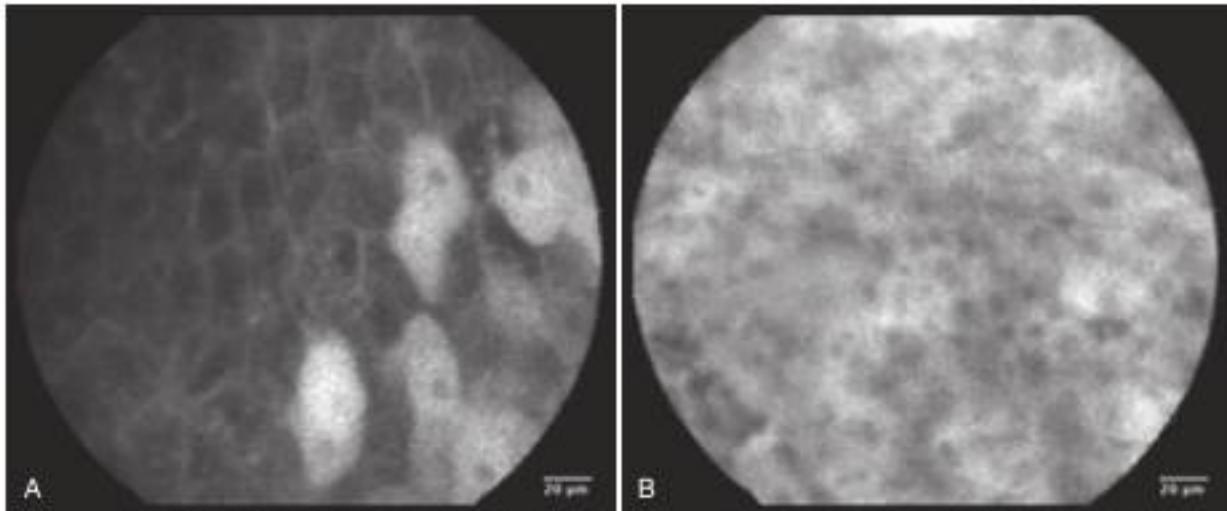

## FUTURE DIRECTIONS FOR NONINVASIVE SCREENING: SEROLOGIC AND STOOL TESTING; MICROBIOTA

Future advances in early detection and diagnosis of ESCC may be facilitated by emerging insights into risk factors and disease pathogenesis, allowing for risk stratification and identification of individuals and groups at risk for ESCC. An active area of current investigation is the role of the microbiome in health and disease through the gastrointestinal tract. The most well-known example is that of *Helicobacter pylori*, which is strongly associated with gastric cancer and inversely associated with esophageal adenocarcinoma, but not associated with ESCC.<sup>29</sup> Data suggest that salivary microbiota may be altered in patients with ESCC<sup>30</sup> and squamous dysplasia<sup>31</sup> compared to nonaffected controls.

Noninvasive stool sample assays have been a staple of colorectal cancer screening, and newer generation tests include options for fecal DNA testing. Whether fecal DNA testing (or other assays) could be an option for ESCC screening will require investigation, which to date has not been reported. Elevated fecal calprotectin levels have been described in patients with esophageal and gastric cancer,<sup>32</sup> although the specificity of this marker, which can be elevated in benign conditions including inflammatory bowel disease, is uncertain. Elevated serum microRNA levels can be detected in patients with ESCC,<sup>33,34</sup> raising the prospect that novel biomarkers may offer a future opportunity for serologic screening.

**FIG 26.9** Confocal laser microscopy. **A**, Confocal image of normal squamous epithelium shows normal cellular structure. **B**, Image of esophageal cancer shows disorganized cells with enlarged and hyperchromatic nuclei. (Photographs courtesy Dr Cuong Nguyen and Dr. Ananya Das.)

Targeted mucosal assessment with molecular probes may allow optimized endoscopic detection and localization of ESCC. Use of fluorescent-labeled, topically administered probes may assist in this fashion. Probes whose ligand is an aminopeptidase expressed and activated in ESCC have been described in *ex vivo* use.<sup>34</sup>

## CONCLUSIONS

ESCC is a leading cause of cancer death worldwide. When diagnosed at a symptomatic phase, ESCC is often already at an advanced stage with attendant poor prognosis. Detection of esophageal squamous dysplasia or early stage ESCC when in a latent, asymptomatic phase can offer opportunities for curative,

endoscopic, esophagus-preserving treatment. For each of these reasons, screening for ESCC is an intuitively attractive option. Endoscopic examination, particularly with Lugol's chromoendoscopy, has high performance characteristics as a screening test for squamous dysplasia/ESCC. This is, however, a costly, resource-intensive examination, which is on one hand not cost-effective in relatively affluent Western countries with low ESCC prevalence, and on the other hand not cost feasible in many resource-limited areas of the world with high ESCC prevalence. Nonendoscopic cytologic screening has proven efficacy in regions of high prevalence. Future disruptive screening technologies may expand opportunities for reduction in mortality from the global ESCC epidemic.

## INTRODUCTION

Esophageal cancer remains the eighth most common cancer and the sixth leading cause of cancer-related mortality worldwide.<sup>1</sup> Two main subtypes exist: esophageal adenocarcinoma (EAC) and esophageal squamous cell carcinoma (ESCC). EAC predominates in North America and Europe, and there has been a steep rise in its incidence over the last several decades.<sup>2</sup> ESCC is most prevalent in Asia and Africa, and accounts for over 90% of esophageal cancers worldwide.<sup>3</sup> The prognosis for esophageal cancer is poor, with an overall 5-year survival of less than 20%.<sup>4</sup> This stems in large part from challenges related to early detection, as the majority of cancers present at advanced stages (T3 and T4) for which effective treatments do not yet exist. However, when esophageal cancer is encountered early (i.e., stage Tis or T1a), survival can be dramatically improved with therapy. Until recently, the only curative treatment option was esophagectomy, which carries substantial risk and may not be advised in patients with significant comorbidities.<sup>5</sup> Improvements in endoscopic resection techniques, namely endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD), devised to procure larger amounts of tissue for accurate staging, have also enabled endoscopists to curatively treat early esophageal cancers.<sup>6</sup> Moreover, residual mucosa that could become neoplastic is treated with ablative therapies that can be applied with less morbidity than previously.<sup>7</sup> Endoscopic methods to treat cancer have become an important tool for the gastroenterologist, and their mechanisms, techniques, and evidence are reviewed in this chapter. Screening and surveillance for Barrett's esophagus is covered in Chapter 25.

ESCC is believed to follow a stepwise process of neoplastic progression. Established risk factors include alcohol, tobacco, exposure to environmental toxins such as polycyclic aromatic hydrocarbons, and potentially nutritional deficiencies.<sup>7</sup> Recent studies (2015) suggest a cost benefit for screening endoscopy or balloon brush cytology in areas of high incidence such as northern

and rural areas of China.<sup>8</sup> At this time, however, there are no widely accepted guidelines for ESCC screening.

## ENDOSCOPIC DETECTION AND DIAGNOSIS

At an early stage, esophageal cancer is usually asymptomatic (without dysphagia, weight loss, or anemia, which tend to reflect advanced disease), and is typically detected during screening or surveillance endoscopy or during the endoscopic evaluation of unrelated abdominal symptoms. Moreover, both histologic subtypes may appear subtle and be easily missed during endoscopy, underscoring the importance of a careful, systematic endoscopic evaluation. EAC is predominantly detected in the distal third of the esophagus, arising from a background of Barrett's epithelium, possibly in the form of an ulceration, an altered mucosal pattern, or a nodularity (Fig. 27.1). EAC may also be detected during random biopsies in the absence of any apparent endoscopic abnormality. Enhanced techniques can be used to complement white light endoscopy (WLE) for a more detailed inspection of Barrett's mucosa and abnormalities. Dye-based chromoendoscopy involves the topical application of methylene blue or acetic acid using a catheter spray.<sup>9,10</sup> These techniques are detailed in Chapter 25.

ESCC is more commonly found in the middle and proximal third of the esophagus. Early signs of ESCC may be as subtle as a mucosal irregularity, sometimes with a thin white coating or a reddish hue. Dye chromoendoscopy, specifically using Lugol solution, can aid in the detection of early ESCC. Lugol solution is sprayed over the esophageal mucosa during endoscopy, and within minutes preferentially stains normal squamous epithelium brown/black. Demarcated, unstained tissue may represent dysplasia, carcinoma, or inflammation (Fig. 27.2). In a study investigating the detection of high-grade dysplasia (HGD) or cancer in a high-risk population from China, the application of Lugol solution improved the sensitivity of WLE from 62% to 96%, while retaining a specificity of 63% (79% prior to staining).<sup>11</sup>

**Abstract**

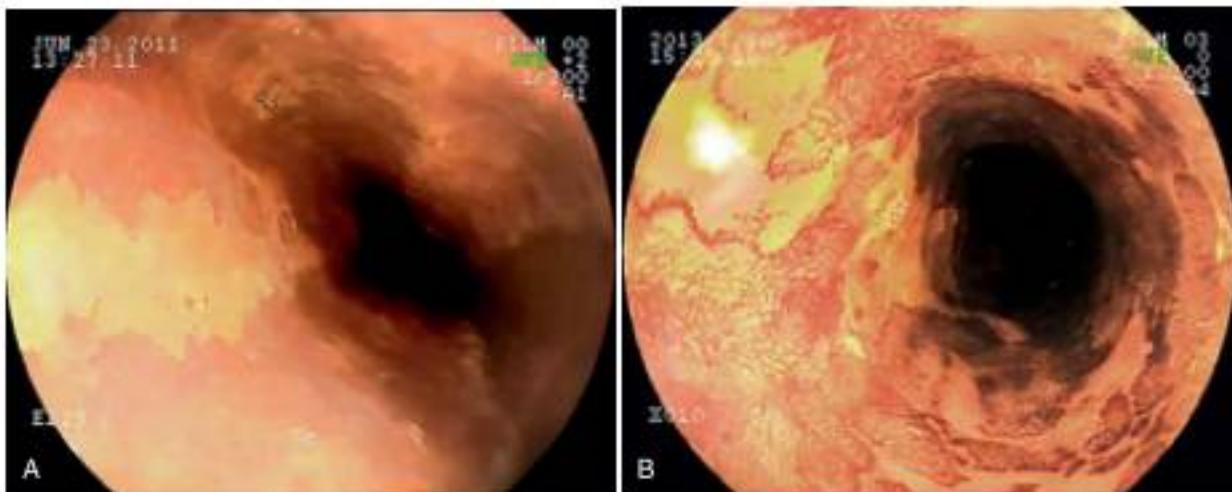

Esophageal cancer is among the most common cancers worldwide, and the prognosis remains dismal. However, when esophageal cancer is encountered early, survival can be dramatically improved with therapy. Until recently, the only curative treatment option was esophagectomy, which carries substantial risk and may not be advised in patients with significant comorbidities. Improvements in endoscopic resection techniques devised to procure larger amounts of tissue for accurate staging, namely endoscopic mucosal resection and endoscopic submucosal dissection, have also enabled endoscopists to curatively treat early esophageal cancers. Moreover, residual mucosa that could become neoplastic is treated with ablative therapies that can be applied with less morbidity than previously. Endoscopic methods to treat cancer have become an important tool for the gastroenterologist, and their mechanisms, techniques, and evidence are reviewed in this chapter.

**FIG 27.1** **A**, Early esophageal adenocarcinoma. **B**, Squamous cell carcinoma.

**FIG 27.2** **A**, Before and **B**, after application of iodine-containing Lugol solution.

In another study, the additional finding of reddish or rose-pink appearance (so-called pink sign) was helpful in differentiating ESCC and HGD from low-grade dysplasia (LGD) or inflammation, with a sensitivity and specificity of 92% and 94%, respectively.<sup>12</sup> Thus, Lugol chromoendoscopy is generally recommended during screening for ESCC. The utility of virtual chromoendoscopy in improving ESCC detection has also been investigated. Using narrow band imaging (NBI), ESCC or dysplasia may appear as a well-demarcated brownish area with distorted patterns of intrapapillary capillary loops (Fig. 27.3). In a prospective, randomized controlled study, virtual chromoendoscopy significantly improved the detection of head, neck, and esophageal squamous cell cancer compared to WLE alone (97% vs. 55%).<sup>13</sup> A 2015 randomized noninferiority trial comparing Lugol and virtual chromoendoscopy concluded there was no significant difference in diagnostic yield.<sup>14</sup>

## STAGING OF EARLY ESOPHAGEAL CANCER

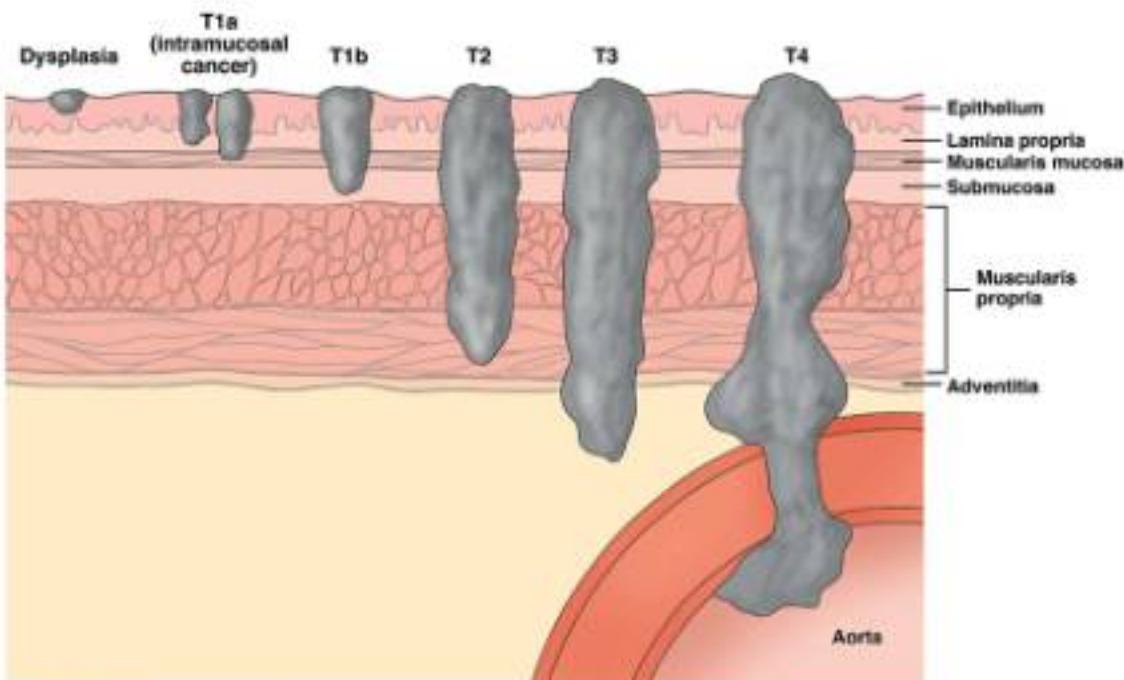

The depth of esophageal cancer invasion (i.e., T staging) is critical in determining the risk of lymph node involvement and whether

a patient is a candidate for curative endoscopic treatment or will need esophagectomy and/or (neo)adjuvant chemoradiotherapy. To understand why, it is helpful to remember that the esophageal mucosal layer is comprised of epithelium, lamina propria, and muscularis mucosa layers. The mucosa is separated from the underlying submucosa by the basement membrane. The esophageal cancer staging system most commonly used is outlined by the American Joint Committee on Cancer.<sup>15</sup> The staging system was updated in 2010, at which time separate staging systems were developed for EAC and ESCC. However, they remain identical with respect to staging of early esophageal cancers. Early esophageal cancers (i.e., stage Tis and T1a) are characterized by confinement to the esophageal mucosal layer. Specifically, stage Tis is characterized by HGD limited to the epithelium (formerly known as carcinoma *in situ*), and stage T1a by lamina propria or muscularis mucosa involvement (intramucosal cancers). Later-stage tumors, beginning with T1b, invade the submucosa (Fig. 27.4).

Submucosal tumor involvement marks an important distinction because it confers a higher risk of lymph node metastasis and usually precludes endoscopic treatment with curative intent.

**FIG 27.3** The added utility of virtual chromoendoscopy (B) to white-light endoscopy (A) in evaluating for dysplasia or squamous cell cancer. Using virtual chromoendoscopy (B), neoplasia may appear as a well-demarcated, brownish area with distorted patterns of intrapapillary capillary loops.

**FIG 27.4** Staging of tumor depth. Stage Tis and T1a tumors are confined to the esophageal mucosa, whereas stage T1b and more advanced tumors invade the esophageal submucosa. (From Rubenstein JH and Shaheen NJ: Epidemiology, diagnosis, and management of esophageal adenocarcinoma. *Gastroenterology* 149(2):302–317.e1, 2015.)

In a large systematic review of 70 studies including 1874 patients undergoing esophagectomy with lymph node dissection for HGD or intramucosal adenocarcinoma, lymph node metastasis was found in 0% of 524 patients with HGD and 1.9% of patients with intramucosal cancer.<sup>16</sup> In another study reviewing the outcomes of the National Cancer Database, the risk of nodal metastasis for T1a disease in patients undergoing esophagectomy for EAC and ESCC was 6.4% and 6.9%, whereas for T1b disease it was 19.6 and 20%, respectively.<sup>17</sup> Hence, the risk of nodal metastasis is much greater for submucosally invasive tumors,

and patients with T1b disease should be referred for consideration of esophagectomy. A subset of patients with T1b disease limited to the superficial third of submucosa (i.e., T1b sm1) and well-differentiated histology without lymphovascular invasion who are not good candidates for surgery may still be treated endoscopically with encouraging outcomes,<sup>18</sup> but this decision should involve a multidisciplinary surgical and oncology discussion.

Staging of potential early esophageal cancers is best achieved by endoscopic methods of tissue acquisition (discussed later). If confinement to mucosa is confirmed, imaging modalities such

as endoscopic ultrasound (EUS) and computed tomography (CT) with or without positron-emission tomography (PET) do not appear to impact the management of early esophageal cancer.<sup>20</sup>

### Endoscopic Inspection

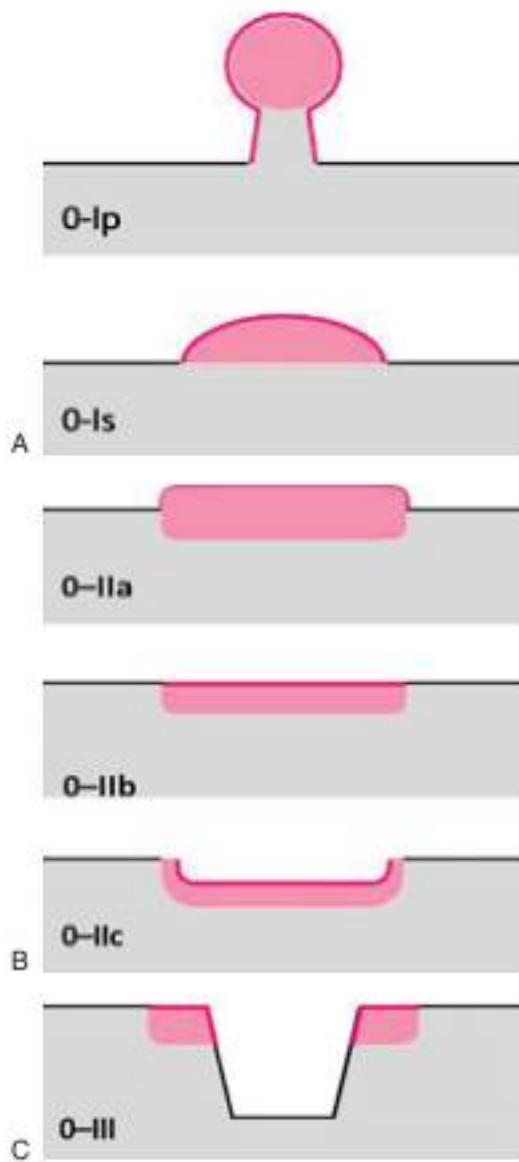

Although tissue acquisition is the gold standard for early esophageal cancer staging, inspection for macroscopic clues may be helpful in predicting tumor depth, particularly for superficial ESCC. Various classification schemes have been described. The Paris classification categorizes superficial-appearance esophageal carcinoma accordingly: type 0-I (protruding), 0-II (without definite protrusion or depression), and 0-III (excavated).<sup>21</sup> Type 0-I and 0-III lesions carry a high likelihood of submucosal invasion (94.7% and 100%, respectively) consistent with stage T1b disease. Type 0-IIa (slightly elevated) and 0-IIb (completely flat) tumors suggest stage Tis or T1a disease. Type 0-IIc (slightly depressed) may be either stage Tis, T1a, or T1b (Fig. 27.5). The utility of NBI magnification in detecting microvascular irregularities such as intrapapillary capillary loops (to differentiate T1a from T1b tumors) has also been reported to have high sensitivity (78%) and specificity (95%).<sup>22</sup> It is worth remembering that documentation of the shape, size, and location (with respect to the gastroesophageal junction) of all potential tumors can aid in planning, if surgery is recommended.

### Endoscopic Resection

The presence of an esophageal nodule or mucosal irregularity in patients with risk factors, especially Barrett's esophagus (BE), should immediately raise concern, due to the high probability of harboring cancer.<sup>23</sup> Biopsies alone have been found to underestimate the degree of dysplasia because of difficulty in judging the extent of invasion, and therefore have been largely supplanted by EMR and ESD, which enable acquisition of larger amounts of tissue for histology. Studies have demonstrated that EMR alters the final histological stage in 30% to 50% of cases when compared to biopsies alone.<sup>23,24</sup> Given the low rate of lymph node metastasis in early esophageal cancer, endoscopic resection has the potential to be simultaneously curative in patients. Resection also has the potential to spare the cost, patient anxiety, and delays in care stemming from other staging modalities in this low-yield setting. Histology from EMR or ESD also provides information on prognostic factors for the survival of patients with early stage esophageal cancer, such as lymphovascular invasion and deep margin involvement (Fig. 27.6).<sup>25</sup> For these reasons, endoscopic resection should be the initial step in the evaluation of visible esophageal nodules or lesions suspicious for early esophageal cancer.

### Endoscopic Ultrasound and PET/CT

EUS can be performed with either dedicated echoendoscopes or high-frequency ultrasound probes to assess the esophageal wall layers and assess tumor depth of invasion, as well as regional lymph node involvement. However, EUS may not be very accurate in staging early esophageal cancers, and may overstage cancers as T1b (due to tumor-associated inflammation), resulting in the exclusion of lesions amenable to endoscopic therapy.<sup>26,27</sup> In a meta-analysis of 12 studies including 292 patients with HGD or early esophageal cancer, EUS had a T-stage concordance of 67% when compared to surgical or EMR pathology.<sup>27</sup> PET/CT has not been demonstrated to be of benefit in patients with established intramucosal cancer. EUS and PET/CT may best be reserved for lymph node evaluation in patients with at least T1b

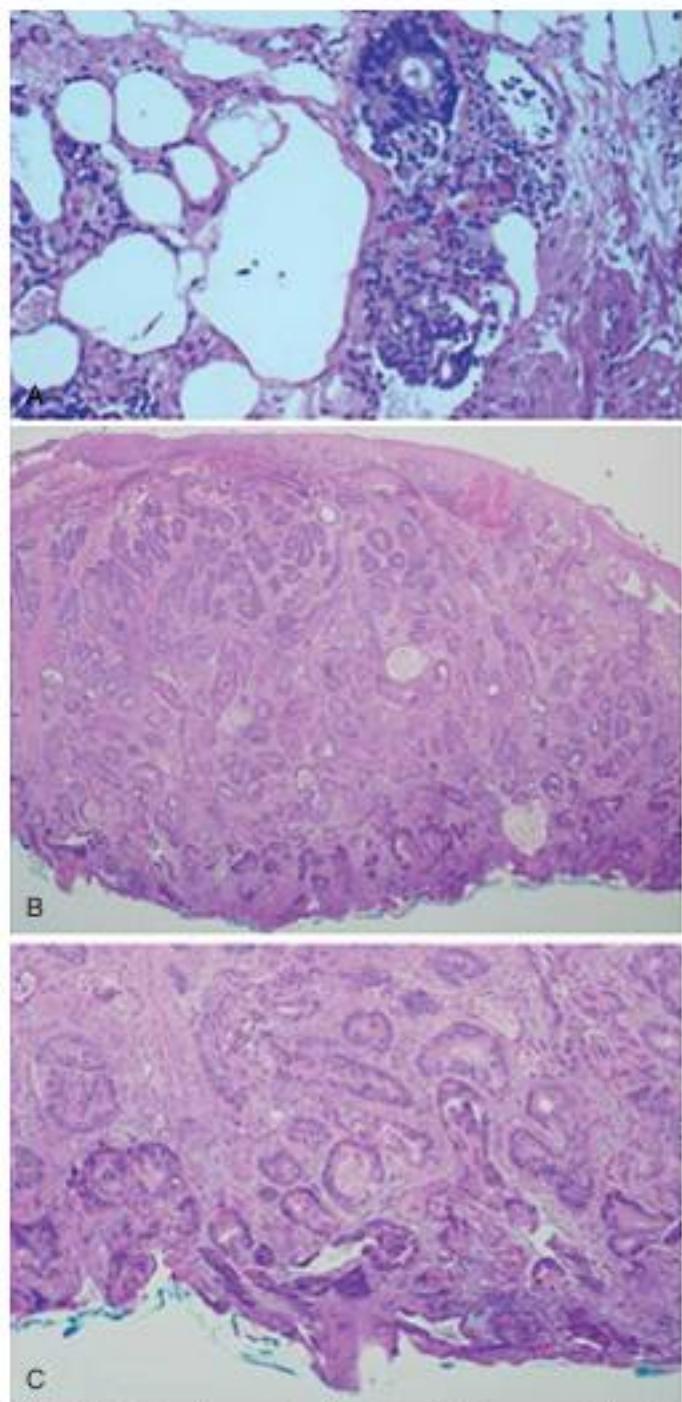

**FIG 27.5** The Paris classification categorizes superficial-appearance esophageal carcinoma as **A**, type 0-I (protruding), **B**, type 0-II (without definite protrusion or depression), or **C**, type 0-III (excavated). Type 0-I and 0-III lesions carry a high likelihood of submucosal invasion, suggesting stage T1b disease, whereas type 0-IIa (slightly elevated) and 0-IIb (completely flat) tumors suggest stage Tis or T1a disease. Type 0-IIc (slightly depressed) lesions may be stage Tis, T1a, or T1b. (Adapted from Endoscopic Classification Review Group: Update on the Paris classification of superficial neoplastic lesions in the digestive tract. *Endoscopy* 37[6]:570–578, 2005.)

disease, particularly if being considered for endoscopic resection, which, in the presence of lymph node metastasis, would necessitate esophagectomy and chemoradiation for the chance of a cure.

## METHODS OF ENDOSCOPIC TREATMENT OF ESOPHAGEAL CANCER

Endoscopic treatment can be broadly divided into tissue-acquiring and tissue ablative therapies. Tissue-acquiring strategies, namely

**FIG 27.6** **A**, Lymphovascular invasion. **B**, Deep margin involvement with **C**, magnification.

EMR and ESD, as mentioned previously, are not only diagnostic but also potentially therapeutic. Ablative therapies induce tissue injury via heat (radiofrequency ablation or argon plasma coagulation [APC]), cold (cryotherapy), or photochemical energy (photodynamic therapy [PDT]), and do not yield tissue for histology. The principle of ablation is based on the concept of inducing squamous re-epithelialization with acid reflux control following ablation of the metaplastic mucosa.

In patients with BE and intramucosal adenocarcinoma treated with endoscopic resection, the risk of metachronous or recurrent

cancer remains substantial (approximately 30%).<sup>20</sup> Thus, ablative therapies are recommended in an effort to eradicate the background of premalignant BE and promote neosquamous re-epithelialization. Additionally, the presence of residual BE mucosa has been shown to be predictive of recurrent cancers.<sup>21,22</sup> If HGD or intramucosal cancer is detected on random biopsies in the absence of visible abnormalities, despite careful examination, ablative therapies should be directly pursued following careful evaluation for any visible abnormalities, which should be endoscopically resected. An algorithmic approach to patients with BE found to have focal lesions, HGD, or cancer is shown in Fig. 27.7.

### Endoscopic Resection

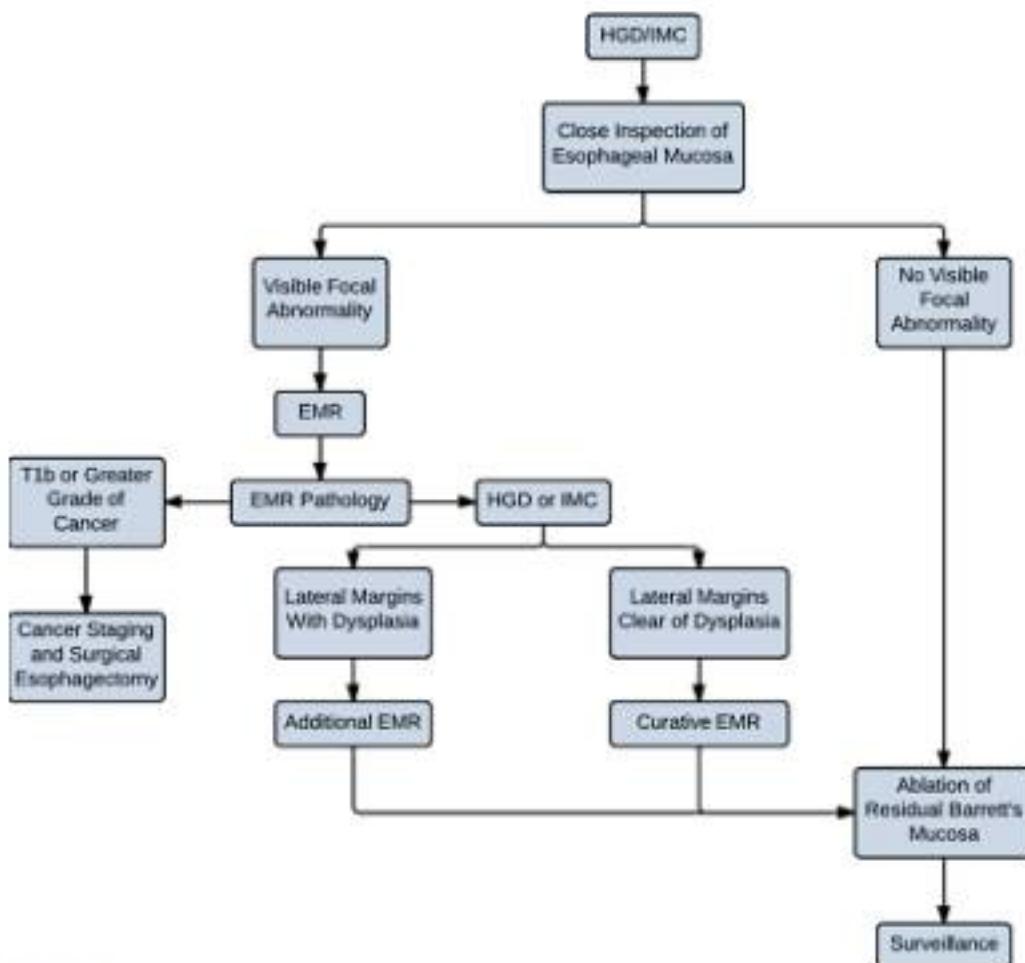

#### Endoscopic Mucosal Resection

EMR was pioneered in Japan for the management of gastric cancer, and has since been successfully applied to the treatment of various other lesions in the gastrointestinal tract. The main indications for performing esophageal EMR are the evaluation and staging of potentially malignant nodular lesions and treatment of established early esophageal cancer.

The two main methods of performing EMR are the cap and snare technique (Cap EMR) following saline injection, and band ligation (Band EMR) with snare resection. Both techniques are considered equally effective, and are demonstrated in Videos 27.1 and 27.2.<sup>23</sup> The cap is available in two styles; one is completely level or straight, whereas the other is oblique. The cap also varies in terms of the consistency of the material from which it is made. Generally, hard plastic caps are favored when there is a need to try to suction more scarred tissue, whereas soft caps are more useful when passing the caps through the upper pharynx, particularly in the presence of stenosis. The oblique cap is favored in resection of larger pieces of tissue, whereas the straight cap may be more favored when precision is required in the amount of tissue targeted for resection. Submucosal injection of a saline-epinephrine solution to lift the lesion may assist with resection and avoid deeper tissue layers. Depending on the visibility of the lesion, the borders may need to be marked using a cautery device (such as a multipolar coagulator) before injection, to ensure that the area to be removed can be visualized after injection. The area of carcinoma may have previously been established by biopsy, and the area is lifted by positioning an injection needle proximal to the lesion. The sequence of an injection with adequate lifting of the target lesion is shown in Fig. 27.8C.

Once the target lesion is lifted by the injection, it can be removed with resection. If removal is not accomplished immediately, inflammation induced by the injection may cause the cancer to become adherent to the submucosa or muscularis propria, which would make resection challenging. The mucosal resection component of this technique is similar to a standard polypectomy, except that suction is needed to create a pseudopolyp for mucosal removal. The endoscope with the resection cap attached is advanced into the stomach. It is generally recommended that the snare be positioned in the antrum of the stomach because the mucosa there is smoother and allows easier deflection of the snare around the diameter of the cap. Individuals experienced in this technique can position the snare using mucosa from the esophagus or proximal stomach, although this can be challenging.

The sequence of positioning a snare around the lip of a mucosal resection cap is shown in Fig. 27.8D. This is often the most difficult portion of the mucosal resection because, if the snare

**FIG 27.7** An algorithmic approach to patients with Barrett's esophagus found to have lesions, HGD, or cancer. EMR, endoscopic mucosal resection; HGD, high-grade dysplasia; IMC, intramucosal cancer. (From Blevins CH, Iyer PG: Endoscopic therapy for Barrett's oesophagus. Best Pract Res Clin Gastroenterol 29(1):167–177, 2015.)<sup>10</sup>

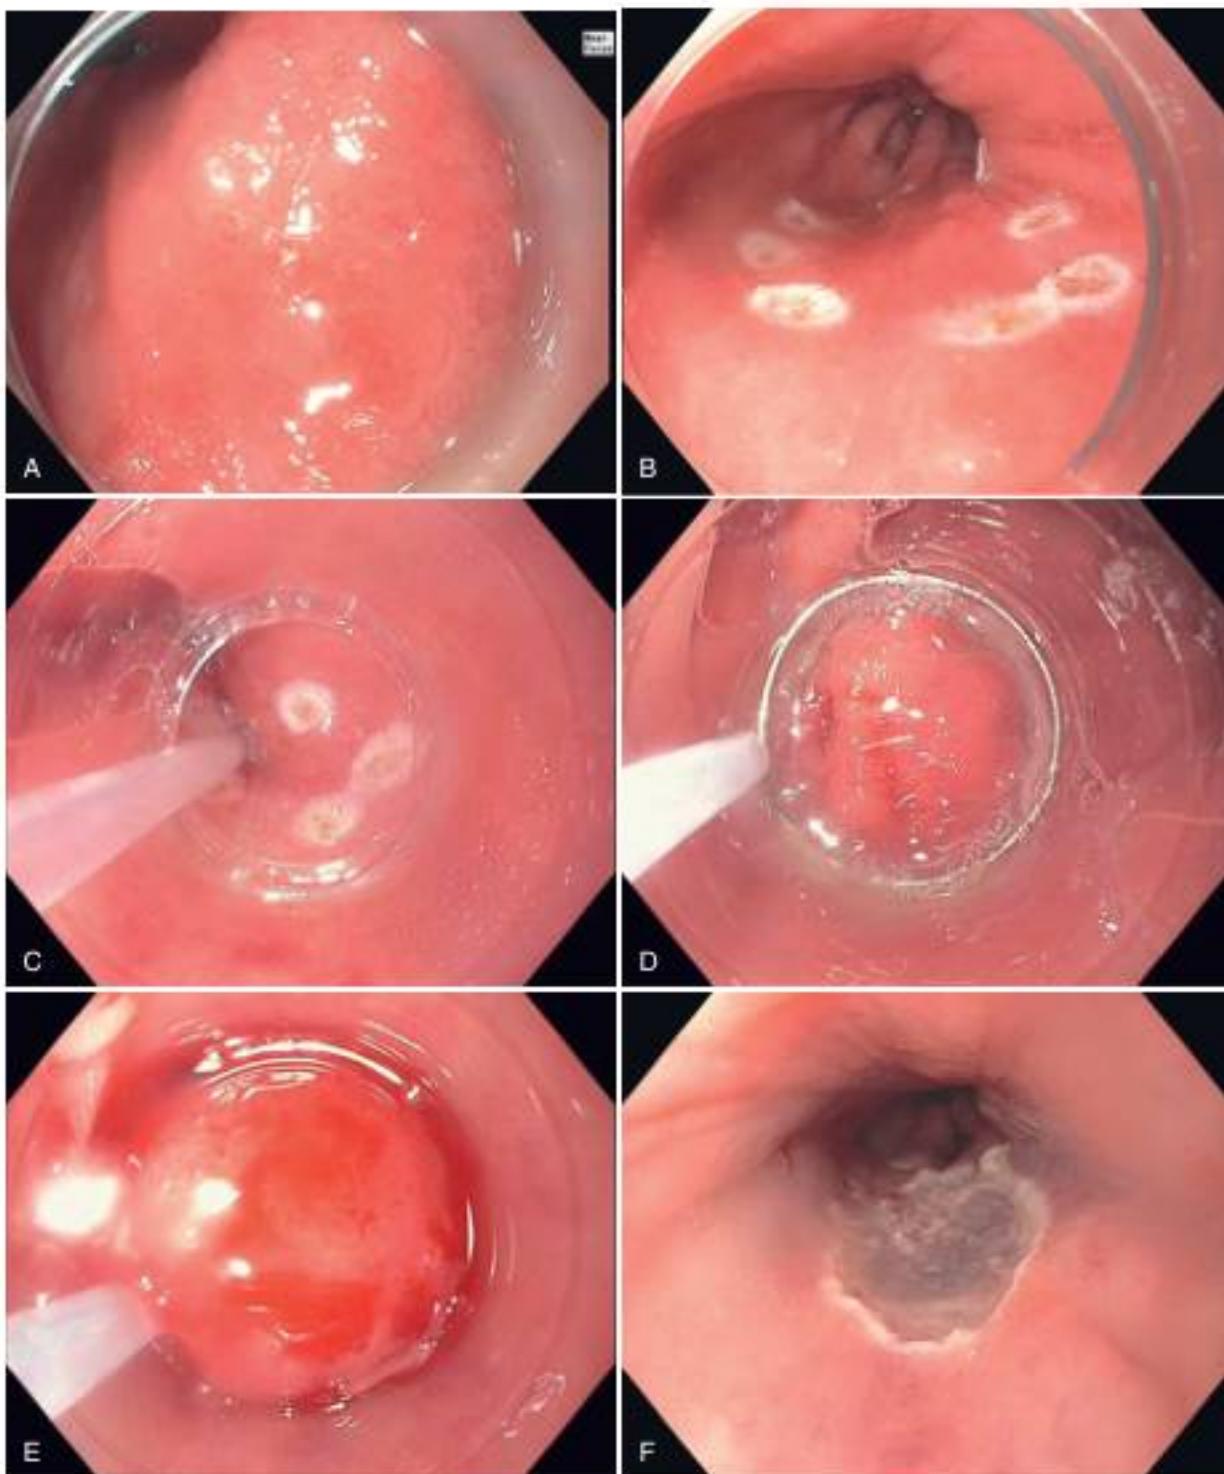

is not properly formed, suctioning the tissue into the cap can result in dislodgment of the snare. In addition, the snare is easily deformed, and can be twisted during the process of forming the loop around the lip of the resection cap, resulting in the need for a new snare.

The tissue resection is completed by suctioning the tissue into the cap, as shown in Fig. 27.8E. When sufficient tissue is suctioned into the cap, the snare is closed, and cautery is applied until the tissue is transected. The average diameter of the resected specimen is approximately 1 cm. The resection and the residual ulcer are shown in Fig. 27.8F. Because lesions may be larger than the size of a single EMR, a second resection can be performed directly adjacent to the first resection; care must be taken not to suction the tissue exposed at the site of the first resection into the cap. Multiple resections in the same area should be attempted only by endoscopists familiar with the mucosal resection technique.

Band EMR is similar, but with some key differences. This technique uses a banding device, much like that used in esophageal variceal band ligation, which contains six bands and allows up to six resections to be performed without removal of the endoscope (Fig. 27.9). Saline injection is often not necessary if the

lesion can be adequately suctioned into the banding cap. A band is then released around the tissue, effectively creating a pseudo-polyp. A hexagonal electrocautery snare inserted through the working channel is used to resect the lesion. EMR fragments are then retrieved using a net-like device. In some centers, the specimens are pinned onto cork boards to orient the pathologists and aid in margin identification. Inking of margins may also be helpful in this regard.

The efficacy of EMR is well established, particularly when the tumor is of a moderate or well-differentiated grade, free of lymphovascular invasion, and confined to the mucosa.<sup>11</sup> In a study of 100 patients with early adenocarcinoma and no high-risk features undergoing EMR, the 5-year survival rate was 98%.<sup>12</sup> In the absence of BE ablative therapy, metachronous cancers were detected in 11% of patients during a mean 37-month follow-up period, but were treated successfully with additional endoscopic therapy. Although no randomized controlled trials comparing EMR with esophagectomy exist, observational studies suggest equivalent rates of cure and survival between the two.<sup>13,14</sup> These data have resulted in the recommendation that endoscopic resection supplant esophagectomy as first-line therapy for mucosal esophageal cancer.<sup>15</sup> Nonetheless, each patient should

**FIG 27.8** Cap-assisted endoscopic mucosal resection of a Barrett's nodule. **A** and **B**, The nodule is identified. It may be helpful to outline the nodule using cautery. **C**, The area is lifted via submucosal saline injection. **D**, A snare is carefully deployed and seated in the inner lip of the cap. **E**, Continuous suction is applied to gather adequate tissue within the cap. **F**, The snare is closed to excise the tissue, leaving behind a typical endoscopic mucosal resection defect.

be approached in a multidisciplinary manner in an effort to provide a full understanding of surgical and oncological treatment options before proceeding with any one therapy.

EMR is very safe. Early complications of EMR include major bleeding (1%–2%) and, rarely, perforation,<sup>3425</sup> whereas

the main late complication is delayed stricture (approximately 1%), which can typically be managed by dilation. EMR may be used to eradicate residual BE via piecemeal circumferential resection, although the risk of stricture formation is much higher compared to radiofrequency ablation (RFA) (discussed later).

**FIG 27.9** Band endoscopic mucosal resection (EMR). **A**, The band EMR kit is shown. **B** and **C**, As with cap-assisted EMR, the lesion is identified and lifted with submucosal injection of saline. **D**, The lesion is suctioned to allow deployment of a band around its base. **E**, An electrocautery snare is used to excise the “pseudopolyp” above or below the band. **F**, The EMR defect is seen (along with others) following multiband mucosectomy.

**FIG 27.10** Various endoscopic "knives" are available for performing endoscopic submucosal dissection. **A**, ITKnife; **B**, ITKnife2; **C**, ITKnife nano; **D**, HookKnife; **E**, TTKnife; **F**, DualKnife; **G**, FlexKnife; **H**, HybridKnife I type; **I**, HybridKnife T type. (**A** to **G**, Courtesy of Olympus Corporation of the Americas, Center Valley, PA; **H** and **I** courtesy of Erbe USA, Inc., Marietta, GA.)<sup>34</sup>

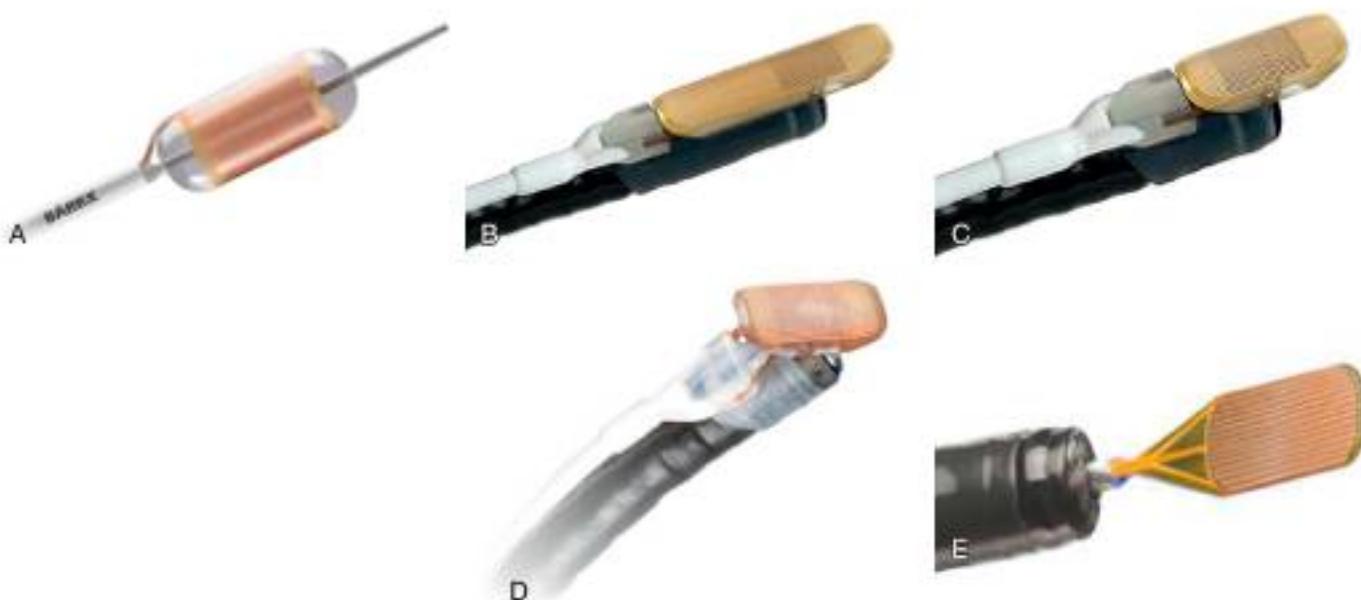

If circumferential or widefield EMR of the residual BE segment is pursued, a stepwise approach is generally recommended over multiple endoscopic treatment sessions, to reduce the risk of strictureting.

#### Endoscopic Submucosal Dissection

A disadvantage of EMR has been the inability to obtain en bloc resection in larger lesions, rendering lateral margins uninterpretable in piecemeal EMR and raising the possibility of residual disease, which may increase the risk of recurrence.<sup>35</sup> ESD has been popularized in Asia as a method to mitigate this risk by allowing en bloc resections, and may be preferred over EMR in lesions larger than 2 cm.

The target lesion is first identified and marked 3 to 5 mm beyond its perimeter using cautery or APC. A submucosal bleb is formed as in EMR by injecting saline, 0.5% hyaluronate, or epinephrine diluted in glycerin. The goal is to allow en bloc dissection in the submucosal plane utilizing "knives." Several such knives with varying morphologies are now available for ESD (Fig. 27.10).

Initially, a circular incision is made around the lesion with a knife to free the lesion completely from the rest of the normal mucosa. Sharp-edged knives, such as the Hook knife or Triangle tip knife (Olympus Corporation of the Americas, Center Valley, PA), have an advantage in that they allow easier application through the tissue. The cut is made carefully to avoid penetrating

**FIG 27.11** Radiofrequency ablation can be delivered circumferentially (**A**) or focally using various kits (**B** through **E**). (From Blevins CH, Iyer PG: Endoscopic therapy for Barrett's oesophagus. *Best Pract Res Clin Gastroenterol* 29[1]:167–177, 2015.)<sup>18</sup>

the entire wall, and once the defect is made, a knife similar to the IT knife (Olympus) is used, as the tip is not sharp enough to penetrate through the muscularis propria. The submucosal dissection is performed using a small dissection cap to lift the mucosa and cut the fibrous tissue that is underneath. This is the most challenging part of the dissection, and requires careful control. The hook knife has an advantage because the knife can "hook" the fibrous tissue from underneath the mucosa, and the cutting can be done more in the endoscopic field of vision. The dissection is a substantial undertaking, although a typical lesion can be removed in 1 to 2 hours by an experienced endoscopist.

Much of the data regarding ESD for esophageal cancer originates from Japan and involves the treatment of ESCC. In a meta-analysis of eight studies comparing ESD with EMR for the treatment of intramucosal cancers, the rates of en bloc resection (97.1% vs. 49.3%) and curative resection (92.3% vs. 52.7%) were superior for ESD.<sup>37</sup> A recent randomized controlled trial compared EMR and ESD for resection of Barrett's-related lesions smaller than 3 cm in 40 patients.<sup>37a</sup> Among those specimens revealing HGD and EAC, the rate of R0 resection (tumor-free resection margins) was higher in the ESD group (10/17) compared to the EMR group (2/17), but there was no significant difference in the rates of complete remission from neoplasia at 3 months. Moreover, ESD was noted to be technically more difficult, and was more time-consuming than EMR (mean procedure duration: 55 vs. 22 minutes). ESD was also associated with two perforations.

### Ablative Therapies

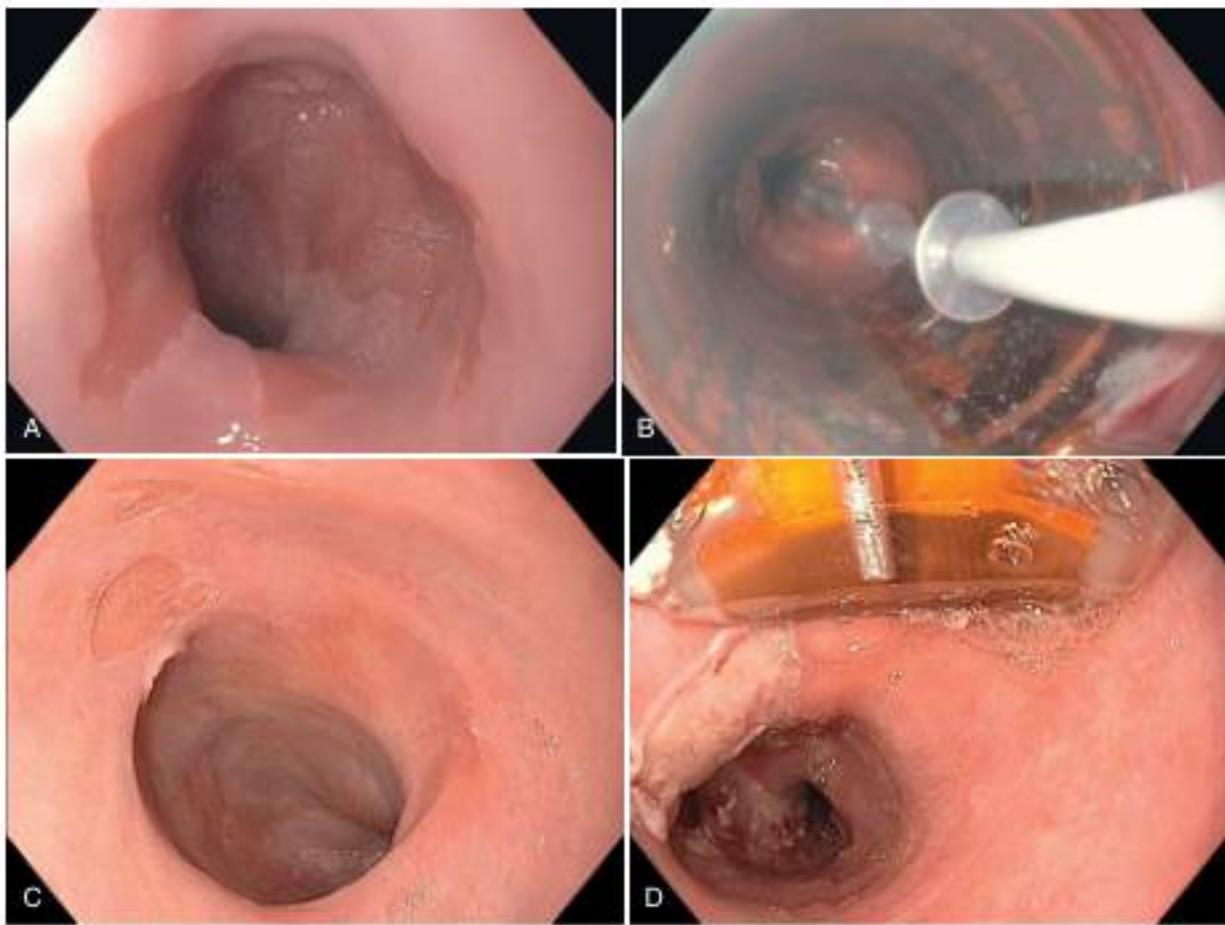

#### Radiofrequency Ablation

RFA employs a bipolar electrode array located on circumferential (balloon) or focal devices that deliver precise amounts of thermal energy in a controllable fashion to the superficial 0.5 to 1.0 mm

of mucosa. Necrosis ensues, and allows re-epithelialization with normal squamous mucosa. RFA is indicated in patients following endoscopic resection of intramucosal adenocarcinoma or HGD in the setting of BE due to the high risk of recurrent and/or metachronous lesions. RFA should also be considered to treat flat dysplasia (HGD and LGD) detected in the absence of a visible lesion.

RFA can be delivered in two ways: circumferentially or focally (Fig. 27.11). Typically, the initial treatment involves circumferential delivery, while follow-up sessions involve focal treatment for residual BE. Preparation for RFA involves cleansing the esophageal wall of mucus using either 1% acetylcysteine or the water jet channel. Next, endoscopic landmarks are identified, specifically noting the distances to the proximal extent of contiguous and circumferential BE and the top of the gastric folds. Time should be taken to exclude the presence of any structures that may compromise balloon expansion, such as strictures or nodularity.

A guidewire is then passed through the working channel into the gastric antrum. Using the original technique, the endoscope is then removed over the guidewire and exchanged for a sizing balloon catheter. The balloon is positioned in the esophagus approximately 3 cm proximal to the top of contiguous BE. Serial balloon diameter measurements are then taken, advancing the balloon distally to the top of the gastric folds in 1 cm intervals. The balloon with the smallest suggested diameter is selected for ablation. The sizing balloon catheter is then exchanged for the appropriately sized balloon catheter and positioned 1 cm proximal to the top of the proximal extent BE, which should be confirmed by parallel endoscopic intubation. The balloon is inflated, and ablation is initiated by pressing the foot pedal for approximately 1 second. The treated area (3 cm in length) is then examined by deflating the balloon, followed by balloon advancement with minimal overlap of the treated area (less than 1 cm). This sequence is repeated until the entire region of BE is treated (Fig. 27.12).

**FIG 27.12** Radiofrequency ablation delivered **A** and **B**, circumferentially using a balloon system and **C** and **D**, focally during follow-up in the same patient for residual Barrett's epithelium.

The balloon is decompressed, removed, and reinflated to allow cleaning of any adherent coagulum. Coagulum should also be gently sloughed from the ablated BE area using the provided soft cap fixed to the end of the endoscope. Ablation of the BE area is then repeated once more in a similar fashion. A balloon ablation device that unfurls to conform to the shape and diameter of the esophagus, eliminating the need for sizing the esophagus before ablation, has recently become available. This device also allows ablation of 4 cm segments in one application instead of the previous 3 cm.

Patients should return in 8 to 12 weeks for follow-up endoscopy, at which time any residual BE can be treated using focal ablation. This technique delivers an electric current through an electrode array stationed on an over-the-scope distal attachment. After a careful endoscopic inspection has been performed and landmark measurements have been obtained, as described previously, the endoscope is removed, and the electrode array is positioned at 12 o'clock in the endoscopic image, followed by careful reintubation. Any residual BE should be held in the 12 o'clock position corresponding to the electrode array, followed by upward tip deflection, causing contact with the mucosa. The energy is activated using the foot pedal at 12 to 15 J/cm<sup>2</sup> (typically 12 J/cm<sup>2</sup>), followed by a second pulse. This technique is then repeated for all areas of residual BE. Coagulum adherent to treated BE mucosa should then be sloughed using the provided cap, and the electrode cleaned externally using wet gauze. The

procedure is completed by performing another round of treatment in a similar fashion.

The efficacy of RFA was established in the Ablation of Intestinal Metaplasia with Dysplasia trial.<sup>38</sup> This was a multicenter, sham-controlled randomized trial in which 127 patients with dysplastic BE (LGD and HGD) were randomized to RFA or sham procedure every 2 months. At 12 months of follow-up, 81.0% of patients with HGD in the ablation group experienced complete eradication of dysplasia and metaplasia (with squamous re-epithelialization), compared with 19.0% in the sham group. Moreover, the rate of progression from HGD to cancer was significantly lower in the group treated with RFA compared to sham (2% vs. 19%, respectively). At 3 years of follow-up, 98% of all patients treated with RFA remained free of dysplasia, and 91% were free of recurrent intestinal metaplasia (accounting for repeat treatments).<sup>39</sup> Several studies have since reported similar findings.<sup>40</sup> RFA can also be effective in treating flat HGD and intramucosal cancer. In a retrospective study assessing the efficacy of RFA in 104 patients with BE who were determined to have HGD or intramucosal cancer in the absence of a visible lesion, the rates for eradication of dysplasia and intestinal metaplasia were 82.7% and 77.6%, respectively.<sup>41</sup>

RFA is a safe procedure with relatively few complications when administered alone, likely secondary to its minimal depth of mucosal penetration and injury. Bleeding, perforation, and death are all rare occurrences. Postprocedurally, chest pain and

dysphagia are common, but typically resolve spontaneously within a few days. Stricture formation is uncommon (at a rate of 5%), and is usually managed with endoscopic dilatation.<sup>6</sup> Its favorable side effect profile, combined with its excellent efficacy and ease of delivery, has resulted in its endorsement as first-line ablative therapy.

### Cryoablation

Cryoablation is an alternative technique for the ablation of BE. Cryoablation is characterized by cycles of rapid cooling (via liquid nitrogen or carbon dioxide) and thawing, resulting in tissue injury needed to promote healing by the squamous epithelium in a background of acid reflux control. The optimal dosimetry is still under investigation, but increased treatment durations are associated with a greater depth of tissue injury. Its advantage over RFA lies in its noncontact application, which facilitates its use in areas of mucosal irregularity. Moreover, cryoablation may cause less distortion of underlying tissue architecture, resulting in less fibrosis and a lower risk of stricture formation.

In preparation for cryoablation with liquid nitrogen, a decompressive gastric tube is inserted into the distal esophagus and antrum to prevent perforation secondary to overinsufflation from evaporated liquid cryogen. A cryotherapy spray catheter is then passed through the working channel of the endoscope and used to spray the liquid cryogen on the affected area (Fig. 27.13). This is delivered by an external console that stores the liquid nitrogen and controls application. The cryogen portion of the cycle lasts 20 seconds (range: 10–30), and is followed by a thawing period of 60 seconds. Typically, 3 to 4 endoscopic sessions are needed to treat long segment BE, and the procedure can be repeated every 6 to 8 weeks until eradication is achieved. A more recent approach involves a conforming balloon that is inflated and internally cooled by a small handheld unit, while a catheter is used for the treatment of focal lesions.

In an initial pilot study involving the monthly application of cryoablation until BE was eliminated, Johnston et al (2005) reported the complete healing of BE in 9 of 11 patients by 6 months of follow-up.<sup>42</sup> In a 2010 multicenter cohort study involving 98 patients with HGD, complete eradication of HGD (with persistent LGD) and complete eradication of all dysplasia in patients with HGD was reported in 97% and 87% of patients,

respectively.<sup>43</sup> Recent studies suggest good durability of eradication at 2 years post-treatment.<sup>44</sup> However, there is concern that recurrent dysplasia may be localized to the area just distal to the neosquamocolumnar junction, and therefore surveillance biopsies of this region may be advised.<sup>45</sup> The utility of cryoablation in treating intramucosal tumors is less well-known, but in a small series of 24 patients, 18 (75%) achieved complete eradication.<sup>46</sup> Cryoablation appears to be comparably effective to RFA in eradicating dysplasia, with lower rates of eradication of all intestinal metaplasia, although no direct comparison trials exist. Major complications from cryoablation are rare, although postprocedural chest pain and dysphagia are common.<sup>47</sup> Currently, cryotherapy is being offered to patients who have failed RFA (salvage therapy), are poor candidates for surgery, or are seeking palliative management.<sup>48</sup>

### Photodynamic Therapy

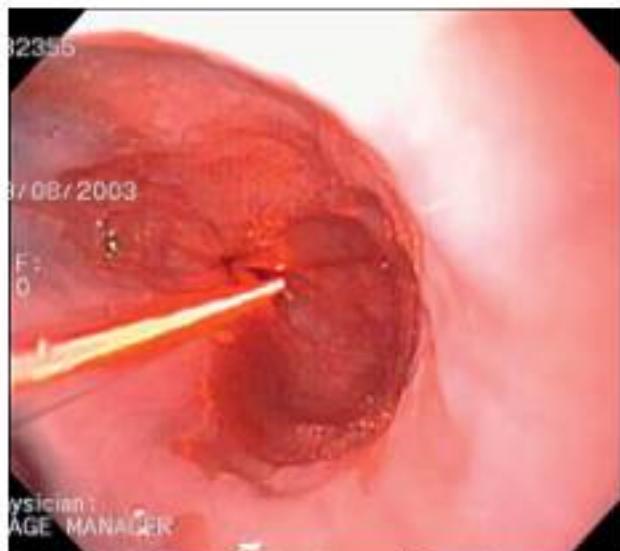

PDT has been investigated as a treatment for cancer since its origins in 1961.<sup>49</sup> The therapy has traditionally involved the use of a combination of a photosensitizer drug and light of a specific wavelength that is required to activate the drug. The typical practice is to administer the drug days or hours before light delivery to allow the photosensitizer to concentrate into the neoplastic tissue. Light from a laser is applied to the mucosa, which causes general tissue destruction and cell death.

Photoradiation is usually performed by placing an optical fiber through the biopsy channel of the endoscope. The tip of this optical fiber has a cylindrical diffusing fiber that can be placed in the lumen of the esophagus. Generally, in the case of an early tumor, the fiber is placed next to or pressed against the tumor (Fig. 27.14). Treatment parameters for PDT for BE-associated neoplasia using porfimer sodium involve a drug dosage of 2 mg/kg body weight. The drug is given 48 hours before PDT. Red light is delivered through a diffusing fiber at a power output of 400 mW/cm fiber, for a total energy of approximately 300 J/cm fiber. If there is no endoscopically apparent disease, and mucosal resection has completely removed the lesion, a smaller dose of light, such as 200 J/cm fiber, can be used to treat the remaining Barrett's mucosa.

The overall results for PDT show good efficacy for early cancers. In a multicenter study comparing PDT to omeprazole, PDT improved the rates of complete eradication of HGD (77%

**FIG 27.13** Cryoablation of Barrett's mucosa. **A**, Before and **B**, immediately after.

**FIG 27.14** Photodynamic therapy of Barrett's mucosa.

vs. 39%) and intestinal metaplasia (52% vs. 7%), as well as progression to cancer (13% vs. 28%).<sup>53</sup> During 5 years of follow-up, 15% of the PDT group progressed to cancer, versus 29% in the omeprazole group. In another long-term study of 66 patients with HGD and early adenocarcinoma undergoing PDT, the 5-year survival rate was 97% for patients with HGD and 80% for patients with early adenocarcinoma.<sup>54</sup>

Complications include a cutaneous photosensitivity reaction, chest pain, dehydration due to the inability to obtain adequate fluid intake, and nausea. Rare side effects include injury of organs that are located near the esophagus, resulting in atrial fibrillation or pleural effusions.<sup>52,53</sup> Esophageal strictures are a major problem, as they occur in approximately one-third of patients treated.<sup>54</sup> These strictures are often quite fibrotic, and require multiple dilations to large diameters to resolve the constriction. PDT is currently listed as an option for ablative therapy by all three major US gastrointestinal societies, but should involve careful patient selection.

#### Argon Plasma Coagulation

APC involves the use of a hemostatic device in a noncontact fashion to cauterize bleeding lesions that are awkward to reach with traditional probes. APC has the ability to treat superficially, and has been thought to present a decreased risk of perforation. Mucosal ablative therapy for BE has been investigated, with good to excellent results.<sup>55,56</sup>

The primary goal of APC is to apply a current to the target lesion without producing a perforation. The argon gas is released under pressure. The endoscopist must be vigilant against allowing the tip of the probe to become embedded in the mucosa during treatment; this could result in the introduction of air into the submucosa or, worse, a perforation. For this reason, coagulation performed with the argon plasma coagulator should be done only while the probe is being withdrawn toward the endoscope; this should ensure that the tip of the probe is not embedded in the mucosa. Settings for treating adenocarcinoma should be in the higher power ranges; a range of 80 to 90 W has been cited in the literature. Higher output powers seem to be associated with improved outcomes in BE with HGD, although complications such as perforation and strictures are also seen at these dosages.

Treatment of intraepithelial carcinoma in BE has been reported in a limited series of patients. In one series of only three intraepithelial cancers, treatment with APC was ineffective and resulted in invasive disease.<sup>57</sup> These cancers also failed treatment with subsequent PDT. Similar results were observed in another small series of three patients with early esophageal cancers who were treated with APC; one recurrence was noted, and was subsequently treated with PDT.<sup>58</sup> Early ESCC and HGD have been treated with APC in Asian populations with good results.<sup>59,60</sup> In one series, 29 patients with ESCC and 42 patients with HGD were first treated with EMR, with any residual disease treated with APC.<sup>60</sup> The early results seem promising, as only three of the cancers (10%) recurred after 4 months. Esophageal strictures were found in four of the cases after EMR of most of the diameter of the esophagus. Overall, it seems that, although APC is well-tolerated with few described complications, its efficacy in the elimination of early esophageal cancer is limited, with significant (33%) failure rates in small numbers of BE-related cancers and lower failure rates (10%) in superficial squamous cell carcinomas. This finding is not surprising, given the decreased depth of injury associated with this treatment.

#### Combined EMR and Ablation

Treatment of early EAC in patients with BE frequently involves EMR for the removal of nodular lesions, followed by RFA for the eradication of underlying intestinal metaplasia, given the high risk of metachronous lesions. In a study including mostly patients with HGD and intramucosal cancer, EMR followed by RFA until complete ablation of BE was achieved resulted in complete eradication of dysplasia in 81% of patients, and clearance of HGD in 86% of patients.<sup>61</sup> This is now the preferred regimen for treating nodular BE, and is endorsed by major gastroenterological societies.

#### FOLLOW-UP

Patients undergoing endoscopic resection with or without ablative therapy for intramucosal EAC require close follow-up for surveillance of metachronous or recurrent lesions.<sup>62</sup> Evidence-based guidelines are lacking, but expert recommendations are to perform surveillance every 3 months for the first year, every 6 months during the second year, and annually the following years.<sup>63</sup>

Similarly, patients whose ESCC has been treated endoscopically require continued endoscopic surveillance, given the risk of head and neck squamous cell carcinoma. Moreover, additional resection and/or ablation may be necessary for recurrent or metachronous ESCC. Surveillance can be performed every 3 months for the first year after treatment, and every 3 to 6 months the following year.<sup>64</sup>

## INTRODUCTION

The incidence of new cases of esophageal and gastroesophageal junction (GEJ) cancer is estimated to be 450,000 per year worldwide. Esophageal cancer is the eighth most frequent malignancy and has the sixth-highest cancer-specific mortality. The estimated 5-year survival rate in Western countries is less than 20% after the diagnosis.<sup>1</sup> In the past, squamous cell carcinoma (SCC) was responsible for more than 90% of cases of esophageal carcinoma, but currently, adenocarcinoma is by far the leading esophageal malignancy, representing more than 60% of overall esophageal cases.<sup>2</sup> This change in the histologic trend probably comes from the modification of risk factors for esophageal cancer, with several risk factors for adenocarcinoma (such as gastroesophageal reflux disease [GERD], Barrett's esophagus, cigarette smoking, obesity, hiatal hernia, and age > 50 years) being very globally distributed.<sup>3</sup> Esophageal SCC is more frequently associated with smoking and alcohol intake. In patients with head and neck cancer, the risk of developing esophageal cancer is increased 3 to 10 times, with incidence ranging from 1% to 8%.<sup>4</sup> SCC is located predominantly in the upper and middle parts of the esophagus.<sup>5</sup> However, there are other nonesophageal cancers that can cause dysphagia, including primary lung cancer, proximal gastric cancer, and mediastinal lymphadenopathy.<sup>6</sup> Adenocarcinoma of the esophagus, on the other hand, is located primarily in the distal esophagus. The poor prognosis of esophageal cancer is mainly due to the late diagnosis of advanced neoplasia, which allows only palliative treatments. The most common clinical symptom at presentation is dysphagia; other symptoms include drooling, thoracic pain, anemia, nausea, and weight loss usually associated with severe malnutrition. Moreover, advanced esophageal neoplasia may be associated in a limited number of cases with the presence of tracheal or bronchoesophageal fistula. Thus, the main goal of the palliative measures is the treatment of dysphagia and eventually the treatment of esophagorespiratory fistulas.<sup>7,8</sup> Significant weight loss and malnutrition as a consequence of malignant dysphagia, as well as cachexia, are predominant

symptoms in esophageal neoplastic strictures. To diagnose nutritional imbalances at an early stage, the European Society for Clinical Nutrition and Metabolism (ESPEN) recommends regular evaluation of nutritional intake, weight change, and body mass index (BMI) at the time of cancer diagnosis and repeated according to the stability of the clinical situation.<sup>9</sup> Esophageal stenting is currently the most effective method for this aim and is used in approximately 50% of patients with inoperable esophageal carcinoma. Tracheoesophageal or bronchoesophageal fistulas usually develop quite late in the context of advanced cancer of the esophagus, lung, or mediastinum, either as a consequence of progressive tumoral invasion or as an adverse event of cancer therapies, in particular chemoradiotherapy. Unfortunately, the clinical condition of such patients has often already significantly worsened at the time they develop a fistula, and the remaining life expectancy is quite short (within weeks to months). Rapid relief of life-threatening symptoms related to the fistula, preferably by minimally invasive treatment such as esophageal stenting, is thus of pivotal importance to improve quality of life. In this chapter, we will address the endoscopic management of malignant dysphagia due to advanced cancer that is not suitable for surgery.

## ESOPHAGEAL STENTS

Thanks to the technologic improvements of the last 20 years, different types of stents have been introduced to the market. Multiple types of self-expandable stents are available. They differ in terms of design, luminal diameter, radial force, flexibility, and degree of shortening after deployment. Available stents can be divided in two main categories: self-expandable metal stents (SEMSs) and self-expandable plastic stent (SEPSs). SEMSs are further subdivided into fully covered (PCSEMS), partially covered (PCSEMS), or uncovered SEMS.<sup>10</sup> SEMS are mainly made of nitinol, a nickel and titanium alloy. In clinical practice, covered stents (partially or full covered) are usually preferred to the uncovered ones. It has been demonstrated that covered stents may delay tumor ingrowth without increasing the risk of

**Abstract**

Esophageal cancer is the eighth most frequent neoplasia; some decades ago the large majority of these cancers were squamous cell carcinomas, but the incidence of esophageal adenocarcinoma has been steadily increasing. Tobacco, Barrett's esophagus, obesity, hiatal hernia, and gastroesophageal reflux disease are the primary causes of adenocarcinoma; tobacco and alcohol consumption are associated with squamous cell carcinomas of the esophagus. The most important clinical symptom at presentation is dysphagia. The poor prognosis of esophageal cancer generally only allows palliative treatment. The main therapeutic goal is the treatment of dysphagia and esophageal fistulas using devices called stents. Esophageal stenting is now considered a viable alternative to surgical treatment and can give an immediate palliation of dysphagia. In this chapter we will address the endoscopic management of esophageal cancer with different types of stents introduced to the market, and in particular, self-expandable metal stents (SEMSs). We will discuss the technique of positioning stents and management of possible complications, such as stent migration, esophageal perforation, bleeding, stent obstruction, and esophageal fistula. Finally, we will discuss the placement of the stent after radiotherapy and chemotherapy.

**TABLE 28.1 Characteristics of Currently Available Types of Metal Stents**

Stent Type	Covering	Length (cm)	Diameter (mm)	Release System	Degree of Shortening	Flexibility	Stent Material	Manufacturer
Alimaxx-ES	Full	7, 10, 12	12, 14, 16, 18, 22	Distal	0%	Moderate to high	Nitinol/polyurethane	Merit, South Jordan, UT
SX-Ella	Full	8.5, 11, 13.5, 15	20, 26	Distal	10%–20%	Low	Nitinol/polyethylene	Ella, Hradec Kralove, Czech Republic
Evolution	Partial/full	8, 10, 12, 12.5, 15	23, 25	Distal	10%–20%	Moderate	Nitinol/Silicone	Cook Medical, Limerick, Ireland
Niti-S	Full/partial	6, 8, 10, 12, 14, 15	16, 18, 20, 22, 24, 28	Proximal/distal	10%	High	Nitinol/polyurethane	Taewoong, Pusan, South Korea
WallFlex	Full/partial	10, 12, 15	18, 23	Distal	30%–40%	Moderate	Nitinol/silicone	Boston Scientific, Marlborough, MA
Ultraflex	Partial/uncovered	10, 12, 15	18, 23	Proximal/distal	30%–40%	High	Nitinol/polyurethane	Boston Scientific, Marlborough, MA
PolyFlex	Full (plastic stent)	9, 12, 15	16, 18, 21	Distal	0%	Low	Polyester/silicone	Boston Scientific, Marlborough, MA

migration.<sup>11</sup> The most common metal stents currently available are listed in Table 28.1.

Of course, an ideal stent that can perfectly fit all clinical situations does not exist. However, all available covered metal stents meet some of the criteria required to palliate malignant dysphagia and to provide temporary relief from refractory esophageal strictures. Some FCSEMS and plastic stents are also approved for temporary stenting in patients with benign recurrent or refractory esophageal strictures.<sup>11</sup>

## MANAGEMENT OF NONOPERABLE ESOPHAGEAL MALIGNANCY

The European Society of Gastrointestinal Endoscopy (ESGE) guidelines suggest:

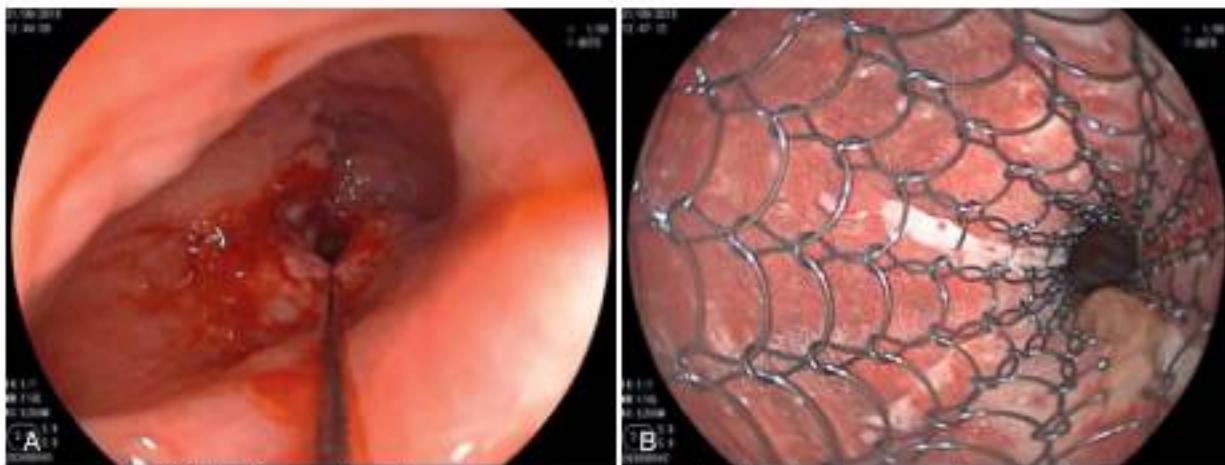

- Placement of PCSEMSs or FCSEMSs for palliative treatment of malignant dysphagia over laser therapy, photodynamic therapy, and esophageal bypass.
- For patients with longer life expectancy, brachytherapy can be considered a valid alternative, or used in addition, to stenting in esophageal cancer patients with malignant dysphagia. Brachytherapy may provide a survival advantage and possibly a better quality of life compared to SEMS placement alone.
- Esophageal SEMS placement is the preferred treatment for sealing tracheoesophageal or bronchoesophageal fistulas.
- The use of concurrent external radiotherapy and esophageal stent treatment is not recommended.
- SEMS placement is also not recommended as a bridge to surgery or prior to preoperative chemoradiotherapy because it is associated with a high incidence of adverse events, and alternative satisfactory options, such as placement of a feeding tube, are available.<sup>11</sup>

## TECHNIQUES OF STENT PLACEMENT

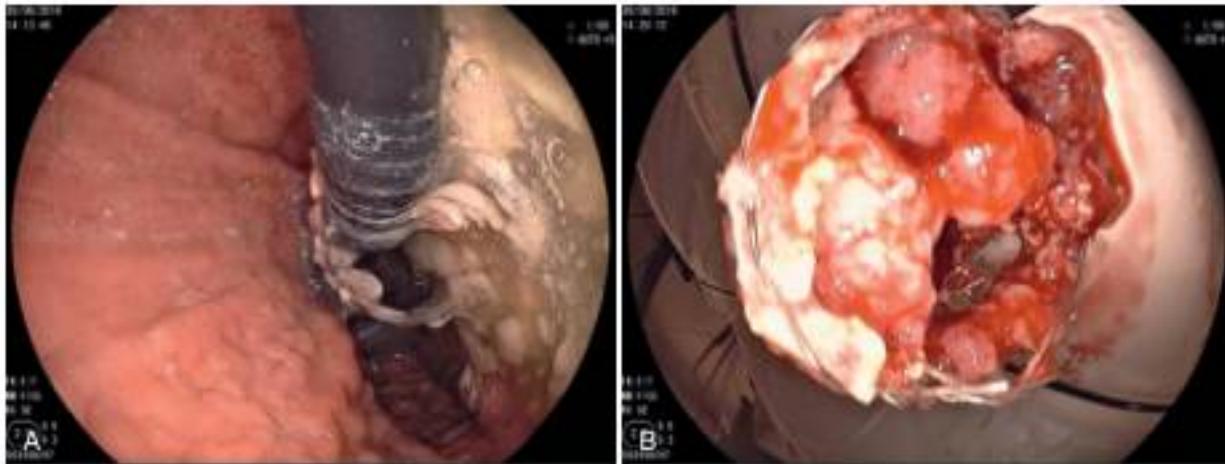

Stent placement should be performed in the endoscopic room by an experienced endoscopist, preferably under deep sedation and fluoroscopy control, and with the support of personnel who are familiar with stent placement and related devices, such as guidewires and catheters. The length and diameter of the stent should be adequately chosen before stent placement according

to stricture size and length: stent length should be 2 cm longer than the distal and proximal border of the neoplasia. Marking of proximal tumor borders is of paramount importance to properly deploy the stent under fluoroscopic control. Some experts prefer to use internal markers as clips or submucosal injection of Lipiodol (Guerbet, Villepinte, France) to achieve a better radiological identification of tumor localization. After proper definition of stricture characteristics (length, size, borders), a super-stiff steel guidewire, such as the Savary guidewire (Cook Medical, Bloomington, IN), is introduced through the stricture under fluoroscopic guidance, with the distal tip placed deeply into the stomach. Occasionally, in cases of very tight strictures, an endoscopic retrograde cholangiopancreatography (ERCP)-like technique with catheters and hydrophilic guidewires may be required to safely cannulate the stricture and advance the guidewire down into the stomach. In such a case the hydrophilic guidewire is then replaced with a stiffer one (i.e., Amplatz, Boston Scientific, Marlborough, MA), which is better able to support the proper advancement of the stent catheter through the stricture. Once the stent is advanced through the esophagus over the guidewire, it should be released slowly and carefully under fluoroscopic and/or endoscopic visualization. Stent deployment can also be performed under pure endoscopic control with results that are comparable in terms of efficacy and safety to stents released under fluoroscopic control. In such a case, a small-caliber scope is usually advanced alongside the stent catheter and used to monitor stent deployment, keeping it a few centimeters proximal to the stricture.<sup>11,12</sup> At the end of the procedure, contrast medium may be injected through the working channel of the scope to confirm the correct positioning of the stent and to exclude complications, such as perforation. After the procedure, the patient should be closely observed in the recovery room to quickly diagnose early procedural-related complications such as hemorrhage, aspiration, perforation, and respiratory failure.

Once immediate complications are excluded, it is possible to restart feeding with fluids and then progressively with semisolids. A special mention should be made on the positioning of the stent in esophageal cancers located close to the upper esophageal sphincter (UES) (Fig. 28.1). These tumors represent only 7% to 10% of all esophageal carcinomas. However, they are considered the most difficult to treat because of possible complications such

**FIG 28.1** **A**, Proximal esophageal cancer immediately distal to the upper esophageal sphincter (UES). **B**, Post successful self-expandable metal stent (SEMS) placement distal to the UES.

**FIG 28.2** **A**, Migrated stent into the stomach. **B**, Stent after successful extraction.

as aspiration pneumonia and proximal migration, as well as the complaint of foreign body sensation and quite relevant local pain in some cases.<sup>14</sup> Several studies have shown that treatment with stents is possible without major complications compared with middle/distal esophageal tumors.<sup>14</sup> In these cases, it is better to perform the procedure under endoscopic and fluoroscopic control using a stent with proximal deployment to allow a more precise release and placement.

## STENT COMPLICATIONS

The placement of esophageal stents as a palliative treatment can cause complications, such as pain, bleeding, migration of the stents, perforations, or the onset of esophageal fistula,<sup>2,3,15,16</sup> with an overall mortality rate of 2.2%.<sup>17</sup> These complications are usually divided according to their appearance, either early (within one week) or late (after 1 week). The most frequently reported complications are stent migration, stent obstruction, and esophageal perforation.<sup>12</sup>

### Stent Migration

Stent migration occurs in approximately 20% of patients and is often reported in noncircumferential esophageal tumors, or with use of a stent which has too small a caliber (Fig. 28.2).

The removal of a migrated stent can be performed endoscopically with foreign body forceps, but it may be challenging due to a number of anatomical and stent-related factors.

Indication for removal must be carefully considered in each patient because most patients do not develop symptoms directly related to a stent residing in the stomach, but have symptoms due to recurrent dysphagia.

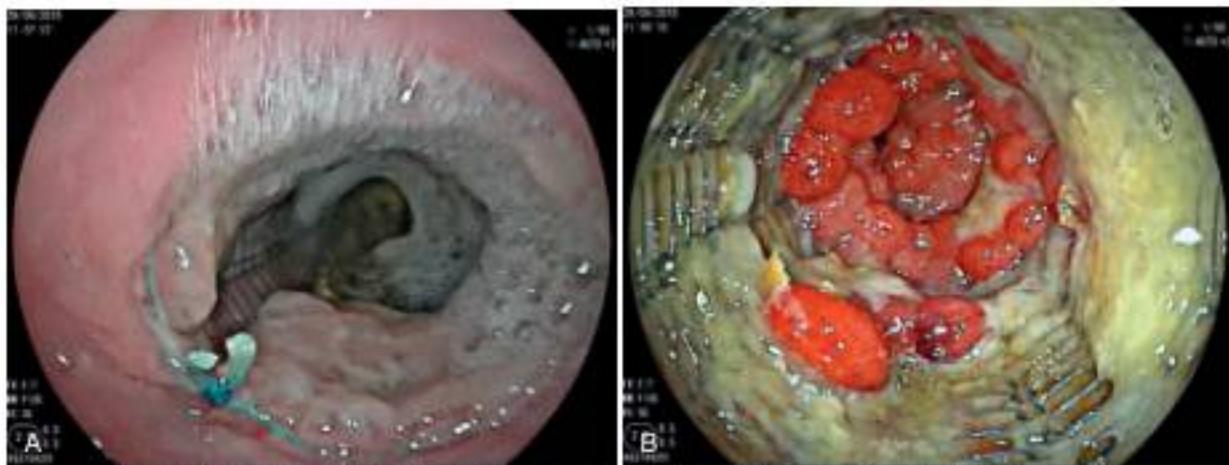

Endoscopic removal will depend on the type of stent and the site of migration. When the stent is migrated distally but still in the esophagus, removal is indicated. Those with a proximal lasso can be easily pulled back by grasping the lasso with forceps, which allows constriction of the upper flange, permitting repositioning or removal. Endoscopic traction of plastic or metallic stents that do not have a proximal lasso might be more difficult (Fig. 28.3). Failure in esophageal stent removal rarely causes other complications, such as satiety.

### Perforation

Perforation may occur in 2% to 8% of cases.<sup>12,13</sup> Early diagnosis of esophageal perforation is essential to avoid a disastrous outcome. Patients who experience pain or crepitus in the neck and chest should be evaluated immediately by chest radiography followed by computed tomography. Confined perforation may be managed conservatively with nothing by mouth, aspiration

**FIG 28.3** **A**, Esophageal stent removal using forceps to grab a proximal lasso. **B**, Stent after being removed from the individual using traction technique.

**FIG 28.4** Stent obstruction due to tissue ingrowth in **A**, the proximal and **B**, distal end of a self-expandable metal stent (SEMS).

of the upper esophagus, antibiotics, and parenteral nutrition. If perforation is noted to occur during the procedure, it is reasonable to attempt to complete stent placement because this may seal the perforation. Aggressive covered stent preinsertion esophageal dilatation, prior esophageal surgery, and necrotic, angulated tumor characteristics may increase the risk of perforation. Perforation during deployment can be caused by the guidewire itself, application of excessive force to the endoscope during attempts to pass the stricture, or excessive dilation of the stricture. If a small perforation is recognized, it will usually seal if a covered stent is placed in the proper position, assuming the stricture can be traversed. Delayed perforation is less common and may be associated to concomitant radiation or chemotherapy. Moreover, pressure necrosis caused by the proximal or distal edge of the stent on the healthy esophageal mucosa may result in the development of a fistula. Delayed perforation and fistula formation are life-threatening complications, with a mortality rate of up to 50%.<sup>13</sup>

### Bleeding

Bleeding may be caused by stent placement but, in most cases, does not require any further intervention. In patients with aortic involvement (i.e., stents are placed either before or after radiation

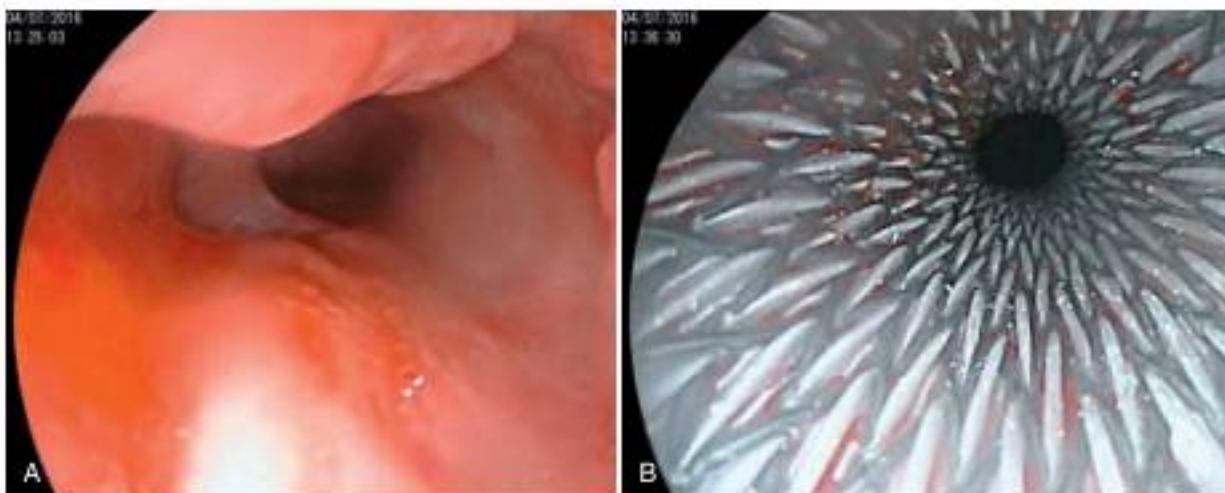

therapy), fatal bleedings are frequent.<sup>10,14</sup> Other possible causes of bleeding are mechanical ulcers due to the positioning of the esophageal stent with the distal end at the level of the gastric greater curvature. Therefore it is recommended to choose a stent with a suitable length, short enough to avoid ulceration but long enough to fully traverse the tumor. Finally, a stent located in proximity to the GEJ can cause reflux esophagitis with bleeding; in these cases, treatment with gastroprotective agents is sufficient.

### Stent Obstruction

Another possible complication is stent obstruction, including tumor ingrowth/overgrowth, nonneoplastic tissue hyperplasia, and food impaction (Fig. 28.4). This complication has been reported in 30% to 40% of cases.<sup>12</sup> Tumor ingrowth is usually treated with the “stent-in-stent technique,” or the positioning of an additional stent inside the previously placed stent. Multiple sessions of endoscopic treatments with argon plasma coagulation (APC) for tissue ablation and debulking have also been used. It is important with this condition to recommend diet adjustments and the selection of liquid foods to facilitate food transit until stent obstruction has been resolved; in addition, the consumption of drugs in liquid form reduces the risk of stent obstruction.<sup>20</sup>

**FIG 28.5** **A**, Esophagorespiratory fistula. **B**, successfully treated with covered self-expandable metal stent (SEMS) placement.

**FIG 28.6** **A**, Partial esophageal stenosis due to persistent bulky tumor after radiation therapy. **B**, After self-expandable metal stent (SEMS) placement.

## ESOPHAGORESPIRATORY FISTULA

Progressive infiltration of the primary esophageal tumor or late effects of previous radiation therapy can be the main causes of an esophagorespiratory fistula or, more rarely, of a fistula between the esophagus and the aorta, the mediastinum, or the pleura. Esophagorespiratory fistulae have been reported in 5% of patients with malignant esophageal strictures treated with stent placement.<sup>21</sup> Fistula formation can result in serious pulmonary infections from aspiration pneumonia. In these cases, it is important to assess the exact location of the fistula by using multiple imaging modalities. In most cases, the best therapeutic option for these types of fistulas is the use of a covered stent (Fig. 28.5).

However, a bronchoscopy is recommended prior to the second stent placement; sometimes it is necessary to place a tracheal stent before the esophageal stent to balance the compression caused by the esophageal stents and consequently avoid acute respiratory failure. Several retrospective and prospective series on endoscopic placement of a covered stent reported a complete sealing of the fistula in more than 90% of patients.<sup>21,22</sup> Aortic

erosion after stent placement is a life-threatening complication that comes with massive bleeding and rapid deterioration of the patient's condition due to shock and anemia. Most of the reported cases have led to patient death before any possible attempt at treatment.

## STENT PLACEMENT AFTER RADIOTHERAPY AND/OR CHEMOTHERAPY

Physicians have historically avoided placing stents in patients with esophageal cancer before chemotherapy and radiotherapy to avoid the risk of complications such as esophageal fistulas.<sup>23</sup> Recent data are quite contradictory with regard to the risk of serious adverse events in patients receiving a stent after radiotherapy alone or in combination with chemotherapy (RTCT). Some studies show an increased risk, whereas other studies, including a meta-analysis, do not report any relationship between SEMS placement after RTCT and the incidence of life-threatening adverse events or survival<sup>23</sup> (Fig. 28.6). It has been reported that the potential increased risk, if any, of developing major complications in patients with prior radiation or chemotherapy may be

mainly related to the radiation-induced damage on the esophageal wall, potentiated by chemotherapy. However, it is difficult to discern whether such stent-related adverse events are due to stents and radiation effects, the advanced nature of the disease process, or both. In general, the decision to place a stent in such situations must be carefully balanced in a multidisciplinary context, with due consideration given to other palliative modalities, and after having specifically informed the patient about the potential risk of life-threatening adverse events. Tailored therapy is the mainstay in challenging patients with recurrent dysphagia and disease progression despite previous attempts with radiation and chemotherapy. However, the ESGE guidelines suggest that the placement of an esophageal stent during concurrent external radiotherapy is not recommended.

## CLINICAL OUTCOMES

Palliative stenting for malignant dysphagia is associated with a technical success of approximately 95%, a very low risk of early major complications (< 5%), and early clinical success of 80%. The median and mean survival after stent placement range from 78 to 83 days and 120 to 126 days, respectively. Survival has not been associated with the type of stent used.<sup>34–37</sup> Reintervention rate is approximately 25% to 35% and is mostly related to tumor ingrowth/overgrowth and stent migration/dislocation. Late complications after placement of esophageal stents may occur in 53% to 65% of patients, with almost half of these patients requiring some form of additional reintervention.<sup>38,39</sup> Procedure-related causes of death are seen in 0.5%–2% of patients, with an increased risk of mortality in those patients who have been previously treated with radiation or chemotherapy.<sup>30,31</sup>

## CONCLUSION

Esophageal stenting is the most frequently used method of treating dysphagia caused by esophageal cancer. Physicians have several choices regarding esophageal stents and should choose the right stent based on the indication and the precise dimension and anatomic characteristics of the stricture, as well as the physician's personal experience. Even though stents are effective in improving dysphagia, the complication rate and the number of reinterventions for recurrent dysphagia are still rather high. Fortunately, many of these complications are within the endoscopist's control and can be successfully managed.

### INTRODUCTION

The word *gastroparesis* is derived from the Greek words *gastro* and *pa'resis*, and translates to partial paralysis of the stomach. The diagnosis of gastroparesis is defined as delayed gastric emptying in the absence of mechanical obstruction, associated with one or more of the following symptoms: postprandial fullness, early satiety, nausea, vomiting, and bloating.<sup>1</sup> Whereas gastroparesis can be associated with diabetes mellitus, neuromuscular and connective tissue diseases, vagal injury, or some medications, in the majority of patients, no underlying etiology is identified, and they are presumed to be idiopathic. For reasons that are not entirely clear, there is a marked gender discrepancy in all subgroups, with women being affected far more often than men. True prevalence data are unclear, with estimates of up to 3%. One large study performed at the Mayo Clinic estimated a community prevalence of 1.8%.<sup>2</sup> However, this may be a significant underestimate of true prevalence, as approximately 40% of patients with functional dyspepsia have delayed gastric emptying on evaluation, and the prevalence of functional dyspepsia has been suggested to be approximately 10% to 15% worldwide.<sup>3</sup> In addition, the societal impact of gastroparesis is significant. Worsening symptoms are accompanied by poor food intake, weight loss, malnutrition, impaired function, and more emergency room visits. Data suggest that hospital admissions for gastroparesis in the United States now exceed those for gastroesophageal reflux, peptic ulcer disease, gastritis, and nausea.<sup>4</sup>

One of the most frustrating aspects of gastroparesis is the paucity of treatment options that are currently available. The only medication that is approved by the Food and Drug

Administration (FDA) at present is metoclopramide, which also has an associated black box warning related to tardive dyskinesia. Other drugs that have shown efficacy in controlled trials are either not available in the United States (domperidone) or have been pulled from the market due to safety concerns (cisapride). Gastric electrical stimulation (GES) was given a Humanitarian Device Exemption by the FDA in 2000 based on the results of a double-blind controlled trial.<sup>5</sup> The lack of established treatment options, in tandem with the significant symptom burden associated with gastroparesis, has led to intense interest in alternative diagnostic and treatment paradigms. In particular, endoscopic options for both diagnosis and therapy have risen to the forefront in recent years, driven by a number of factors: (1) the paucity of accepted medical treatment options, (2) increased understanding regarding the pathophysiology of gastroparesis, and (3) technical advances in endoscopy that have expanded the feasibility of interventional endoscopic options. In this chapter, we will present our understanding of the current role of endoscopy in the diagnosis and treatment of gastroparesis, and will speculate on what the near future holds.

### PHYSIOLOGY OF GASTROPARESIS

Although delayed gastric emptying is the *sine qua non* of gastroparesis, it is well-recognized that multiple mechanisms are at play in addition to gastric emptying with regards to symptom pathogenesis. The National Institutes of Health (NIH) Gastroparesis Clinical Research Consortium, consisting of six Academic Motility Centers, has played an integral role in advancing our understanding of pathogenesis, but much remains to be learned.

### Abstract

Gastroparesis is defined as delayed gastric emptying in the absence of mechanical obstruction. Current treatment options are limited, with only one medication currently approved by the Food and Drug Administration. Recent advances in our understanding of pathophysiology have led to the recognition that gastroparesis is a heterogeneous disorder with multiple clinically relevant subsets. Over time, the role of the endoscopist has become key in the management of this disorder. For patients with predominant pyloric dysfunction, endoscopy in particular plays a major role in both diagnosis and therapy. Antroduodenal manometry, use of wireless motility capsules, use of the functional lumen imaging probe (impedance planimetry), and electrogastrography (EGG) have all been proposed as viable modalities to assess pyloric function. Endoscopic treatment options for pyloric dysfunction include treatment with botulinum toxin, transpyloric stent placement, and gastric pyloromyotomy. Through deep tissue biopsy, endoscopy is also emerging as a means to better understand pathophysiology and perhaps stratify patients into histologically-relevant subsets. Temporary gastric electrical stimulation has been proposed as a means to assess the clinical response to permanent implantation, although this remains controversial. Finally, endoscopy continues to have a role in the placement of enteral feeding and venting tubes. While our understanding of gastroparesis continues to evolve, the role of the endoscopy remains paramount in the management of this disorder.

### Keywords

gastroparesis  
antroduodenal manometry

gastric electrical stimulation

In addition to objective impairment of gastric emptying, subsets of affected patients have also been shown to have impaired fundic accommodation, gastric dysrhythmias, impaired gastroduodenal coordination, abnormal duodenal signaling, autonomic dysfunction, visceral hypersensitivity, and abnormal central processing of peripheral stimulation.<sup>6</sup> Each of these mechanisms may play a role in the clinical presentation of subsets of affected patients, and it is unlikely that symptoms can be attributed to a uniform origin.

This recognition of gastroparesis as a heterogeneous process is perhaps best exemplified through the lens of histopathology. Recent studies undertaken through the NIH gastroparesis consortium have utilized full-thickness gastric biopsies to evaluate for histopathologic changes that may provide evidence as to underlying mechanisms. These investigations have led to intriguing observations, including loss of interstitial cells of Cajal (ICCs), abnormal macrophage-related immune infiltrates, and decreased nerve fibers.<sup>7–10</sup> One common theme that has emerged is that the histopathologic pattern observed in these patients can be variable. For example, a depletion of ICC numbers in the smooth muscle of the antrum or gastric body has been recognized in up to 40% of severe gastroparetics not responding to medical therapies and requiring surgery to place a gastric electrical stimulator device (Enterra, Medtronic, Minneapolis, MN). However, approximately 50% of such severely symptomatic patients had a normal number of ICCs.<sup>11</sup>

Recent research (2016) has also expanded our understanding of the role of pylorus in gastroparesis through looking at the histopathology of this region in patients with severe disease who underwent surgery to insert a gastric electric stimulator and/or perform a pyloroplasty. In one series, approximately 70% of gastroparetic patients had pyloric ICC loss. Moreover, collagen fibrosis was observed in the pylorus of more than 80% of these patients. These findings may help explain pyloric dysfunction in gastroparesis, making interventions in the pyloric region a reasonable therapeutic approach in these patients. This study also identified eosinophilic inclusion bodies in the antrum and/or the pylorus, which were limited to diabetic gastroparetic patients. The clinical role of these inclusion bodies remains unclear, and further investigation is needed.<sup>12</sup>

Studies of the histopathology of the stomach in gastroparesis have relied on patients with severe cases who underwent surgery, which allowed full-thickness biopsies of the gastric wall to be taken. Therefore, a knowledge gap still remains in regard to patients with mild or moderate symptoms who are treated medically. Minimally invasive techniques such as percutaneous endoscopically assisted transenteric full-thickness gastric biopsy<sup>13</sup> or biopsies utilizing endoscopic ultrasound guidance<sup>14</sup> may allow us to study the gastric tissue in patients with less severe gastroparesis and provide further insight into the potential mechanisms of disease pathogenesis and progression.

Overall, there does not appear to be any single gold standard histopathologic marker for gastroparesis as the disorder is currently defined. It is likely that our current definition of gastroparesis, which relies on symptoms in tandem with gastric emptying, lumps many related subgroups under the same umbrella. As data emerge, there will be refinement of the underlying mechanisms of symptom pathogenesis and the relative importance of each mechanism in the development of individual symptoms, and there will also likely be a change in disease nomenclature based on recognition of clinically meaningful subgroups.

## THE ROLE OF ENDOSCOPY

The role of endoscopy in the diagnosis and management of gastroparesis has evolved in the past decade. Endoscopy has always been required to exclude gastric outlet obstruction, peptic ulcer disease, malignancy, or significant inflammation prior to establishment of the diagnosis of gastroparesis, a functional disorder of gastric emptying. However, the role of endoscopy has recently expanded to include more in-depth diagnostic investigations, as well as novel treatment options. In this chapter, we will focus on the numerous primary roles endoscopy plays in the diagnosis and management of gastroparesis. Specifically, we will review the data regarding endoscopic therapeutic advances in subsets of patients who may have primary pyloric dysfunction (either in isolation or in tandem with other defects); examine the role of endoscopy in the acquisition of full-thickness biopsies; evaluate the role of endoscopic temporary GES; and review the data regarding endoscopic venting/feeding options for patients with refractory symptoms. This is by no means an exhaustive account of all the ways in which endoscopy can be of benefit in gastroparesis; however, we have tried to highlight recent advances and the state of the art as we see it today.

## PYLORIC DYSFUNCTION

Whereas multiple mechanisms may be responsible for symptom pathogenesis in affected patients, pyloric dysfunction has received significant attention. Pyloric involvement in symptom pathogenesis has been speculated for some time, with the first report of successful intrapyloric botulinum toxin injection for gastroparesis appearing as an abstract at the annual meeting of the American College of Gastroenterology almost 20 years ago.<sup>15</sup> However, recent developments in diagnostic technology and endoscopic therapeutic options have brought this issue to the forefront.<sup>16</sup>

### Endoscopic Diagnostic Options for Pyloric Dysfunction

There are multiple means by which pyloric function can be assessed endoscopically, but no true gold standard, as each available modality assesses a different aspect of pyloric function. Traditional investigation relied on fluoroscopy and routine endoscopy to assess for pyloric outlet obstruction. Although both these investigations are adequate for detection of obstruction, neither assesses muscular function reliably enough to guide definitive treatment, and they certainly cannot quantify pyloric dysfunction. Scintigraphy is considered a gold standard for assessment of motility, but it does not evaluate pyloric function as an isolated component of the emptying process. When further diagnostic information is needed with regards to pyloric function, there are four additional modalities available for investigation, some of which are accessible via endoscopy, and some of which require more specialized motility equipment. At present, all are complementary, and there is not a true gold standard amongst the group; however, that may change in upcoming years as additional data emerge.

Antroduodenal or pyloric manometry (ADM) involves the placement, either via endoscopy or fluoroscopy, of a manometry catheter with multiple pressure sensors across the pylorus such that sensors are present in both the gastric antrum, the duodenum, and the small bowel. The initial papers evaluating the role of ADM in the assessment of pyloric pressure in health and disease stemmed from investigators at the University of

Southern California and the Mayo Clinic in the mid-1980s.<sup>17,18</sup> Investigators at the Mayo Clinic showed that some patients with gastroparesis had prolonged pyloric pressurization and more intense contraction, which they labeled "pylorospasm." ADM may identify a subset of patients who are more likely to have pyloric dysfunction; however, this technology has not been widely adopted, as the pylorus is relatively short, migration of the catheter is common, the technique is cumbersome and resource-intensive, and few companies produce the necessary equipment. At present, ADM is largely limited to only a few tertiary referral centers. One potential change in recent years has been the development of high-resolution manometry catheters with shorter interval spacing of pressure sensors, which could lead to less risk of migration over the course of the study. Researchers from Temple University investigated the role of a high-resolution ADM catheter in 10 patients, but data using this technology in clinical care are extremely limited at present, and it is unclear how much of an inroad high-resolution ADM will be able to make, given the high cost of the equipment and the significant risk for sensor injury in the course of endoscopic placement. Whereas ADM is the traditional means for assessment of pyloric function, it has not achieved a strong clinical foothold in its three decades of availability (largely for the reasons mentioned previously), and likely will not in the future, unless a low-cost high-resolution dedicated ADM catheter is developed for routine clinical use.

The wireless motility capsule is a wireless, ingestible medical device that measures pH, pressure, and temperature throughout the gastrointestinal tract. This was approved by the FDA in 2006 for the evaluation of gastric emptying in patients with suspected gastroparesis. Given the relative ease of this technology as compared to ADM, there has been speculation that perhaps similar information could be derived with regards to pyloric pressurization without the hassle of performing ADM. However, there are also reasons why this may not be feasible, as (a) the wireless motility capsule is not fixed in space, but rather allowed to move with contractions (perhaps making it less reliable for detection of contractile amplitude and frequency at a single or specific site) and (b) passage of the capsule through the pylorus itself would be relatively brief, perhaps giving only limited information with regards to pyloric function. Data with regards to antroduodenal pressure patterns in patients with gastroparesis are very limited. There has only been one direct comparison between ADM and the wireless motility capsule,<sup>19</sup> and only one key paper investigating gastric motility recordings in patients with gastroparesis versus healthy controls.<sup>20</sup> However, neither of these papers evaluated pyloric function specifically. Investigators from Johns Hopkins evaluated the role of the wireless motility capsule in the assessment of intrapyloric pressure and suggested a correlation between this measurement and gastric emptying as detected by scintigraphy.<sup>21</sup> However, the utilization of the wireless motility capsule to evaluate pyloric function is still in the research phase, and progress seems unlikely. This could change with further models or improvements on the wireless motility capsule principles, and as additional data emerge.

Impedance planimetry, otherwise known as the functional lumen imaging probe (FLIP), has recently emerged as a legitimate means by which to measure pyloric diameter and distensibility. This device was approved by the FDA in 2010, but has only recently entered routine clinical practice. Most studies to date have utilized FLIP in the assessment of esophageal disorders; however, there is a growing body of literature reporting on the

use of FLIP in the assessment of pyloric distensibility. Gourcerol et al (2015) recently evaluated pyloric compliance in healthy controls and patients with gastroparesis and reported that patients with gastroparesis had lower pyloric compliance versus healthy controls. They also noted that pyloric compliance correlated with symptom severity, quality of life, and gastric emptying, and potentially predicted clinical response to pyloric dilatation.<sup>22</sup> Investigators from Temple University evaluated FLIP in 54 patients with gastroparesis, and reported a wide range of values in symptomatic patients. They noted correlation between pyloric diameter and symptoms of early satiety and postprandial fullness. Most interestingly, however, their data suggested that FLIP could be used to identify a distinct subset of patients with decreased pyloric distensibility. Finally, Snape et al (2016) at the California Pacific Medical Center utilized FLIP, sleeve manometry, and gastric emptying studies in 114 patients with symptoms suggestive of gastroparesis. Similar to the findings from the Temple University group, they reported a correlation between symptoms and pyloric distensibility, as well as the ability of FLIP to potentially identify a clinically meaningful subset with possible pyloric dysfunction.<sup>23</sup> Whereas data are still emerging with regards to FLIP and gastroparesis, what has been published to date is encouraging, and suggests that FLIP can be utilized to identify a subgroup of patients with decreased pyloric distensibility. Whether this information will lead to more tailored therapy and the identification of a clinical subset that may more readily benefit from pyloric-directed therapy remains to be seen, and further investigation is ongoing.

With regards to logistics, FLIP is commonly, though not always, performed in conjunction with endoscopy. The catheter has a 3-mm outer diameter. While different balloon lengths are available, a length of 8 cm seems to be most often employed for evaluation of the pylorus. Different investigators have utilized various means of placement. Gourcerol and colleagues placed the catheters transnasally and positioned the device across the pylorus using videofluoroscopy; however, both studies from the United States utilized endoscopic placement. The device is too wide to fit in the working channel of a standard diagnostic endoscope; however, it can fit in the working channel of a large-channel therapeutic endoscope, and this is likely the easiest means to secure appropriate placement. Other options include tying a suture to the end of the device and pulling it across the pylorus with biopsy forceps, or trying to direct passage of the catheter past the pylorus with the endoscope; however, both these approaches add time and complexity to the procedure. Moreover, it is theoretically possible that using a biopsy forceps to drag the catheter across the pylorus before measurement may impact the recorded parameters (as opposed to passing the catheter directly across the pylorus from a therapeutic endoscope). In our experience, utilizing the working channel of a large-channel therapeutic endoscope appears to be the easiest means of quickly and reliably measuring pyloric distensibility.

Finally, any discussion of pyloric functional assessment would not be complete without a brief mention of EGG. EGG involves the placement of cutaneous leads to record gastric rhythm, and is performed at certain tertiary referral centers. It is not an endoscopic technique, nor does it evaluate pyloric function per se. However, there was a recent report by Wellington et al (2017) at Wake Forest evaluating EGG as a means to predict response to pyloric intervention. The normal gastric electrical rhythm (or slow wave frequency) is three cycles per minute, and the investigators noted that patients with documented gastric

emptying delay and symptoms consistent with gastroparesis would invariably have a disorganized, dysrhythmic pattern. However, if pyloric dysfunction (as opposed to another etiology for symptom pathogenesis) is a major component of the gastroparesis, then the gastric rhythm as measured by EGG would be regular, and the amplitude of the three-cycles-per-minute rhythm could be more pronounced. They reported that, in patients with a normal EGG and suspected pyloric dysfunction, the clinical response rate to pyloric intervention (botulinum toxin or balloon dilatation) was 78%.<sup>24</sup> Although these data are from only one center, they do raise the question of whether EGG, which is not interventional, easy to perform, and low-risk, could help stratify patients for targeted therapy aimed at pyloric intervention.

### Endoscopic Therapeutic Options for Pyloric Dysfunction

Given the paucity of treatment options available for gastroparesis, there has been significant interest in therapy aimed at pyloric disruption. This generally has fallen into five distinct subgroups: balloon dilatation, botulinum toxin injection, transpyloric stent placement, surgical pyloroplasty, and endoscopic pyloromyotomy. The data with regards to balloon dilatation are quite limited, and even the appropriate balloon size is not agreed upon. Most data suggest an 18- to 20-mm size with a 1 minute duration of distention. There are no reports of long-lasting benefit with this intervention, although several small studies do report transient symptom improvement.<sup>22,24</sup>

Botulinum toxin is a potent neurotoxin that inhibits acetylcholine release from presynaptic cholinergic receptors, and has been utilized in the treatment of multiple gastrointestinal motility disorders, most prominently achalasia. The first case report of prepyloric botulinum toxin use for gastroparesis was in 1988 by Sharma and colleagues.<sup>13</sup> This was followed by a number of small case series showing significant improvement in select patients.<sup>25–28</sup> Given the increasing use of botulinum toxin injection for the clinical treatment of gastroparesis, two randomized, double-blind, placebo-controlled trials were conducted. The first was by investigators at Leuven University in Belgium. They evaluated 23 patients with gastroparesis using a crossover protocol. Patients received 100 units of botulinum toxin or saline every 4 weeks, with symptom scores and gastric emptying assessed at baseline and after each intervention. Gastric emptying and symptom improvement were recorded after both interventions (botulinum toxin injection and saline injection) and were noted to be improved; however, there was no statistically significant difference between the two treatments.<sup>31</sup> The second randomized trial was performed by investigators at Temple University. Thirty-two patients were randomized to receive either botulinum toxin (200 units) or placebo (saline injection). Similar to the Belgium trial, both groups were noted to have improvement in symptoms and gastric emptying after 1 month; however, there was no significant difference between the two groups.<sup>32</sup>

The negative findings from these two randomized placebo-controlled trials tempered the excitement about prior case reports. A systematic review published in 2010 incorporating the data to date concluded that "there is no evidence to recommend botulinum toxin injection for the treatment of gastroparesis,"<sup>33</sup> and the American College of Gastroenterology Clinical Guideline on the Management of Gastroparesis stated with a high level of evidence that botulinum toxin was not recommended for patients with gastroparesis.<sup>34</sup> However, there are some important caveats that need to be mentioned to round out the botulinum toxin story. To begin with, both randomized controlled trials were

small, and perhaps not adequately powered to detect a significant difference in a small subgroup of patients with pyloric dysfunction. Secondly, larger case reports have since emerged that suggest that, in a carefully selected group of patients, the benefit may be more significant. The largest series to date is from investigators at the University of Michigan. They evaluated 179 patients receiving botulinum toxin injections between 2001 and 2007. Overall, there was improvement in 51.4% of patients; however, when a higher dose of botulinum toxin was used (200 units), the percentage that derived improvement increased to 76.7%. Other factors that predicted response in that series included female gender, age less than 50, and a nondiabetic, nonsurgical etiology.<sup>35</sup> Finally, it is important to note that neither of the randomized trials evaluating botulinum toxin specifically stratified patients based on suspicion for pyloric dysfunction. Given that pyloric dysfunction affects a subset of patients with gastroparesis, the jury is still out regarding the efficacy of botulinum toxin administration to patients with high suspicion for pyloric dysfunction. This point is evidenced by the good responses to pyloric botulinum toxin injection reported in the subset of patients with gastroparesis secondary to accidental vagotomy (usually accompanying a surgical fundoplication). It is known that a vagotomy inhibits pyloric relaxation and coordination with antral motility.

Given the suspicion that pyloric dysfunction may play a role in some patients with gastroparesis, and the development of temporary through-the-scope stents, investigators at Johns Hopkins evaluated the use of temporary transpyloric stent placement as salvage therapy in patients with refractory gastroparesis. In the initial report of three patients, placement of a double-layered, fully covered Niti-S self-expandable metal stent (Taewoong Medical, Gyeonggi-do, South Korea) across the pylorus resulted in both clinical and scintigraphic improvement.<sup>36</sup> This was followed by a retrospective evaluation of 30 patients treated with stent placement as salvage therapy. Over half of the patients were treated in the midst of hospitalization, and all had failed conventional therapy to date. Clinical response was reported in 75% of patients, although the duration of follow-up was relatively short. Stent migration was a persistent problem, and occurred in 48% of patients despite the use of endoscopic suturing techniques during stent placement. The authors proposed that stent placement could be used as a potential salvage therapy and also, potentially, as a means to select which patients may benefit from more definitive pyloric intervention.<sup>37</sup> However, it should be noted that, although these results seem encouraging, all the data to date with regards to transpyloric stent placement have been from one center, and at present, there are no prospective trials available to evaluate this modality. With that caveat, transpyloric stent placement is a tool in the armamentarium of the therapeutic endoscopist, and further study is needed to determine the prospective efficacy, duration of benefit, predictors of response, and whether clinical response to stent placement predicts response to pyloroplasty/myotomy.

Surgical pyloroplasty has been used as a drainage procedure after elective vagotomy and for the treatment of mechanical obstruction for over 40 years, but has recently returned to the forefront for treatment of patients with gastroparesis. Investigators from Oregon reviewed their experience with 28 patients and reported improvement in symptoms, gastric emptying via scintigraphy, and prokinetic use, with 83% of patients overall reporting improvement at 1 month follow-up.<sup>38</sup> This was followed by a second report evaluating 175 patients who underwent

**FIG 29.1** These images depict several key stages of a gastric peroral endoscopic myotomy procedure in a patient with refractory gastroparesis. **A**, Pylorus before intervention. **B**, Tunnel created by submucosal dissection. **C**, Myotomy. **D**, Clips used to close the mucosal entry site. **E**, Postprocedure pylorus, with clear widening as compared to the initial image. Othman, Assistant Professor of Medicine in the Division of Gastroenterology and Hepatology, and Director of Advanced Endoscopy, Baylor College of Medicine, Houston, TX.)

laparoscopic pyloroplasty. Gastric emptying time significantly improved in 86% of patients and normalized in 77%, with corresponding symptom improvement. Of note, however, 105 of the patients had a concurrent fundoplication for reflux, and a number of patients went on to require additional surgical intervention.<sup>39</sup> Investigators from Texas Tech University have evaluated the clinical efficacy of pyloroplasty combined with GES, and found that patients who received both interventions had significantly accelerated gastric emptying, as well as symptom improvement, compared to patients receiving GES alone.<sup>40</sup> Investigators at Emory University reported on pyloroplasty in 50 patients from 2006 through 2013. Symptom improvement was reported in 82%, although it should be noted that the majority of the patients in this series had prior foregut surgical intervention. There are no reported prospective randomized trials comparing surgical pyloroplasty with other interventions for gastroparesis, although currently there is a randomized blinded trial at Texas Tech University, El Paso, comparing surgical pyloroplasty to the combination of GES and surgical pyloroplasty.

The success of surgical pyloroplasty combined with the clear efficacy of peroral endoscopic myotomy for the treatment of achalasia has fueled interest in endoscopic pyloromyotomy for treatment of refractory gastroparesis. The first feasibility studies were performed in a porcine model in 2012 by Kawai and colleagues.<sup>41</sup> The first human report emerged from Johns Hopkins University in late 2013.<sup>42</sup> This has been followed by a wave of reports from multiple groups showing efficacy in small numbers of patients.<sup>43–47</sup> Gonzalez et al (2017) from Aix-Marseille University, France investigated the role of endoscopic pyloromyotomy

in 12 children with refractory gastroparesis and reported a technical success rate of 100% with no adverse events, significant symptom improvement in 85%, and normalization of gastric emptying in 75% of cases.<sup>48</sup> Dacha et al (2017) from Emory University School of Medicine, Atlanta recently reported their experience with endoscopic pyloromyotomy in 16 patients with refractory gastroparesis. They reported clinical improvement of symptoms in 81%, significant improvement in gastric emptying, and no adverse events.<sup>49</sup> Finally, Khashab et al (2017) recently reported on the results of a multicenter international study involving 30 patients with refractory gastroparesis. They reported a clinical response in 86% of patients during a median follow-up of 5.5 months, with lack of response seen in only four of 30 patients. Normalization of gastric emptying was seen in 47%, and an additional 35% were noted to have objective improvement. Two adverse events were noted (capnoperitoneum and a prepyloric ulcer)<sup>50</sup> (Fig. 29.1 and Video 29.1).

Summing this data in aggregate, the published responses to pyloric intervention in open-label and retrospective reports are impressive. However, these results should be interpreted cautiously, given the negative results from the only two randomized controlled trials (both utilizing botulinum toxin). Whereas the favorable reports of pyloric stent placement, surgical pyloroplasty, and endoscopic pyloromyotomy raise optimism regarding the future of pyloric treatments for gastroparesis, there is an urgent need for prospective randomized studies to evaluate these techniques. Given the heterogeneous nature of gastroparesis, we also strongly advocate for use of pyloric diagnostic techniques (in particular impedance planimetry) to select patients who may benefit

from more invasive pyloric intervention. Not all patients with gastroparesis will be expected to have pyloric dysfunction, and the exact size of this subset is unclear. Tailoring appropriate therapy to the appropriate patient is going to be a key part of adequately evaluating these techniques. This is a rapidly changing field, and one that is likely to see evolving expansion in the upcoming years as techniques become more streamlined and more technologic advances are made.

## FULL-THICKNESS GASTRIC BIOPSY

One of the major advances produced by the NIH gastroparesis consortium has been the identification of clear histopathologic changes in select patients with gastroparesis and the recognition that these changes are not uniform, but rather heterogeneous, with identification of clear histopathologic subsets. To date, there are no convincing data that identification of histopathologic subsets leads to improvement in clinical care; however, these data are relatively new, and the expectation of the authors is that future research will attempt to tailor specific mechanism-based therapies to specific histopathologic subsets. As such, there will likely be an increasing need for biopsy acquisition deeper than the mucosal and submucosal layers. This has colloquially been referred to as full-thickness gastric biopsy.

Initial reports of full-thickness gastric biopsy relied solely on surgical acquisition of tissue, either during a dedicated surgical procedure for tissue acquisition, or concurrently with another indicated procedure such as GES.<sup>51–53</sup> In 2008, the Mayo Clinic reported on endoscopic deep tissue acquisition in a porcine model using a double endoscopic mucosal resection technique. Whereas adequate tissue was obtained for staining of myenteric ganglia, delayed perforation was reported, limiting enthusiasm for this technique.<sup>54</sup> In 2010, investigators from the University of Calgary evaluated the role of a percutaneous, endoscopically assisted transenteric approach in a canine model, using a spring-loaded 14-gauge biopsy needle inserted through a 3-mm abdominal wall incision into the antrum under endoscopic guidance.<sup>55</sup> This was followed by a pilot study in 10 patients in 2011 that reported technical success, although smaller tissue samples were obtained than via surgery.<sup>56</sup>

In part due to the rapid expansion of the use of peroral endoscopic myotomy, the development of submucosal endoscopic access techniques has fueled development of this technique. Investigators from the Mayo Clinic reported on their experience of using submucosal endoscopy to obtain full-thickness gastric biopsies in a porcine model in 2012.<sup>57</sup> These investigators subsequently reported on a novel technique for gastric endoscopic muscle biopsy using a double resection clip-assist technique, in which endoscopic mucosal resection was performed to unroof and expose the muscularis propria, after which the muscularis propria was retracted into the cap of an over-the-scope clip. The clip was then deployed, creating a pseudopolyp of muscularis mucosa, which was then resected. Although the report describes the technique as "easy to perform," it should be noted that the paper included only three patients.<sup>57</sup>

Othman et al (2016) from Texas Tech University also reported on tissue acquisition from the muscularis propria of the gastric wall in patients with gastroparesis using endoscopic ultrasound (EUS)-guided fine-needle acquisition (FNA) biopsies (using a 19-gauge needle). They evaluated 11 patients from whom samples were taken via this approach in comparison to surgical biopsy acquisition during gastric electrical stimulator placement within

24 hours. They noted adequate histologic assessment of ICCs in 81% of patients and adequate assessment of the myenteric plexus in 54% of patients. There were no adverse effects noted during the study.<sup>58</sup>

At present, the ideal way to obtain full-thickness gastric biopsies is not clear. EUS-guided FNA certainly may be the easiest approach, and, as detailed previously, may provide adequate information in a majority of patients. Although submucosal dissection and the double resection clip-assist technique will likely provide more substantial tissue samples, these procedures are also more time-consuming, and require significantly more technical expertise. Surgical tissue acquisition remains the gold standard, although it is our hope that, as endoscopic techniques become more refined, surgical tissue acquisition will only be required in cases where a concurrent surgery is being performed for other clinical indications. In addition, it should be noted that all of these publications have reported on a relatively small number of patients. With that caveat, however, we envision nonsurgical methods for deep tissue acquisition as a key component of endoscopic care for gastroparesis going forward. If these techniques can provide information on the spectrum of ICCopathy and other tissue abnormalities in mild, moderate, and severe patient settings, they will hopefully lead to guided treatment algorithms and better outcomes.

## TEMPORARY GASTRIC ELECTRICAL STIMULATION

GES was approved by the FDA under a Humanitarian Device Exemption for treatment of patients with chronic, intractable nausea and vomiting secondary to gastroparesis in 2000. Although there are significant data suggesting clinical improvement in patients after GES,<sup>59</sup> the role of and place for GES in gastroparesis has not been established. Two randomized controlled trials evaluating the efficacy of GES for gastroparesis did not meet their primary endpoints; however, both studies had methodologic issues that may explain these results. In the initial double-blind trial conducted in 2000, the period of activation/inactivation was only 1 month, but the study showed significant improvement at 12 months of follow-up. In the second randomized trial, all patients were activated for 6 weeks following surgery before randomization to "off" or "on" treatment periods. However, in both studies (one of which involved diabetic gastroparesis patients and the other of which involved patients with idiopathic gastroparesis), patients who continued to have GES activation were significantly improved at the end of the study (12 months after implantation) as compared to baseline.<sup>59,60</sup>

GES traditionally requires surgical implantation of the device. As clinical response is not universal, there has been interest in potential diagnostic studies that may predict which patients will respond to surgical implantation. With that background, temporary endoscopic GES has garnered favor as a potential predictor of surgical response. Initial reports of temporary placement involved the use of a concurrent gastrostomy tube; however, in 2005, Abell and colleagues first reported on endoscopic implantation without the need for a concurrent gastrostomy. They used a temporary cardiac pacing lead that was passed through the working channel of an endoscope, screwed into place in the gastric mucosa, and then secured with placement of three to five clips. The lead was passed through the mouth or nose and attached to an external GES device, and the patient received temporary pacing via this arrangement. An initial report indicated a rapid improvement in vomiting frequency scores.<sup>61</sup>

Since this initial report, Abell and colleagues pursued a randomized, placebo-controlled crossover trial of temporary electrical stimulation for 72 hours, involving 58 patients. Vomiting decreased in both groups after the index endoscopy, with greater response seen in the group receiving active stimulation. Although the overall treatment effects in the study did not meet statistical significance, differences in favor of stimulation were suggested.<sup>30</sup> A further report evaluated temporary stimulation in 379 patients with gastroparesis-like syndrome. During this study, there was significant improvement in gastric emptying, for patients with both delayed and rapid gastric emptying, and significant improvement in symptoms (nausea, vomiting, and total symptom scores).<sup>31</sup>

Although using temporary gastric stimulation as a tool for predicting the success of a surgically implanted permanent device is a very appealing concept, there are many concerns: (1) the ability to reverse vomiting that has been present for months and years in 3 days does not seem likely, and is not borne out by using the same GES parameters in a permanently implanted device; (2) normalized gastric emptying in both slow and rapid settings has not been found in other reports; (3) the parameters used have been shown not to affect the electrical dysrhythmias present in gastroparesis patients; and (4) adoption of this technique has been limited by the unpredictable duration of electrode attachments to gastric mucosa, as well as the new understanding that the pylorus must also be addressed to improve gastroparesis. Both from a gastric emptying endpoint and a symptom resolution standpoint, better predictive testing will be needed. However, the pioneering work of Dr. Abell in this field may lead to better electrode recording methods in patients, helping study pathophysiology and response to treatment.

## ENTERAL TUBES

For patients with severe disease, enteral tubes can be considered as a therapeutic option for either gastric venting (with the hypothesis that gastric distention is contributing to symptoms) or postpyloric feeding. With regards to venting procedures, there are several options, including a nasogastric tube, gastrostomy, and gastrojejunostomy. Placement of a nasogastric tube is often preferred in the acute setting, as it is less invasive; however, this can be associated with patient discomfort, and cannot be tolerated for long-term use. Placement of a gastrostomy tube is one way to address gastric decompression, and can be used intermittently for venting of secretions to decrease vomiting and fullness when patients are symptomatic. However, placement of a gastric tube may complicate future interventions (including gastric electrical stimulator placement), and can lead to cosmetic issues, leakage, infection, and other complications, while also setting a very negative precedent that decompression of gastric contents is condoned with any threshold of discomfort. This actually limits the normal fundic/proximal stomach relationship, and can also lead to serious potassium deficiency. A gastrojejunostomy tube has the potential to combine venting and postpyloric feeds in one device; however, migration from the proximal jejunum with coughing and/or retching is a frequent complication.<sup>32,33</sup>

Postpyloric feeding has a clear role in patients with severe symptoms who are unable to support their nutritional needs. In patients with isolated gastroparesis, placement of a feeding jejunostomy tube has been shown to reduce hospitalization, maintain nutrition, and improve symptoms.<sup>1,34</sup> Several options

exist for postpyloric feeding. Placement of a nasoduodenal or nasojejunal tube is often the first avenue explored to ensure that postpyloric feeding is tolerated, as gastroparesis is often linked with extensive gastrointestinal dysmotility. However, nasoduodenal or nasojejunal tubes are not a long-term option. Direct endoscopic placement of a jejunostomy tube or a gastrojejunostomy tube is usually the more definitive long-term option, but the former can be associated with leakage, cosmetic issues, and infection, whereas the latter frequently migrates.<sup>35</sup> The gastrojejunostomy tube also partially blocks the pyloric opening, and hence may theoretically compromise resumption of oral intake. We believe a surgically placed jejunostomy tube (J tube) is the best option when long-term (3 months or more) use is being contemplated. The usual size is a 14- to 16-Fr diameter, which can also permit medications to be administered through the tube once they are dissolved. Infections are not generally an issue, and the tube is typically well-tolerated by the patient. Nocturnal J-tube feeding is recommended, with patients trying to eat during the day with no concurrent J-tube feedings. The laparoscopically placed surgical J tube also allows the surgeon to obtain a biopsy of gastric antral smooth muscle and thus histologically examine the ICCs, neurons, and smooth muscle for diagnostic and/or prognostic applications.

## FUTURE DIRECTIONS

The role of endoscopy in the management of gastroparesis has changed, and is due to shift further in upcoming years. There is increasing recognition that gastroparesis, as defined today, is a heterogeneous disorder, and that neither the presence of specific symptoms nor the time course of gastric emptying is a true gold standard for diagnosis. Histopathology may be the missing link that allows more finite classification of these patients and better identification of underlying mechanisms, with the end result of tailored patient-specific care. We envision an increasing role for endoscopy in the acquisition of deep tissue in a minimally invasive fashion, and see this resulting in a paradigm shift for this disorder, consistent with the well-accepted statement that "tissue is the issue." With easier tissue acquisition and an increased ability to visualize the myenteric plexus and ICCs, we hope to see the identification of clinically meaningful subsets. For those patients with pyloric dysfunction, endoscopic techniques will continue to expand, aimed both at the identification of pyloric dysfunction, as well as further refinement of pyloric disruption techniques.

Gastroparesis can now be viewed in a similar light to achalasia, where loss of esophageal motility in the body of the esophagus is accompanied by impaired relaxation of the lower esophageal sphincter. In gastroparesis, there is impaired electrical and motor function in the antrum, accompanied by pyloric sphincter dysfunction and poor opening/compliance of the pylorus. In any given gastroparesis patient, both aspects need to be recognized and therapeutically addressed, although in some patients one aspect may be more dominant.

High-resolution EGG has identified multiple variants of gastric dysrhythmia, and there is no reason to think that treatment of these entities via endoscopic approaches may not be feasible in the future. In addition, as GES devices become more compact and submucosal dissection techniques become more refined, we predict that GES devices could be inserted through endoscopes. Targeted endoscopic drug or stem cell delivery (specifically ICC stem cells) may also be an option in the future, specifically with endoscopic delivery into the antral smooth muscle.

## CONCLUSIONS

Endoscopy plays a key role in the diagnosis and management of gastroparesis. In a conventional sense, endoscopy is required to both establish and confirm the diagnosis of gastroparesis. Postpyloric feeding may be required to stabilize patients nutritionally while diagnostic studies and therapy proceed. Recent reports have highlighted the identification of a subset of patients with prominent pyloric dysfunction, and endoscopy plays a role in both the identification of this subset and the treatment of these patients. Impedance planimetry has emerged as a novel tool for assessing pyloric distensibility and compliance, and could potentially be used to identify a subgroup of patients in whom endoscopic techniques for pyloric disruption can be utilized. Advances in endoscopic techniques have led to the development of numerous methods by which full-thickness gastric biopsy can be obtained and clear histopathologic subsets can be identified, with the hope of identifying subgroups for which treatment decisions can be based on these histologic features. Finally, endoscopy may play a role in placing both temporary and permanent electrical stimulation devices, and certainly in facilitating electrical recording of gastric smooth muscle. We predict that the role for endoscopy should only continue to expand in the future, and that a revolution in this area is clearly underway.

## INTRODUCTION

Examination of the stomach by upper endoscopy often results in the incidental finding of gastric polyps or thickened gastric folds. Gastric polyps are estimated to be identified in 6% to 8% of all upper endoscopy exams.<sup>1</sup> Most series report that the most common type of polyp encountered is the fundic gland polyp (FGP) (77% to 80%), followed by the hyperplastic polyp (17% to 19%),<sup>1,2</sup> though series differ through time and based on the series of patients being evaluated. Generally, patients with gastric polyps are asymptomatic but polyps may cause clinical manifestations, including gastrointestinal (GI) bleeding, iron deficiency anemia, and gastric outlet obstruction. Many of these lesions are benign, whereas others have malignant potential; understanding and recognizing the various diagnoses and malignant risk may impact endoscopic treatment, future management, and surveillance recommendations.

Gastric polyps are generally defined as lesions in the lumen of the stomach with protrusion above the mucosal plane.<sup>3</sup> These lesions may be epithelial or subepithelial at their presentation. This chapter reviews the most common etiologies of epithelial gastric polyps and discusses the endoscopic approach to management of these lesions. Subepithelial lesions are discussed in Chapter 31 of this text. At the conclusion of this chapter, we discuss the evaluation of thickened gastric folds and outline the endoscopic approach to these entities.

## GASTRIC POLYPS

There are several types of epithelial gastric polyps encountered, including those that are generally benign (FGPs, hyperplastic polyps, hamartomatous polyps/juvenile polyposis), those that have malignant potential (gastric adenomas, gastric carcinoids types 1, 2, 3), and those that are malignant (gastric cancer). Endoscopic features may suggest the diagnosis, but histology is generally necessary to confirm the type of polyp encountered. Recommendations for further management may be based on the size, symptoms, and type of polyp identified.

## Fundic Gland Polyps

The most common gastric polyp encountered during upper endoscopy is the FGP (Fig. 30.1), which account for greater than 70% of all polyps identified during upper endoscopy and have a prevalence of 3% in the general population. FGPs are generally incidentally identified and are most often asymptomatic in patients. FGPs may occur as single or multiple epithelial lesions often clustered with a grape-like appearance. They are predominantly located in the gastric fundus or proximal body of the stomach, and are generally small, varying from 1 mm to occasionally up to 2 cm.

Endoscopic appearance is generally suggestive of these lesions with bland overlying glistening mucosa of pale color; however, diagnosis of these lesions is confirmed by histology after biopsy or removal of representative lesions. Histology reveals the classic appearance of dilated oxyntic glands with flattened parietal cells forming a microcystic appearance.<sup>4</sup>

The pathogenesis of FGPs is unknown. Sporadic FGPs are more commonly seen in women than in men.<sup>5</sup> They may be frequently seen in conjunction with *Helicobacter pylori* (*H. pylori*) infection.<sup>6</sup> FGPs have been thought to occur more frequently in patients taking proton pump inhibitors (PPIs), though a causal relationship has not been demonstrated. A 2016 meta-analysis of 12 papers found an increased odds ratio of PPI use with the development of FGPs.<sup>4</sup> Overall, sporadic FGPs are benign entities with no clinical consequence.<sup>5</sup>

Multiple FGPs are seen in association with familial adenomatous polyposis (FAP) syndrome (Fig. 30.2). Patients with FAP will have hundreds to thousands of FGPs in the gastric fundus and body, and may have no such polyps in the antrum. In patients with FAP, FGPs have a similar benign natural history, but there are reports of conversion of benign FGPs to dysplastic lesions in as many as up to 40% of cases.<sup>7</sup>

For patients without FAP, FGPs usually require no intervention. Biopsies on initial endoscopy to confirm the diagnoses are standard. Once diagnosed as FGPs, no surveillance is recommended; however, because of the risk of neoplastic transformation,

**Abstract**

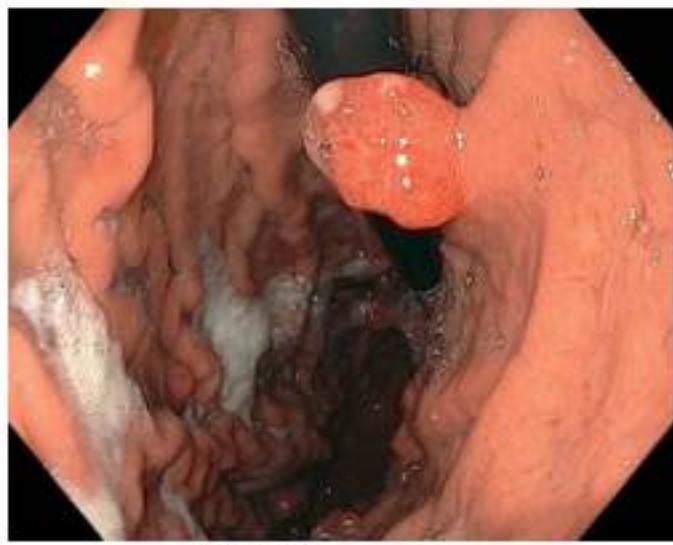

Examination of the stomach by upper endoscopy (EGD) often results in the incidental finding of gastric polyps or thickened gastric folds. Gastric polyps have been identified in 6% to 8% of all upper endoscopy exams. Most series report that the most common type of polyp encountered is the fundic gland polyp (77% to 80%) followed by the hyperplastic polyp (17% to 19%), though series differ through time and based on the series of patients being evaluated. Generally, patients with gastric polyps are asymptomatic, but polyps may cause clinical manifestations including gastrointestinal bleeding, iron deficiency anemia, and gastric outlet obstruction. Many of these lesions are benign, whereas others have malignant potential; understanding and recognizing the various diagnoses and malignant risk may impact endoscopic treatment, future management, and surveillance recommendations. Gastric polyps are generally defined as lesions in the lumen of the stomach with protrusion above the mucosal plane. These lesions may be epithelial or subepithelial at their presentation. This chapter reviews the most common etiologies of epithelial gastric polyps and discusses the endoscopic approach to management of these lesions. At the conclusion of this chapter, we discuss the evaluation of thickened gastric folds and outline the endoscopic approach to these entities.

surveillance with biopsies of these lesions in FAP patients is recommended.

### Hyperplastic Polyps

Hyperplastic polyps are the second most common type of polyps encountered in routine upper endoscopy (Fig. 30.3). These polyps are generally felt to be benign; however, several series have identified the presence of dysplasia (0.2% to 10%) or adenocarcinoma (0.6% to 3%) within these lesions.<sup>7–12</sup> Endoscopically, hyperplastic polyps have a wide range of appearances. There may be one or multiple. They can arise in any part of the stomach. They may be small, starting at a few millimeters in size, to large, mimicking the appearance of carcinoma. They may be sessile or pedunculated. The overlying mucosa may appear normal or may appear erythematous and with patches of exudate as the size increases.

Hyperplastic polyps have been associated with *H. pylori* gastritis and chronic gastritis, noted in association with autoimmune or atrophic gastritis with pernicious anemia.<sup>13,14</sup> Histology reveals submucosal edema, prominent foveolar hyperplasia, and inflammation of the lamina propria.

The approach to endoscopic management of hyperplastic polyps is debated. Biopsy of representative lesions to establish the diagnosis is recommended. Removal of polyps is generally individualized based on the size, appearance, histology, and clinical presentation. Some authors advocate for removal of all hyperplastic polyps above 5 mm because of the potential for development of dysplasia.<sup>14</sup> Generally, though, authors believe the risk of malignant transformation is low. Thus, large polyps should be sampled or removed depending on safety and feasibility of doing so. Bleeding polyps or those thought to be contributing to symptomatic anemia should be considered for polypectomy. Whether surveillance endoscopy should be performed after biopsy of hyperplastic polyps is also unclear. In our practice, hyperplastic polyps are not generally surveyed unless dysplasia has been established on first endoscopy. The presence of *H. pylori* should also be assessed and treated as this has been associated with reduced polyp recurrence and reduced progression to cancer.<sup>14</sup>

### Gastric Adenoma

Adenomatous polyps of the stomach are less common and constitute approximately 10% of polyps identified (Fig. 30.4).<sup>15</sup> Gastric adenomas are premalignant, with an increasing risk of developing into adenocarcinoma based on the size and degree of dysplasia of the lesion. Sporadic gastric adenomas may be found arising from normal or atrophic mucosa. Patients with genetic predisposition to gastric cancer, including FAP or hereditary nonpolyposis colon cancer syndrome (HNPCC), have an increased risk of developing gastric adenomas that are likely to progress to cancer. These lesions may be found anywhere in the stomach but have a predisposition to the antrum.

Endoscopically, these lesions can range in size from a few millimeters to centimeters. They may be single or multiple. The mucosal surface generally contains a cerebriform mucosal pattern. These lesions may be polypoid or sessile, raised, or flat.

**FIG 30.4** Gastric adenoma.

**FIG 30.5** Gastric carcinoid Type 1.

Histologically, gastric adenomas exhibit columnar epithelium with elongated atypical nuclei and increased mitotic activity. Adenomas may have varying degrees of tubular, villous, or tubulovillous architecture. Dysplasia and carcinoma are more frequently noted in villous or tubulovillous adenoma histologies. Similarly, the presence of increasing degrees of villous features correlate with increased risk of progressing to cancer. Adenomas may be associated with more advanced lesions in other areas of the stomach and necessitates a thorough exam of the entire gastric mucosa. One 2009 study noted 7% of adenomas had high grade dysplasia, and 3.7% of patients with adenomas had synchronous lesions with adenocarcinoma.<sup>2</sup>

Because of the malignant potential of these lesions, all gastric adenomas should be completely removed endoscopically if feasible, and surgically if needed. After resection, surveillance endoscopy is warranted to evaluate for residual or metachronous lesions.

### Gastric Carcinoma

Gastric carcinoma can be identified as a gastric polyp or a gastric mass. Differentiation between gastric adenoma and gastric carcinoma can be difficult endoscopically and often requires histology for determination. The epidemiology, endoscopic appearance, and management of early or polypoid gastric carcinomas is discussed in detail in Chapter 32.

### Gastric Carcinoid

Gastric carcinoid can be incidentally identified in the stomach on routine endoscopy or may be identified after presentation with symptoms. Gastric carcinoids represent 2% of all gastric polyps identified on endoscopy.<sup>15</sup> They may appear as an epithelial or subepithelial lesion. Gastric carcinoids are subdivided into three different types.

Type 1 lesions are the most common and represent 70% of gastric carcinoids (Fig. 30.5). They are usually asymptomatic and are identified in patients with prolonged hypergastrinemia, usually associated with autoimmune chronic atrophic gastritis. Type 1 gastric carcinoid lesions are generally small, multiple, and benign with a low risk of progression to malignancy. They

are often clustered in the gastric body or fundus, with a smooth erythematous surface. Histology reveals sheets of neuroendocrine enterochromaffin-like cells (ECLs). Diagnostic confirmation of Type 1 gastric carcinoids usually requires identification of serum hypergastrinemia, the presence of serum parietal cell and intrinsic factor antibodies, and the histologic presence of diffuse atrophic gastritis in the flat mucosa of the fundus, body, and antrum. Type 1 gastric carcinoids have a low risk of growth or progression and can generally be monitored with annual surveillance endoscopy with endoscopic or surgical intervention reserved for large or progressive lesions.

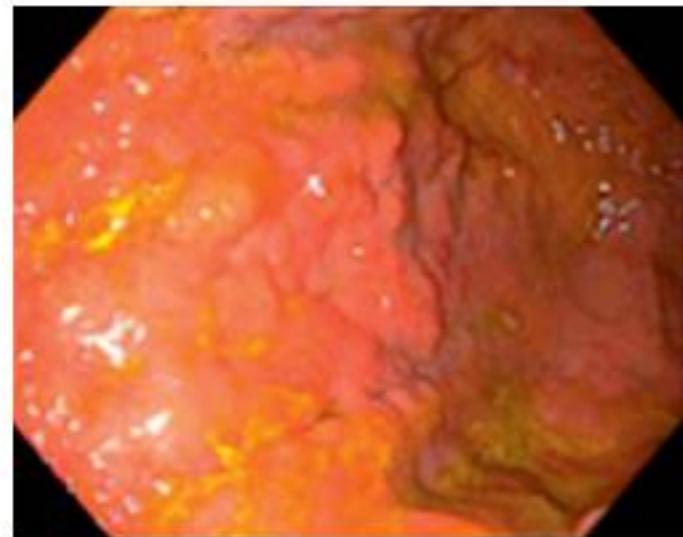

Type 2 gastric carcinoids are similar to the type 1 lesions histologically, and are also caused by the unabating stimulation by gastrin hormone in patients with Zollinger-Ellison Syndrome (ZES), or functional gastrinoma. Such patients may also have multiple carcinoids in the fundus and body, in association with hypertrophied gastric epithelium. There is usually no evidence of parietal cell and intrinsic factor antibodies, nor atrophy of the gastric epithelium in such patients. Similar to type 1 lesions, the risk of metastatic spread of these carcinoids is low and patients can generally be monitored with annual surveillance endoscopy.

Type 3 gastric carcinoids usually present as isolated lesions that are similar in histology to type 1 and 2 lesions, but develop autonomously, without underlying hypergastrinemia (Fig. 30.6). These lesions often appear to be larger at presentation, have deeper penetration into the stomach wall, and are more likely to be associated with metastases to lymph nodes or distant organs at the time of diagnosis.

The management of patients with gastric carcinoids is usually tailored to the type and underlying stimulus. In the case of type 1 and 2 carcinoids, the ongoing stimulation of gastric epithelium by gastrin hormone will result in recurrent formation of these lesions. Because of the low risk of metastases with these lesions, the management usually consists of endoscopic resection for lesions larger than 1 cm and annual surveillance. An alternative strategy is to perform a surgical intervention to reduce the gastrin level. In type 1 carcinoid, the most effective surgical strategy is antrectomy as it removes the source of high gastrin secretion from the antral G cells, which are overactive as a result of the

**FIG 30.6** Gastric carcinoid Type 3.

**FIG 30.7** Thickened gastric folds due to gastric adenocarcinoma.

achlorhydria caused by parietal cell destruction. In Type 2 carcinoid, surgical removal of the gastrinoma, if feasible, will likewise remove the source of gastrin hormone and result in the complete cessation of gastric carcinoid growth.

For type 3 carcinoid, which is completely autonomous of gastrin stimulation, complete excision of the primary lesion prior to development of metastases via endoscopic or surgical resection is warranted and should result in long-term cure.

## ENDOSCOPIC RESECTION

Endoscopic resection of gastric polyps is generally performed via similar techniques despite the etiology or histology of the gastric polyp. The general approach to endoscopic technique begins with a complete assessment of the type of polyp to be removed and the malignant potential of the polyp. For polyps less than 1 cm in size, snare polypectomy with or without cautery techniques are often effective at complete removal of benign gastric polyps. For polyps that are greater than 1 cm in size and with histology suggestive of a premalignant or malignant condition, endoscopic ultrasound (EUS) can be a supplemental tool to aid in the determination of whether endoscopic resection is feasible for curative intent. EUS evaluation can confirm that the abnormality visualized endoscopically is limited to the superficial or deep mucosal layers without demonstration of submucosal invasion. For polyps limited to the mucosal layers, saline injection lift technique with subsequent endoscopic mucosal resection (EMR) can generally be employed for complete removal of gastric polyps. Depending on the size and location of the lesion, EMR may be performed with the aid of a band ligator device. EMR is ideally performed en bloc with one piece but can be removed in a piecemeal fashion if necessary, with the goal being to eliminate all abnormal tissue. Additional endoscopic techniques have been developed to target lesions, including endoscopic submucosal dissection for lesions involving the submucosa or lesions suspected

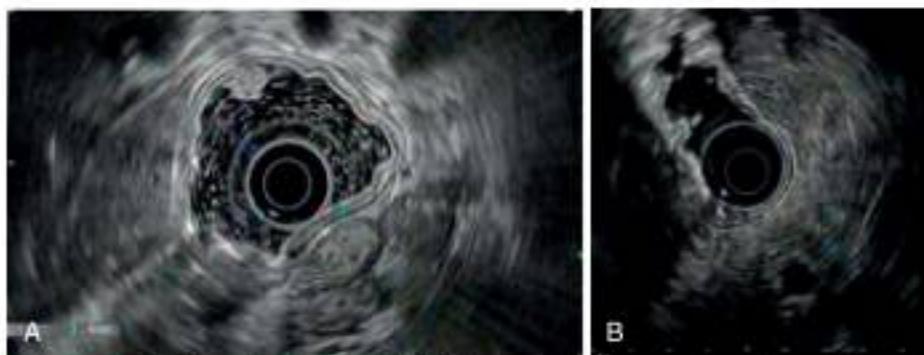

to harbor malignancy. Chapter 32 in this text provides a greater discussion of these techniques.

## THICKENED GASTRIC FOLDS

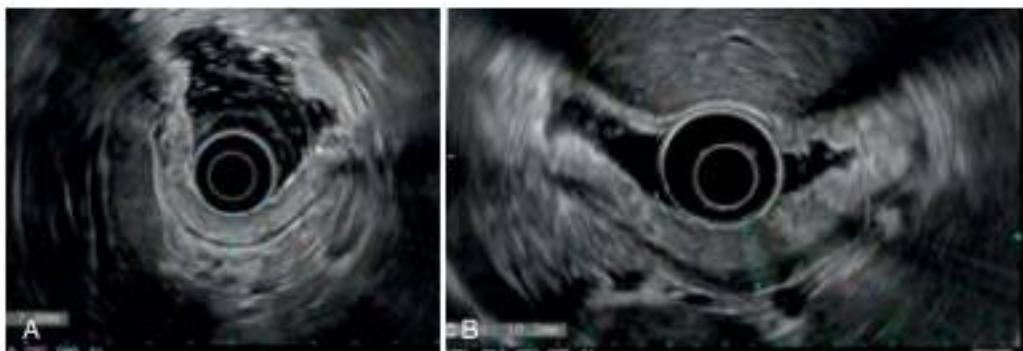

Thickened gastric folds are often identified on endoscopy, barium upper GI series, and computed tomography (CT) scanning of the abdomen as part of a work-up for symptoms, or may be identified incidentally during routine examinations (Fig. 30.7). The differential diagnosis is broad, including malignancies such as adenocarcinoma and lymphoma, or benign conditions such as hypertrophic gastritis or chronic *H. pylori* associated gastritis.<sup>16</sup> Less common causes include Menetrier's disease, infiltrative diseases such as amyloidosis and anisakiasis, lymphoid hyperplasia, and ZES. Rarely, metastatic cancer from a distant primary site (breast cancer, lung cancer, and melanoma) may present as large gastric folds.<sup>17</sup>

Work-up of thickened gastric folds generally starts with mucosal biopsy, but mucosal biopsies are often unable to provide a diagnosis and biopsy of deeper layers through several different methods must be considered. Standard endoscopic biopsy specimens usually contain superficial mucosa ranging in size from 2 to 4 mm. Large fragment biopsies have been proposed using snare electrocautery. This technique provides the ability to obtain full thickness or deeper specimens in an effort to increase the diagnostic yield, but has not been widely accepted because of the perceived risk of major complications, most notably hemorrhage or perforation.<sup>18–20</sup> When repeated attempts at endoscopic biopsy are inconclusive and the index of suspicion for malignancy is high, EUS-guided fine-needle aspiration (FNA) may be attempted for diagnosis. Laparotomy or laparoscopy may be indicated to obtain a full-thickness biopsy of the stomach wall when repeated endoscopic biopsies have been inconclusive.

The differential diagnosis of thickened gastric folds varies widely from entirely benign etiologies to diffuse malignant processes, and a prompt diagnosis is important for the appropriate triage of the patients. In the work-up of this finding, EUS evaluation is often warranted and can be particularly useful in providing diagnostic information that would help determine the best

**FIG 30.8** **A** and **B**, Endoscopic ultrasound (EUS) demonstrating a normal gastric wall layer pattern.

**FIG 30.9** **A** and **B**, Endoscopic ultrasound (EUS) demonstrating a thickened gastric wall due to linitis plastica gastric adenocarcinoma.

approach to achieve an accurate diagnosis. EUS has been shown to primarily aid in identifying which layer of the gastric wall is thickened for targeted approaches at that layer. The normal gastric wall has a thickness of 3 to 5 mm. Most of the gastric wall layers are distinctly visualized on EUS examination (Fig. 30.8): layer 1, superficial mucosa; layer 2, deep mucosa and muscularis mucosa; layer 3, submucosa; layer 4, muscularis propria; and layer 5, subserosa and serosa. The thickness of each particular layer tends to be similar in the normal state, so an increase in size of any individual or multiple layers is easily recognized during EUS examination and can help formulate a differential diagnosis and guide further diagnostic work-up targeting the thickened layers. Specifically, loss of wall layer pattern or thickening in the muscularis propria (layer 4) has been shown to be most concerning for malignant involvement (Fig. 30.9).<sup>21,22</sup> Additionally, thickening in the mucosal layer or the muscularis mucosa can generally be diagnosed by forceps biopsies, "well biopsies" (where the forceps are placed repeatedly at the same site to obtain deeper sampling), or large particle biopsies using snare cautery. Thickening of deeper layers of the stomach wall, namely the submucosa and/or muscularis propria, has been a challenge for standard endoscopic techniques and may need to be approached by the large particle snare cautery biopsy technique, or with EUS-guided FNA of the specific thickened layer. If these approaches fail to determine the cause of thickening, then a surgical full thickness biopsy may be required.

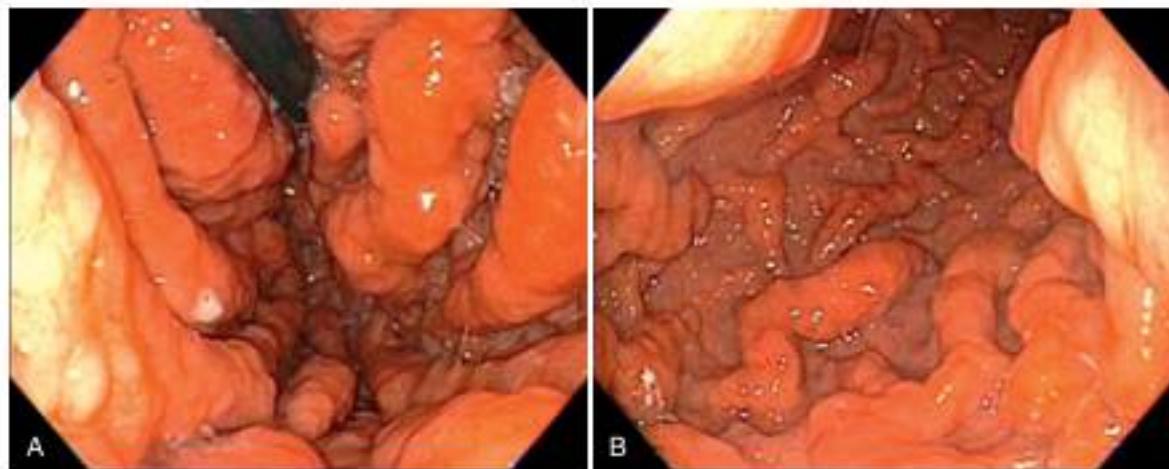

### Malignancy

The differential diagnosis for thickened gastric folds often includes malignancy. The most common type of malignancy that presents

**FIG 30.10** Thickened gastric folds due to linitis plastica gastric adenocarcinoma.

in this fashion is gastric adenocarcinoma, which can present in some patients as linitis plastica (Fig. 30.10). Linitis plastica represents a diffuse process within the gastric body of enlarged, often edematous and erythematous, folds with poor distensibility of the gastric wall with insufflation. A high index of suspicion must be present when this appearance is identified, as mucosal

**FIG 30.11 A and B.** Thickened gastric folds due to mantle cell lymphoma.

biopsies are often negative and deeper biopsies are required to make the diagnosis, as described earlier.

Lymphoma is another malignancy that can present as diffuse thickening of gastric folds (Fig. 30.11). There are various subtypes of non-Hodgkin's lymphoma that may infiltrate into the gastric wall and result in diffusely thickened folds. The mucosa is similarly often edematous and erythematous, but generally distensibility of the stomach may be maintained.

Finally, other malignancies on rare occasions may spread to the stomach and cause thickened gastric folds. Lobular breast cancer, lung cancer, and melanoma have been described in cases to involve the stomach. Similar to gastric adenocarcinoma, this may present as a *linitis plastica* appearance, or may be diffuse in the stomach. Metastatic malignancy may be difficult to diagnose on mucosal biopsies alone and may require deeper tissue sampling.

When malignancy is causing the presentation of thickened gastric folds, symptoms such as early satiety, weight loss, or anemia are often present. Additionally, in patients with malignancy, other corroborating examinations, including CT scans, may suggest the finding of thickened gastric folds prior to the patient's presentation for endoscopy. Patients with symptoms secondary to thickened gastric folds require management targeted at their underlying malignancy and often are unable to maintain nutrition because of the diffuse nature of malignancy involving the stomach. As such, these patients are sometimes sent to gastroenterologists for supplemental treatment, such as placement of percutaneous endoscopic jejunostomy tubes.

#### Menetrier's Disease

Menetrier's disease is a rare disease that can result in diffusely thickened or giant gastric folds. Menetrier's disease generally presents with a clinical syndrome of weight loss, edema, and diarrhea secondary to protein losing enteropathy.<sup>23,24</sup> The diagnosis is made by endoscopy, which reveals the appearance of thickened or giant gastric folds diffusely and most pronounced in the fundus and the body. There are often mucosal changes, including erosions or ulcerations. EUS examination of these folds generally reveals thickening in layers 2 and 3 of the gastric wall and mucosal biopsies are often insufficient to make the diagnosis. Histology of these areas reveal pronounced foveolar hyperplasia, cystic dilation, and glandular atrophy. The cystic glands may also extend into the superficial submucosa, causing gastritis cystic profunda.

The clinical pattern of symptoms in conjunction with the histology is used to make the diagnosis of Menetrier's disease. Treatment of this entity is often challenging and various medical therapies have been tried, including treatment of any coexisting infection such as *H. pylori*. In patients refractory to medical management or with severe symptoms, gastrectomy is often indicated and can be curative. Publications have shown effective treatment with monoclonal antibodies to the epidermal growth factor receptor.<sup>25</sup>

#### CONCLUSION

Gastric polyps and thickened gastric folds are commonly encountered during routine endoscopy or as part of work-up of symptoms including nausea, early satiety, vomiting, weight loss, or anemia. Diagnosis often requires histology in the form of biopsies and occasionally requires EUS for further evaluation. Once histology is established, endoscopic treatment with polypectomy or EMR is often warranted for certain premalignant or early malignant lesions.

## INTRODUCTION

Neoplasms of nonepithelial origin, although uncommon, are lesions that a gastrointestinal (GI) endoscopist can expect to encounter with some regularity. Although the number of such pathologic entities is manageable small, the spectrum of clinical behavior manifested by these lesions spans from trivial to life-threatening. The difficulty in managing patients with such lesions is that the tumor originates from within the GI tract wall and often appears as a mass beneath otherwise normal mucosa. Encountering such a seemingly innocent façade behind which lurks a range of ominous possibilities, the GI endoscopist is challenged to use additional diagnostic tools appropriately to direct the patient's care.

## EPIDEMIOLOGY

The clinical starting point for patients with lesions of nonepithelial origin is the discovery of a mass impinging on the GI tract mucosa from beneath, the so-called submucosal tumor (Fig. 31.1). In its classic form, a discrete tumorous appearance is present with overlying mucosa that, although most commonly bland, may be erythematous, pale, dimpled, or ulcerated. Lesions are often initially identified at esophagogastroduodenoscopy (EGD), but the patient may also be referred to an endoscopist for evaluation of an abnormal radiograph (e.g., barium contrast examination).

Applied literally, the term *submucosal* would imply the presence of an intramural mass originating in the submucosal layer of the GI wall. Therefore, the term *subepithelial* tumor or lesion is the preferred nomenclature for describing a range of lesions

that create a similar appearance, including intramural and extramural structures. Such subepithelial tumors (SETs) may include both neoplastic and non-neoplastic masses, and even mucosal neoplasms have been reported to exhibit a submucosal appearance. Examples of nonepithelial lesions in all four categories are listed in Table 31.1. This discussion centers on neoplasms that primarily originate from nonepithelial GI tract cell lines, but all types of pathology must be considered when developing a management plan.

Depending on the clinical circumstances and type of tumor, the lesion may cause symptoms such as bleeding, obstruction, or pain. However, such lesions are commonly serendipitously found during evaluation for a different, unrelated problem. Because most such lesions are asymptomatic, epidemiologic data are skewed by the nature of their discovery incidental to a different, usually unrelated condition. In one study of 15,104 EGD reports, SETs were identified in 0.36%.<sup>2</sup> As most in this series were life-threatening tumors, the study database likely underreported less serious lesions. Many such lesions turn out to be normal extramural organs. Allgayer (1995)<sup>3</sup> found that among 30 patients referred for subepithelial lesions (SELs), normal extramural structures were present in 14 (47%). Motoo et al (1994)<sup>4</sup> also reported normal organs in 16 of 19 SELs, as did Caletti et al (1989)<sup>5</sup> in 10 of 25 tumors; organs identified include the spleen, liver, splenic vessels, and pancreas.

Because SETs are often left in situ, the pathologic distribution among tumors is unknown. It is reported that 1% to 3% of resected gastric tumors are stromal cell tumors;<sup>6</sup> it can be inferred that the actual incidence, when including tumors that were not resected, is considerably higher. In a small prospective study<sup>7</sup>

**Abstract**

Neoplasms of nonepithelial origin, although uncommon, are lesions that a busy gastrointestinal (GI) endoscopist can expect to encounter with some regularity. Although the number of such pathologic entities is manageable small, the spectrum of clinical behavior manifested by these lesions spans from trivial to life threatening. The difficulty in managing patients with such lesions is that the tumor originates from within the GI tract wall and often appears as a mass beneath otherwise normal mucosa. Encountering such a seemingly innocent façade behind which lurks a range of ominous possibilities, the GI endoscopist is challenged to use additional diagnostic tools appropriately to direct the patient's care.

**TABLE 31.1 Types of Masses Causing Esophageal and Gastric Subepithelial Tumors**

	Neoplastic Masses	Non-Neoplastic Masses
Intramural masses	Stromal cell tumor	Varices
	Lipoma	Duplication cyst
	Granular cell tumor	Inflammatory granuloma
	Lymphoma	Foreign body (e.g., surgical suture or clip)
	Fibrovascular polyp	Pancreatic rest
	Hemangioma/hemangiosarcoma	
	Lymphangioma/lymphangiosarcoma	
Extramural masses	Metastatic neoplasm	
	Primary neoplasm of adjacent organs (benign and malignant)	Benign lymph node
	Metastatic lymph node	Inflammatory mass of adjacent organs (e.g., pancreas, spleen) Organomegaly (e.g., spleen, liver)

American Society for Gastrointestinal Endoscopy (ASGE) guideline<sup>6</sup> on the role of endoscopy in the management of premalignant conditions of the stomach focuses primarily on mucosal lesions, but does include that endoscopic ultrasound (EUS) with or without fine-needle aspiration (FNA) is the preferred technique to characterize subepithelial gastric lesions. Symptoms attributed to the mass nearly always drive further investigation, but our own EUS study of a subset of such lesions found that nearly 90% were asymptomatic.<sup>7</sup> GI bleeding may be seen in many SELs, most commonly in the form of slow blood loss causing iron-deficiency anemia. The surface of the tumor may be ulcerated in such cases (Fig. 31.2). Malignant tumors may be more prone to ulceration and bleeding;<sup>8</sup> this might be taken as a sign of a potentially malignant form that compels definitive treatment. However, benign lesions may also cause severe bleeding,<sup>9</sup> and occasionally rapid hemorrhage may occur.<sup>10</sup> Less often, GI tract obstruction may be caused by such masses,<sup>11</sup> especially if the lesion is located in a narrow area such as the esophagogastric junction or pylorus; intussusception caused by such masses has been reported.<sup>12</sup> Pain may be a presenting complaint, especially if the SET is neoplastic or malignant.<sup>13</sup>

Because most lesions are incidentally found during endoscopic examination for another problem, the clinical features of subepithelial masses are primarily those that, in the endoscopist's opinion, compel further evaluation. Size greater than 2 cm has been proposed as an ominous finding,<sup>14</sup> and lesions with an ulcerated or irregular (lumpy) surface often undergo additional testing or treatment. Patients with SETs who have a prior history of malignancy should receive further evaluation to exclude metastatic disease. Finally, patients with SETs that change appearance on serial examination are usually directed by an alert clinician to further testing.

among 45 SETs, most were found to have a benign appearance that required no follow-up. From these available data, it may be cautiously concluded that SETs are found in less than 1% of routine upper endoscopy examinations, half of such lesions are found to be normal extramural structures, most remaining lesions are benign, and stromal cell tumors constitute most such neoplasms.

## CLINICAL FEATURES

Lumps and bumps of all sorts are regularly encountered in endoscopic examinations; the decision regarding which to evaluate further depends on the endoscopic appearance, the clinical circumstances, and the inclination of the endoscopist. A 2015

## PATHOLOGY

Extramural masses compose half of suspected SELs and include normal organs, non-neoplastic masses, and extramural neoplasms. Normal liver, spleen, pancreas, gallbladder, colon, and kidney all have been reported to appear as suspected SELs.<sup>14–16</sup> Vascular

**TABLE 31.2 Classification of Gastrointestinal Mesenchymal Tumors**

Tumor Type	Examples
Stromal tumors	GIST; smooth muscle tumors (leiomyoma, leiomyosarcoma), glomus tumors, leiomyomatosis, pleomorphic sarcoma
Neural tumors	Neuroma/neurofibroma, paraganglioma, ganglioneuromatosis
Endothelial and vascular tumors	Hemangioma, hemangiosarcoma, Kaposi's sarcoma, lymphangioma
Lipocytic tumors	Lipoma, liposarcoma, lipohyperplasia (ileocecal valve), lipomatosis (colon)
Granular cell tumor	Granular cell tumor
Inflammatory fibroid polyp	Inflammatory fibroid polyp
Fibrohistiocytic tumors	Fibrovascular polyp, fibrous histiocytoma, desmoid tumors (mesentery), fibroepithelial polyp
Striated muscle tumors	Rhabdomyosarcoma

GIST, gastrointestinal stromal tumor.

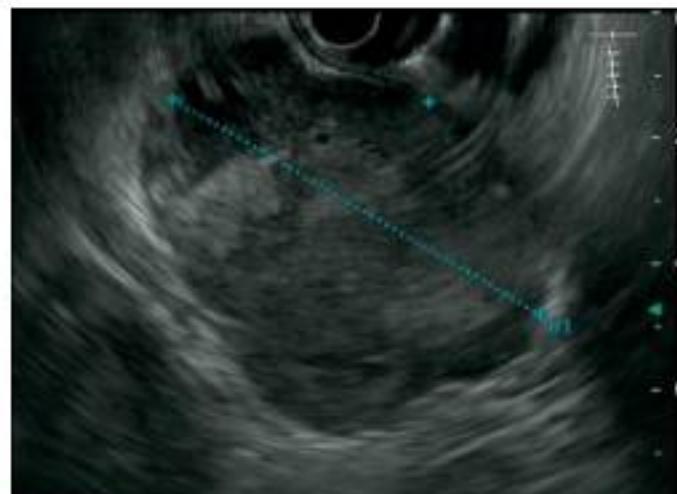

Data from Lawrin K, Riddel RH, Weissman WM: Mesenchymal tumors. In: *Gastrointestinal Pathology and Its Clinical Implications*, New York, 1992, Igaku-Shoin, pp 284-341.

structures often produce the appearance of a discrete tumor, including normal vessels of the spleen<sup>17</sup> and abnormal vessels such as varices and aneurysms.<sup>18</sup> Neoplasms and non-neoplastic masses involving these same organs can also produce this appearance, as can such masses involving the peritoneum, mediastinum, and the lymph nodes adjacent to the upper GI tract. The various malignancies, cysts, and inflammatory masses of these structures need no further elaboration here because a large variety of such findings have been noted in the case report literature.

Masses that arise within the wall of the esophagus and stomach require further discussion, particularly because many are peculiar to the GI tract. Most neoplasms in this category are mesenchymal tumors, meaning that they arise from cells of mesodermal origin. Most such neoplasms are clinically benign, although, as discussed subsequently, tumor histology may not provide reliable clues to malignant behavior. A large variety of such neoplasms have been described (Table 31.2), but most are exceedingly rare. The SETs most likely to be encountered in the esophagus and stomach in a routine clinical setting are discussed here.

### Gastrointestinal Stromal Tumor

Most mesenchymal GI tumors are pale, firm, spherical, or ovoid structures embedded in the wall of the affected organ. The microscopic appearance of muscle-like eosinophilic, spindle-shaped cells in uniform sheets and the proximity of the tumors to the muscular wall layers led early observers to believe that these tumors were of myogenic origin,<sup>19</sup> hence the name "leiomyoma" and its variations (e.g., leiomyosarcoma, leiomyoblastoma). However, it later became clear that these neoplasms not only are not of obvious myogenic origin but also often lack any specific markers of differentiation whatsoever.<sup>20</sup> Immunohistochemical analyses showed variable expression of smooth muscle features such as desmin and actin, and neural proteins such as S-100.<sup>21</sup> For the sake of clarity, these lesions came to be referred to as gastrointestinal stromal tumors (GISTs), an acknowledgment

**FIG 31.3** Endoscopic ultrasound (EUS) imaging of a large lobular gastric gastrointestinal stromal tumor (GIST) arising from the fourth wall layer (demarcated with a +).

that they originate in mesenchymal stroma. Endoscopically, GISTs appear as a dome-shaped, firm subepithelial mass. Central umbilication or frank ulceration is common, and there may be a lobulated or irregular appearance (see Fig. 31.1; Video 31.1). GISTs are noted to arise from the fourth wall layer with EUS imaging (Fig. 31.3).

A significant breakthrough occurred with the discovery that most GI stromal tumors stain positive for a specific membrane protein, designated CD117.<sup>22</sup> The protein was subsequently identified as one of a class of stem cell factor (SCF) receptors. SCF receptors can exist as either soluble or transmembrane receptors; CD117 was subsequently identified as KIT, a transmembrane tyrosine kinase receptor<sup>23</sup> first found in a feline sarcoma (hence "kit" for kitten).<sup>24</sup>

Abnormal cell growth is a fundamental element of cancer physiology, and hyperfunction of the KIT receptor can lead to neoplasia. This concept is supported by the observation that nearly all GISTs express KIT. It has further been observed that the interstitial cells of Cajal (ICC) share some phenotypic and ultrastructural similarities with GIST and normally express the KIT receptor; this observation has led to the current hypothesis that GISTs arise from ICC<sup>25</sup> or from ICC precursor cells. This hypothesis is bolstered by the observation that ICC cells are seen outside the GI tract, and likewise extra-intestinal GIST have been described.<sup>26,27</sup> Finally, it has been noted that this gain-of-function mutation is not found in true leiomyomas.<sup>28</sup> Some pathologists have suggested that CD117 positivity is required to confirm a diagnosis of GIST.<sup>29</sup> It is now known, however, that a few otherwise obvious GISTs do not express KIT. Many of these tumors have been identified as expressing platelet-derived growth factor receptor  $\alpha$  (PDGFR $\alpha$ ), another distinct tyrosine kinase receptor that also mediates many of the same growth and antiapoptotic proliferation pathways.<sup>30</sup> Several gain-of-function mutations have been reported in the PDGFR $\alpha$  gene, and the resulting tumors are otherwise indistinguishable from GISTs that are KIT-positive. There also remains a small subset of GISTs that express neither KIT nor PDGFR $\alpha$ ; presumably other pathophysiological pathways exist to account for these, including other tyrosine kinase gain-of-function mutations.

Nearly all upper GI tumors of this type occur in the stomach, but duodenal lesions have been described.<sup>11</sup> Most esophageal stromal tumors lack the CD117 protein and may be true leiomyomas.<sup>12</sup> The tumors are most often solitary except in the case of specific disease entities such as Carney's triad (GIST, pulmonary chondroma, and extra-adrenal paraganglioma). Germline KIT mutation kindreds have been described,<sup>13</sup> however, in which case multiple GISTs are seen. Giant sizes of greater than 10 cm have been noted, but most tumors are less than 3 cm.

Pathologically, the tumor usually consists of uniform pale tissue, although hemorrhagic and necrotic areas may be seen. Microscopically, the cells are spindle shaped with uniform nuclei and general cytologic uniformity. Some cell groups may show epithelioid configurations (closely packed polygonal cells), and there may be nuclear pleomorphism. It has been observed more recently that the histologic pattern is sometimes related to the nature of the underlying genetic abnormality; KIT mutations at exon 13 or 17 more often show spindle cell morphology,<sup>14</sup> whereas PDGFR $\alpha$  GISTs often exhibit epithelioid histology.<sup>15</sup> Ultrastructural cellular abnormalities have also been linked to specific gene mutations.<sup>16</sup> Recent research (2015) has linked some specific mutations with clinical features and outcomes; for instance, KIT exon 9 mutations show higher risk of progression and lower 5-year relapse-free survival than those with exon 11 mutations.<sup>17</sup> It has long been known that malignant behavior in GISTs is difficult to predict given the relatively bland cytology and slow growth of these neoplasms. It has been reported that even small, benign-appearing stromal tumors have been known to metastasize.<sup>18</sup> This discovery led to considerable confusion about the appropriate criteria to categorize these tumors as benign or malignant. Older pathologic scoring systems relied on numerous histologic features<sup>19</sup> and were plagued with problems. More recent attention has focused on the size of the tumor and the number of mitoses observed (mitotic index), at least in part because these are easily quantifiable findings. In one study of 100 cases, tumors with more than 5 mitoses per 10 high-power fields (HPFs) were significantly more likely to metastasize, although 40% of malignant lesions in that study had fewer mitoses.<sup>20</sup> In another study, multivariate analysis of various clinical and pathologic features in 122 specimens showed that more than 10 mitoses/50 HPFs correlated with poor outcome, whereas site, epithelioid histology, and tumor size were not independently predictive.<sup>21</sup>

Attempts to correlate tumor marker status such as CD117 positivity with malignant behavior have produced generally confusing or negative results,<sup>22</sup> as have studies of specific KIT mutations<sup>23,24</sup> and other tumor markers.<sup>25,26</sup> Older GIST scoring systems have been abandoned following a National Institutes of Health (NIH) consensus conference, which defined malignancy risk based on size and mitotic index alone.<sup>27,28</sup> The NIH criteria divide tumors into four categories of malignant risk (Table 31.3), an acknowledgment that even the most innocent lesion poses a slight but definite risk of malignant behavior.

If all such neoplasms entail malignant risk, prudence might dictate that they should always be resected. However, more recent data suggest that GISTs are more common than previously thought. Up to 10% of resection and autopsy specimens contain such tumors,<sup>29</sup> and microscopic GISTs (also called seedling GISTs, minimal GISTs, or GIST tumorlets) can be seen in 35% of some patient groups.<sup>30,31</sup> These incidental and microscopic GISTs display the same KIT and PDGFR $\alpha$  mutations as their larger counterparts. The finding that synchronous GISTs from the same patient

**TABLE 31.3 National Institutes of Health Criteria for Malignant Risk in Gastrointestinal Stromal Tumors**

Risk Level	Size (cm)	Mitoses/50 HPF
Very low risk	< 2	< 5
Low risk	2–5	< 5
Intermediate risk	< 5 5–10	6–10 < 5
High risk	> 5 > 10 Any	> 5 Any > 10

HPF, High-power field.

Data from Berman JJ, O'Leary TH. Gastrointestinal stromal tumor workshop. *Hum Pathol* 32:578–582, 2001; Toquet C, Le Neel JC, Guillou L, et al: Elevated ( $>$  or = 10%) MIB-1 proliferative index correlates with poor outcome in gastric stromal tumor patients: A study of 35 cases. *Dig Dis Sci* 47:2247–2253, 2002; Hedstrom JL, Ekstrand M, Viestenzberg P: Endoscopic diagnosis of submucosal gastric lesions: the results after routine endoscopy. *Surg Endosc* 5:20–30, 1991.

regularly show different gene mutations (and are independent sporadic GISTs) confuses the picture further.<sup>32</sup> GISTs that were earlier classified as metastatic or recurrent may have been distinct neoplastic events. If it turns out that most small and asymptomatic GISTs stay that way, a conservative approach may be the most prudent.

A second breakthrough in GISTs has been the development of tyrosine kinase inhibitors such as imatinib mesylate, which are effective in reducing KIT enzyme activity and are useful for tumor treatment. Imatinib targets the specific abnormal enzyme activity in the neoplasm and does not rely on generalized cytotoxicity for its effect. In an open-label study of 147 patients with unresectable malignant GISTs, an overall response rate of 38% was seen.<sup>33</sup> Among responders, results are often dramatic. A number of newer compounds with similar tyrosine kinase inhibitory function have been examined in GISTs and have been found to be effective. Sunitinib and regorafenib have shown effectiveness, particularly in imatinib-resistant tumors, as have a variety of agents that target downstream oncogenetic proteins.<sup>34</sup> The recognition of the malignant potential of GIST, combined with the availability of effective treatment even for unresectable disease, has compelled new thinking in the accurate diagnosis of this neoplasm.

### Glomus Tumors

Glomus tumors are mesenchymal tumors that generally occur in the skin; a morphologically similar lesion has long been known in the stomach.<sup>35</sup> They arise from modified cells of the glomus body that regulate arteriolar blood flow. They are typically located in the antrum and are generally small, although they can range up to 5 cm.<sup>36</sup> These usually appear as circumscribed hypoechoic masses in the third or fourth layer and can have a characteristic peripheral halo around them. There may have arterial enhancement on computed tomography (CT) scanning similar to hemangiomas. An immunohistochemical study of 32 cases showed that all examined glomus tumors were negative for desmin, S-100, CD34, and KIT,<sup>37</sup> suggesting a different histogenesis from leiomyomas, neuromas, and GISTs. They will typically stain positive for actin. A larger retrospective study of 1894 resected gastric mesenchymal tumors revealed 11 gastric glomus tumors.<sup>38</sup>

This same study showed that all glomus tumors examined stained positive for  $\alpha$ -smooth muscle actin, laminin, collagen type IV, and vimentin. No C-kit mutations were present. Previous studies have suggested a malignancy risk that is low but not zero. Another study<sup>53</sup> suggested that metastases were found in 38% of glomus tumors (52 cases) and that the possible risk factors for malignancy included deep location, size greater than 2 cm, atypical mitotic figures, moderate-to-high nuclear grade, and greater than 5 mitotic figures per 50 HPFs. Typically, the main goals in diagnosing glomus tumors of the stomach have been to differentiate them from other tumors such as GISTs.

### Neural Tumors

Technically, most tumors that appear to be of neural origin continue to be classified as stromal tumors, although the more recent revolution in GIST understanding brought about by the discovery of CD117 mutations has led to confusing terminology in some cases, including neural tumors. Many experts consider stromal tumors that are positive for S-100 and negative for CD117 to be of neural origin.

Neural tumors may represent glial cell proliferation, sometimes in combination with other neural elements. *Neuroma*, *neurofibroma*, and *schwannoma* are largely interchangeable terms, although some pathologists observe differences among these lesions. When ganglion cells are present, the term *ganglioneuroma* is often applied. They seem to arise from ganglion cells in either the myenteric plexus or submucosal plexus. Schwannomas are slow-growing tumors derived from Schwann cells, which are typically found in the subcutaneous tissue of the distal extremities or head/neck. They are extremely rare in the GI tract, but the stomach is the most common site. Typical histology reveals atypical spindle cells in a microtrabecular pattern, S-100 positivity, negative glial fibrillary acidic protein, and negative c-KIT<sup>61</sup> as well as negative staining for CD34, desmin, and smooth muscle actin. Previous studies have found no malignant variants.<sup>62</sup> Incidence of Schwannomas is predominantly based on case reports, but has been estimated to be 0.2% of all gastric tumors.

### Neuroma and Neurofibroma

Neuroma and neurofibroma are well-circumscribed, nonencapsulated tumors arising from either the submucosa or the muscularis propria layer. Except in the case of von Recklinghausen's neurofibromatosis, they are usually solitary nodules. They consist of bland spindle-shaped cells and are often classified as neuromas (as opposed to GISTs) if neural markers are identified on immunohistochemical stain.

### Gangliocytic Paraganglioma

Gangliocytic paragangliomas are rare tumors that range from 0.5 to 4 cm in size and are found in the periampullary duodenum. They may be present in either the submucosa or the muscularis propria layers and consist of a combination of ganglion cells, columnar or polymorphic epithelioid cells, and spindle cells (staining positive for S-100) with a cord-like arrangement that may be of neural derivation<sup>63</sup>; they usually also contain a component resembling carcinoid tumor or neuroendocrine cells. Immunocytochemically, somatostatin is usually present, and other neuropeptides may also be seen, including chromogranin A. They are always benign but may be locally infiltrative and can present as bleeding from surface ulceration/erosion. Diagnosis is typically focused on differentiating this from neuroendocrine tumors that could have some malignant potential.

### Endothelial and Vascular Tumors

Cavernous hemangiomas are vascular neoplasms that rarely occur in the GI tract and even more rarely in the upper tract. They appear as sessile red or blue nodules and can be difficult to distinguish from vascular ectasias (which are not neoplastic). A malignant counterpart, hemangiosarcoma, is exceedingly rare but has been described in nearly all parts of the GI tract.<sup>64</sup> Lymphatic tumors are also exceedingly rare in the GI tract, primarily being reported in the duodenum. They are described as having a smooth, sessile, or polypoid translucent appearance endoscopically.<sup>65</sup> Histologically, they are mucosal or submucosal and contain hamartomatous rather than true neoplastic elements<sup>66</sup>; they are always benign.

### Lipocytic Tumors: Lipoma and Liposarcoma

Lipomas are usually harmless neoplasms arising from submucosal adipocytes. They are most common in the colon but may appear in any part of the GI tract, particularly the gastric antrum.<sup>67</sup> The typical endoscopic appearance is a pale yellowish, soft submucosal tumor; usually a solitary lesion is seen. The overlying mucosa can sometimes be tented up with a biopsy forceps, and the lesion deforms easily when pushed with the forceps (pillow sign). Histologically, such tumors are encapsulated and consist of typical benign mature lipocytes. When they contain a large number of blood vessels, they are sometimes called angioliomas. It is rarely necessary to evaluate them further or remove them unless they cause bleeding or obstruction. They are normally small, but giant lipomas have been described<sup>68</sup> that can cause obstruction or intussusception.<sup>69</sup> The clinically aggressive malignant form, liposarcoma, is exceedingly rare.<sup>70</sup>

### Granular Cell Tumor

The esophagus is the most common site of granular cell tumors (approximately 75% of granular cell tumors were esophageal in one study), but they may be found throughout the GI tract. They are most often located in the submucosa and often have a polypoid shape. Multiple tumors are common. They are of Schwann cell origin and consist of masses of histiocytes-like cells containing periodic acid-Schiff-positive cytoplasmic granules. A literature review of 117 cases found dysphagia to be the most common symptom in roughly half of patients; three-fourths were smaller than 2 cm.<sup>71</sup> Malignancy appears rare and in the same review four cases were locally invasive, but distant metastases were not noted. In another study,<sup>72</sup> 1% to 2% of cases were reported as malignant. They generally appear as yellowish, plaque-like, round or oval lesions less than 2 cm across.<sup>73</sup> The overlying squamous epithelium of the esophagus may show pseudoepitheliomatous hyperplasia.<sup>74</sup> If this is misinterpreted as metaplastic mucosal transformation, confusion may lead to additional investigations in search of an epithelial neoplasm. Another recent study published in 2015 reviewed 98 granular cell tumors from 95 patients.<sup>74</sup> They found a 2.2:1 male predominance and also noted that gastric and colonic granular cell tumors were larger and their growth pattern was more infiltrative. One colonic tumor in this study had infiltration to pericolonic soft tissue and lymph node metastasis. High expression of S-100 protein, CD56, CD68, and SOX-10 was also seen.

### Inflammatory Fibroid Polyp

Inflammatory fibroid polyps are uncommon tumors that can occur anywhere in the GI tract; the stomach is the most common

site,<sup>70</sup> but they have been described elsewhere.<sup>71</sup> Pathologically, they consist of nonencapsulated myxoid stroma that includes blood vessels, inflammatory cells, and invariably eosinophils. The eosinophilic infiltrate had previously led to the (now discarded) designation of this tumor as localized eosinophilic gastroenteritis. They are often small, but giant tumors have been described that can cause (as usual) bleeding, obstruction, or intussusception.<sup>72</sup> Current theories of their pathogenesis focus on myofibroblasts or fibroblasts,<sup>73</sup> but the cell of origin is unknown. They tend to originate in the muscle layers of the GI tract wall, beginning as an intramural bulge but later assuming a polypoid shape; there may often be a significant extramural (subserosal) extension. There seems to be no malignant potential.

### Fibrous (Fibrovascular) Polyp

Fibrous polyps are esophageal tumors that can grow to an enormous size. They occur predominantly in male patients, usually originate in the upper esophagus, and often assume a polypoid shape.<sup>74</sup> Tumors up to 20 cm have been described<sup>75</sup> and can cause dysphagia, globus, bleeding, and asphyxiation from laryngeal impaction.

Although these tumors may have ulcerated overlying mucosa, the sheer size of the lesion may make it difficult to identify endoscopically.<sup>76</sup> Histologically, a large variety of cytologic elements are seen, including spindle cells, lipocytes, mononuclear inflammatory cells, and vascular connective tissue. However, because some typical characteristics of inflammatory fibroid polyps are lacking and because of differing epidemiology and location, these lesions are classified separately from inflammatory fibroid polyps and should not be confused with them, despite the similar names. They are of uncertain histogenesis but do not seem to possess malignant potential. Nevertheless, because fatal outcomes have been described arising from the mechanical size of these tumors, removal is considered prudent, which can either be via endoscopic or surgical techniques.

### Metastatic Tumors

Intramural metastases to the GI tract are less common than compression or invasion from extramural cancer. In a study of gastric mural metastases, the most common primary sites were lung, breast, and esophagus, but malignant melanoma was the most frequent tumor to metastasize to the stomach. Half appeared endoscopically as SETs, and the rest were ulcerated or fungating; one-third showed multiple lesions.<sup>77</sup>

### Cystic Tumors

Various cystic intramural lesions may manifest as SELs. In an individual patient, it may be unclear until EUS is performed that these tumors are cystic. However, it is worth collectively listing lesions (some of which have already been discussed) that can assume such an appearance. Small lymphatic ectasias are a common endoscopic finding,<sup>78</sup> particularly in the duodenum, and represent cystic structures less than 5 mm in size; they are not neoplasms. Duplication cysts are another non-neoplastic intramural cyst that may be seen as SELs. These are very rarely encountered lesions in the upper GI tract<sup>79,80</sup> and are caused by embryonic epithelial nodules that fail to regress. Brunner's gland hamartomas and heterotopic pancreas have also been described as having a cystic appearance.<sup>81</sup> Among neoplastic cysts, lymphangiomas<sup>82</sup> and hemangiomas<sup>83</sup> (and hemangiosarcomas) assume a cystic appearance. In addition, any malignant neoplasm with central necrosis may appear as a cystic intramural lesion.

## DIFFERENTIAL DIAGNOSIS

As has been shown, SELs may represent the full spectrum of symptoms and pathology from innocent to critical. Various diagnostic tools are available to sort out the possibilities.

### Conventional Endoscopy, Computed Tomography, and Transabdominal Ultrasound

Confronted with a SEL, the alert endoscopist should not permit the presence of mucosa between the endoscopic camera and the mass to preclude preliminary conclusions about the nature of the unseen tumor. Despite the multitude of possibilities already discussed, a short list of half a dozen lesions covers nearly everything likely to be found in all but the largest referral centers. Each has distinctive clinical and endoscopic features (Table 31.4) to provide an adequate preliminary assessment, which can be used to direct further management.

Routine endoscopic pinch biopsies are often performed but rarely yield diagnostic material, even when large size (jumbo) pinch forceps are used.<sup>84</sup> Other efforts to obtain tissue during routine endoscopy have been described, including standard FNA needles,<sup>85</sup> a special guillotine aspiration biopsy needle,<sup>86</sup> and mucosal stripping followed by forceps biopsy<sup>87</sup>; these show variable success but have not yet gained widespread acceptance.

Conventional CT has traditionally been unhelpful in evaluating intramural tumors because of their small size, but new CT methods show promise. Multidetector high-resolution CT scanners can identify most tumors larger than 1 cm, although further characterization may be difficult.<sup>88</sup> Three-dimensional computerized reconstruction techniques are also able to detect intramural tumors reliably and may provide useful images.<sup>89</sup> Ongoing improvements in CT resolution may yet result in clinically important images and allow diagnosis radiologically. CT scanning can reveal large lesions, and National Comprehensive Cancer Network (NCCN) guidelines have recommended using CT for monitoring for recurrent or metastatic disease, as well as to gauge the response to therapy.<sup>90</sup> FDG (fluorodeoxyglucose)-positron emission tomography/CT can also be useful in staging of GISTs and can help diagnose, stage, and monitor.

Conventional transabdominal ultrasound has likewise been unhelpful in this setting, but similar to CT, useful progress is being reported. High-resolution transabdominal ultrasound, using transducer frequencies of 5 MHz or 7.5 MHz, and a

**TABLE 31.4 Endoscopic Appearance of Typical Upper Gastrointestinal Subepithelial Lesions**

Clinical Characteristics	Most Likely Tumor
Lower esophagus: < 2 cm, plaque-like, firm, yellowish, sometimes multiple	Granular cell tumor
Upper esophagus: firm, large, polypoid	Fibrous (fibrovascular) polyp
Stomach: ovoid, firm, any size, single lesion	GIST
Stomach: < 1 cm, firm, dimpled	Heterotopic pancreas
Any organ: translucent, soft	Lymphangioma
Any organ: soft, yellowish, soft, compressible, any size, single lesion	Lipoma

GIST, gastrointestinal stromal tumor.

water-filled stomach, provides remarkable imaging of tumors 10 mm in size and their relationship to the five-layer GI tract wall.<sup>34</sup> Although unsuitable for obese patients or many anatomic tumor locations, this technique could potentially supplement many EUS examinations of such tumors at centers where such equipment is available.

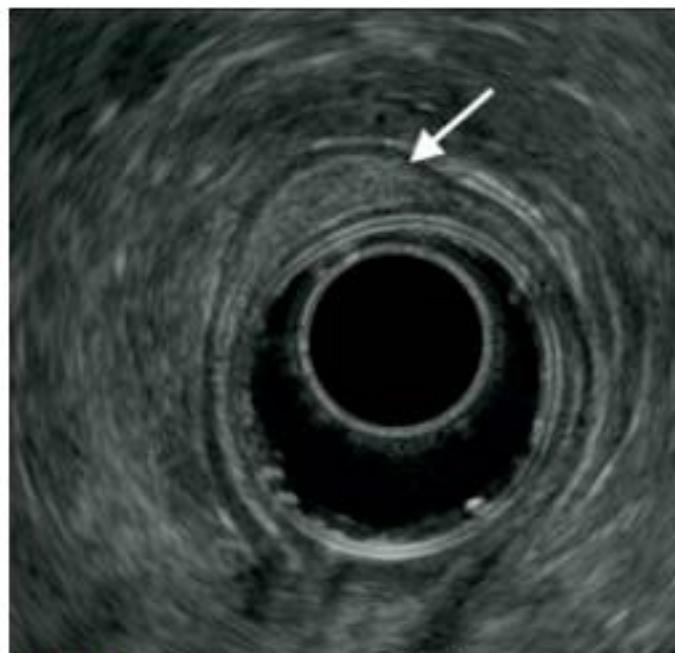

### Endoscopic Ultrasound

High-resolution scanning from an intraluminal position makes EUS ideally suited for evaluation of SELs and for complete characterization of intramural masses that are identified. Extramural impression from normal and abnormal structures can be reliably shown, and intramural masses can be readily characterized. The ability to relate intramural tumors to the five-layer wall structure of the GI tract permits conclusions about the origin of the lesion (and its probable histology) and, where appropriate, the degree of local invasion (T stage). Table 31.5 lists some important features that can be derived from EUS and which are usually helpful in diagnosing the lesion and directing further management.

Several studies have documented the ability of EUS to characterize such lesions accurately. Yasuda et al (1990)<sup>35</sup> reported their experience with 308 patients, including 210 SELs. Characteristic echo features of benign and malignant stromal tumors, varices, cysts, lipomas, lymphoma, and aberrant pancreas were described. Rösch et al (2002)<sup>36</sup> described the appearance of 102 SELs collected in a multicenter German study group. Characterizing the accuracy of EUS for this purpose is difficult and depends on the question being asked. The ability of EUS to measure tumor size accurately has been documented<sup>37</sup> as has reliability in identifying extramural structures. However, distinguishing among different classes of lesions (e.g., cystic, fatty, stromal) or pathologic entities (e.g., stromal tumor, carcinoid) is hampered by the fact that pathologic confirmation is not uniformly available in these research subject groups. Rösch and coworkers<sup>36</sup> reported sensitivity and specificity figures of 64% to 92% and 80% to 100%, for various types of pathologic distinctions being examined.

These and other authors have characterized the typical appearance of several intramural lesions. Lipomas (Fig. 31.4) are brightly echogenic structures with uniform echotexture and

well-demarcated margins (Video 31.2), and they are generally associated with the submucosal layer (layer 3). They are easily deformed by compression from the transducer tip. Because they are virtually always benign, identifying continuity of the muscularis propria layer behind the tumor is helpful in confirming the diagnosis. Varices (Fig. 31.5) are also easy to recognize as anechoic vermiform structures. They are nearly always in groups,

**FIG 31.4** Endoscopic ultrasound (EUS) of gastric lipoma. Note uniform hyperechoic echogenicity and submucosal position with intact muscularis propria layer (arrow).

**FIG 31.5** Endoscopic ultrasound (EUS) of gastric varices. Note anechoic serpiginous structures; that demonstrate blood flow with on real-time Doppler imaging.

**TABLE 31.5 Important Endoscopic Ultrasound Features in Intramural Masses**

Attribute	Attribute Values
Location	Organ (e.g., stomach) and position (e.g., greater curve)
Size	Measured in three dimensions if possible
Background echogenicity	Hypoechoic, hyperechoic, or anechoic
Focal echogenicity	Hypoechoic foci, hyperechoic foci, both, or neither
Shape/margin shape	Round, oval, smooth margins, irregular margins
Margin definition	Well-defined margins, poorly defined margins
Position/origin relative to wall layers	Involves mucosa, submucosa, muscularis propria
Tumor extension or invasion	T stage relative to site organ

and extramural varices can usually be seen. When a variceal structure is seen in isolation, a hemangioma or lymphangioma should be considered because these may have a similar appearance (Video 31.3). Cysts such as duplication cysts also have an anechoic internal structure (Fig. 31.6), although debris may be seen as hyperechoic foci within the cyst structure. Aberrant pancreas (Fig. 31.7) is usually suspected by the endoscopic appearance, and the EUS structure of a hypoechoic lesion associated with the submucosal layer is confirmatory. Internal echogenic spots are often observed with this lesion.

The most frequent finding is of a hypoechoic intramural structure (Figs. 31.8 and 31.9). Various tumors, mostly neoplasms, can have this appearance, including GISTs, carcinoids, granular cell tumors, lymphomas, and metastatic tumors. These lesions all show generally hypoechoic (ground-glass) background echotexture, often containing hyperechoic foci or hypoechoic and anechoic foci (or both hyperechoic and hypoechoic foci).

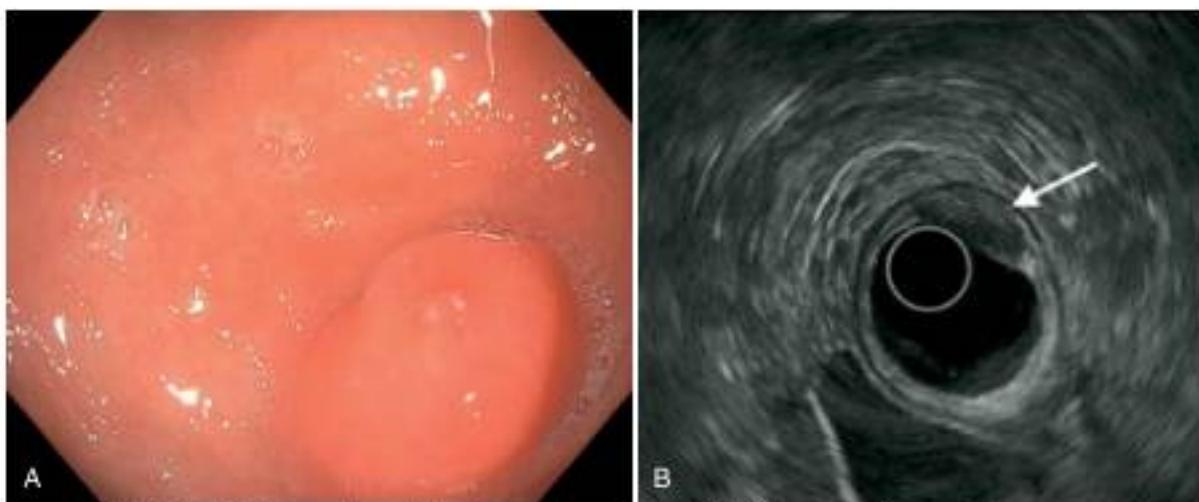

**FIG 31.6** Endoscopic ultrasound (EUS) of a large esophageal duplication cyst.

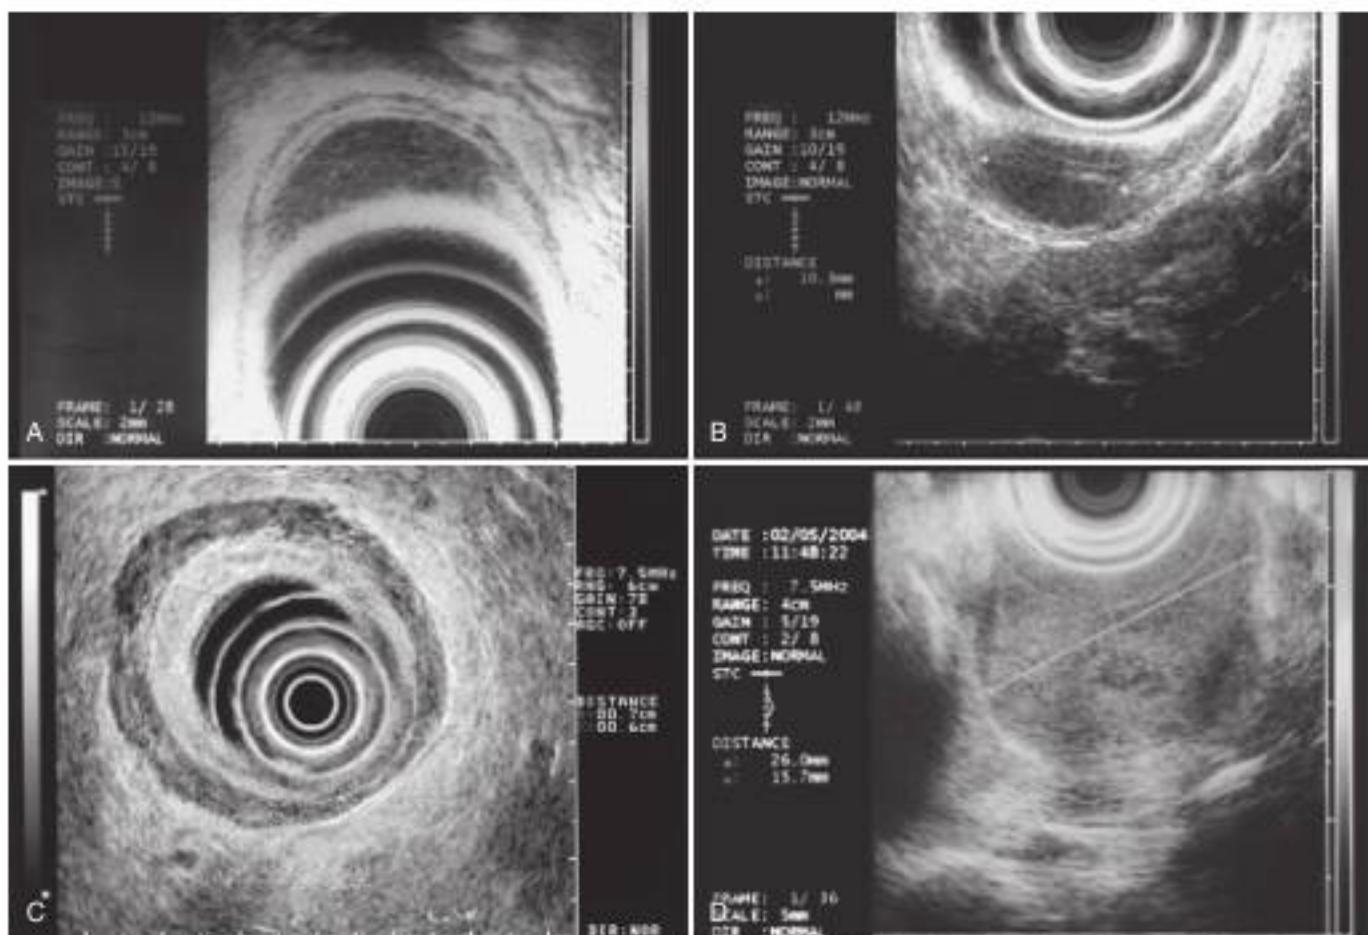

The tumor margins are typically well defined and smooth, and the overall shape is round or oval. Despite the similarities, some EUS clues may help distinguish among these lesions. Granular cell tumors, usually located in the esophagus, are typically seen within the third (submucosal) echo layer and are generally smaller than 2 cm (see Fig. 31.8A). Carcinoid tumors are most common in the mucosal and submucosal layers (see Fig. 31.8B), as are lymphomas (see Fig. 31.8C), whereas metastatic tumors (see Fig. 31.8D) may occupy any layer in any organ.

Stromal tumors (see Fig. 31.9) are typically located in the muscularis propria layer and indistinguishably blend into it. Their most innocent appearance is of rounded, well-circumscribed, smooth tumors of 1 to 2 cm with uniform echogenicity (see Fig. 31.9A). Other EUS features may be seen, however, and significant effort has been expended to determine whether those features can distinguish benign from malignant behavior. Giant size (see Fig. 31.9B) and irregular or knobby margins (see Fig. 31.9C) have been imputed to predict malignancy, as have internal foci that are hyperechoic or hypoechoic (see Fig. 31.9D).

Early proposals that all these features were ominous<sup>68</sup> have been investigated further with mixed results. Tsai et al (2001)<sup>69</sup> showed a correlation of each of these features with malignant histology, but no single factor or combination of factors yielded satisfactory diagnostic accuracy. Chak et al (1997)<sup>70</sup> showed sensitivity figures of 80% to 100% for malignancy in a retrospective videotape study using these factors, but there was only fair-to-moderate intraobserver agreement for the factors themselves, especially for hyperechoic and hypoechoic foci; specificity was 80%. A multicenter prospective study of 198 tumors attempted to validate these criteria further and found that tumor size, surface ulceration, non-oval shape, and irregular or indistinct margins were associated with malignancy, whereas hyperechoic and hypoechoic internal foci were not correlated.<sup>71</sup> The authors also reported that serial surveillance of initially innocent lesions by repeat EUS provided a very low yield of additional malignant neoplasms. Reviewing the literature on the subject collectively, most experts agree that size greater than 3 cm and irregular or indistinct margins are worrisome features.

**FIG 31.7** **A**, Endoscopic and **B**, endoscopic ultrasound (EUS) imaging of an ectopic pancreas (i.e., pancreatic rest) in the gastric antrum. Note the central umbilication with imaging and on EUS; this appears as a heterogeneous structure located in the mucosal layer and submucosal layer (arrow).

**FIG 31.8** Endoscopic ultrasound (EUS) appearance of intraepithelial neoplasms. **A**, Granular cell tumor of the esophagus, seen as a hypoechoic structure located within the submucosal layer (note intact muscularis propria layer). **B**, Carcinoid tumor of the duodenum, a hypoechoic tumor in the submucosa. **C**, Infiltrating lymphoma causing thickening of both the third and the fourth echo layers. **D**, Large metastatic tumor that mostly replaces the entire wall locally.

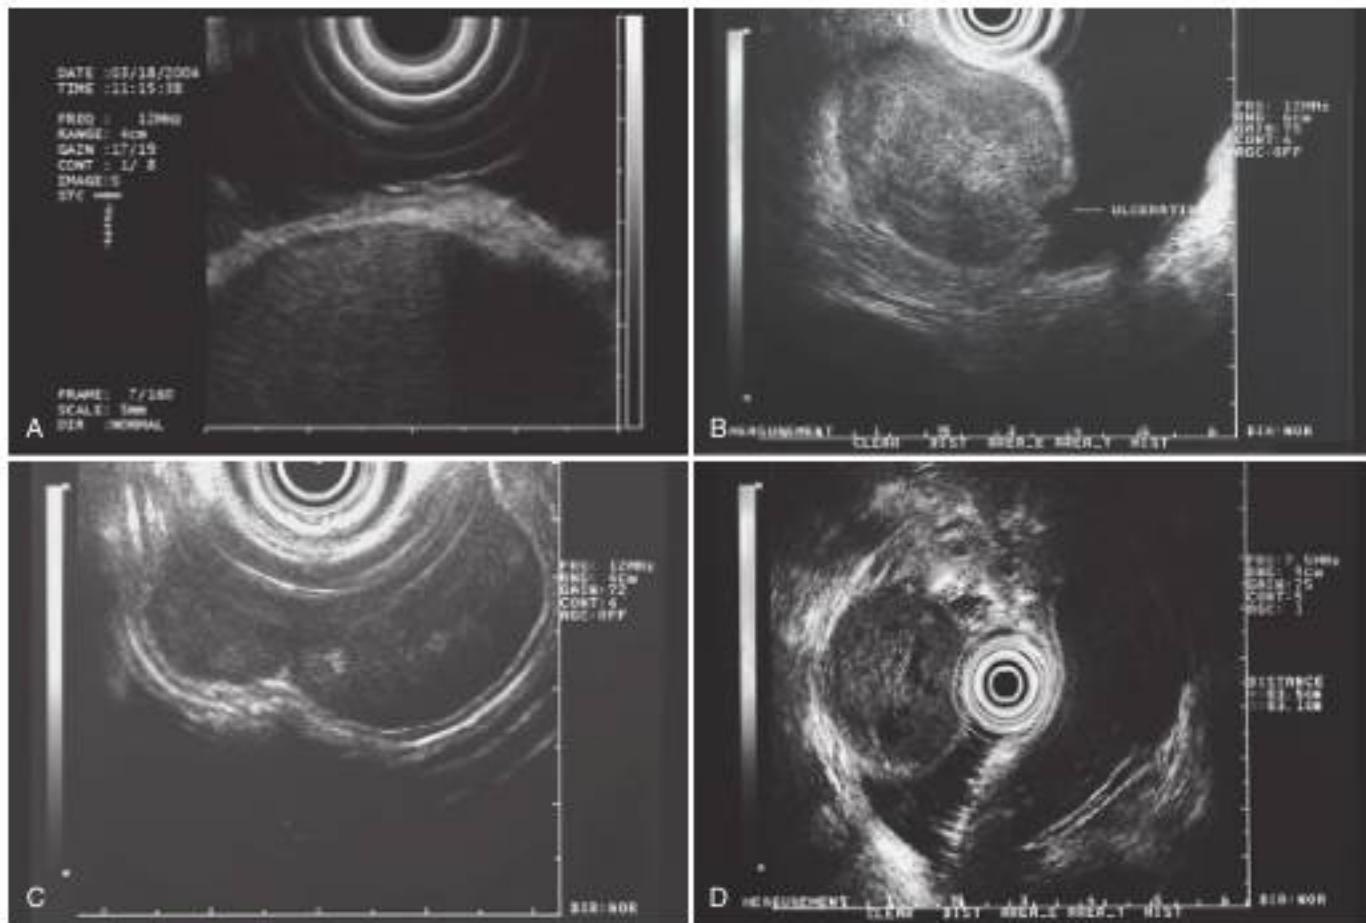

### Fine-Needle Aspiration

Given the ambiguous predictive value of EUS morphology in identifying tissue histology or predicting malignant behavior when considering hypoechoic intramural tumors, efforts to obtain diagnostic tissue assume greater importance. Transcutaneous sampling under CT or ultrasound guidance is possible for some lesions and can yield diagnostic material in up to three-fourths of lesions.<sup>101</sup> Likewise, endoscopic FNA by direct puncture or under EUS guidance has been reported to yield adequate diagnostic material in up to 90%<sup>102</sup> and, when combined with immunohistochemical stains, can distinguish GIST from leiomyoma.<sup>102</sup> However, anecdotal reports suggest that a large number of FNA passes may be needed to secure adequate diagnostic tissue. Such specimens may be adequate to distinguish other neoplasms from GISTS, but they are unable to reliably distinguish benign from malignant GISTS. The fact that the cellularity is insufficient to obtain a mitotic index is a major obstacle, but the addition of immunohistochemical stains in biopsy specimens, including c-KIT and Ki-67, improves the diagnostic accuracy of stromal tumors<sup>103</sup> and can suggest malignant risk. Case series of an “unroofing” technique for tissue acquisition from lesions of the muscularis propria has been described.<sup>104</sup> A 2000 modeling study suggested that biopsy can improve clinical management of

hypoechoic tumors,<sup>105</sup> lending support to the routine performance of needle biopsy of hypoechoic tumors, with immunostaining when appropriate. Recently there have been advances in needle design, with fine-needle biopsy (FNB) needles becoming more commonly used to hopefully improve tissue acquisition and thus improve definitive diagnosis with fewer passes. Previous studies using Trucut biopsy showed improved diagnostic yield (77.8% vs. 38.7%,  $p < 0.001$ ) compared with standard FNA with fewer non-diagnostic specimens.<sup>106</sup> A 2017 article showed improved adequacy of tissue acquisition determined by immunohistochemical staining (64.8% of FNA group and 100% in FNB group,  $p = 0.006$ ) with no significant change in safety, although the sample size for the FNB group was small (15 patients).<sup>107</sup>

### TREATMENT

The initial management of intramural tumors typically involves a decision as to whether the lesion will be resected and how that will be accomplished. New diagnostic and therapeutic options make the decision easier. The use of EUS appearance combined with FNA or FNB specimens and immunostaining provides important information to direct the choice. Similarly, new options for removing the tumors have emerged to supplant or replace the traditional choice of open laparotomy or thoracotomy.

**FIG 31.9** Endoscopic ultrasound (EUS) appearance of gastrointestinal stromal tumors (GISTs).

**A.** Benign-appearing GIST. Note small size, layer four (muscularis propria) location, and smooth and well-defined margins. **B.** Large gastric GIST greater than 3 cm with surface ulceration and hyperechoic internal foci. **C.** GIST with multilobed irregular margins and hyperechoic foci. **D.** Hypoechoic (anechoic) foci within large GIST.

### Indications and Contraindications

Several clear-cut indications have emerged to direct resection of intramural tumors. Most obvious is the presence of symptoms that are caused by the lesion, such as bleeding, obstruction, or intussusception. Beyond this, lesions that are malignant or pose a significant risk of becoming malignant require resection, whereas clearly benign tumors, such as granular cell tumors and lipomas, pose no meaningful malignant risk and may be safely left in situ. Because GISTs comprise most intramural tumors, it remains to identify which hypoechoic lesions are GISTs and how high the malignant risk is for a given GIST. For this reason, EUS combined with FNA or FNB and immunostaining is emerging as the diagnostic procedure of choice. In a 2002 study, 71% of resected hypoechoic tumors were GISTs; 12% of these were malignant GISTs, and another 41% were GISTs of indeterminate malignant potential.<sup>5</sup> Given what seems to be a significant malignant risk among such tumors, criteria to direct resection should have high sensitivity, even at the expense of low specificity. It seems reasonable to perform resection of hypoechoic tumors with size greater than 3 cm, irregular or indistinct margins, ulceration, or non-oval shape. Rapid growth on serial examination, although not a validated criterion, is nevertheless a sufficiently alarming finding also to direct removal of the tumor.

### Preoperative History and Considerations

In selecting patients with GISTs who should be directed to surgical resection, it is important to maintain perspective on the actual level of malignant risk compared with the surgical risk. Despite the suggestion that the proportion of GISTs containing a meaningful malignant risk may approach 50%, it remains widely accepted that most GISTs, if left alone, remain benign and asymptomatic. Among patients with an average surgical risk, it is reasonable to maintain a low threshold for resection of tumors with alarming EUS or histologic features. EUS features that have previously been described as being predictive of malignant risk include irregular extraluminal margin, cystic spaces, and lymph nodes with a malignant pattern.<sup>107</sup> A review of 14 patients found that EUS features including tumor size, irregular extraluminal border, local invasion, and heterogeneity correlated with intermediate- or high-risk malignant potential.<sup>109</sup> However, for patients with advanced age or significant comorbidities that render surgical resection risky, a higher threshold is warranted. In such patients, a more diligent search for immunohistochemical markers of malignancy, such as MIB-1 or Ki-67, would be prudent in directing surgery, as the presence of staining for Ki-67 in particular may point to a more aggressive lesion. Studies have suggested that GISTs larger than 2 cm or with EUS features associated with

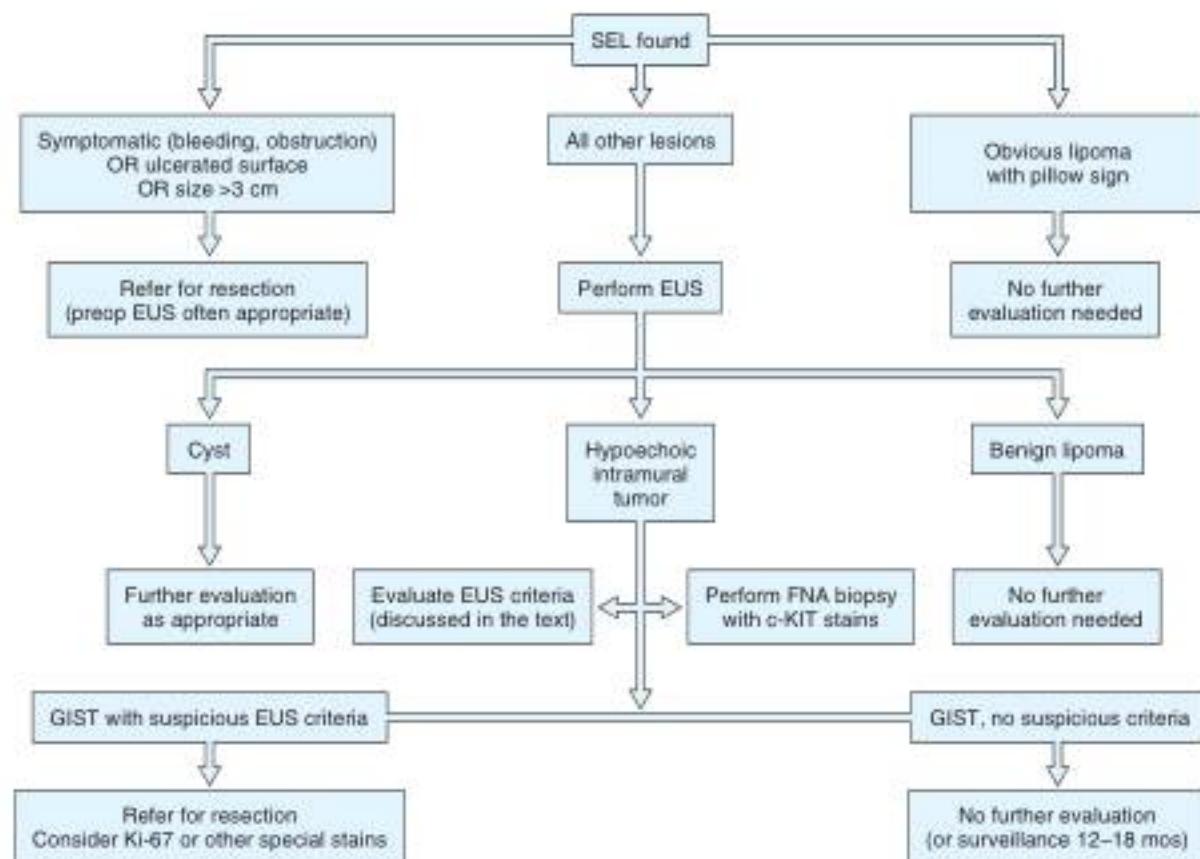

malignant potential such as greater size, lobulated forms, irregular borders, and echogenic foci should be considered for resection. A retrospective review of 75 patients with surgically resected 2- to 5-cm GISTs found that tumor size and EUS features (heterogeneity, hyperechoic foci, calcification, cystic change, hypoechoic foci, lobulation, and ulceration) could not be used to preoperatively predict the risk of malignancy.<sup>118</sup> Previous NCCN guidelines from 2007 recommended resection for all GISTs larger than 2 cm.<sup>92</sup> Recent ASGE guidelines recommended annual EUS surveillance of GISTs smaller than 2 cm if surgical resection is not performed.<sup>9</sup>

### Description of Techniques

Some SETs are appropriate for endoscopic removal. Numerous reports document success in removal of tumors of the mucosa or submucosa, including lipomas, inflammatory fibroid polyps, carcinoids,<sup>110</sup> and granular cell tumors.<sup>111</sup> Stromal cell tumors that do not involve the muscularis propria can also be successfully removed endoscopically.<sup>112</sup> Generally, a snare or injection-assisted snare technique is described, although newer techniques of endoscopic submucosal dissection (ESD) may be required for larger lesions. Bleeding is the most common complication and may require transfusion, endoscopic therapy,<sup>110</sup> or surgery.<sup>113</sup> Despite the reported success of this technique, the number of tumors appropriate for endoscopic removal is limited. The most problematic intramural tumors are tumors that show EUS features of GIST (see Video 31.1); because most of these involve the muscularis propria, they were previously thought to be unsuitable for endoscopic treatment. Recent advances in ESD techniques

have shown that small SELs arising from the muscularis propria can be removed, but techniques that include closure of the muscularis propria (and possibly the serosa) will be required for endoscopic removal of tumors involving that layer.<sup>114,115</sup> There have also been advancements in developing endoscopic full-thickness resection (EFTR) with the aid of over-the-scope clips, and a recent study (article in press) of nine patients undergoing EFTR for subepithelial and epithelial lesions (five lesions in the stomach or duodenum) demonstrated an effective procedure (R0 resection confirmed in all cases) with no reported adverse events.<sup>116</sup>

Advances in minimally invasive surgery have made laparoscopic removal possible for many such tumors. Several small case series describe successful laparoscopic removal of GISTs in various gastric sites,<sup>117,118</sup> including the posterior wall of the stomach.<sup>119</sup> Tumors up to 7 cm in size can be removed.<sup>120</sup> Surgical techniques described include tumor enucleation, wedge resection, and partial gastrectomy. A combined endoscopic and laparoscopic approach may be required when the tumor cannot be readily identified from the serosal surface.<sup>121</sup> In these small series, few complications are reported,<sup>122</sup> but conversion to open resection may be required.<sup>123</sup> A more recent (2002) retrospective study comparing open and laparoscopic resection of GISTs found a shorter mean hospital stay for the latter (3.8 days vs. 6.2 days) but otherwise comparable technical and safety outcomes,<sup>122</sup> and a smaller prospective study found a similar decrease in hospital stay but also noted hospital costs to be 31% less in the laparoscopy group.<sup>125</sup> It has been emphasized that such resections require a high degree of technical skill in laparoscopic surgery.<sup>122</sup> As experience widens,

**FIG 31.10** Provisional treatment algorithm. EUS, endoscopic ultrasonography; FNA, fine-needle aspiration; GIST, gastrointestinal stromal tumor; SEL, subepithelial lesion.

it is likely that laparoscopic resection will become the procedure of choice in the near future for GISTs requiring removal; the convenience and patient acceptance of this method may lead to decreased resistance to resection of GISTs of equivocal malignant potential.

## FUTURE TRENDS

An alert reader perusing the literature on the subject must be struck by the extremely variable quality of the data available. It cannot be otherwise: all the lesions discussed here range from "uncommon" to "never in my lifetime," and even the largest of case series rarely contains more than a few dozen individuals. Developing a management algorithm, or even a reasonable plan for a single patient, based on such scant data is a hazardous undertaking.

Despite the dearth of clinical material, great strides have been made. The advance in the understanding of stromal tumors by the discovery of KIT and its dovetailing with other known oncogenic markers has provided great insight into the histogenesis and growth mechanism of these neoplasms and has pioneered treatment agents, such as imatinib, of novel therapeutic action. Extending this work will provide exciting new insights and therapies, and the "Grail" of GISTs, a reliable test of benign versus malignant behavior, may be right around the corner. Another revolution has been in the development of advanced endoscopic and laparoscopic surgical approaches to these tumors. The ability to remove intramural masses safely and reliably in what may soon become an outpatient procedure enormously increases the management options. However, the pressure on GI endoscopists to establish efficacy and cost efficiency in endoscopic management is also substantially increased. Multiple endoscopic evaluations and serial surveillance of SELs, by either EGD or EUS, makes little sense when the tumor can be easily and conveniently dispensed with altogether.

More recent modeling suggests that the GI endoscopist who cannot establish definitive patient management in an average of 1.7 EUS examinations may not be cost effective.<sup>8</sup> This suggestion leads to what is, from the GI endoscopist's perspective, a critical need. Clinical studies that reliably define SETs that require further investigation and that establish the performance characteristics of EUS and other diagnostic modalities would permit the endoscopist to direct further management of SETs safely and reliably. A provisional treatment algorithm is proposed here (Fig. 31.10), but substantial work remains to be done to validate the steps that would translate this provisional algorithm into a reliable management tool.

## INTRODUCTION

The incidence and mortality of gastric cancer have decreased in recent decades because of the reduction of *Helicobacter pylori* infection, development of endoscopic equipment, and refinement of endoscopic diagnostic and treatment techniques. However, it still remains among the most common malignancies, particularly in Asian countries. Although the prognosis of advanced gastric cancer is poor, the long-term outcome of early gastric cancer is favorable, so it is very important to endoscopically recognize cancers in the early phase. Therefore, endoscopists and gastroenterologists must have sufficient knowledge to provide a better quality of life and prognosis for patients with gastric cancer.

## EPIDEMIOLOGY

Almost 1 million new cases of gastric cancer were estimated to have occurred in 2012 (952,000 cases, 6.8% of the total), making it the fifth most common malignancy in the world after cancers of the lung, breast, colorectum, and prostate.<sup>1</sup> More than 70% of cases occur in developing countries, and half the world total occurs in Eastern Asia. Age-standardized incidence rates are approximately twice as high in men as in women, ranging from 3.3 in Western Africa to 35.4 in Eastern Asia for men, and from 2.6 in Western Africa to 13.8 in Eastern Asia for women (Fig. 32.1).

Gastric cancer is the third leading cause of cancer death in both sexes worldwide (723,000 deaths, 8.8% of the total). The highest estimated mortality rates are in Eastern Asia (24 per

100,000 in men, 9.8 per 100,000 in women), with the lowest in Northern America (2.8 and 1.5, respectively). High mortality rates are also present in both sexes in Central and Eastern Europe, and in Central and South America.

### *Helicobacter pylori*

In 1994, International Agency for Research on Cancer clarified *H. pylori* as a definite carcinogen of gastric cancer, and it is well known that most gastric cancer patients are positive for *H. pylori* infection.<sup>2</sup> *H. pylori* contributes to the development and progression of chronic gastritis that is present in most cases of gastric cancer, and it is associated with an increased cancer risk.<sup>3</sup> In fact, approximately 99% of Japanese gastric cancer patients are positive for *H. pylori*, and there is very low risk of gastric cancer in individuals that are negative for *H. pylori* infection.<sup>4</sup> The rates of incidence of and mortality from gastric cancer are still high in Japan, but there is a tendency to decrease both of these because of the recent reduction of *H. pylori* infection cases and the widespread use of eradication therapy for *H. pylori* (Fig. 32.2).<sup>5</sup> In addition, it has been reported that eradication therapy reduces the risk of gastric cancer as well as occurrence of metachronous gastric cancer after endoscopic resection.<sup>6,7</sup>

## BACKGROUND OF DIAGNOSIS FOR EARLY GASTRIC CANCER

Treatment of gastric cancer remains a major clinical challenge. Survival of patients with early gastric cancer (EGC) is excellent, so early detection is essential for providing a more favorable

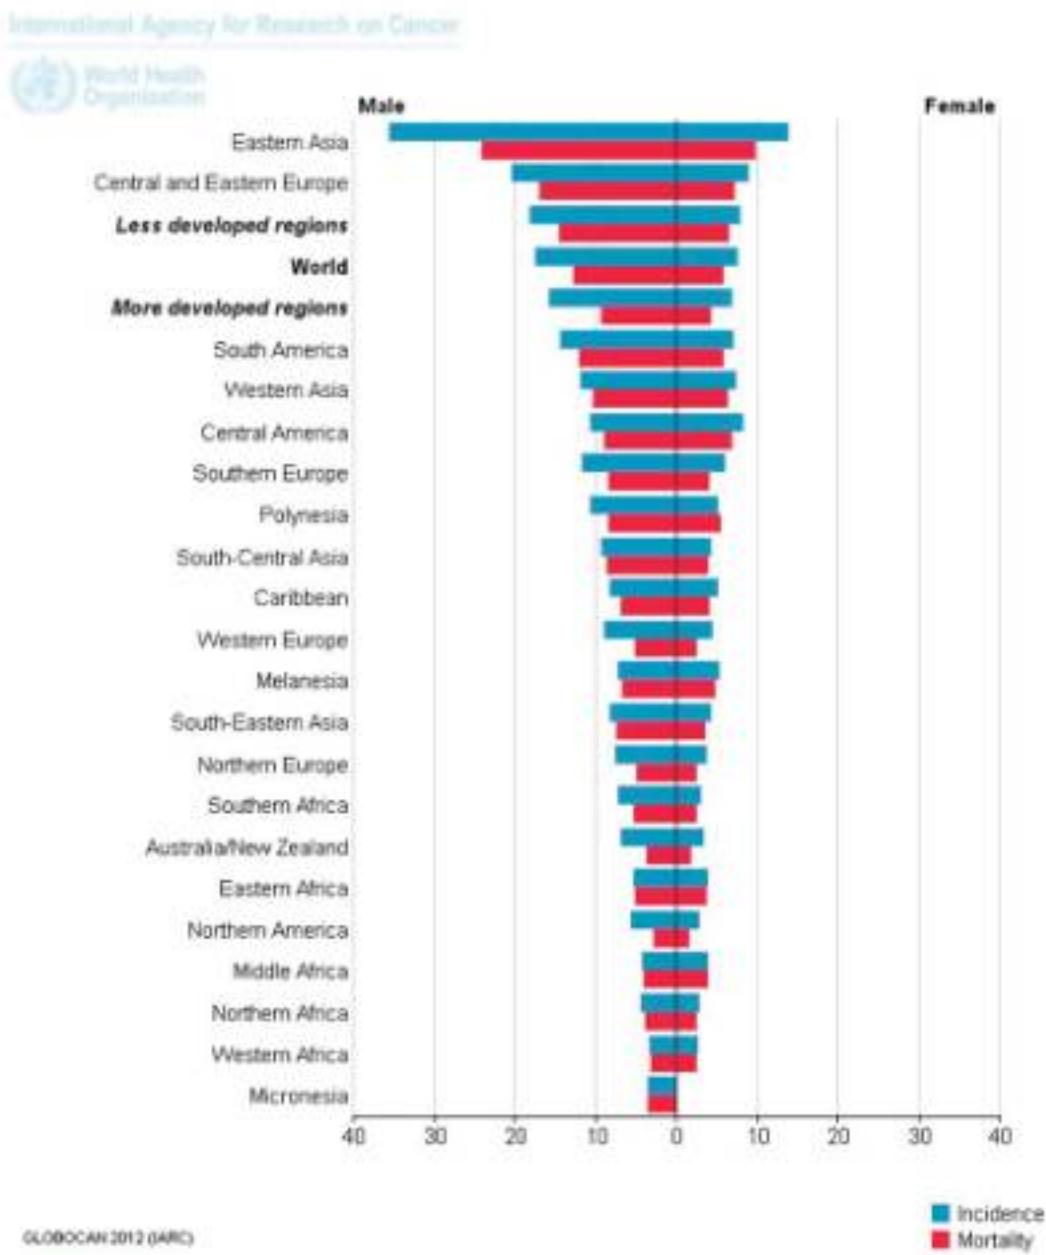

### Abstract

Gastric cancer is the third leading cause of cancer-related death in both sexes worldwide. However, the incidence and mortality of gastric cancer is decreasing due to the recent reduction of *Helicobacter pylori* infection and the widespread use of eradication therapy for *H. pylori*. Although the prognosis of advanced gastric cancer is poor, the long-term outcome of early gastric cancer (EGC) is favorable; therefore it is very important to endoscopically detect EGC and neoplastic lesions. As a first step, it is important to motivate even asymptomatic individuals to undergo an endoscopy screening examination. Next, a fundamental understanding of EGC and proper endoscopic techniques such as adequate preparation, systematic examination and use of chromoendoscopy, optical image-enhanced endoscopy, and targeted biopsy are essential for early detection. Finally, accurate endoscopic estimation of invasion depth for EGC is required for making proper decisions on treatment strategy.

Endoscopic resection is indicated for EGCs with a negligible risk of lymph node metastasis. The technique of endoscopic resection has been improved from endoscopic mucosal resection to endoscopic submucosal dissection (ESD). ESD offers the advantage of achieving en bloc resection. Step-by-step training is important for training in ESD techniques. The technique employed for ESD depends on which type of device (IT-type or needle-type knife) is used during the procedure. ESD is associated with a relatively high risk of complications. Endoscopists must be aware of not only the incidence and risk factors for complications, but must also know how to effectively manage these complications.

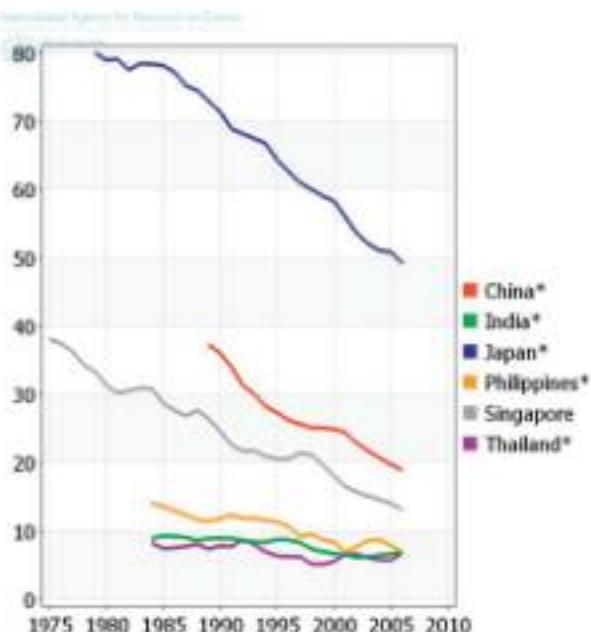

**FIG 32.1** Estimated age-standardized rates (world) per 100,000 gastric cancer patients. (From International Agency for Research on Cancer [IARC]: GLOBOCAN 2012: Estimated cancer incidence, mortality and prevalence worldwide in 2012. Available at [http://globocan.iarc.fr/Pages/fact\\_sheets\\_cancer.aspx](http://globocan.iarc.fr/Pages/fact_sheets_cancer.aspx). Accessed April 19, 2017.)

prognosis.<sup>3–11</sup> The 5-year disease-specific survival rate for surgical cases of intramucosal and submucosal invasive cancer is 99.3% and 96.7%, respectively.<sup>11</sup> It is also important for ensuring a better overall quality of life because endoscopic treatment provides a minimally invasive local resection for EGC with a negligible risk of lymph node metastasis, thereby preserving the patient's stomach.<sup>12–14</sup>

Japan has had a well-organized mass screening program for gastric cancer as an integral part of the public health service since the mid-1960s.<sup>15</sup> The Japanese mass screening program, however, most often utilizes gastrophotofluorography, which has comparatively poor resolution, and thus the sensitivity for EGC

has been quite low (39%) despite the sensitivity for advanced gastric cancer being high (92%).<sup>16</sup> Recent advances in endoscopy have had a substantial impact on improving early diagnosis, and EGC now accounts for approximately 50% of all gastric cancers treated at major medical facilities in Japan.<sup>17</sup> In fact, most cases (78%) of EGC at the National Cancer Center Hospital (NCCCH) in Tokyo were recently detected by endoscopy.<sup>17</sup> A preponderance of those patients with EGC were asymptomatic, and therefore it is extremely important to motivate adults to undergo an endoscopy examination even if they are asymptomatic. It has been reported that the results of a community-based, case-control study by endoscopic screening suggest a 30% reduction in gastric

**FIG 32.2** Trends in the incidence of stomach cancer in selected countries according to age-standardized rate (W) per 100,000 men. \*, Regional data. (From International Agency for Research on Cancer [IARC]: GLOBOCAN 2012: Estimated cancer incidence, mortality and prevalence worldwide in 2012. cancer mortality by endoscopic screening compared with no screening within 36 months before the date of diagnosis of gastric cancer.<sup>19</sup> Consequently, the guidelines for screening of upper gastrointestinal tract malignancies have been revised to allow the usage of endoscopy, which is expected to increase the early detection of gastric cancer.<sup>19</sup>

## DESCRIPTION OF EGC

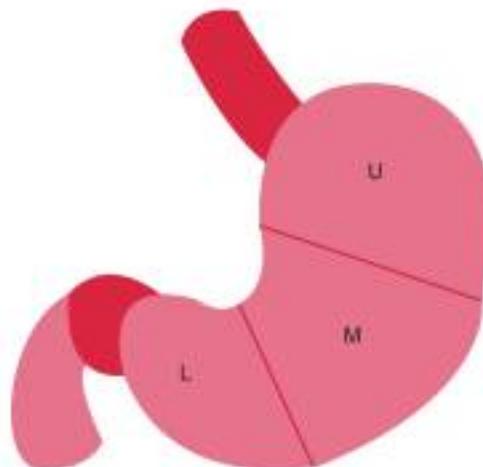

It is vital to describe tumors accurately using defined terminology to facilitate effective communications among endoscopists, surgeons, and pathologists.<sup>20,21</sup>

### Tumor Location

The stomach is anatomically divided into three parts: the upper, middle, and lower thirds, as determined by lines connecting the trisected points on the lesser and greater curvatures (Fig. 32.3). The stomach's cross-sectional circumference is divided into four equal sections: the lesser and greater curvatures and the anterior and posterior walls.<sup>20</sup>

### Macroscopic Type

Macroscopic types are defined as polypoid (0-I) and non-polypoid (0-II and 0-III). The polypoid (0-I) type is subdivided into protruded sessile (0-Ia) and protruded pedunculated (0-Ib) subtypes. The non-polypoid type is subdivided into superficial elevated (0-IIa), flat (0-IIb), superficial depressed (0-IIc), and excavated (0-III) subtypes. A mixed type (e.g., 0-IIa+IIc, 0-IIc+IIa) is diagnosed whenever a lesion consists of at least two distinct macroscopic types and/or subtypes (Fig. 32.4).<sup>20,21</sup>

**FIG 32.3** Three parts of the stomach. U, Upper third; M, middle third; L, lower third.

### Tumor Invasion Depth

EGC is defined as cancer in which tumor invasion depth is confined to the mucosa or submucosa regardless of the presence of regional lymph node metastasis.<sup>20</sup> In Western countries, intramucosal cancer is commonly interpreted as high-grade dysplasia, particularly in relation to differentiated adenocarcinoma.

## ENDOSCOPIC DIAGNOSIS OF EGC

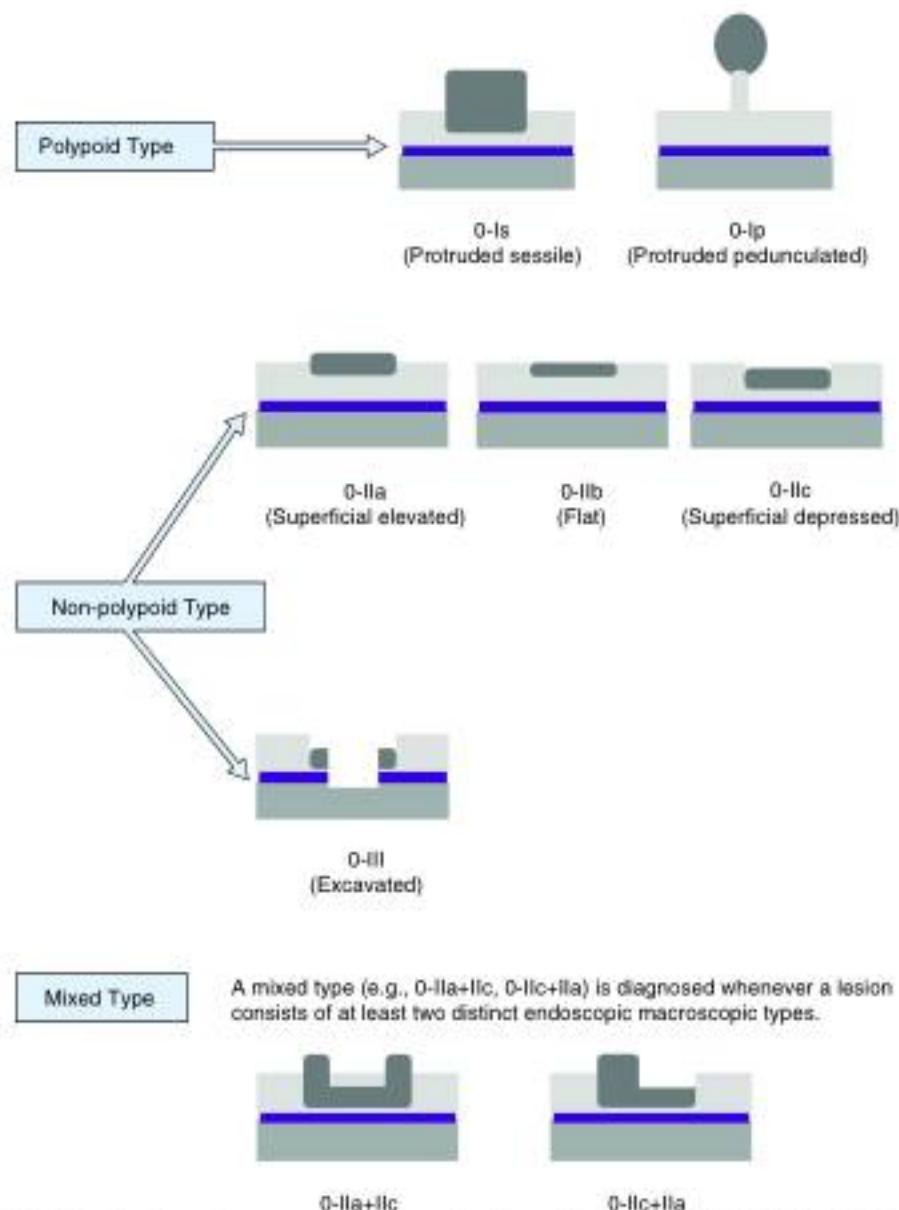

EGC is usually characterized by only a slight change on the surface mucosa, particularly when the tumor invasion depth is intramucosal, so careful observation is paramount for detection.

### Preparation

Optimal mucosal visualization is required for a thorough endoscopic examination. Mucosal flushing techniques have become standard practice in Japan to decrease foam and mucus that can obscure the field of view (Fig. 32.5).<sup>22,23</sup> Anti-foaming agents such as simethicone have been used since the 1950s, and more recent studies have shown that the addition of a mucolytic agent such as proteases further improves mucosal visualization. Flushing the entire stomach is time-consuming, but the early detection of EGC is difficult when large volumes of mucus and foam are present on the surface of the mucosa. Optical digital chromoendoscopy (e.g., narrow-band imaging [NBI, Olympus, Tokyo, Japan], etc.) and magnifying endoscopy are not helpful without this basic step. In addition, patients are routinely instructed to drink 100 mL of water containing 2 mL of simethicone and 20,000 units of Pronase (Sigma-Aldrich, St. Louis, MI) (a commercially available mixture of proteases) 10 minutes prior to endoscopy examination at NCCH to shorten flushing time.

### Systematic Examination

A systematic recording routinely produces 30 to 40 endoscopic images of the whole stomach, including suspected lesions as well as normal-appearing areas (Fig. 32.6; Video 32.1). It is very important to maintain an adequate bend of the endoscope and to use the retroflexion view for the gastric body and cardia, as various angles and views are useful to detect the tiny abnormalities. Moreover, cloudiness of the lens also interferes with a careful observation, so one should use a lens cleaner just before

**FIG 32.4** Classification of macroscopic types of early gastric cancer. (Modified from Endoscopic Classification Review Group: The Paris endoscopic classification of superficial neoplastic lesions: esophagus, stomach, and colon: November 30 to December 1, 2002. *Gastrointest Endosc* 58(6):S3–S43, 2003.)

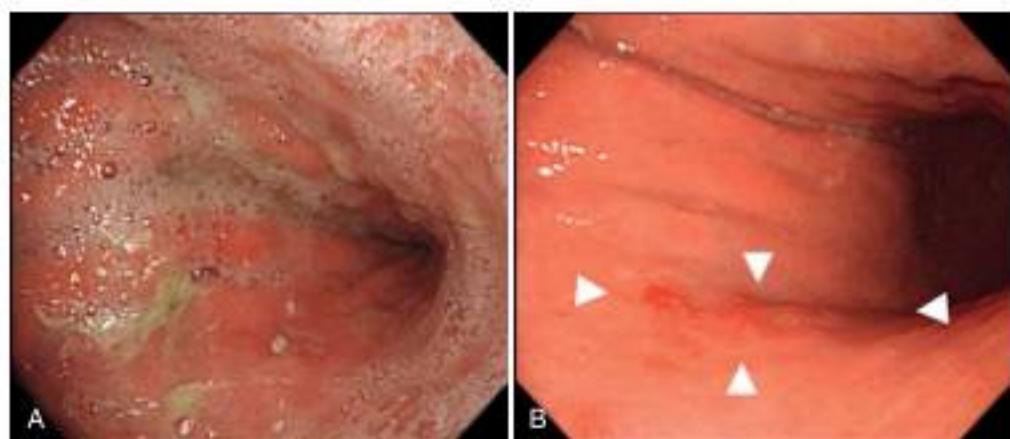

endoscopy. Some EGCs involve only a slight mucosal change that may be misdiagnosed as gastritis or erosions, so it is important to review the database of endoscopic images cautiously. Such endoscopic images are also useful for educational purposes and especially helpful for less experienced endoscopists. During endoscopy, adequate air insufflation is necessary, particularly to detect lesions located between folds (Fig. 32.7).

### Identification and Diagnosis of EGC

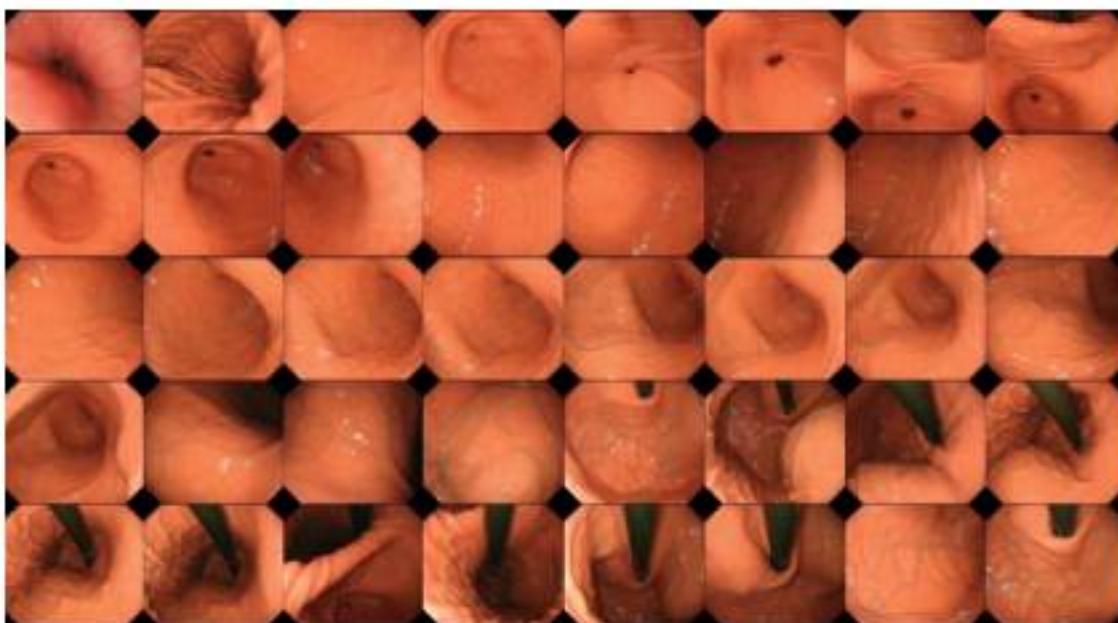

#### Chromoendoscopy

Appropriate use of chromoendoscopy helps to highlight tissue appearance (Figs. 32.8–32.10).<sup>24–27</sup> In the stomach, 0.2% indigo-carmine dye solution is generally used as a topical contrast agent in Japan. It is essential to wash and remove any mucus on the

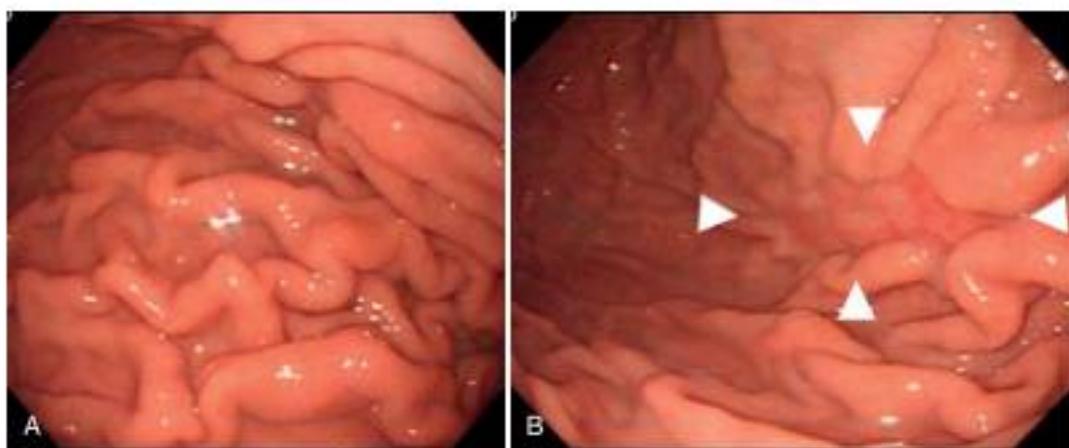

surface of the mucosa before using indigo-carmine dye, as lesions with a clear border cannot be easily visualized in the presence of mucus. Examination time is limited, however, so it is impractical to spray indigo-carmine dye throughout the stomach during every examination. Consequently, an abnormality suggesting possible EGC, such as a subtle red or pale color change or a slightly depressed or elevated change in the mucosa, should first be detected before spraying indigo-carmine dye (see Figs. 32.8–32.10). Other subtle changes that suggest possible EGC include a rough mucosal surface, an altered or missing vascular pattern, and loss of luster. The most important consideration is to identify the abnormal finding using white-light imaging before applying other modalities including chromoendoscopy, NBI, and magnifying endoscopy.

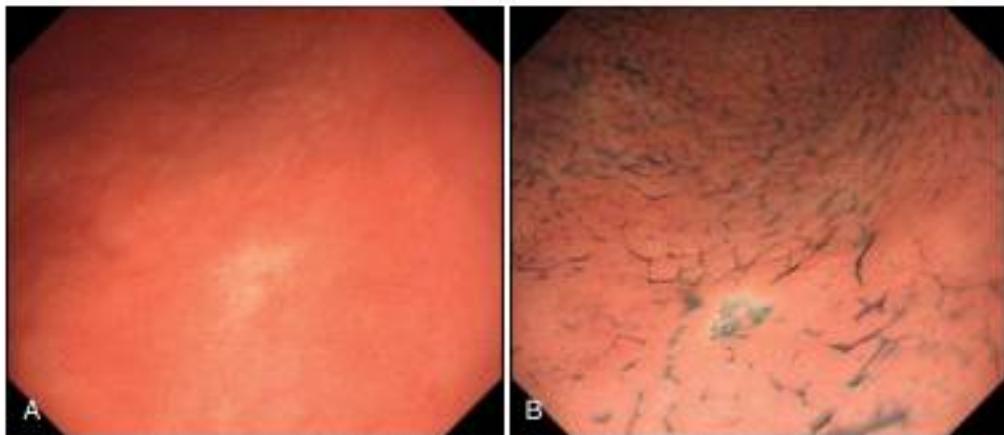

**FIG 32.7** **A**, Gastric mucosa before insufflation. **B**, Adequate insufflation reveals a gastric lesion that was hidden in the folds (arrowheads).

**FIG 32.8 A and B.** Examples of differentiated-type early gastric cancer. Reddish depressed lesions can be seen in the atrophic area.

**FIG 32.9 A and B.** Examples of differentiated-type early gastric cancer. Note elevated lesions with reddish color in the atrophic area.

**FIG 32.10 A and B.** Examples of undifferentiated-type early gastric cancer. Note the pale depression in the near atrophic border.

#### Recent Advanced Techniques and Magnifying Endoscopy

Recent endoscopic imaging technology advances such as NBI, blue laser imaging, and iScan (Pentax Medical, Tokyo, Japan) with magnification have enabled endoscopists to observe microvascular (MV) and microsurface (MS) patterns.<sup>28-29</sup> In 2016, the magnifying endoscopy simple diagnostic algorithm for early

gastric cancer (MESDA-G) was proposed by three Japanese institutions<sup>30</sup> (Fig. 32.11). If we detect a suspicious lesion, identification of a demarcation line (DL) between the lesion and the background mucosa is the first step in distinguishing EGC from a noncancerous lesion.<sup>30</sup> If a DL is absent, the diagnosis of a benign lesion may be made.<sup>31</sup> If a DL is present, the

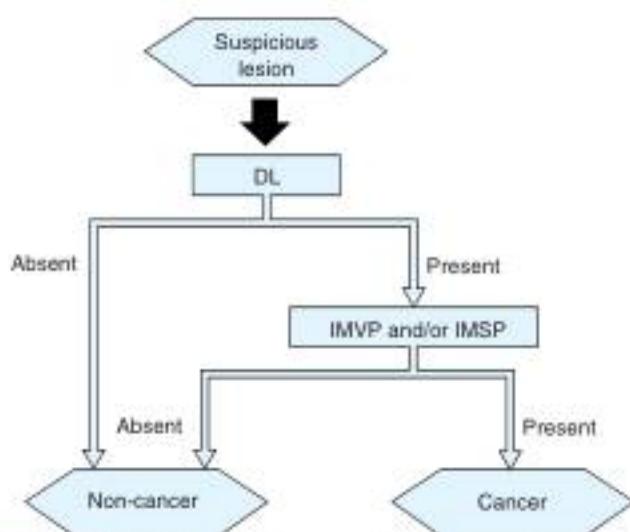

subsequent presence of an irregular MV pattern and an irregular MS pattern should be determined.<sup>30</sup> If irregular MV and/or MS patterns are present within the DL, the diagnosis of EGC can be made (Figs. 32.11 and 32.12).<sup>30</sup>

### Histology

Histological type correlates with macroscopic appearance and tumor location (Table 32.1). Macroscopically, most

undifferentiated-type EGCs consist of depressed lesions that are pale in color, whereas most differentiated-type EGCs are either depressed lesions that are red in color or elevated lesions that are either red or pale in color. The most frequent location also differs between the two histological types. Most differentiated-type EGCs are located in an atrophic area and most undifferentiated-type EGCs are located either in a non-atrophic area or near an atrophic border (see Figs. 32.8–32.10). As a result, the presence and extent of any atrophic change must be considered during endoscopic examination.

It is well known that there are many differences in histopathological diagnosis between Japan and Western countries. Since the Vienna classification was published in 2000, differences have been elucidated in the gastrointestinal tract between the East and West (Table 32.2).<sup>31</sup> It is generally thought to be divided

into three categories, which include adenoma (low-grade dysplasia in the West), intramucosal adenocarcinoma (high-grade dysplasia in the West), and submucosal adenocarcinoma.

### Targeted and Negative Biopsy

After detecting a lesion, we perform a biopsy for histological diagnosis. Random biopsies are not recommended, but a targeted biopsy is important for accurately diagnosing EGC. If we examine an EGC that has already been diagnosed histologically and is thought to be a candidate for endoscopic resection, negative biopsies taken from the surrounding area of the lesion are necessary to confirm the extent of malignant cells and prevent a positive margin for cancerous cells in the resected specimen histologically. A targeted biopsy from the lesion should only be performed if an abnormality that is suspicious of EGC is identified in the screening or surveillance endoscopy. After confirming the biopsy result, re-examination is usually conducted as a pre-treatment check, including negative biopsies taken from the surrounding area, to know a treatment plan with scope movement, angle, and distance between the scope and lesion. Because endoscopic diagnosis is subjective, there is always the possibility of misdiagnosis as well as the risk of performing an unnecessary biopsy.

### ENDOSCOPIC STAGING OF INVASION DEPTH

Accurate endoscopic determination of invasion depth for gastric cancer is crucial for making a proper decision on treatment strategy. Endoscopic resection preserves the stomach, thus improving patient quality of life compared with surgery, and is accepted in many countries as a less invasive method for local resection of EGCs that have a negligible risk of lymph node metastasis.<sup>32,33</sup> Remarkable progress has been made in the development and refinement of endoscopic resection methods over the past 20 years. Techniques including endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD) have become the standard treatment method. At the same time, the indications for endoscopic resection have expanded.<sup>34,35</sup> Consequently, the number of EGC patients undergoing endoscopic resection is increasing, particularly in Asian countries.<sup>36-40</sup> Therefore, accurate differential endoscopic diagnosis between mucosal and submucosal invasion depths of EGC has become even more important for determining the indications for such procedures. Endoscopy

**TABLE 32.3 Correlations Between Macroscopic Type and Invasion Depth of Early Gastric Cancer**

Macroscopic Type	INVASION DEPTH	
	Mucosal	Submucosal
0-I (n = 66)	43% (28)	57% (38)
0-IIa (n = 358)	71% (254)	29% (102)
0-IIb (n = 10)	80% (8)	20% (2)
0-IIc (n = 1488)	63% (931)	37% (557)
0-IIa+IIc (n = 19)	53% (10)	47% (9)
0-IIa+IIc (n = 132)	35% (46)	65% (86)
0-IIc+III (n = 15)	60% (9)	40% (6)
Total (n = 2086)	62% (1286)	38% (800)

is the primary modality for diagnosing gastric cancer, but it can also be helpful in determining invasion depth. Direct visualization is somewhat subjective in nature, however, and there is a need for objective criteria.

A system for classifying macroscopic types of gastric cancer was first introduced in Japan, and correlations have subsequently been reported between macroscopic type and invasion depth of EGC.<sup>24,41</sup> Macroscopic classification is a relatively objective criterion, therefore, and its proper use is helpful in the determination of invasion depth.

### Correlations Between Macroscopic Type and Invasion Depth

Table 32.3 indicates the correlations between macroscopic type and invasion depth for EGC previously reported in the Paris endoscopic classification of superficial neoplastic lesions.<sup>21</sup> In general, non-polypoid type without mixed type (0-IIa, 0-IIb, or 0-IIc) lesions have a lower risk of submucosal invasion compared with polypoid-type (0-I) and 0-IIa+IIc mixed type lesions. A description of the endoscopic estimation of invasion depth for EGC according to each macroscopic type is given in the following section.

#### Cases

##### A. 0-I type

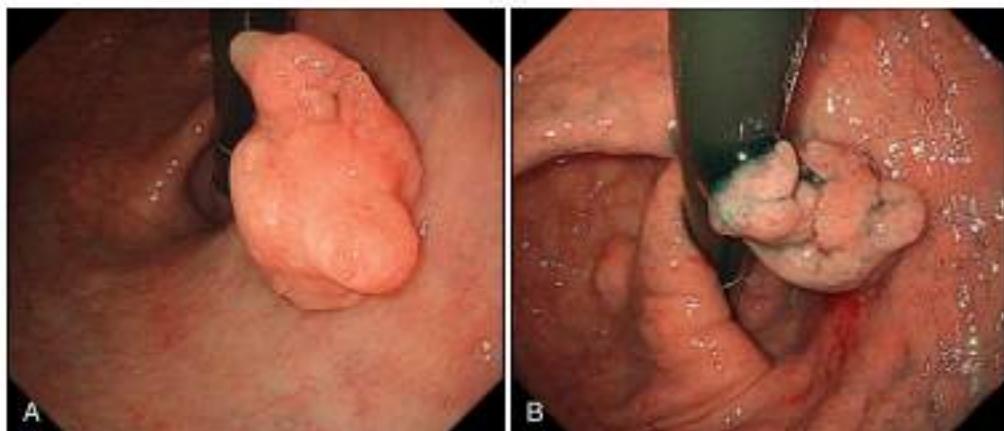

- ✓ Tumor size correlates with depth of invasion, as lesions ≤ 2 cm usually indicate mucosal invasion (Fig. 32.13)
- ✓ Lesions > 3 cm have an even higher probability of submucosal or deeper invasion (Fig. 32.14)
- ✓ Lesions between 2 and 3 cm have an approximately 50% probability of submucosal invasion. Sessile subtype lesions have a somewhat higher risk of submucosal invasion compared with pedunculated subtype lesions

##### B. 0-IIa type

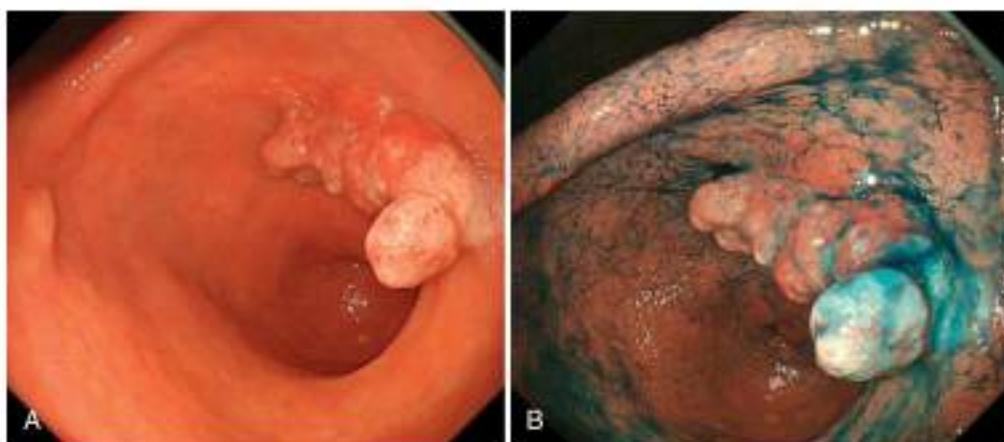

- ✓ Depth of invasion is usually mucosal, as tumor size does not correlate with invasion depth (Fig. 32.15)
- ✓ Lesions with a central depression or uneven surface are associated with submucosal invasion (Fig. 32.16)

##### C. 0-IIc type

- ✓ The following endoscopic findings suggest submucosal invasion:
  - Thickening of the gastric wall at the depression (see Fig. 32.16)

**FIG 32.13 A and B.** Example of a mucosal lesion. Endoscopic images reveal a polypoid-type (0-II) lesion 20 mm in size with subpedunculation on the lesser curvature of the upper gastric body.

**FIG 32.14 A and B.** Example of a lesion with submucosal invasion. Endoscopic images reveal a polypoid-type (0-I) lesion 35 mm in size with a reddish color and erosion on the lesser curvature to posterior wall of the antrum.

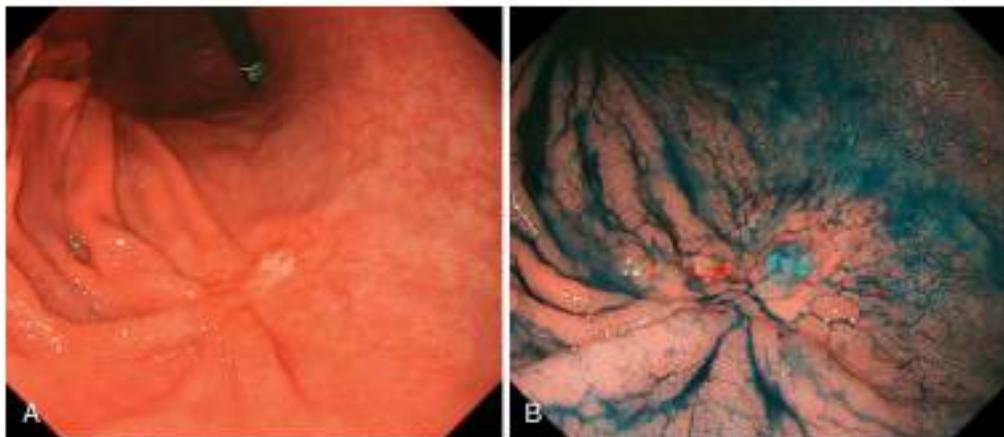

**FIG 32.15 A and B.** Example of a mucosal lesion. Endoscopic images reveal a superficial elevated-type (0-IIa) lesion 20 mm in size on the posterior wall of upper gastric body.

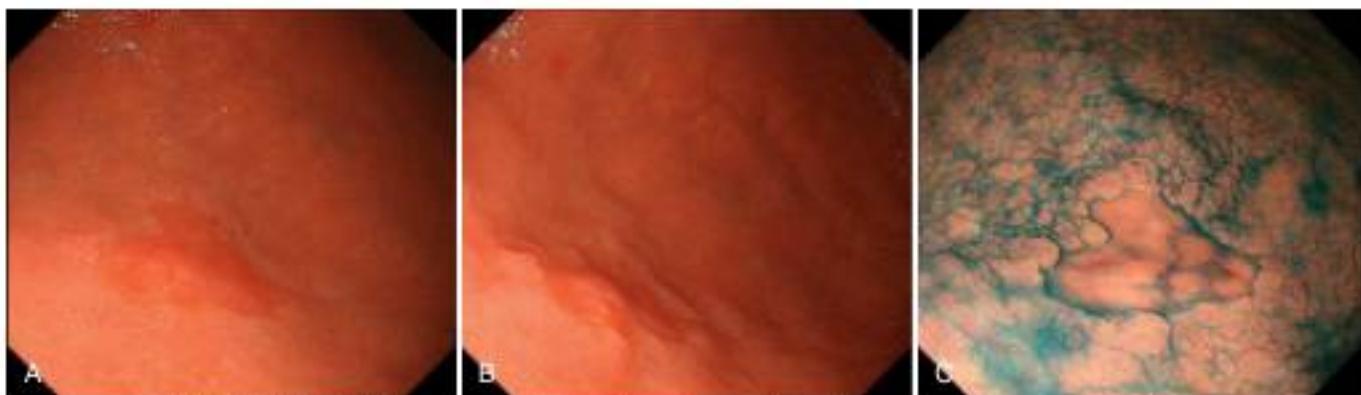

- Rigidity of the gastric wall at the depression (Figs. 32.16 and 32.17)
- Disappearance of mucosal surface pattern in the depression (Fig. 32.18)
- Nodule in the depression (uneven surface) (see Fig. 32.18)
- Intense redness of the depression (Fig. 32.19)
- Depression with submucosal tumor-like surrounding elevation (Fig. 32.20)
- Swelling of converging folds (Fig. 32.21)
- ✓ Lesions without any of the aforementioned findings are probably mucosal lesions (Fig. 32.22)

**FIG 32.16 A and B,** Example of a lesion with submucosal invasion. Endoscopic images reveal superficial elevated-type lesion with a central depression (0-IIa+IIc) 15 mm in size on the greater curvature of the middle gastric body. Lesion indicates thickening of the gastric wall and rigidity.

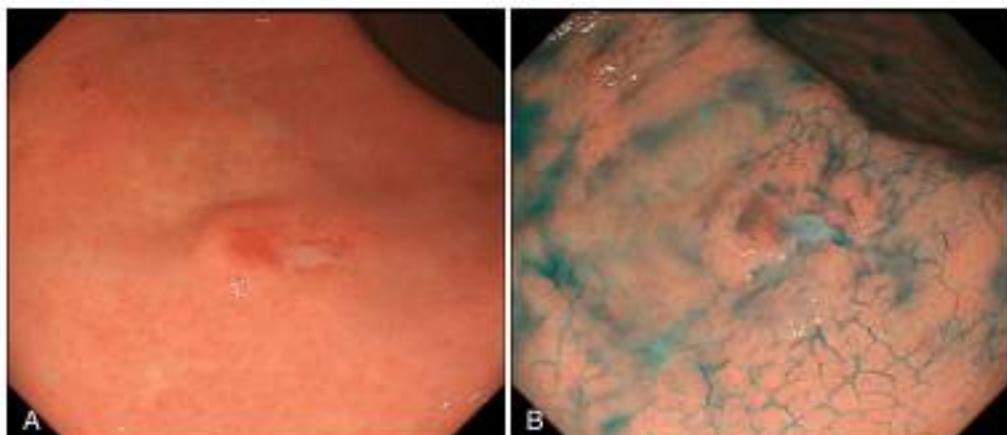

**FIG 32.17 A and B,** Example of a lesion with submucosal invasion. Endoscopic images reveal a superficial depressed type (0-IIc) lesion with an ulcer scar 30 mm in size on the anterior wall of the middle gastric body. There is wall thickening and rigidity in the center of the ulcer scar.

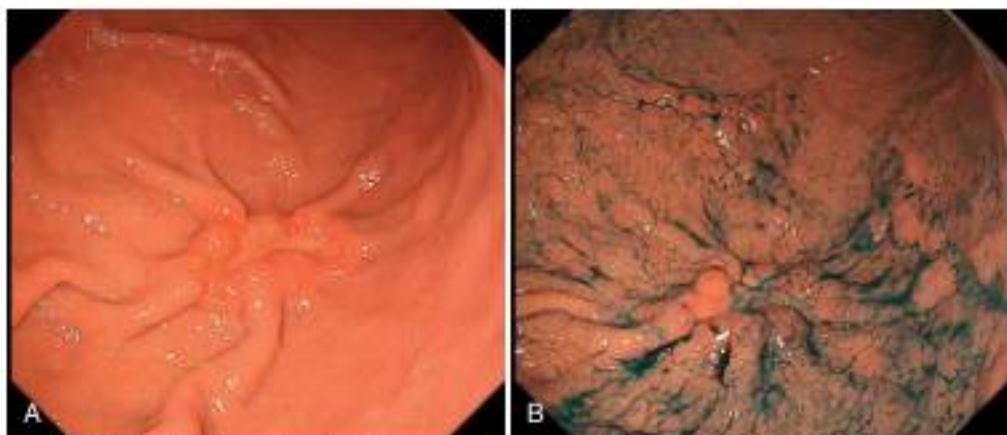

**FIG 32.18 A to C,** Example of a lesion with submucosal invasion. Endoscopic images reveal an intensely reddish superficial depressed type (0-IIc) lesion with nodular finding 15 mm in size on the greater curvature of the lower gastric body. Chromoendoscopy using indigo-carmine dye shows disappearance of the mucosal surface pattern in depression.

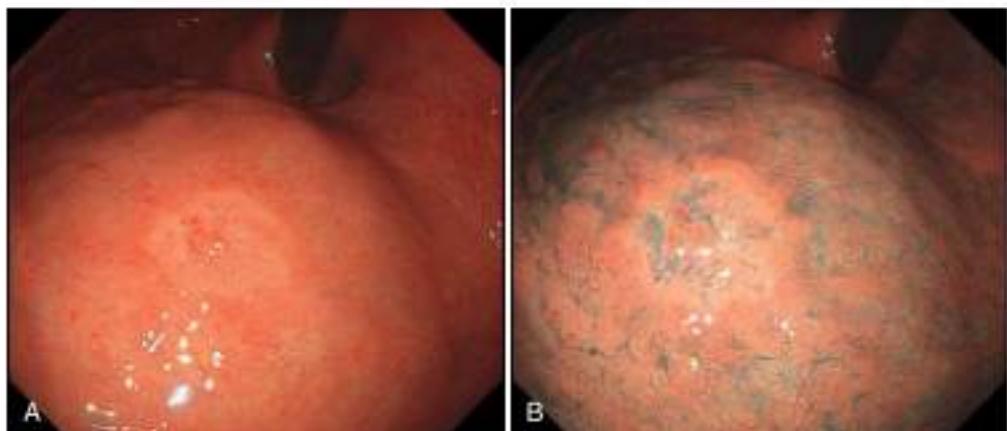

**FIG 32.19 A and B.** Example of a lesion with submucosal invasion. Endoscopic images reveal a remarkably reddish superficial elevated-type lesion with a central depression (0-IIa+IIc) 20 mm in size on the greater curvature of the middle gastric body. The tumor has a strongly reddish depression with surrounding elevation.

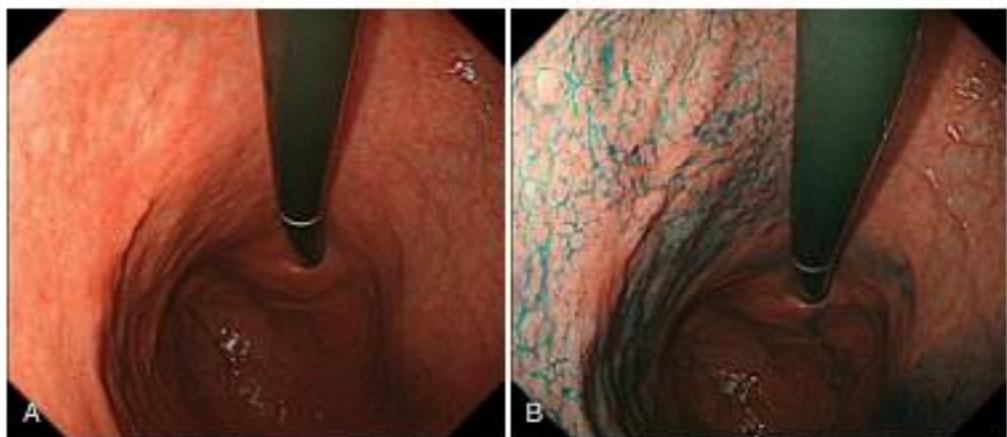

**FIG 32.20 A and B.** Example of a lesion with submucosal invasion. Endoscopic images reveal a superficial depressed type (0-IIc) lesion with surrounding elevation 15 mm in size on the greater curvature of the upper gastric body. The tumor has a submucosal tumor-like surrounding elevation on the oral side.

**FIG 32.21 A and B.** Example of a lesion with submucosal invasion. Endoscopic images reveal a superficial pale depressed type (0-IIc) lesion having fold convergences with swelling 30 mm in size on the greater curvature of the lower gastric body. The tumor has wall thickening and remarkable surrounding elevation with swelling fold convergences.

**FIG 32.22 A and B.** Example of a mucosal lesion. Endoscopic images reveal a superficial depressed type (0-IIc) lesion without any endoscopic findings that suggest submucosal invasion 10 mm in size on the anterior wall of the middle gastric body.

**FIG 32.23 A and B.** Example of a mucosal lesion. Endoscopic images reveal a superficial depressed-type (0-IIc) lesion with ulcer scar 30 mm in size on the posterior wall of the middle gastric body. There was no finding of submucosal invasion.

- ✓ Mucosal lesions are generally smaller than submucosal lesions
- ✓ For lesions with an ulcer, it is difficult to estimate invasion depth because fibrosis results in rigidity. Mucosal lesions with an ulcer do not usually have thickening of the gastric wall, submucosal tumor-like surrounding elevation, or a large nodule in the depression (Fig. 32.23). In contrast, submucosal lesions with an ulcer often have thickening of the gastric wall (see Fig. 32.21)
- D. 0-IIa+IIc type
- ✓ Mixed types, particularly 0-IIa+IIc types, are generally associated with submucosal invasion (Fig. 32.24)
- ✓ When IIc components are clearly seen as less prominent, the lesion is often submucosal (Fig. 32.25)

### Endoscopic Ultrasonography

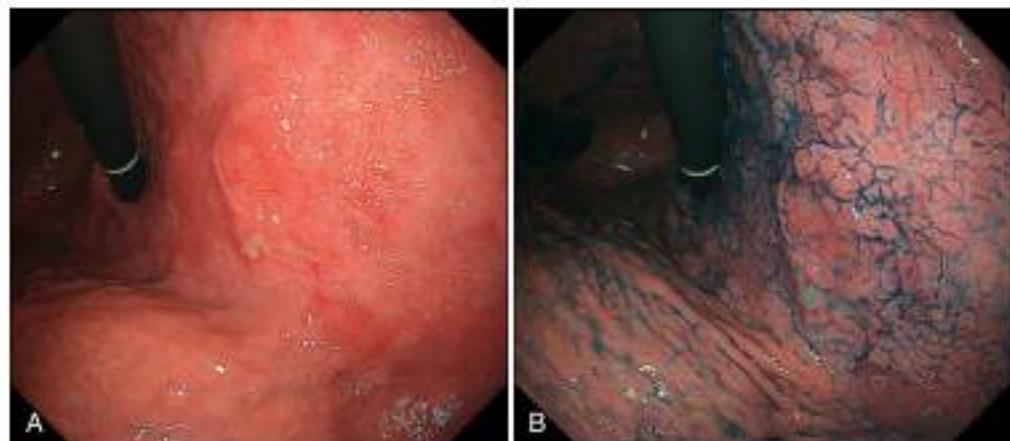

Endoscopic ultrasonography (EUS) is one of the current modalities for determining invasion depth for EGC. In particular, EUS using a miniprobe (20 MHz) has demonstrated a high diagnostic accuracy for distinguishing between mucosal and submucosal lesions.<sup>44–47</sup> EUS accuracy is lower, however, for patients with larger lesions, undifferentiated-type lesions, lesions with concomitant ulceration, protruded lesions (type 0-I), and lesions

located in the upper third of the stomach.<sup>48,49</sup> In daily clinical practice the application of EUS for all EGCs is impractical, and therefore it should be reserved for selected cases in which tumor depth is difficult to determine. Although there are generally fewer EGC cases and more EUS examinations in Western countries, the convex method of EUS is not adequate to obtain a precise image of each layer and accurately diagnose tumor depth of the mucosa or submucosa.

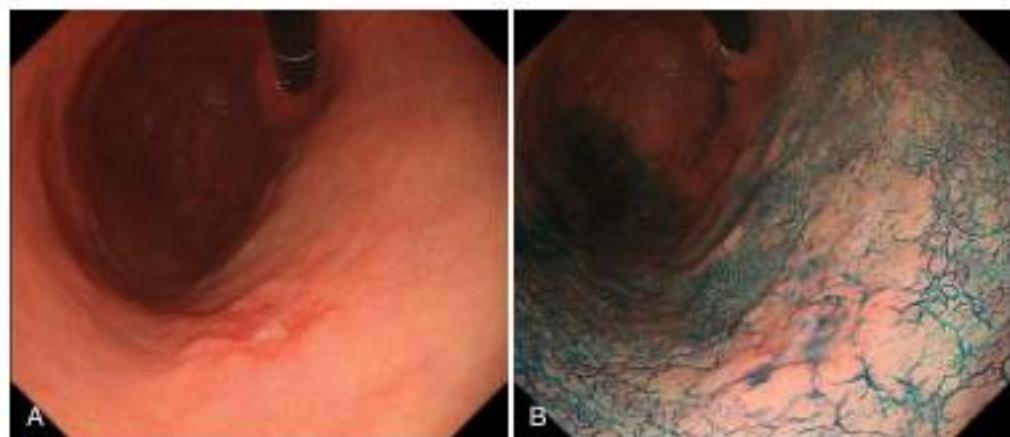

When using a miniprobe, the normal gastric wall is visualized as the mucosa (combination of the first and second hypoechoic layers) and the submucosa (third hyperechoic layer). The muscularis propria is visualized as the fourth hypoechoic layer and the fifth hyperechoic layer is the serosa, including the subserosa (Fig. 32.26).<sup>50</sup> According to Yanai et al (1993), the thin layer between the second and third hyperechoic layers corresponds to the muscularis mucosae.<sup>51</sup> Invasion depth is diagnosed by the presence or absence of normal gastric wall architecture destruction (Figs. 32.27 and 32.28).

### Depth Predictive Score

The Paris classification provides a relatively objective method for endoscopic diagnosis of EGC macroscopic types while simultaneously estimating invasion depth. Endoscopic prediction

**FIG 32.24 A and B.** Example of a lesion with submucosal invasion. Endoscopic images reveal a mixed-type lesion with elevation and slight central depression (0-IIa+IIc) 20 mm in size on the lesser curvature of the middle gastric body. The whole area of the lesion shows elevation and hardness.

**FIG 32.25 A and B.** Example of a lesion with submucosal invasion. Endoscopic images reveal a mixed-type lesion with elevation and clear depression in the greater curvature side (0-IIa+IIc) 30 mm in size on the anterior wall of the middle gastric body. The depression area is seen as well-demarcated reddish change.

of invasion depth, however, is not always accurate, even with the proper use of macroscopic classification when supported by EUS, and thus further improvement in determining the depth of invasion is still necessary.<sup>32,33</sup> As a result, we have suggested a simple invasion depth predictive scoring system to more accurately and objectively estimate the invasion depth of EGC.<sup>34</sup> This concept is particularly expected to contribute to EGC diagnosis in Western countries.

### SUMMARY OF DIAGNOSIS

Although endoscopic diagnosis and staging of EGC remain a clinical challenge, they are imperative for providing a better patient prognosis and quality of life. As a first step, it is important to motivate even asymptomatic individuals to undergo an endoscopy screening examination. Next, a fundamental understanding of EGC and proper endoscopic techniques such as adequate preparation, systematic examination, and the use of chromoendoscopy, optical image-enhanced endoscopy, and targeted biopsy are essential for early detection. Finally, accurate

endoscopic estimation of invasion depth for EGC is required for making proper decisions on treatment strategy.

### BACKGROUND OF ENDOSCOPIC RESECTION FOR EGC

Endoscopic resection is widely accepted as an effective, minimally invasive treatment technique for EGC with a negligible risk of lymph node metastasis.<sup>14,35</sup> Endoscopic resection preserves the functional stomach and therefore improves patient quality of life compared with radical surgery. Remarkable progress has been made in the past decade in the field of endoscopic resection for gastric cancer, both in terms of expansion of the indications and in terms of improvements of the technique. The indications for endoscopic resection of EGC have been expanded based on an estimation of the risk of lymph node metastasis in cases of EGC from a large number of surgical cases.<sup>33,35</sup> The technique of endoscopic resection has been improved from EMR to ESD for R0 resection.<sup>36–43</sup> EMR procedures include inject and cut, strip biopsy, EMR with a cap-fitted endoscope, endoscopic

aspiration mucosectomy, and EMR with a ligating device, etc., whereas ESD is a relatively new endoscopic resection method that facilitates en bloc resection. This section addresses the indications, results, some technical tips, and complications of ESD for EGC.

### Indications of ESD for EGC

Endoscopic resection is generally indicated for EGC patients with a negligible risk of lymph node metastasis because it is a local resection without lymph node dissection. The estimated incidence of lymph node metastasis in mucosal and submucosal gastric cancer is approximately 3% and 20%, respectively.<sup>32,33</sup> If patients who have zero risk of lymph node metastases could be identified with certainty, endoscopic resection would be the ideal treatment method for these patients. However, it is not possible to exclude the presence of lymph node metastasis by computed tomography, positron emission tomography or EUS with certainty because lymph node metastases from EGC are often too small. As a result, the indication for endoscopic

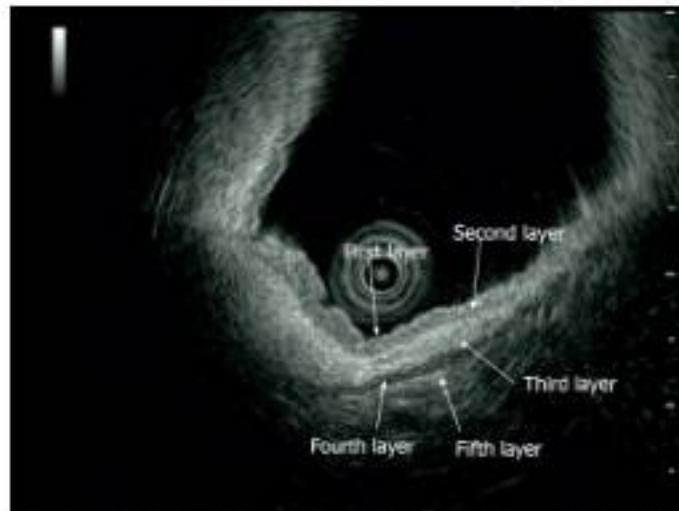

resection in patients with EGC is determined based on evaluation of clinicopathological findings that are considered to be associated with a negligible risk of lymph node metastasis. In the past, the accepted indications for endoscopic resection in cases of EGC were small intramucosal cancers measuring 2 cm or less in diameter, differentiated histopathological type, and absence of ulceration.<sup>34</sup> In an effort to expand the indications, Gotoda et al (2000) and Hirasawa et al (2009) reviewed surgical cases and identified other characteristics of EGC that were associated with a negligible risk of lymph node metastasis, as follows:<sup>32,33</sup>

Differentiated histopathological type, intramucosal cancer, greater than 2 cm in diameter, without ulceration

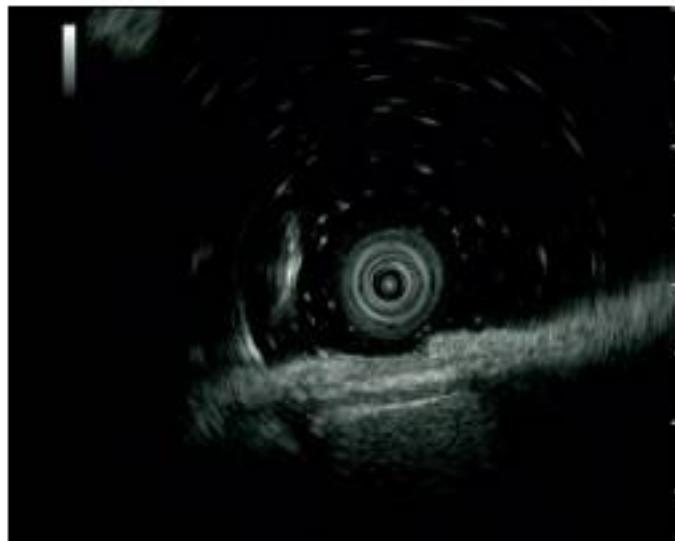

Differentiated histopathological type, intramucosal cancer, 3 cm or less in diameter, with ulceration

Undifferentiated histopathological type, intramucosal cancer, 2 cm or less in diameter, without ulceration

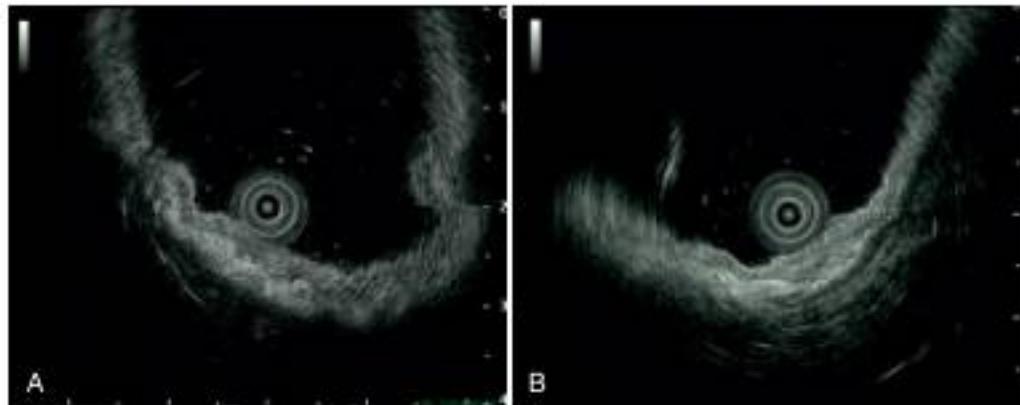

Differentiated histopathological type, 3 cm or less in diameter, minute submucosal (SM1) cancer

**FIG 32.26** Endoscopic ultrasound features of a normal gastric wall. The first and second hypoechoic layers correspond to the mucosa, the third hyperechoic layer represents the submucosa, the fourth hypoechoic layer represents the muscularis propria, and the fifth hyperechoic layer represents the serosa, including the subserosa.

**FIG 32.27** Example of a mucosal lesion. Endoscopic ultrasound reveals irregularity of the first layer and low echoic change of the second layer. The third layer is intact, and the thin, low echoic line that indicates the muscularis mucosae can be seen between the second and third layer.

**FIG 32.28 A and B**, Example of a lesion with submucosal invasion. Endoscopic ultrasound reveals the thickness of the second layer and thin third layer, with the fourth layer intact.

Note that lymphovascular infiltration (ly(-), v(-)) should always be excluded, as this finding correlates with a greatly increased risk of lymph node metastases. The histopathological type is classified as either differentiated type or undifferentiated type. The former includes papillary adenocarcinoma and tubular adenocarcinoma (well and moderately differentiated), and the latter includes poorly differentiated adenocarcinoma, signet ring cell carcinoma, and mucinous adenocarcinoma.

Thus, these expanded indications now include larger lesions and lesions with ulceration. Such lesions were previously resected surgically owing to the difficulty in effectively using EMR techniques for resection in this context. As a result, ESD was developed to achieve en bloc resection even for larger and ulcerative lesions.

### Clinical Results

ESD is associated with a very high rate of en bloc resections, regardless of the tumor location, tumor size, and the presence of ulceration. In our previously published case series, we achieved a very high rate (98%; 1008/1033 patients) of en bloc resections.<sup>42</sup> Similarly, other studies have also reported high rates of en bloc resection, ranging from 92.7% to 98.0%.<sup>41,42,43-45</sup> In addition, a meta-analysis revealed a higher rate of en bloc resection in patients undergoing ESD compared with those undergoing EMR.<sup>46</sup> After ESD, the curability is assessed based on the completeness of removal of the primary tumor and a zero possibility of lymph node metastasis. If the lesion was resected en bloc and is a ly(-), v(-) intramucosal cancer without ulceration, with negative resected margins, 2 cm or less in diameter, and shows differentiated histopathological type, it can be considered a curative resection. If a lesion was resected en bloc with negative margins, is ly(-), v(-), and fulfills one of the following criteria (Fig. 32.29):

1. > 2 cm in diameter, differentiated histopathological type, intramucosal, without ulceration, or
2. ≤ 3 cm in diameter, differentiated histopathological type, intramucosal, with ulceration, or
3. ≤ 2 cm in diameter, undifferentiated histopathological type, intramucosal, without ulceration, or
4. ≤ 3 cm in diameter, differentiated histopathological type, SM1 invasion then the resection can be considered an "extended-indication" curative resection. As for the long-term outcomes of curative resection and extended-indication curative resection, there have been few published reports with median follow-up periods of more than 5 years.<sup>43-46</sup> The Japan Clinical Oncology Group (JCOG) carried out a clinical trial validating

gastric ESD for expanded indications, with the exception of those with undifferentiated type (previously mentioned lesions 1 and 2) (JCOG 0607), and the 5-year overall survival (OS) was 97.0% (95% confidence interval [CI]: 95.0%–98.2%).<sup>70</sup> The lower limit of the 95% CI for the 5-year OS was higher than the threshold 5-year OS (86.1%), and the primary endpoint was met. Therefore, ESD has become a standard treatment for EGC of expanded indications based on these results. Furthermore, a clinical trial assessing the validation of gastric ESD for expanded indications with undifferentiated-type (JCOG 1009/1010) has already finished enrollment and is now in the observation phase.<sup>71</sup> Moreover, a Japanese multicenter, prospective cohort study of endoscopic resection for EGC using a Web registry (J-WEB/EGC) is now ongoing, with approximately 10,000 patients in 41 institutions throughout Japan. It is hoped that the study will clarify long-term outcomes.<sup>72</sup>

### Technical Tips Regarding ESD Performed for EGC

#### Basic Movement Is Dependent on ESD Device

A number of ESD devices have been developed that have just now become available for clinical use. These devices are divided into two major types: the IT-type knife and needle-type knife devices. The IT-type knife devices include the IT knife, IT knife 2, and IT knife nano (KD-611L, KD-611L, KD-612L; Olympus Medical Systems Corp., Tokyo, Japan), and the needle-type knife devices include the needle knife, hook knife, Dual Knife, (KD-1L-1, KD-620LR, KD-650 L; Olympus Medical Systems Corp., Tokyo, Japan), and FlushKnife BT (DK2618JB; Fujifilm Corp., Tokyo, Japan), among others. Importantly, these two different types of devices require completely different approaches. The IT-type knife has an insulated ceramic ball at the tip of the knife, which prevents gastric wall perforation. Therefore, we use the metallic blade between the tip and the sheath while using the IT-type knife for cutting. When using the IT-type knife, it must be pulled from the far side to the near side before the metallic blade can be used for cutting purposes. In contrast, ESD performed with a needle-type knife device requires an entirely different approach. As the tip of the knife is not insulated, the tip can be used for cutting purposes. Basically, the knife tip should be slid from the near side to the far side to avoid perforation. Pulling of a needle-type knife from the far side to the near side, as in the case of the IT-type knife, is associated with a high risk of perforation.

### ESD Strategy

The ESD procedure consists of the following steps:

1. The lesion margin is identified and marked at a distance of approximately 3 to 5 mm outside the margin by argon plasma coagulation or with a needle-type knife
2. The mucosa is lifted by submucosal fluid injection followed by mucosal incision with the ESD knife
3. Submucosal dissection under the lesion is performed with the ESD knife

The set-up of high-frequency electrical surgical units (VIO300D; ERBE Corp., Tübingen, Germany and ESG-100; Olympus Medical Systems Corp., Tokyo, Japan) depends on the endoscopist's preference. The set-up of the gastric ESD used in our endoscopy unit is shown in Table 32.4.

When we use the IT-type knife as the main device for ESD, an initial incision is made at the far point (i.e., as shown on the TV monitor) with the needle-type knife, because a subsequent mucosal incision using the IT-type knife is then performed from

the far side to the near side. When a lesion is located on the antrum, ESD is performed with a straight view, so that the initial incision is made at the distal side of the lesion, which corresponds to the far side on the TV monitor (Video 32.2). In contrast, the procedure is reversed for lesions located on the gastric body: the initial incision is made on the proximal side of the lesion, which corresponds to the far side on the TV monitor, because we use the retroflex view for lesions located on the gastric body. The mucosal incision is started from the point of the initial incision and pulled toward the near side. The IT-type knife should be placed in a tangential position parallel to the mucosa, and not in a vertical position, to provide for adequate depth of the mucosal incision. The final step is the actual submucosal dissection under the lesion. Submucosal dissection using the IT-type knife can also be performed from the near side on the TV monitor because it is easier to dissect lengthwise than widthwise using the IT-type knife. Therefore, we start the submucosal dissection from the distal outside to the proximal inside. We then proceed to make a depression at the near side, after which we dissect widthwise, hooking the IT-type knife on the edge of the depression. It is important to always move parallel to the gastric wall curvature to avoid perforation. Recently, we have reported the near-side approach method to more easily control bleeding and to shorten the procedure time for the lesion located on the gastric body, although the conventional method that is described earlier is the basic strategy (Video 32.3).<sup>73</sup>

In contrast, the procedure is reversed when the needle-type knife is used as the main device for ESD. The incision is started from the near side on the TV monitor, and then the knife tip is slid from the near side to the far side. Submucosal dissection using the needle-type knife is also performed from the near side to the far side (see Video 32.3). Thus, ESD requires a completely different approach, depending on which type of device is being used during the procedure.

### Training for ESD

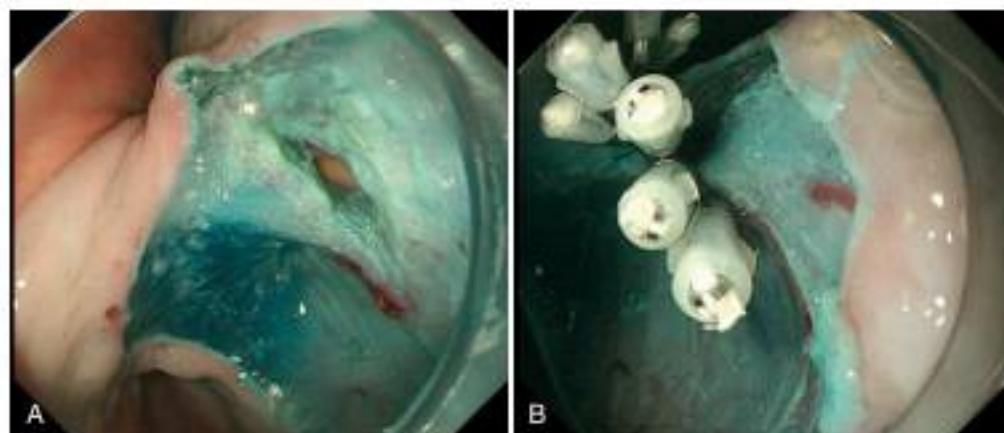

ESD requires a high level of technical expertise, and it may appear technically challenging to less experienced endoscopists. ESD trainees at the NCCH in Tokyo, Japan, follow a step-by-step process for learning ESD techniques. The first step entails acquiring a basic knowledge and understanding of EGC and ESD, in particular, the diagnosis of EGC and the indications for ESD. The next step for trainees is to observe expert endoscopists in action as they perform various ESD procedures. The third step involves trainees acquiring firsthand experience by assisting experts during actual ESDs. This is followed by the fourth step, in which ESD training is further refined using animal models. In the final step, it is important for trainees to start performing ESDs on lesions that are technically less challenging, including those that are located in the lower third of the stomach and those that are small in size and do not show ulcer fibrosis. Trainees perform their first 10 ESDs with direct hands-on support from highly qualified endoscopists, and then start to perform ESDs by themselves with mostly verbal guidance from expert endoscopists. As their ESD technique improves, trainees are gradually assigned to perform ESDs on lesions located in the middle and upper thirds of the stomach, and lesions that are larger in size. Based on our training program, the step-by-step training system at our center has been highly effective, with an en bloc resection rate of 100% and a low complication rate. As a result of this program, the point on the learning curve at which our trainees acquire the basic technical skills for successfully performing ESD in the lower third of the stomach is 30 cases.<sup>74</sup>

### COMPLICATIONS

ESD is associated with a relatively high risk of complications. Bleeding and perforation are the two major complications. Endoscopists must be aware not only of the risk factors and the incidence of complications, but they must also know how to effectively manage complications.

#### Perforation

Most perforations occur during ESD, and the reported risk of perforation is in the range of 1.2% to 5.2% for gastric ESD.<sup>42,43,58,62-65,75-81</sup> In terms of delayed perforation occurring after the completion of gastric ESD, in one study such perforations occurred in six (0.5%) out of 1159 consecutive patients with 1329 EGCs treated by ESD.<sup>61</sup> The possible mechanisms for perforations induced by ESD are unanticipated injury of the muscularis propria caused by insufficient submucosal injection or miscalculation of the gastric wall curvature. To avoid perforation, adequate space in the submucosal layer between the muscularis propria and the mucosal layer is essential. To this end, a sufficient amount of submucosal injection solution must be injected. To lift the mucosa for the longer procedure period required by ESD, the effectiveness of sodium hyaluronate, glycerol, or a combination of sodium hyaluronate and glycerol has been reported previously.<sup>41,42-44</sup> The use of an injection solution mixed with indigo-carmine dye for submucosal injection is effective for better recognition of the gastric wall curve because it allows distinction of the (white) muscularis propria from the (blue) submucosal layer. The use of a transparent attachment to the scope to lift the mucosal layer is also useful for recognizing the gastric wall curve. If perforation is recognized during the procedure, endoscopic clipping can be performed (Fig. 32.30). In

**FIG 32.30 A and B.** Endoscopic submucosal dissection (ESD) was performed for early gastric cancer located in the gastric angle, and perforation occurred during submucosal dissection. En bloc resection was immediately completed and perforation can be seen clearly with extra-wall yellow tissue. The endoscopic closure using endo-clips was successfully conducted and the patient had no symptoms after the ESD procedure.

the past, gastric perforations occurring during endoscopic resections of early cancers invariably necessitated emergency surgery, which effectively meant that all the benefits of endoscopic resection were lost. Endoscopic clips were originally developed for hemostatic purposes. Closure of a perforation using such clips after snare excision of a gastric leiomyoma was first reported by Binmoeller et al in 1993.<sup>55</sup> In 2006, endoscopic closure with endoscopic clips for endoscopic resection-related gastric perforations was reported to be effective in a series of consecutive cases.<sup>56</sup> In that study, 115 (98.3%) of 117 patients with gastric perforations were successfully treated conservatively by the use of endoscopic clips for closure of the perforations.

### Bleeding

Bleeding complications associated with ESD can be subdivided into immediate (intraoperative) bleeding occurring during the procedure and delayed bleeding occurring after the procedure. Immediate bleeding is infrequent with EMR, but is quite common with ESD. Management of immediate bleeding plays a critical role in the successful completion of ESD. Electrocautery is used for hemostasis in cases of immediate bleeding occurring during ESD, because endoscopic clips interfere with the subsequent resection procedure.<sup>51,52</sup> Electrocautery is usually carried out using different devices depending on the degree of bleeding. Minor oozing can be controlled by electrocautery using a cutting device, such as the IT knife 2, Hook knife, Dual knife, and FlushKnife BT. It is also necessary to pre-coagulate to prevent bleeding using a cutting device when vessels are found during the procedure. Electrocautery using hemostatic forceps, such as the Coagrasper (G) (FD-410LR/FD-412LR; Olympus Medical Systems Corp.) or hot biopsy forceps (Radial Jaw; Boston Scientific Japan Corp., Tokyo, Japan), is suitable for arterial bleeding. The critical step for achieving adequate hemostasis is identification of the exact bleeding point using water flushing. Endoscopes equipped with water jet systems (GIF-Q260J; Olympus Medical Systems Corp.; EG-450RD5; Fujifilm Corp., Tokyo, Japan), which are useful for precisely determining the bleeding point, have recently become available for clinical use.

The reported incidence of delayed bleeding after ESD is in the range of 0% to 15.6%.<sup>42,43,50,51,53,56–58,61,62</sup> This wide range is

partly due to differences in the definition of delayed bleeding among reported studies. If delayed bleeding were defined as bleeding requiring endoscopic treatment with any clinical symptoms of bleeding such as hematemesis and melena, the reported incidence is 3% to 8%.<sup>42,43,50,51,53,56–58,61,62</sup> All endoscopic treatment modalities can also be used individually or in combination for achieving hemostasis in cases of delayed bleeding after endoscopic resection. Different modalities are applied according to the time of onset of delayed bleeding. In cases with delayed bleeding occurring in the early phase after ESD, the artificial ulcer floor is still soft with little granulation tissue, so that endoscopic clips or electrocautery using hemostatic forceps can be applied to control the bleeding. In cases of delayed bleeding occurring in the later phase after ESD, the artificial ulcer floor is hard with granulation tissue, so the injection method is preferably used to control bleeding.

### SUMMARY OF ENDOSCOPIC TREATMENT

Endoscopic resection is indicated for EGCs with a negligible risk of lymph node metastasis. ESD offers the advantage of achieving en bloc resection. Step-by-step training is important for training in ESD techniques. The technique employed for ESD depends on which type of device (IT-type knife or needle-type knife) is used during the procedure. ESD is associated with a relatively high risk of complications. Endoscopists must be aware of not only the incidence and risk factors for complications, but they must also know how to effectively manage these complications.

## MALIGNANT GASTRIC OUTLET OBSTRUCTION

Malignant gastric outlet obstruction (MGOO) is a syndrome caused by intestinal obstruction due to tumor growth in the pyloric region or duodenum (Fig. 33.1). Because of this mechanical obstruction, food and fluids accumulate in the stomach, which results in gastric distention. Patients with MGOO usually present with nausea and vomiting (85%), regurgitation (70%), abdominal pain (65%), and complaints of early satiety.<sup>1,2</sup> Western studies mainly report pancreatic cancer (51%–73%) as the underlying disease,<sup>1,2,3</sup> whereas gastric cancer (31%–69%) is the main cause of MGOO in Asian studies.<sup>2–11</sup> Other causes for MGOO are bile duct cancer, metastatic disease, duodenal cancer, gallbladder cancer, ampullary cancer, and lymphoma.<sup>1,2,11</sup> MGOO can be a clinical diagnosis when a patient with a known advanced gastroduodenal malignancy develops obstructive symptoms due to disease progression. However, at first presentation and when an intervention is considered, adequate imaging (i.e., contrast-enhanced computed tomography [CT] scan) is required to confirm tumor growth in the pyloric-duodenal region, to examine the location, extent, and resectability of the tumor, to look for signs of biliary obstruction, and to exclude a second intestinal obstruction distal to the duodenum. One should also be aware of benign causes of gastric outlet obstruction, such as motility disorders, pancreatic pseudocysts, ulcer-related complications, caustic ingestion, gallstone obstruction (Bouveret's syndrome), Crohn's disease, tuberculosis, or bezoars.<sup>12–14</sup> Endoscopy can therefore be of additional value in the diagnostic process to examine and sample the gastroduodenal area. Cytological or histological confirmation of malignancy is desirable before a definite surgical or endoscopic intervention is offered to the patient.

## PALLIATIVE TREATMENT: SURGICAL BYPASS VERSUS ENDOSCOPIC STENT PLACEMENT

Patients with MGOO usually have advanced, unresectable disease with a poor prognosis. A mean survival of approximately 100

days (3.3 months) has been reported in a meta-analysis.<sup>15</sup> Palliative measures should therefore aim for comfort and resolution of obstructive symptoms. Traditionally, patients underwent surgical gastrojejunostomy to bypass the malignant obstruction. Nowadays, endoscopic self-expandable metal stent (SEMS) placement is also a valid treatment option for the palliation of MGOO. Three randomized controlled trials (RCTs) have been published that compared surgical gastrojejunostomy with SEMS placement (Table 33.1).<sup>16–18</sup> The largest and most recently published trial showed that a surgical gastrojejunostomy (open procedure in 16/18 patients) was superior to endoscopic SEMS placement with regard to long-term relief of symptoms, recurrent obstructive symptoms, and reinterventions.<sup>16</sup> There were no differences in health-related quality of life scores and overall survival.<sup>16</sup> The other two trials did not report significant differences in long-term outcomes between surgical gastrojejunostomy and SEMS placement, but the RCTs all showed clear benefits of SEMS placement in the short term: patients had a more rapid recovery of oral food intake and a shorter hospital stay.<sup>16–18</sup> SEMS placement also resulted in lower medical costs per patient.<sup>16</sup> Based on these results, the authors of the largest trial recommended SEMS placement only in patients who have a life expectancy of less than 2 months.<sup>16</sup> The better long-term outcomes of surgical gastrojejunostomy in comparison with SEMSs have also been confirmed by more recently published studies, including a meta-analysis.<sup>19,20</sup> So, because of the better short-term results (faster recovery of oral intake and shorter hospitalization), endoscopic SEMS placement is generally offered as a palliative intervention to patients in poor clinical condition who are unfit for surgery and have a short life expectancy of weeks to a few months.

## THE ENDOSCOPIC PROCEDURE

### Preparation and Materials

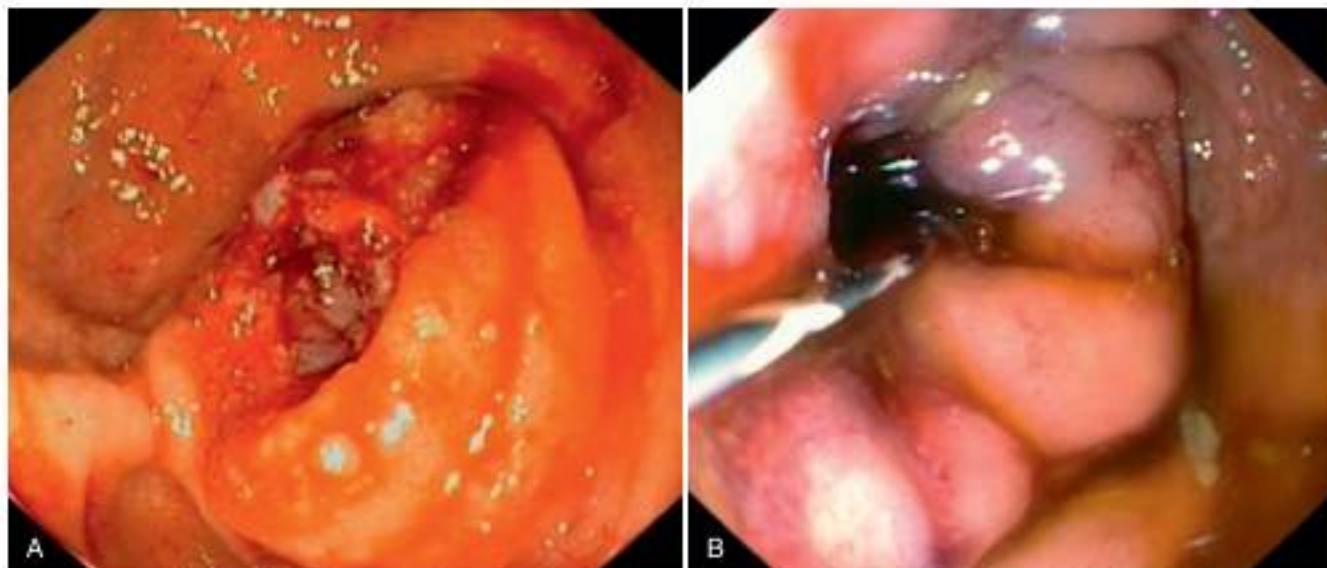

Endoscopic SEMS placement is generally performed as an outpatient procedure. Endoscopic gastroduodenal SEMS placement carries a high risk of aspiration because of the food and fluid accumulation in the stomach. Therefore, it is recommended

**Abstract**

Malignant gastric outlet obstruction (MGOO) is a syndrome caused by intestinal obstruction due to peripyloric or duodenal tumor growth. Patients with MGOO usually have unresectable disease with a poor prognosis. Treatment should therefore focus on comfort and resolution of obstructive symptoms. Endoscopic self-expandable metal stent (SEMS) placement is a minimally invasive alternative to the traditional surgical gastrojejunostomy for the palliation of MGOO. Gastroduodenal SEMS placement is a feasible procedure with technical success rates of 90%–100%. Improvement in oral food intake or relief of obstructive symptoms is achieved in 63%–99% of patients. Clinical failure of SEMSs mainly depends on the patient's performance status and the presence and extent of peritoneal carcinomatosis. SEMSs remain patent for a median period of 73–91 days. Stent dysfunction occurs in approximately 20% of patients, and mainly involves reobstruction by tumor growth (13%) or stent migration (4%). The latest randomized controlled trials (RCTs) have shown lower reobstruction rates and superior stent patency for partially covered SEMSs in comparison with uncovered SEMSs. Patients treated with SEMSs have better short-term outcomes compared with surgical gastrojejunostomy, including a faster recovery of food intake and shorter hospitalization. Gastrojejunostomy is superior in the long term, with lower recurrent obstruction and reintervention rates. Endoscopic SEMS placement is a valid alternative to surgical gastrojejunostomy for the palliation of MGOO. Because of the better short-term outcomes, SEMS placement is generally recommended to patients in poor clinical condition who have a short life expectancy of weeks to months.

that the patient fast from solids for at least 12 hours before the procedure, instead of the regular 6–8 hours before upper gastrointestinal endoscopy. Depending on the patient's symptoms, gastric tube placement is indicated to empty the stomach before the endoscopic procedure. Intubation can be considered even when the aspiration risk is anticipated to be high. SEMS placement can be performed under conscious sedation (e.g., with midazolam or fentanyl) or deep sedation with propofol. In most cases of symptomatic MGOO, the tumor cannot be traversed with the endoscope. Therefore, fluoroscopic guidance is recommended

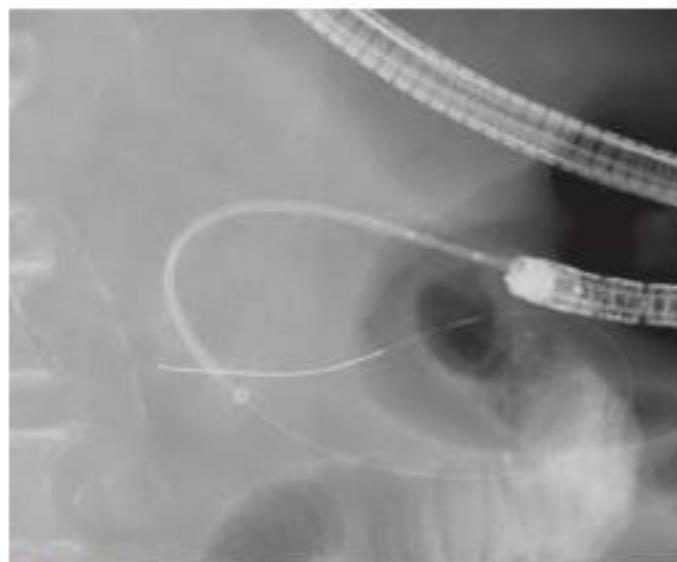

because it enables the endoscopist (1) to check whether cannulation through the tumor has been successful (intraluminally into the distal duodenum), (2) to get an impression of the length of the obstruction, and (3) to optimize the positioning and deployment of the SEMS using the radiopaque markers on the stent delivery system and using the visibility of the SEMS itself. A mono- or multilumen endoscopic retrograde cholangiopancreatography (ERCP) guiding catheter is used to advance a guidewire across the obstructing tumor into the distal duodenum and jejunum.

### Cannulation

The technical success rate of gastroduodenal SEMS placement is high (90%–100%), but when technical failure occurs, it is mainly caused by the inability to pass the guidewire across the tumor.<sup>21</sup> This critical maneuver also carries a small (< 1%) risk for guidewire perforation.<sup>21</sup> Successful cannulation therefore starts with a good endoscopic position. Before gently advancing the guidewire, the endoscopist should carefully inspect the obstruction to get an impression of the lumen and the direction in which the guidewire should be advanced. Once the guidewire is past the obstruction, a catheter (either mono- or multilumen) can be advanced over the guidewire. The advantage of a multilumen guiding catheter is that a contrast agent can be injected through the open lumen without the need to first remove the guidewire. On the other hand, a monolumen catheter costs less, and should therefore be used in the case of easy access through the stricture with the guidewire. To choose the optimal stent size, the endoscopist estimates the length of the tumor using contrast injection to delineate the distal margins of the tumor or by pulling back an inflated balloon into the distal end of the stricture under fluoroscopic guidance. With the latter technique, an extraction balloon should be used to prevent any perforation that may occur due to accidentally inflating a dilation balloon inside the stricture. Interpretation of CT imaging before starting the endoscopic procedure can also help estimate the size of the tumor.

### SEMS Deployment

The next step is to exchange the guiding catheter for the stent delivery system (Fig. 33.2). Nowadays, stent delivery systems are usually designed for through-the-scope (TTS) deployment, whereas some SEMS designs are delivered over a guidewire using fluoroscopy, also referred to as over-the-wire (OTW). TTS delivery systems require a working channel of at least 3.7 mm, necessitating the use of a therapeutic endoscope. With OTW delivery systems, the endoscopist can also reintroduce the

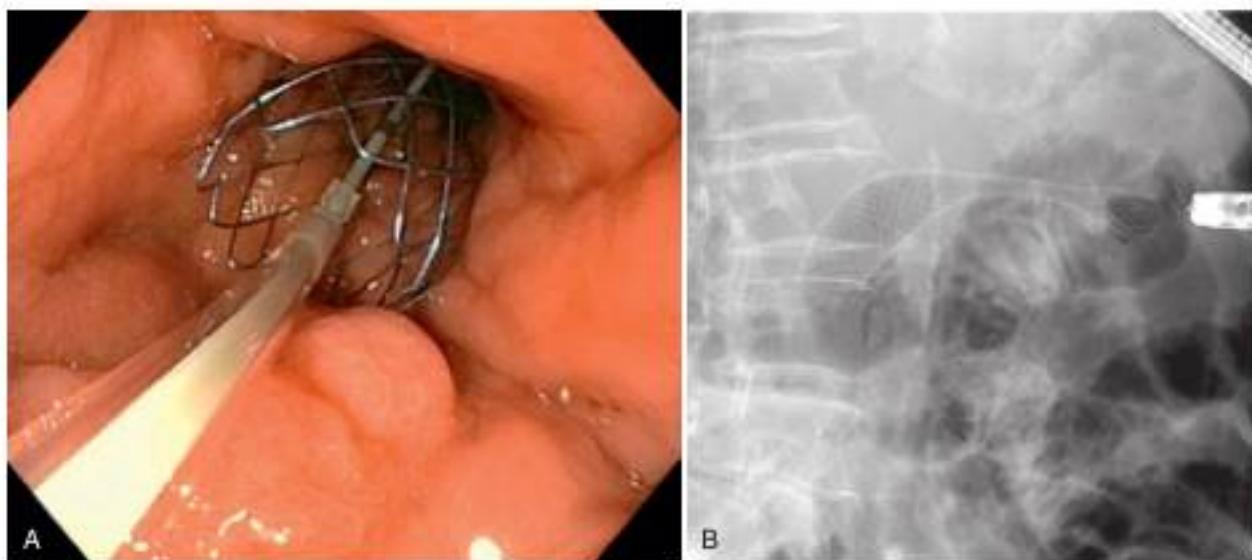

**FIG 33.2** Fluoroscopic image of a through-the-scope self-expanding metal stent delivery system that is being advanced over the guidewire.

endoscope alongside the stent delivery system for an endoscopic view during SEMS deployment. Endoscopy allows visualization of the proximal end of the SEMS, which is usually indicated by a colored mark on the delivery system. So, together with an endoscopic view and fluoroscopic guidance, optimal positioning of the SEMS can be achieved. Once the endoscopist is satisfied with the position, the SEMS can be carefully deployed by pulling back the outer sheath that covers the SEMS. The endoscopist should be aware that SEMSs can shorten upon deployment. It is therefore important to read the instructions supplied by the manufacturer to understand what the radiopaque markers on the SEMS itself or on the stent delivery system indicate. Most stent delivery systems also allow for recapture and repositioning of the SEMS until a certain "point of no return" has been reached. Once the SEMS is fully deployed (Fig. 33.3), it takes 1–3 days to reach the maximum expansion diameter. Therefore, patients are instructed to carefully expand their diet from liquids to soft solids to solid food in the first 3 days after the procedure. In the palliative setting, patient comfort and personal dietary wishes should be respected as much as possible, but at the same time, patients should be instructed as to how to prevent food bolus obstruction of the SEMS. Some recommend a low-fiber diet and, when possible, that the SEMS is placed distal to the pylorus so that only digested stomach contents will pass through the SEMS. Others allow patients with a gastroduodenal SEMS to have a normal diet and prefer placing the proximal flare of the SEMS against the pylorus to prevent migration into the distal small bowel. Data are lacking to support either of these practices. Nevertheless, patients should be instructed to chew well, to avoid swallowing large pieces of food, and to have a glass of water present when eating. They should also be careful when eating (or avoid eating) solid foods that may easily obstruct the SEMS, such as mushrooms or meat or fish containing pieces of bone.

### SELF-EXPANDABLE METAL STENTS

The endoscopist should be aware that there are different stent models available for the treatment of MGOO. The main problems encountered with the use of SEMSs are tumor growth through or over the stent mesh and stent migration, which causes the recurrence of obstruction symptoms. The current stents therefore all have features designed to reduce these risks. SEMSs generally consist of a wire mesh framework made of nitinol, an alloy of nickel and titanium. They usually have a cup- or funnel-shaped flare at the proximal side or at both ends. SEMSs can be uncovered or covered by a silicone or polytetrafluoroethylene membrane. The covering prevents tumor ingrowth, and thereby reduces the risk of recurrent obstruction. Covered stent models are either fully covered or partially covered. Partially covered stent designs have the advantage of preventing tumor ingrowth due to their partial covering, and they also reduce the risk of stent migration because the uncovered parts of the SEMS become embedded by the intestinal wall. Four RCTs have been published that compared the outcomes of uncovered and covered SEMSs for the treatment of MGOO (Table 33.2).<sup>123–24</sup> The authors of the largest and most recently published trial (2015) concluded that the partially covered SEMS used in their study was superior to the uncovered SEMS regarding stent patency and the reobstruction rate.<sup>2</sup> Another trial also reported significantly fewer reinterventions with the use of a partially covered SEMS because of a lower rate of reobstruction due to tumor in- or overgrowth.<sup>21</sup> The two other trials were included in a meta-analysis that compared the clinical

outcomes of uncovered and covered SEMSs for the palliation of MGOO.<sup>23</sup> A total of 849 patients from nine comparative studies were analyzed, and showed no significant differences in stent patency, overall complications, and reintervention rates.<sup>23</sup> The only significant association was the higher migration rate and lower reobstruction rate seen with the use of covered SEMSs.<sup>23</sup>

### PREDICTORS FOR STENT FAILURE

Clinical success of SEMS placement is usually defined as improvement in oral food intake or relief of obstructive symptoms in the first week after the procedure. In the literature, the clinical success rates range from 63%–99%.<sup>1,3,20–28</sup> Performance status and the presence of peritoneal carcinomatosis have been identified as important predictors for clinical failure after SEMS placement. A Karnofsky performance score of 50 or less and an Eastern Cooperative Oncology Group performance status of 3 or higher were independent predictors for clinical failure, with odds ratios ranging from 1.2–10.2.<sup>2,11,29–31</sup> The same applies to the presence of peritoneal carcinomatosis, with odds ratios ranging from 1.2–35.7.<sup>7,8,20,29,30</sup> One should realize that the aforementioned factors are only relative contraindications because clinical success rates of 69% and 88% have been reported in patients with a Karnofsky performance score of 50 or less or peritoneal disease, respectively.<sup>9,31</sup> Therefore gastroduodenal SEMS placement in patients with a poor performance status and/or peritoneal carcinomatosis should be considered on an individual basis. Other variables such as the site of obstruction, administration of chemotherapy, and the underlying malignancy showed inconsistent correlations with the clinical outcomes of SEMS placement.<sup>3,7–9,11,20,21–36</sup>

### STENT PATENCY AND ADVERSE EVENTS

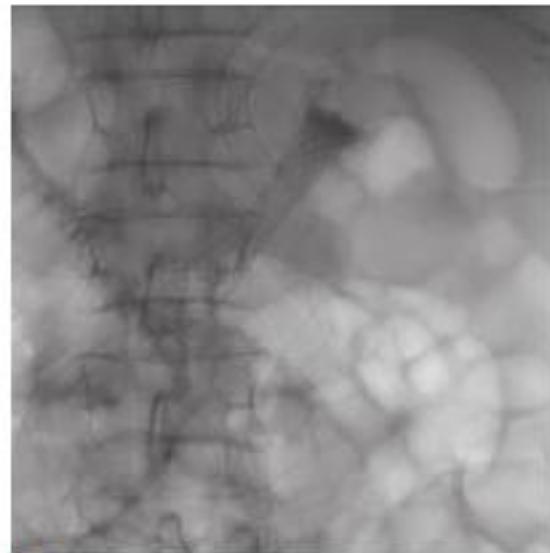

In the RCTs, stent dysfunction from any cause during follow-up was reported in 16%–59% of patients, depending on the type of SEMS (see Table 33.2).<sup>1,22</sup> Large prospective cohort studies have reported a median stent patency ranging from 73–91 days.<sup>2,28</sup> A pooled analysis of the prospective literature including almost 1300 patients reported that stent dysfunction occurred in 20% of patients treated with pyloric or duodenal SEMS placement.<sup>21</sup> Stent dysfunction mainly consists of reobstruction due to tumor growth (13%) and stent migration (4%).<sup>21</sup> The use of uncovered SEMSs is associated with reobstruction (15% vs. 5%), whereas covered SEMSs show an increased risk of stent migration (11% vs. 2%).<sup>21</sup> Other stent-related adverse events are relatively rare, and include: stent compression by tumor pressure (< 2%), insufficient stent expansion (< 1%), food occlusion (< 1%), and stent fracture (< 1%).<sup>21</sup> Recurrent obstructive symptoms caused by stent dysfunction can be treated with a second SEMS by stent-in-stent placement (in case of reobstruction; Video 33.1) or stent replacement (in case of migration). The outcomes of secondary SEMS placement for stent dysfunction are comparable to the outcomes of primary SEMS placement: in retrospective series, the technical and clinical success rates ranged from 98%–100% and 81%–92%, respectively.<sup>32–43</sup> Stent dysfunction after secondary SEMS placement was reported in 17%–34% of cases.<sup>32–41</sup>

Another non-negligible risk is the occurrence of intestinal perforation. This has been reported in approximately 1% of patients who underwent gastroduodenal SEMS placement.<sup>21</sup> Perforations can be procedure-related or can develop at any

time after the procedure, and often result in surgical repair.<sup>21</sup> Gastrointestinal bleeding occurred in 4% of patients, although major bleeds were rare (< 1%).<sup>21</sup> Table 33.3 provides an overview of the adverse events reported in the prospective literature after pyloric or duodenal SEMS placement for MGOO.

### BILIARY DRAINAGE

A point of discussion is whether or not duodenal SEMS placement should be preceded by biliary SEMS placement. After duodenal SEMS placement, endoscopic biliary access via ERCP through the SEMS will be technically challenging. When signs of biliary obstruction are already present, then biliary drainage is indicated before the duodenal SEMS procedure. It has been demonstrated in uncontrolled retrospective series that combined biliary and duodenal stenting is feasible and effective (Fig. 33.4).<sup>31–33</sup> So far, there is no convincing evidence to combine duodenal SEMS placement with preceding biliary SEMS placement when the patient does not have any clinical, biochemical, or radiological signs of a biliary outflow obstruction. An observational study retrospectively compared the occurrence of obstructive jaundice after duodenal covered SEMS placement in patients with (N = 53) or without (N = 53) a concomitant biliary SEMS.<sup>36</sup> In both groups, no cases of jaundice were reported after 90 days of follow-up, although the duodenal SEMS covered the major duodenal papilla in all patients.<sup>36</sup> Another retrospective comparative study also suggested that covered SEMS placement across the papilla did not increase the risk of reintervention.<sup>37</sup> When a patient develops obstructive jaundice or cholangitis after duodenal SEMS placement, biliary drainage can be achieved via the percutaneous transhepatic route. There are also reports of endoscopic biliary SEMS placement through the mesh of a duodenal SEMS.<sup>34–40</sup> The evidence of endoscopic ultrasound (EUS)-guided biliary drainage by choledochoduodenostomy or hepaticogastrostomy using a SEMS or a plastic stent is emerging, but randomized studies are still lacking.<sup>40–44</sup>

**FIG 33.4** Fluoroscopic image with a duodenal self-expanding metal stent (SEMS) that bridges the major duodenal papilla with a biliary SEMS in situ.

## NEW DEVELOPMENTS

Endoscopic bypass of the obstructed gastric outlet by an endoscopically created gastrojejunostomy is a developing area.<sup>18–20</sup> The aim of this minimally invasive technique is rapid relief of obstruction due to the endoscopic approach, as well as long-term intestinal patency conferred by the gastroenteric anastomosis that bypasses the obstructed duodenum. Two studies reported the use of magnets to create a pressure-induced fistula between

the gastric wall and the jejunum.<sup>21,22</sup> After dilation of the duodenal stenosis, a magnet was placed distally from the tumor that was then joined with a magnet in the stomach. After 7 to 10 days, a SEMS with wide flanges was placed through the fistulous tract. Success rates of 87% (13/15) and 67% (12/18) were reported.<sup>21,22</sup> Stent migration was the main problem encountered, occurring in approximately 25% of patients.<sup>21,22</sup> One of the studies was prematurely terminated because of an intestinal perforation caused by the distal end of the stent.<sup>22</sup> A more recently published

technique to create a gastrojejunostomy is EUS-guided placement of a lumen-apposing metal stent (LAMS).<sup>63–67</sup> In this approach, the small bowel adjacent to the gastric wall is identified with EUS. To facilitate EUS visibility, one can use contrast injection, a water-inflated balloon, or a double-balloon tube to fill a segment of the small bowel with water. The small bowel loop is subsequently punctured with a fine-needle aspiration needle, and a guidewire is advanced through the needle into the distal jejunum. The puncture tract is either dilated or entered using the cautery tip of the LAMS delivery system. Under fluoroscopic guidance, the LAMS is placed through the gastrojejunostomy anastomosis to ensure luminal patency. In pilot studies, the technical and clinical success rates ranged from 90%–92% and 85%–100%, respectively.<sup>63–67</sup> No cases of stent migration were reported with the use of LAMSs. In one study, technical failure (2/20) was caused by dislocation of the jejunal loop, resulting in misplacement of the LAMS with direct visualization of the abdominal cavity through the LAMS.<sup>65</sup> Thus, endoscopic bypass seems to be a promising alternative to surgical gastrojejunostomy, although we need more experience with the technique and evaluation by RTCs to determine its role in the management of MGOO.

### INTRODUCTION

Duodenal polyps are uncommon. They can be found in 0.3%–4.6% of patients undergoing upper gastrointestinal endoscopy, and are usually an incidental finding.<sup>1–4</sup> Adenomas account for approximately 7% of all duodenal polyps. They are most commonly found in the second part of the duodenum, and are usually solitary, flat, sessile lesions.<sup>5–8</sup> Duodenal adenomas can be classified as papillary adenomas (PAs) when primarily involving the papilla Vateri, or duodenal adenomas (DAs) when there is no involvement of the papilla. These adenomas can be further classified as sporadic papillary adenomas (SPAs) or sporadic duodenal adenomas (SDAs), i.e., those not associated with genetic polyposis syndromes, or as those related to familial adenomatous polyposis (FAP). It is estimated that 40% of duodenal adenomas are sporadic and 60% are related to FAP.<sup>9</sup>

Endoscopic resection (ER) of DA and PA is quickly becoming the treatment of choice for noninvasive lesions, even when they are very extensive.<sup>10–14</sup> Although no systematic comparative data exist, due to the lower risks of morbidity, mortality, and long-term digestive dysfunction, ER is considered preferable to surgery. ER in the duodenum requires a diverse range of endoscopic skills. These include proficiency in advanced endoscopic resection techniques, experience with pancreaticobiliary endoscopy, and the ability to identify and manage complications. These procedures should be performed by experienced endoscopists practicing in tertiary referral centers with access to surgical and interventional radiology support. A structured approach to lesion assessment, technical aspects of resection, and postresection surveillance is required.

### EPIDEMIOLOGY AND NATURAL HISTORY

SDAs are rare, and most are discovered incidentally during esophagogastroduodenoscopy (EGD) performed for other indications.<sup>1,15</sup> In a similar fashion to colonic carcinogenesis, 30%–80% of SDAs demonstrate malignant progression through the adenoma-to-carcinoma pathway. In one study, 21% of lesions with low-grade dysplasia (LGD) showed progression to high-grade dysplasia (HGD), and the presence of HGD and a lesion size of more than 20 mm were independently associated with progression to adenocarcinoma.<sup>16</sup> In other studies, invasive adenocarcinomas were often found within small bowel adenomas, and residual adenomatous tissue was found adjacent to, or within, most carcinomas.<sup>15,17</sup> It is therefore recommended that all SDAs be removed.

SPAs are also uncommon, and have been reported to occur at a rate of 0.04%–0.12% in autopsy series.<sup>18,19</sup> Today, with the increasing performance of EGD and endoscopic retrograde cholangiopancreatography (ERCP), these adenomas are more frequently recognized at an asymptomatic stage. Similar to SDAs, SPAs appear to follow the adenoma-to-carcinoma paradigm, and should thus be removed.<sup>20,21</sup> However, SPAs are thought to progress to cancer more rapidly than nonpapillary duodenal adenomas.<sup>22</sup>

The molecular and genetic pathways of the adenoma-to-carcinoma sequence in SDA/SPA are less well established. In one study, approximately 75% of duodenal adenomas (both sporadic, FAP-related, and those involving the papilla) showed Wnt signaling pathway abnormalities.<sup>23</sup> KRAS mutations were found in 18% of SDAs, 9% of FAP-related adenomas, and 44% of SPAs.

**Abstract**

Duodenal polyps are uncommon. They can be found in 0.3%–4.6% of patients undergoing upper gastrointestinal endoscopy, and are usually an incidental finding. Adenomas account for approximately 7% of all duodenal polyps. They are most commonly found in the second part of the duodenum, and are usually solitary, flat, sessile lesions. Duodenal adenomas can be classified as papillary adenomas (PAs), when primarily involving the papilla Vateri, or duodenal adenomas (DAs), when there is no involvement of the papilla. These adenomas can be further classified as sporadic papillary adenomas (SPAs) or sporadic duodenal adenomas (SDAs), i.e., those not associated with genetic polyposis syndromes, or as those related to familial adenomatous polyposis (FAP). It is estimated that 40% of duodenal adenomas are sporadic and 60% are related to FAP. Endoscopic resection (ER) of DA and PA is quickly becoming the treatment of choice for noninvasive lesions, even when they are very extensive. Although no systematic comparative data exist, due to the lower risks of morbidity, mortality, and long-term digestive dysfunction, ER is considered preferable to surgery. ER in the duodenum requires a diverse range of endoscopic skills. These include proficiency in advanced endoscopic resection techniques, experience with pancreaticobiliary endoscopy, and the ability to identify and manage complications. These procedures should be performed by experienced endoscopists practicing in tertiary referral centers with access to surgical and interventional radiology support. A structured approach to lesion assessment, the technical aspects of resection, and postresection surveillance is required.

ampullectomy  
nonampullary adenoma  
ampullary adenoma  
endoscopic mucosal resection  
duodenal adenoma

No BRAF mutations were identified, and both p53 and DNA mismatch repair mutations were rare. In another study, the CpG island methylator phenotype (CIMP) was analyzed in ampullary and nonampullary SDAs.<sup>34</sup> Thirty-three percent of duodenal adenomas were CIMP+, and CIMP+ status was associated with advanced age, large lesions, villous histology, MLH1 methylation, and KRAS mutations. These results suggest that duodenal adenomas develop via similar mechanisms as colonic adenomas, and that CIMP+ duodenal adenomas may have a higher risk of developing malignancy.

SDAs are also considered surrogate markers for colonic neoplasia. Several retrospective case control studies have demonstrated a significantly higher risk of colonic neoplasia in patients with sporadic duodenal adenomas when compared with their matched controls (relative risk [RR] 2.5–7.8).<sup>25–28</sup> Thus, all patients with SDA/SPA should undergo colonoscopy at some point.

In contrast, patients with FAP have a much higher prevalence of DA or PA. Duodenal or papillary adenomas are found in more than 90% of patients with FAP, and 3%–10% will progress to malignancy over their lifetime.<sup>27–30</sup> In patients with FAP, duodenal adenomas are usually multiple, sessile, and located in the second and third parts of the duodenum.<sup>31</sup> The Spigelman staging system<sup>32</sup> is used to stratify disease burden and predict the risk of malignant transformation. The risk of duodenal cancer increases with age and with progressive adenoma stage.<sup>26,33</sup> DA may also occur in association with MYH-associated polyposis and Lynch syndrome.<sup>34,35</sup>

## CLINICAL PRESENTATION

As previously mentioned, DAs are usually asymptomatic, and the majority are discovered incidentally during routine EGD performed for other indications. Rarely, very large lesions may present with gastrointestinal bleeding or obstructive features. PA may present with abdominal pain, recurrent pancreatitis, malaise, or anorexia. However, most noninvasive lesions are asymptomatic and are found incidentally during EGD or ERCP performed for other indications. Symptoms such as jaundice may result from invasive malignancy or intraductal extension, but may alternatively be caused by a concurrent benign condition such as common bile duct (CBD) stones.

## INDICATIONS AND PATIENT SELECTION

ER should be considered for any noninvasive DAs/PAs, because it potentially offers significant advantages over operative management. Long-term cure rates can be expected in more than 90% of patients undergoing ER. Periprocedural complications are not uncommon (bleeding up to 25%, perforation up to 3%, recurrence up to 30%); however, they are usually not severe, and are managed successfully endoscopically or with conservative management without long-term sequelae.<sup>12,36–40</sup> In comparison, a conservative surgical procedure (transduodenal resection/ampullectomy) carries a morbidity rate of 20%–30%, a mortality rate of 0%–6%, and a residual disease rate of 13%–100%. The more radical pancreaticoduodenectomy has even higher rates of morbidity and mortality (25%–50% and 3%–9%, respectively).<sup>41–46</sup>

The patient's medical history, including his or her medication list, has to be thoroughly reviewed and the patient's comorbidities constantly factored into the therapeutic process. This is especially important because, compared with similar size adenomas in the

colon, the risk for malignant transformation appears to be reduced, the time course more prolonged, and the ER procedure more technically challenging and associated with greater incidence of complications.<sup>31</sup>

To achieve endoscopic cure, the entire lesion must be accessible to resection, and the risk of submucosal invasive cancer (SMIC) and lymph node metastases (LNM) negligible. Lesions with LGD or HGD confined to the mucosa are considered suitable for ER.<sup>47</sup> Lesions with suspected SMIC or LNM require surgery to achieve cure, and are not suitable for ER. For PA, lymphovascular invasion and moderate or poor tumor differentiation confer additional risks for LNM.<sup>48–50</sup> T1 lesions (limited to the papilla vateri or sphincter of Oddi) harbor an appreciable rate of LNM (18%) and are best managed surgically.<sup>49,51</sup> Papillectomy may serve as the definitive staging tool and finally determine the need for additional therapy such as surgery. On the other hand, endoscopic cure of selected well-differentiated T1 papillary carcinomas has been demonstrated in small case series,<sup>49</sup> presenting a therapeutic alternative for patients unfit for surgical resection.

PA may contain an intraductal component or a lateral spreading component, or can involve the minor papilla. PA with intraductal extension limited to the papillary complex or extending 1 cm or less beyond the duodenal wall may be removed by ER. Lesions with more extensive intraductal involvement have higher failure rates with ER, and at present are best referred for surgical resection, although with expanding possibilities of cholangioscopy, such as intraductal radio frequency ablation (RFA), this may change in the future.<sup>52–56</sup> Lateral spreading lesions of the papilla (LSL-P) may be very large (in excess of 50–60 mm) and involve the entire duodenal circumference. Although uncommon, LSL-Ps may be cured endoscopically at rates comparable to lesions confined to the papilla, albeit with an elevated risk of bleeding.<sup>47,57</sup> Lesions involving the minor papilla are rare, hence data on resection and outcomes are limited.<sup>57,58</sup>

## LESION ASSESSMENT AND STAGING

The lesion's size, the degree of circumferential involvement, and the relationship to the papilla should be carefully assessed. This may require use of a side-viewing duodenoscope. Chromoendoscopy or narrow-band imaging may be used to better delineate the lesion margin and histologic grade.<sup>59</sup> For DA, the presence of a depressed component (0-IIc of the Paris classifications), a type V Kudo pit-pattern, surface bleeding, fixation to the duodenal wall, or ulceration or a nonlifting sign raise concern for SMIC, and warrant consideration for surgical referral.<sup>1</sup> For PA, smooth, elevated lesions and an umbilicated appearance may be associated with a higher risk of SMIC.<sup>47,60</sup> According to Japanese data, ER of DA can be performed on lesions with a depressed element (Paris IIc, Ila + IIc) up to 10 mm in diameter and on nondepressed adenomas up to 50 mm in diameter, as the risk of SMIC in these groups is very low.<sup>61</sup> In expert hands, lesions up to 80 mm and even full circumference lesions without evidence of SMIC can be successfully removed by piecemeal endoscopic mucosal resection (EMR), albeit with higher risks of complications (mainly delayed bleeding).<sup>39,62,63</sup>

For FAP-related DA/PA, the neoplastic burden in the duodenum (as assessed by the Spigelman endoscopic and histologic classification system) is an additional factor in the selection of ER versus surgical management.<sup>32</sup> At present, it is not clear whether endoscopic intervention significantly alters the course of the disease or avoids the need for major surgery (Whipple

resection) in patients with a significant duodenal polyp burden. However, it is current practice to endoscopically remove all large ( $> 1$  cm) duodenal adenomas in patients with FAP unless there is suspicion of advanced histology and submucosal invasion (SMI).

The role of endoscopic ultrasound (EUS) in the assessment of DA has not been systematically evaluated, but its use is likely to be limited (similar to its use for large laterally spreading lesions in the colon), as advanced endoscopic imaging appears to be the most accurate means of predicting SMIC. However, for PA, especially lesions greater than 2 cm, preresection staging with EUS, magnetic resonance cholangiopancreatography, contrast-enhanced multidetector computed tomography (CT), and careful cholangiopancreatography (usually at the time of ampullectomy) are usually necessary. The presence of SMI or LNM, the extent of any intraductal component, and the presence of pancreatic duct anatomic variants (such as pancreas divisum) are assessed. No one test has emerged as the gold standard for T or N staging, and they are considered complementary. EUS provides superior T staging and comparable N staging to CT and magnetic resonance imaging.<sup>14,15</sup> Published accuracy rates vary from 55% to 90% in T staging and 50% to 80% in N staging.<sup>16</sup>

## RESECTION PRINCIPLES AND TECHNIQUES

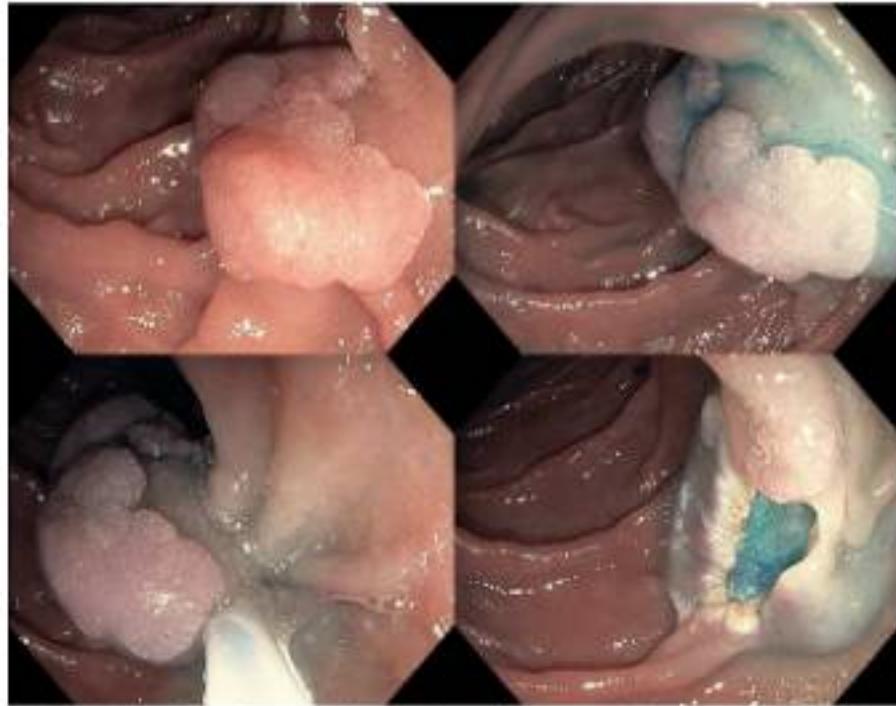

### Duodenal Adenoma

- As most DAs are flat sessile lesions, ER is most commonly accomplished by standard EMR (Video 34.1).<sup>31,67</sup> Modifications to the standard technique, such as cap-assisted EMR and underwater EMR, have also been described.<sup>68,69</sup>
- En bloc EMR is considered for lesions up to 15–20 mm, whereas larger lesions require piecemeal EMR for complete and safe removal (Figs. 34.1 and 34.2).<sup>1,13</sup> Smaller piece sizes are required in the duodenum as compared with the colon, and safety should always be the primary concern.

- Endoscopic submucosal dissection has limited applicability in the resection of DA, due to an unacceptably high frequency of severe complications (mainly perforations, which occur in up to 25% of cases) during or following the procedure.<sup>70,71</sup>
- The submucosal injection solution is composed of a colloid solution (most commonly 0.9% saline, succinylated gelatin, or hydroxyl-ethyl-starch); diluted epinephrine, which may reduce intraprocedural bleeding; and an inert dye (indigo carmine or methylene blue), which delineates the submucosal layer from the underlying muscle layer. The submucosal injection should create a robust and sustained "cushion" between the mucosa and the muscularis propria, thus reducing the risk of deep tissue entrapment in the snare, transmural thermal injury, and perforation.<sup>13,67,72</sup>
- Microprocessor-controlled electrosurgical generators delivering alternating cycles of high-frequency short-pulse cutting with more prolonged coagulation current are most commonly used today. Tissue impedance is sensed via signals from the return electrode, adjusting power output accordingly to minimize the risk of deep tissue injury.
- $\text{CO}_2$  should be used routinely. Abundant data from colonoscopy, ERCP, and colonic EMR studies demonstrate that the use of  $\text{CO}_2$  results in a significant reduction in postprocedural pain and admissions, without any adverse effects.<sup>73,74</sup>

### Papillary Adenoma

- The standard technique for en bloc papillectomy has been described in detail (Video 34.2).<sup>60</sup> Briefly, the snare tip is anchored above the apex of the papilla at approximately the 12 to 1 o'clock position. The snare is then opened fully, and gently drawn down over the papilla as the endoscope is advanced. The snare is then closed slowly and fully while the tip is maintained impacted above the papilla. The mobility of the papilla relative to the duodenal wall is confirmed, and

**FIG 34.1** En bloc endoscopic mucosal resection of a 15-mm duodenal lateral spreading lesion.

**FIG 34.2** Piecemeal endoscopic mucosal resection of a 40-mm duodenal lateral spreading lesion.

the lesion is transected by continuous current application (we use Endocut Q effect 3 cut duration 1, cut interval 6; ERBE, Tübingen, Germany) (Fig. 34.3).

- En bloc papillectomy is associated with a lower rate of incomplete resection and residual disease.<sup>35,71</sup> Lesions limited to the papillary mound, or those with less than 10 mm extension to the duodenal wall and that are up to 20 mm in size, can usually be resected en bloc (Fig. 34.4).<sup>35,36,60</sup>
- Prior sphincterotomy should definitely be avoided because the papillary complex tends to retract following sphincterotomy, and this can seriously impede attempts at en bloc resection.
- For LSL-P, resection of the extrapapillary component follows the principles of EMR for DA.<sup>14,31</sup> Resection should preferably proceed along the duodenal folds, aiming to isolate the papilla for en bloc resection at the end (Video 34.3). Care should be taken to avoid overinjection or injection within the papillary mound, which may lead to a buried papilla between adjacent elevated mucosa ("canyon effect"), hindering adequate snare capture (Fig. 34.5).
- Pancreatic stent placement reduces the risk of postprocedure pancreatitis, and should be performed routinely.<sup>76,77</sup> The pancreatic orifice is usually identified as a slit-like opening in the 5 o'clock position within the base of the papillectomy site.
- Cholangitis following ampullectomy is uncommon, and routine postpapillectomy sphincterotomy or stenting is not mandatory.<sup>77</sup> However, for advanced resection requiring a longer procedure time, multiple submucosal injections, and extensive

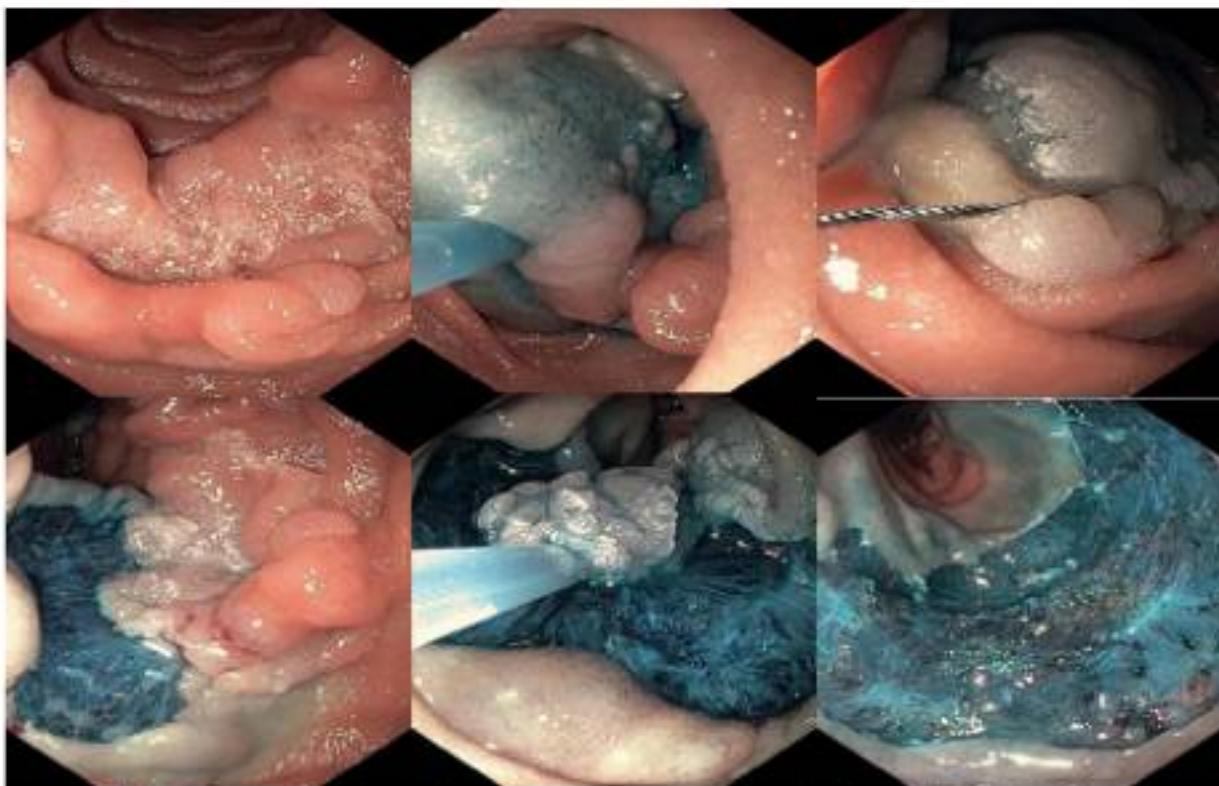

piecemeal resection, we often perform biliary stenting to avoid the small risk of papillary stenosis and cholangitis.<sup>37,47,78</sup>

- When intraductal extension is suspected, balloon trawls can be used to deliver distal disease for snare resection.<sup>79</sup> Alternatively, if the CBD is large enough, a fully covered self-extending metal stent (FCSEMS) can be placed and removed at scheduled surveillance. This will result in a CBD orifice of 10 mm in diameter, and easy access can be obtained to excise the residual tissue.

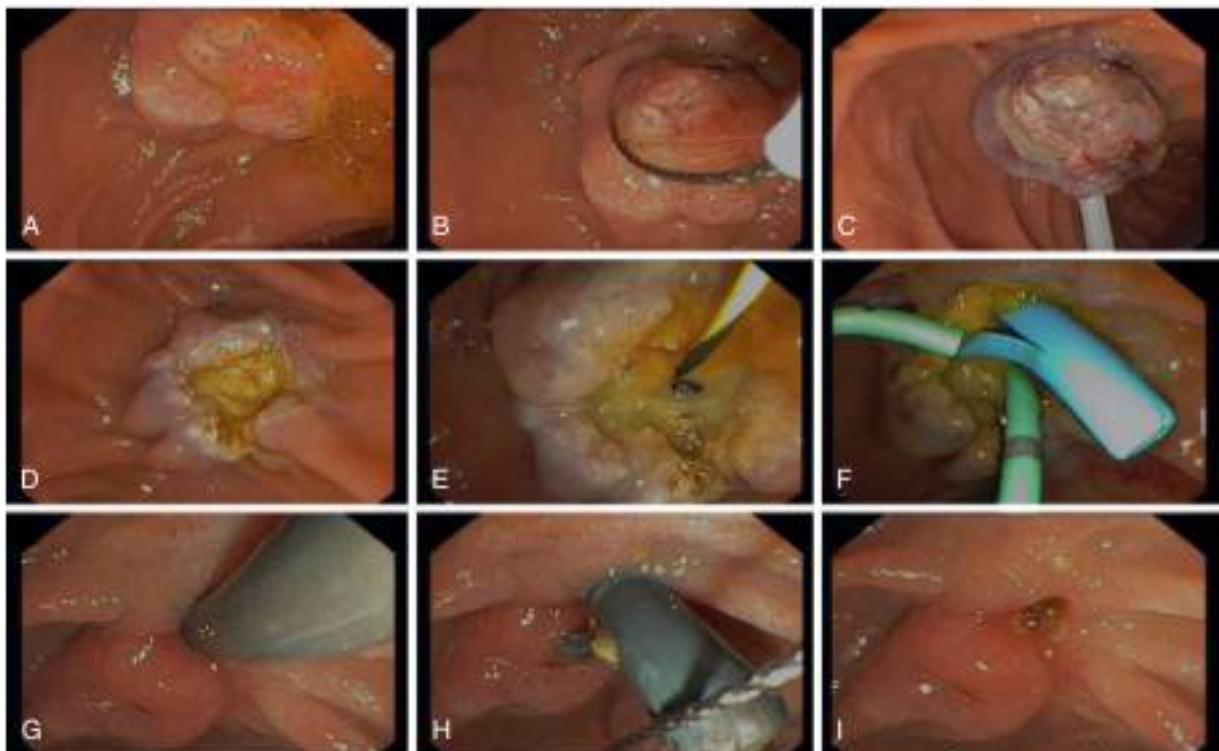

#### Postprocedure Care

ER of DA/PA is best scheduled during the morning to allow ample time for recovery and identification of adverse events. We routinely admit all patients for observation over a period of 24 hours. However, practice differs between centers, and in some, patients are discharged following an uncomplicated resection of DA/PA. If there is significant postprocedural pain, imaging from the case is carefully reviewed, and a CT scan with oral contrast ordered. Patients who are well may be discharged the following day. High-dose proton pump inhibitors (PPIs) are prescribed for 4 to 6 weeks, although there are no systematic data to support this practice. For PA, an abdominal film is obtained after 10 to 14 days to ensure pancreatic duct stent migration. A stent that has not migrated is removed endoscopically.

Surveillance endoscopy is performed at 4 to 6 months following the index procedure. If an FCSEMS was inserted during the index procedure, it is removed then. This can be successfully achieved in all cases in our experience, and complications related

**FIG 34.4** En bloc papillectomy of a 15-mm papillary adenoma. **A**, After careful interrogation, **B**, the snare is anchored at the 11 o'clock position and **C**, brought down over the papilla. **D**, Following transection, **E**, the pancreatic duct is cannulated. In this case, **F**, biliary stenting is also performed. **G-I**, During surveillance, the stents are removed, revealing a clean scar with no residual adenoma.

**FIG 34.5** **A**, Endoscopic resection (ER) of lateral spreading lesions of the papilla. **B** and **C**, Piecemeal endoscopic mucosal resection of the lateral spreading component is performed. **D**, Isolating the papilla for en bloc resection. **E** and **F**, ER is followed by pancreatic and biliary stenting. **G–I**, The stents are removed during surveillance.

to stent removal are rare.<sup>30,31</sup> The post-ER scar (and the distal CBD in PA cases) is carefully examined endoscopically for the presence of residual/recurrent neoplastic tissue, which can be managed by snare excision. If the tissue is especially adherent, then cold forceps avulsion followed by thermal ablative techniques (such as snare tip soft coagulation [STSC] or, more recently, RFA) can be used.

#### Adverse Events

Despite the advantages of ER for noninvasive DA/PA, the incidence of treatment-related adverse events is generally greater than for ER of similar-sized lesions elsewhere in the gastrointestinal tract. Contributing factors include a relatively thin, fixed duodenal wall, a rich vascular supply, and additional site-specific complications such as pancreatitis. Tables 34.1 and 34.2 summarize outcomes and adverse events of ER of PA and DA, respectively.

Bleeding is the most common adverse event following ER of DA/PA. Intraprocedural bleeding is common, varies greatly between studies due to heterogeneity in definition, and can usually be successfully managed endoscopically. We prefer STSC (Soft Coag effect 4, 80W, ERBE VIO 300 [ERBE, Tübingen, Germany]) as previously described for colonic EMR for nonpulsatile intraprocedural bleeding.<sup>32</sup> Pulsatile bleeding or bleeding unresponsive to STSC can be controlled with coagulation forceps using the same electrocautery settings. Endoscopic clip placement may be applied where other therapies fail, but caution should be exercised to avoid clipping muscle to muscle; because the duodenal wall

is relatively fixed, the muscle layer can be torn, and delayed perforation may ensue. We prefer to clip mucosa to mucosa.

Delayed bleeding occurs in 2%–18% and in 5%–26% of patients following ER of PA and DA, respectively, increasing up to 30% in patients with lesions greater than 30 mm in size,<sup>7,12,14,22,70,75,76,83–89</sup> with the most consistent risk factor being lesion size.<sup>40,85,86</sup> Patients without hemodynamic compromise or evidence of ongoing bleeding may be managed conservatively with inpatient observation, intravenous PPI, and fasting, as bleeding may be self-limiting. If endoscopic intervention is required, coagulation forceps are preferred after careful localization of the bleeding point. In cases with massive bleeding unresponsive to endoscopic therapy, angiographic embolization should be considered. ER in the duodenum is a very high bleeding risk procedure, and we generally advocate a more conservative approach to management of periprocedural anticoagulation and antiplatelet therapy than for procedures performed elsewhere in the gastrointestinal tract. An individualized approach in coordination with the cardiology/hematology team regarding bridging of necessary anticoagulation and withholding of antiplatelet therapy is advised.<sup>33</sup>

Perforations are reported in 0%–3.6% of patients undergoing ER of PA/DA.<sup>8,12,24–26,31,32</sup> Early recognition and management are crucial. Endoscopic clip closure is feasible and suitable for injuries detected during the procedure. Small delayed perforations may respond to hypervigilant conservative management comprising intravenous antibiotics, bowel rest, and close clinical and

radiological monitoring.<sup>75</sup> CT with oral contrast is the diagnostic procedure of choice, and if a large perforation is identified or an active leak persists, early surgical repair is indicated.<sup>93,94</sup> For ER of PA, FCSEMS are highly valuable for distal CBD or periampullary injuries.<sup>95</sup>

#### Unique Site-Specific Complications

Pancreatitis complicates 4%–20% of ER procedures performed to treat PA.<sup>52,57,75,96</sup> Randomized and observational data support

the routine placement of pancreatic stents,<sup>77</sup> and 5Fr stents are preferred over 3Fr stents.<sup>78</sup> We recommend deployment of the stent with the proximal tip below and not crossing the genu. Cholangitis is uncommon, and may be managed with intravenous antibiotics. ERCP and stent placement may be necessary. Papillary stenosis is an uncommon long-term complication occurring in 1%–2% of cases.<sup>47,70,98</sup> In our experience, most cases resolve following careful balloon dilation and/or serial stent placements. Duodenal luminal stenosis can occur after ER of lesions

with extensive circumferential involvement.<sup>62</sup> In such cases, a preemptive dilation management strategy commencing 3 to 4 weeks after resection is appropriate.<sup>59</sup>

### Endoscopic Outcomes

Outcomes of ER for DA and PA are reported mainly in retrospective case series, which are usually small and heterogeneous in terms of patient and lesion characteristics. Nevertheless, complete successful removal of DA/PA in a single session has been reported in 70% to 100% of cases, and long-term endoscopic cure of DA/PA can be expected in more than 80% of cases.<sup>3,12,52,53,75,76,83-89,91,98</sup>

Several studies reported on the number of EMR sessions required to achieve complete resection of DA. In these studies, 80% of adenomas were completely removed in a single EMR session, 17% in two sessions, and the remaining 3% in three sessions. A relationship between lesion size, percentage of luminal circumference involved, and EMR success has also been demonstrated,<sup>5</sup> with success rates of 94.7%, 45.5%, and 0% for lesions involving less than 25%, 25%–50%, and greater than 50% of the luminal circumference, respectively. In a recent report from a high-volume center, 87.5% of fully circumferential lesions, both with and without papillary involvement, were successfully removed in a single session.<sup>63</sup>

Recurrence of PA/DA following ER is not uncommon (0%–36% for DA and 0%–33% for PA),<sup>12,13,52,53,75,76,83-89,98</sup> and lesion size and piecemeal resection have been identified as risk factors for recurrence.<sup>50,53</sup> These relatively high recurrence rates highlight the need for a meticulous surveillance protocol, which includes initial endoscopic surveillance at 4 to 6 months with subsequent annual surveillance for 5 years to detect late recurrences.<sup>75</sup> For PA, endoscopic surveillance is performed with a side-viewing instrument. The mucosal papillectomy site is inspected, and cholangiography with balloon trawl is often performed as well. Treatment of recurrent/residual disease can be safely and effectively accomplished with a combination of snare resection (we recommend Forced Coag effect 2, 30W, ERBE VIO 300 [ERBE, Tübingen, Germany]), cold forceps avulsion, and adjuvant thermal ablation. When significant thermal therapy is applied adjacent to the biliary or pancreatic orifice, a stent should be placed to mitigate the risk of pancreatitis, cholangitis, and early stricture formation.

### CONCLUSION

ER for DA/PA is a highly effective, though complex, endoscopic procedure. Although no direct comparisons exist, modeling suggests comparable efficacy with superior morbidity, mortality, and cost profile compared with surgery.<sup>100</sup> The adverse event rate of ER for DA/PA is significant compared with other endoscopic therapies, and as such they should be performed by experienced advanced endoscopists practicing in tertiary referral centers. A careful, structured, multidisciplinary approach to patient and lesion assessment, endoscopic management, and surveillance is mandatory.

### INTRODUCTION

Acute colonic pseudo-obstruction (ACPO) is a disorder characterized by massive dilation of the colon in the absence of mechanical obstruction. This severe motility disturbance, also known as *Ogilvie's syndrome*,<sup>1</sup> usually develops in hospitalized patients, and is associated with various medical and surgical conditions. The tension on the colon wall resulting from the extreme dilation can lead to ischemic necrosis and perforation, especially in the cecum. The rate of spontaneous perforation has been reported to be 3% to 15%, with an attendant 40% to 50% mortality rate.<sup>2-5</sup> Despite the potential risk of perforation, approximately 75% of patients with ACPO recover over an average of 3 to 5 days when treated using a variety of conservative measures.<sup>1,4</sup> During the sometimes prolonged recovery phase, however, ACPO contributes greatly to patients' discomfort and immobilization, and prevents institution of enteral nutrition.

The risk of major complications/mortality and the morbidity of the long recovery led to a search for effective and safe therapies, not only to prevent ischemia and perforation but also to speed resolution. Very few controlled trials have evaluated the standard therapies used for ACPO. Nonetheless, conservative management strategies such as nasogastric (NG) suction and measures taken to correct precipitating factors have been the mainstay of treatment.

For the minority (approximately 25%) of patients who fail to respond to conservative therapy and for patients who have severe or prolonged colonic dilation risking perforation, more active interventions are instituted. In the past, surgical cecostomy and hemicolectomy were the main options for severe or refractory cases. Subsequently, colonoscopy and various radiologic procedures were reported to help decompress the colon.<sup>3-11</sup> Medications such as neostigmine have also been shown to be effective.<sup>12</sup> The

timing and combination of conservative and more active interventions must be individualized according to the severity of ACPO and the patient's comorbidities.

### EPIDEMIOLOGY

ACPO is relatively uncommon. It can be triggered by various acute medical and surgical illnesses. Typically, rapid-onset abdominal distension begins within a few days of the start of the underlying illness.<sup>2</sup> Because ACPO is uncommon, one must look at reviews that examine several years of reported cases before one can draw conclusions about the epidemiology of the condition. Numerous case reports and reviews describe specific triggers. However, each proposed underlying condition seems to be associated with the development of ACPO in only a very small percentage of cases (Table 35.1). ACPO has been reported after various surgeries, including orthopedic, urologic, gynecologic, and neurologic surgeries, as well as organ transplants.<sup>2,4,13-18</sup> It is seen in obstetrics after vaginal deliveries and cesarean sections.<sup>19</sup> Trauma and burn patients sometimes develop ACPO.<sup>2,4,20</sup> Various medical illnesses are known to cause ACPO, including sepsis, respiratory failure, mechanical ventilation, renal failure, myocardial infarction, vascular emergencies, sickle cell crisis, and cancer.<sup>3,4,21-23</sup> Many medications can precipitate or worsen ACPO, especially narcotic analgesics and any medication that decreases peristalsis, such as tricyclic antidepressants or anti-cholinergic drugs.<sup>5,8,20-23</sup> Although the connection between any of these causes and ACPO is most likely through a disturbance in the autonomic innervation of the bowel, other variables, such as patient age, comorbidities, and factors such as immobility, medications, and electrolyte imbalances, are contributing factors.<sup>2</sup>

In one review of 351 ACPO cases from 1948 to 1980, 88% followed surgery, trauma, or acute medical illness.<sup>3</sup> The remaining

**Abstract**

Acute colonic pseudo-obstruction (ACPO) is a disorder characterized by massive dilation of the colon in the absence of mechanical obstruction. This severe motility disturbance, also known as Ogilvie's syndrome, usually develops in hospitalized patients and is associated with various medical and surgical conditions. The tension on the colon wall resulting from extreme dilation can lead to ischemic necrosis and perforation, especially in the cecum. Approximately 75% of patients with ACPO recover over an average of 3 to 5 days when treated with conservative measures. During the recovery phase, however, ACPO causes significant discomfort and immobilization and prevents institution of enteral nutrition. The risk of major complications, mortality, and the morbidity of the long recovery led to a search for effective and safe therapies, not only to prevent ischemia and perforation, but also to speed resolution. The first step in management of ACPO is to confirm the diagnosis and rule out true obstruction, usually by CT scan. Then, conservative measures like NPO status, nasogastric suctioning, rectal tube, mobilization of patient, correction of electrolyte abnormalities, and discontinuation of anti-motility medications like narcotics have been shown to succeed in most patients. For the 25% of patients who fail to respond to conservative therapy, more active interventions are instituted. Medication therapy with neostigmine, a cholinesterase inhibitor, has been shown to be rapidly effective and safe in most patients. Colonoscopy with decompression tube placement is generally next for those failing neostigmine. Surgery is reserved for those with perforation and/or severe ischemic necrosis.

			Renal failure	
			Electrolyte imbalance (potassium, magnesium, calcium, phosphorus)	
			Viral infections (herpes, varicella zoster)	

12% were classified as idiopathic. This review reported a 15% perforation rate, with a 45% mortality in patients with colonic perforation. This high mortality was attributed in part to the fact that these patients already had serious underlying medical or surgical problems.

In another review of 400 patients from 1970–1985, 95% of the cases had identifiable underlying medical, surgical, or obstetric conditions<sup>4</sup>; this left only 5% to be categorized as idiopathic. ACPO usually developed within 5 days of onset of the underlying condition. The median patient age was approximately 60 years, and the male-to-female ratio was 1.5:1. The perforation rate was 20%, and mortality in patients with perforation was approximately 40%. Overall, mortality in the group was 15%. The mortality rate was affected by age, cecal diameter, length of dilation of colon, presence of ischemia in the bowel wall, and patient comorbidities. One important observation in this review was that patients with a cecal diameter of 8 to 25 cm usually had viable colon without significant ischemia. Thus, cecal size alone is not the only factor in the risk of perforation. Other variables, such as the acuity of the onset and the duration of distention, were also potentially important factors.

A more recent review by Ross et al (2016) of over 100,000 cases from 1998–2011 found a higher rate of ACPO incidence than previously reported (approximately 100/100,000 adult inpatients/year). They noted that, although the incidence rate has increased, the overall mortality has decreased. They found a 7.7% overall mortality. There was, as expected, much higher mortality in those that failed medical therapy and needed endoscopy or surgery.

## PATHOGENESIS

In 1948, Ogilvie<sup>1</sup> first described massive colonic distention in two patients who exhibited onset of abdominal distention over a few weeks, rather than the more acute presentation that we currently refer to as Ogilvie's syndrome. Ironically, by today's criteria, neither patient would be categorized as having ACPO. Both patients were ultimately found to have widespread intra-abdominal malignancy with retroperitoneal involvement of nerve plexuses, leading Ogilvie to speculate that disruption of the autonomic innervation of the colon was the underlying cause of the disorder.<sup>1</sup>

Despite the wide variety of possible triggers for ACPO, the presentation is remarkably consistent. Generally, patients develop severe abdominal distention within 5 days of the onset of the medical or surgical insult. The intestinal dilation is usually most pronounced in the colon, especially proximal to the splenic flexure. On x-ray examination, the appearance is very similar to that of a patient who actually has an obstruction near the upper left colon/splenic flexure, leading to the term *pseudo-obstruction*. These facts led to the hypothesis that the final common pathway of the development of the disease is an acute cessation of effective colonic motility resulting from a disruption of the autonomic supply of the left side of the colon. One hypothesis was that excess sympathetic stimulation of the colon was inhibiting contraction. This hypothesis seemed to be supported by the observation that ACPO can occur in any sort of severe physical stress. In addition, epidural anesthesia to decrease sympathetic output has been reported to be beneficial for ACPO.<sup>20</sup> However, when guanethidine was used to block sympathetic tone, there was very little effect on colonic function in patients with ACPO.<sup>21</sup>

The leading current theory about the pathogenesis of ACPO is that a decrease in parasympathetic stimulation of the colon is more important than an excess of sympathetic input.<sup>21</sup> In the study of guanethidine mentioned previously, patients were first given guanethidine and then treated with neostigmine to block acetylcholinesterase. Patients had a prompt return of colonic function only after receiving the neostigmine, leading to the idea that a loss of parasympathetic tone is important in the development of ACPO. Some authors speculate that the parasympathetic deficiency is most pronounced in the left colon because of disruption of supply from the sacral plexus; this may explain why the left colon is contracted and aperistaltic in ACPO. Since these pioneering studies, the one medical treatment that has had the most consistent success in treatment of ACPO has been the use of neostigmine to cause a sudden increase in acetylcholine concentration at parasympathetic nerve synapses and an increase in colon peristalsis. However, there are other complex mechanisms that are thought to contribute to ACPO, including changes in nitric oxide release, stimulation of opioid receptors on the bowel wall, reflex inhibition of colonic motility caused by stretch-sensitive mechanoreceptors in the gut wall once severe dilation has occurred.<sup>22</sup>

Other factors that likely contribute to the pathogenesis of ACPO are chronic underlying bowel motility disorders and constipation, patient immobility, electrolyte imbalance, medications such as narcotics, and mechanical ventilation. These other factors may worsen the autonomic imbalance, directly suppress muscular function of the colon, or simply increase the amount of gas that is entering the digestive tract, as occurs with mechanical ventilation. At least 50% of patients with ACPO have significant electrolyte abnormalities, especially low potassium, magnesium, and calcium.<sup>4</sup> Secretory diarrhea (with high potassium and low sodium concentration in the stool) can occur in ACPO. This is thought to be due to the effects of autonomic nervous system disturbance and colonic distension on the activity of the apical (BK) potassium channels in the colonic mucosa.<sup>11</sup>

The most feared complication of ACPO is colon perforation. When perforation occurs, it is usually in the right colon, especially the cecum. This relates to the high wall tension in the cecum leading to ischemic necrosis and wall disruption. The right side of the colon, which naturally has a thinner wall and a larger diameter than the left side, has the highest wall tension when the colon is distended. This occurrence is described well by Laplace's law:  $T = P \times R/2d$ , where  $T$  is wall tension,  $P$  is pressure in colon lumen,  $R$  is radius of the colon, and  $d$  is the thickness of the colonic wall. This equation helps explain how small changes in colonic radius in the setting of severe distention of the thin-walled cecum can lead to relatively large changes in wall tension and increase the risk of perforation.

Usually the perforation risk is not very high in patients with a cecal diameter of less than 12 cm. Nonetheless, studies have shown that patients with ACPO and a cecal diameter greater than 25 cm can recover without incident, and that this may also occur in patients with prior or chronic dilation. Other variables, such as elasticity of the muscle wall, adequacy of blood supply, and time course of distention, must be important as well in determining whether the colon remains viable. Some studies indicate an association between the duration of ACPO and perforation risk, and indicate that patients with persistence of distention for more than 5 days have higher perforation rates.<sup>34</sup>

## CLINICAL FEATURES

ACPO is seen mainly in patients who are hospitalized for an acute medical, surgical, obstetric, or traumatic event. The condition progresses at a variable rate, usually over 2 to 7 days. The nearly universal symptom is progressive abdominal distention. The reported frequency of other symptoms is quite varied. Abdominal pain (10%–80%), nausea (10%–60%), vomiting (10%–60%), diarrhea (30%–40%), constipation (40%–50%), and respiratory compromise resulting from distention all have been reported.<sup>3–13</sup> Patients with ischemia and perforation are much more likely to have abdominal pain and fever.

Physical examination findings include a markedly distended abdomen that is usually tympanitic on percussion. Bowel sounds are often present. Although some tenderness has been noted (in 60% of patients in some reports), significant tenderness or guarding should raise suspicion for perforation.

Laboratory abnormalities include an elevated white blood cell count in up to 25% of patients without perforation and in almost 100% of patients with perforation.<sup>4</sup> Abnormalities are often seen in electrolytes such as potassium, calcium, magnesium, and phosphorus. Abnormal thyroid function is not caused by ACPO, but can occur concurrently, and is thought to contribute

to colonic dysfunction. These various laboratory values should be checked in patients with ACPO and corrected, as needed.

Abdominal x-ray films show distention of the colon that is usually most pronounced in the cecum, as well as the ascending and transverse areas. In contrast to patients with severe obstipation, the colon is filled primarily with gas, not stool. There is often an apparent "cutoff" near the splenic flexure with a collapsed left colon. The location of the cutoff varies. In one review, the cutoff was at the splenic flexure in 56% of patients, at the hepatic flexure in 18%, and at the descending or sigmoid colon in 27%.<sup>20</sup> Although the small bowel usually exhibits less dilation in ACPO, one report indicated that 80% of patients had some small bowel dilation.<sup>21</sup> Air-fluid levels have been reported in 40% of patients. On x-ray, gas in the bowel wall and free intraperitoneal air are indicative of colonic ischemic necrosis and perforation, respectively. Radiographic studies like computed tomography (CT) scan or water-soluble contrast enema are often needed to rule out a true mechanical obstruction. As discussed in the treatment section, the use of water-soluble contrast material has been reported to have a therapeutic effect in some patients.<sup>32,33</sup> Abdominal CT scan with intravenous (IV) contrast has largely replaced contrast enemas in most centers for a number of reasons. In addition to being easier to perform, CT is safe and is often readily available. There is concern about perforation with contrast enema, as the study may put more pressure into an already distended colon. The CT accurately measures cecal diameter, which is important in determining risk of perforation. CT can detect thickening of the bowel wall and bowel wall gas as an indicator of ischemic necrosis and impending perforation.<sup>15</sup>

## DIFFERENTIAL DIAGNOSIS

Two major considerations in the differential diagnosis of ACPO are mechanical bowel obstruction and toxic megacolon resulting from an enteric infection or inflammatory bowel disease (IBD). In addition, patients are sometimes first diagnosed with chronic colonic pseudo-obstruction when they are hospitalized for other reasons, making it important to establish early that the condition is truly acute and not chronic.

Mechanical colon obstruction from causes such as colon cancer, sigmoid volvulus, and diverticulitis must be confidently ruled out before considering specific therapies for ACPO. Often, the fact that patients with ACPO continue to have watery bowel movements is helpful to indicate that a complete obstruction is unlikely. In some cases, the presence of some gas in the rectum or throughout the entire colon, as seen on plain x-ray, also helps rule out obstruction. Nonetheless, these indicators are not totally reliable. Either CT scan, water-soluble contrast enema, or colonoscopy may be required to rule out mechanical obstruction.

Toxic megacolon resulting from infections such as *Clostridium difficile* should be considered in patients who have been exposed to antibiotics or prolonged care in a hospital or nursing facility, where they may have contracted the infection. Generally, such patients have severe diarrhea before the onset of the abdominal distention. Other colonic infections leading to toxic megacolon have been reported, particularly in immunosuppressed patients. In some cases, these patients have a presentation that is seemingly indistinguishable from classic ACPO. However, when the colonic distention is due to infection, patients usually have (1) an elevated white blood cell count; (2) more widespread thickening of the bowel wall on x-ray films (especially on CT); and (3) endoscopic

evidence of severe colonic erythema, edema, ulceration, or pseudomembranes on flexible sigmoidoscopy or colonoscopy. Stool studies for enteric pathogens and *C. difficile* toxin are important in this setting.

Similarly, toxic megacolon resulting from IBD can usually be differentiated from ACPO by a review of the patient's clinical history, laboratory results, x-ray films, and findings on endoscopy.<sup>35</sup> Patients with IBD should have had a history of diarrhea (often bloody) and abdominal cramps before the development of colonic distention. Blood test results usually show leukocytosis. Abdominal x-ray films/CT often show bowel wall edema. Sigmoidoscopy should show changes consistent with IBD.

Lastly, the presence of chronic pseudo-obstruction can often be excluded by a careful review of the patient's history, old records, and prior abdominal radiographs when available.

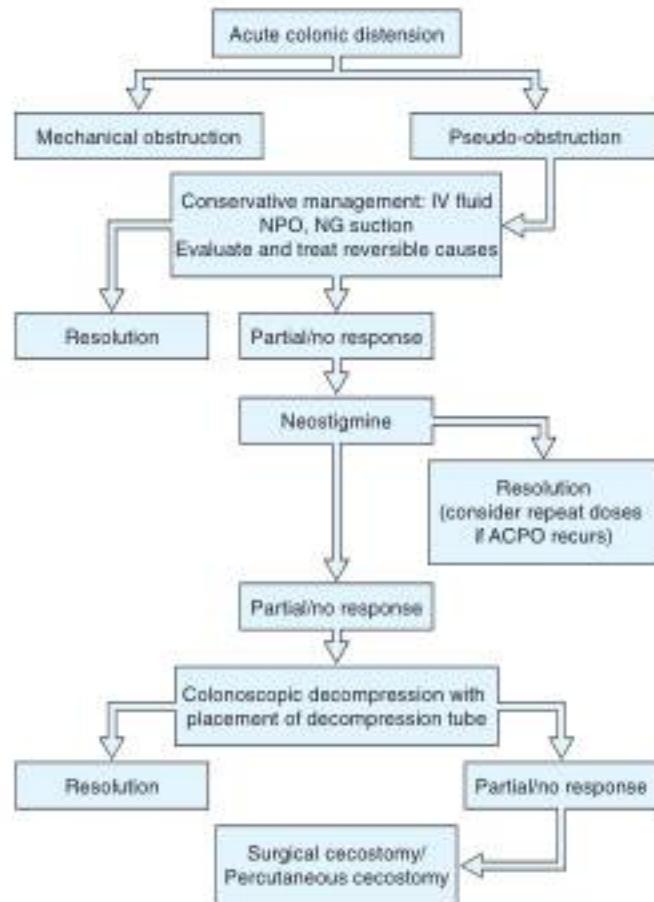

## TREATMENT

Because ACPO is uncommon, there have been few randomized controlled trials to actually test the treatments that are currently considered the standard of care. Most data are from reviews, observational studies, and case presentations. Therapy is generally divided into conservative measures and active interventions. Because at least 75% of patients with ACPO experience resolution with a combination of conservative measures, these are generally tried first for at least 24 to 48 hours in most patients before more active interventions are considered.<sup>36</sup> Reported success from these measures ranges from 33% to 100%, and is usually approximately 75%.<sup>37</sup>

The following sections describe conservative therapy, medication therapy, colonoscopy, and surgical approaches for ACPO. These treatments are often combined (simultaneously or sequentially). Conservative measures are typically continued when more active interventions are added. The order and combination of these measures must be individualized to a patient's clinical presentation and course. For instance, a patient with a cecal diameter of over 12 cm and other high risk features may be better served by starting active therapy sooner, rather than waiting 24 to 48 hours while giving conservative measures. There have been a number of excellent reviews recently on the topic of treatment of ACPO.<sup>32,38–40,50</sup> Fig. 35.1 outlines a proposed treatment algorithm for most patients with ACPO, modified from the American Society for Gastrointestinal Endoscopy (ASGE) practice guideline on treatment of this condition.<sup>34</sup> In the algorithm, a key point is that this is a treatment for acute colonic distention, not chronic pseudo-obstruction. First, ischemia and perforation need to be excluded. Then, mechanical obstruction from tumors or benign strictures (e.g., diverticulosis, sigmoid volvulus, etc.) is treated with endoscopic techniques or surgery, or at least ruled out with appropriate imaging. Finally, one starts down the path of the algorithm to treat ACPO only after all these other possibilities are convincingly ruled out.

### Conservative Therapy

Conservative measures for treatment of ACPO include most, if not all, of the following, depending on individual circumstances.<sup>35</sup> The patient is made *nil per os* (NPO), and NG suction is used to prevent more gas from entering the gastrointestinal tract. At least initially, osmotic laxatives (especially fermentable ones like lactulose) should be avoided, as they can increase colonic distension and gas. Patients should be mobilized as much as possible. If the patient is bed-bound, the patient's position should be

**FIG 35.1** Suggested algorithm for the management of acute colonic pseudo-obstruction (ACPO). This algorithm has been adapted from the practice guideline published by the American Society for Gastrointestinal Endoscopy. IV, intravenous; NG, nasogastric; NPO, *nil per os*. (From Dominitz J, Baron T, Harrison M, et al: The role of endoscopy in the management of patients with known and suspected colonic obstruction and pseudo-obstruction. *Gastrointest Endosc* 71[4]:669–679, 2010.)

changed often from side to side and, when possible, into the prone and knee-to-chest position. A search for contributing factors should be made, with correction of as many as possible. One should withdraw medications that interfere with colonic motility, such as narcotic analgesics, anticholinergics, and calcium channel blockers. Laboratory tests should include complete blood count, comprehensive chemistry panel, and lactic acid level. If there is diarrhea, then stool should be sent for *C. difficile* toxin detection and for cultures. Electrolyte imbalance (especially potassium, calcium, magnesium, and phosphorus) should be corrected. Regular rectal examinations every 6 hours have been advocated as a way to encourage passage of colonic gas. Placement of a rectal tube is more often used for this purpose. Gentle tap water enemas are controversial, but are advocated by some authors as a way to liquefy remaining stool. A water-soluble contrast enema, which can liquefy stool, is commonly performed to exclude mechanical obstruction. Some authors have reported a stimulant effect on motility that sometimes speeds recovery.<sup>35</sup> The use of prophylactic antibiotics has not been studied, and is not common practice. If a patient has a fever or an elevated white blood cell

count, broad-spectrum antibiotics can be considered while a careful evaluation is under way for signs of colonic ischemia, perforation, or other infections.

Conservative measures are continued for 24 to 48 hours before more active intervention is initiated. This recommendation is not based on controlled data, but rather on the observation that patients whose severe colon dilation (> 12 cm) persists for 4 to 5 days have a higher risk of ischemia and perforation.<sup>4</sup>

Although conservative therapy is generally successful, return of colon function in responders takes an average of 5 days. During this time, patients are contending with the consequences of ACPO, including distention, pain, prevention of enteral nutrition, compromised respiratory status, and delay in ambulation that can lead to other morbidities such as thromboembolism, atelectasis, and pneumonia. These facts have led to a search for a safe and effective treatment not only for patients who are refractory to conservative measures but also to provide a prompter resolution early in the course of the illness. Numerous active interventions have been reported to be useful for ACPO, including medications such as neostigmine,<sup>12</sup> colonoscopy with or without placement of a decompression tube,<sup>31–33</sup> diatrizoate meglumine (Gastrografin [Bracco Diagnostics Inc., Monroe Township, NJ]) enema,<sup>33</sup> radiologic procedures such as placement of a colonic decompression tube,<sup>11</sup> cecostomy (surgical, endoscopic, or radiologic), and surgical resection of part of the colon (mainly reserved for cases of perforation or significant ischemic necrosis).

### Medical Therapy

Medications that stimulate colon motility have become the key part of active therapy. The most promising medication so far for treatment of ACPO is neostigmine, an inhibitor of acetylcholinesterase. Neostigmine causes a transient but significant increase in acetylcholine concentration, resulting in a pronounced increase in cholinergic stimulus throughout the body, including in the colon wall at the synapses between the gut wall nerves and the gut smooth muscle. The leading theory about the pathogenesis of ACPO is that there is an autonomic imbalance, with an increase in sympathetic tone and a decrease in the parasympathetic stimulus of the colon. Both these changes are thought to have a negative impact on colon motility. This theory led to studies of drugs that either decrease sympathetic tone or increase parasympathetic tone as a means to restore colon function.

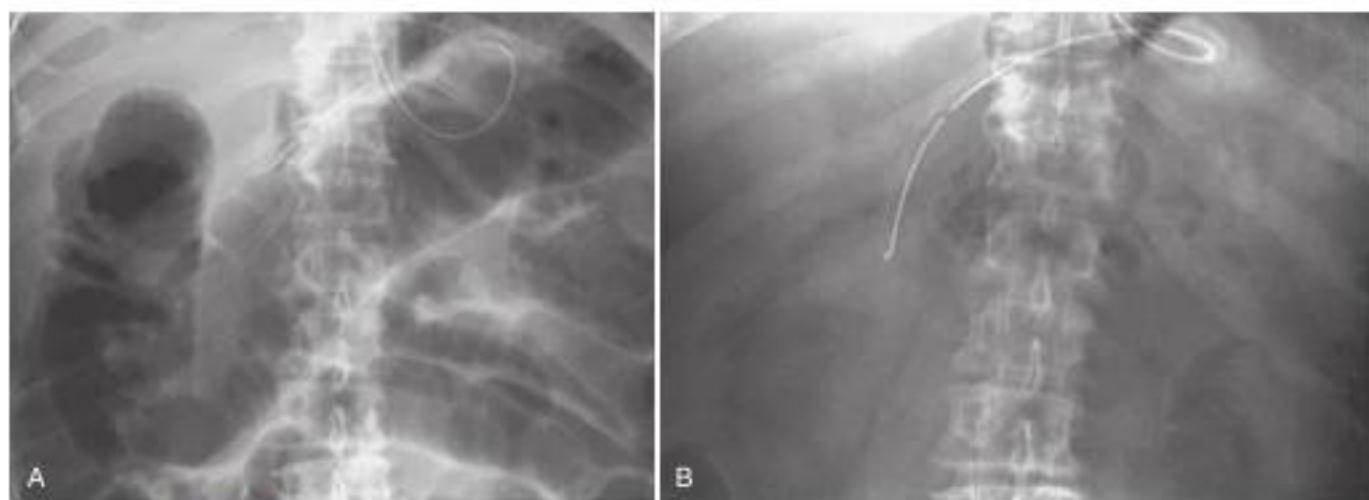

In the 1960s, Neely and Catchpole (1971)<sup>34</sup> studied the effects of guanethidine (a sympathetic antagonist) and neostigmine (Prostigmin [Abbott Bioresearch Center, Worcester, MA], a cholinergic drug) on small bowel motility and found that these medications seemed to restore peristalsis. In 1992, Hutchinson and Griffiths<sup>35</sup> treated 11 ACPO patients first with guanethidine and then with neostigmine. They found that 8 of 11 patients had prompt return of bowel motility but only after the neostigmine infusion. In 1995, Stephenson and coworkers<sup>14</sup> presented results from a study showing that 11 of 12 ACPO patients treated with 2.5 mg of IV neostigmine had prompt resolution of their condition. These observations were confirmed by subsequent studies, including prompt clinical resolution in 75% of ACPO cases as presented by Turegano-Fuentes and coworkers<sup>37</sup> in 1997 and in 26 of 28 cases treated by Trevisani and colleagues,<sup>38</sup> whose results were published in 2000. Physiologic studies with neostigmine indicate that its indirect effect on muscarinic receptors in the bowel wall, which are presumably mediated through increased local acetylcholine concentrations, results in

increased colonic tone and increased coordinated colonic propulsion.<sup>39</sup>

Because ACPO often resolves with conservative therapy alone, controlled trials of neostigmine and other therapies are important. The first prospective randomized controlled trial on the use of IV neostigmine included 21 patients with ACPO (refractory to at least 24 hours of conservative measures and with a cecal diameter > 10 cm) who were randomly assigned to receive a 3-minute IV infusion of either 2.0 mg of neostigmine or saline administered by a physician blinded to the treatment allocation.<sup>12</sup> The endpoints included immediate passage of flatus and stool; the amount of decrease in the measured abdominal girth; and the change in the diameters of the cecum, ascending, and transverse colon on abdominal x-ray films obtained 3 hours later (Fig. 35.2). Of the 11 patients randomly assigned to neostigmine, 10 had prompt resolution with substantial responses in all the measured endpoints. The one nonresponder subsequently had a response when an open-label neostigmine dose was given 3 hours later. The median time to passage of flatus was 4 minutes (range 3–30 minutes). None of the patients given placebo responded, despite the continuation of conservative measures in all patients. Seven patients from the placebo group were subsequently treated with open-label neostigmine 3 hours later, and all had a prompt response. Since this publication, several uncontrolled studies and case reports have also reported similar results, with approximately 80% to 90% of patients usually showing a prompt response to the drug. Different doses have been used, ranging from 1 mg to 2.5 mg, either by slow IV push or by IV infusion for instance, over 30 minutes. A similar number of patients exhibited a sustained response after a single dose of neostigmine in these other studies as well, usually approximately 60% to 70%.<sup>40–42</sup> Some studies have shown success with repeated doses of the drug for patients with partial responses and recurrences, with the number of patients experiencing a sustained response increasing to the 80% to 90% range.<sup>43</sup> See Table 35.2 for a summary of the evidence for the use of neostigmine for ACPO.<sup>12,40,42</sup>

Factors that predict response to neostigmine have been examined. One retrospective review showed an 89% initial response and a 61% sustained response to a single dose of neostigmine. The authors found that narcotic medication use decreased not only the spontaneous resolution rate but also the response rate to neostigmine. Ambulatory patients had higher response rates as well. Interestingly, colon diameter and the duration of ACPO before treatment did not influence response rate.<sup>44</sup> Another prospective study enrolled 27 patients and found that electrolyte abnormalities and the use of antimotility drugs were associated with decreased response to neostigmine.<sup>44</sup>

Side effects of neostigmine include abdominal pain, nausea, vomiting, sweating, excess salivation, bronchospasm, and symptomatic bradycardia. Patients at risk for bradycardia, such as patients with preexisting bradyarrhythmias and patients receiving  $\beta$ -blockers, are at potentially higher risk of complications from neostigmine, as are patients with severe bronchospasm. Some caution in patient selection is needed. Nonetheless, neostigmine can be used in most patients with ACPO when proper monitoring and precautions are in place. Patients should be kept supine on a pad or bedpan for the first 30 minutes after neostigmine administration, and should be monitored by continuous electrocardiogram and frequent, intermittent blood pressure measurements. Transient bradycardia can occur but usually resolves quickly without treatment because of the short half-life of

**FIG 35.2** **A**, Dilated transverse colon and hepatic flexure in a patient with acute colonic pseudo-obstruction. A nasogastric tube is present in the stomach. **B**, Colonic gas is no longer present 3 hours after administration of neostigmine. The nasogastric tube remains in place. neostigmine. Atropine should be immediately available but should be given only if bradycardia is severe, prolonged, or associated with significant hypotension or persistent symptoms. Although neostigmine is partly cleared by plasma cholinesterase, approximately one-half of the clearance occurs in the kidneys; patients with renal failure have a prolonged half-life of neostigmine. In anephric patients, the elimination half-life is approximately 180 minutes, compared with 80 minutes in patients with normal renal function.<sup>20</sup>

Administration of glycopyrrolate, a selective anticholinergic agent, has been proposed as a way to decrease neostigmine side effects like bradycardia and bronchoconstriction. Because it has less effect on the bowel, glycopyrrolate might not interfere with the stimulatory effect of neostigmine in restoring colonic contraction. Although there has not been an organized study on this combined neostigmine/glycopyrrolate administration specifically in patients with ACPO, one controlled study in spinal cord injury patients showed that the combination was as effective as neostigmine alone in prompting colon evacuation. In addition, bradycardia and bronchoconstriction were not seen when the drugs were given together.<sup>21</sup> Because it seems to be rapidly effective in most patients with ACPO and has a low side effect profile

compared with other active therapies, such as colonoscopy or surgery, neostigmine appears early in the suggested treatment algorithm (see Fig. 35.1).<sup>3,7,12</sup> Although mainly studied in adult patients, there have been case reports of successful use in pediatric patients as well.<sup>22,23,24</sup> Most studies indicate that, as long as conservative measures are continued, the recurrence rate of ACPO after neostigmine is low.<sup>12</sup> Nonetheless, repeat doses can be tried in case of recurrence before resorting to more invasive techniques. Because the elimination half-life is 80 minutes, retreatment is not advisable at intervals less than every 3 hours.

Because there is the issue of recurrence of colonic distension after neostigmine, as well as after colonoscopic decompression, efforts have been made to reduce recurrence. One controlled study showed that, after successful decompression with either neostigmine or colonoscopy (with decompression tube placement), the administration of polyethylene glycol solution (PEG) twice daily (orally or per NG mixed with water) for 7 days reduced the recurrence rate for colonic distension (0/15 in PEG group vs. 5/15 in placebo group).<sup>25</sup>

Slower infusion of neostigmine has been proposed for ACPO. Neostigmine drip over 24 hours at 0.4 to 0.8 mg/hr has been shown to be very effective in critically ill intensive care unit

patients with ileus and ACPO. Eleven out of thirteen patients in the neostigmine group recovered bowel motility and passed stools, whereas none of the eleven in the placebo group did. Interestingly, these authors did not observe the neostigmine side effects of bradycardia or bronchospasm.<sup>70</sup> Others have also shown success in treating patients who were refractory to bolus neostigmine by giving slow infusion of neostigmine at 0.4 mg/hr. There were few side effects.<sup>71</sup>

Although oral neostigmine is not recommended, a long-acting oral acetyl cholinesterase inhibitor, pyridostigmine, has been tested in patients with ACPO. Seven patients with refractory ACPO that recurred after neostigmine treatment and colonic decompression were given pyridostigmine 10–30 mg PO twice daily. All seven had successful resolution of ACPO.<sup>72</sup>

Other medical therapies have been reported, including prokinetic drugs such as metoclopramide,<sup>73</sup> erythromycin,<sup>70,74</sup> and cisapride.<sup>75</sup> Most of these reports have been anecdotal, involving only one or two patients. Published reports on the use of metoclopramide have been disappointing. Some reports have questioned the wisdom of applying a prokinetic such as metoclopramide out of concern that its main stimulus is on emptying the upper gut; this theoretically may deliver even more gas to the colon without adequate stimulus of the colon itself, and worsen the distention there. As the use of opioid medications has been associated with ACPO, and also with failure to respond to conservative and neostigmine therapy, there may theoretically be some benefit to the use of peripheral  $\mu$ -opioid receptor blockers like methylnaltrexone. There are case reports of the successful use of methylnaltrexone in ACPO.<sup>71,76</sup> However, the results from studies on the use of this and other peripheral  $\mu$ -opioid receptor antagonists like alvimopan have been quite mixed.<sup>71,75,76</sup> Additionally, case reports have described some success with 5-HT<sub>4</sub> receptor agonists like prucalopride and tegaserod, but more study is needed.<sup>77,78</sup>

### Colonoscopy

Colonoscopy is useful in treating ACPO in many ways. First, it is used to suction extra gas and decompress the colon directly. Colonoscopy is also used to rule out mechanical obstruction and to check for signs of colonic mucosal ischemia and necrosis. Lastly, it can be used to place a guidewire into the proximal colon, over which a decompression tube can be placed. The reported rate of intubation proximal to the hepatic flexure in the setting of ACPO is at least 70%.<sup>3</sup>

Although there are no randomized controlled trials proving its efficacy, colonoscopic decompression has been central in the treatment of ACPO patients who fail conservative and pharmacologic measures. Its successful use was first reported in 1977 by Kukor and Dent.<sup>8</sup> Since then, numerous uncontrolled studies have reported initial clinical success with colonoscopy in approximately 70% of cases.<sup>8,9,13</sup> Nonetheless, a high recurrence rate of 40% may lead to the need for repeated colonoscopies (sometimes two or more additional procedures) to maintain the response.<sup>13,51,89</sup> Several authors have reported a lower recurrence rate if a decompression tube is left in place, especially if it is proximal to the hepatic flexure.<sup>32</sup> One institution compared the recurrence rate in patients who received colonoscopy with decompression tube placement with historical controls who received colonoscopy alone, and found recurrence rates of 0% versus 45%, respectively.<sup>25</sup> Some authors have criticized uncontrolled studies on colonoscopic decompression because they do not include control groups that receive conservative therapy alone (which may have differed over

time) and have a referral bias, in that they only involve patients who were specifically referred for the purpose of colonoscopic decompression.<sup>3,24</sup>

The potential benefits of colonoscopy with respect to diagnosis and therapy need to be weighed against the risks of the procedure. The risk of further inflating and stretching an already dilated and unprepared colon leads many to suggest that colonoscopy should not be used up front as a diagnostic tool, especially as there are safer diagnostic alternatives like CT scan.<sup>48,49</sup> As a therapeutic maneuver, colonoscopy has more acceptance, but is still considered a high risk procedure with uncertain outcome that often needs to be repeated due to recurrence of ACPO, clogging, or dislodgement of the decompression tube, if one is placed.<sup>3</sup> A summary of the expert consensus on several aspects of therapeutic colonoscopy for ACPO follows.<sup>50</sup> Colonoscopy in ACPO patients is technically difficult (performed in the unprepared colon of seriously ill patients) and carries an increased perforation risk of approximately 3%.<sup>50,54</sup> It should be performed only by expert endoscopists. A gentle tap water enema can be given first, but is usually not needed because the stool remaining in the colon is usually already liquefied. In addition, enemas may increase the risk of perforation in patients with ACPO. During colonoscopy, air insufflation must be kept to a minimum. Use of carbon dioxide is preferable because it can be absorbed. As each new dilated segment is entered with the colonoscope, it should be suctioned and decompressed. The mucosa should be washed periodically to examine for ischemic changes, including duskeness to frank cyanosis, mucosal hemorrhage, and ulceration. Cecal intubation is desirable but not critical. One should try to advance the colonoscope at least to the hepatic flexure. Fluoroscopy is useful for helping determine the position of the colonoscope tip and for placement of a decompression tube, and should be used regularly.

Traditionally, it has been recommended that, if mucosal ischemia is found, the colonoscope should be withdrawn, and the patient should be sent for urgent surgical resection, usually of the right colon, which is usually the area that is most severely affected. However, successful treatment with conservative measures and tube decompression has been reported even in patients with endoscopic evidence of ischemia without necrosis (e.g., deep ulceration, exudate, black mucosa).<sup>50</sup> Thus, colonoscopic decompression can still be tried as the primary therapy when the mucosal appearance noticeably improves promptly with decompression, or if the changes seen indicate that there is still intact colon wall (erythema, mucosal hemorrhage, and scant shallow ulceration only).

A tube for decompression should be placed at the initial colonoscopy, if possible. This can be a frustrating endeavor, and even with excellent technique and fluoroscopic guidance, there is a tendency for the decompression tube to migrate distally in the colon either during placement, when the guidewire is pulled back, or in the 24 hours after placement. Various techniques have been described. The most popular and most effective to date is the placement of a guidewire through the colonoscope when the colonoscope tip is in the cecum or at least proximal to the hepatic flexure. The colonoscope is withdrawn over the wire, and the wire is used to guide a decompression tube into position. Fluoroscopy should be used to confirm that the colonoscope is in a straight or a "question mark" configuration without looping prior to placement of the guidewire, and to assure that the guidewire remains in a nonlooped configuration during withdrawal of the colonoscope and subsequent passage of the

decompression tube. A final position of the tube with the tip proximal to the splenic flexure can be satisfactory. Commercially available decompression kits use a 0.035-inch wire, an inner stiffening catheter, and outer drainage catheters that range from 7-Fr to 14-Fr in diameter. Other authors suggest using stiffer wires and larger tubes, such as a modified 18-Fr Levin or an NG tube. The tube is taped securely to the buttock, placed on low intermittent suction, and flushed with water (50–150 mL) at least every 6 hours to decrease clogging. Endoscopic treatment of ACPO was reviewed by Saunders in 2007,<sup>13</sup> and was also outlined in 2010 in the ASGE practice guideline.<sup>14</sup>

Daily abdominal x-ray films should be performed. The diameter of the cecum, ascending colon, and transverse colon should be tracked, and one should be vigilant for signs of pneumatosis and free intraperitoneal air. Although there is sometimes a dramatic decrease in colonic dilatation immediately after decompression, more commonly the colonic dilatation decreases gradually (Fig. 35.3). One study showed that the mean change in cecal diameter 4 hours and 1 day after colonoscopic decompression was only approximately 2 cm.<sup>15</sup> Thus, patience is advised, as long as the patient is clinically improving and the tube is in good position and flushes easily.

One report describes an alternative method for advancing a transanal decompression tube into the proximal colon using a steerable tricomponent coaxial catheter under fluoroscopic guidance.<sup>16</sup> Successful placement proximal to the hepatic flexure and decompression were seen in four consecutive patients. Percutaneous endoscopic cecostomy<sup>17</sup> can be performed in patients with refractory or recurring colonic distention, so long as there are no signs of ischemic necrosis. The technique is

virtually identical to the placement of a percutaneous endoscopic gastrostomy. Acute and delayed complications, including perforation, abscess, and peritonitis, are reported to be an issue with percutaneous cecostomy.<sup>18,19,20</sup>

### Surgery

Surgery is reserved for patients with ACPO who fail medical and colonoscopic therapy, or for patients with advanced ischemia or evidence of colonic perforation. Retrospective studies have shown that surgery is associated with higher morbidity and mortality than other therapies. This finding probably reflects the fact that the patients selected for surgery had more severe ACPO and more serious underlying conditions, although the extra morbidity of general anesthesia and an abdominal operation in such patients undoubtedly also has a significant impact.

For patients without peritoneal signs or evidence of perforation or severe ischemic bowel, tube cecostomy is advocated. Cecostomy has a high success rate in terms of decompression of the right colon.

For patients with peritoneal signs, a more extensive exploration is recommended, with the surgical findings guiding the type of intervention.<sup>21</sup> If, at surgery, a viable cecum is found, a tube cecostomy can still be performed. However, if there is significant ischemia or perforation, then colonic resection is advised, with the decision whether to do a primary anastomosis versus an ileostomy and mucous fistula depending on the patient's condition and the degree of peritoneal contamination.

In addition to the more traditional open surgical approach and placement of a Foley catheter or similar drain into the cecum, there are other variations on the technique. One is to perform

**FIG 35.3** **A**, Plain abdominal radiograph from a patient with acute colonic pseudo-obstruction. **B**, Radiograph after colonoscopy and placement of a 14-Fr colonic decompression tube reveals a significant reduction in colonic gas. (From Nietsch H, Kimmey MB: Acute colonic pseudo-obstruction. In Waye J, Rex DK, Williams CB, editors: *Colonoscopy: principles and practice*, London, 2004, Blackwell Science, pp 596–602.)

laparoscopy first to check cecal viability, and then to use the laparoscope to help place a cecostomy tube. T-fasteners are used to hold the cecal wall up against the abdominal wall.<sup>44</sup>

Other methods of placing cecal tubes have been reported.<sup>45</sup> Radiologic methods have used fluoroscopy or CT scan to guide placement of T-fasteners and drainage tubes in the cecum.<sup>46,47,48</sup> Most authors argue that, given the availability and effectiveness of neostigmine and colonoscopy, surgery should be reserved for patients who have signs of perforation or peritonitis. Surgery for decompression in "refractory" cases should be infrequent.<sup>42,48,49</sup>

## FUTURE TRENDS

The major challenge in assessing therapies for ACPO is that it is an uncommon condition that most often occurs in seriously ill hospitalized patients. It causes perforation in approximately 3% of patients, with up to 50% mortality if this occurs. Thus, prospective controlled studies designed to demonstrate a difference in hard endpoints such as perforation and death are not likely to be forthcoming. However, controlled trials that track intermediate endpoints such as colon diameter and clinical resolution of the distention are possible. Since the first randomized controlled trial was performed using neostigmine, there have been a number of other trials, mostly retrospective and uncontrolled, that confirmed that the initial and sustained success for neostigmine is approximately 80% to 90%, and that it is often useful in recurrences. In addition, there is evidence that PEG solutions are helpful in preventing recurrences after initial success with conservative measures, neostigmine, or colonoscopy.

Most cases of ACPO resolve with conservative therapy, but the time to resolution can be many days, making spontaneous resolution still a significantly morbid event. Emphasis should be placed on finding therapies that speed resolution safely and with minimal dependence on invasive procedures. A 2012 review concluded that neostigmine certainly speeds resolution of ACPO.<sup>47</sup>

Because ACPO can occur as the result of nearly any severe medical condition or any surgery, it is hard to imagine how to prevent it completely. Nonetheless, certain situations are especially associated with ACPO, such as severe trauma, major orthopedic procedures, and pelvic surgeries. Although this has not been systematically studied, it is logical to hypothesize that early, prophylactic application of some of the measures described in the sections on conservative and medication therapy might prevent some cases.

Medication is likely to be the biggest area of future research in ACPO. Although it already has a good track record, neostigmine has its limitations. It is relatively contraindicated in patients with certain cardiac and pulmonary conditions, and a significant minority of ACPO patients do not respond to it or experience recurrence after an initial response. As has been reviewed in this chapter, there may be ways to address these limitations. One is to infuse neostigmine more slowly, such as over 30 minutes, or even as a 24-hour infusion at 0.4–0.8 mg/hr. Another is to pretreat with glycopyrrolate, which has been shown to block the cardiac and respiratory side effects without much impact on neostigmine's effect on the bowel.<sup>100</sup> Whether this combination will be as successful as neostigmine alone remains to be proven. For recurrent or refractory ACPO, oral pyridostigmine or 24-hour infusion of neostigmine have both shown promise, but confirmatory studies are needed.

Safer prokinetic agents could be applied earlier and more liberally. These could include  $\mu$ -opioid receptor antagonists and

5-HT<sub>4</sub> receptor agonists to restart bowel motility. These could be helpful as preventive treatment in high-risk patients (like certain surgical and trauma cases), in initial medical therapy, and also to prevent recurrences. So far, none of these "safer" agents have come anywhere close to the effectiveness of neostigmine, but hopefully there will be more research on them in the future.

Lastly, although colonoscopy already has a high success rate, improvements in minimally invasive endoscopic techniques would be of further benefit, such as better decompression tubes.

Nevertheless, it is important to remember that, despite all the research on new therapies, three out of four patients do resolve with standard conservative measures, as outlined in this chapter. For the one in four that does not respond, we are fortunate to have a treatment algorithm that works for most cases. Additionally, there is hope that, in the future, with more study and further improvements to this algorithm, ACPO will usually be corrected promptly, greatly decreasing its morbidity and mortality.

## INTRODUCTION

Colorectal cancer (CRC) is a global public health threat. The lifetime risks of an individual developing or dying from CRC are approximately 5% and 2.5%, respectively; worldwide, there are an estimated 1.4 million new cases and 700,000 deaths annually.<sup>1</sup> In the United States, approximately 135,000 new cases and 49,200 deaths were estimated to occur in 2016.<sup>2</sup>

The fundamental aim of screening for CRC is to decrease CRC risk, as well as mortality, which is related directly to disease stage at diagnosis. Patients with early-stage disease are usually asymptomatic and have high 5-year survival rates; therefore, the key to timely diagnosis is the identification of at-risk patients before symptoms occur. CRC is an eminently "screenable" cancer: the disease is common and generally has a long latency period, early detection can decrease mortality, effective screening methods are available, resources are available to provide screening and to provide diagnostic tests for those with positive screening results, screening is cost-effective, and screening modalities are accepted by patients and health care providers. Population-based studies show that screening can decrease the incidence of and mortality from CRC. In the United States, there has been a steady decline in the overall incidence of CRC in individuals 50 years or older since 1985, a trend that has been partly attributed to screening.<sup>3,4</sup> Beyond early detection, a unique attribute of CRC is that it is amenable to primary prevention (Fig. 36.1) via the detection and removal of precancerous polyps.

Several different strategies for CRC screening exist, each with advantages and limitations pertaining to effectiveness, risk, cost, and availability. Some countries, such as the United States, Germany, and Poland, have well-established colonoscopy-based screening programs, whereas others utilize fecal tests and sigmoidoscopy as "gateway" tests and refer patients with positive results to colonoscopy. Modern screening strategies emphasize

the importance of prevention and risk stratification, grouping patients into average- and high-risk categories.<sup>5</sup> The final common pathway for all screening programs is colonoscopy; hence, the effectiveness of screening depends heavily on the availability of high-quality colonoscopy.

This chapter will provide an overview of CRC epidemiology and present screening and surveillance approaches for average-risk and high-risk individuals.

## EPIDEMIOLOGY

### Global Perspective

The incidence of CRC varies around the world, with the highest rates reported in industrialized Western countries. Conversely, the rates are lowest in India and Africa.<sup>1</sup> Migrant studies show relatively rapid rises in incidence in immigrant groups, usually matching host country rates within two generations. These observations highlight the importance of environmental, lifestyle, and dietary factors in the pathogenesis of CRC.

### Demographic Factors

Age is the single most important risk factor for CRC. The incidence increases gradually with age, and increases exponentially after the age of 50 (Table 36.1).<sup>2</sup> Nearly 95% of cases are diagnosed after age 50, providing a strong rationale for the recommendation to start screening at 50 for most average-risk individuals. Although men have higher age-adjusted CRC incidence and mortality, the cumulative lifetime risk of CRC is similar for men and women (4.7% and 4.4%, respectively). Race and ethnicity are also important risk factors (Table 36.2). African Americans have the highest incidence and mortality rates among all racial groups in the United States,<sup>2</sup> but uncertainty remains regarding whether this is due primarily to biological differences, lifestyle factors, or disparities in access to health care. A family history of CRC

**Abstract**

Colorectal cancer (CRC) is a global public health threat. The lifetime risks of an individual developing or dying from CRC are approximately 5% and 2.5%, respectively; worldwide, there are an estimated 1.4 million new cases and 700,000 deaths annually. The fundamental aim of screening for CRC is to decrease CRC risk and mortality. CRC is amenable to screening and is a largely preventable cancer, through the detection and removal of precancerous polyps. Several different strategies for CRC screening exist, each with advantages and limitations pertaining to effectiveness, risk, cost, and availability. Modern screening strategies emphasize the importance of prevention and risk stratification, grouping patients into average- and high-risk categories. The final common pathway for all screening programs is colonoscopy; hence, the effectiveness of screening depends heavily on the availability of high-quality colonoscopy. This chapter will provide an overview of CRC epidemiology, and present screening and surveillance approaches in average-risk and high-risk individuals.

TABLE 36.1 Probability (%) of Colorectal Cancer by Age and Sex

	Male	Female
< 49 yr	0.3 (1 in 300)	0.3 (1 in 318)
50–59 yr	0.7 (1 in 149)	0.5 (1 in 195)
60–69 yr	1.2 (1 in 82)	0.9 (1 in 117)
≥ 70 yr	3.7 (1 in 27)	3.4 (1 in 30)
Lifetime	4.7 (1 in 21)	4.4 (1 in 23)

Data from Siegel RL, Miller KD, Jemal A: Cancer statistics, 2016. CA Cancer J Clin 66(1):7–30, 2016.

TABLE 36.2 Incidence and Mortality of Colorectal Cancer by Race and Ethnicity

Race	INCIDENCE		MORTALITY	
	Male	Female	Male	Female
White	47.4	36.2	18.2	12.9
Black	60.3	44.1	27.6	18.2
Asian	39.0	29.2	13.0	9.4
American Indian	50.4	40.1	18.8	15.6
Hispanic	44.6	30.6	15.6	9.6

Rates are per 100,000 population and are age-adjusted to the 2000 United States standard population.

Data from Siegel RL, Miller KD, Jemal A: Cancer statistics, 2016. CA Cancer J Clin 66(1):7–30, 2016.

is present in approximately 20% of CRC cases.<sup>5</sup> A systematic review of lifetime risk associated with familial CRC found that the relative risk of CRC was 2.3 with an affected first-degree relative, 3.9 if the relative was diagnosed before age 45, and 4.2 if more than one relative was affected.<sup>6</sup> The effect of family history on risk of CRC decreases with age, and some analyses report that the risk is mildly increased if there is a second- or third-degree relative with CRC.<sup>6</sup> A family history of adenomatous polyps before the age of 60 has also been reported to increase CRC risk, but this may only be true if the index family member had advanced adenomas.<sup>7</sup>

### Modifiable Risk Factors

It is estimated that two-thirds of the risk for CRC may be attributable to potentially modifiable environmental factors. There is considerable evidence linking cigarette smoking, obesity, metabolic syndrome, low levels of physical activity, and heavy

alcohol consumption with increased CRC risk.<sup>8</sup> Diets that are high in fat and red meat and low in fiber have also been linked to CRC development. Conversely, there is strong evidence showing that individuals who use nonsteroidal antiinflammatory drugs (NSAIDs) and aspirin have a lower risk of developing colon adenomas and CRC. In addition, calcium supplementation and postmenopausal hormone replacement therapy have been associated with decreased CRC risk. It is important to emphasize that these medications are associated with adverse effects, and universal CRC chemoprevention is not recommended in lieu of screening in average-risk individuals. However, the United States Preventive Services Task Force (USPSTF) recently issued a Grade B recommendation to initiate low-dose aspirin use for the primary prevention of cardiovascular disease (CVD) and CRC in adults aged 50 to 59 years<sup>10</sup> who have a 10% or greater 10-year CVD risk, are not at increased bleeding risk, have at least a 10-year life expectancy, and are committed to taking low-dose aspirin daily for at least 10 years.

### PATHOGENESIS

CRC is a heterogeneous disease with regards to tumor development, and each CRC is characterized by a unique molecular profile. Until recently, conventional adenomas were thought to be the only major CRC precursor, with the Fearon-Vogelstein model<sup>11</sup> describing a sequence of progressive molecular alterations leading from adenoma to carcinoma. It is currently recognized that there are three major pathways to colorectal carcinogenesis: the chromosomal instability (CIN) pathway, the microsatellite instability (MSI) pathway, and the serrated neoplasia pathway. It is important to know that these pathways are not mutually exclusive, but the understanding that there are three main pathways has changed the CRC pathogenesis paradigm and impacted approaches to screening and surveillance.

CIN accounts for approximately 60%–70% of all CRCs, and is initiated by mutation of the adenomatous polyposis coli (APC) gene. Subsequent mutations in KRAS and p53 are involved in the progression of an adenoma to advanced adenoma and cancer. CRCs arising along the CIN pathway are typically microsatellite stable and have low level of CpG island methylation. The CIN pathway is thought to take approximately 10 to 15 years from adenoma to CRC.

The MSI pathway is also adenoma-based, and approximately 15% of all CRCs demonstrate MSI. Some of these cancers arise from germline mutations in the mismatch repair (MMR) genes (Lynch syndrome). The majority, however, are associated with epigenetic hypermethylation of the MLH1 MMR gene, which is also one of the molecular events in the serrated neoplasia pathway. Progression to cancer along the MSI pathway is accelerated compared to CIN, taking 3 to 5 years.

The serrated neoplasia pathway is increasingly recognized as an important contributor to CRC. The molecular hallmark is hypermethylation of the promoter CpG island, and the precursor lesion is the sessile serrated polyp (SSP), which can conceptually be thought of as an adenoma equivalent. Hypermethylation is an epigenetic phenomenon, as it alters gene expression without affecting the genetic sequence.<sup>12–15</sup> Tumors that exhibit hypermethylation can be classified as CpG island methylator phenotype (CIMP) high or low. The presence of CIMP is strongly linked with mutations in the oncogene BRAF, which have been observed even in diminutive serrated aberrant crypt foci.<sup>16,17</sup> MLH1 hypermethylation with subsequent microsatellite instability leads to

**TABLE 36.3 Screening in Patients at Increased or High Risk for Colorectal Cancer**

Persons at High Risk	Start Time	Recommended Strategy
FAP	Age 10–12 years	Annual sigmoidoscopy and counseling to consider genetic testing for APC mutations. Colectomy should be considered if FAP is confirmed by genetic testing.
Lynch syndrome	Age 20 to 25 years or 10 years before the youngest case in the immediate family	Colonoscopy every 1–2 years. Genetic counseling to consider testing for MMR mutations. Screening for extracolonic cancers.
Chronic ulcerative colitis or Crohn's colitis	8 years after the onset of pancolitis or 12–15 years after the onset of left-sided colitis	Colonoscopy every 1–2 years. Screening for dysplasia using chromoendoscopy with targeted biopsies, or random biopsies.
<b>Persons at Increased Risk</b>		
CRC or adenomatous polyps in a first-degree relative ≥ 60 years or in two second-degree relatives with CRC	Age 40 years	Intervals as per average-risk screening recommendations.
CRC or adenomatous polyps in a first-degree relative before 60 years or in two or more first-degree relatives at any age	Age 40 years, or 10 years before the youngest case in the family	Colonoscopy every 5 years.
Personal history of resected CRC		High-quality perioperative clearing, followed by colonoscopy 1 year after resection. If negative, repeat in 3 years. If 3-year examination is negative, repeat in 5 years and at 5-year intervals thereafter. Local surveillance can be considered for rectal cancer resected without total mesorectal excision.
One or two small tubular adenomas		Colonoscopy after 5–10 years.
Three to ten adenomas or one adenoma ≥ 1 cm or any adenoma with vilous features or high-grade dysplasia		Colonoscopy after 3 years.
More than 10 adenomas		Colonoscopy after < 3 years.
Piecemeal resection of sessile adenoma		Colonoscopy after 2–6 months.

APC, adenomatous polyposis coli; CRC, colorectal cancer; FAP, familial adenomatous polyposis; MMR, mismatch repair gene.

the development of cytological dysplasia within the SSP and accelerates the progression to CIMP high CRC.<sup>18,19</sup> Available evidence suggests that the progression time for the serrated neoplasia pathway is comparable to that of the CIN pathway, although an aggressive course has been observed when MLH1 is inactivated.

## SCREENING STRATEGIES: GENERAL APPROACH

As previously discussed, cancer screening is traditionally focused on the detection of early asymptomatic disease (secondary prevention). However, because most CRCs develop from precursor polyps, there is an opportunity for primary prevention via the detection and removal of polyps. The most recent US guidelines distinguish between tests designed for cancer detection and those designed for cancer prevention.<sup>5</sup> The "ideal" screening strategy has not been defined, as screening decisions often depend on resource availability, variation between and within countries, and patient and provider preference. The mainstay tests for early cancer detection are the fecal tests; these are most effective in programmatic approaches (the test is repeated at regular intervals, and there is high patient compliance) and when colonoscopy resources are available to investigate positive tests. The main modality for cancer prevention is colonoscopy because it alone can provide the benefit of polyp detection and polypectomy in one examination. In any context, it is critical that providers

recognize higher risk situations, as such patients require more intensive screening (Table 36.3). This includes patients with a personal history of CRC or adenomatous polyps, a personal history of inflammatory bowel disease (ulcerative colitis or Crohn's disease), a strong family history of CRC or polyps, or a known family history of a hereditary CRC syndrome such as familial adenomatous polyposis or Lynch syndrome. Average-risk patients, who contribute the largest proportion of CRC cases, can be offered the screening modalities and testing intervals discussed in subsequent sections (Table 36.4).

Several groups have issued CRC screening guidelines, with differing recommendations regarding preferred strategies (Table 36.5). In general, however, the guidelines agree that CRC screening is indicated starting at the age of 50 in average-risk individuals, and should be part of a programmatic structure that ensures that tests are repeated at recommended intervals and that positive tests are followed up appropriately.

## SCREENING IN AVERAGE-RISK INDIVIDUALS

### Stool-Based Colorectal Cancer Screening Tests

Randomized controlled trials (RCTs) have shown that, among patients who undergo screening with fecal occult blood testing (FOBT) compared to unscreened controls, cancers are discovered at an earlier stage, and mortality is reduced by 15% to 33%.<sup>21–24</sup> In the 30-year follow-up study of the Minnesota FOBT trial,

**TABLE 36.4 Screening Modalities (ACS-MSTF-ACR Guidelines)**

Test	Interval	Key Points
<b>Tests for Early CRC Detection</b>		
High-sensitivity gFOBT	Annual	2-3 samples at home; Positive test requires colonoscopy
FIT	Annual	Needs to be programmatic Positive test requires colonoscopy
Stool DNA	Every 3 years	Collection more challenging (packing, preservatives) Higher cost Positive test requires colonoscopy
<b>Tests for CRC Prevention</b>		
FSIG	Every 5 years	Bowel preparation More discomfort (no sedation) Limited protection Positive test requires colonoscopy
Colonoscopy	Every 10 years	Complete bowel prep Sedation is usually used Higher risk (bleeding, perforation); risks are rare and associated with polypectomy
DCBE	Every 5 years	Complete bowel preparation More discomfort (no sedation) Falling out of favor Option if incomplete colonoscopy and no CTC
CTC	Every 5 years	Complete bowel preparation Polyps ≥ 6 mm require colonoscopy Polyps < 5 mm not reported Extracolonic abnormalities

ACR, American College of Radiology; ACS, American Cancer Society; CTC, colorectal cancer; DCBE, double contrast barium enema; FIT, fecal immunochemical test; FSIG, flexible sigmoidoscopy; gFOBT, guaiac fecal occult blood test; MSTF, Multi-Society Task Force.

Modified from Levin B, Lieberman DA, McFarland B, et al: Screening and surveillance for the early detection of colorectal cancer and adenomatous polyps. 2008: a joint guideline from the American Cancer Society, the US Multi-Society Task Force on Colorectal Cancer, and the American College of Radiology. *Cancer J Clin* 58(3):130-160, 2008.

**TABLE 36.5 Colorectal Cancer Screening Recommendations for Average-Risk Individuals**

Guideline	Recommendation Highlights
USPSTF	Adults aged 50 to 75 years: Screen for CRC starting at age 50 years. Adults aged 76 to 85 years: The decision to screen for CRC is an individual one. Screening tests There are numerous screening tests to detect early-stage colorectal cancer, including stool-based tests (gFOBT, FIT, and FIT-DNA), direct visualization tests (flexible sigmoidoscopy, alone or combined with FIT), colonoscopy, and CT colonography, and serology tests (SEPT9 DNA test). The USPSTF found no head-to-head studies demonstrating that any of these screening strategies are more effective than others, although they have varying levels of evidence supporting their effectiveness, as well as different strengths and limitations. Starting and stopping ages The USPSTF concluded that the evidence best supports a starting age of 50 years for the general population. The age at which the balance of benefits and harms of CRC screening becomes less favorable varies based on a patient's life expectancy, health status, comorbid conditions, and prior screening status. The USPSTF does not recommend routine screening for CRC in adults 86 years and older. The USPSTF concludes with high certainty that the net benefit of screening for CRC is substantial. The USPSTF concludes with moderate certainty that the net benefit of screening for CRC in adults aged 76-85 years who have been previously screened is small. Adults who have never been screened are more likely to benefit. Screening is most appropriate for those healthy enough to undergo treatment and those without comorbid conditions that significantly limit their life expectancy.
ACS-MSTF-ACR	Make a distinction between tests for early CRC detection (fecal tests) and structural tests leading to CRC prevention, with a preference for tests with higher sensitivity that do not require frequent application. The health care provider should inform the patient about the benefits and drawbacks of each option to help decision making.
ACG	Preferred screening/prevention test: Colonoscopy Preferred screening/detection test for patients who decline cancer prevention tests: FIT African Americans: Offer screening starting at age 45.
NCCN	Preferred strategy: Colonoscopy every 10 years. Alternatives: Yearly gFOBT or FIT, or sigmoidoscopy every 5 years with or without annual stool testing.
Canadian Task Force on Preventive Health Care	Adults aged 50 to 74: Either gFOBT or FIT every 2 years or flexible sigmoidoscopy every 10 years. Adults aged ≥ 75: No screening. Colonoscopy not recommended for CRC screening.

ACG, American College of Gastroenterology; ACR, American College of Radiology; ACS, American Cancer Society; CRC, colorectal cancer; FIT, fecal immunochemical test; gFOBT, guaiac fecal occult blood test; MSTF, Multi-Society Task Force; NCCN, National Comprehensive Cancer Network; USPSTF, United States Preventive Services Task Force.

CRC mortality was reduced with annual screening (relative risk [RR] 0.68; 95% confidence interval [CI] 0.56–0.82) and biennial screening (RR 0.78; 95% CI, 0.65–0.93).<sup>25</sup> "Traditional" FOBT involves the use of an alpha-guaiaconic acid–impregnated card and a hydrogen peroxide developing solution.<sup>26</sup> The presence of heme results in a chemical reaction that causes the card to turn a bluish-green color. Three separate samples are needed to maximize sensitivity, and annual testing is recommended.

The newer fecal immunochemical test (FIT) involves the use of labeled antibodies on a card, which bind specifically to human hemoglobin. CRC screening by annual FIT testing has been recommended by the United States Multi-Society Task Force (USMSTF).<sup>27</sup> Erosions or stomach ulcerations due to chronic NSAID or aspirin use do not alter FIT performance because globin (as opposed to heme) is degraded in the small intestine. FITs are typically quantitative but can be designed to indicate a positive test depending upon a prespecified cutoff. A commonly used cutoff is 20 µg hemoglobin (Hgb)/g feces. In one study, at a cutoff of 20 µg Hgb/g feces, the specificity of FIT was 95%. In addition, the FIT had a much higher sensitivity than the FOBT (73.3% vs. 33.3%, respectively).<sup>28</sup> As the FIT uses only a single card and requires no special dietary restrictions, it may be associated with higher patient compliance than the FOBT.<sup>29</sup> Large observational studies examining results from programs using FIT-based screening demonstrated significant reductions in CRC mortality.<sup>30,31</sup>

The FIT has been shown to have a high sensitivity for CRC; approximately 80% in a large meta-analysis.<sup>32</sup> However, the sensitivity of FIT for advanced adenomas (23.8%) is lower than it is for CRC,<sup>33</sup> and test is relatively insensitive for SSPs because these lesions tend to be less vascular than conventional adenomas and thus less prone to bleeding.

Currently, there are four long-term trials comparing the FIT to colonoscopy-based screening (Table 36.6). It is anticipated that these trials will provide important outcome data, including CRC mortality and incidence. Interim results of the Spanish colonoscopy versus fecal immunochemical testing in colorectal-cancer screening (COLONPREV) trial have shown that, likely due to a higher participation rate, the FIT had similar CRC detection rates (30 CRCs; 0.1%) compared to colonoscopy (33 CRCs; 0.1%), whereas colonoscopy had higher rates of advanced adenoma detection than the FIT (1.9% vs. 0.9% respectively,  $p < 0.001$ ). These findings demonstrate the magnitude of the impact that participation rates can have in large CRC screening programs.

A consensus statement for the FIT was recently published by the USMSTF on Colorectal Cancer.<sup>29</sup> The recommendations

provided can be divided into several categories. With regards to the FIT performance, the USMSTF recommends:

- Screening using one sample collected annually
- Use of quantitative tests versus qualitative using a lower cutoff level (20 µg/g or lower)
- Patients should be told that they should not adjust their diet or medications during stool collection for the FIT
- The sample should be a spontaneously passed stool rather than one collected from a digital rectal exam in the office
- There should be no need to adjust handling of the sample based on temperature

The USMSTF also provides recommendations for standards to ensure the quality of a FIT screening program:

- ≥ 60% of those offered testing should complete the process
- < 5% should have samples that cannot be processed by the lab
- ≥ 80% of those with a positive FIT result should have a colonoscopy
- Adenoma detection rate (ADR) targets for colonoscopies done for positive FIT results should be ≥ 45% in men and ≥ 35% in women

The rationale for using fecal DNA (fDNA) for CRC screening is that tumor cells and DNA are shed in the feces of adults with these cancers.<sup>34</sup> An early study examined an fDNA test that was designed to detect CIN abnormalities (*k-ras*, APC, and *p53*), BAT-26 (a measure of MSI), and DIA (DNA Integrity Assay), a marker for dysfunctional apoptosis.<sup>35</sup> However, the sensitivity for CRC was low (51.6%).

Modifications to the fDNA test have included new markers such as the hypermethylated *vimentin* gene, as well as methods to neutralize the effect of bacterial enzymes.<sup>36</sup> A 2014 trial compared the fDNA test to the FIT in nearly 10,000 patients who had a complete screening colonoscopy (n = 9989).<sup>37</sup> The sensitivity for CRC was higher for the fDNA test than for the FIT (92.3% vs. 73.8%). Specifically, the fDNA test detected 60 of a total of 65 cancers, whereas the FIT detected 48. Both tests performed poorly with respect to the detection of advanced neoplastic lesions (fDNA sensitivity: 42.4%, FIT sensitivity: 23.8%); however, the fDNA test outperformed the FIT for the detection of serrated lesions, likely due to its hypermethylation assay.

### Serological Biomarkers

Hypermethylated Septin 9 is a biomarker that has been shown to be present in a high percentage of CRC tissue specimens, as well as in the blood of patients with CRC. The use of a blood test to screen for CRC has several advantages, including no sedation requirement, no bowel preparation requirement, and

**TABLE 36.6 Ongoing Screening Colonoscopy Randomized Controlled Trials**

RCT	Setting	Comparison	Primary Outcome
ColonPrev NCT00906997	Spain	Screening colonoscopy versus biennial FIT	10-year CRC and incidence
NordICC NCT00883792	Sweden, Norway, the Netherlands, Poland	Screening colonoscopy versus no screening	15-year CRC and incidence
CONFIRM (VA-CSP 577) NCT01239082	United States VA system	Screening colonoscopy versus annual FIT	10-year CRC mortality
SREESCO NCT02078804	Sweden	Screening colonoscopy versus 2 RT rounds versus no screening	15-year CRC mortality

CRC, colorectal cancer; FIT, fecal immunochemical test; RCT, randomized controlled trial.

the lack of potential complications arising from the test. Recent studies (2015) have demonstrated that the sensitivity of the Septin 9 blood test for CRC ranges from 51% to 95.6%, and the specificity ranges from 80% to 98.9%.<sup>35</sup> However, the sensitivity for adenomas is much lower (10% in one study).<sup>36</sup> Thus, the septin 9 blood test is not currently recommended as a primary screening modality.

### Tests for Structural Examination of the Colon

#### Sigmoidoscopy

The value of sigmoidoscopy for CRC screening is now supported by RCT evidence showing significant levels of protection against CRC (Table 36.7).<sup>37–40</sup> Sigmoidoscopy effectively protects against distal CRC and is an attractive option, given its cost-effectiveness and lower risk for harm than colonoscopy. The benefit of a one-time sigmoidoscopic examination to decrease the risk of CRC mortality extends beyond 10 years.<sup>41</sup> No RCTs comparing colonoscopy with sigmoidoscopy have been or are likely to be performed in the near future; however, indirect comparisons of results from observational studies suggest that there is a 40% to 60% lower CRC incidence and mortality risk after screening colonoscopy, although risk reduction was statistically significant for deaths from cancer of the proximal colon only.<sup>42</sup> The use of sigmoidoscopy in the United States has been declining, coincident with the rise of screening colonoscopy.

#### Colonoscopy

Colonoscopy has been increasingly used as a CRC screening modality in the United States since the 1990s. Colonoscopy allows direct visualization of the entire colon, it can interrupt the progression of precancerous polyps to cancer by polypectomy, and it allows clinicians to determine appropriate surveillance intervals based on the findings of the index examination. Other advantages include less frequent intervals between examinations and increasing acceptability and tolerability of modern sedation techniques. Average-risk patients with negative screening colonoscopy results have lower CRC incidence on long-term follow-up, extending beyond 10 years.<sup>43,44</sup> Screening colonoscopy was first endorsed by professional societies in 1997<sup>45</sup> and approved for Medicare beneficiaries in 2001. RCTs comparing colonoscopy to other modalities are now underway, but there is a large body of observational literature supporting the effectiveness of screening colonoscopy. A recent (2016) population-based German study showed that cancers detected by screening colonoscopy had a lower stage than those diagnosed by colonoscopy in patients with symptoms; the magnitude of stage shift was comparable

to patients undergoing screening by the FOBT.<sup>46</sup> The National Polyp Study<sup>47</sup> reported a 76% reduction in the incidence of CRC in a cohort of patients with adenomas who underwent colonoscopy and polypectomy compared with a Surveillance, Epidemiology, and End Results reference group, and follow-up revealed a 53% reduction in CRC mortality after a median of nearly 16 years.<sup>48</sup> However, several studies published subsequent to the National Polyp Study have shown lower reduction in CRC incidence after colonoscopy and polypectomy. Important observations can be derived from recent studies. First, although colonoscopy can achieve significant overall levels of protection against CRC, it may not protect against proximal CRC to the same extent as it does against distal CRC (Table 36.8).<sup>49,51–54</sup> Second, and arguably more importantly, the issue of variable protection against CRC appears to be intricately linked to operator-dependent quality factors. The issue of optimal bowel preparation is largely addressable with the adoption and widespread use of split dosing, in which at least half of the preparation is given on the morning of the colonoscopy. Such regimens improve preparation quality, particularly in the right colon.<sup>55</sup> However, most of the limitations of colonoscopy can be accounted for by operator-dependent, and thus potentially reversible, factors. The ADR is now validated as a powerful surrogate marker of colonoscopy performance quality. In a large study based on data from the Polish CRC screening program, Kaminski et al (2010)<sup>56</sup> showed that the risk of interval CRC was 10-fold higher for patients who underwent colonoscopy by operators with an ADR less than 20% compared with those with an ADR 20% or higher. Corley et al (2014)<sup>57</sup> evaluated 314,872 colonoscopies performed by 136 gastroenterologists in the Kaiser Permanente Northern California system and ADRs ranging from 7.4% to 52.5%. Among patients of physicians with ADRs in the highest quintile, as compared with patients of physicians with ADRs in the lowest quintile, the adjusted hazard ratio for any interval cancer was 0.52 (95% CI, 0.39–0.69), for advanced-stage interval cancer, 0.43 (95% CI, 0.29–0.64), and for fatal interval cancer, 0.38 (95% CI, 0.22–0.65). Each 1% increase in the ADR was associated with a 3% decrease in the risk of cancer (hazard ratio, 0.97; 95% CI, 0.96–0.98). The specialty of the colonoscopy provider is associated with quality, with gastroenterologists outperforming other specialists. Variable quality also affects polypectomy. Pohl et al (2013)<sup>58</sup> performed biopsies on the margins of 346 polypectomy sites after apparently complete resection. The incomplete resection rate (as evidenced by residual microscopic neoplastic tissue) was 10% and ranged from 6.5% to 22.7% among different endoscopists. Larger polyp size and SSP histology were predictors of incomplete resection.

**TABLE 36.7 Flexible Sigmoidoscopy Randomized Controlled Trials**

Author (Year)	Setting	Primary Comparison	CRC Incidence (95% CI)	CRC Mortality (95% CI)
Atkin (2010) UK Trial	United Kingdom	Invitation for one-time screening between ages 55 and 64 versus no further contact	HR = 0.77 (0.70–0.84)	HR = 0.69 (0.59–0.82)
Segnan (2011) SCORE	Italy	Invitation for one-time screening between ages 55 and 64 versus no further contact	RR = 0.82 (0.69–0.96)	RR = 0.78 (0.56–1.06)
Schoen (2012) PLCO	United States	Screening between ages 55 and 74 and repeat screening in 3–5 years, versus usual care	RR = 0.79 (0.72–0.85)	RR = 0.74 (0.63–0.87)
Hoff (2014) NORCCAP	Norway	One-time screening with or without one-time screening FOBT, compared to no screening	HR = 0.80 (0.70–0.92)	HR = 0.73 (0.56–0.94)

Intention-to-treat (intention-to-screen) for all analyses.

CI, confidence interval; CRC, colorectal cancer; FOBT, fecal occult blood testing; HR, hazard ratio; RR, relative risk.

**TABLE 36.8 Association of Colonoscopy and Colorectal Cancer Incidence and Mortality**

CI, confidence interval; CRC, colorectal cancer; OR, odds ratio; PR, prevalence ratio; SEER, Surveillance, Epidemiology, and End Results; SMR, standardized mortality ratio.

It is estimated that more than 70% of interval CRC cases are attributed to missed lesions, with incomplete resection accounting for another 10% to 27%.<sup>59</sup> This means that the great majority of the variable effectiveness of colonoscopy is attributed to operator-dependent factors, which could potentially be overcome with educational and quality improvement initiatives. Quality monitoring and improvement are now an integral part of modern colonoscopy practice (Table 36.9).<sup>60</sup>

There has been considerable recent interest in the serrated neoplasia pathway, given its disproportionate contribution to interval CRC. Hyperplastic polyps (HPs) were long considered to be benign lesions with no clinical significance. However, these lesions are part of a larger heterogeneous group of lesions known as serrated polyps, and SSPs and traditional serrated adenomas (TSAs) are considered premalignant, similar to conventional adenomas. Distinguishing HPs from SSPs can be difficult, due to poor reproducibility among pathologists' readings, as well as overlap in morphological features, and the proportion of HPs that have been reclassified as SSPs after pathologic reassessment has ranged from 5.8% to 11.8%.<sup>61–65</sup> SSPs can be flat and more difficult to detect and resect completely than adenomas. Thus, it is not surprising that detection rates can vary among endoscopists<sup>66,67</sup> and centers.<sup>68</sup> There have been several small reports that demonstrate a long-term risk for CRC in patients with serrated polyps.<sup>63,68,70</sup> However, data from 2015 suggest that patients with large serrated polyps may have a similar risk for CRC as patients with advanced neoplasia in a follow-up period of approximately 10 years.<sup>71</sup> One large study from Norway observed that out of 23 large unresected serrated polyps, none progressed to malignancy.<sup>71</sup> These data suggest that large serrated lesions may represent surrogate markers for individuals at risk for CRC, rather than precursors. A 2016 large population-based study conducted in Denmark showed that patients with SSPs were three times more likely to develop CRC on follow-up, whereas the odd ratios for patients with dysplastic SSP and TSA were 4.76 and 4.84, respectively.<sup>72</sup> The USMSTF on Colorectal Cancer guidelines for colonoscopy surveillance after screening and polypectomy present recommendations for surveillance of individuals with SSP<sup>73</sup> that generally follow an approach similar to that recommended for conventional adenomas (Table 36.10).

However, it is important to recognize that these recommendations are based on low-quality data, and longitudinal follow-up studies are needed to better inform surveillance after SSP resection.

### Computed Tomography Colonography

The 2008 USMSTF guidelines recommend computed tomography colonography (CTC) every 5 years as an acceptable CRC screening test.<sup>74</sup> The American College of Gastroenterology guidelines recommend that CTC replace double contrast barium enema as an alternative to their preferred screening test, conventional colonoscopy.<sup>75</sup> CTC has also been recently included as a CRC screening option by the recent USPSTF recommendations.<sup>76</sup>

CTC is a process that uses computed tomography (CT) to recreate the large bowel in two- or three-dimensional images. The CTC images, which are typically interpreted by a radiologist, are used to detect polyps in the large bowel that appear as protruding lesions into the lumen. The process involves the patient cleansing their large bowel with a purgative agent, similar to conventional colonoscopy. The bowel regimen also involves the intake of a tagging solution that contains barium sulfate to identify stool. The patient then undergoes a process similar to a CT, with air or CO<sub>2</sub> used to insufflate the large bowel through a tube inserted into the rectum. If polyps are detected during CTC, a referral must be made for a conventional colonoscopy. Absolute CTC contraindications include pregnancy and an allergy to iodinated contrast.

Potential advantages for CTC include the lack of a sedation requirement and good performance for large lesions (> 1 cm).<sup>77,78</sup> The American College of Radiology Imaging Network trial, which enrolled 2500 participants, demonstrated a high (90%) sensitivity for large ( $\geq 1$  cm) polyps.<sup>77</sup> CTC also has a low complication rate of 0.03% or less.<sup>79–81</sup> One benefit of CTC as compared to conventional colonoscopy is increased patient compliance with screening. Compliance rates for screening were improved in military facilities where CTC was offered as an option.<sup>82</sup> The development of a noncathartic preparation regimen may offer the greatest advantage to CTC with regards to compliance. Studies have demonstrated sensitivities of nearly 80% for polyps of 6 mm or larger.<sup>83,84</sup> Another trial in which patients were invited for CTC versus conventional colonoscopy screening demonstrated

**TABLE 36.9 Colonoscopy Quality Indicators**

<b>Preprocedure</b>			
1. Frequency with which colonoscopy is performed for an indication that is included in a published standard list of appropriate indications, and the indication is documented	Process	> 80%	
2. Frequency with which informed consent is obtained, including specific discussions of risks associated with colonoscopy, and fully documented	Process	> 98%	
3. Frequency with which colonoscopies follow recommended post-polypectomy and post-cancer resection surveillance intervals and 10-year intervals between screening colonoscopies in average-risk patients who have negative examination results and adequate bowel cleansing (priority indicator)	Process	≥ 90%	
4. Frequency with which ulcerative colitis and Crohn's colitis surveillance is recommended within proper intervals	Process	≥ 90%	
<b>Intraprocedure</b>			
5. Frequency with which the procedure note documents the quality of preparation	Process	> 98%	
6. Frequency with which bowel preparation is adequate to allow the use of recommended surveillance or screening intervals	Process	≥ 85% of outpatient exams	
7. Frequency with which visualization of the cecum by notation of landmarks and photo documentation of landmarks is documented in every procedure (priority indicator)	Process		
Cecal intubation rate with photography (all examinations)		≥ 90%	
Cecal intubation rate with photography (screening)		≥ 95%	
8. Frequency with which adenomas are detected in asymptomatic average-risk individuals (screening) (priority indicator)	Outcome		
Adenoma detection rate for male/female population		≥ 25%	
Adenoma detection rate for male patients		≥ 30%	
Adenoma detection rate for female patients		≥ 20%	
9a. Frequency with which withdrawal time is measured	Process	> 98%	
9b. Average withdrawal time in negative result screening colonoscopies	Process	≥ 6 min	
10. Frequency with which biopsy specimens are obtained when colonoscopy is performed for an indication of chronic diarrhea	Process	> 98%	
11. Frequency of recommended tissue sampling when colonoscopy is performed for surveillance in ulcerative colitis and Crohn's colitis	Process	> 98%	
12. Frequency with which endoscopic removal of pedunculated polyps and sessile polyps < 2 cm is attempted before surgical referral	Outcome	> 98%	
<b>Postprocedure</b>			
13. Incidence of perforation by procedure type (all indications vs. colorectal cancer screening/polyp surveillance) and post-polypectomy bleeding	Outcome		
Incidence of perforation—all examinations		< 1:500	
Incidence of perforation—screening		< 1:1000	
Incidence of post-polypectomy bleeding		< 1%	
14. Frequency with which post-polypectomy bleeding is managed without surgery	Outcome	≥ 80%	
15. Frequency with which appropriate recommendation for timing of repeat colonoscopy is documented and provided to the patient after histologic findings are reviewed	Process	≥ 90%	

From Rex DK, Schoenfeld PS, Cohen J, et al. Quality indicators for colonoscopy. *Am J Gastroenterol* 110(1):72–90, 2015.

that the rate of identifying advanced neoplasia by CTC was similar, largely due to a higher compliance in the CTC arm of the study.<sup>73</sup>

The potential downsides for CTC were outlined by the Centers for Medicare and Medicaid Services (CMS) in their denial of coverage for CRC screening.<sup>74</sup> Concerns raised included the low sensitivity and specificity for smaller polyps, high colonoscopy referral rate for abnormal findings (up to 30%),<sup>75</sup> and high rates of extracolonic findings.<sup>76,77</sup> There was also concern about the performance of CTC in older adults, including rates of colonoscopy referral.<sup>77,78,79</sup> Radiation exposure from initial CTC and the attendant follow-up studies is also an issue.

Denial of coverage for screening by CMS has limited the widespread use of CTC. In practice, CTC is currently mostly used to complete the large bowel evaluation in patients who have had an incomplete colonoscopy or cannot undergo

colonoscopy. Overall, CTC performs well for cancers and large (> 1 cm) polyps, but concerns regarding smaller lesions (< 6 mm), radiation exposure, surveillance intervals, and extracolonic findings mean that further study is still needed. However, the noncathartic CTC may increase patient participation, and thus help reduce CRC incidence and mortality.

### Colon Capsule Endoscopy

The colon capsule was first used 10 years ago, and has since been modified to include a wide-angle lens and the ability to take up to 35 images per second, increasing its sensitivity. A 2010 meta-analysis of 14 studies demonstrated that the sensitivity of the second-generation capsule is 86% and 87% for polyps of 6 mm or larger and 10 mm or larger, respectively.<sup>80</sup> Colon capsule endoscopy (CCE) has received approval by the Food and Drug

**TABLE 36.10 Post-Polyectomy Surveillance Guidelines in Average-Risk Individuals**

Baseline Finding	Recommended Interval (Years)
No polyps	10
Small rectal or sigmoid hyperplastic polyps	10
1–2 small tubular adenomas	5–10
3–10 tubular adenomas	3
> 10 adenomas	< 3
Villous adenoma or adenoma with high-grade dysplasia	3
Small SSP without dysplasia	5
SSP ≥ 10 mm, or SSP with dysplasia, or TSA	3
Serrated polyposis syndrome	1

\*Small = < 10 mm; SSP, sessile serrated polyp; TSA, traditional serrated adenoma.

and Administration for use in individuals with incomplete colonoscopies. Thus, the role of CCE is to complete large bowel inspection of adults who have had an incomplete colonoscopy.<sup>29</sup> In a study of 75 patients with an incomplete colonoscopy, CCE visualized the proximal colon that was not seen in the colonoscopy exam in more than 90% of cases.<sup>30</sup> The effectiveness of CCE can be limited by poor bowel preparation. Thus, patients whose exams are limited by an inability to purge their colon may not be good candidates for CCE. This technology may be most useful for patients whose colonoscopy is limited by anatomical abnormalities related to tortuous or redundant large bowels. Current USMSTF, USPSTF, and American College of Gastroenterology Guidelines for CRC screening do not include CCE.<sup>27,29,31</sup> More data regarding performance characteristics will be needed to address the role of CCE in CRC screening.

## SURVEILLANCE

Surveillance intervals should be based on evidence showing that interval examinations prevent interval CRC and decrease cancer-related mortality; however, guidelines are currently based on advanced adenomas as a surrogate marker. Key principles of current guidelines are the risk stratification of patients based on the findings at the baseline colonoscopy and the assumption that the baseline colonoscopy is of high quality and involved adequate bowel preparation (see Table 36.10). The USMSTF guidelines<sup>27</sup> identify two major risk groups based on the likelihood of developing advanced neoplasia during surveillance: low-risk adenomas (1–2 tubular adenomas < 10 mm) and high-risk adenomas (adenomas with villous histology, high-grade dysplasia, ≥ 10 mm, or three or more adenomas). Conversely, the British Society of Gastroenterology<sup>32</sup> stratifies patients into three groups: low risk (1–2 adenomas < 10 mm), intermediate risk (3–4 small adenomas or one ≥ 10 mm), and high risk (≥ 5 small adenomas or ≥ 3 with at least one ≥ 10 mm), and they recommend that the high-risk group undergo surveillance at 1 year because of concerns about missed lesions at baseline.

Patients with resected CRC represent a high-risk group requiring a more intensive approach. The USMSTF has published updated guidelines<sup>33</sup> that recommend, in addition to high-quality

perioperative clearing colonoscopy, surveillance after 1 year, followed by colonoscopy at 3- and 5-year intervals.

## INTRODUCTION

Related to the central role of colonoscopy within colorectal cancer (CRC) screening and surveillance, most gastroenterologists spend the majority of their time in the colon looking for and removing neoplastic polyps in an effort to reduce the risk of CRC incidence and death.<sup>1,2</sup>

However, the benefit of colonoscopy in reducing CRC relies on the adequate detection and removal of polyps. Although the majority of CRC that are diagnosed following a colonoscopy are likely related to missing a lesion at the prior colonoscopy, incomplete resection has been considered to be a cause for these post-colonoscopy cancers in 10% to 30% of cases.<sup>3</sup> For colonoscopy to be effective, it is therefore not only important to minimize miss rates, but also to assure complete polyp resection.

Studies have shown that incomplete resection is frequent. In the Complete Adenoma Resection (CARE) study, 10% of all 5- to 20-mm neoplastic polyps were incompletely removed.<sup>4</sup> Perhaps more important, there was a broad variation across endoscopists from 6% to 23% incomplete resection rate. This underlines the need for improving quality of resection and agreeing on a standardized approach. This chapter will review safe and effective resection techniques of colonic lesions. Specifically, we will review what is needed to perform polyp resection, basic and advanced polypectomy, special techniques to improve efficacy and safety of resection, and discuss future directions.

## DIFFERENTIAL DIAGNOSIS

Colonic lesions are classified as either epithelial or nonepithelial. Epithelial lesions include neoplastic adenomas (serrated, tubular, tubulovillous, villous), carcinomas, and nonneoplastic polyps (hyperplastic, juvenile, hamartoma, inflammatory). Occasionally, numerous lesions are encountered during colonoscopy of patients who have polyposis syndromes, including familial adenomatous polyposis (adenomas), Peutz-Jeghers syndrome (hamartomas), juvenile polyposis (juvenile polyps), or Cowden's syndrome (hamartomas). In addition, patients with hereditary non-polyposis CRC may harbor multiple advanced neoplastic lesions. Nonepithelial colonic lesions typically arise in the submucosa, muscularis propria, or serosal layers of the colonic wall and include lipomas, leiomyomas, carcinoids, lymphomas, and metastatic tumors. Indentations of the colonic wall by adjacent organs or endometrial implants on the serosa can also have the appearance of subepithelial lesions.

Careful endoscopic observation of the surface features of the lesion can often allow differentiation of epithelial from nonepithelial origin because nonepithelial lesions are usually covered by normal mucosa. Using currently available high-definition colonoscopes with image-enhanced capabilities, such as narrow-band imaging (NBI), it is increasingly possible to distinguish between nonneoplastic and neoplastic polyps, and to recognize superficial early adenocarcinoma.<sup>5,6</sup> Lesions that are amenable

**Abstract**

Most of the benefit of colorectal cancer screening and surveillance relies on the detection and resection of precancerous colorectal polyps. Although much emphasis has been given to improving adenoma detection, it is equally important to assure complete resection of neoplastic polyps. The aim of this chapter is to provide a conceptual and practical guide to effective and safe polyp resection. The chapter first highlights general considerations on polyp resection, in particular how assessment of a polyp will guide the decision for the appropriate resection technique. For instance, recognizing signs of early cancer is a prerequisite to performing advanced resection techniques such as endoscopic mucosal resection or submucosal dissection. This chapter then describes individual resection techniques of basic and advanced polypectomy. One focus on the basic polypectomy section is the shift from hot to cold snare resection for diminutive and small polyps. The section on advanced techniques describes endoscopic mucosal resection and submucosal dissection. Of particular interest are indications for submucosal dissection versus mucosal resection. Finally, this chapter provides an outlook into the future and direction for further study.

**Keywords**

resection

to endoscopic resection are typically mucosal lesions. Subepithelial lesions can sometimes be removed safely when they are located above the muscularis propria, as evidenced by their endoscopic appearance, response to submucosal saline injection, and, if needed, endoscopic ultrasound. Generally, biopsy should be performed if possible for lesions that are not amenable to endoscopic resection to ascertain their histology. These lesions should be endoscopically marked for surgical planning with submucosal tattoo and/or radiopaque clips.

## CONSIDERATIONS BEFORE POLYP RESECTION

### Indications and Contraindications

Treatment decisions must consider whether substantial risks exist and whether the patient's overall life expectancy is likely to be affected by the generally slow progression of colonic adenomas. The average transition time from non-advanced adenoma to cancer has been estimated to take more than 20 years,<sup>2</sup> so patients with advanced comorbid illnesses and limited life expectancy may not benefit from adenoma resection.

Colonoscopy is usually inappropriate in patients who are pregnant<sup>3</sup> or have fulminant colitis, suspected intestinal perforation, fresh intestinal anastomosis, a recent myocardial infarction, or stroke. With respect to antithrombotic management, polypectomy and mucosal resection are considered higher risk procedures and should generally not be performed in patients who have uncorrected bleeding disorders. High-quality bowel preparation is crucial for detection of subtle lesions and for resection of particularly large or difficult lesions when an elevated risk of perforation exists. Poor bowel preparation is also a contraindication for performance of complex polypectomy due to the risk of peritoneal contamination in the event of a perforation.

### Management of Antithrombotic Agents

Polypectomy and mucosal resection are considered procedures at higher risk for bleeding.<sup>4</sup> Risks related to interrupting antithrombotic medications for polypectomy need to be balanced against the risks of significant bleeding during and after the procedure. Recommendations for the management of antithrombotic agents are provided in the recently updated American Society for Gastrointestinal Endoscopy (ASGE) guidelines.<sup>5</sup>

### Anticoagulant Agents

Patients on warfarin at relatively low risk of thromboembolic complications can discontinue the medication 5 days before the procedure and resume it shortly after polypectomy. Patients on a novel oral anticoagulant should discontinue the medication between 1 and 6 days prior to surgery dependent on the half-life of the medication and the creatinine clearance.<sup>6</sup> High-risk patients, such as patients with atrial fibrillation and concomitant valvular disease, should be bridged with heparin or a heparin derivative (e.g., low-molecular-weight heparin). Warfarin generally can be resumed on the night of the procedure, with heparin resumed earlier at 2 to 6 hours after the procedure if necessary, based on the risk of thrombosis. Although there are no data on when to resume novel oral anticoagulants, these agents should probably be restarted 5 to 7 days after a large polyp resection with a higher bleeding risk to achieve a therapeutic level.<sup>7,8</sup>

### Antiplatelet Agents

Whereas the risk of polypectomy bleeding is low for patients on acetylsalicylic acid (ASA) or nonsteroidal antiinflammatory

drugs (NSAIDs), patients on thienopyridine (e.g., clopidogrel) have a high bleeding risk.<sup>9</sup> Therefore, patients on ASA/NSAIDs should continue these medications. Cessation may only be considered for patients at low risk for a thromboembolic event and who are undergoing a complex polypectomy (e.g., endoscopic mucosal resection [EMR] or endoscopic submucosal dissection [ESD]). Generally, when we believe that the risk of bleeding after endoscopic removal of a large or complex lesion is significant, we recommend that patients refrain from taking platelet inhibitors 7 days before the procedure and for approximately 7 days after it.

Thienopyridines should be stopped, or switched to ASA if the thromboembolic risk is high. Patients on double antiplatelet agents (ASA and clopidogrel) should stop the thienopyridine 5 to 7 days prior to the procedure, and ASA should be continued. Following drug-eluting coronary stent placement, an elective procedure should be deferred if possible up to 12 months, until ASA can be safely withheld.<sup>9</sup>

### Antibiotic Prophylaxis for Endocarditis

The ASGE and the American Heart Association guidelines state that antibiotic prophylaxis solely to prevent infective endocarditis is no longer recommended before endoscopic procedures, including diagnostic colonoscopy and polypectomy.<sup>10</sup>

## INSTRUMENTS AND EQUIPMENT

Dependent on the complexity of polypectomy, knowledge and familiarity with required equipment and accessories is essential for safe and effective polyp resection.

### Colonoscope

The choice of colonoscope is dependent on personal preference. It needs to promote adequate position, visualization, and resection of the colonic lesion. The colonoscope should allow adequate flushing and be equipped with a water jet. Simethicone is often added to water to eliminate gas bubbles and improve visualization. Simethicone residue within the endoscope may be difficult to remove, and some manufacturers recommend the lowest dose of simethicone possible.<sup>11</sup>

### CO<sub>2</sub> Insufflation

Insufflation should be done with CO<sub>2</sub>. Its clinical utility as an insufflating gas for colonoscopy has been well established.<sup>12</sup> CO<sub>2</sub> is readily absorbed through the colonic mucosa. Because of the lower amount of retained gas in the colon, patients are more comfortable and less likely to have abdominal pain following the procedure. It is also nonflammable, and the risk of colonic perforation, which has been reported with air insufflation, should be zero. Finally, there have been rare case reports of fatal air embolism with other endoscopic interventions. Such risk does not exist when using CO<sub>2</sub> as the insufflating gas.

### Snares

Both the endoscopist and the endoscopy assistant must be familiar with the type of snare used. These individuals must understand and have tactile knowledge of the opening and closing of the snare, the closing pressure required to produce optimal coagulation, and the relationship between the size of the tissue being strangulated and the amount of snare being closed. Various snares, each with a slightly different feature, are used for polypectomy and mucosal resection. The choice is based on personal preference, the size of the lesion, and the applied technique. Typically, small

snares are used for small polyps, and larger snares for larger polyps. Stiffer snares are used for colonoscopic mucosal resection so that flat or depressed lesions and a healthy margin can be more easily captured in the snare.<sup>14,15</sup>

### Injection Fluid

EMR and ESD generally require submucosal injection. Saline injection tends to be adequate for most cases of EMR. For more complex EMR cases and for all colorectal ESD, a solution that provides a longer-lasting submucosal cushion is highly recommended. At present in the United States, there is only one Food and Drug Administration-approved submucosal injectate (Elevive, Aries Pharmaceuticals, Inc., San Diego, CA). It contains a composition of polymer chains to provide a lasting cushion and methylene blue. Clinical studies are lacking, but preliminary data from animal model work appear promising.<sup>16</sup> Based on local availability the following solutions can be used off label:

- Normal saline can be used in the majority of cases of colonic EMR.
- Worldwide, hyaluronic acid (MucoUp, Seikagaku Corporation, Tokyo, Japan) is the most commonly used injection solution for colorectal ESD.
- Sodium hyaluronate (Healon, Abbott, Chicago, IL) dispensed as 10 mg/mL 0.85-mL syringe is available in the US and is approved for intraocular injection during ophthalmic surgery. A typical dilution for ESD is one 0.85 mL syringe of hyaluronic acid mixed with 2.5 mL of normal saline and dye (indigo carmine or methylene blue) to desired color. Although this type of solution provides for excellent submucosal lift, the cost tends to be prohibitive for routine use.
- Hydroxyethyl starch (Heta starch; available as Voluven, Fresenius Kabi Ltd., Runcorn, United Kingdom or Hespan, B. Braun Medical, Melsungen, Germany) dispensed as 500-mL bags. No dilution is necessary, dye can be added to the desired color, and the solution can be directly used for submucosal injection at the time of ESD. No data are available for the use in ESD, but a randomized controlled study showed that hydroxyethyl starch is superior to normal saline for EMR.<sup>17</sup>
- Hypromellose (Gonak, Akorn, Inc., Lake Forest, IL) is an ophthalmic solution used as artificial tears and is dispensed as a 15-mL vial. Typical dilution for ESD is to mix one 15-mL vial with 85 mL of normal saline. The use of hypromellose has been shown to be safe and effective in EMR, but data specifically pertaining to ESD are not available.<sup>18</sup>
- Succinylated gelatin (Gelufusine, B. Braun Medical) is a volume expander that is not available in the US. Its physical properties are similar to hydroxyethyl starch. It has been shown to reduce the number of resections during piecemeal mucosal resection and overall procedure time when compared with normal saline solution.<sup>19</sup>

### Electrocautery

High-frequency electrical current is employed to facilitate cutting and to coagulate vessels at the resection margin. Electrical current is transformed to heat at high frequencies. The amount of heat that is produced in the tissue and determines cautery effects is dependent on the current density and tissue resistance. Current density is dependent on the contact (e.g., snare diameter); the smaller the contact area the higher the current density and the higher the heat. During polyp resection, the snare serves as the active electrode (high current density and heat), and the circuit is completed via a conducting grounding pad that is affixed

to the patient's skin. Whereas current density is high at the snare, it is low at the grounding pad, and typically not noticed by the patient.<sup>20</sup>

Most electrocautery units allow three cautery modes: *cutting*, *coagulation*, or a *blend* of both. The *cutting* mode delivers a continuous sine-wave voltage pattern. When sufficient voltage is delivered with a resultant high current density, electrosurgical cutting ensues. This mode allows a swift cut through tissue without deep thermal tissue injury. The polyp base is desiccated based on the applied mechanical pressure of the snare loop onto the polyp base. This mode does not provide sufficient cautery time to seal blood vessels and bleeding is therefore a concern. In contrast, the *coagulation* mode provides less high-density current and therefore less heat. The tissue is coagulated while the snare is closed. This type of electrocautery snare resection may be considered a mechanical cut supported by coagulation. The concern is deep mural cautery injury. To minimize risk, cautery units provide a setting of cutting current alternating with coagulation current, also called *blended* mode. Realizing that heat production is dependent on tissue resistance, which is dependent on water content and changes during cautery, some cautery units provide a microprocessor-controlled current, which adjust the delivered energy to tissue resistance. This approach may optimize coagulation and cutting effects, and minimize risk.

Data on the optimal electrocautery mode are limited. A 2004 survey found that 46% of US endoscopists used blended and 46% coagulation mode.<sup>21</sup> Two retrospective studies suggest that coagulation may increase the risk of delayed bleeding and blended current of immediate bleeding.<sup>22,23</sup> Thus, the optimal electrocautery mode for polyp resection remains an important clinical question.

### Argon Plasma Coagulation

Argon plasma coagulation (APC) is often used during EMR to cauterize residual polyp tissue and to ablate the resection margin.<sup>24–27</sup> APC produces electrically conducting argon plasma by guiding argon gas through a delivery catheter that also contains an electrode for delivery of high-frequency current. APC generally creates uniformly deep zones of desiccation, coagulation, and devitalization less than 3 mm in depth. Because the argon plasma conducts the current, APC can be applied without tissue contact.<sup>20</sup>

### Other Instruments

Other instruments that are often used during polypectomy and mucosal resection include the standard sclerotherapy injection needle, endoclip, endoloop, and retrieval net.<sup>28,29</sup> Detailed examples of use of these instruments, which are important for colonoscopic resection, are described subsequently in the section on Techniques.

## GENERAL APPROACH TO REMOVING A COLORECTAL POLYP

Independent of the type or complexity of resection, the following six components are common to all endoscopic resections of colonic lesions (Table 37.1). These include assessment of the lesion, decision whether to resect, position, resection, checking for completeness, retrieval and preparation of the specimen for interpretation.

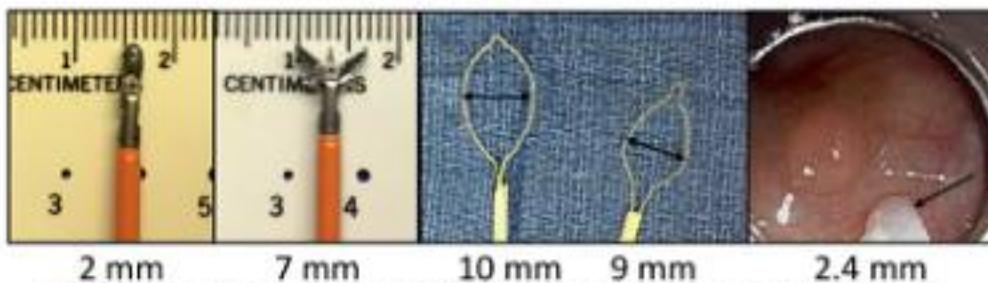

### Assessment of the Polyp

The macroscopic classification of adenomas and early colorectal neoplasms is crucial in the discussion of diagnosis and treatment

**TABLE 37.1 Components of Polyp Resection**

Components of Resection	Approach	Questions
1. Assess the lesion		
Size	Use objective size reference	What tool for resection?
Morphology	Paris classification	Invasive cancer?
	LST	What portion to resect first?
Surface pattern	NICE (Kudo, Sand) Submucosal injection	Invasive cancer?
Nonlifting sign		Invasive cancer?
2. Decide whether to resect	Weigh pros and cons	Sufficient skill, support, equipment?
3. Assume optimal position	Consider cap, retroflexion, overtube, gastroscope	Should be easy?
4. Complete resection	Basic vs. advanced	How to assure curative resection?
5. Assure completeness of resection	Take time and use enhanced imaging	Did I achieve a healthy margin?
6. Retrieve and prepare the polyp	Suctioning, Roth net or with the scope, pin large specimen to orient lesion for pathologic sectioning and assessment.	Is the deep margin free of cancer?

LST, Lateral spreading tumor; NICE, Narrow-Band Imaging International Colorectal Endoscopic.

**FIG 37.1** Examples of tools that can be used as a reference to estimate polyp size.

of early CRC. Typically, endoscopic resection can be considered for mucosal lesions. Submucosal lesions may require additional endosonographic evaluation. The following characteristics affect the decision whether to resect and what approach to choose.

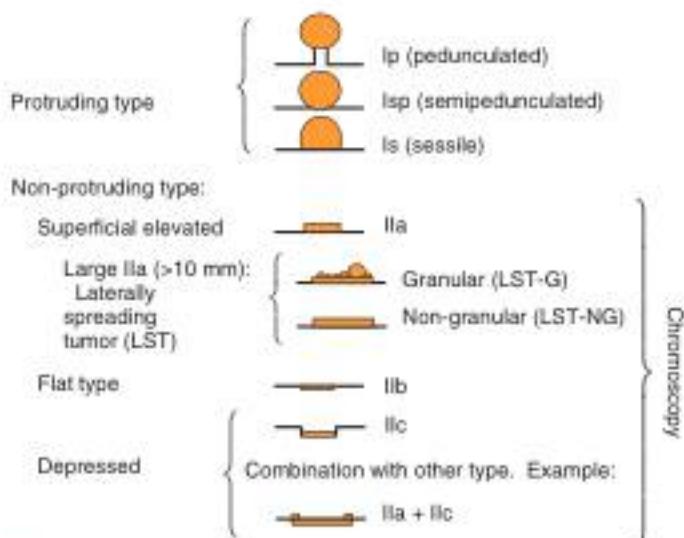

### Size

Several studies have shown variability in estimation of polyp size.<sup>30–32</sup> To minimize subjectivity, a reference tool may be used to estimate size. For instance, snares have predefined opening diameters and can serve as a reference (e.g., 10 mm) when positioned on or aside the polyp (Fig. 37.1). Furthermore, the snare catheter has a determined size (2.4 mm) and can also serve as a reference tool. Catheter tips could also be marked (mm/cm) to allow a more accurate assessment of size; however, this is cumbersome in clinical practice, and more applicable to studies. Because risk and surveillance management is based on size ranges, one may label polyps of 10 mm or less as diminutive (1–5 mm) and small (6–9 mm), estimate large ( $\geq 10$  mm) by 5-mm increments up to 30 mm, and 10-mm increments for larger lesions. For very large lesions, the extent of the lesion circumference (25% increments) and across more than one fold should be noted, as these may affect difficulty of resection or risk of stenosis. To recognize the full extent of a lesion also requires clear visualization of the margin of the lesion. Digital or traditional chromoendoscopy typically help to contrast the lesion from the normal mucosa. A distal attachment cap is helpful to "spread out" the lesion slowly and inspect the margin. Submucosal injection with a contrast agent may further demarcate the lesion more clearly. Marking of the margin may be helpful in some cases before mucosal resection and submucosal dissections.

### Morphology

Appearance is an important aspect to consider in preparation for resection. It provides information on the risk of prevalent cancer. In Western countries polyps have been broadly classified into pedunculated, sessile, and flat lesions. More recently, the Paris classification (2002), which is built on the well-established Japanese classification, has been promoted for worldwide use (Fig. 37.2).<sup>33,34</sup> The Paris classification broadly categorizes lesions into protuberant (Paris I) and flat lesions (Paris II). Protuberant lesions protrude more than 2.5 mm from the mucosa into the lumen. These include pedunculated (Ip), subpedunculated (Isp), and sessile (Is) lesions. Flat lesions are categorized as elevated lesions (but less than 2.5 mm height) (IIa), completely flat lesions that are leveled with the surrounding mucosa (IIb), and depressed lesions that are beneath the level of the surrounding mucosa (IIc). A polyp may also be elevated and have a depressed area, in which case it should be labeled IIa + c. Some snare catheters measure 2.5 mm in diameter and can therefore help to distinguish between Paris I and II.

More recently non-pedunculated lesions larger than 10 mm have been described as lateral spreading tumors (LSTs) (Fig. 37.3). The term refers more to the growth pattern rather than the endoscopic appearance. LSTs are categorized into LST-granular (LST-G), which have a carpeted nodular appearance, and into LST-nongranular (LST-NG), which may present with a flat surface or bulky appearance. This distinction is important, because LST-NG are more likely to contain invasive cancer. LST-NG are also more difficult to resect and may require en bloc resection to ensure cure. As with Paris, there could be a combination of both characteristics, which is called *mixed LST*.

**FIG 37.2** Macroscopic classification of early neoplastic lesions of the colon and rectum. This classification provides a more precise schematic description of early neoplastic lesions. In addition to the commonly described pedunculated and sessile lesions, the classification provides the appropriate descriptors for flat and depressed lesions. The classification is particularly useful for the endoscopist in deciding the treatment strategy of early colorectal carcinomas because the risk of submucosal invasion of these lesions corresponds to the endoscopic appearance and size. Image-enhanced endoscopy is useful to study the surface details and border of the non-protruding type. LST-G, Granular laterally spreading tumor; LST-NG, nongranular laterally spreading tumor; LST, laterally spreading tumor.

### Surface Pattern

Since Kudo published his description of polyp surface pattern in 1996, several other classifications have been introduced.<sup>33</sup> The Kudo classification relies on chromoendoscopy and high-magnification imaging (100 $\times$ ) to visualize mucosal pit patterns, which can provide insights as to the pathology of the lesion. Pit patterns may reflect the tangential structure of the glands of the lesion. As the structural organization of the glands becomes disordered or even absent, as it does in invasive carcinoma, the pattern may become disorganized. The pit pattern may therefore provide clues about the presence and degree of neoplasia. According to Kudo, such assessment requires additional dye staining and high-magnification endoscopes. Dye-based enhancement typically includes diluted indigo carmine. Crystal violet, although not available for use in the United States, is also often applied in Japan when using high optical magnification (Fig. 37.4).

With the advancements in image-enhanced endoscopy, Kudo's principles have been applied to readily available high-resolution endoscopy and digital chromoendoscopy. Most commonly used are Sano and NBI International Colorectal Endoscopic (NICE) classifications, both using NBI. Sano classifies polyps into three categories (I, II, and IIIa and IIIb) based on presence, order, and regularity of capillary vessels.<sup>34</sup> The NICE classification uses polyp color, vessels, and surface pattern to categorize polyps into three types (Fig. 37.5).<sup>35</sup> A bland color, none or isolated lacy vessels, and a uniform pattern of spots (crypts) characterize hyperplastic

polyps (NICE Type 1). In contrast, adenomas have an overall brown appearance, and oval, tubular, or branched white structures surrounded by brown vessels (NICE Type 2). Invasive cancer is characterized by disrupted or absent vessels and an amorphous or absent surface pattern (NICE Type 3). Accurate recognition of polyp architecture and surface pattern is important when considering real-time optical polyp diagnosis as part of a resect-and-discard strategy, and when making a decision whether to attempt a polyp removal.

The application of a standard classification of colorectal lesions is the first step in stratifying which lesions are more likely to contain advanced pathology. Standard imaging, in some cases with image enhancement, is generally adequate to assess cancer depth.

### Nonlifting Sign

Observation of the lesion during and after submucosal saline injection during mucosal resection is a simple but important method to assess the potential for deeply invasive carcinoma (Fig. 37.6).<sup>36–40</sup> Lesions may not lift because of desmoplastic reaction, invasion from the lesion itself, or submucosal fibrosis from prior multiple biopsy, cautery, tattoo injection, or ulceration. Several studies have reported the diagnostic operating characteristics of the nonlifting sign. The positive predictive value of the nonlifting sign is approximately 80%.<sup>41</sup> The correlate of the nonlifting sign when submucosal injection is not used is the inability to capture the lesion in the snare. Difficulties encountered during attempted snare resection should alert the endoscopist to the possibility of deep invasion.

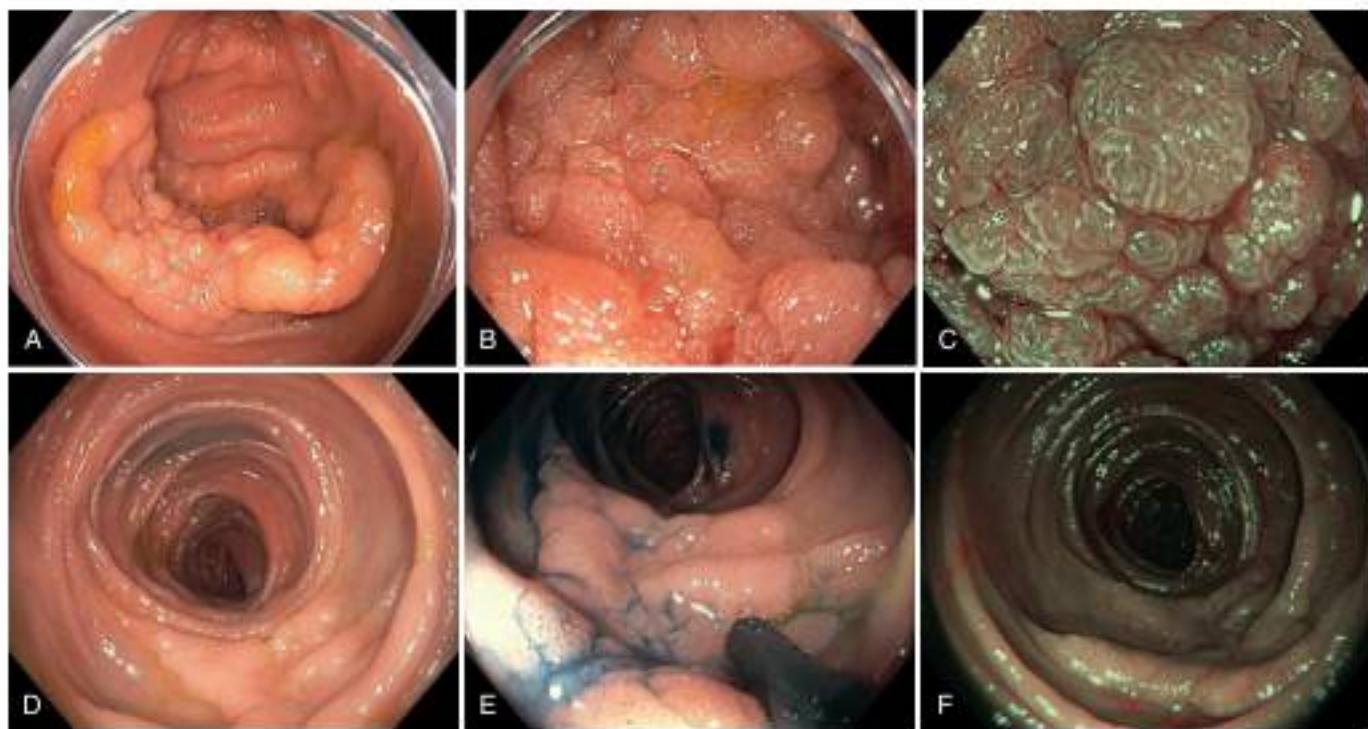

### Decision to Resect a Polyp

The decision on whether and how to resect a polyp is influenced by three main questions:

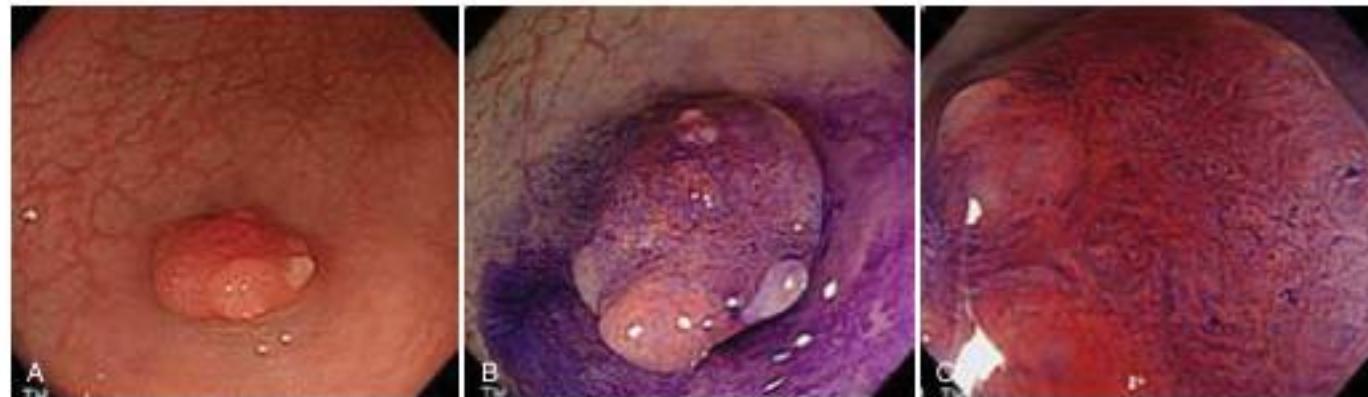

1. What is the malignant potential?
2. Do I have the skill to perform a complex resection?
3. Do I have technical assistance, the necessary equipment, and time to perform the resection?

Colonoscopic resection should be performed in patients for whom the removal of a polyp is likely to provide benefit. Endoscopic assessment for possible prevalent cancer and its depth of invasion are important in planning the resection. Lesions assessed to be noninvasive are most likely to benefit from endoscopic treatment. Lesions with minimal or moderate risk for submucosal invasion can be treated with endoscopy (see later), provided that the endoscopist believes that the lesion can be safely removed in its entirety and that the potential benefits of endoscopic treatment outweigh the risks. Patients whose lesions are strongly suggestive of invasive cancer should be referred to surgery after a confirmatory biopsy because endoscopic resection would expose them to unnecessary risks. Colonoscopic resection of neoplasms with deeply submucosal invasive cancer is generally difficult, has a high risk of bleeding, perforation, recurrence, and metastasis, and should be avoided.

A resection should only be performed if the endoscopist has the knowledge and expertise and supporting staff to complete the procedure. This is particularly relevant for removal of larger lesions by EMR or ESD. Rescheduling the patient may appear as a disservice to the patient. However, it may benefit the patient overall and improve outcome. The patient may be better served, when referred to a specialist, if the resection is not performed under time pressure, and if increased risks and alternatives are discussed with the patient prior to resection.

**FIG 37.3** Non-polypoid lesions 10 mm or larger in diameter are referred to as laterally spreading tumors (LSTs). They have a low vertical axis and extend laterally along the luminal wall. LSTs are morphologically subclassified into granular type (LST-G) (**A–C**), which have a nodular surface, and nongranular type (LST-NG), which have a smooth surface (**D–F**). This macroscopic distinction is important to facilitate the endoscopic removal plan as it provides information about the risk of cancer or submucosal fibrosis to anticipate the technical ease or difficulty of the removal.

**FIG 37.4** Close-up observation of the surface of lesions using magnification endoscopy with crystal violet chromoscopy can improve endoscopic assessment. **A**, A 7-mm superficial elevated lesion with depression. **B**, Crystal violet has been applied. **C**, On close examination using magnification endoscopy (100x), the pit pattern was consistent with a deeply submucosal invasive pattern. The patient underwent surgical resection where a deep submucosal invasive adenocarcinoma metastatic to local lymph nodes (2/7) was removed.

### Colonoscope Position

An important aspect of endoscopist skill to perform endoscopic interventions is to achieve full control over the tip of the endoscope and assume an optimal position to complete the task. For polyp resection, this includes the “o’clock” position of the lesion and the distance of the lesion to the tip of the endoscope. Naturally, a 5 to 6 o’clock position is ideal with colonoscopes that

have the working channel opening in the same location. The key is not the position of the lesion, but the position of the lesion in reference to the endoscope. The endoscope-to-lesion distance is optimal if it allows full control over accessory equipment when engaging the polyp. As a general rule, closer is better. The optimal position is dependent on techniques and the tools, and affected by location of the lesion in the colon and with respect to a fold. For EMR and ESD, sufficient time should be

	Type 1	Type 2	Type 3
Color	Same or lighter than background	Browner relative to background	Brown to dark brown relative to background; sometimes patchy whiter areas
Vessel	None, or isolated lacy vessels coursing across the lesion	Brown vessels surrounding white structures	Has area(s) of disrupted or missing vessels
Surface Pattern	Dark or white spots of uniform size, or homogeneous absence of pattern	Oval, tubular or branched white structure surrounded by brown vessels	Amorphous or absent surface pattern
Most Likely Pathology	Hyperplastic or Sessile Serrated Polyps (SSP)	Adenoma	Deep submucosal invasive cancer
Examples			

**FIG 37.5** Narrow Band Imaging International Colorectal Endoscopic (NICE) Classification. Optical diagnosis of diminutive colorectal polyps by using the NICE classification. The use of confidence levels (high or low) in making an optical diagnosis is important in its implementation in clinical practice.

**FIG 37.6** Nonlifting sign. The lesion has a full appearance that suggests invasive cancer, but prior pathology revealed only villous adenoma. **A–C**, Nonlifting sign. Injection of saline mixed with diluted indigo carmine into the submucosa beneath this lesion does not result in lifting of the lesion; instead, the lesion infolds as only the submucosa of the normal surrounding mucosa is expanded.

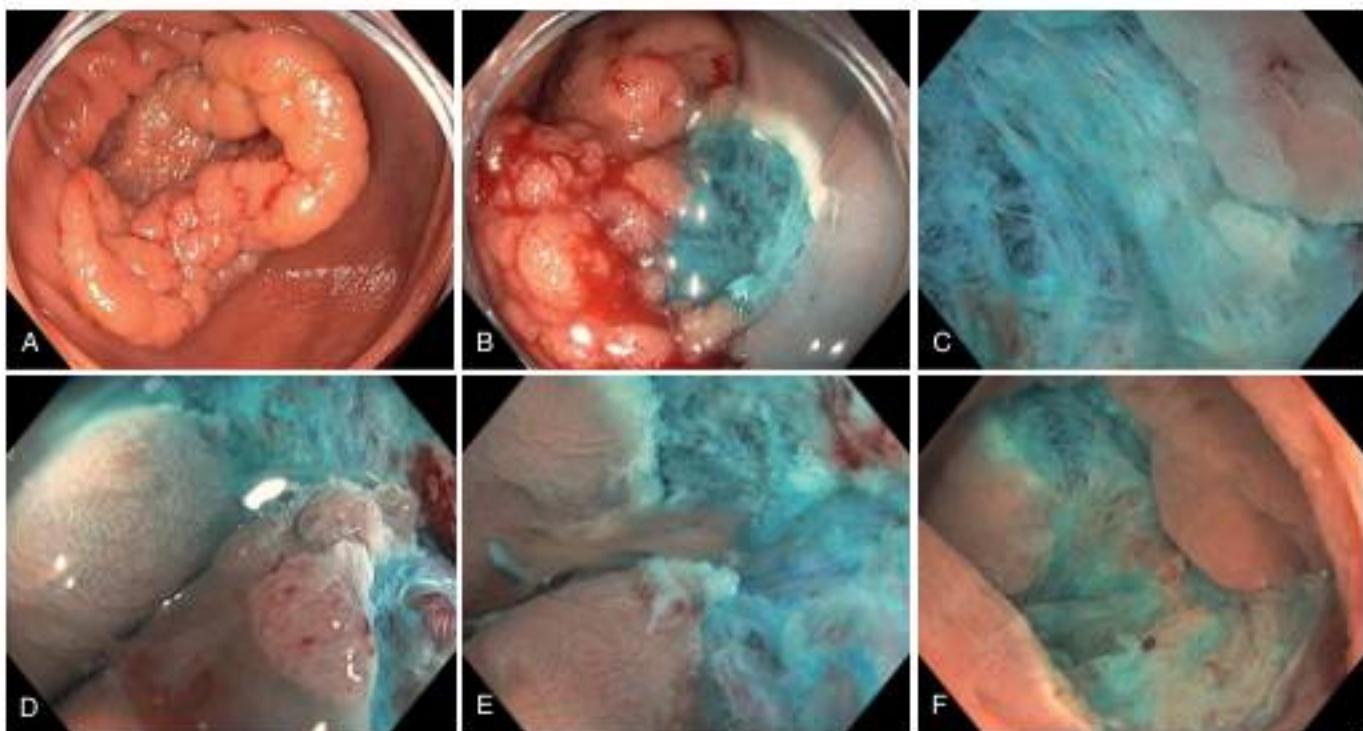

spent to assess the optimal position for resection, including the possibility of retroflexion. If the location is difficult, alternative approaches should be considered. These include the use of an overtube (for proximal lesion location) and use of a gastroscope (easier retroflexion in the rectum). A distal transparent cap that extends beyond the tip of the endoscope may ease resection of more complex lesions.<sup>12</sup> The cap allows stabilization of the mucosa and may improve position to lesions that are located on the proximal side of a fold.

### Method of Resection

The type of resection is primarily defined by size and endoscopist preference. Different resection techniques are described later.

### Completeness of Resection

Completeness of resection has received much attention over the past years. We realized that polyps are often incompletely resected, and that incomplete resection likely contributes to the risk of

**FIG 37.7** Inspect resection margins. **A**, Large cecal lateral spreading granular-type lesion. **B**, Inject and cut endoscopic mucosal resection is initiated from the periphery with clean margin. Further inspection shows **C**, no local residual, and **D**, local neoplastic residual, which is then **E**, removed using snare resection. **F**, Complete inspection of the margin defect shows no visible residual.

post-colonoscopy cancers, that is, those that occur after a complete colonoscopy.<sup>3,4</sup> Therefore, extra attention should be given to the polyp margin after resection. Although no study has formally examined the benefit, detailed inspection of the margin to assess for residual polyp tissue should be done. Although digital chromoendoscopy (e.g., NBI) may be used, the time spent to meticulously examine the resection margin is probably the most important aspect to assure completeness of resection. A distal cap may help to improve visualization of the margin. Residual polyp tissue should be removed (Fig. 37.7).

### Retrieval and Preparation for Pathology

Each polyp should be retrieved for pathology examination. Retrieval options are based on the location, the size of the resected polyp, the type of the colonoscope (diameter of working channel), and the need for completing the remaining examination. Most polyps are sufficiently small to fit through the working channel. Larger polyps may be retrieved with a net or by suctioning them onto the orifice of the working channel and withdrawing them with the endoscope. Both options require reintroduction of the colonoscope to complete the examination. In some instances, one may decide to further cut a larger lesion into smaller pieces to allow suction through the working channel and avoid reintroducing the colonoscope.

In some countries, it is mandatory for the pathologist to provide information on the margins of the resected polyp.<sup>3,4,41</sup> However, there has been no study that clearly shows that polyp tissue at the margin of the resected polyp is predictive of incomplete resection. Moreover, cautery artifact and orientation of the specimen may impair adequate evaluation of margin involvement.

For larger lesions with signs of advanced neoplasia and early cancer, specimens should be prepared for optimal pathology assessment and to allow interpretation of a deep margin of an early cancer. For this purpose, specimens are pinned on a cork or on styrofoam before fixation in formalin. This will help the pathology assistant to cut and prepare specimens for optimal orientation. Mucosal or early submucosal cancers have a low risk of lymph node involvement. If the deep margins of such lesions are clear, surgery may be avoided. The risk and benefits of this decision, however, need to be discussed with the patient.

## RESECTION TECHNIQUES

### Basic Polypectomy

#### Definition

Basic polypectomy refers to resection of a polyp with one tool that does not require additional adjunctive means. Polyps that can be removed by basic resection technique are typically small, and because most polyps are small, the vast majority of polyps can be removed by this technique. Generally, all polyps should be removed by mechanical means. Two tools are available: biopsy forceps and resection snare. Both can be used with and without electrocautery, which is also known as cold and hot resection. The addition of electrocautery may reduce the immediate risk of bleeding and promote complete polyp removal by ablating residual polyp tissue. To date, there is little evidence to support the benefit of electrocautery resection for basic polypectomy.

The upper size limit that supports a basic resection technique (and that does not require submucosal injection) is unclear, and depends on local practice and individual preference. In a 2016

**TABLE 37.2 Recommended Resection Method by Polyp Size**

Polyp Size	Resection Method
1–2 mm	Cold forceps or cold snare
1–9 mm	Cold snare
≥ 10 mm	Hot snare with or without submucosal injection (consider cold snare if concerns about deep thermal injury)
≥ 15 mm	Submucosal injection/EMR
≤ 25 mm	Attempt en bloc EMR

EMR, Endoscopic mucosal resection.

study, hot snare resection was similarly effective in completely removing polyps up to 14 mm in size when compared to resection following submucosal injection. Whereas there was a non-significant trend favoring submucosal injection for polyps of 15 to 19 mm, submucosal injection showed a clear benefit for polyps 20 mm or larger.<sup>43</sup> These results reflect our current practice. Whereas most polyps up to 15 mm may be removed without submucosal injection, submucosal injection is used for larger polyps. Table 37.2 provides the suggested resection approach based on polyp size.

### Resection Tools

Hot forceps resection has been commonly used in the past. However, it is often incomplete, and histopathology specimens may be difficult to interpret.<sup>44,47</sup> The greatest concern is the potential for deep tissue injury and increased risk of postpolypectomy syndrome, delayed bleeding, and perforation.<sup>47</sup> Therefore, hot biopsy forceps should not be used for basic polyp resection.

Cold forceps resection is the most commonly used means for resection for small diminutive polyps ( $\leq 4$  mm) in the United States.<sup>48</sup> Despite its inefficiency for resection of larger lesions, it is still frequently used for large polyps.<sup>49</sup> Cold snare resection is frequently used for diminutive polyps, and hot snare resection has been the most common resection method for removal of polyps of 5 mm or greater.<sup>48</sup>

Head-to-head comparisons of cold forceps with cold snare resection have shown that both are equally effective for complete polyp removal for up to 3-mm polyps, whereas resection of larger polyps is more frequently complete when using a snare.<sup>50–52</sup> However, even with a snare, incomplete resection of diminutive and small polyps occurs.<sup>53</sup> A dedicated cold snare with a stiff wire may more frequently allow complete resection than a standard snare that is typically used for cold or hot snare resection. In one study dedicated cold snare resection of up to 10-mm polyps resulted in a lower incomplete resection rate of 9% compared to 21% when using a standard snare.<sup>53</sup> In clinical practice, however, most endoscopists currently use a hot snare for polyps that are 5 mm or larger.<sup>48</sup> It should be noted that there is no evidence that the addition of cautery promotes completeness of resection. The results of the CARE study, where all 5- to 20-mm polyps were removed by hot snare, still found an incomplete resection rate for 5- to 7-mm polyps of 6%, very similar to results from cold snare studies. More recently, cold snares have been used for resection of larger polyps. Although it may lead to mild immediate bleeding (similar to taking mucosal biopsies), studies suggest that cold snare resection of polyps up

to 10 mm in size is at least as safe and effective as hot snare resection.<sup>53,54–58</sup> In one randomized study among patients who were on anticoagulants, the risk of immediate and delayed bleeding with cold snare resection was lower compared with hot snare resection (immediate bleeding: 6% vs. 23%; delayed bleeding: 0% vs. 14%).<sup>54</sup> Although mild bleeding after cold snare resection may occur, two other randomized studies have described no immediate bleeding event that required an intervention (e.g., clip placement).<sup>53,56</sup> The upper size limit for cold snare resection is yet unclear. Case series have reported feasibility of piecemeal removal of polyps larger than 20 mm in size.<sup>57,58</sup> In their 2017 guidelines the European Society of Gastrointestinal Endoscopy supports the resection of all sessile polyps larger than 10 mm with cold snare resection owing to its superior safety profile.<sup>14</sup> Cold snare resection of larger polyps (< 20 mm) can be considered if there is concern about deep thermal injury. Evidence for these recommendations is still lacking. It remains unclear if the increased need for piecemeal resection with larger polyp size will increase the risk for incomplete removal.

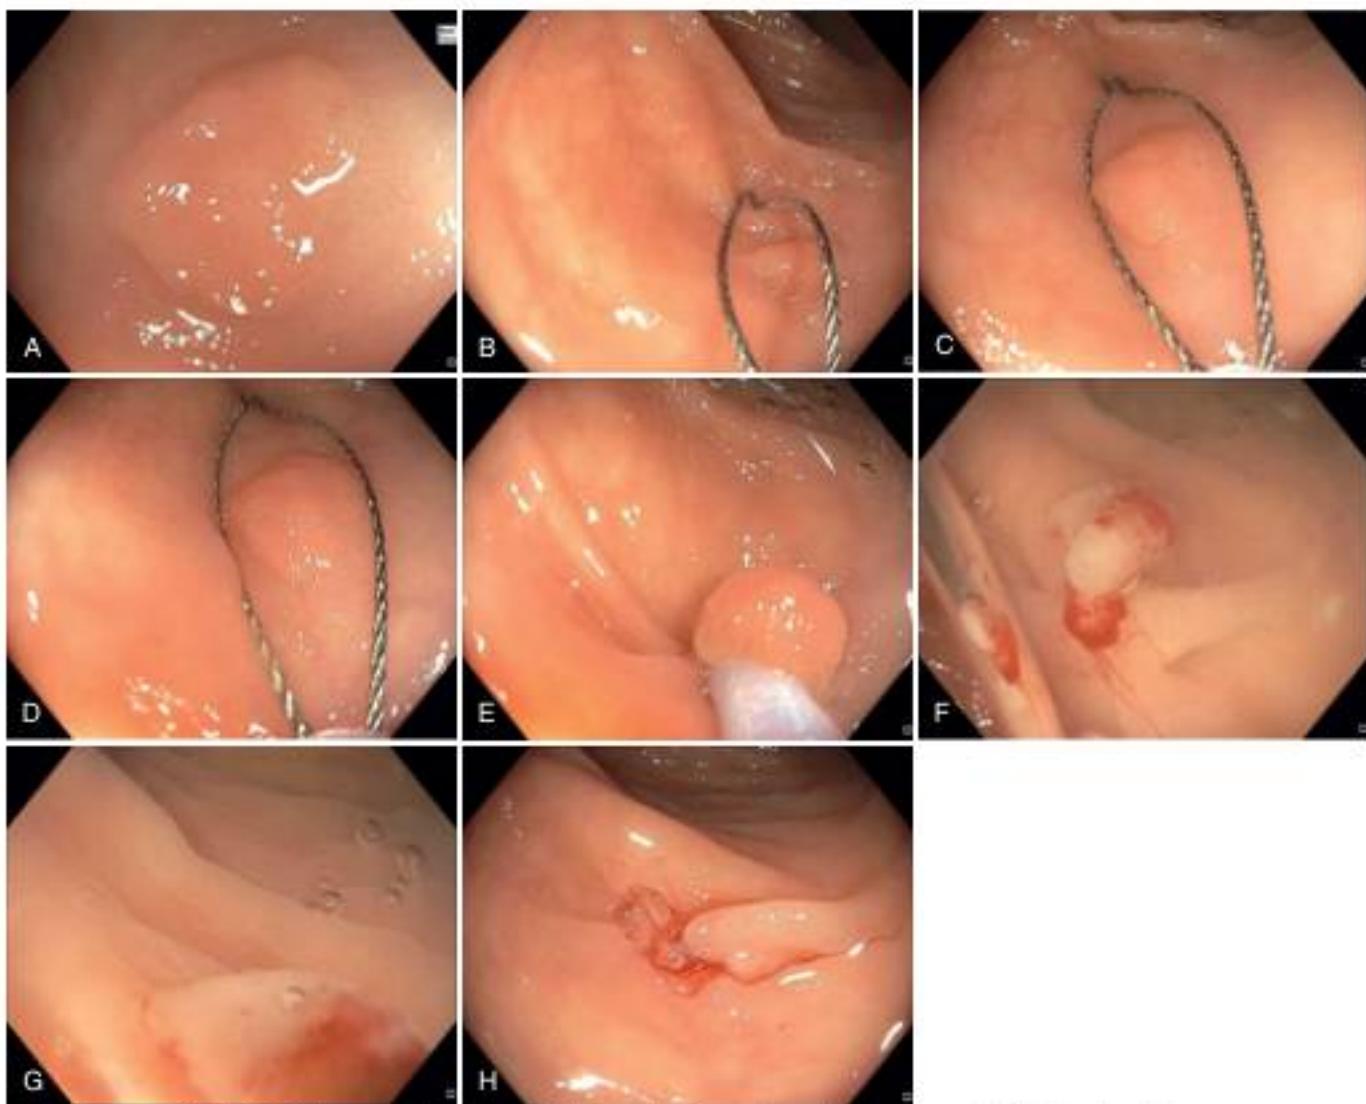

### Cold Forceps Technique

A cold forceps may be used for resection of polyps that are more difficult to engage with a snare, either related to location or due to very small size ( $\leq 2$  mm). The added benefit of using a forceps is immediate retrieval of the specimen with the forceps. The disadvantage is the possibility of not removing the entire polyp and the need for a repeat bite, which makes the resection via piecemeal resection and increases uncertainty for complete removal.<sup>59</sup> Using a large-capacity forceps does not seem to decrease the need for additional biopsies but may improve completeness of resection,<sup>59,60</sup> and even after visibly complete removal resection may still be incomplete in 20% of polyps of 6 mm or less.<sup>60</sup> Therefore, we consider it preferable to use a cold snare for all polyps of 3 mm or larger.

### Cold Snare Technique

We suggest a cold snare as the primary resection tool for all diminutive polyps (Fig. 37.8). A cold snare can be safely used for polyps up to 10 mm in size. Some snares do not allow swift cold cutting through the base, and a dedicated cold snare may be preferable. Hot snare resection for polyps of 6 mm or larger remains an alternative. Polyps larger than 10 mm should be removed by hot snare given the lack of robust data for efficacy and safety of cold snare resection.

After sufficient insufflation and assuming an optimal position, the snare is opened and placed around the polyp head. The goal is to obtain a small healthy tissue margin around the polyp base to ensure complete resection. This is achieved by first carefully anchoring the snare tip at the proximal side of the polyp, approximately 1 to 2 mm away from the polyp base. The snare is then placed around the polyp base and the tip of the snare catheter gently anchored 1 to 2 mm distal to the polyp margin. The snare is slowly closed while maintaining gentle pressure of the catheter tip on the mucosa and suctioning some air. This gentle push allows engagement of a small healthy margin (Video 37.1). The removed polyp will remain at the resection spot and can now be easily accessed and retrieved through the working channel. Inspection of the margin follows the resection. Additional washing with the water jet may help to reduce mild bleeding, and also leads to mild submucosal lifting of the margin, which may then facilitate the ability to assess the margin. Residual polyp tissue can be removed with a cold snare or a forceps. There

**FIG 37.8** Cold snare polypectomy technique. **A**, Diminutive colon adenoma. **B**, Position the lesion at 5 o'clock in line with the colonoscope accessory channel. Engage the snare tip against the mucosa on the proximal side of the lesion, and open slowly. **C**, Open the snare until it has normal surrounding tissue and slightly move the endoscope distally as the snare is being opened according to the size of the lesion. **D**, While the snare is initially "closed" in a slow and steady manner, keep the endoscope tip deflection downward to apply gentle pressure against the mucosa (the ensnared polyp should not be lifted or tented during closure). **E**, Continue to maintain some tension on the snare catheter with gentle forward pressure during closure to avoid slipping of the snare upward, away from the submucosa and consequent shaving of the lesion. As the snare wire is closed, it will capture normal tissue. **F**, Once you have secured the normal tissue, then the lesion can be "cut." The snare "close" is slow and steady, the snare "cut" is faster. **G**, In the 5 o'clock position, the cut polyp typically remains in place for efficient retrieval. **H**, Minor post-cold snare oozing is expected and self-limiting.

have been no studies to show that a larger mucosal defect related to a healthy margin is associated with a higher risk of bleeding. Small flat lesions may be difficult to remove. Aspirating the lesion into the suctioning channel of the colonoscope for 5 seconds will create a pseudopolyp (suction pseudopolyp technique) and facilitates snare capture and resection.<sup>11</sup>

#### Hot Snare Technique

Resection with electrocautery snare is very similar to the cold snare technique, with the exception of the cutting maneuver.

The polyp is sufficiently exposed by insufflating air and brought into an optimal position. The polyp is then engaged by anchoring the catheter tip 1 to 2 mm distal to the polyp base. The snare is then closed while maintaining gentle pressure with the catheter tip onto the mucosa and suctioning some air. After tightly closing the snare around the polyp base, the entrapped polyp is now lifted or "tent" away from the colonic wall to avoid deep cautery tissue injury (Video 37.2). The polyp is then resected by applying electrocautery while fully closing the snare. The lift-and-cut technique represents the major difference compared with the

gentle push-and-cut technique with cold snare resection. It is possible that lifting of the entrapped polyp may promote snare slippage away from the polyp base and therefore not include a healthy margin. Following the lift-and-cut resection, the margins should be carefully examined for residual polyp tissue.

Some endoscopists prefer to take the snare from the assistant and cut through the polyp base when applying electrocautery. This may be of benefit when performing resection of larger polyps to get a "feel" of the amount of entrapped polyp. This tactile feedback may be more relevant when applying forced coagulation, which can be understood as cautery-assisted mechanical cutting. In contrast, blended current applies a high energy and desiccates through tissue ("like a hot knife through butter") based on the pressure applied by the snare on the tissue. Here, the intermittent coagulation current "seals" any potentially bleeding vessels. The tactile feedback is therefore less present when applying this electrocautery mode. Overall, there have been no formal studies to show that any available setting should be preferred (Box 37.1).

### Advanced Polyp Resection

#### Snare-Loop Polypectomy

Pedunculated and semipedunculated lesions (Paris I<sub>p</sub> and I<sub>s</sub>) may be resected by snare-loop polypectomy at the middle or

upper stalk. Sessile lesions can be resected by a similar technique at the base. Large polyps (> 2 cm) or polyps with a thick stalk carry a higher risk of immediate or delayed bleeding. Prophylactic treatment to close off blood vessels in the stalk before resection prevents immediate or delayed bleeding (Fig. 37.9).<sup>62–64</sup>

One prophylactic method is the application of endoloops, which are detachable nylon loops that are applied to the base of the polyp stalk to strangulate the vessels supplying the polyp. Randomized trials have shown that prophylactic placement of an endoloop significantly reduced the rate of bleeding.<sup>62–65</sup> Another randomized trial of large pedunculated colon polyps showed significantly lower and less severe delayed bleeding among patients following prophylactic detachable snare placement and clip application to the residual stalk compared with patients who underwent prophylactic epinephrine injection alone.<sup>66</sup> However, placement of the endoloop in pedunculated polyps that have short stalks can be difficult. Massive bleeding can occur if the endoloop slips right after snare polypectomy.<sup>67</sup> In addition, the endoloop is made of nylon, which can be too floppy for ensnaring the polyp. In a more recent randomized trial (2014) among 195 patients with pedunculated polyps with a minimum stalk diameter of 5 mm, the bleeding rate was similar following prophylaxis with placement of an endoloop (5.7%) or clips (5.1%).<sup>67</sup> Although this study showed that prophylactic clipping was not inferior to using an endoloop, placement of clips for polyps with a large stalk may be difficult to achieve.

Because massive colonic bleeding can easily cause immediate loss of visualization, other prophylactic techniques may be more appropriate. Seitz et al (2003) used diluted epinephrine to inject to the base of the stalk before polypectomy.<sup>68</sup> Because the effect of epinephrine is transient, the site was then clipped. Other authors have reported safe use of endoclips before polypectomy (Fig. 37.10).<sup>69</sup> En bloc resection is a key component of precise pathologic staging in cases of polyps containing invasive cancer. A case series of giant pedunculated polyps described a greater than 80% volume reduction after 4 to 8 mL of 1:10,000 epinephrine injections into both the polyp head and the stalk. The dramatic volume reduction decreased the need for piecemeal

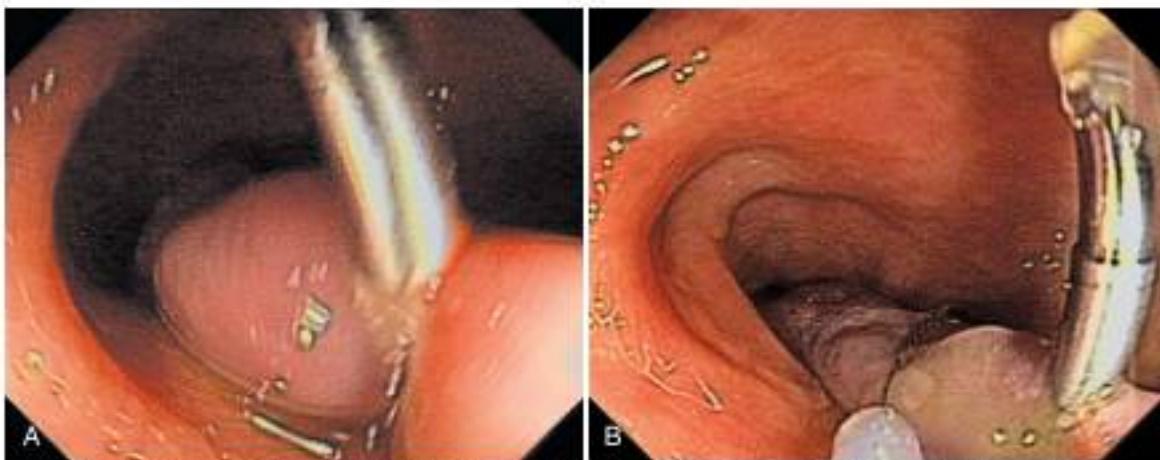

#### BOX 37.1 Rules of Endoscopic Resection

1. Remove in one piece if safely possible
2. Finish polyp resection in one session. A delayed resection will increase the risk of incomplete polyp removal
3. Obtain a healthy margin
4. Mechanical removal is superior to ablation
5. Avoid taking a biopsy if a patient will return for an EMR or ESD. High-quality endoscopic images are superior to biopsy for the referring endoscopist to assess the amenability of the lesion for endoscopic resection and plan for the appropriate resection procedure

EMR, endoscopic mucosal resection; ESD, endoscopic submucosal dissection.

**FIG 37.9** Use of the endoloop in pedunculated polyp to prevent postpolypectomy bleeding. The endoloop is used like a snare, except it can be detached after its deployment at the base of the polyp. **A**, The endoloop has been applied at the base of a large pedunculated lesion to ligate the feeding vessel. **B**, The polyp head has an ischemic purple appearance, and then an electrocautery snare has been placed above the loop with sufficient room to prevent the endoloop from slipping off after transection. The ideal way to snare a pedunculated polyp that has been looped is to tighten the snare as much as possible to make the snared plane smaller than the plane that has been looped. **C**, Resection site immediately after resection. A small blood vessel is visible. There was no bleeding after resection.

**FIG 37.10** An alternative to endoloops for preventing postpolypectomy bleeding is the endoclip. **A**, A single endoclip has been applied at the lower part of a long polyp stalk. **B**, The polyp appeared dusky after the endoclip placement, indicating effective strangulation of the stalk. The snare was subsequently positioned above the clip, and electrocautery was applied. It is important to avoid touching the clip with the snare during electrocautery application.

**FIG 37.11** Endoscopic polypectomy of colonic lipoma (well known to be benign) is known to carry a high risk of perforation. The ligate and let go technique is safe and efficacious to treat colonic lipoma. **A**, Typical appearance of a colonic lipoma. Originally, the lesion was sessile (not shown), but by repositioning the patient to make it "hanging," the lesion became pedunculated because its weight had pulled it from its point of attachment. **B**, Ligation of the point of attachment using an endoloop caused the lesion to become ischemic. **C**, Biopsy on biopsy showed the naked fat, confirming the diagnosis. There was no residual on follow-up colonoscopy a few months later.

resection.<sup>68</sup> In addition to reducing bleeding, the prophylactic use of the endoloop or endoclip at the base of large pedunculated polyps to facilitate en bloc rather than piecemeal resection has been described. The loop-and-let-go technique may be useful for the treatment of large pedunculated lesions, especially colonic lipomas (Fig. 37.11).<sup>69</sup>

### Endoscopic Mucosal Resection

Non-polypoid lesions can be difficult to capture with standard snare and polypectomy techniques, and it may be impossible to perform en bloc resection of large flat lesions using standard polypectomy techniques. Furthermore, the application of electrocautery may lead to a burn injury of the muscularis propria. A mucosal resection technique using submucosal injection can ameliorate these technical difficulties and risks. The indications of colonoscopic mucosal resection and submucosal dissection are presented in Box 37.2.

Various resection techniques have been described.<sup>70</sup> EMR refers to the inject-and-cut technique, which is most common. It was first described as the stripped biopsy method by Karita et al (1991).<sup>71</sup> The key aspects of submucosal injection are to inject a sufficient amount and to recognize the presence of the nonlifting sign. The ideal solution, which would form a substantial bulge and would not dissipate quickly, has not yet been defined. Physicians in the United States routinely use saline (Fig. 37.12).

Over the past decade, EMR has replaced surgical resection. It has been shown that it can achieve complete polyp removal in more than 90% of lesions.<sup>72,73</sup> Considering the morbidity and potential mortality (albeit low) with surgical resection, and the required postsurgical care, EMR is more cost effective than surgical resection.<sup>74</sup> Therefore, endoscopic resection should be the first-line treatment for any colon polyp.

Submucosal injection lifts the polyp from the submucosal layer. The benefit is threefold. It creates a more protuberant

### BOX 37.2 Indications for Colonoscopic Mucosal Resection and Submucosal Dissection

- I. Requires a team to safely and efficaciously perform endoscopic mucosal resection (EMR) or submucosal dissection
- II. The neoplasm does not have features of deep submucosal or deeper invasion
- III. EMR: Lesion (non-polyoid or sessile) with mucosal neoplasia requiring resection at the submucosa to ensure cure. If the lesion is suspected to contain high-grade dysplasia or superficial submucosal invasion, EMR is indicated, provided that the lesion is within the scope of the EMR technique for en bloc removal
- IV. Endoscopic submucosal dissection: Lesion requiring en bloc resection:
  - 1) Lesions for which en bloc resection with snare EMR is difficult to apply
    - Large nongranular lesion (laterally spreading tumor-nongranular) with slight depression
    - Lesions with suspected cancer and suggesting shallow submucosal invasion
    - Large depressed-type tumors
  - 2) Mucosal tumors with submucosal fibrosis
  - 3) Sporadic localized tumors in conditions of chronic inflammation such as ulcerative colitis
  - 4) Local residual or recurrent early carcinomas after endoscopic resection
- V. Pathologic evaluation provided proof of cure:
  - A. Well-differentiated carcinoma (without poorly differentiated)
  - B. Without lymphatic or vascular invasion
  - C. Intramucosal cancer, regardless of size (limit of involvement in the United States)
  - D. Minute submucosal invasion less than 1000 µm from the muscularis mucosa, or if the muscularis mucosa is absent, depth of measurement is performed from the surface of lesion
  - E. Vertical and lateral margins are free of carcinoma

higher risk of prevalent cancer than an LST-G.<sup>77</sup> Cancer is more commonly located in the protuberant portion (Paris Ia) of the polyp. Retrieval of this specimen and preparation for pathology evaluation as detailed previously is mandatory to assess for possible deep invasion of cancer.

- Submucosal injection can help to improve visualization and positioning of the polyp. For instance, if a polyp is partially or completely located behind a fold, injection should start from the proximal margin of the lesion. This will lift the polyp toward the visual field of the colonoscope and ease resection.
- Submucosal injection may be applied liberally and may be used to "mold" the shape of the lifted lesion (dynamic injection; Fig. 37.13). By changing the needle catheter during injection (e.g., lifting), using subtle tip deflection into the lumen, gentle pull of the needle catheter back, and slight suctioning of the lumen, the shape of the submucosal cushion can be changed, which may improve positioning of the polyp and enhance engagement of the polyp into the snare.

The technical approach to EMR follows the principles of hot snare resection (Video 37.3). After the submucosal injection, the snare is positioned around the target area. A rim of normal mucosa is included. While maintaining gentle pressure of the snare onto the colonic wall, air is gently aspirated, and the snare closed. This combined maneuver of aspiration and closure promotes full engagement of the target tissue into the snare. Once the snare is closed, air is reinflated to visualize adequate entrapment of the polyp. The snare catheter is then moved back and forth (tucking) to ensure that no muscularis propria is enclosed in the snare. If the endoscopist is confident that snare closure is optimal, the snare is moved away from the wall and completely closed while applying electrocautery. After resection, the area should be flushed and carefully inspected for deep mural injury. A black or a yellow "bull's eye" at the resection base (or yellow "target sign" at the base of the resected polyp) may indicate perforation or impending perforation (serosal fat). Such a defect needs to be closed immediately. Once closure is ensured, resection can be continued. After the entire polyp is removed, the resection margin and the polyp base are carefully examined using white light and digital chromoendoscopy for any remaining polyp tissue.

Removing residual tissue islands may be challenging. The general principle holds that mechanical removal is superior to ablation. A dedicated stiff cold snare may engage small polyp islands more reliably. If this is not possible, residual tissue can be removed by avulsion. The tissue is grabbed with a forceps and pulled slowly and tangentially to obtain a larger tissue piece. Any bleeding that occurs with these cold resection techniques is typically mild and self-limited. If mechanical attempts to remove residual tissue fail, ablation should be applied. This can be done with APC. Alternatively, soft coagulation cautery may be safely applied through the snare tip.

Following visible complete resection, additional ablation of the resection margin may reduce risk of recurrence (see later). Retrieval of resection specimen can be accomplished with a net and withdrawal of the colonoscope. Specimens that indicate suspicion of prevalent cancer should be pinned to allow optimal preparation by the pathology lab for assessment of deep margin involvement.

#### Modified EMR Techniques

**Underwater resection.** Complete water immersion of the polyp may facilitate capture of the lesion with the snare and promote

lesion, particularly of flat polyps, which can then be more easily engaged into a snare. It provides a safety cushion between the mucosal polyp and the muscularis propria when applying electrocautery by better distribution of current into the wide fluid cushion.<sup>78</sup> Last, the added contrast media generally demarcates the polyp margin from normal surrounding mucosa.

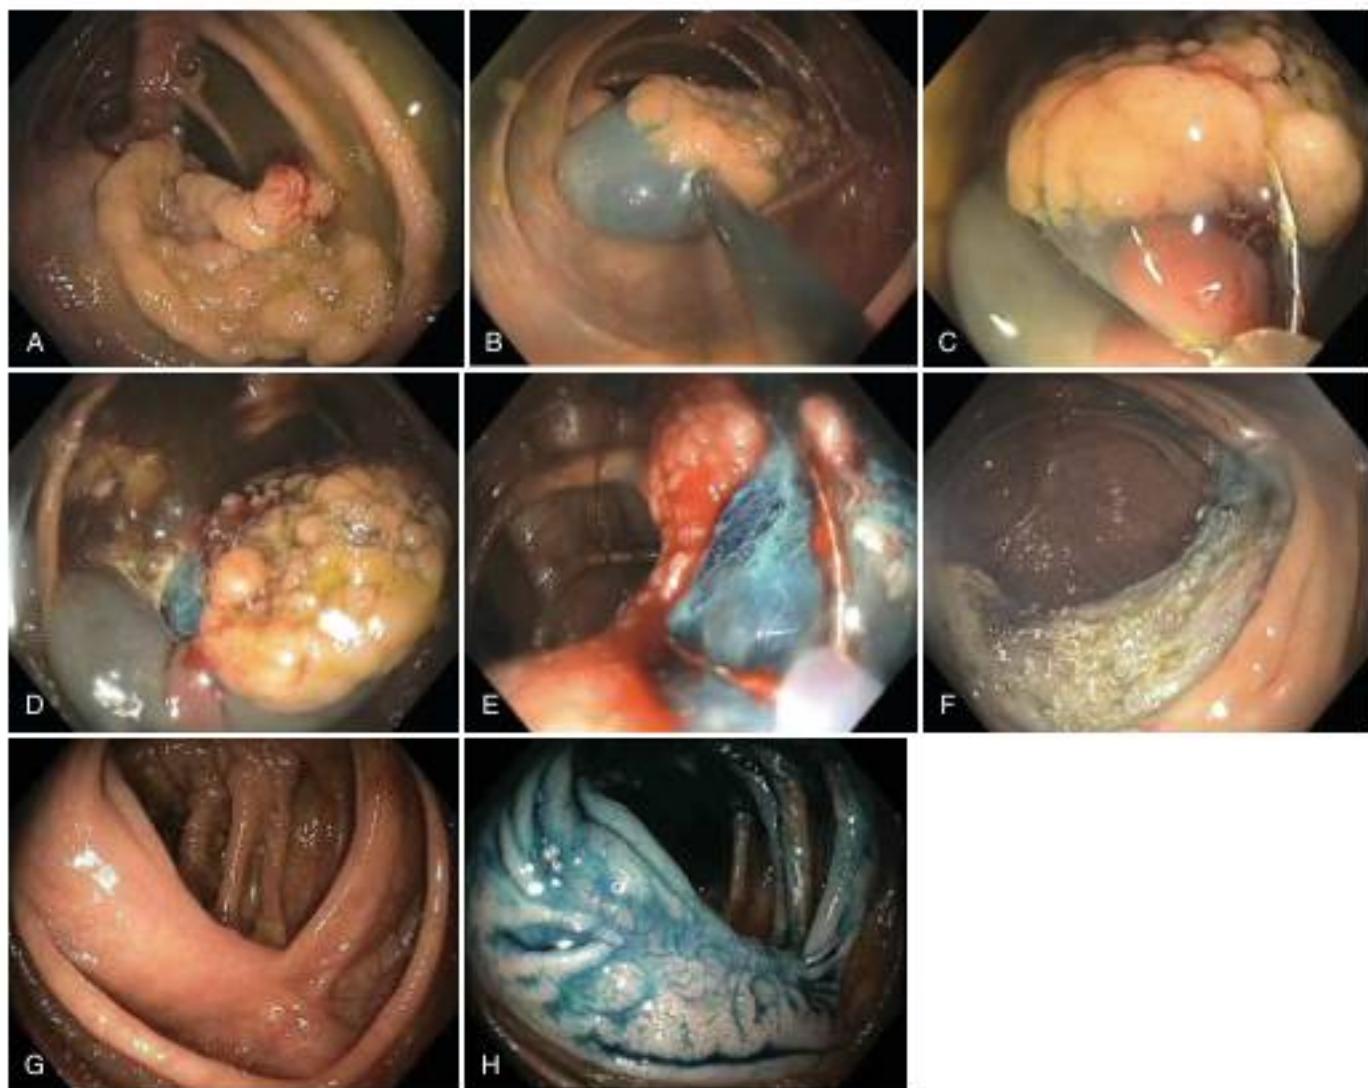

When should EMR instead of simple snare resection be used? A 2016 study suggests a possible benefit of submucosal injection for lesions 15 mm or larger, and clear benefit for lesions greater than 20 mm.<sup>43</sup> In practice, the size cutoff is determined by local practice and individual preference. Anecdotally, European endoscopists tend to inject smaller polyps than endoscopists from North America.

Once the decision is made to proceed with EMR, the resection needs to be planned. Can the lesion be removed in one piece (en bloc), or will it require piecemeal resection? If piecemeal, where should the resection start? Which snare is preferable?

**En bloc resection:** Resection in one piece is typically attempted for polyps up to 25 mm in size. It is associated with a lower risk of recurrence when compared to piecemeal resection.<sup>79</sup> The complication risk may be increased when attempting larger en bloc resection. The technique of en bloc resection is identical to hot snare resection following submucosal injection.

**Piecemeal resection:** The approach to piecemeal resection depends on the morphology, size, and location of the lesion. The following suggestions should be considered:

- The area of the polyp with the highest risk of cancer should be resected first. An LST-NG or mixed morphology has a

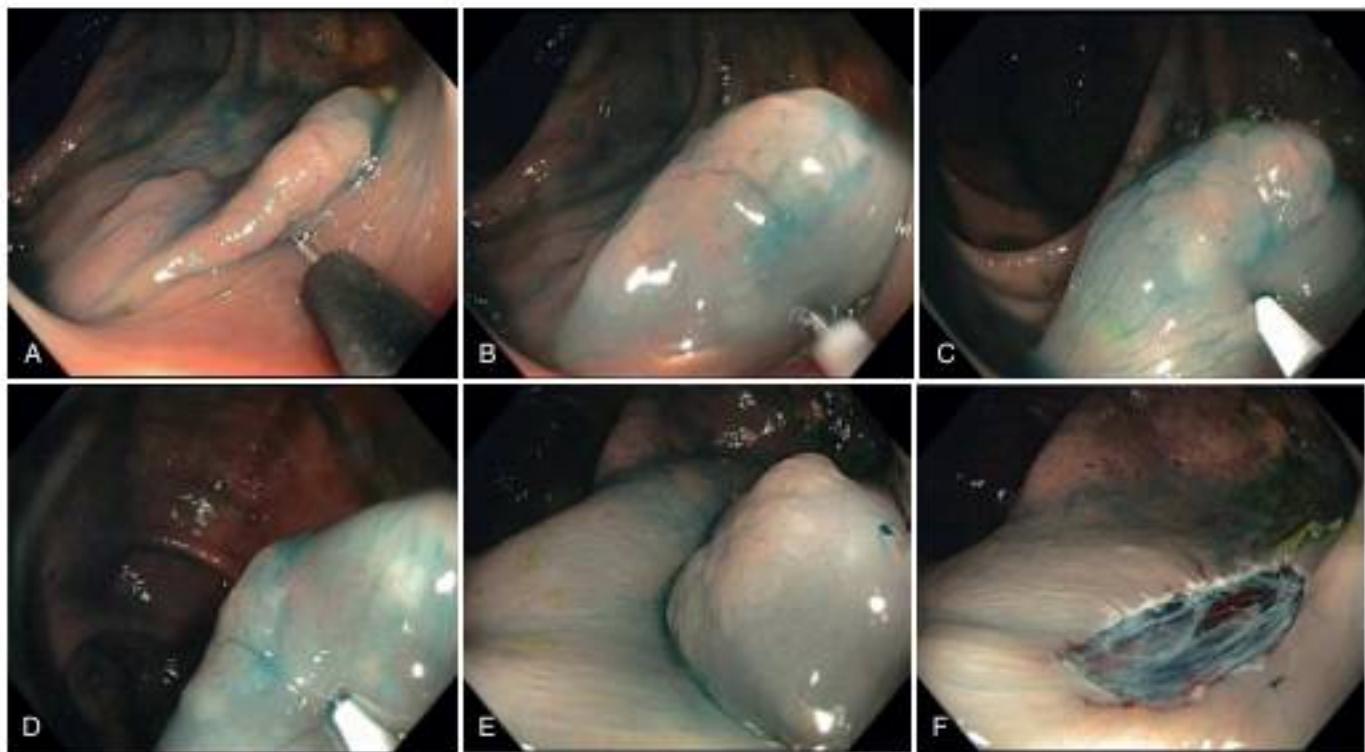

**FIG 37.12** Piecemeal resection of a large lateral spreading granular type lesion. A biopsy had been performed to document that the lesion was a large villous adenoma, as was suspected from its endoscopic appearance. **A**, The lesion was located adjacent to the ileocecal valve. **B**, A large amount (40–50 mL) of saline mixed with a few drops of 0.2% indigo carmine was injected into the submucosa to lift the lesion. Efforts were made to inject so that the lesion does not tilt away from the colonoscope. **C**, The first piece was resected using a stiff snare at the edge of the lesion. By resecting the lateral margin first, the endoscopist developed an understanding of the depth of the lesion and the location of the submucosal plane. **D**, A small piece of the lesion had been resected. The visible bluish layer was the submucosa. **E**, Subsequent resections were performed without proceeding deeper than the submucosa. The remaining large piece of the lesion was snared. Note the position of the snare: parallel with the bowel wall. **F**, Appearance after piecemeal resection, which was completed approximately 40 minutes later. Argon plasma was applied to ensure complete eradication of the villous adenoma. **G** and **H**, The area of prior resection on follow-up 3 months later. There was no residual adenoma.

en bloc resection. Within the water-filled colon segment, the colonic wall is not expanded, and the muscularis propria tends not to involute into the lumen and become at risk for capture in the snare. Submucosal injection to create a safety cushion can therefore be deferred.

In a recent study, en bloc resection of 2- to 4-cm polyps was accomplished in 29 out of 53 lesions (55%). Outcomes were at least comparable to standard EMR with four complications, including one delayed bleeding event. Recurrence at first follow-up

was noted in 5% of patients. The drawback of this technique is impaired visualization in patients with suboptimal prep or with intraprocedural bleeding. However, these results encourage comparative studies.

**Cold snare resection EMR.** The upper size limit for cold resection of polyps has been increased to include LST lesions. The argument for cold snare resection is to lower the risk of delayed bleeding complications. Furthermore, complications related to cautery use, such as perforation or post-polypectomy syndrome,

**FIG 37.13** Dynamic submucosal injection. **A**, We evaluate a 15-mm superficially elevated serrated-appearing lesion under white light with diluted indigo carmine solution. In preparation for resection, we ensure optimal positioning of the targeted lesion to the 5–6 o'clock position and plan the path of injection. **B**, We place the needle catheter next to the lesion to then expose and insert the needle into the submucosa. **C**, We rapidly inject the mixture of saline and diluted indigo carmine into the submucosa with simultaneous adjustments of the needle catheter and endoscope tip to ultimately lift the lesion upward. **D**, As the injection proceeds to the right, the direction of the injection is slightly altered to the left and then upward again in order to guide the creation of the focal submucosal bleb. **E**, During this process, we slightly suction the lumen in order to decrease wall tension, and then are able to place a snare around the lesion, and **F**, complete en bloc resection.

would not occur with this technique. Case series have shown that it is technically feasible and does not lead to increased intra-procedural bleeding complications.<sup>37,38</sup> Drawbacks may include impaired visualization from intraprocedural bleeding and smaller resection pieces. Both may increase the risk of recurrence.<sup>39</sup> Data on longer-term outcomes and recurrence are needed, and this approach is therefore considered experimental.

**Submucosal resection with band ligation.** This technique can be particularly useful for resection of submucosal lesions, such as carcinoid tumors in the rectum (Fig. 37.14).<sup>79,80</sup> After the endoscope is fitted with the ligation device, the target area is ligated, with or without prior deep submucosal injection. Standard polypectomy is performed below the rubber band. Small submucosal lesions may require prior markings at their periphery, achieved by brief bursts of cautery using the tip of a snare, because such lesions may be difficult to find after the ligation device has been fitted to the endoscope. Cap-assisted EMR has been popular and efficacious for resection of superficial early cancer in the esophagus and stomach, but in general it should not be used in the colon, as the thin muscularis propria of the colon can easily be suctioned into the cap, potentially leading to perforation.

### Special Considerations

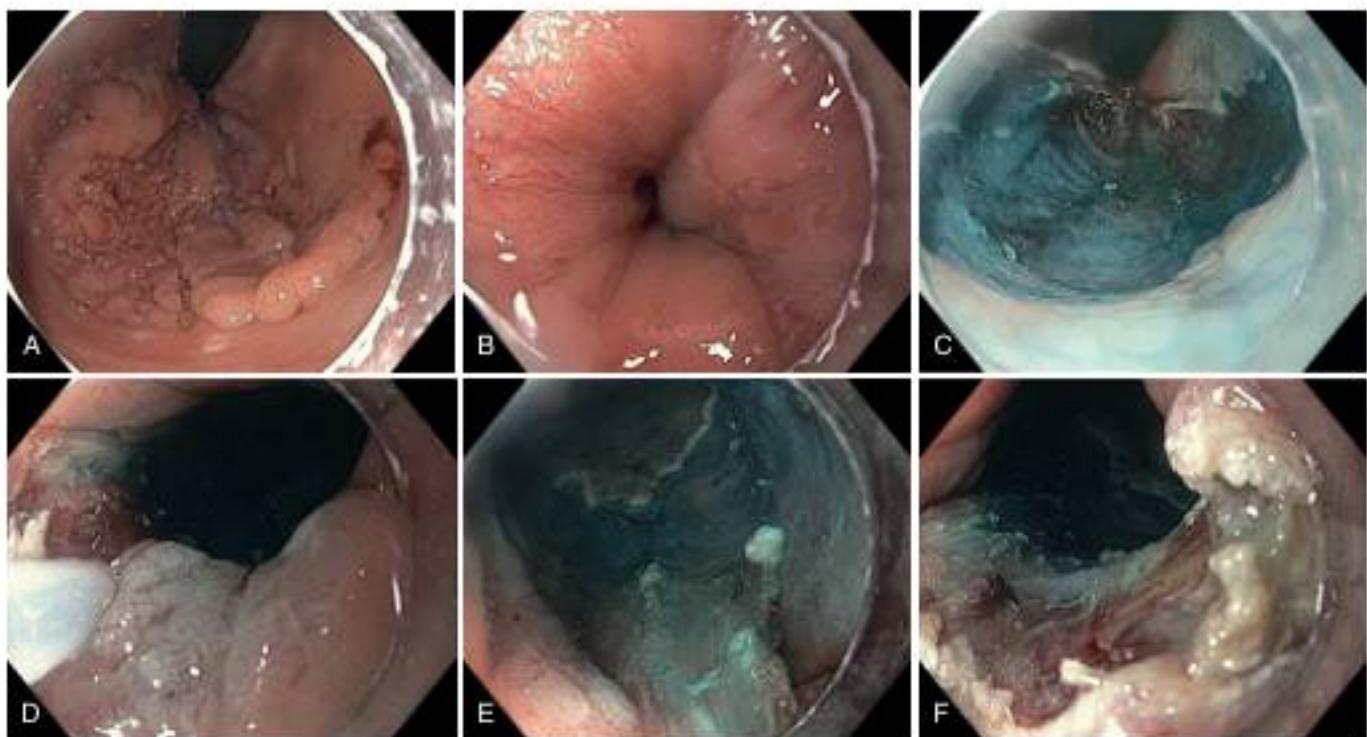

**Location in the ileocecal (IC) valve.** Position in the IC valve is not necessarily a contraindication for EMR. In a case series of 53 patients, LSTs could be successfully removed, and surgery avoided, in 43 patients (81%).<sup>81</sup> Recurrence was observed in 8 patients (20%), which could be managed endoscopically in all cases. Infiltration of the ileum and involvement of both IC valve lips were associated with failure of EMR. It should be pointed out that the published data are from a very experienced group and that technical success may not be generalizable. Furthermore, these results also point out that documentation of localization should be detailed and should state whether the superior and inferior lips, and the anterior and posterior angles of the IC valve, are involved.

**Location in the appendiceal orifice.** Extension of a lesion into the orifice of the appendix is only possible if the margin within the orifice is visible, which is in accordance with the principles of mucosal resection.

**Location at the anorectal junction.** Lesions involving the anal canal may be technically challenging because of impaired visibility (Fig. 37.15). Resection may be facilitated with the use of a cap (antegrade view) and the use of a gastroscope, which has greater

**FIG 37.14** Endoscopic submucosal resection of a small carcinoid tumor in the rectum using a band ligation device. **A**, Lesion. **B**, After deep submucosal injection of saline and placement of a band using the ligation device, a snare is seen transecting the lesion as cautery is applied. **C**, Resection margin. The lesion was contained within the resected specimen with a clear margin (not shown). By cutting immediately below the band, a deeper resection can be performed.

**FIG 37.15** Distal rectal lesion involving the anal canal. **A**, A large 5-cm lateral spreading granular type lesion on the anterior wall of the distal rectum is seen in retroflexion, and **B**, extending into the anal canal. **C**, Piecemeal endoscopic mucosal resection is performed, and the mucosal defect can be seen. **D**, Inspection of the anal canal for residual neoplasia to target for resection requires the use of a cap. Position of the snare for resection of the neoplasia. **E** and **F**, Further inspection shows no further residual.

flexibility when resection is performed in retroflexion. Resection may include the squamous epithelium of the anal canal, which has a somatic sensory nerve supply and therefore requires anesthesia prior to resection. For such instances, a long-acting local anesthetic (e.g., bupivacaine) may be added to the submucosal injection fluid. Furthermore, rectal veins drain directly into the systemic system and not through the portal system with

its protective reticuloendothelial function. This may increase the risk of systemic bacteremia related to repeated submucosal injection and large-field resection, and antibiotic prophylaxis may be considered (although this has not been adopted into guidelines). Finally, hemorrhoidal plexus may be a concern for increased bleeding. However, the hemorrhoid vessels are located deep within the submucosa and are protected by the submucosal

cushion. Injection should be placed just aside the hemorrhoidal columns to lower bleeding risk and ensure a safe submucosal lift between the polyp and the hemorrhoids. The Australian Colonic Endoscopic Resection (ACE) study group describes their standardized approach using local anesthetics and prophylactic antibiotics for lesions greater than 40 mm and within 5 cm of the dentate line.<sup>32</sup> Efficacy and safety was similar to resection of lesions in the proximal rectum.

**Circumferential extension.** No size limit for resection of LST lesions has been described. Polyps up to 16 cm in size have been excised by EMR. However, size appears to be less a limiting factor for mucosal resection than polyp morphology or location. Lesions that occupy the entire circumference are rare. In a case series, they represented approximately 1% of all LSTs larger than 20 mm, with the majority being located in the rectum or sigmoid colon.<sup>33</sup> Complete removal was accomplished of all 12 lesions in this series. Luminal stenosis after resection is a concern, although symptomatic stricturing that required dilatation occurred in only two cases (17%). Recurrence after resection, which appears to be more frequent than seen with the average LST, could be successfully treated by repeated endoscopic resection.

**Submucosal lesions.** Endoscopic resection is also used increasingly to remove submucosal lesions, where the risk of metastasis is low.<sup>34</sup> In particular, rectal carcinoids up to 10 mm without any adverse features can be treated by endoscopic resection. A 2014 systematic review supports endoscopic resection of up to 16-mm rectal carcinoids followed by careful histological assessment.<sup>34</sup>

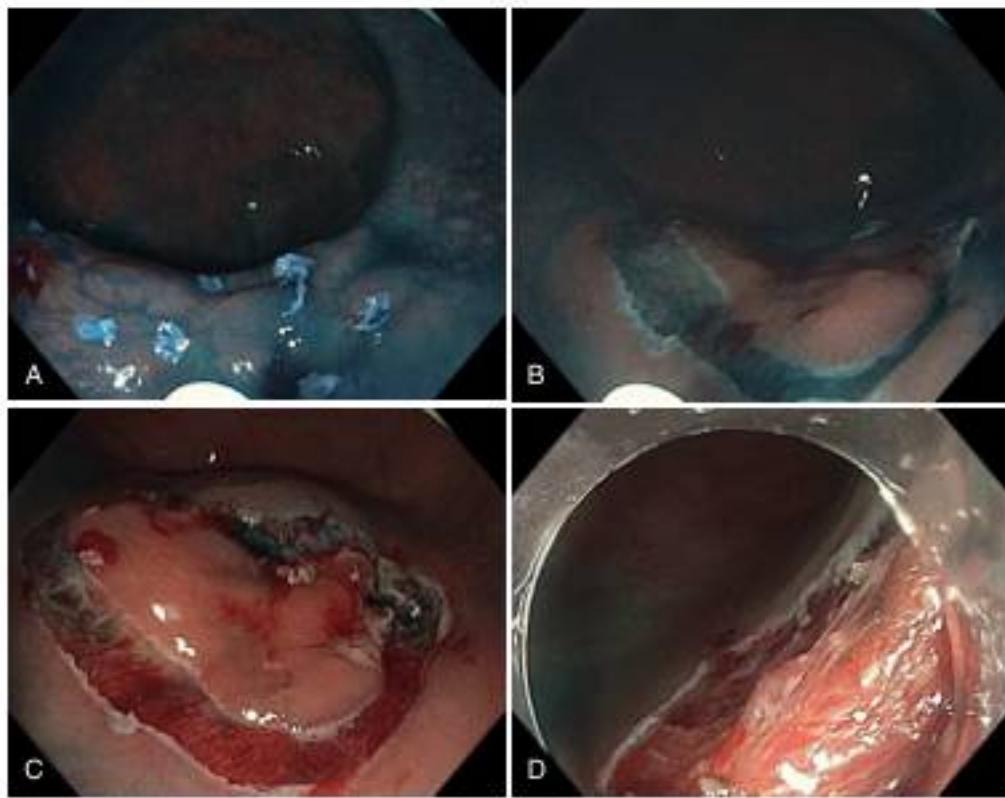

### Endoscopic Submucosal Dissection

En bloc endoscopic resection of early gastric cancer was first described in 1988,<sup>35</sup> but it was not until 1999 that the first report of the use of a specialized knife was published in the Japanese literature<sup>36</sup> and soon after the term *ESD* was coined. Although the development of endoscopic therapy of early gastric cancer was the main driving force behind the evolution of ESD in the East, the first English language description of ESD was in the rectum.<sup>37</sup> Since then in the East, ESD has quickly gained popularity and has become a routinely used modality for the management of superficial lesions containing early cancer or high-grade dysplasia throughout the gastrointestinal tract.

The use of ESD over EMR in selected colonic lesions has been supported by two meta-analyses showing well-documented higher en bloc and curative resection rates, as well as decreased local recurrence.<sup>38,39</sup> An increased rate of adverse events with ESD mostly related to perforation and bleeding was shown in one of these meta-analyses,<sup>39</sup> but this was not confirmed by the other meta-analysis.<sup>38</sup> Importantly, the overwhelming majority of adverse events were successfully managed by endoscopic means. Nevertheless, ESD tends to be a lengthier procedure than EMR and requires extensive training. As a result, in the West expertise is not widely available.

At present, the majority of colonic lesions can be managed by EMR, but ESD expands the opportunity for patient cure and should be given strong consideration in the following circumstances<sup>40</sup>:

- LST-NG type. This recommendation is driven by the higher propensity of LST-NG for submucosal invasion. Even if malignant submucosal invasion is not present, LST-NGs tend to not to lift well with submucosal injection due to submucosal fibrosis, which makes EMR technically difficult and complete resection frequently unsuccessful.
  - Large LST-G type. ESD should be considered in LST-Gs measuring greater than 30 mm with large nodule(s) or large depressed areas due to the higher risk of submucosal invasion in these lesions.<sup>31</sup>
  - Mucosal tumors with submucosal fibrosis, such as seen with post-EMR recurrences, lesions only partially removed by EMR, lesions that have been sampled with partial snare resection to obtain a large specimen for pathology, and tattoo placed under the lesion. Similarly, lesions in conditions of chronic inflammation, such as ulcerative colitis, tend to have a higher degree of submucosal fibrosis and may preferentially be approached by ESD.<sup>32</sup>
  - Lesions with high suspicion for invasive cancer with invasion into the superficial submucosa (< 1000 µm). Assessment of invasion depth is typically based on the Kudo classification, and Kudo pattern Vi is consistent with superficial submucosal invasion whereas Kudo pattern Vn is seen with deep invasion. This differentiation can be very difficult if expertise in magnification endoscopy and chromoendoscopy with crystal violet is not available. The more practical NICE classification has been shown to have high sensitivity and specificity to detect deep submucosal invasion (NICE Type 3), precluding the use of ESD.<sup>33</sup> Patients with T1 lesions with less than 1000-µm submucosal invasion, well differentiation, and without lymphatic or vascular invasion have minimal risk of lymph node metastasis. Thus, patients can be informed about the risk of metastasis compared with the risk of surgery in making a decision regarding surgical resection.
- ESD in the colorectum follows the same principles as ESD in the esophagus and stomach,<sup>41</sup> but as the technique has evolved a few technical considerations and variations have emerged.
- Mucosal markings around the lesion are typically not needed because lesion border tends to be easy to identify.
  - A full circumferential incision is usually not done. The typical strategy of colorectal ESD is to perform a partial circumferential incision followed immediately by some submucosal dissection. This strategy is mostly driven by the very quick dissipation of the submucosal injectate. To further address this issue, the pocket-creation technique has been described. After creating an initial mucosal incision large enough to accommodate passage of the scope into the submucosal space, a large submucosal pocket is created undermining the lesion. This prevents leakage of injection solution and provides good tissue traction.<sup>42</sup>
  - Change of patient position is frequently needed to provide some gravity-driven tissue retraction. Counter-traction is not easy to achieve, but the string and clip method appears to be more practical and may be considered in select cases.<sup>43</sup>
  - A variety of bridging techniques have been described using a combination of components from ESD and EMR techniques. Multiple terms have been used in the past (circumferential incision EMR, circumferential submucosal incision EMR, EMR pre-cutting, universal ESD), but the Japan Gastroenterological Endoscopy Society (JGES) guidelines streamlined the terminology and now two categories are recognized: pre-cutting EMR and hybrid ESD<sup>44</sup>:
    - In pre-cutting EMR, the tip of a standard snare or ESD knife is used to create a circumferential incision around the lesion. This is followed by application of snare for lesion removal without any submucosal dissection.
    - In hybrid ESD circumferential incision is performed and some degree of submucosal dissection is carried out prior

**FIG 37.16** Hybrid endoscopic submucosal dissection. **A**, Non-polypoid flat dysplastic lesion is seen in a patient with ulcerative colitis. The periphery is marked. Severe submucosal fibrosis prevents both lifting and snare capture of the lesion, and **B**, hybrid endoscopic submucosal dissection (ESD) is pursued, with circumferential incision using a dual knife, and **C**, some submucosal dissection. **D**, The post-resection defect is seen.

to the application of the snare. Again, the tip of a snare or dedicated ESD knife can be used for the circumferential incision/submucosal dissection portion of the procedure (Fig. 37.16).

- Injection solution that provides a long-lasting submucosal cushion is required for ESD. This is preferred in the colon, where normal saline injection tends to dissipate rapidly. The available injection solutions options are discussed earlier in this chapter in the section on **Instruments and Equipment**.
- Specialized electrocautery equipment and in-depth knowledge of electrocautery principles are essential for successful ESD:
  - The use of an electrocautery unit providing modulated current capabilities is mandatory. The ASGE Technology Status Evaluation Report provides a detailed review of the technical characteristics and the available options in the United States.<sup>23</sup>
  - The exact settings of the electrosurgical generator (type of modulated current, power output, effect, duration, etc.) vary for different stages of the procedure (e.g., marking vs. circumferential incision vs. submucosal dissection), the type of instrument used, the lesion location (e.g., stomach vs. colon), and the different models of electrocautery generators. Some specific suggestions are summarized in a 2015 ASGE Technology Status Evaluation Report focusing on ESD.<sup>24</sup>
- It should be emphasized that the recommended electrocautery settings differ greatly among experts performing an ESD. The main reason for this substantial variability is

that beside the factors listed earlier (stage of the procedure, type of instrument, and lesion location), other variables can significantly contribute to the final tissue effect. These include the surface area of the device electrode in contact with the tissue, the speed of movement of the electrode, the pressure applied with the electrode, the presence of coagulated tissue debris sticking to the electrode, the target tissue itself (fibrotic vs. high water content), and the grounding pad placement (pad should be placed on the patient flank rather than the lower extremity). Therefore, expert recommended settings will be a good starting point, but it is critical to note that the final tissue effect will significantly depend on a multitude of other factors, most importantly, the endoscopist's ESD technique.

ESD has expanded our armamentarium to manage dysplastic and early cancerous lesions in the colon and is now routinely performed in the East. As ESD evolves, the anticipation is that increasing training opportunities, device innovations, and familiarity with the procedure will lead to full acceptance with expanding indications in the West.

## TECHNIQUES TO IMPROVE EFFICACY AND SAFETY OF POLYPECTOMY

### Prevention and Treatment of Recurrence

Because prior resection attempts increase the risk, one basic rule of EMR is to complete the resection in one setting. Of note, intraprocedural bleeding is a risk factor for recurrence. The reason

**TABLE 37.3 Factors Associated With Delayed Bleeding Following Endoscopic Resection of Large Non-Pedunculated Colorectal Polyps**

\*Lesions were removed by endoscopic mucosal resection, endoscopic submucosal dissection (ESD), or hybrid ESD.

<sup>a</sup>Proximal to transverse colon.

<sup>b</sup>Complete closure vs. no closure (historical controls).

<sup>c</sup>Complete closure vs. no closure; clip closure was selective at endoscopist discretion.

<sup>d</sup>p = 0.012.

<sup>e</sup>Microprocessor controlled vs. not microprocessor controlled.

<sup>f</sup>Any antiplatelet agent.

<sup>g</sup>Aspirin.

ASA, Aspirin; RCT, randomized controlled trial.

for this is very likely related to impaired visualization and missing residual polyp tissue.

Non-visible residual polyp at the resection margin has been considered the source for regrowth. Therefore, some endoscopists use ablation of the margin after visibly complete removal. A small randomized trial of using APC of the resection margin after resection in 21 patients showed a lower recurrence rate in the ablated patients (1/10 vs. 7/11).<sup>77</sup> However, this study was criticized for its small sample size and high incomplete resection rate in the control group (64%). In addition, the study was performed before high-definition endoscopes and digital chromoendoscopy were available. Recent preliminary results from the ACE group (2016) support ablation of the margin after resection. Among a total of 768 patients with polyps of 20 mm or larger, ablation of the margin using soft coagulation reduced the polyp recurrence rate from 20% to 6%.<sup>78</sup> In contrast, the same group showed that extending the resection to include a large, healthy margin did not appear to reduce the recurrence rate (12% in the standard group vs. 10% in the healthy margin group).<sup>79</sup> Despite these two seemingly opposing findings, the conclusion is twofold. First, ablation of the margin may be considered in routine practice. Second, even with dedicated attention to the margins, recurrence will occur in some patients. A possible reason for recurrence despite clearing the margins may be related to tissue bridges between the removed pieces that may serve as the nidus for regrowth.<sup>100</sup> Therefore, fewer pieces may lower the risk of recurrence; however, this has not been formally examined. Resection of recurrent lesions should follow the same principles of initial resection, that is, mechanical before ablation. However, in some instances, surgical removal is needed.

### Reducing the Risk of Delayed Bleeding

Delayed bleeding is the most common serious complication related to EMR. Table 37.3 provides a summary of prior studies that examined potential risk factors. Size and proximal location, particularly in the ascending colon and cecum, have been consistently shown to be associated with increased risk of delayed bleeding.<sup>78,101,102</sup> Other factors that were found in some but not other studies include age 75 years or older, comorbidities (ASA ≥ 3), use of anticoagulation medication,<sup>101</sup> and use of electrocautery that is not microprocessor controlled.<sup>78</sup>

Two interventions have been examined to reduce the risk of delayed bleeding. First, the addition of epinephrine to the submucosal injectate does not appear to reduce the risk of delayed bleeding after EMR.<sup>78</sup> Second, closing the mucosal defect after resection with clips may reduce the risk of delayed bleeding.<sup>101–103</sup> A larger retrospective study by Liaquat et al (2013) showed a delayed bleeding rate of 2% if clip closure was performed compared with a 10% bleeding rate when the mucosal defect was not closed with clips.<sup>102</sup> These results are supported by a large prospective cohort study from Spain, where complete clip closure was associated with a reduced bleeding risk (whereas risk appeared to be increased if the defect was only partially closed).<sup>101</sup> Both studies are limited by their design (retrospective, uncontrolled). Selection bias is a potential problem, and obtained results may be affected by unmeasured confounders (for instance, lesions that were clipped might have been lower risk lesions). Therefore, the results cannot be generalized. A 2015 randomized trial from China might have overcome such limitations; however, smaller lesions (≥ 10 mm) were included, different resection methods applied (EMR, ESD, and hybrid ESD), and outcomes,

particularly bleeding, not clearly defined.<sup>113</sup> The detected difference in delayed bleeding of 1.1% in the clip closure group compared with 6.7% in the control group therefore needs to be interpreted with caution. Although these studies suggest that clip closure may reduce the risk of delayed bleeding, convincing evidence for this approach is still lacking and it can therefore generally not be recommended. Aside from efficacy, cost-effectiveness analyses do not currently support general clip closure after EMR.<sup>99,104</sup> Clip closure may be considered for individual patients that are considered at higher risk of bleeding (proximal location and on anticoagulation). A large-scale multicenter, randomized trial is under way and will provide further guidance ([ClinicalTrials.gov](#) identifier: NCT01936948).

### Marking the Polypectomy Site

The site of a lesion can be marked with ink (e.g., SPOT, GI Supply, Camp Hill, PA) injected into the submucosa or by placement of a single or multiple radiopaque clips (Fig. 37.17).<sup>105,106</sup> Both techniques are safe and simple to perform, although the endoclip may not be palpable and may not stay in place for a prolonged period. If marking is performed prior to endoscopic resection, it is important to inject the ink several centimeters away from the lesion because the injectate will result in submucosal fibrosis that can complicate resection.

### Retrieving the Specimen

The benefits of mucosal resection or polypectomy can be assessed only by a properly prepared pathologic examination. The retrieval net is useful in recovering a specimen<sup>107</sup> from an en bloc resection of a flat or depressed lesion. Smaller pieces can be collected through the accessory channel. The net, snare, basket, and multipronged grasper are other accessories that can be useful for removal of large pedunculated polyps.

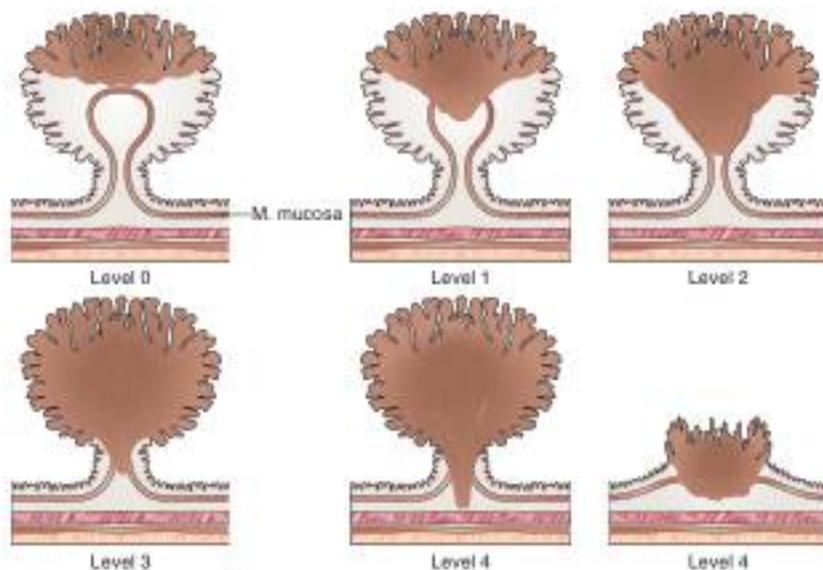

## MANAGEMENT AND SURVEILLANCE AFTER POLYPECTOMY

Surveillance guidelines, for example, from the US Multi-Society Task Force on Colorectal Cancer, should be applied to determine the appropriate colonoscopy surveillance interval following polyp removal.<sup>108</sup> After piecemeal resection of large lesions, a repeat colonoscopy is typically performed within 3 to 6 months to assess for local recurrence.<sup>109</sup> The postmucosectomy scar site should be carefully examined; image-enhanced endoscopy techniques may be useful to show the presence of the innominate grooves across the scar and normal pit or microvessel patterns. Khashab et al (2009) reported a high predictive value for long-term eradication in cases where the postmucosectomy scar site showed both normal macroscopic and microscopic (biopsy) findings.<sup>110</sup> In cases with residual neoplasia, appropriate therapy with biopsy or repeat EMR is prudent, and another surveillance colonoscopy should be performed at 6 months. There is no clear guidance regarding a surveillance interval following a normal first follow-up examination. Even in the absence of biopsy-proven recurrence or residual adenoma at initial surveillance colonoscopy within 6 months, there is still a risk of recurrence at the following examination within the following year that may range between 4% and 10%.<sup>111,112</sup> Therefore, a second surveillance examination 1 year after the first seems appropriate. If negative, the surveillance interval may be extended to 3 years. Subsequent intervals may then follow based on findings and in accordance with the guidelines.<sup>108</sup>

The management of patients with polypoid lesions with invasive carcinoma is evolving. With increased ability to remove larger lesions, more patients are found to have T1 cancer within a removed polyp. The risk of recurrence is dependent on the risk of incomplete resection and lymph node metastasis.

**FIG 37.17** **A**, India ink injection is used to mark an ulcerated depressed lesion. **B**, India ink solution was injected submucosally at three separate points. The depressed lesion was later shown to be an adenocarcinoma invading deep into the submucosa. Locations of the tattoos (distal, proximal, same level of the lesion) must be documented precisely, especially in cases of flat and depressed lesions. These lesions are often not palpable by the surgeon. Sometimes an endoclip is used in addition to India ink to mark the site on radiographs taken immediately after colonoscopy; this can assist in surgical planning, particularly when laparoscopic resection is contemplated in cases in the left colon. In these cases, the clip, as seen in the abdominal x-ray, can provide the precise location of the lesion.

**FIG 37.18** Haggitt et al (1985)<sup>111</sup> stratified the level of cancer submucosal invasion by the following criteria: *level 0*, carcinoma in situ (i.e., no extension below the muscularis mucosae); *level 1*, carcinoma invading through the muscularis mucosae but limited to the head of the polyp [i.e., above the junction between the adenoma and its stalk]; *level 2*, carcinoma invading the level of the neck [i.e., the junction between adenoma and its stalk]; *level 3*, carcinoma invading any part of the stalk; and *level 4*, carcinoma invading into the submucosa of the bowel wall below the stalk. In malignant sessile lesions, invasive carcinoma is considered as level 4.

Endoscopic resection has been shown to be safe and curative for low-risk T1 cancers, – those with only superficial submucosal invasion ( $\leq 1000 \mu\text{m}$ ), absence of poor differentiation, tumor budding, or lymphovascular invasion<sup>109–111</sup> (Fig. 37.18). Risk of recurrence after resection of low-risk cancers is approximately 1%; however, it increases to 5% for cancers with high-risk histological features.<sup>110,112,113</sup> The risk of recurrence also appears to be greater for rectal cancers compared with other colon cancers.<sup>112</sup> Among patients with recurrence, however, the prognosis may be poor. Given the importance of complete resection to achieve cure, endoscopists need to have a high degree of suspicion for possible early invasive carcinoma. Image-enhanced techniques are therefore a mandatory asset for complex polyp removal. If early invasive cancer is suspected, and endoscopic resection is still considered, en bloc resection should be the goal as it improves the chance of complete removal. In these cases, ESD may be the preferred choice.

## COMPLICATIONS

Complications of polypectomy and mucosal resection include bleeding, transmural burn, and perforation. Familiarity with the endoscopic findings, symptoms, and signs and treatment of complications is a prerequisite for performance of colonoscopic polypectomy and mucosal resection.

### Postpolypectomy Bleeding

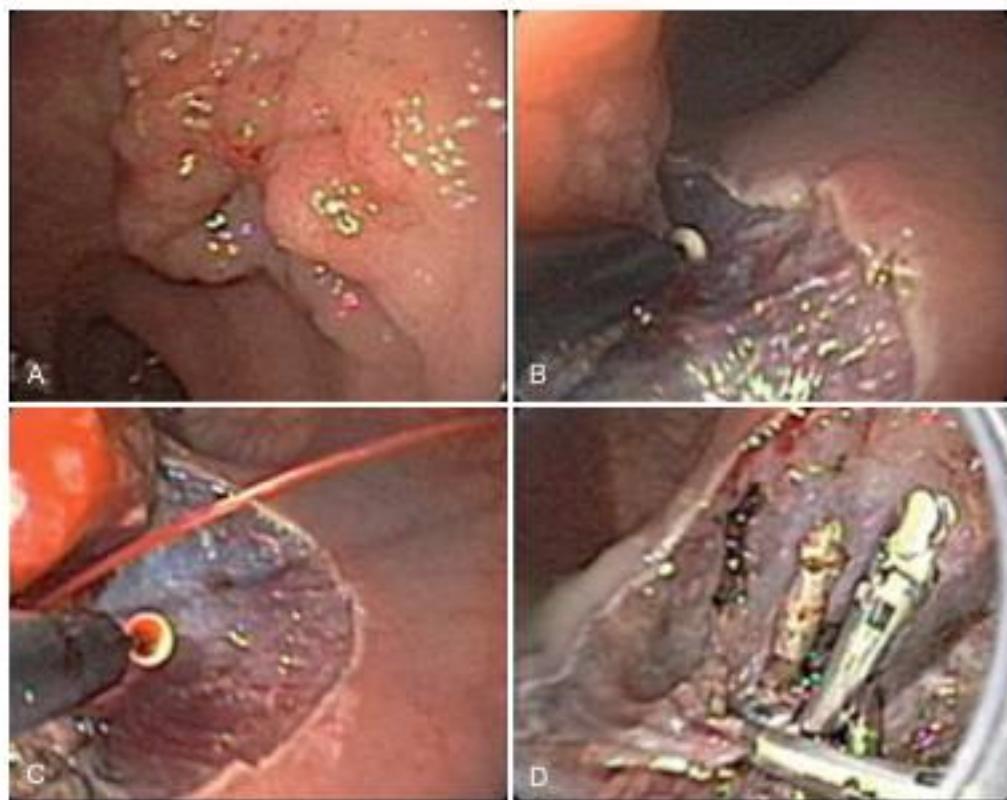

Postpolypectomy bleeding can occur during or after the procedure. The overall risk of severe bleeding related to polypectomy has been reported from large studies to be between 0.4% and 0.9%, or approximately 1 in 200 procedures.<sup>114–118</sup> The reported incidence varies according to the definition of bleeding, as well as the size

and type of lesions resected. It increases with polyp size and proximal polyp location. Delayed bleeding is the most common complication following EMR, occurring in 2% to 10% of patients, and several techniques may be applied to prevent risk of bleeding, as discussed earlier.

A variety of techniques are useful to treat active immediate or delayed bleeding. In cases with delayed bleeding, the bowel should be purged prior to performing the colonoscopy, although successful treatment of delayed postpolypectomy bleeding without prior bowel preparation has been reported and may be useful in more severe bleeding events.<sup>119</sup> These include application of a hemoclip or an endoloop, the use of APC, injection of dilute epinephrine, cauterization using monopolar or bipolar instruments, soft coagulation current, or use of a coagulation grasper (Coagrasper, Olympus, Center Valley, PA).<sup>120,121</sup> The selected method depends on the severity of bleeding and the bleeding lesion. For mild bleeding, our preferred technique is application of soft coagulation current.<sup>122</sup> More severe bleeding can be controlled with the coagrasper or with a hemoclip (Fig. 37.19). If endoscopic treatment fails, selective angiogram with embolization or surgery is employed.

### Postpolypectomy Syndrome

Postpolypectomy syndrome, also called transmural burn syndrome, is thought to occur when cautery injury causes full-thickness necrosis of the bowel wall. Patients typically present with fever, localized abdominal tenderness (often with rebound tenderness), and leukocytosis. Computed tomography may show local inflammatory changes that may mimic findings of diverticulitis. The onset of symptoms is commonly within a few hours of the polypectomy. It occurs in 0.1% to 0.5% of patients following a polypectomy.<sup>114,123</sup> Patients who are suspected to have

**FIG 37.19** Immediate endoscopic submucosal dissection (ESD) bleeding. **A**, A large lateral spreading granular type rectal lesion. **B**, ESD technique is performed to remove the lesion. **C**, During submucosal dissection, arterial bleeding is encountered. **D**, Hemostasis is achieved using endoscopic clips, and the resection is complete.

postpolypectomy syndrome typically require admission with bowel rest and antibiotics, although successful outpatient treatment has been described.<sup>123</sup> Most patients recover uneventfully.

### Perforation

Perforation can occur when the muscularis propria is included in the tissue grasped by a snare; this accident may happen, for example, when a large sessile polyp that is draped over a fold is grasped in its entirety. Perforation is rare with basic polypectomy, and occurs in up to 1% with EMR and 4% with ESD.<sup>20,94,95,124,125</sup> Techniques that may decrease the risk of capturing the muscularis propria have been summarized. A target sign at the base of the mucosal defect or the polyp following a resection is a sign of deep wall injury. A yellow defect target sign may represent serosal fat and indicates impending perforation. In the Australian cohort EMR of 911 large sessile polyps, a target sign was noted in 1.5% and an open perforation in 0.5%. All lesions were successfully closed with clips.<sup>126</sup> Other studies have similarly shown that the majority of perforations following a polyp removal can be closed with clips.<sup>101,123,127</sup>

### FUTURE TRENDS

Basic polyp resection has seen a shift from hot to cold snare resection. Although early studies suggest that cold snare resection is at least as safe and effective as hot snare resection, future studies should provide more solid data from comparative effectiveness

studies and identify the upper size limit for routine cold snare removal.

Advances in the technology and technique of colonoscopy have allowed us to manage increasingly complex colorectal lesions via endoscopy. Learning and using these new technologies and techniques may be demanding, but they enable us to perform endoscopic resections of larger, more complex lesions that previously would have required major abdominal surgery. Considering efficacy and cost, it is no longer justified to perform surgical resection of these lesions as the first treatment approach. At the same time, practice may vary. Regional or population-based studies may help to understand variations and whether additional training is required to provide effective and safe care. Particularly with respect to the resection of larger colorectal lesions, the following questions deserve attention:

- How can EMR reliably achieve complete resection?
- What technique provides the safest resection and minimal risk of bleeding?
- What is the optimal electrocautery setting for resection?
- How should antithrombotic agents be managed following removal of large polyps?
- When should ESD be used instead of EMR?

Studies are ongoing that will provide some answers to these questions and provide guidance to establishing a standardized efficacious and safe approach to resection of large colorectal lesions. Although resection of large lesions is technically feasible, resection may be tedious, is often incomplete at the initial session,

requires extensive skill and experience, and the risk of complications is still substantial. These drawbacks call for a more elegant, safe, and reliable technique. Modified EMR and ESD techniques are attempts in that direction. New ideas and technological developments are needed to optimize our current techniques.

Finally, we recognize that resection of large lesions requires advanced endoscopy skills. Large polyp resection should be performed by endoscopists with sufficient experience and training in removing such lesions. Simplifications in the technology and techniques of resections would allow them to be used more widely and ultimately benefit more patients.

Diagnosing and Assessing Disease Presentation, 425		

## INTRODUCTION

Over the past several decades, endoscopy has become an integral tool for diagnosing inflammatory bowel disease (IBD), including ulcerative colitis (UC) and Crohn's disease (CD), and staging disease activity. Both CD and UC are characterized by the presence of intestinal inflammatory changes and ulcerations, which are detected during an endoscopic evaluation and confirmed by histopathology examination of specimens obtained during endoscopy. However, the endoscopic evaluation of IBD includes not only diagnosing the disease, assessing the disease's extent, and staging its activity, but also monitoring the responses to various medical therapies (with mucosal healing serving as a predictor of disease course) and managing the disease's complications. Several endoscopic scoring systems have been utilized for assessing and staging disease activity, thus allowing estimates of the prognosis and efficacy of medical treatment in IBD patients.<sup>1–3</sup>

Current endoscopic modalities utilize not only high-definition endoscopes, but can also apply wide-field techniques such as chromoendoscopy (both dye-based and electronic based techniques) and, in some centers, small-field technologies such as confocal laser endomicroscopy (CLE) and endocytoscopy (EC), which facilitates our ability to not only detect but also to further characterize mucosal abnormalities and image ongoing physiologic processes *in vivo*. These newer endoscopic imaging technologies may not only further improve detection and characterization of mucosal lesions, but also may have the potential to assess severity, disease extent, and response to treatment in patients with IBD.

Other endoscopic imaging tools, such as wireless video capsule endoscopy (VCE) and balloon-assisted enteroscopy, also include enhanced imaging of the small bowel (SB) in the setting of CD.

In this chapter, we review the most recent advances of endoscopic evaluation in the diagnosis and staging of IBD, and ultimately the role of endoscopy in the effective care of patients with IBD.

## ENDOSCOPIC EVALUATION OF INFLAMMATORY BOWEL DISEASE

### Diagnosing and Assessing Disease Presentation

Colonoscopy with endoscopic evaluation of the colon and distal ileum with biopsy is required in all patients who are clinically suspected of having IBD to effectively diagnose, stage disease activity and severity, and differentiate between UC and CD or other inflammatory entities such as ischemic colitis, infectious colitis, and diverticular-associated colitis. Based on various studies, colonoscopy with histopathology can accurately diagnose CD versus UC in 90% of patients.<sup>4</sup> Endoscopic features such as rectal sparing, the presence of skip lesions, terminal ileal involvement, fistulas, and strictures can be seen in CD (Figs. 38.1–38.3), whereas endoscopic features such as diffuse inflammatory changes with superficial ulcerations are suggestive of UC (Fig. 38.4). However, these endoscopic features are not specific to either CD or UC (Videos 38.1–38.3). Histopathology examination based on biopsies obtained from both normal-appearing mucosa and abnormal mucosa is an integral component of endoscopic evaluation in patients suspected to have IBD. Specific histologic features associated with chronic inflammation will permit differentiation of IBD from other colitides such as infectious colitis, segmental colitis associated with diverticulosis, and ischemic colitis. However, the diagnosis of CD based on endoscopic evaluation with histopathology assessment may still be challenging. Patients with a colonic presentation of IBD in whom the disease cannot be classified as UC or CD colitis are determined to have an unclassified type of IBD (IBD-U) (Fig. 38.5).<sup>5,6</sup>

Patients with CD may present with continuous rectal inflammation involving the whole rectum and extending more proximally without the presence of skip areas, deep ulcerations, and certain histologic features such as the presence of granulomas on histopathology examination.<sup>7</sup> In fact, some patients with CD may still have colonoscopy examinations with biopsies, which cannot

**Abstract**

Endoscopy has become an essential tool for diagnosing inflammatory bowel disease (IBD), including Crohn's disease (CD) and ulcerative colitis (UC), and staging the disease activity. The endoscopic assessment of IBD ranges from diagnosing the disease, assessing the disease's extent, and staging its activity, to monitoring the responses to various medical therapies with the assessment of mucosal healing serving as a predictor of disease course and response to therapy, to finally treating the disease's complications. Several different endoscopic scoring systems have been utilized for staging the activity of the disease, thus allowing estimates of the prognosis and efficacy of medical treatment. In this chapter, we will discuss the endoscopic assessment of IBD, including diagnosis and staging of the disease, and ultimately the role of endoscopy in the effective management of patients with IBD.

**Keywords**

endoscopic assessment  
inflammatory bowel disease  
Crohn's disease  
ulcerative colitis

**FIG 38.1** Cobblestoning mucosa in active Crohn's disease.

**FIG 38.3** Crohn's colitis with aphthous ulcerations and white exudate.

**FIG 38.2** Multiple serpiginous ulcers in a patient with Crohn's disease.

**FIG 38.4** Ulcerative colitis with superficial ulceration, edema, and mucosal friability extending in a confluent manner starting from the rectum.

differentiate from that of UC. These patients with continuous inflammation beginning in the rectum and extending more proximally may be thus erroneously classified as having UC without further evaluation of the terminal ileum (TI). Thus, additional endoscopic evaluation of the TI during each colonoscopy examination is required to establish an appropriate diagnosis of IBD (Fig. 38.6). It may permit differentiation of UC from CD and further characterization of the subtypes of ileitis, specifically, CD ileitis and backwash ileitis. Backwash ileitis is typically a short segment of mildly inflamed mucosa of TI in the setting of existing colitis extending from the cecum without further progression to ulcerations, stenosis, and stricturing.<sup>3</sup> Colonic pseudopolyps are usually seen in patients with UC, as the repeated cycle of ulceration and deposition of granulation tissue during the healing phase results in the development of inflammatory polyps (Fig. 38.7).

Diagnosing CD with SB involvement may be particularly challenging. The presence of SB involvement can be confirmed

in approximately 80% of patients with CD, including one-third of all cases with CD presenting with only isolated SB disease.<sup>1</sup> The most frequently encountered SB mucosal abnormalities suggestive of IBD include erosions, ulcers, erythema, villous blunting, and strictures, although they are not pathognomonic for CD as they can be seen in other conditions mimicking IBD. Table 38.1 summarizes frequent findings in IBD patients based on an endoscopic and histopathological evaluation.

VCE is another endoscopic tool that enables noninvasive visualization of the entire SB mucosa and is utilized in patients with suspected CD and established IBD, allowing the assessment of encountered SB mucosal abnormalities (see Figs. 14.4 and 17.5, as well as Videos 17.4 and 17.5).<sup>9–12</sup> Capsule endoscopy (CE) has been found to be more beneficial compared with push enteroscopy or radiologic imaging such as small bowel follow-through and computed tomography enterography in the

**FIG 38.5** Colitis with superficial ulceration and edema. This appearance can be seen in both Crohn's colitis and ulcerative colitis.

**FIG 38.7** Pseudopolyps in a patient with ulcerative colitis.

**FIG 38.6** A patient with ileitis due to Crohn's disease with erythema, edema, and ulceration of the terminal ileum.

evaluation of patients with known CD.<sup>15</sup> The absence of typical capsule endoscopy features has a negative predictive value ranging from 96% to 100% based on available studies.<sup>13–15</sup>

VCE plays a role in re-evaluating patients with diagnosed UC when there is a question of a potential misclassification or potential misdiagnosis, as there are also certain conditions in which appearances can mimic CD-related changes, including nonsteroidal antiinflammatory drug (NSAID)-related injuries, ischemia, radiation enteritis, and drug-induced enteritis. Mehdi-zadeh et al (2008) confirmed that 15% of a total of 120 patients with UC were found to have CD based on the CE findings.<sup>16</sup>

Further SB visualization can be achieved with device-assisted enteroscopy such as single-balloon and double-balloon enteroscopy (DBE), as well as push enteroscopy.<sup>17–20</sup> The diagnostic yield of balloon-assisted enteroscopy has been reported to be

up to 59%.<sup>17</sup> Mensink et al (2010) demonstrated that DBE evaluation was deemed to change clinical management in 74% of patients with CD with SB involvement, as well as facilitate achievement of clinical remission in 88%.<sup>19</sup>

Based on a meta-analysis, the diagnostic yield of both VCE and DBE is comparable; however, VCE is still favored for the initial diagnostic approach as it is considered to be a non-invasive tool.<sup>17–19</sup>

In the pediatric population, upper endoscopy (esophagogastroduodenoscopy [EGD]) is routinely performed when suspecting IBD, given the incidence of macroscopic involvement of the upper gastrointestinal tract reported to be as high as 30%, as well as the presence of microscopic changes seen in up to 60%.<sup>20–22</sup> This approach is supported by guidelines introduced by the European Crohn's and Colitis Organization (ECCO) recommending EGD for all pediatric patients suspected of having IBD, but it is not recommended routinely in adult populations.<sup>20,21</sup>

CD and UC can be classified based on endoscopic evaluation of disease location, maximal endoscopic involvement, and endoscopic presentation such as stricture, penetrating versus nonstricture, and nonpenetrating disease.<sup>23–25</sup> This classification is known as the revised Montreal classification and is highlighted in detail in Table 38.2.

The lack of clearly visible endoscopic features of inflammation may not always correlate with histopathology assessment. Therefore, obtaining biopsies during endoscopic evaluation from various segments of the colon, including those with a normal endoscopic appearance, is necessary for the true assessment of disease extent in patients with suspected IBD.<sup>24</sup>

### Staging Disease Activity

#### Definition of Mucosal Healing

Mucosal healing (MH) refers to the endoscopic assessment of disease activity, and it has become increasingly important in the clinical management of patients with UC and CD. In addition, it has recently been used as an endpoint for clinical trials.<sup>1,23</sup> In general, there are no validated definitions of MH in the setting of IBD. MH has been typically recognized as a lack of ulcerations and erosions, and it has unequivocally been associated with better outcomes, including decreased hospitalization rates, sustained

**TABLE 38.1 Frequent Endoscopic and Histopathology Findings in Ulcerative Colitis and Crohn's Disease**

Disease	Colonoscopy With Ileoscopy	Esophagogastroduodenoscopy	Capsule Endoscopy	Histopathology
Ulcerative colitis	Rectum involved with continuous inflammatory changes and evident demarcation between normal and abnormal mucosa Mucosal granularity, edema Friability and bleeding Pseudopolyps Backwash ileitis	Normal esophagus, stomach, and duodenum	Normal appearing small bowel, with the exception of backwash ileitis	Distorted crypt architecture Abscesses Goblet cells decrease Basal plasmacytosis Paneth cell metaplasia
Crohn's disease	Inflammatory changes either limited to the rectum, left colon, right colon, or diffuse May also extend to the ileum Segmental involvement, subtle and/or serpiginous ulcers Cobblestoning Further features that can be present or absent: Rectal sparing Aphthous ulcers Perianal ulcers Fistula Strictures	Inflammatory changes in the duodenum, edema, erythema, erosions, ulcers with thickened folds, friable mucosa Duodenal strictures Pyloric stricture	Mucosal abnormalities, erythema, edema, erosions, ulcers	Distorted crypt architecture Occasional abscess Patchy distribution Non-caseating granulomas

**TABLE 38.2 Revised Montreal Classification for Ulcerative Colitis and Crohn's Disease**

Ulcerative Colitis (UC)	UC Definition	Endoscopic Involvement
E1	Proctitis	Rectum
E2	Left-sided colitis	Distal to splenic flexure
E3	Extensive colitis	Proximal to splenic flexure
Crohn's Disease (CD)	CD Location	CD Behavior
A1 ≤ 16 years	L1: ileal	B1: non-stricturing, nonpenetrating
A2 = 17–40 years	L2: colonic	B2: stricturing
A4 > 40 years	L3: ileocolonic	B3: penetrating
	L4: isolated upper GI	ep: perianal disease is present

clinical remission, decreased need for corticosteroid use, decreased risk of colorectal cancer, and decreased rates of colectomy.<sup>25–29</sup>

In patients with UC, the absence of friability and erosions with the presence of a normal vascular pattern of the mucosa appears to represent an adequate definition of MH, as the presence of disease activity involves abnormality of the mucosa. This has been recognized by the International Organization of Inflammatory Bowel Disease (IOIBD) as "absence of friability, mucosal bleeding, erosions, and ulcers in all visualized segments are the required components of genuine endoscopic healing."<sup>2</sup> However, this definition has not been consistently accepted, as some studies

**FIG 38.8** Mucosal healing with persistent colonic aphthous ulcers.

also include features of erythema and friability in the definition of MH.<sup>30</sup> On the other hand, diagnosing MH in CD may be particularly challenging given the transmural nature of the disease. Currently, in the setting of CD, MH has been recognized as the absence of any visible ulcers.<sup>31</sup> However, depending on the trial, the descriptive definition of MH in CD has also included an absence of inflammation, luminal narrowing, aphthous lesions, superficial and deep ulcerations, and nodules (Fig. 38.8).<sup>32–34</sup>

#### Endoscopic Scoring Systems in Ulcerative Colitis

A 2014 systematic review of the measurement of endoscopic healing in UC clinical trials revealed that currently utilized indices, such as the sigmoidoscopic component of the Mayo Clinic score

**TABLE 38.3 Indices of Endoscopy-Based Disease Activity Used in Ulcerative Colitis: Mayo Endoscopic Score (1987) and UCEIS (2012)**

Index	Study Design	Description	Applications	Level of Validation
Mayo Endoscopic Score (1987)	Prospective study	Four-grade scale: (1) Normal or inactive disease (2) Mild disease: erythema, decreased vascular pattern, mild friability (3) Moderate disease: marked erythema, absent vascular pattern, friability, erosions (4) Severe disease: spontaneous bleeding, ulcers	Numerous clinical trials	Not validated
UCEIS (2012)	Used in prospective studies	Grading system with a total score of 3–11 comprising three variable subscores: 1. Vascular patterns: normal, patchy obliteration, obliterated 2. Bleeding: – None – Mucosal – Luminal: – Mild – Moderate-to-severe 3. Erosions and ulcers: – None – Erosions – Superficial ulcer – Deep ulcer	Recently developed	Validated

UCEIS, Ulcerative Colitis Endoscopic Index of Severity.

Data from Schroeder KW, Tremain WJ, Istrup DM: Coated oral 5-aminosalicylic acid therapy for mildly to moderately active ulcerative colitis: A randomized study. *N Engl J Med* 317:1625–1629, 1987; Troxell SP, Schnell D, Kraeski P, et al: Developing an instrument to assess the endoscopic severity of ulcerative colitis: the Ulcerative Colitis Endoscopic Index of Severity (UCEIS). *Gut* 61:535–542, 2012.**TABLE 38.4 Mayo Scoring System for Assessment of Ulcerative Colitis Activity**

Stool frequency	0 = Normal 1 = 1–2 stools/day more than normal 2 = 3–4 stools/day more than normal 3 = > 4 stools/day more than normal
Rectal bleeding	0 = None 1 = Visible blood with stool less than half of the time 2 = Visible blood with stool half of the time or more 3 = Passing blood alone
Mucosal appearance at endoscopy	0 = Normal or inactive disease 1 = Mild disease (redness, decreased vascular pattern visible, friability) 2 = Moderate disease (marked erythema, no vascular pattern visible, friability, erosions) 3 = Severe disease (bleeding, ulceration)
Physician's global assessment of disease activity	0 (normal), 1 (mild), 2 (moderate), 3 (severe)

From Lewis JD, Shaikun C, Nessel L, et al: Use of the invasive components of the Mayo Score to assess clinical response in ulcerative colitis. *Inflamm Bowel Dis* 14(12):1660–1666, 2008.

and the Ulcerative Colitis Endoscopic Index of Severity (UCEIS), show the most promise as reliable evaluative tools of endoscopic disease activity in UC (Table 38.3).<sup>25</sup> The frequently used endoscopic component of the Mayo Clinic score, introduced by Schroeder et al in 1987, is based on an evaluation of vascular pattern, erythema, friability, erosions, and ulcerations.<sup>26</sup> The complete Mayo Scoring System (MCS) includes both endoscopic and clinical findings (Table 38.4).<sup>26</sup> Four variables of the MCS

comprise stool frequency, rectal bleeding, physician's global assessment, and assessment of endoscopic severity seen in the rectosigmoid mucosa.<sup>25</sup> Complete response is defined as 0 for all defined variables. Partial response is defined as a substantial but incomplete improvement. The Mayo Endoscopic Score has been used in numerous trials and has been easy to apply in clinical practice, although interobserver agreement can vary. Some studies confirmed a high level of agreement (intraobserver: intraclass correlation coefficient [ICC]: 0.89; 95% confidence interval [CI]: 0.85–0.92), interobserver ICC: 0.79; 95% CI: 0.72–0.96), whereas others demonstrated only a fair or moderate agreement.<sup>25,27</sup> According to prior studies, the main limitation of using the Mayo score was assessment of mucosal friability. Subjective assessment of the mucosa lead to removal of friability in subsequent endoscopic scores and resulted in lack of validation.<sup>25,27</sup> However, in a systematic review by Samaan et al (2014), a variable of mucosal friability reported the highest agreement of over 90% among observers.<sup>25</sup> Feagan et al (2007) demonstrated that improvement in the Mayo score is clinically relevant, as it correlates with improvement in quality of life.<sup>28</sup> According to the Active Ulcerative Trials (ACT-1 and ACT-2) of infliximab, MH assessed by a Mayo Clinic score of 0 or 1 at week 8 (8 weeks after receiving infliximab) was associated with a significantly lower colectomy rate beyond 54 weeks.<sup>29</sup>

In addition, a new validated index, known as the UCEIS, has been introduced.<sup>25</sup> This index contains more detailed information on endoscopic assessment, such as vascular pattern, bleeding, and the presence of erosions/ulcerations, scored in the most severely affected part of the colon, and it additionally excludes friability from the analyzed parameters (Table 38.5). The UCEIS was originally developed as an 11-point score comprised of erosions/ulcers (1–4), vascular pattern (1–3) and bleeding (1–4). This scoring system has been simplified to an 8-point tool with parameters such as erosions/ulcers (0–2), vascular pattern (0–2),

**TABLE 38.5 The Ulcerative Colitis Endoscopic Index of Severity**

Descriptor (Score Most Severe Lesions)	Likert Scale Anchor Points	Definition
Vascular pattern	Normal (0)	Normal vascular pattern with arborization of capillaries clearly defined, or with blurring or patchy loss
	Patchy obliterations (1) Obliterated (2)	Patchy obliteration of vascular pattern Complete obliteration of vascular pattern
Bleeding	None (0)	No visible blood
	Mucosal (1)	Some spots or streaks of coagulated blood on the surface of the mucosa ahead of the scope, which can be washed away
	Luminal mild (2)	Some free liquid blood in the lumen
	Luminal moderate or severe (3)	Frank blood in the lumen ahead of the endoscope or visible oozing from the mucosa after washing away intraluminal blood or visible oozing from a hemorrhagic mucosa
Erosions and ulcers	None (0)	Normal mucosa, no visible erosions or ulcers
	Erosions (1)	Very small ( $< 5$ mm) defects in the mucosa white and yellow in color, with a flat edge
	Superficial ulcer (2)	Large ( $> 5$ mm) defects in the mucosa, which are discrete fibrin-covered ulcers when compared with erosions, but remain superficial
	Deep ulcer (3)	Deeper excavated defects in the mucosa, with a slightly raised edge

CDEIS, Crohn's Disease Endoscopic Index of Severity; SES-CD, Simple Endoscopic Score for Crohn's Disease.

Data from Mary JV, Modigliani R: Development and validation of an endoscopic index of the severity for Crohn's disease: a prospective multicentre study. Groupe d'Etudes Therapeutiques des Affections Inflammatoires du Tube Digestif (GETAID). Gut 30:983–989, 1989; Daperno M, D'Haens G, Van Assche G, et al: Development and validation of a new, simplified endoscopic activity score for Crohn's disease: the SES-CD. Gastroenterol Endosc 60:505–512, 2004.

and bleeding (1–4), and was found to have a satisfactory interobserver agreement ( $\kappa$  of 0.5).<sup>42</sup> The study has acknowledged the importance of using a standardized system of descriptive findings by observers for endoscopic severity evaluation, as well as the role of endoscopist experience and utilization of a centralized review of endoscopic video images.<sup>42,43</sup> All these factors may influence interobserver variations of disease activity endoscopic assessment. Feagan et al (2013) demonstrated excellent interobserver and intraobserver agreement of the UCEIS assessment among seven experienced central readers.<sup>44</sup> However, there are also some potential limitations of this index. The specific cutoffs corresponding to remission versus mild, moderate, and severe disease have not yet been fully characterized. In addition, Colombel et al (2016) confirmed that there is a high degree of correlation between findings from rectosigmoidoscopy versus colonoscopy in assessment of disease activity based on the UCEIS scores.<sup>45</sup> Nevertheless, the UCEIS index thus far represents the

only validated endoscopic index for the evaluation of patients with UC and it is currently utilized in ongoing clinical studies.

#### Endoscopic Scoring Systems in CD

A 2014 systematic review of the measurement of endoscopic disease activity and MH in CD reviewed all available indices for CD and concluded that the Crohn's Disease Endoscopic Index of Severity (CDEIS) and the Simple Endoscopic Score for Crohn's Disease (SES-CD) are the most studied tools, although further validation for their broad use is still required<sup>46</sup> (Table 38.6).

The CDEIS, introduced in 1989 by Mary and Modigliani, is based on recognition of elementary features (no ulcerated lesions, ulcerations, and stenosis) associated with the pattern of their surface in five segments (rectum, sigmoid and left colon, transverse colon, and right colon and ileum).<sup>33</sup> Calculation of the CDEIS is very time consuming and requires significant training and experience, thus it is not broadly used. The calculated CDEIS

score ranges from 0 to 44 and is illustrated in Table 38.6.<sup>32</sup> The CDEIS scores specific features such as the presence of deep ulcerations (12 if present), superficial ulceration (6 if present), the length of ulcerated mucosa ranging from 0 to 10 cm with scores of 0 to 10 according to the involved length, and finally the length of the diseased mucosa (0–10 cm). The numbers are added in each segment and divided by the number of segments evaluated. Additional points are given for an ulcerated stenosis, and a further 3 points are given for a nonulcerated stenosis. Based on subsequent studies, endoscopic remission (minor or no mucosal lesions) is defined as a CDEIS score less than or equal to 6, while complete endoscopic remission (mucosal healing; i.e., no lesions at all or scattered lesions) is defined as a CDEIS score of less than or equal to 3 or less than or equal to 4.<sup>46–51</sup> An endoscopic CDEIS response has been defined as a decrease from baseline of at least 3 points or 5 points or reduction of CDEIS by 50% or 75%.<sup>46–50</sup> Geboes et al (2005) defined the severity of the disease as mild, moderate, or severe based on CDEIS scores of below 5, between 5 and 15, and above 15, respectively.<sup>51</sup> Even though the CDEIS provides a complete and detailed examination of disease activity, the interobserver agreement for grading superficial and deep ulcerations is only reported to be fair, according to studies.<sup>46</sup> However, a 2016 study concluded that central reading of the CDEIS by four readers to evaluate CD severity had a very high level of intra-rater agreement (intraobserver ICC: 0.89; 95% CI: 0.86–0.93), although lower inter-rater agreement was seen (ICC: 0.71; 95% CI: 0.61–0.79).<sup>52</sup> The CDEIS has been used in trials on tumor necrosis factor (TNF) antagonists, thiopurines, and steroids.<sup>53</sup>

On the other hand, the simple endoscopic score for CD appears to be more practical and is based on four endoscopic variables to be scored 0–3 in the same five ileocolonic segments.<sup>54</sup> The SES-CD was demonstrated to have a high degree of correlation, with the CDEIS for grading of disease activity and responsiveness to changes in disease activity showing similar intraobserver and interobserver agreement.<sup>53,54</sup> Central reading of SES-CD by four experienced gastroenterologists was determined to have a high level of intra-rater and inter-rater reliability (intraobserver reliability ICC: 0.91; 95% CI: 0.87–0.94 and interobserver reliability ICC: 0.83; 95% CI: 0.75–0.89) based on data from a 2004 study.<sup>54</sup>

A CDEIS decrease of 6 points represents endoscopic response, according to some studies.<sup>46</sup> In a post-hoc analysis of data from the Study of Biologic and Immunomodulator Naive Patients in Crohn Disease (SONIC) trial, Ferrante et al (2013) concluded that endoscopic response (defined as a decrease from baseline in SES-CD or CDESIS of at least 50%) achieved at week 26 of treatment identified those most likely to be steroid free in clinical remission at week 50.<sup>55</sup> Further validation studies of indices are still needed, however.<sup>53,54</sup> Recent studies by Bouguen et al (2014)<sup>54,55</sup> evaluated the utility of MH as a treatment target in clinical practice settings. In individual settings of CD and UC, repeated endoscopic assessment of the disease within a minimum of 24 weeks, and treatment adjustments made based on that assessment, have improved the likelihood of achieving MH. However, further studies are needed to validate these observations. The practice of evaluating for MH after medication adjustment has been termed "treat to target."

Endoscopic evaluation of the intestinal mucosa also plays an important role in the postoperative management of patients with CD and allows the tailoring of medical therapy based upon the individual patient's disease behavior.<sup>54,56</sup> Staging of the severity

**TABLE 38.7 Rutgeert's Scale in Assessment of Postoperative Crohn's Disease (Endoscopic Recurrence Score)**

Endoscopic remission	<ul style="list-style-type: none"> <li>• I0: No lesions</li> <li>• I1: ≤ 5 aphthous lesions</li> </ul>
Endoscopic recurrence	<ul style="list-style-type: none"> <li>• I2: &gt; 5 aphthous lesions with normal intervening mucosa</li> <li>• I3: diffuse aphthous ileitis with diffusely inflamed mucosa</li> <li>• I4: diffuse inflammation with large ulcers, nodules and/or narrowing</li> </ul>

Data from Rutgeert P, Geboes K, Vantrappen G, et al. Predictability of the postoperative course of Crohn's disease. *Gastroenterology* 99(4):966–963, 1990.

of endoscopic activity is assessed using Rutgeert's scores, which rank inflammation grossly from 0 to 4 in the neoterminal ileum where inflammatory changes after ileocolonic resection for CD typically recur.<sup>56</sup> The Rutgeert's score is based on an assessment of the number of aphthous lesions that are present, as well as the extent of ileitis and the presence of features such as ulcers, nodules, and narrowing (Table 38.7).<sup>56</sup> Based on this classification, patients with less severe endoscopic appearance and a score of 1 or less had a lower risk of clinical recurrence (8.6% at 8 years) after ileocecal resection, whereas 100% of patients with severe endoscopic changes and a Rutgeert's score of 4 had symptomatic recurrence by 4 years.<sup>56</sup> The endoscopic assessment of the neoterminal ileum between 6 and 12 months postsurgery is recognized to be helpful in risk-stratifying patients prior to initiating medical management, and can prevent symptomatic recurrence and the need for subsequent surgical interventions.<sup>5,57</sup> De Cruz et al (2015) utilized the Rutgeert's Postoperative Endoscopic Index in a randomized clinical trial aiming to identify the optimal strategy to prevent postoperative disease recurrence of CD.<sup>58</sup> The Postoperative Crohn's Endoscopic Recurrence (POCER) trial demonstrated that choosing treatment according to the clinical risk of recurrence and a postoperative colonoscopy at 6 months enabled clinicians to tailor therapy to the patient.<sup>58</sup> All patients with a high risk of recurrence in the study received postoperative anti-TNF or thiopurine therapy, and were randomly assigned to either an active group including a 6-month postoperative colonoscopy or a standard group with no 6-month postoperative colonoscopy. Selective immunosuppression, adjusted for early recurrence based on colonoscopy rather than routine use, lead to disease control in most patients.<sup>58</sup> This approach of personalized medicine with selective immunosuppression use, based on the endoscopic evaluation, adjusted for early recurrence rather than routine use, leads to disease control in most patients and is a viable strategy in high-risk patients.<sup>58</sup>

#### Crohn's Disease Small Bowel Endoscopic Scores

Scoring systems have been also utilized in SB assessment of CD by VCE.<sup>59–61</sup> The traditional threshold of more than three ulcers to diagnose CD has been proposed by Mow et al (2004), which yields a positive predictive value of only 50% lacks assessment of the distribution and severity, and has also not been formally validated.<sup>60</sup> The capsule endoscopy Crohn's disease activity index (CECDAI) was developed and subsequently validated with a scoring index, allowing the distinction between proximal and distal SB, as well as further evaluation of parameters such as inflammation, extent, and the presence of strictures.<sup>60,61</sup> The

Lewis score has been introduced and is comprised of a cumulative scoring system based on the features and distribution of villous edema, ulceration, and stenosis.<sup>61</sup> This scoring system has been converted into a software application that calculates the score automatically. The final score is calculated by adding the inflammatory score of the worst affected tertile to the scores of stenosis. The scoring system has been validated for reporting SB inflammatory activity with strong interobserver agreements in a practical clinical setting.<sup>13,62</sup> Cotter et al (2015)<sup>63</sup> confirmed strong interobserver agreements for determination of the Lewis score in a practical clinical setting, thus further validating this score for SB inflammatory activity. The Lewis score may show potential to be used for the diagnosis, staging, follow-up, and therapeutic assessment of CD with isolated SB involvement. Further validation studies assessing the clinical significance of inflammatory changes, as well as response to therapy, are still required.

There are no additional standardized scoring systems to evaluate SB lesions based on enteroscopy evaluation.

### The Role of Endoscopy in Diagnosing and Staging Complications of IBD

#### Strictures

Strictures as complications of IBD occur in 25% of patients with CD and 10% with colonic IBD.<sup>64</sup> Endoscopic dilations have been demonstrated to be an effective and safe treatment for short strictures caused by CD, impacting substantially on the natural history of these patients (Fig. 38.9; also see Video 17.16).<sup>65</sup> Specifically, balloon dilation of strictures shorter than 4 cm and anastomotic stricture have been demonstrated to have better dilation outcomes. Endoscopic strictures in patients with UC require re-evaluation for SB disease to see if the disease is truly UC or CD. If UC is present, surgery is appropriate because a stricture can represent a colonic malignancy.<sup>66</sup> In a 2015 retrospective study of patients with IBD undergoing surgery for colonic strictures, 3.5% were found to have dysplasia or cancer.<sup>67</sup>

#### Perianal Fistulas

Endoscopic ultrasound has been used for the assessment of perianal fistulas and abscesses. A meta-analysis by Siddiqui et al (2012) on performances of magnetic resonance imaging (MRI) and endoanal ultrasound in CD patients demonstrated comparable sensitivities at detecting perianal fistulas, although the specificity for MRI was higher than that for endoanal ultrasound.<sup>68</sup> Both specificity values were still considered to be diagnostically

poor; however, pelvic MRI has been recommended as the initial evaluation for perianal fistulas, according to ECCO guidelines.<sup>67</sup> Current American Society for Gastrointestinal Endoscopy (ASGE) guidelines suggest using endoscopic ultrasound for characterizing and managing fistulous perianal CD in conjunction with other imaging modalities.<sup>69</sup>

### Role of the Latest Endoscopic Advances for Diagnosing and Staging Disease Activity in IBD

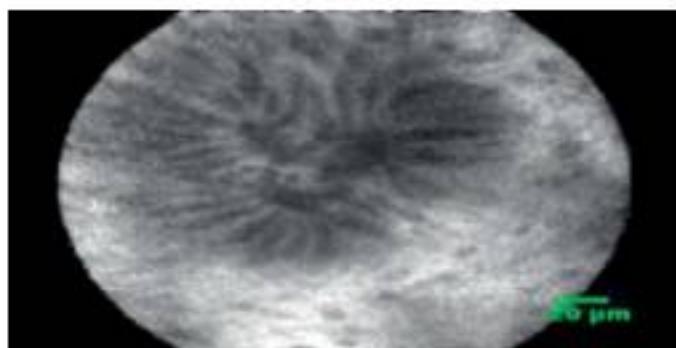

Over the last few decades, wide-field technologies with virtual chromoendoscopy (narrow-band imaging [NBI; Olympus, Tokyo, Japan], Fujinon intelligent color enhancement system [FICE; Fujinon, Saitama, Japan], iScan [Pentax Medical, Montvale, NJ]), and small-field technologies (such as CLE and EC) have been investigated to characterize detected mucosal abnormalities in patients with IBD. Virtual chromoendoscopy is known as the "push-button switch technique," and is based on capturing various wavelengths of reflected light through optical filters (NBI) or digital postprocessing of the endoscopic images (iScan, FICE). By enhancing altered mucosal surface and vascular patterns, virtual chromoendoscopy may image early signs of disease activity in a process known as angiogenesis within otherwise normal-appearing mucosa.<sup>70</sup> Neumann et al (2013) demonstrated that virtual chromoendoscopy with iScan has the potential to enhance assessment of disease severity and extent in mild or inactive IBD patients.<sup>66</sup> In their randomized controlled study of 78 patients with IBD, the endoscopic prediction of inflammatory extent and activity based on high-definition white light (HDWL) and virtual chromoendoscopy was made and compared with histological results.<sup>66</sup> Interestingly, the use of virtual chromoendoscopy did not significantly change the duration of the examination, but it significantly improved the characterization of mucosal inflammation and extent.<sup>66</sup> When compared with histological assessment, the overall agreement was 48% and 53% for HDWL assessment and 92% and 89% for virtual chromoendoscopy assessment, respectively.<sup>66</sup>

Further visualization of colonic mucosa with an image of ongoing physiologic processes *in vivo* can be achieved with small-field technologies such as CLE and EC.

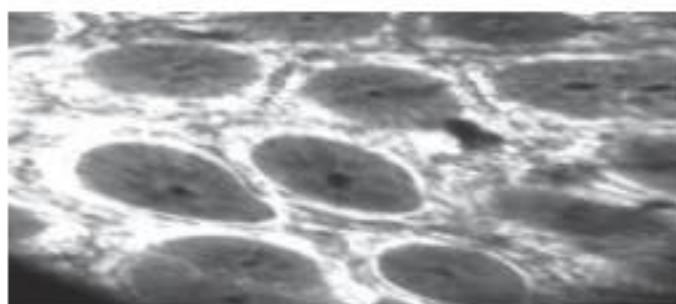

EC (Olympus, Tokyo, Japan) allows microscopic imaging of the gastrointestinal mucosa after application of topical absorptive contrast with up to 1400-fold magnification. In a pilot study of IBD patients, Neuman et al (2013)<sup>71</sup> confirmed that EC could easily distinguish all inflammatory cells with a very high level of accuracy and demonstrated excellent 100% concordance

**FIG 38.9** **A**, Ulcerated Crohn's stricture at the anastomosis. **B**, Balloon dilation of the stricture. **C**, Appearance of the stricture after dilation.

**FIG 38.10** Confocal images of the colonic mucosa showing early inflammatory changes with increased colonic crypt tortuosity and fusion in a patient with Crohn's colitis.

**FIG 38.11** Confocal images of inflamed colonic mucosa with augmented vascularization and increased cellular infiltration in a patient with Crohn's colitis.

between EC and histopathology assessment for grading intestinal activity.

CLE can be performed using a Food and Drug Administration (FDA)-approved device: a standalone probe (herein termed *probe-based confocal laser endomicroscopy* [pCLE]) capable of passage through the accessory channel of most endoscopes (Cellvizio, Mauna Kea Technologies, Paris, France) and allowing 1000-fold magnification. Once the mucosal abnormality is detected during endoscopic evaluation, it can then be interrogated further by the confocal system for *in vivo* histology.<sup>68</sup> The CLE technique can also play a role in assessing and staging disease activity in addition to targeting biopsies to improve the early detection of neoplasia.<sup>68,69</sup>

Neumann et al (2012) proposed the Crohn's Disease Endomicroscopic Activity Score (CDEAS) to evaluate CD colitis activity *in vivo* based on typical inflammatory findings such as increased colonic crypt tortuosity, enlarged crypt lumen, microerosions, augmented vascularization, and increased cellular infiltration within the lamina propria (Figs. 38.10 and 38.11).<sup>69</sup> Quiescent CD colitis was also noted to have a significant increase in crypt and goblet cell numbers.<sup>69</sup> The inflammation activity of UC using CLE was also evaluated by Li et al (2010).<sup>70</sup> In their study, the endomicroscopy evaluation of crypt architecture and fluorescein leakage correlated well with traditional histology.<sup>70</sup>

Furthermore, CLE has also been studied to assess gastrointestinal barrier function. Using this technique, Kieslich et al (2012) demonstrated that they could detect single-cell shedding and barrier loss in the TI of IBD patients and therefore predict relapse.<sup>71</sup> Specifically, CLE was used in detecting shedding

epithelial cells and local barrier defects with fluorescein effluxing through the epithelium. Experiments on mice confirmed inward flow through some leakage-associated shedding events, which was increased when luminal osmolality was decreased. Interestingly, in IBD patients in clinical remission, this increased cell shedding with fluorescein leakage was associated with subsequent relapse within 12 months of endomicroscopic examination ( $p < 0.001$ ).<sup>70</sup> The sensitivity, specificity, and accuracy of this grading system to predict a flare was 62.5% (95% CI: 40.8%–80.4%), 91.2% (95% CI: 75.2–97.7) and 79% (95% CI: 57.7–95.5), respectively.<sup>70</sup> This represents the truly great potential of the CLE system in staging disease activity and predicting disease course with a subsequent relapse. Similarly, Lim et al (2014) noted that CLE can detect epithelial damage and barrier loss in the duodenum of patients with CD and UC that is not apparent on conventional endoscopic evaluation.<sup>71</sup>

CLE has been also utilized for endoscopic molecular imaging, which has potential to enhance the detection of disease-specific targets and provide molecular-targeted therapies. The pilot study by Atreya et al (2014)<sup>72</sup> evaluated response to biological treatment with anti-TNF therapy. Topical antibody administration in 25 patients with CD led to the detection of intestinal membrane-bound TNF (mTNF)+ immune cells during CLE examination.<sup>72</sup> Patients with high numbers of mTNF+ cells had significantly higher short-term response rates (92%) at week 12 upon subsequent anti-TNF therapy compared with patients with low amounts of mTNF+ cells (15%).<sup>72</sup>

These results may facilitate early patient stratification in choosing therapeutic approaches. Endoscopic evaluation may also evolve beyond simply acting as a diagnostic tool into a prediction tool for molecular therapies in inflammation, guiding the treatment of patients, assessing the efficacy of biological treatment, and providing truly individualized therapy approaches.

## SUMMARY

In summary, endoscopy is considered the gold standard technique for the diagnosis and staging of IBD and the evaluation of MH. Once IBD is diagnosed, frequent endoscopic assessment is associated with a higher rate of achieving MH.<sup>73</sup> Incremental changes in medication dosage or alteration of medications can occur. Frequent evaluation of the mucosa and optimization of therapy to achieve MH has been termed "treat-to-target."<sup>74</sup> Several studies have considered MH as an endpoint of significant importance, demonstrating that normalization of mucosa assessed by endoscopy and confirmed by histology ("deep remission") correlates with better clinical outcomes.<sup>75,76</sup>

Mucosal biopsy identifies persistent histologic disease activity, although the long-term clinical benefit of histological healing remains to be fully determined in spite of currently increasing evidence that supports achieving MH during therapy as a sign of adequate efficacy of treatment, reducing the need for hospitalization and surgical management, and impacting health-related quality of life in IBD patients.<sup>76,77</sup> The definition of MH has also been further defined in the setting of UC by the proposed guidelines, but needs to be further clarified in the setting of CD.<sup>1</sup> Current endoscopic tools (such as, for instance, the Mayo Endoscopic Score, CD Endoscopic Index of Severity, CDAL, etc.) utilized for assessment of disease were not initially created in accordance with the current mandate of the FDA, which requires the use of validated patient-reported outcomes (PROs). The current focus of the FDA is aimed at establishing and defining

validated PROs in order to use this as a primary endpoint in clinical trials of IBD.<sup>62</sup> In the setting of IBD, PROs may provide an important complement to objective measures of intestinal inflammation otherwise obtained from endoscopic evaluation, and will serve as the ultimate endpoint in clinical trials. Currently, testing and refinement of proposed PRO measures in IBD are being investigated. Two interim PRO measures have been introduced.<sup>63</sup> In the setting of UC, a two-item PRO, including rectal bleeding and stool-frequency parameters of the MCS, has been used. In the setting of CD, a two-item PRO comprised of abdominal pain and stool frequency from the CDAI has been developed (PRO-2).<sup>64</sup>

Peyrin-Biroulet et al. (2016) proposed staging disease severity based on three domains, including impact of the disease on the patient (clinical symptoms, quality of life measured by PROs), measurable inflammatory burden based on endoscopic assessment and value of C-reactive protein, and disease course (including structural damage, history of surgical or intestinal resections, perianal disease, etc.).<sup>74</sup>

In the near future, a combination of symptomatic evaluation with defined PRO combined with endoscopic evaluation and staging severity of intestinal inflammation and assessing disease course may be particularly useful in staging disease severity in clinical practice as the main treat-to-target IBD-management strategy.

## INTRODUCTION

Patients with long-standing inflammatory bowel disease (IBD) are at an increased risk for development of colorectal cancer (CRC).<sup>1,2</sup> Risk factors for the development of CRC in ulcerative colitis (UC) or Crohn's colitis include young age of disease onset, longer duration of disease, greater extent of colonic involvement, coexistent primary sclerosing cholangitis (PSC), active endoscopic or histological inflammation, family history of CRC in a first-degree relative diagnosed before 50 years of age, a history of dysplasia, stricturing disease in UC, inflammatory ("pseudo") polyps, a shortened tubular colon, and possibly male gender.<sup>3-9</sup>

Of all the risk factors associated with the development of CRC in IBD, colitis-related dysplasia appears to confer the greatest risk, leading gastrointestinal (GI) societies to advocate colonoscopic surveillance to detect dysplasia in high-risk patients.<sup>3-7,10,11</sup> The goal of endoscopic surveillance is to reduce mortality and morbidity of CRC by either detecting and resecting dysplasia or detecting CRC at an earlier and potentially curable stage.<sup>12,13</sup> Surveillance strategies, until recently, relied on examination of the mucosa with targeted biopsies of visible lesions and random biopsy sampling, based on the prevailing notion that dysplasia is frequently not associated with visible mucosal abnormalities.<sup>14</sup> Meanwhile, advances in optical technology allowing for greater endoscopic identification of dysplasia and consensus that most dysplasia in patients with IBD is visible have led to a paradigm shift in our approach to surveillance and management of dysplasia.<sup>12,15</sup> This chapter will review the epidemiology of CRC in IBD, the evolution in our understanding of dysplasia, outline the most recent surveillance guidelines from scientific societies, and discuss the management of dysplasia and controversies therein.

## EPIDEMIOLOGY OF CRC IN IBD

Colorectal cancer (CRC) in IBD, accounting for 1% to 2% of CRC cases in the general population, is responsible for 10% to

15% of all deaths in IBD patients.<sup>16</sup> Indeed, after genetic causes of CRC (such as familial adenomatous polyposis and Lynch syndrome), IBD ranks as the third highest risk factor for CRC, underpinning the need to better define associated risk factors and optimize surveillance strategies, thereby achieving meaningful reduction in IBD-CRC associated morbidity and mortality.<sup>17</sup>

The risk of CRC in IBD (and UC in particular) increases with time but risk estimates have been difficult to quantify, often limited by heterogeneity and methodology in the retrospective cohorts studied. A large meta-analysis in 2001 estimated a cumulative CRC risk of 2% at 10 years, 8% at 20 years and 18% after 30 years of colitis.<sup>18</sup> A 2012 population-based study from Copenhagen County, Denmark, demonstrated a decreasing incidence of CRC in IBD patients over the last few decades.<sup>19</sup> More recently (2015), a 40-year colonoscopic surveillance program from St. Mark's Hospital, UK, reported a cumulative incidence of developing CRC in IBD patients at 0.1% in the first decade since UC symptom onset, followed by 2.9%, 6.7%, and 10% by the second, third, and fourth decade, respectively.<sup>20</sup> The authors reported a significant decrease in the incidence of colectomy for dysplasia and a reduction in the incidence rate of advanced CRC and interval cancers over 4 decades of surveillance.<sup>20</sup> Population-based meta-analyses have shown an overall CRC incidence ratio of 1.7 in all IBD patients,<sup>21</sup> with patients with CD reported to have a 1.9-fold<sup>22</sup> and patients with UC having a 2.4-fold increase in lifetime CRC risk compared to the general population.<sup>22</sup> Thus, recent studies suggest a decrease in the risk of CRC in IBD, a temporal reduction that may be explained by more aggressive control of inflammation through medication, the greater uptake of surveillance colonoscopy allowing detection and resection of dysplastic lesions before the development of CRC, and appropriate timing of colectomy.<sup>23,25</sup>

## RISK FACTORS FOR CRC IN IBD

Several risk factors are associated with the development of CRC in UC or Crohn's colitis as stated previously and include young

### Abstract

Patients with long-standing inflammatory bowel disease (IBD) are at an increased risk for development of colorectal cancer (CRC). Of all the risk factors associated with the development of CRC in IBD, colitis-related dysplasia appears to confer the greatest risk. The goal of endoscopic surveillance is to reduce mortality and morbidity of CRC by either detecting and resecting dysplasia or detecting CRC at an earlier and potentially curable stage. Surveillance strategies have relied on examination of the mucosa with targeted biopsies of visible lesions and random biopsy sampling. Advances in optical technology allowing for greater endoscopic identification of dysplasia and consensus that most dysplasia in patients with IBD is visible have led to a paradigm shift in our approach to surveillance and management of dysplasia. New imaging techniques such as chromoendoscopy (CE), narrow band imaging (NBI), and confocal endomicroscopy have been developed and recent evidence suggests that CE or high-definition white light endoscopy (HD WLE) are superior for dysplasia detection as a surveillance technique where appropriate expertise is available. Adoption of CE as the gold standard of surveillance has been met with skepticism from conflicting data, operational barriers, and the need to understand the true impact of increasingly higher dysplasia detection on overall CRC mortality. This chapter will review the evolution in our understanding of dysplasia, outline the most recent surveillance guidelines, and discuss the management of dysplasia and controversies therein.

age of disease onset, longer duration of disease, greater extent of colonic involvement, coexistent PSC, active endoscopic or histological inflammation, family history of CRC in a first-degree relative diagnosed before 50 years of age, a history of dysplasia, stricturing disease in UC, inflammatory ("pseudo") polyps, a shortened tubular colon, and male gender.<sup>3,10–12</sup> (Fig. 39.1). Subtotal colitis or pancolitis confers the highest risk of developing CRC and patients with colonic CD disease involving more than one-third of the colon are also at increased risk of CRC.<sup>27–29</sup> The extent of colonic involvement should be based on both endoscopic and histological criteria and on whichever reveals more extensive disease.<sup>3,10–12</sup> Although patients with proctitis or distal proctosigmoiditis alone are not at increased risk compared with the general population, many patients with proctitis will develop more proximal disease over the course of their lifetime and a screening colonoscopy is recommended 8 years after the onset of symptoms even in patients with previously isolated proctitis to confirm extent of disease.<sup>3,26,28,31</sup> The relative risk (RR) of CRC rises with longer disease duration and is the rationale behind initiation of surveillance colonoscopy after 8 to 10 years of disease.<sup>10,34</sup> PSC confers a high risk for CRC. A meta-analysis of 11 trials reported a 4-fold increased risk of developing colonic neoplasia in patients with PSC and UC compared to those with UC alone.<sup>35</sup> Additionally, several clinical trials have demonstrated a persistently elevated risk of CRC in PSC despite undergoing orthotopic liver transplantation.<sup>36–38</sup> Thus, patients with IBD and PSC should undergo surveillance colonoscopy annually beginning at the time PSC is diagnosed.<sup>3,10,31</sup> Studies examining a link between early age of onset of IBD and CRC are conflicting and the American Gastroenterological Association (AGA) recommends that surveillance be based on duration of illness and not chronological age.<sup>3</sup>

The known risk factors for CRC in IBD are almost all non-modifiable with the possible exception of inflammation.<sup>3,10,39</sup> A positive association between the degree of microscopic inflam-

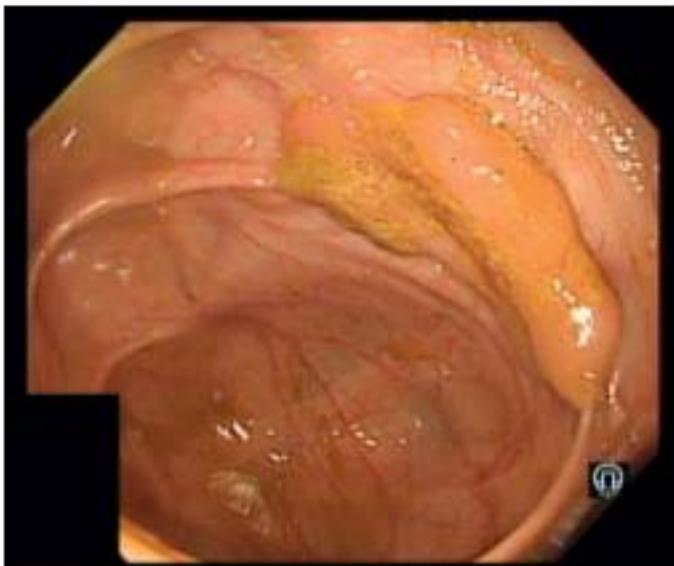

mation and advanced neoplasia has been noted in several studies.<sup>8,13,39,40</sup> Colonic strictures in UC (but not in CD), a shortened tubular colon, and multiple pseudopolyps also increase CRC risk, with the latter significantly limiting the ability to adequately survey the colon.<sup>39–42</sup> These clinically important associations must be considered when counselling patients about their risk of developing CRC and planning surveillance examinations.

### Dysplasia

The detection of dysplasia is currently the best marker of CRC risk in IBD patients, the prevention of which is the ultimate goal of surveillance colonoscopy.<sup>43–45</sup> Biopsies taken at surveillance colonoscopy should be graded as "positive" for dysplasia, "negative" for dysplasia, or "indefinite" for dysplasia and further classified as low-grade dysplasia (LGD), high-grade dysplasia (HGD), or carcinoma.<sup>46</sup> Considerable interobserver variability exists amongst pathologists around interpretation of "low-grade" dysplasia and "indefinite for dysplasia" categories, mandating a second opinion from a specialist GI pathologist to confirm dysplasia when detected.<sup>47</sup> Older guidelines recommended that lesions be characterized as sporadic adenomas if found outside an area of known colitis or as dysplasia-associated lesion or mass (DALM) if detected within an area of colitis; however, this terminology has been abandoned and should no longer be used.<sup>3,10,31,48,49</sup> The terms "visible" and "invisible" should be used instead to describe dysplasia within clearly identified lesions or within random biopsy samples, respectively, with the addition of terms for ulceration and border of the lesion.<sup>31,45</sup> Visible dysplasia is further classified as polypoid (pedunculated or sessile) or nonpolypoid (superficial elevated, flat or depressed) in accordance with the Paris Classification<sup>43,49</sup> (Figs. 39.2 and 39.3). Accordingly, the term *endoscopically resectable* indicates that distinct margins of the lesion can be identified, the lesion appears completely excised on visual inspection after endoscopic resection,

**FIG 39.3** Nonpolypoid dysplasia. (From Kakkar A, Farre F: Diagnosis and management of colorectal neoplasia in patients with inflammatory bowel disease. In Baumgart DC [Ed]: *Crohn's Disease and Ulcerative Colitis: Epidemiology and Immunobiology to a Rational Diagnostic and Therapeutic Approach*. New York, 2012, Springer, pp 701–712.)

**FIG 39.4** Polypoid lesion in the cecum in quiescent ulcerative colitis. (Courtesy Dr. Regi George, Pennine Acute Hospitals, Manchester, UK.)

histological assessment of the resected specimen is consistent with complete removal, and that biopsy specimens taken from mucosa immediately adjacent to the resection site are free of dysplasia on histological assessment (Fig. 39.4).<sup>43</sup>

Recognition that most dysplasia is endoscopically visible, bolstered by advanced imaging techniques facilitating dysplasia detection, has had a significant impact on modern dysplasia management and surveillance strategies.

### Dysplasia Surveillance

The aim of endoscopic surveillance is the reduction of mortality and morbidity from CRC through detection and resection of dysplasia or by detecting CRC at earlier and potentially curable stages.<sup>13</sup> Endoscopic surveillance has been shown to reduce the risk of death from CRC in the IBD population and also to be cost-effective in various case-series, case-control studies and population-based cohort studies.<sup>36–39</sup> Thus, despite the lack of randomized controlled trials, the invasive nature of assessment, and utilization of societal resources, surveillance colonoscopy in IBD patients has been endorsed by multiple societies.<sup>1–7,10,11</sup> Most societies recommend that all patients with UC (including isolated proctitis) and Crohn's colitis should be offered screening colonoscopy approximately 8 to 10 years after onset of clinical symptoms to stage disease extent and evaluate features that may confer a higher risk for IBD-CRC.<sup>3–7,10,11</sup> In the absence of evidence from prospective studies, societies vary in their recommendations with surveillance intervals after a screening colonoscopy but universally agree and recommend annual screening for patients with the highest risk of IBD associated CRC.<sup>5–7,10,11</sup> Thus, patients with concomitant PSC, extensive colitis with active endoscopic or histological inflammation, a family history of CRC in a first-degree relative under the age of 50, a personal history of dysplasia, and stricturing disease (in UC patients) should be offered annual surveillance. Normal appearing mucosa appears to be associated with a lower risk of IBD associated colorectal neoplasia.<sup>40</sup> The British Society for Gastroenterology (BSG), European Crohn's and Colitis Organization (ECCO), National Institute for Health and Clinical Excellence (NICE), and Cancer Council of Australia (CCA) support a risk-stratification approach, increasing surveillance intervals to 5 years in lowest risk patients.<sup>4,7,10</sup> Societies in the United States do not currently recommend lengthening the surveillance interval to beyond 3 years.<sup>3,5,6,41</sup> Recommendations from the AGA guidelines are outlined in Box 39.1. The BSG guidelines incorporating risk factors and newer imaging techniques are outlined in Fig. 39.5.

The success of surveillance depends on several factors, of which the ability to detect dysplasia is probably most crucial. Surveillance traditionally performed by taking random colonic biopsies was based on the premise that dysplasia is frequently not associated with mucosal abnormalities.<sup>12,14</sup> To detect dysplasia with 90% probability, 33 serial colonic biopsies from four quadrant biopsy specimens need to be obtained every 10 cm from each anatomical segment of the colon, a practice endorsed by many GI societies.<sup>3–5,13</sup>

Evolution in endoscopic technology from standard definition (SD) colonoscopy using video chips to high-definition (HD) colonoscopy, and indeed evidence that most dysplasia is visible at standard white light colonoscopy, has challenged the practice of random biopsy sampling as the basis of surveillance assessment.<sup>12,45</sup>

The practice of random biopsies would sample less than 1% of total colonic mucosa, and one study suggested that up to 1266 random biopsies would be needed to detect one additional episode of dysplasia.<sup>43,48</sup> In a study in which UC patients underwent colonoscopy every 2 years, interval cancers were observed to develop between 10 and 28 months after dysplasia-free examination, reflecting poorly on the practice of random biopsies alone for dysplasia detection at surveillance.<sup>36,37</sup>

Surveillance strategies must take additional aspects such as resectability of dysplasia, anatomical features such as pseudo-polyps, and a shortened tubular colon into consideration; these

**BOX 39.1 AGA Surveillance Guidelines for CRC in Inflammatory Bowel Disease**

- All patients, regardless of the extent of disease at initial diagnosis, should undergo a screening colonoscopy a maximum of 8 years after onset of symptoms, with multiple biopsy specimens obtained throughout the entire colon, to assess the true microscopic extent of inflammation.
- Patients with ulcerative proctitis or ulcerative proctosigmoiditis are not considered at increased risk for IBD-related CRC and thus may be managed on the basis of average-risk recommendations.
- Patients with extensive or left-sided colitis should begin surveillance within 1 to 2 years after the initial screening endoscopy.
- Patients with PSC should begin surveillance colonoscopy at the time of PSC diagnosis and then yearly.
- Patients with a history of CRC in a first-degree relative, ongoing active endoscopic or histologic inflammation, or anatomic abnormalities (shortened colon, multiple pseudopolyps, or strictures) may benefit from more frequent surveillance colonoscopy.
- Representative biopsy specimens from each anatomic section of the colon is recommended. Though no prospective trials have determined the optimal number of biopsies to take, one study has recommended a minimum of 33 biopsy specimens.
- Surveillance colonoscopy should ideally be performed when the patient is in remission.
- These recommendations apply to patients with Crohn's colitis who have disease involving at least one-third of their colon.

AGA, American Gastroenterological Association; CRC, colorectal cancer; IBD, inflammatory bowel disease; PSC, primary sclerosing cholangitis.

From Farre FA, Odze RD, Iaden J, Itzkowitz SH: AGA technical review on the diagnosis and management of colorectal neoplasia in inflammatory bowel disease. *Gastroenterology* 138(2):748-774.e4, 2010.

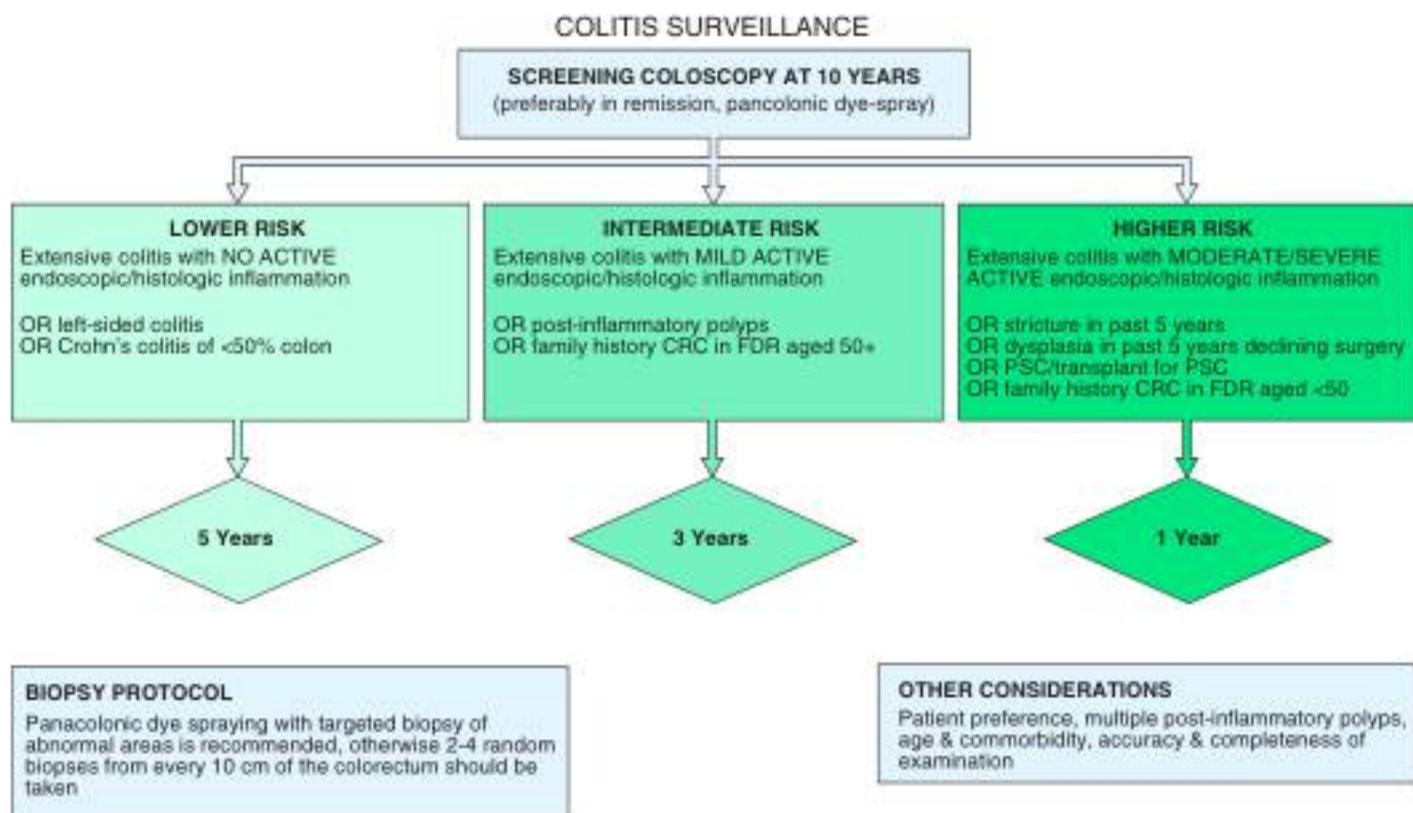

may pose difficulties with dysplasia detection. Furthermore, colonic inflammation can make pathologic discrimination of dysplasia difficult; thus surveillance should ideally take place when the patient is in clinical remission. These factors merit careful consideration with patients when committing to a surveillance program. Evidence suggests that patients do not wish to consider colectomy until there is a relatively high certainty of cancer underpinning the importance of careful consideration and meticulous assessment, employing best available technology and technique to detect and resect dysplasia to avoid IBD-associated CRC and colectomy.<sup>38</sup>

New imaging techniques such as chromoendoscopy (CE), narrow band imaging (NBI), and confocal endomicroscopy have been developed as an adjunctive technique to detect more subtle mucosal abnormalities. Several studies have demonstrated a superior diagnostic yield and therapeutic advantage with CE when compared with standard random biopsy and white light technique for index screening of dysplasia in colitis,<sup>39-43</sup> supported by meta-analyses providing evidence that the use of CE with targeted biopsies is 8.9 times more likely to detect any dysplasia and 5.2 times more likely to detect nonpolypoid dysplasia than white light endoscopy (WLE) with random biopsy.<sup>44-45</sup> This evolution in knowledge has seen cautious translation in societal recommendations over the years. Although the American College of Gastroenterology's (ACG) 2010 guidelines considered it premature to endorse CE in low-risk patients,<sup>3</sup> the Crohn's and Colitis Foundation of America's (CCFA) 2004 and AGA's 2010 guidelines considered CE with targeted biopsies as a reasonable alternative to WLE for endoscopists experienced in this

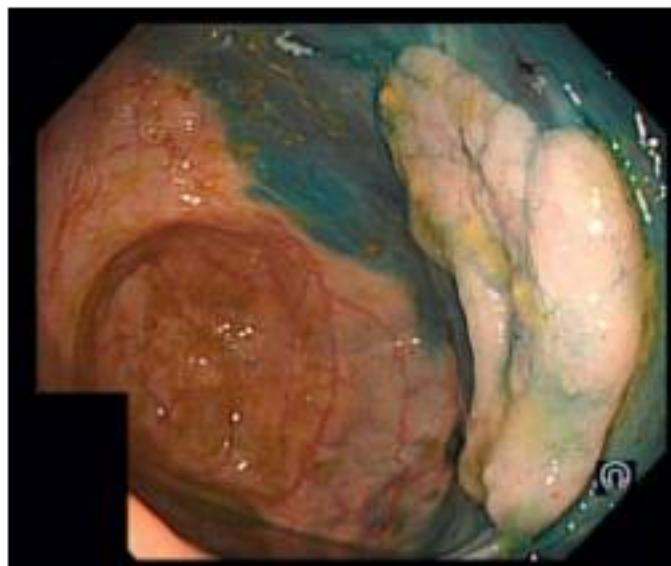

technique.<sup>3,4</sup> CE with targeted biopsies is endorsed by all recent European guidelines (ECCO, BSG, NICE) and recent American Society for Gastrointestinal Endoscopy (ASGE) guidance.<sup>5,7,10</sup> The recently published Surveillance for Colorectal Endoscopic Neoplasia Detection and Management in Inflammatory Bowel Disease Patients: International Consensus Recommendations (SCENIC) recommends CE over standard white light colonoscopy and suggest CE over HD colonoscopy for dysplasia surveillance in IBD, with meta-analysis demonstrating a significantly greater proportion of dysplasia detection at CE (RR 1.8, absolute risk increase 6%) than white light colonoscopy alone.<sup>46</sup> Furthermore, this strategy has also been shown to be cost-effective, especially with increasing surveillance intervals based on the risk of CRC.<sup>46</sup>

CE involves the use of topical contrast agents, either 0.1% methylene blue or 0.03% to 0.5% indigo carmine. Excellent bowel preparation is a prerequisite. Colonic mucosa is sprayed segmentally with contrast agent after cecal intubation and upon withdrawal, using a spray catheter or through the forward water-jet channel using an automated pump.<sup>39-41,45-47</sup> CE enhances mucosal irregularities and helps delineate the lesion morphology, size, and border to evaluate for endoscopic features of submucosal invasion (Figs. 39.6 and 39.7; Videos 39.1 and 39.2). Thus, endoscopically resectable lesions may be resected if feasible, or tattooed and referred to an endoscopist with expertise in endoscopic mucosal resection or dissection as appropriate. Targeted biopsies should be taken from lesions deemed endoscopically unresectable and lesions of uncertain significance. Furthermore, at least two histological staging biopsies from several colonic segments are recommended to determine histological extent and severity of disease, which, in turn, affects the risk of dysplasia.<sup>46,7,10</sup> Random biopsies are not recommended if CE is used for dysplasia surveillance.<sup>46,10,11,31</sup> Despite heightened sensitivity of CE in detecting dysplastic foci and other purported benefits, its universal adoption and acceptance has been met with some scepticism.<sup>48</sup> The natural history of additional, smaller, flatter lesions identified at CE is poorly understood.<sup>49</sup> The rate of progression from indefinite and LGD to cancer appears to be low in some high-risk cohorts, even when considering variables such as PSC and previous advanced dysplasia.<sup>49-52</sup> Moreover, data from the Surveillance, Epidemiology and End results Medicare-linked database of patients over 67 years old showed that interval cancers 6 to 36 months after colonoscopy occurred in a much higher proportion of patients with IBD (15.1% with Crohn's disease and 15.8% with ulcerative colitis) than patients without IBD (5.8%), suggesting that clinically relevant areas of neoplasia may be missed with current colonoscopy surveillance.<sup>53</sup> Considering this, the SCENIC consensus acknowledges that its recommendation for CE over HD white light colonoscopy is conditional, being based on small observational studies.<sup>46,7,31</sup>

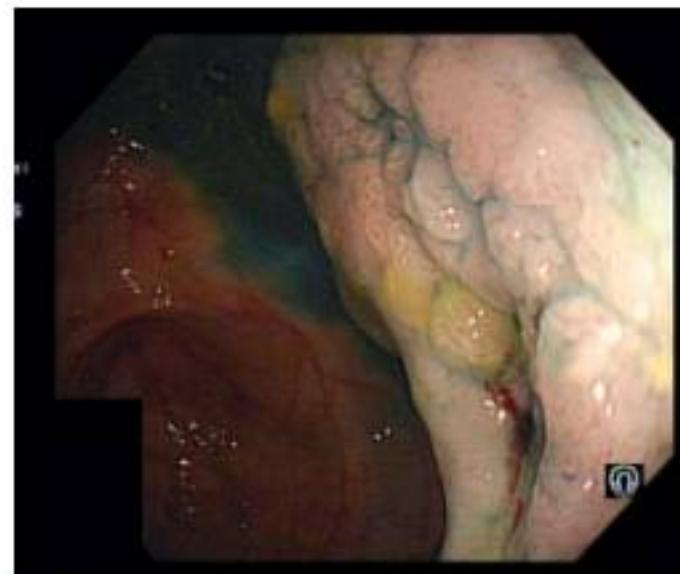

Since the publication of the SCENIC consensus paper in 2015, several studies have added to the body of evidence supporting CE as the preferred technique, with others expressing reservations regarding its universal adoption, through demonstration of its limitations and identifying gaps in our knowledge and understanding of the natural history of dysplasia.<sup>51,74-76</sup> Marion et al (2016) reported a follow-up evaluation of their 2008 study of patients in an IBD surveillance program.<sup>74,75</sup> Sixty-eight patients (from the original cohort of 115), with median disease duration of 21 years, were followed over a 5-year period, between 2005 and 2011. All patients underwent colonoscopy surveillance with random biopsy specimens, targeted WLE, and dye-spray CE. After a mean of three surveillance colonoscopies per patient, six

dysplastic lesions were detected by random biopsy technique, as compared with 11 and 27 dysplastic lesions seen at WLE and CE respectively.<sup>74</sup> CE demonstrated superiority to random biopsy specimens (odds ratio [OR] 5.4; 95% confidence interval [CI], 2.9–9.9) and targeted WLE (OR 2.4; 95% CI, 1.4–4.0). A negative result from CE assessment was the best indicator for a dysplasia-free outcome and a positive result was associated with earlier referral for colectomy (hazard ratio [HR] 12.1; 95% CI, 3.2–46.2). Notably, of the 10 patients with dysplasia referred for colectomy, no carcinomas were found.<sup>74</sup>

Gasia et al (2016), studied a cohort of 454 IBD patients undergoing surveillance assessments between 2011 and 2014.<sup>75</sup> Patients were examined using WLE, HD colonoscopy, virtual electronic, or dye spray CE. Just under one-third of patients underwent WLE or HD colonoscopy with random biopsy, and 14% had virtual CE with random biopsies. A smaller number of patients underwent dye-spray CE with random ( $n = 4$ ) or targeted ( $n = 24$ ) biopsies. Targeted biopsies identified more neoplastic lesions than random biopsies (19% vs. 8%). Four dysplastic lesions were seen at HD WLE. The investigators found no difference in yield between dye CE, virtual CE, and targeted WLE in the cohort of 454 patients studied. No dysplasia was identified, however, from random biopsy samples alone.<sup>75</sup> The futility of random biopsy has been demonstrated repeatedly and convincingly in several prospective studies.<sup>25,48,56</sup>

In a large Dutch multicenter study, Mooiweer et al (2015) studied the outcomes of adoption of CE from 440 colonoscopies in 401 patients compared with historical outcomes of 1802 colonoscopies in 772 patients with WLE.<sup>76</sup> No difference in dysplasia detection was noted in both groups (11% vs. 10%). An inherent limitation of the retrospective study was the lack of data for examination factors (including bowel prep and withdrawal time), but the remarkably stable neoplasia detection over a 10-year period in highly experienced hands suggests that CE is not superior to WLE.<sup>76</sup>

In contrast, another study from St. Mark's Hospital, London, reporting a 40-year experience with colonoscopic surveillance, found a recent increase in the incidence rate of dysplasia since the adoption of high-definition white light endoscopy (HD WLE) and CE for surveillance, but no decrease in the rate of colon cancer.<sup>77</sup> Although CE seemingly did not affect the outcome of CRC in IBD, there was a significant increase in the proportion of early-stage (Duke's A and B) versus late-stage (Duke's C & D) CRC in the most recent decade. HD WLE and CE were introduced at St. Mark's in 2006 and although patients were not randomized to CE between 2006 and 2012, the CRC incidence rate was 2.2/1,000 patient-years in patients receiving at least one CE versus 4.6 in those who had never received CE ( $p = 0.02$ ).<sup>77</sup> Deepak et al (2016) from the Mayo Clinic reported an incremental diagnostic yield from CE.<sup>78</sup> In this retrospective study, IBD patients with colorectal dysplasia on WLE, endoscopic, and histologic findings (median disease duration 18 years) were compared among the index WLE, first, and subsequent CE.<sup>78</sup> Of 95 index cases, dysplasia was identified in 55 patients at index WLE. The first CE identified dysplastic lesions in 50 patients (34 new lesions not seen at index WLE), endoscopic resection was performed for 43 lesions, and 14 patients underwent surgery with two cases of CRC and three cases of HGD. From subsequent CE assessments, 34 lesions were identified in 20 patients. The data support CE as a surveillance procedure in high-risk patients.<sup>78</sup> Indeed, one of the arguments against "CE for all surveillance" is that the natural history of dysplastic lesions identified at CE remains

unknown. Choi et al (2016) identified four characteristics that were significantly associated with a later diagnosis of HGD or CRC.<sup>79</sup> Nonpolypoid lesion appearance, defined as Paris type 0-II (visible, slightly elevated, or depressed), type 0-III (excavated), or plaque-like, was the strongest factor (HR 8.6; 95% CI 3–24.8), but macroscopically invisible dysplasia (HR, 4.1; 95% CI, 1.3–13.4), lesion size of 1 cm or greater (HR, 3.8; 95% CI, 1.5–13.4), and previous history of indefinite dysplasia (HR, 2.8; 95% CI, 1.2–6.5) were also significant predictors. There was also strong positive correlation between the number of these risk factors present and a subsequent HGD or CRC diagnosis. The strongest risk factor, nonpolypoid dysplasia, was found at significantly greater frequency in those patients who underwent CE rather than white-light colonoscopy (15.8% vs. 7.8%, respectively), although exposure to CE did not lower the risk of HGD or CRC after Bonferroni correction for multiple testing.<sup>79</sup>

Successful delivery of dysplasia surveillance using CE, however, hinges on several factors, including appropriate training and expertise (endoscopist and nurses), lesion recognition, and interobserver variability amongst pathologists identifying and grading dysplasia, as well as operational barriers, such as the availability of dye and equipment and procedural time, which results in some hesitancy amongst gastroenterologists in adopting CE, and referral to "experts" for its provision in some instances.<sup>80</sup> The evidence favors CE for surveillance where suitable expertise is available and is backed by several scientific societies and international consensus opinion.<sup>6,10,45</sup> What constitutes "appropriately trained" for CE is currently debatable, as there is no standardized definitions or accreditation process. One study suggested that completion of 16 CE procedures may be adequate for dysplasia detection training using this modality, but this has not since been replicated.<sup>73</sup> A recent multicenter study from Spain has provided "real-world" experience in support of CE for IBD surveillance, challenging skepticism regarding the effectiveness of CE outside of a clinical trial setting and potential limitations posed by less experience with CE.<sup>81</sup> In a prospective study performed between 2012 and 2014, 350 patients with IBD on dysplasia surveillance were systematically evaluated using WLE (SD in 41.5% and HD in 58.5%) for each colonic segment, followed by CE with 0.4% indigo carmine. An incremental yield of 57.4% was noted with CE, comparable between SD and HD colonoscopy (51.5% vs. 52.3%;  $p = 0.30$ ). A further interesting observation was a comparable dysplasia detection between expert and nonexpert colonoscopists (18.5% vs. 13.1%;  $p = 0.20$ ) and no significant learning curve.<sup>81</sup> Endoscopic findings predictive of dysplasia were proximal colonic lesions, protruding morphology, loss of innominate lines, and a neoplastic Kudo pit pattern. Arguable limitations of the study include the potential for a "Hawthorne effect" (diligence with performance of colonoscopy in a prospective study) and an incremental yield from a "second look;" as there was also a small sample size, this study does provide proof of principle for the wider and realistic adoption of CE for dysplasia surveillance in high risk IBD patients and potentially in "nonexpert" hands.<sup>81</sup> Several excellent resources, however, are available for colonoscopists to enhance their skills.<sup>45,60,81</sup> Meanwhile, evolution in our knowledge of the natural history of dysplasia and the clinical implications of dysplasia found by CE through its wider adoption may close many gaps in our understanding of its real place in surveillance. Until then, the bulk of the evidence favors CE with targeted biopsy in individuals at high risk or those with previous dysplasia. In the remaining majority of patients undergoing surveillance

### BOX 39.2 Summary of Recommendations for Surveillance and Management of Dysplasia in Patients With Inflammatory Bowel Disease

#### Detection of Dysplasia on Surveillance Colonoscopy

- When performing surveillance with white light colonoscopy, high definition is recommended rather than standard definition (strong recommendation, low-quality evidence).
- When performing surveillance with standard-definition colonoscopy, chromoendoscopy is recommended rather than white light colonoscopy (strong recommendation, moderate-quality evidence).
- When performing surveillance with high-definition colonoscopy, chromoendoscopy is suggested rather than white light colonoscopy (conditional recommendation, low-quality evidence).
- When performing surveillance with standard-definition colonoscopy, narrow band imaging is not suggested in place of white light colonoscopy (conditional recommendation, low-quality evidence).
- When performing surveillance with high-definition colonoscopy, narrow band imaging is not suggested in place of white light colonoscopy (conditional recommendation, moderate-quality evidence).
- When performing surveillance with image-enhanced high-definition colonoscopy, narrow band imaging is not suggested in place of chromoendoscopy (conditional recommendation, moderate-quality evidence).

#### Management of Dysplasia Discovered on Surveillance Colonoscopy

- After complete removal of endoscopically resectable polypoid dysplastic lesions, surveillance colonoscopy is recommended rather than colectomy (strong recommendation, very low-quality evidence).
- After complete removal of endoscopically resectable nonpolypoid dysplastic lesions, surveillance colonoscopy is suggested rather than colectomy (conditional recommendation, very low-quality evidence).
- For patients with endoscopically invisible dysplasia (confirmed by a GI pathologist) referral is suggested to an endoscopist with expertise in IBD surveillance using chromoendoscopy with high-definition colonoscopy (conditional recommendation, very low-quality evidence).

GI, gastrointestinal; IBD, inflammatory bowel disease.

From Laine L, Kaltenbach T, Barkun A, et al: SCENIC International consensus statement on surveillance and management of dysplasia in inflammatory bowel disease. *Gastrointest Endosc* 81(3):489–501, e26, 2015.

colonoscopy, careful assessment with either HD WLE and random biopsies or CE with dye spray may be appropriate with no compelling mandate for one over the other at the present time. A summary of recommendations from the SCENIC consensus for surveillance and management of dysplasia in patients with IBD is outlined in Box 39.2.

## OTHER ADVANCED IMAGING MODALITIES

### Narrow Band Imaging

NBI, an optical CE technology that uses filters to enhance the contrast of the mucosa and vasculature, has not demonstrated an increased yield for dysplasia detection in randomized studies comparing NBI to either SD WLE or HD WLE.<sup>32–40</sup> Studies comparing NBI with CE have reported a numerically higher detection rate with CE but at meta-analysis the difference was not statistically significant.<sup>41</sup> A prospective, multicenter tandem surveillance study in patients with UC, comparing WLE with targeted and random biopsies to NBI, found no difference in

dysplasia detection rates.<sup>42</sup> The SCENIC consensus does not recommend NBI over dye spray CE.<sup>43</sup>

### Confocal Laser Endomicroscopy

Confocal laser endomicroscopy (CLE) allows for "real-time" histology of lesions already detected at colonoscopy using intravenous administration of stains such as fluorescein. The endoscope integrates a confocal laser microscope into the distal tip of a conventional endoscope, or a CLE probe, which is passed through the working channel. After topical or intravenous application of a fluorescence agent, the CLE probe is applied to the mucosal surface. Fluorescein highlights the extracellular matrix allowing for *in vivo* evaluation.<sup>44</sup>

In a prospective trial with 161 UC patients randomized to combined CE and CLE or conventional WLE, neoplasia detection was 4.75-fold more with the combined approach ( $p = 0.005$ ) requiring 50% fewer biopsies ( $p = 0.008$ ) compared with conventional WLE.<sup>45</sup> A prospective study compared WLE with random and targeted biopsies (group I), CE with random and targeted biopsies (group II) and CLE with random and targeted biopsies (group III). No neoplasia was detected in group I; HGD was detected in two patients (4% detection rate) in group II; and in group III, HGD was detected in four patients (8% detection rate,  $p = 0.05$ ).<sup>46</sup> Notably, all four lesions identified as neoplasia in the CLE group during the procedure were later confirmed at histology. The increased diagnostic yield of CLE with the need for fewer biopsies has been confirmed by other studies.<sup>47,48</sup> Despite encouraging data, the technique is currently limited by the increased length of time, being approximately 15 to 25 minutes more than WLE with target biopsy and CE with targeted biopsy, respectively;<sup>49</sup> a steep learning curve and cost (up to US \$175,000 for the probe based system).<sup>45,49–54</sup>

### Endocytoscopy

Endocytoscopy (EC) is a novel technique that allows highly magnified (up to 1400 $\times$ ) images of subcellular structures.<sup>55</sup> It uses either probe-based systems or EC-fitted endoscopes to obtain histology-equivalent images of the mucosa, following pretreatment with mucolytic agents and staining with dyes such as methylene blue and crystal violet.<sup>56</sup> A pilot study demonstrated that EC may accurately differentiate inflammatory cell populations in IBD, with prognostic implications, but no studies on dysplasia surveillance have been published to date.<sup>57</sup> The potential for EC to detect high-grade intraepithelial neoplasia in polyps, and to identify early dysplastic changes as part of the adenoma carcinoma sequence, shows promise for future applications in colitis-associated dysplasia.<sup>57,58</sup>

### Molecular Imaging

The application of fluorescent substances (antibodies, nanoparticles, lectins, and peptides) acting as probes targeting molecular targets that play a role in GI disease is under study.<sup>59,60</sup> In a murine model, an enzymatically activated probe to detect cancer on a background of colitis, cancerous, and dysplastic cells showed a higher signal than inflamed tissue, confirmed at histology.<sup>61</sup> In a 2014 phase 1 study, patients with Crohn's disease with increased expression of membrane-bound tumor necrosis factor (TNF) as detected following the application of a fluorescent antibody to mTNF (probe), showed a higher response rate to anti-TNF therapy than patients with low mTNF expression.<sup>62</sup> This is an exciting advance with much promise for the potential for personalized management in the near future.<sup>63</sup>

### Stool DNA Testing

The potential for stool DNA testing for genetic alterations that are part of the carcinogenesis cascade in IBD (e.g., BMP3 and mNDRG4) to improve colonoscopic yield is being studied.<sup>103</sup> In a 2016 study, using a Markov model to simulate the clinical course of chronic ulcerative colitis, analysis of stool DNA with CE for patients with positive results was noted to be more cost-effective than CE or WLE alone.<sup>104</sup> Cytobiology assays appear promising for detecting precancerous and cancerous lesions.<sup>105</sup> Likewise, molecular testing for alterations in mucosal antigens, cellular DNA content (e.g., p53 and APC gene mutations), and aneuploidy appear promising, although the predictive value of these changes is presently unclear.<sup>105,106</sup>

### MANAGEMENT OF DYSPLASIA

The ability to accurately identify dysplasia and determine its potential resectability is key to further management.<sup>107</sup> CE and other image enhancing techniques have enhanced dysplasia detection and lesion delineation as described earlier. The SCENIC consensus recommends that lesion morphology be described as polypoid (pedunculated or sessile) or nonpolypoid (slightly elevated, flat, or depressed) and lesion borders classified as distinct or indistinct.<sup>6,10,107</sup> The presence of any overlying ulceration or features of submucosal invasion (such as depression or failure to lift with submucosal injection) may be indicative of underlying malignancy.<sup>108</sup>

A lesion detected at endoscopy should be identified as being within or outside an area of known colitis. Lesions in segments outside an area of known colitis should be treated as sporadic adenomas with standard post-polypectomy surveillance recommendations.<sup>3,10,107</sup> Lesions in an area of known colitis should be assessed for endoscopic resectability and completely resected, if possible, by an experienced endoscopist regardless of underlying colitis or grade of dysplasia. Inflammation, friability, and scarring can make such resection technically more difficult, in which case tattooing and photo documentation should be considered to aid subsequent surveillance or resection.<sup>6,10,109</sup> Colonic mucosa adjacent to the raised lesion should also be biopsied to evaluate for dysplasia. If complete resection is achieved, with dysplasia-free margins and no invisible dysplasia elsewhere in the colon, surveillance colonoscopy may be recommended rather than colectomy.<sup>3,10</sup> Societal recommendations with respect to surveillance after recommendations vary. Thus, ECCO recommends surveillance with CE at 3 months and then at least annually, whereas US Multi-Society guidelines suggest a close surveillance (< 12 months) for larger sessile lesions removed in piecemeal fashion or via endoscopic mucosal resection or endoscopic submucosal dissection, with longer surveillance intervals if the initial repeat colonoscopy result is negative.<sup>3,10</sup> Long-term follow-up studies of endoscopically resectable polypoid lesions are reassuring, demonstrating a low risk of developing dysplasia or carcinoma at follow-up,<sup>108–112</sup> with a 2014 meta-analysis also demonstrating a low risk of IBD-CRC following resection of polypoid dysplasia.<sup>113</sup> Patients diagnosed with dysplasia are themselves more likely to refuse or delay colectomy and prefer surveillance colonoscopy<sup>10</sup> and willing to accept an immediate colectomy only when the risk of synchronous CRC rises to above 73%.<sup>10</sup>

The management of nonpolypoid dysplastic lesions is more challenging. Two studies have demonstrated high cure rates after

complete resection of circumscribed lateral spreading lesions and lesions with HGD.<sup>114,115</sup>

The SCENIC consensus supports surveillance colonoscopy after complete removal of endoscopically resectable nonpolypoid dysplastic lesions.<sup>10</sup> This recommendation is conditional, recognizing the higher CRC risk and greater endoscopic difficulty with resectability conferred by nonpolypoid lesions. Other guidelines recommend colectomy for nonpolypoid dysplastic lesions, considering such lesions generally not amenable to endoscopic resection.<sup>10</sup>

The management of endoscopically invisible dysplasia detected by random biopsies alone has also evolved considerably. Invisible dysplasia was defined by SCENIC as dysplasia identified on random (nontargeted) biopsies of colon mucosa without a visible lesion.<sup>10</sup> Data from St. Mark's Hospital using SD WLE indicates that 20% of patients with flat LGD detected by random biopsies had CRC at the time of immediate colectomy.<sup>10</sup> Ullman et al (2003) found synchronous advanced lesions, including flat HGD or CRC in 23% of patients undergoing colectomy for flat LGD detected on random biopsies using SD colonoscopes.<sup>116</sup> A systematic review of 20 studies and 477 patients with invisible LGD noted that 22% of patients with invisible LGD who had colectomy had CRC.<sup>117</sup> This rate of progression has been challenged by other studies.<sup>118–120</sup> Lim et al (2003) noted a 3% initial and 10% subsequent rate of progression from LGD to CRC in a ten-year period.<sup>118</sup> Extrapolation from data from previous studies should factor in recent recognition that most dysplasia is in fact visible, as well as evolution in endoscopic technology, which suggests that random biopsies showing invisible dysplasia in previous studies may have been taken from previously unrecognizable lesions, now visualized with modern endoscopic techniques.<sup>12,143</sup>

Studies from 2015 of CE or HD WLE have reported a 10% incidence of invisible dysplasia.<sup>10</sup> Until further evidence and our understanding of the natural history of dysplasia evolves and influences our practice through translation into more robust recommendations from GI Societies, the current consensus is as is outlined hereafter. The 2010 AGA guideline recommends colectomy for multifocal flat LGD.<sup>10</sup> The BSG also considers colectomy the best option for LGD but suggests CE if there is uncertainty with the diagnosis and regular surveillance for patients who decline colectomy.<sup>10</sup> The SCENIC consensus supports confirmation of dysplasia by a second GI pathologist and referral to an endoscopist with expertise in IBD surveillance and CE with HD to better inform subsequent decisions regarding surveillance versus colectomy.<sup>10</sup> If a visible dysplastic lesion is identified in the same region of the colon as the invisible dysplasia and the lesion can be resected endoscopically, it is suggested that such patients may remain in a surveillance program. If dysplasia is not found, individualized discussions involving the risks and benefits of surveillance versus colectomy are suggested.<sup>10</sup> Colectomy is the treatment of choice when HGD is confirmed by a second GI pathologist, or incompletely resected raised dysplasia is discovered.<sup>3,10,107</sup> In a review of 10 prospective surveillance trials from 1992, including 1225 patients, the prevalence of synchronous CRC in patients with flat HGD was 42%.<sup>121</sup> In the St. Mark's study of 600 patients in a surveillance program over 40 years, 45.5% of patients with flat nontargeted HGD detected on random biopsies using SD colonoscopes who underwent immediate colectomy had evidence of CRC in the colectomy specimen. Of those who deferred colectomy and continued surveillance, 25% later developed CRC.<sup>10</sup> The high rate of synchronous carcinomas,

AGA, <sup>14</sup> 2010	Adenoma-like DALM; surveillance 16-mo	Non-adenoma-like DALM; colectomy	Confirm by expert GI pathologist Colectomy	Confirm by expert GI pathologist Colectomy vs. intensified surveillance
ASGE, <sup>15</sup> 2015	Endoscopic surveillance at 1–6 and 12 months with biopsies of resection site	Repeat colonoscopy to check if endoscopically resectable. If unresectable, biopsy and tattoo. If dysplasia or cancer confirmed proctocolectomy is recommended.	Confirm by expert GI pathologist and if confirmed recommend colectomy	Confirm by expert GI pathologist Repeat colonoscopy with surface chromoendoscopy by experienced colonoscopist. Obtain random biopsies in addition to targeted biopsies of lesions seen. Endoscopically invisible multifocal LGD recommend colectomy. For unifocal, flat, endoscopically invisible LGD decision should be individualized to offer colectomy vs. surveillance at 6 mo then annually
CCFA, <sup>16</sup> 2005				Confirm by expert GI pathologist Multifocal or repetitive: colectomy Unifocal: colectomy; if patient opts for surveillance, then < 6-mo intervals recommended

ACG, American College of Gastroenterology; AGA, American Gastroenterological Society; ASGE, American Society for Gastrointestinal Endoscopy; BSG, British Society for Gastroenterology; CCA, Cancer Council of Australia; CCFA, Crohn's and Colitis Foundation of America; DALM, dysplasia-associated lesion or mass; ECCO, European Crohn's and Colitis Organization; GI, gastrointestinal; LGD, low-grade dysplasia.

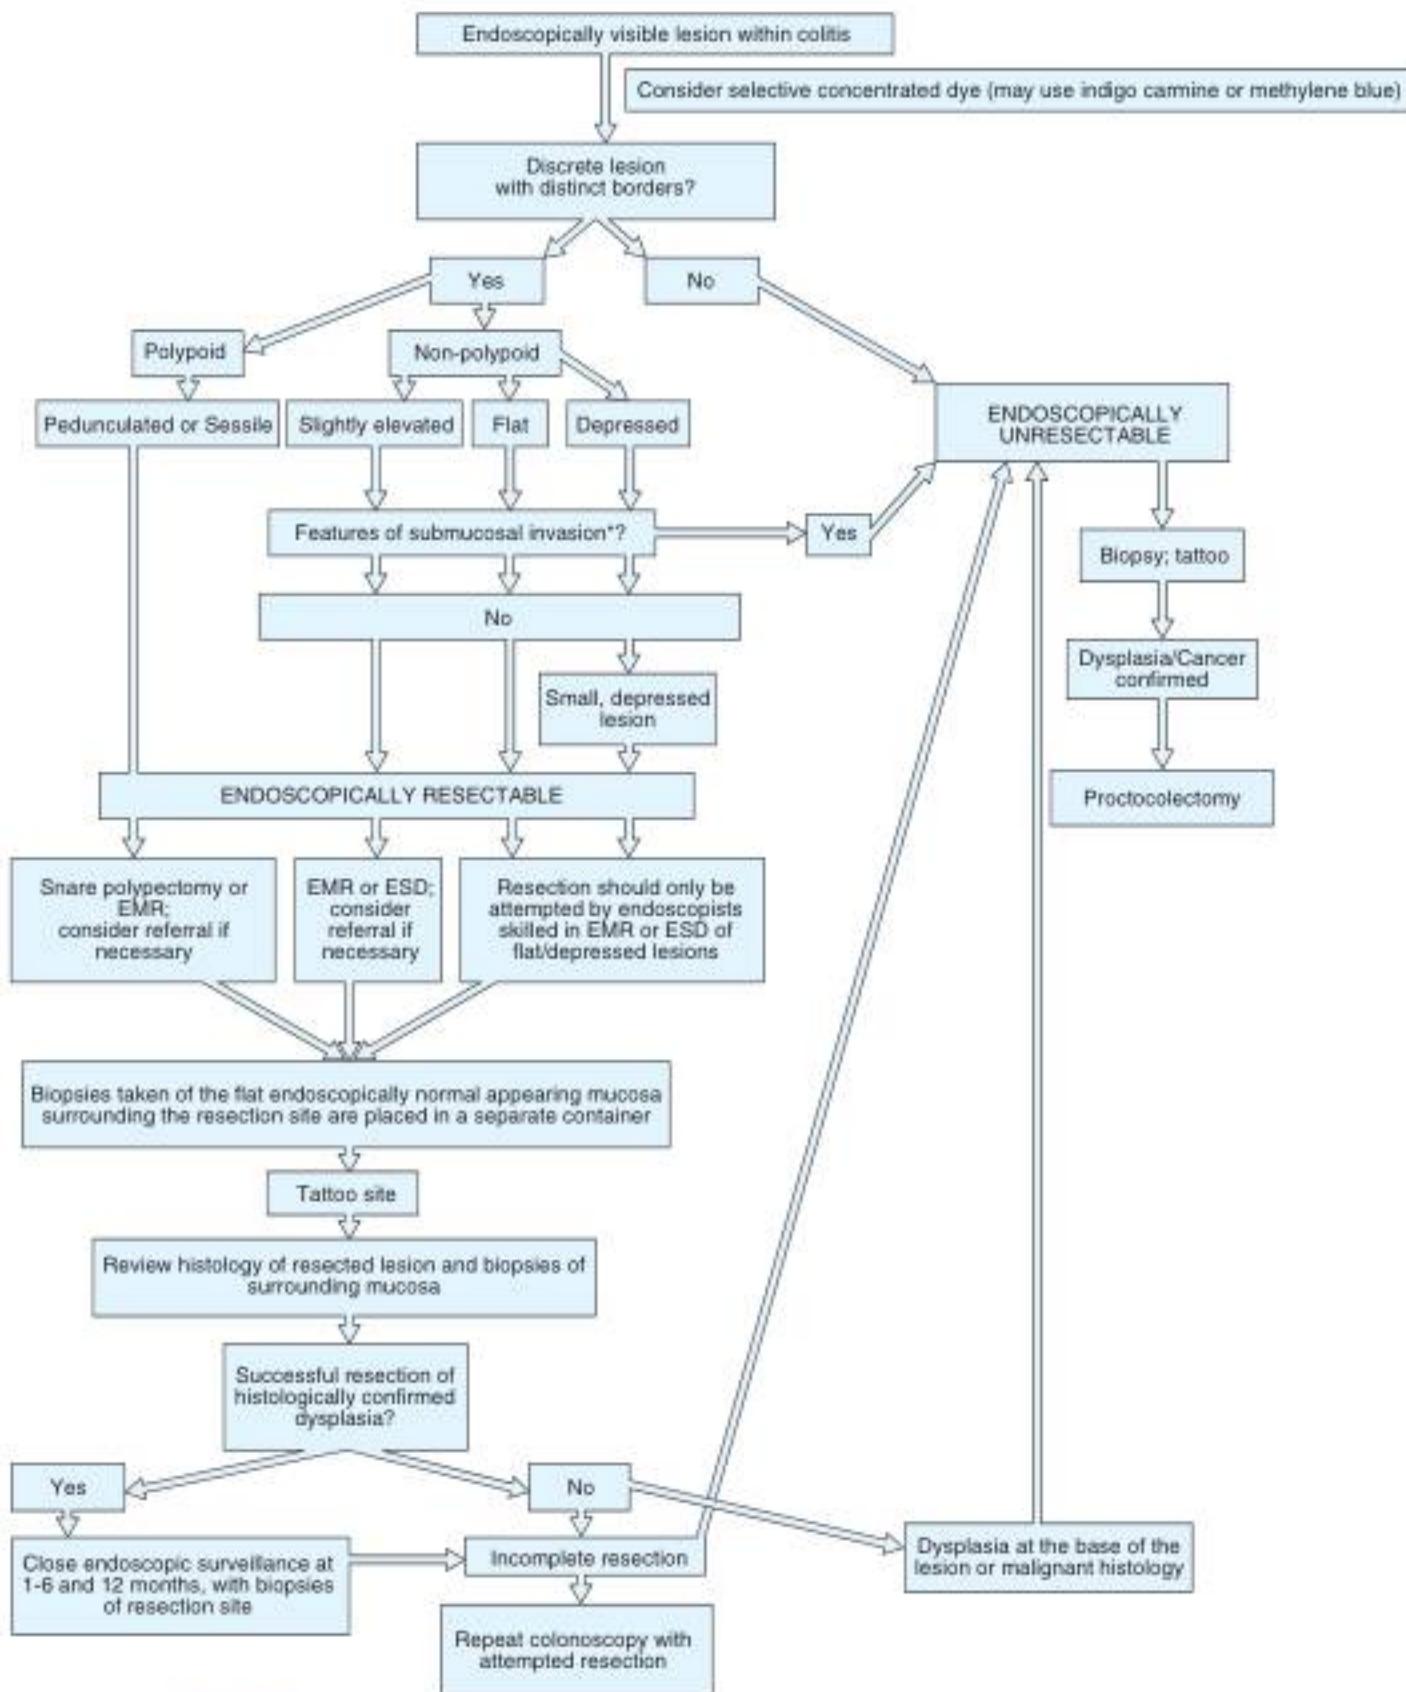

when flat nontargeted HGD is found, is an indication for colectomy.<sup>1</sup> An endoscopically unresectable lesion or a lesion with dysplasia in the adjacent mucosa is an indication for colectomy.<sup>1,5,14,16,18</sup>

It is difficult to distinguish regeneration and repair from dysplasia in the presence of chronic active inflammation, frequently resulting in a pathologic finding that is "indefinite for dysplasia." Less is known about its significance in assessing CRC risk. In a study of 56 patients with biopsies indefinite for dysplasia, a 9% 5-year progression rate to HGD or CRC was observed.<sup>11,19</sup> Inflammation is possibly the only modifiable risk factor for CRC in IBD with a positive association between the degree of microscopic inflammation and advanced neoplasia.<sup>8,16,19,20</sup> Consequently, aggressive treatment of the underlying inflammation followed by endoscopic reevaluation, preferably with CE, is therefore

recommended.<sup>8,21</sup> Furthermore, because the progression to CRC in patients with dysplasia is higher than without dysplasia, a further surveillance examination is advisable within 3 to 6 months.<sup>5</sup> A summary of societal guidelines for the management of dysplasia detected at endoscopic surveillance is shown in Table 39.1. The updated 2015 algorithm suggested by the ASGE for endoscopically visible lesions is shown in Fig. 39.8.

## CONCLUSION

Colorectal cancer is a serious and potentially life-threatening complication of long-standing and extensive UC and colonic Crohn's disease. Of the myriad risk factors associated with the development of CRC in IBD, colitis-related dysplasia appears to confer the greatest risk. All patients with IBD should undergo

**FIG 39.8 Recommended management of lesion detected during endoscopic surveillance.** \*Features of submucosal invasion include: depressions, failure to lift with attempted submucosal injection, or presence of overlying ulceration. *EMR*, endoscopic mucosal resection; *ESD*, endoscopic submucosal dissection. (From ASGE Standards of Practice Committee, Shergill AK, Lightdale JR, et al: The role of endoscopy in inflammatory bowel disease. *Gastrointest Endosc* 81(5):1101-1121, e1-e13, 2015.)

an initial surveillance colonoscopy 8 years after disease onset to assess the extent of colonic involvement, stratify risk of dysplasia, and determine surveillance interval. The goal of endoscopic surveillance is to reduce mortality and morbidity of CRC by either detecting and resecting dysplasia or detecting CRC at an earlier and potentially curable stage.

Understanding that most dysplasia is visible at colonoscopy, coupled with advances in optical technology, allowing for greater endoscopic resolution of dysplasia, has led to a paradigm shift in our approach to surveillance and management of dysplasia, with the bulk of evidence favoring CE or HD WLE at the very least for dysplasia detection. Adoption of CE as the gold standard of surveillance has been met with by skepticism, from conflicting data, operational barriers, and the need to understand the true impact of increasingly higher dysplasia detection on overall CRC mortality. The bulk of evidence, however, backed by recent consensus opinion, favors CE as a surveillance technique where appropriate expertise is available. Valid debate amongst experts notwithstanding, implementation of a risk stratification protocol that includes CE would be an effective approach, allowing earlier detection of dysplasia and colorectal neoplasia, determination of surveillance intervals with appropriate allocation of resources, and limiting morbidity from CRC, and indeed colonoscopy itself. Further prospective data are needed to define the true and long-term impact of dysplasia detection with modern techniques relating to IBD-CRC detection and survival. Meanwhile, the development of newer optical techniques and noninvasive methods for dysplasia detection has exciting implications for further research. The prospect of further intellectual effort invested in innovating and improving skills with established dysplasia detection techniques being rewarded through meaningful outcomes for our patients is now realistic.

# Colonic Strictures

*Andrew P. Copland and Andrew Y. Wang*

## CHAPTER OUTLINE

Introduction, 446	Management of Benign Colonic Strictures, 448	Other SEMS-Related Adverse Events, 452
Initial Evaluation, 446	Management of Malignant Colonic Strictures, 450	Conclusion, 452
Technical Considerations for Balloon Dilation, 446	Palliative Stenting, 450	
Technical Considerations for Use of SEMS, 448	Stenting as a Bridge to Surgery, 451	

## INTRODUCTION

Colonic strictures are encountered with relative frequency in gastroenterology and colorectal surgery practices. The causes of these strictures are quite varied but the most common etiologies in adults include malignancy, diverticular disease,<sup>1</sup> ischemic injury,<sup>2</sup> inflammatory bowel disease (Crohn's disease),<sup>3</sup> surgical anastomoses, and radiation injury.<sup>4</sup> Less commonly, they can be seen in association with nonsteroidal antiinflammatory drug (NSAID)-induced injury,<sup>5</sup> pancreatitis,<sup>6</sup> endometriosis,<sup>7</sup> and as a complication of infections such as amebiasis.<sup>8</sup> A number of technical advances have made endoscopic management of these strictures possible. Endoscopic balloon dilation has been utilized since the 1980s,<sup>7–9</sup> whereas endoscopic placement of self-expanding metal stents (SEMS) has become increasingly utilized since the early 1990s.<sup>10</sup> Prior to any diagnostic or therapeutic endoscopy, patients with suspected colonic stricture or obstruction must be assessed with a careful physical examination and noninvasive radiographic imaging to exclude a surgical abdomen and the presence of luminal perforation.

## INITIAL EVALUATION

Understanding the underlying etiology of a colonic stricture is critical to managing it appropriately. The diagnostic and therapeutic approach varies widely depending on whether a stricture is related to benign disease versus a malignancy. Inflammatory, ischemic, or anastomotic colon strictures can often be managed with endoscopic balloon dilation, but a malignant colonic stricture typically will not respond to conventional dilation therapy and will require either placement of a SEMS or surgical alternatives, such as diversion or resection.

In addition to identifying the etiology of a colonic stricture, it is also critical to define the location and morphology of the stricture. Fluoroscopic imaging (typically a barium enema or Gastrografin [Bracco Diagnostics Inc., Monroe Township, NJ] enema if a leak is suspected; Fig. 40.1A) or cross-sectional imaging

(typically computed tomography scan [CT scan] with intravenous contrast in addition to oral or rectal contrast; see Fig. 40.1B) are important in confirming and delineating a colonic stricture. These radiographic imaging modalities are important to determine the number and location of colonic strictures, the degree and length of stricture, and whether a perforation has already occurred. Additionally, cross-sectional imaging (typically a CT scan) enables assessment of the surrounding soft tissue, lymph nodes, and more distant organs, which can be critical in cases of mass lesions, as well as in inflammatory bowel disease, which can be further complicated by fistulas or abscesses.<sup>11</sup> Diagnostic endoscopy is also important in determining the etiology of a stricture as it can enable sampling for pathological diagnosis.

## TECHNICAL CONSIDERATIONS FOR BALLOON DILATION

Dilating balloons are commercially available from various manufacturers. Balloon lengths range from 5.5 to 8 cm, and the dilating widths range from 6 to 20 mm, with various atmospheres of pressure being required to achieve a different balloon size depending on the balloon and manufacturer. Dilating balloon catheters come in gastroscope and colonoscope/enteroscope lengths and they can be purchased either with or without the ability to accommodate a guidewire. Most diagnostic gastrosopes (with a 2.8-mm accessory channel), and both pediatric and adult colonoscopes will accommodate these "through-the-scope" (TTS) catheters.

The commercially available dilating balloons can appear somewhat opaque when dilated in an insufflated lumen (particularly if they are filled with contrast for visualization under fluoroscopy). Replacing the air/CO<sub>2</sub> interface with water while pulling the dilated balloon snugly against the endoscope lens makes the balloon more transparent, allowing some visualization of the stricture lumen during dilation (Fig. 40.2, Video 40.1). When the lumen proximal to the stricture is endoscopically visible, fluoroscopy is not required. However, when visualization

**Abstract**

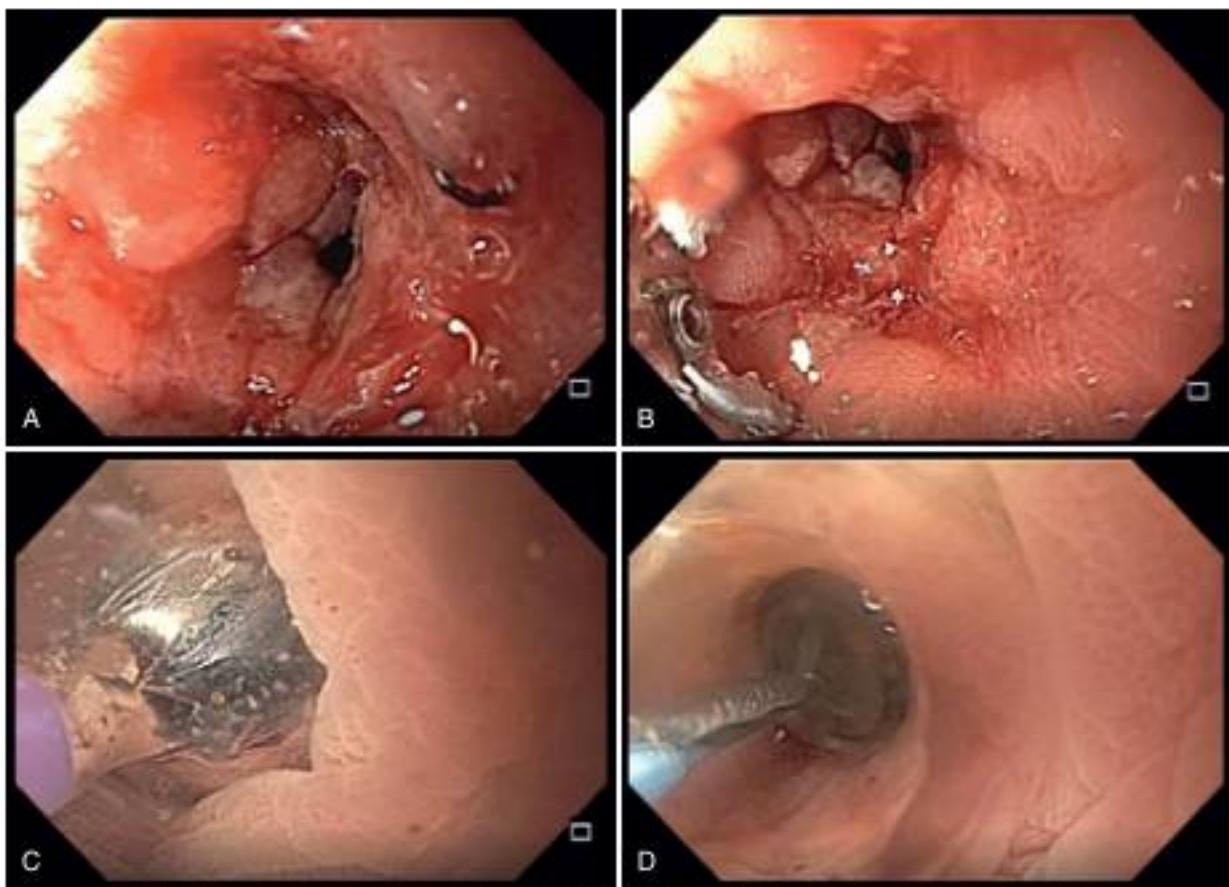

Colonic strictures present an interesting clinical and technical challenge to the gastrointestinal endoscopist. Endoscopic diagnosis and therapy can contribute meaningfully to the care of patients with benign and malignant strictures with a reasonable risk profile. Endoscopic dilation of benign strictures can help patients avoid the morbidity associated with operative resection. For patients with malignant strictures, endoscopic placement of self-expanding metal stents can offer palliation of obstruction at the end of life or, in select patients, serve as a bridge to a safer, less morbid surgery. The role of the gastrointestinal endoscopist in the diagnosis and management of colonic strictures is sure to evolve as endoscopic techniques are refined and as new technologies and medical therapies are developed.

cancer

**FIG 40.1** An “apple-core” lesion, which is pathognomonic for colonic adenocarcinoma, was found on **A**, a barium enema and **B**, on sagittal-views on a computed tomography (CT) scan. This left-sided colon stricture measured approximately 3 cm in length and would be ideal for stenting (as palliation or to assist in a single-stage surgical resection), as the proximal and distal colonic segments are straight and as this is a single stricture that is relatively short.

**FIG 40.2** A patient with a history of colonic diverticulitis who underwent sigmoid colectomy and colostomy with subsequent takedown of the colostomy. **A**, She developed a tight stricture at the left-sided colorectal anastomosis that was erythematous and edematous. **B**, The stricture was approximately 3 mm in width (compared to opened biopsy forceps). **C**, A long 0.035-inch guidewire was passed across the stricture and a through-the-scope dilating balloon was used to dilate the stricture to 11 mm. **D**, Water was infused and the balloon was pulled close to the scope lens enabling visualization of the lumen of the stricture during dilation.

is poor due to tight, long, or angulated strictures, fluoroscopic guidance facilitates passage of a guidewire and then the dilating balloon catheter. Fluoroscopy is also valuable as contrast can be injected after dilation to ensure that contrast remains intraluminal and that there is no extravasation of contrast to suggest a bowel perforation.

For strictures that are tight, long ( $> 4$  cm), or otherwise complex, a "ball-tipped" catheter can be used to inject contrast, navigate the stricture (given itsatraumatic tip), and pass a guidewire. Additionally, dilation of strictures with significant inflammation, evidence of fistula, or an associated abscess should be avoided. Whereas most endoscopists likely have experience with TTS balloon dilation, there are no well-studied standard protocols for how to perform balloon dilation. In general, communication between the endoscopist and the assistant who is inflating the dilating balloon is critical, particularly as resistance to expansion of the balloon allows real-time assessment of the adequacy and risk of the dilation. Once a balloon size is reached that results in significant resistance to moving the balloon, most endoscopists adhere to the "rule of 3s," whereby dilation to three additional sizes provides treatment effect but also limits the risk of perforation (e.g., sequential dilation from 8 to 9 mm and then to 10 mm, etc.).<sup>12</sup>

Examination of a stricture can be done through the balloon or by deflation of the balloon in between sequential dilations. Evidence of a significant mucosal rent, or particularly of visible muscle fibers, should be a signal to cease further dilation. For a tight stricture, repeated dilations could be done in 2 to 4 weeks, with a reasonable eventual goal luminal diameter of 15 to 20 mm. If a stricture fails to respond or remain patent over two to three serial dilations, an alternative approach, such as surgical resection, should be strongly considered.

## TECHNICAL CONSIDERATIONS FOR USE OF SEMS

Colonic SEMS have received United States Federal Drug Administration (FDA) 510(k) premarketing clearance "for palliative treatment of [colonic obstruction or] colonic strictures caused by malignant neoplasms, and to relieve large bowel obstruction prior to colectomy in patients with malignant strictures" (FDA 510(k): K113510, K061877). Furthermore, all commercially-available SEMS in the United States are uncovered, due to the high rate of migration associated with covered SEMS.<sup>13</sup> A comprehensive treatise on the use of colonic SEMS can be found in the American Society for Gastrointestinal Endoscopy Technical Review on "Role of self-expandable stents for patients with colon cancer."<sup>14</sup>

In general, uncovered SEMS in the United States come in discrete sizes that fall between 5.7 and 12 cm in length and with available body widths of 20, 22, and 25 mm (with variably flanged ends that are wider than the width of the stent body). Most commercially available uncovered SEMS in the United States are constrained on a 10-Fr catheter that can fit through the accessory channel of an adult colonoscope or through a therapeutic gastroscope, which allows for the stent to be placed using both endoscopic and fluoroscopic visualization.

In certain clinical situations, covered esophageal stents have also been used in an off-label manner to treat colonic strictures, particularly in cases of benign disease. Most covered esophageal stents come on a stiff introducer (ranging from 16-Fr to 24-Fr in size) that must be passed over a guidewire and cannot be passed through the scope channel or through severely angulated

areas (Video 40.2). These covered esophageal stents are constrained on shorter catheters, which usually limits their use to left-sided colonic strictures. There is one commercially available covered esophageal stent in the United States made by Taewoong Medical (Niti-S Esophageal TTS, Gyeonggi-do, South Korea) that comes on a 10.5-Fr flexible constraining catheter that can be deployed through the channel of a therapeutic gastroscope, which might enable successful covered metal stenting of difficult to reach or angulated colonic strictures (Video 40.3). We use covered esophageal stents to treat refractory or recurrent non-malignant colonic strictures as an alternative to surgery; they may also be considered in patients with colonic obstruction with an uncertain diagnosis of malignancy.

We recommend using fluoroscopy whenever possible when attempting colonic stenting to help define the stricture and to adjunctively guide stent placement using the endoscope.<sup>11</sup> For left-sided colonic strictures, a therapeutic gastroscope is often the instrument of choice, but for right-sided strictures, a colonoscope may be required. Once the stricture has been reached, a long guidewire with a floppy tip (typically 0.035-inch guidewire for added stiffness) is passed across the stricture. We then suggest passage of a retrieval balloon of appropriate length across the stricture, which is then inflated to a large diameter (12–15 mm) and pulled back to define the proximal border of the stricture. An external marker (unbent paper clip affixed to the body) or an internal marker (endoclip or submucosal injection of a small amount of contrast) can then be placed to pinpoint the stricture for stenting. Deployment of TTS uncovered or covered metal stents follow similar principles and involve an assistant deploying the stent while the endoscopist pulls back on the restraining catheter until the stent is released.

## MANAGEMENT OF BENIGN COLONIC STRICTURES

The published literature on the management of benign colonic strictures is largely focused on the inflammatory bowel disease population; in particular, on patients with Crohn's disease who will typically form strictures around the ileocecal valve and at surgical anastomoses (Fig. 40.3). The available data on management of strictures from other etiologies, such as diverticular disease, colonic ischemia, and radiation injury, are limited, and recommendations in the management of colonic strictures in these populations is largely extrapolated from patients with Crohn's disease or based on expert opinion.

The goal of endoscopic therapy for benign colonic strictures, in particular for stenotic surgical anastomoses, is to avoid the morbidity associated with surgical interventions in favor of less invasive therapy, sometimes coupled with medical therapy of any underlying disease. Endoscopic balloon dilation is the most often utilized tool. The technical success for strictures of the colon, including anastomotic strictures, is in excess of 86%.<sup>14–18</sup> In a retrospective study by Singh et al (2005),<sup>14</sup> a high technical success rate of 96.5% was reported following 29 dilations of 20 colon strictures with a long-term success rate of 76.5%. Similarly, Foster et al (2008)<sup>15</sup> reported a retrospective series of 24 patients with small and large bowel strictures who underwent a total of 71 dilations on 29 strictures. In this series, 92% of patients experienced symptomatic improvement.

However, long-term results are more tempered and suggest that nonmalignant colonic strictures often require subsequent interventions, including redilation and sometimes surgery. One large retrospective series spanning 22 years of experience found

**FIG 40.3** A 22-year-old man with long-standing ileal Crohn's disease presented with intermittent small bowel obstruction. **A**, Colonoscopy found an erythematous, ulcerated, stricture that was 3 to 4 mm in diameter. **B**, Injection of contrast via the colonoscope demonstrated a 5-cm-long, high-grade stricture consistent with fibrostenotic Crohn's disease that developed despite the patient having been on biologic therapy. Endoscopic balloon dilation to 10 mm resulted in temporary improvement in obstructive symptoms, but operative resection was eventually required for definitive management of this long fibrotic stricture.

that patients treated with balloon dilation required surgery in 13%, 26%, and 38% of cases at 1-, 3-, and 5-year follow-up, respectively.<sup>20</sup> Van Assche et al (2010)<sup>19</sup> described a retrospective series of 139 patients who underwent endoscopic dilation for short (<5 cm) strictures and found that, whereas technical success rates were high (97%), 46% of patients required repeat dilation and 24% required a subsequent surgery over a median follow-up of 5.9 years. Another study in 2015 retrospectively reviewed a large series of 185 patients who underwent 462 endoscopic dilations over a mean follow-up of 3.9 years. They found that 36% of these patients required surgery.<sup>21</sup> The same group also demonstrated that patients with Crohn's who underwent surgery after dilation were more likely to require a stoma in their operative management (odds ratio [OR] 3.33, confidence interval [CI]: 1.14–9.78) and more likely to have a postoperative surgical site infection (OR 3.16, CI: 1.01–9.84). In aggregate, these data suggest that approximately 60% to 75% of patients with benign colonic strictures who undergo endoscopic dilation could avoid surgical intervention over a 5-year period.

It is important to know that balloon dilation for benign strictures, particularly in patients with Crohn's disease, is not without risk. Procedural complications can occur in approximately 5% of cases, with perforation occurring in 1.4% to 2.5% of cases and significant bleeding occurring in approximately 1% of cases.<sup>18,19</sup> Reassuringly, when compared to surgery, the rate of adverse events from endoscopic dilation in patients with Crohn's strictures is comparable to that associated with a planned surgical intervention.<sup>20</sup>

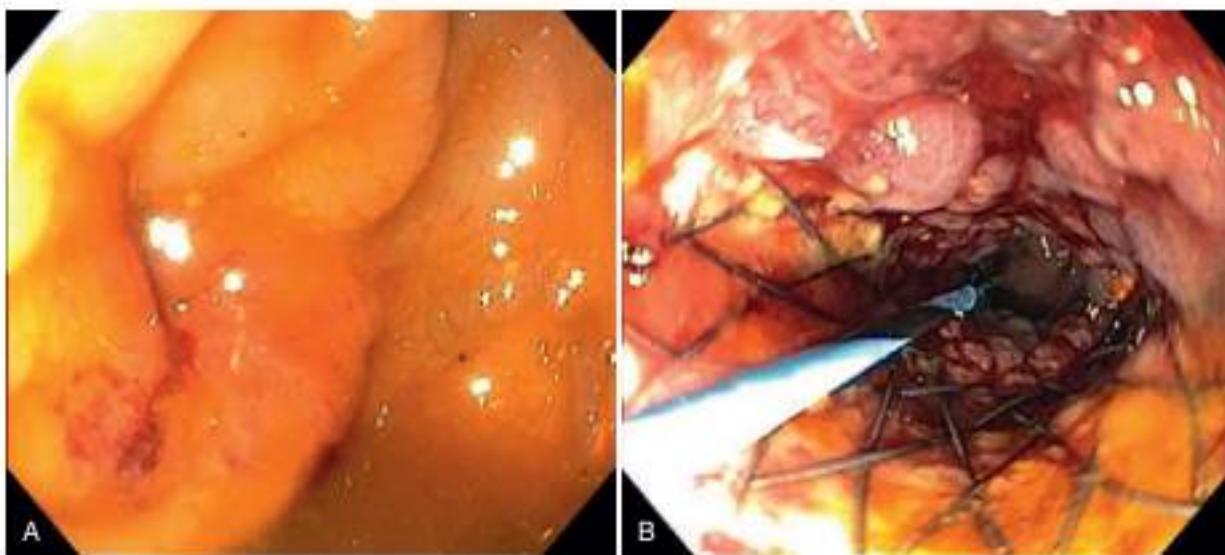

There are few validated clinical predictors for response to successful dilation of benign strictures. One important consideration is the complexity of the stricture. Patients with complex anastomoses or multiple strictures are less likely to have good treatment effect compared to those with a short, focal stricture in a straight colonic segment. A systematic review by Hassan et al (2007)<sup>22</sup> noted that the rate of long-term success was significantly higher for strictures less than 4 cm in length (OR

4.01). In the context of Crohn's disease, it is preferable to avoid dilation of an inflamed stricture given the transmural nature of Crohn's disease and the increased risk of perforation. In addition to conferring a higher risk of adverse events, the presence of ulcers within a stricture has also been noted to be a poor prognostic factor for dilation success, as has smoking.<sup>23</sup>

The available data on endoscopic therapy for other benign strictures, such those resulting from ischemic injury, diverticular disease, and radiation injury are limited. However, in general, we would recommend starting with graded endoscopic balloon dilation for treatment of nonmalignant colonic strictures prior to considering other alternatives.

One adjunctive therapy aimed at enhancing the effect of endoscopic dilation of benign strictures is steroid injection. East et al (2015)<sup>24</sup> demonstrated in a pilot study that, among 13 patients who underwent dilation, steroid injection was surprisingly associated with reduction in time to redilation. Conversely, a double-blind, randomized control trial of 29 pediatric patients with Crohn's strictures evaluated the use of intralesional steroid injection (triamcinolone 40 mg diluted in 5 mL of normal saline, which was injected deeply into the mucosa in 4 quadrants every 2 cm within the stricture) following balloon dilation (to a goal of 18 mm). These investigators demonstrated a statistically increased amount of time free from redilation ( $p = 0.04$ ) and free of surgery in the steroid-treatment arm.<sup>25</sup>

SEMS should not be the first-line choice for management of benign colonic strictures, particularly as there are no FDA-approved covered colonic SEMS, and as uncovered colonic SEMS are typically not removable. However, for nonmalignant colonic strictures that are refractory or recurrent despite repeated attempts at endoscopic dilation, off-label use of fully covered SEMS is a consideration (see Videos 40.2 and 40.3). Caruso et al (2015)<sup>26</sup> reported on the use of fully covered SEMS for refractory anastomotic colorectal strictures and reported a 100% rate of technical and early clinical success in 16 patients with a median follow-up of 21 months. Prolonged clinical success was achieved in 9/16

**FIG 40.4** A patient with metastatic colon cancer presented with symptoms of obstruction. **A.** The colonic lumen was edematous and found to be completely obstructed. An uncovered self-expanding metal stent was deployed with immediate improvement in the luminal diameter. **B.** After stent deployment the obstructing tumor is more visible thorough the lattices of the stent. Please also refer to Video 40.4.

(56%) cases. There were no reported major complications, including perforation or bleeding. Stent migration occurred in 19% of cases, and larger median stent diameter was significantly associated with a more successful clinical outcome (26 mm vs. 20 mm,  $p = 0.006$ ). Small et al (2008)<sup>3</sup> reported on a series of 23 patients with benign, obstructive, left colon strictures from 1999 to 2006 who had placement of uncovered or partially covered SEMS as a bridge to surgery. These investigators reported a high technical success rate of 95% in patients who had predominantly diverticular/inflammatory (16/23 patients) strictures. Major complications occurred in 38% of patients and included stent migration ( $n = 2$ ), reobstruction ( $n = 4$ ), and perforation ( $n = 2$ ). Of the 19 patients who went on to have colectomy, 8 (42%) did not need a stoma after stenting.

Lastly, endosurgical techniques using a sphincterotome or a needle-knife to perform stricturoplasty have been described, which involves making careful radial incisions along the circumference of the stricture.<sup>20,21</sup> Whereas there is evidence that this may be a viable approach in select cases, such procedures should only be performed by interventional endoscopists with considerable experience and expertise and in settings with the appropriate radiological and surgical backup.

## MANAGEMENT OF MALIGNANT COLONIC STRICTURES

The majority of malignant colonic strictures are caused by primary colorectal adenocarcinoma with the predominant lesion being found in the sigmoid or left colon.<sup>22</sup> Balloon dilation is not a useful therapeutic approach in the context of malignant colon strictures and management has focused on the appropriate use of SEMS and surgical intervention. SEMS can be used to treat patients with colonic strictures to (1) serve as palliation of obstructive symptoms in nonoperative candidates or (2) relieve acute obstruction as a bridge to surgery.

### Palliative Stenting

SEMS are an important consideration for palliation among patients with incurable or inoperable malignant bowel obstruction (Fig. 40.4, Video 40.4). This approach can reduce rates of permanent ostomies, surgical morbidity, and length of hospital stays in this difficult-to-treat patient population.<sup>23–27</sup> In a retrospective series from 2011, Lee et al<sup>21</sup> noted a comparable success rate with palliative surgeries (100%) versus palliative SEMS placement (95.8%,  $p = 0.12$ ). The SEMS group also had fewer early complications than the surgery group (15.5% vs. 32.9%,  $p = 0.015$ ). The median duration of patency was shorter in the SEMS group (137 days) compared to the palliative surgery group (268 days,  $p < 0.001$ ). However, after patients with SEMS occlusion were restented (required in 18 of the 30 patients), this extended the median patency duration to 229 days, resulting in comparable patency in both groups. Rates of major complications were not statistically different between the two groups (SEMS: 18.3% vs. surgery: 8.2%;  $p = 0.074$ ). A randomized control study conducted in Australia enrolled 52 patients with a malignant, incurable, large-bowel obstruction (majority of patients from colorectal cancer) who were randomly assigned to surgical decompression or stent insertion. In this study of patients with advanced cancers and limited life expectancy (median survival of 5.2 months in the SEMS group and 5.5 months in the surgery group), stent use was found to be associated with several advantages including a quicker return to diet, decreased stoma rates, reduced post-procedural stay, and some quality-of-life benefits.<sup>24</sup>

As with any interventional procedure, a candid discussion regarding the risks and benefits of palliative SEMS placement is paramount and should be undertaken in the context of a patient's outlook, goals of care, and expected subsequent oncologic therapy. Some studies have suggested that, whereas short-term results, such as relief of obstruction, are quite good, there may be an increased rate of severe SEMS-related complication in the

longer-term. A study by Fernandez-Esparrach et al<sup>25</sup> in 2010 described a prospective series of 47 patients in whom colorectal stenting for malignant obstruction was attempted. Eighty percent of these patients underwent stenting for palliative intent and median follow-up was 130 days. In this study, the long-term clinical failure rate was reported at 51% with major complications including stent migration (22%), recurrent obstruction (17%), perforation (7%), and tenesmus (5%). Stent migration was noted to occur between 6 and 56 days, whereas reobstruction was noted to occur between 67 and 332 days. One perforation in this study occurred 34 days after stent insertion, whereas the other two perforations occurred within the first 4 days following SEMS placement.

In our practice, we offer palliative uncovered SEMS placement to any patient with incurable cancer that presents with malignant colorectal obstruction without signs or evidence of perforation. Whereas a discussion between the endoscopist and the patient (which would ideally include the patient's family or support system) is of paramount importance given the potential risks associated with SEMS placement, we also make every effort to discuss the clinical situation with our surgical and medical oncology colleagues. Determination of which patients are deemed incurable and would benefit from palliative stenting might best be decided by multidisciplinary consultation or after discussion in a dedicated tumor board meeting. For example, given current treatment paradigms, oligometastatic colon cancer with isolated metastasis to the lung or liver may be amenable to chemotherapy and resection with some possibility of long-term remission or cure,<sup>36</sup> which might make palliative stenting (even for a temporary period) undesirable given the risks associated with the procedure. As current chemotherapy regimens can enable patients with advanced or metastatic colorectal cancer to have an expected survival often measured in years,<sup>37</sup> it is very important to inform patients regarding the potential long-term adverse events associated with colonic stenting, including bleeding and perforation. Finally, whereas we and others recommend SEMS placement as the preferred treatment for palliation of malignant colonic obstruction, prophylactic colonic stent placement is not recommended in patients who are not yet symptomatic.<sup>11</sup>

### Stenting as a Bridge to Surgery

Patients with severe colonic obstruction are unable to undergo bowel preparation, which obviates a one-stage resection for left-sided colon cancers. However, preoperative colon preparation is not necessary in patients with obstruction from right-sided colon cancers. In addition to concerns regarding adequate colon preparation prior to surgery, patients who have colonic obstruction often have electrolyte disturbances and malnutrition due to progressive obstruction. As such, emergency surgery in the setting of a colon-cancer-related obstruction is associated with approximately 12% operative mortality, in addition to a significant rate of postsurgical complications.<sup>38</sup> Furthermore, postoperative mortality has also been shown to be higher in patients undergoing emergency surgery for colon cancer as compared to elective surgery.<sup>32,38</sup>

Retrospective and nonrandomized data have characterized SEMS placement as a useful way to avoid emergency surgery and bridge patients with colonic obstruction to an elective operation, thus reducing the need for a stoma and a staged-surgical procedure. Several pooled analyses have demonstrated rates of clinical success in excess of 91%.<sup>39-42</sup> In a prospective study of 182 patients from two large multinational registries by

Jimenez-Perez et al (2011),<sup>39</sup> the use of SEMS as a bridge to surgery in patients with malignant left-sided colorectal obstructions had a procedural success rate of 98% and a clinical success rate of 94%. The overall rate of adverse events was 7.8% (with 3% perforations, 1.2% stent migrations, 0.6% bleeding, and persistent colonic obstruction in 1.8%) and involved one death due to perforation. One hundred and fifty patients were able to undergo elective operations, and from this group only 9 patients (6%) required the creation of a stoma. Other series have suggested that SEMS placement as a bridge to surgery may decrease complication rates and shorten hospital stays.<sup>42</sup> Brehant et al (2009)<sup>41</sup> showed, in a series of 30 patients with mainly left-sided malignant colorectal obstructions treated with SEMS, that a diverting colostomy was able to be avoided in 77% of patients.

However, prospective randomized controlled trials (RCTs) have shown mixed outcomes regarding use of SEMS as a bridge to an elective or one-stage operation. In the first major RCT of SEMS as a bridge to elective surgery, Cheung et al (2009)<sup>43</sup> randomized 48 patients between 2002 and 2005 to either emergency open surgery or emergent SEMS placement with a subsequent one-stage laparoscopic procedure. The technical success rate was high at 83%, and the study noted no procedural complications associated with stenting. Furthermore, 67% of patients who underwent SEMS followed by laparoscopic surgery at a median of 10 days after stenting had a successful one-stage procedure, whereas only 38% of the patients who underwent emergency open surgery had a one-stage procedure. The SEMS group in this study had no permanent stomas. Other, larger studies have shown less encouraging results. Pirlet et al (2011)<sup>44</sup> published a French, multicenter, RCT that included 60 patients with malignant, left-sided, large bowel obstructions who were recruited between 2002 and 2006. Patients were randomized to either emergency surgery or SEMS placement with subsequent elective surgery. This study was ended early due to an increased rate of adverse events (two perforations during stenting procedures and an unexpectedly high rate of technical failures). This study demonstrated a low technical success rate of only 47% for SEMS placement and was not able to demonstrate a meaningful difference in their primary outcome of temporary or permanent stoma rates between treatment arms. Final analysis revealed no difference in secondary outcomes of mortality, morbidity, or length of hospital stay. In this trial, SEMS placement was attempted by radiologists in 13 patients and by gastroenterologists in 17 patients.

Another multicenter randomized trial by the Dutch Stent-In study group<sup>45</sup> enrolled 98 patients before it too was suspended after interim analysis showed no decisive clinical advantage of SEMS as a bridge to elective surgery versus emergency surgery for malignant bowel obstruction. Six of 47 patients in the SEMS arm experienced guidewire or SEMS-related perforation, and there was more postoperative anastomotic leakage in the SEMS arm (5/47 patients) compared to the emergency surgery arm (1/51 patients). Final analysis showed no difference between the treatment groups in 30-day mortality, overall mortality, and morbidity. Despite a goal of reducing need for stomas, over half of the patients in both groups required stomas during their clinical course. This was in part driven by an increased rate of anastomotic leak in the SEMS group requiring reoperation. This study from the Dutch Stent-In study group is also the only RCT to characterize quality-of-life outcomes for which there were no differences between the SEMS and surgery groups. In comparison to the French study,<sup>44</sup> SEMS were placed in this Dutch study

only by experienced endoscopists who had placed more than 20 enteral stents, including at least ten colonic stents.<sup>11</sup>

Finally, a Cochrane analysis from 2011 examined five randomized trials comparing the use of SEMS versus emergency surgery in 207 patients with malignant colonic obstructions.<sup>14</sup> This pooled analysis again demonstrated a high rate of technical success for SEMS placement at 86%, and a rate of complications similar to that of emergency surgery. Successfully placed stents migrated out of place in only 2.1% of cases, and stent obstruction was relatively rare at 2.1% in the first 30 days. The overall 30-day mortality was similar among patients who underwent colonic stenting compared to those who had emergency surgery (2.3% for both groups); however, the total length of hospital stay was shorter in the colonic stenting group (11.5 days vs. 17.2 days).

Because of studies such as those presented, the European Society of Gastrointestinal Endoscopy (ESGE) Clinical Guideline on "Self-expandable metal stents for obstructing colonic and extracolonic cancer" recommends against use of colonic SEMS placement as a bridge to elective surgery.<sup>11</sup> However, it is our opinion that there is likely a select group of patients with malignant colonic obstruction who might benefit from SEMS placement as a bridge to either a more controlled elective operation or towards a single-stage procedure (for patients with left-sided obstruction). In particular, colorectal stenting as a bridge to surgery might offer a more favorable risk-benefit ratio in populations who require medical optimization prior to an operation, such as those with advanced age or complex medical comorbidities, including cardiopulmonary, renal, or metabolic disease.<sup>11</sup> The timing of subsequent elective surgery may also be an important variable in relieving obstructions in these subsets of patients. Prior studies have typically pursued elective surgery in fewer than 10 days after stent placement.<sup>11–13</sup> Given the lack of high-level evidence to support stenting (as a bridge to surgery) over emergency surgery for malignant colonic obstruction, the best outcomes are likely to be achieved if only those patients with favorable stricture location and morphology are offered preoperative stenting, and if these increased-risk procedures are performed by experienced endoscopists who also know when to abort a procedure if the odds of clinical success seem low once the stricture is endoscopically and fluoroscopically evaluated.

## OTHER SEMS-RELATED ADVERSE EVENTS

The most serious SEMS-related adverse event is, of course, perforation, which can occur in the process of stenting (due to scope trauma or by guidewire or device passage) or after stent deployment. However, the most frequent SEMS-related adverse events include minor bleeding, abdominal pain, and stent migration.<sup>12</sup>

Whereas many studies have suggested that SEMS-related perforation occurs in less than 5% of cases, this complication does remain a prime concern among patients treated with SEMS.<sup>14–32</sup> A meta-analysis by Van Halsema et al<sup>43</sup> in 2014 pooled 4086 patients who underwent colorectal stent placement and demonstrated higher rates of perforation with a rate of 18.4% for benign strictures and a rate of 7.5% for malignant strictures. On subgroup analysis, patients who underwent dilation after stent placement had a significantly increased risk of perforation when compared to the nondilation group (20.4% vs. 0%, 95% CI: 6.5%–48.8%). This study also found that patients treated with a chemotherapy regimen containing the antiangiogenic

drug bevacizumab had an increased risk of perforation (12.5%, 95% CI: 6.4%–22.8%) as compared to patients who had no concomitant chemotherapy (9.0%, 95% CI: 7.2%–11.1%). Patients and referring physicians who request SEMS placement in the setting of large bowel obstruction from colorectal cancer should be aware of this issue, as some oncologists will not use bevacizumab in patients with SEMS for fear of a combined increased risk of hemorrhage and perforation. Furthermore, patients and referring surgical oncologists also need to be aware that a SEMS-related perforation in the setting of a resectable colorectal cancer might expose the peritoneum or retroperitoneum to cancer seeding, which may make a curable cancer incurable.

Stent migration is a relatively common event that can occur on average in 10% to 12% of cases.<sup>33–35</sup> Covered SEMS, which again are used in an off-label manner in the colon, are more prone to stent migration. Fortunately, SEMS migration can typically be managed endoscopically by removing the migrated stent with the goal of either placing a larger stent or a different type of stent that might be less prone to migration. Other alternatives to replacing a migrated SEMS include observation (particularly if the stricture has become more patent following stenting) or more definitive surgical intervention.

## CONCLUSION

Colonic strictures present an interesting clinical and technical challenge to the gastrointestinal endoscopist. Endoscopic diagnosis and therapy can contribute meaningfully to the care of patients with benign and malignant strictures with a reasonable risk profile. Endoscopic dilation of benign strictures can help patients avoid the morbidity associated with operative resection. For patients with malignant strictures, endoscopic placement of SEMS can offer palliation of obstruction at the end of life or, in select patients, serve as a bridge to a safer, less morbid surgery. The role of the gastrointestinal endoscopist in the diagnosis and management of colonic strictures is sure to evolve as endoscopic techniques are refined and as new technologies and medical therapies are developed.

### INTRODUCTION

The diagnosis and management of luminal gastrointestinal (GI) tract infections has been an essential component of the practice of gastroenterology since the birth of the subspecialty. The emergence of endoscopy with mucosal biopsy as a safe and accurate diagnostic tool for patients with suspected infection has elevated the GI endoscopist to a key partner in the management team. The importance of the endoscopist may be best appreciated for patients who develop GI complications related to immune suppression, such as after organ transplantation, during chemotherapy, or with human immunodeficiency virus (HIV) infection. In these settings, infections are frequent, and the differential diagnosis and diagnostic approach to GI symptoms often differ from the normal host. This chapter provides an overview of GI infections from the endoscopist's perspective based on organ systems because the clinical presentation generally points to the site of gut involvement and dictates the diagnostic strategy. Several common themes are applicable to most GI infections:

1. The clinical presentation is dictated by the infecting pathogen.
2. The specific immunodeficiency state, its pathophysiology, and severity dictate the spectrum of complicating pathogens.
3. The severity and chronicity of infection for an immunosuppressed patient are dictated by the cause, duration, and type of immunodeficiency.
4. The endoscopic features of any GI infection are variable and overlapping, making definitive diagnosis by biopsy essential when other tests such as stool culture are negative. Biopsy of normal mucosa may be necessary in some situations.

### EPIDEMIOLOGY

#### Immune Competent Patients

The frequency of luminal GI infections, spectrum of pathogens, severity of infection, and organ involvement are dictated by the combination of exposure, predilection (host factors), and organ-specific tropism of the infecting pathogen (Box 41.1). Most infections are transmitted by the fecal-oral route via contaminated food or water and are typically self-limited.<sup>1</sup> With the increase in international travel, geography plays an increasingly important role in the prevalence of some GI infections. Traveler's diarrhea, usually caused by enterotoxigenic *Escherichia coli*, is characteristically seen with travel to developing countries.<sup>2</sup> These travelers are at increased risk of other causes of diarrhea including invasive bacteria like *Campylobacter* and parasites like *E. histolytica*.

Pathogens are endemic in certain portions of the world and in specific regions within countries. For example, in the United States, histoplasmosis is endemic in the Midwest and Mississippi Valley. *Mycobacterium tuberculosis* (TB) is endemic in third world countries, and involvement of the GI tract is well recognized. Medications can also be an important risk factor. Antibiotics are the major risk factor for *C. difficile* infection (CDI). There is increasing evidence that acid suppressing medications increase the risk of most enteric infections, perhaps even CDI.<sup>3</sup>

#### Immune Suppressed Patients

For immunosuppressed patients, the incidence and severity of infection are often linked to the cause and degree of the immunodeficiency state. In addition, they are subject to opportunistic infections, defined as infection by a microorganism that does not typically cause disease. Patients undergoing solid organ

**Abstract**

Gastrointestinal infections are common and gastroenterologists typically participate in the patients' care, especially when the disease is severe. Endoscopy is commonly performed as part of the evaluation and management of the disease. A variety of disorders may predispose the patient to infection, and in the immunosuppressed patient the cause and outcome are dictated by the severity of immunosuppression.

transplantation are at a heightened risk of infection early after transplantation because of profound medication-induced immunodeficiency.<sup>13</sup> It is also during this time that latent infections such as cytomegalovirus (CMV) and *Strongyloides* may become manifest. Over time, however, as drug-induced immunosuppression decreases as drugs are tapered, the incidence of infections decreases. Moreover, infections are more commonly observed after heart transplantation than liver transplantation because more potent and prolonged drug-induced immunosuppression is required to prevent cardiac rejection.

For patients infected with HIV, the incidence of GI infections increases markedly as immune function deteriorates, and the infection risk can be accurately stratified by the absolute CD4 lymphocyte count and HIV-1 RNA levels as higher HIV levels and lower CD4 lymphocyte counts correlate with the risk of opportunistic infections.<sup>14</sup>

Rarely, opportunistic infections have been observed in the apparently normal host, but in contrast to an immunodeficient patient, these infections are typically self-limited. Generally, the more severe the immunodeficiency state required for development of an opportunistic infection, the less likely the pathogen will be observed in the normal host. For example, until the advent of transplantation, CMV was a rare pathogen, and its identification in any patient suggests some type of immune dysfunction.<sup>9,10</sup> CMV is regarded as one of the most common opportunistic infections owing to the high prevalence of prior exposure to CMV, as reflected by seropositivity rates of more than 90% in developed countries,<sup>11,12</sup> and to the fact that CMV disease generally occurs from rerudescence of latent infection during periods of profound immunosuppression.

In summary, a careful history regarding potential exposure, cause and stage of immunodeficiency, if present, and specific epidemiologic factors germane to the clinical presentation will often help determine the potential causes of infection.

## PATHOGENESIS

The pathogenic mechanisms of luminal GI infections include: (1) exposure to a pathogen, (2) reactivation of prior infection (rerudescence), (3) overgrowth of a commensal organism, and/or (4) local spread or dissemination. The specific organ involved with any infectious process, other than local spread, is dictated by the organ-specific tropism of the infecting pathogen. *Candida* and herpes simplex virus (HSV) almost exclusively infect squamous epithelium, whereas *Campylobacter jejuni* and *Shigella* species are colonic pathogens. Inherent to any discussion of pathogenesis is the issue of host-related factors. Numerous nonspecific and immune-based defense mechanisms both prevent and attenuate GI infections.<sup>15</sup> These defenses may be altered by disease, medications, organ dysfunction or organ absence (e.g.,

splenectomy), or as a part of the aging process. Saliva provides an effective physical barrier because of its physical properties. Moreover, immunoglobulins that are present in saliva and in intestinal secretions provide an important early line of defense. Gastric acid is a barrier to enteropathogens, and hypochlorhydria has been shown to be a risk factor for the development of cholera and other GI infections.<sup>1,14</sup> GI motility propels ingested pathogens through the gut and prevents stasis, which can lead to bacterial overgrowth. Inherent antibacterial proteins secreted by Paneth cells, termed *defensins*, seem to play a key role in the host response to bacterial infections of the gut.<sup>15,16</sup> The normal gut microbiota also plays a vital role in the prevention of infection such as CDI; its role in the prevention of other infections is unknown.

The mucosal immune system is composed of inflammatory cells, most notably T cells.<sup>11,17</sup> After exposure to a foreign antigen, these cells differentiate into helper or cytotoxic cells depending on whether the cells express the CD4 or CD8 receptor. The release of cytokines by these cells plays a crucial role in limiting infection but can also result in tissue damage. The critical role of the mucosal immune system in preventing and controlling infections is best shown by the array and severity of luminal GI infections that occur in AIDS, in which there is a progressive loss of CD4 lymphocytes from both the systemic circulation and the mucosal-based immune system.<sup>18,19</sup> Following HIV infection, there is a rapid, substantial and perhaps irreversible loss of mucosa associated lymphoid tissue based CD4 T-cells. Loss of these cells predisposes to small intestinal infections by opportunistic infections such as cryptosporidiosis and microsporidiosis. Likewise, lymphocyte dysfunction, either medication-induced or as part of an immunodeficiency state, predisposes to symptomatic primary infection or rerudescence (e.g., CMV).

In immune compromised patients, most viral GI infections considered here result from rerudescence of infection rather than recent exposure (primary infection). Normally, exposure to these infections occurs during childhood, and the systemic and mucosal-based immune systems keep these infections controlled. However, with immunodeficiency, disease may become overt. Conversely, *Candida* is a commensal organism of the oropharynx and esophagus and, although usually present in small numbers, overt *Candida* infection can be observed even in the normal host under certain conditions, such as antibiotic use; use of inhaled or ingested corticosteroids; antacid therapy or hypochlorhydria states; diabetes mellitus; alcoholism; malnutrition; old age; radiation therapy to the head, neck, and chest; and esophageal motility disturbances. Alterations in cellular immunity lead to Candidal colonization and superficial infection, whereas humoral immunity (granulocytes) prevents invasive disease and dissemination. Under conditions of absolute granulocytopenia or severely impaired granulocyte function, commensal bacteria, particularly gram-positive organisms, including *Streptococcus viridans*, *Staphylococci*, and other bacilli, may invade mucosa that has been damaged from gastric acid reflux disease, from radiation therapy, or from chemotherapy, leading to an active local infection and potential dissemination.<sup>20</sup>

GI infections may result secondarily from active disease in adjacent organs. Esophageal disease may be caused by contiguously infected mediastinal lymph nodes or pulmonary parenchymal infection<sup>21</sup> and by spread of infection via a draining fistula or obstructed lymphatics, resulting in tracheoesophageal fistula.<sup>22</sup> Widespread lymphohematogenous dissemination of opportunistic infections causes either diffuse or focal disease anywhere in the

gut; this process is generally limited to only the most severely immunocompromised patients.<sup>23,24</sup>

Most intestinal infections result in tissue inflammation of varying degrees. Local upregulation of cytokines plays a central role in the local immune response to the pathogen but may also cause tissue injury. CMV esophagitis is associated with high mucosal concentrations of the proinflammatory cytokine tumor necrosis factor.<sup>25</sup> Toxin production, virulence factors, and the local microbiome will also determine the clinical expression and tissue damage caused by many GI infections, especially bacterial infections.<sup>26,27</sup>

Luminal digestive tract infections occur under specific epidemiologic conditions and in the appropriate host. The tissue-based immune system is crucial for preventing opportunistic infections; when this system is absent, infection with such pathogens may be chronic and potentially life-threatening. Exposure to the pathogen is important; however, concurrent predisposing factors that were elucidated previously, such as antibiotic or chemotherapy treatment, can play a pathogenic role in both the normal and the immunosuppressed host.

## CLINICAL AND ENDOSCOPIC FEATURES

Numerous factors guide the approach to a patient with suspected GI infection. Given the breadth of potential etiologic pathogens, the diagnostic approach should be based on the character and chronicity of the symptoms, the organ system(s) involved, and the findings on physical examination.

### Esophagus

#### Clinical Features

The most common cause of esophageal infection in both the normal host and the immunosuppressed patient is *Candida*, followed by the herpesviruses.<sup>28</sup> CMV occurs more commonly in patients with AIDS, whereas HSV is more often observed in the normal host and non-HIV-infected immunosuppressed patients.<sup>29,30</sup> Odynophagia is the characteristic symptom of esophageal infection, and infections resulting in esophageal ulceration almost uniformly cause odynophagia.<sup>28–30</sup> Although less common, dysphagia may be observed with esophageal infections, especially *Candida esophagitis*, or may represent esophageal obstruction or dysmotility from the infection or its sequelae (e.g., stricture). Odynophagia is almost uniformly present and is characteristically severe with CMV esophagitis. Chest pain, weight loss, and fever may be reported. The onset of symptoms is often more subacute than the acute presentation of HSV. A prior or coexistent diagnosis of CMV infection in other organs (e.g., retinitis or colitis) is frequent. Although rare in transplant patients, retinitis may be observed in approximately 15% of AIDS patients at the time of diagnosis of GI disease.<sup>31</sup> Bleeding is generally observed only when there is ulceration, and although generally mild, it can be severe if there is an associated coagulopathy. Pulmonary symptoms may predominate when there is fistula formation to the tracheobronchial tree or coexistent pulmonary involvement. Patients with AIDS often have multiple coexisting esophageal disorders, which further complicates management.<sup>26,27</sup>

Physical examination, particularly of the oropharynx, may be helpful in suggesting the diagnosis of esophageal infection. Approximately two-thirds of patients with AIDS and esophageal candidiasis have oral candidiasis (thrush).<sup>32</sup> In other immunocompromised patients, oropharyngeal candidiasis is also com-

monly associated with esophageal candidiasis.<sup>23</sup> Thrush may be absent, however, if antifungal therapy, such as nystatin, is currently administered. The presence of oropharyngeal candidiasis does not prove that *Candida* is the only cause of symptoms, and the absence of oropharyngeal candidiasis does not exclude *Candida esophagitis*. Patients with chronic mucocutaneous candidiasis may have fungal involvement of various mucous membranes, hair, nails, and skin and may have a history of adrenal or parathyroid dysfunction. Coexistent oropharyngeal ulceration is common in patients with HSV esophagitis but is infrequent in patients with CMV esophagitis or other systemic infections.<sup>31,34</sup>

After *Candida* species, herpesviruses are the most frequent infectious agents that cause esophagitis. After organ transplantation, HSV and CMV occur with equal frequency as causes of esophagitis,<sup>23</sup> whereas in patients with AIDS, HSV esophagitis is uncommon and far less frequent than CMV. In a study of 100 HIV-infected patients with esophageal ulcers, HSV was found in only nine (in four patients it was a copathogen with CMV).<sup>33</sup> HSV esophageal infection commonly manifests with the sudden onset of severe odynophagia, heartburn, or chest pain.<sup>28,30</sup> Autopsy studies suggest that esophageal symptoms may be absent. Herpes labialis (i.e., cold sores) and oropharyngeal ulcers may coexist, antedate, or develop during the esophageal infection, whereas skin infection is rare.<sup>23</sup> Numerous systemic manifestations, including low-grade fever or upper respiratory symptoms, may precede the onset of esophageal symptoms. In untreated immunocompetent persons, spontaneous resolution of HSV esophageal infection occurs within 2 weeks of the onset of symptoms. Rarely, bleeding is the initial presentation and may be observed in the absence of esophageal complaints.

The frequency of esophageal involvement with other pathogens is rare. Bacterial esophagitis has been observed in patients with severe neutropenia, usually patients with hematologic malignancies, but occasionally it is observed after bone marrow transplantation,<sup>35</sup> diabetic ketoacidosis,<sup>36</sup> steroid therapy, or in AIDS.<sup>37,38</sup> The presentation is similar to the presentation with other infectious agents.<sup>39</sup> Fungi other than *Candida* species and parasitic diseases have rarely been reported to involve the esophagus.<sup>41–45</sup>

The symptoms of esophageal TB depend on the degree and type of involvement.<sup>22,46</sup> Systemic symptoms of fever and weight loss are common. Pulmonary complaints often predominate because of a fistula to the trachea, bronchus, or pleural space. Dysphagia may be prominent with the formation of long strictures or traction diverticula resulting from the fibrotic response. Upper GI hemorrhage caused by esophageal ulcers or tuberculous arterioesophageal fistulas may rarely be the primary manifestation.<sup>47</sup> Other mycobacterial infections such as *Mycobacterium avium complex* (MAC) are rare.<sup>48</sup>

Barium radiography plays a minor role in the diagnosis of esophageal infection. In any patient, the presence of severe odynophagia limits the ability to drink barium, hampering the adequacy of the examination. Although specific barium esophagram findings may be more typical for certain disorders,<sup>49</sup> given the potential overlap, many of the findings are nonspecific, and endoscopy with biopsy is generally indicated. The wide spectrum of causes, coupled with the specific antimicrobial regimens that are required, necessitates a definitive diagnosis rather than empiric antimicrobial therapy except when *Candida* is highly expected. Nevertheless, a sinus tract or fistulous connection to the bronchial tree or mediastinum at the level of the hilum is highly suggestive of TB, although it may also be the result of malignancy. An esophageal neoplasm may be mimicked by an ulcerated

tuberculous granulomatous mass or CMV ulcer.<sup>31,32</sup> Chest radiography or computed tomography (CT) scan of the chest may support the diagnosis of TB, although a tissue diagnosis will be required.

#### Endoscopic Features

The characteristics of the esophageal lesions provide very important diagnostic clues. The location, size, and appearance of all endoscopic abnormalities should be documented because these features form the basis of the differential diagnosis and are useful for comparison on follow-up endoscopic examinations. The differential diagnosis of the lesion dictates how lesions should be sampled and what recommendations for diagnostic testing should be made on the biopsy or cytologic specimens (discussed later). Serologic testing plays no significant role in the diagnosis of acute infectious esophagitis. Endoscopic examination of the esophagus is the most sensitive and specific method for diagnosing esophageal candidiasis (Table 41.1).

The gross endoscopic appearance of *Candida esophagitis* is pathognomonic (Fig. 41.1) and may be graded according to published criteria.<sup>33</sup> A large, well-circumscribed ulceration should not be attributed to *Candida*. The endoscopic characteristics of HSV esophagitis reflect the pathologic changes. HSV esophagitis appears as discrete, usually small (< 1 cm), well-circumscribed, shallow ulcers; a diffuse erosive esophagitis; or, rarely, vesicles (Fig. 41.2).<sup>34</sup> Small, scattered lesions covered with exudate mimic esophageal candidiasis. Deep ulcers, as seen with CMV, are very rare. CMV esophagitis is characteristically associated with one or more ulcerations that can be quite striking in patients with AIDS. Nevertheless, as with other infections, variability has been reported with appearances ranging from multiple shallow ulcers, to solitary giant ulcers, to a diffuse superficial esophagitis (Fig. 41.3).<sup>35</sup> Although serologic testing is not helpful because of the high rate of prior exposure to CMV, the absence of CMV DNA or antigenemia in the blood would suggest an alternative diagnosis. Esophageal TB can manifest with a fistula to the tracheobronchial tree that is easily visualized endoscopically and rarely as an ulcer or mass lesion resembling a neoplasm. In normal hosts from

**FIG 41.1** *Candida esophagitis*. Multiple yellow plaques coat the esophageal lumen. In several areas, the plaque has been removed, showing a normal-appearing underlying mucosa.

endemic areas in South America, *Trypanosoma cruzi* may involve the myenteric plexus of the esophagus, resulting in Chagas' disease and an appearance that is indistinguishable clinically, radiographically, manometrically, and endoscopically from idiopathic achalasia.<sup>36</sup> This diagnosis may be established by antibody testing. The endoscopic appearances of other rare infections have been described in case reports and resemble other infections.

#### Stomach

##### Clinical Features

Gastric infections are typically manifested by upper abdominal pain that is generally steady and may radiate to the back. Associated symptoms may include nausea with or without vomiting; vomiting may be prominent when mucosal infection is severe. Infrequently, nausea alone in the absence of abdominal pain

may be observed. Fever and weight loss are variable. Diarrhea may be the prominent symptom if the infecting pathogen also involves the small bowel (e.g., *Cryptosporidium*). Bleeding, both occult and overt, is usually a marker of mucosal ulceration. However, because most gastric infections are superficial, severe bleeding is unusual unless there is an associated coagulopathy.

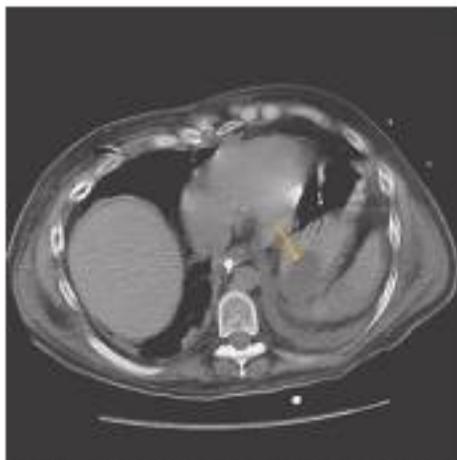

Worldwide, *Helicobacter pylori* is the most common gastric infection regardless of immune status. The prevalence of an infection has generally decreased in some parts of the world, particularly in the United States, although infection can approach 80% or more in selected populations.<sup>55</sup> The presence of *H. pylori* is also associated with hypochlorhydria (fasting gastric pH > 4) and the combination of *H. pylori* infection and HIV infection is more strongly associated with the prevalence of hypochlorhydria than either infection alone.<sup>56,57</sup> Because of the relative infrequency of gastric infections, understanding of the presentation and endoscopic findings of most of these infections is based on case reports or small series. With the exception of *H. pylori*, most infections of the stomach occur in the setting of an immunodeficiency state and include CMV; parasites and mycobacteria are uncommon.<sup>58</sup> In HIV-infected patients, there appears to be an inverse correlation between immune suppression as noted

by CD4 lymphocyte count and the prevalence of active *H. pylori* infection.<sup>57</sup>

The primary symptom is dictated by the underlying cause. CMV gastric infection typically produces ulceration; abdominal pain with or without bleeding is the most frequent presentation. Mucosal infections that result in gastritis without ulceration, such as cryptosporidiosis, more commonly manifest with nausea without pain or may be asymptomatic. *H. pylori* infection of the stomach is generally considered an asymptomatic infection in most people regardless of immune status, but can be associated with dyspepsia and duodenal or gastric ulcer. Tuberculosis may cause antral narrowing with outlet obstruction, ulcer, or intramural abscess. Physical examination is generally unrevealing. Mild abdominal pain may be elicited on palpation of the epigastrium. Radiologic studies may suggest the presence of gastric infection. Although abnormalities can often be identified, the findings are typically nonspecific, and further investigation with endoscopy is often required. Barium findings of gastric infection may include fold thickening or ulceration, whereas the most common CT finding is wall thickening, usually diffuse, and focal lesions mimicking a mass lesion (Fig. 41.4). Neoplasms result in either focal or diffuse wall thickening depending upon etiology.

**FIG 41.2** Herpes simplex virus esophagitis. There are multiple small ulcers, some of which have a "volcano" appearance typical for herpes simplex virus. The intervening mucosa is normal.

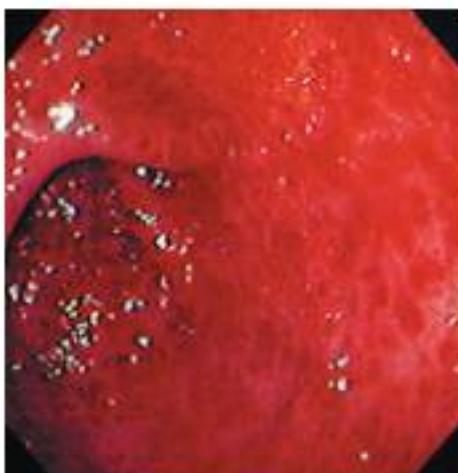

**FIG 41.4** Gastric mucormycosis. Computed tomography (CT) scan shows a large hypodense area in the gastric wall (arrow).

**FIG 41.3** Cytomegalovirus esophagitis. **A**, Two ulcers in the mid-esophagus with normal surrounding mucosa. **B**, Large hemicircumferential ulcer in the mid-esophagus with heaped-up margins.

### Endoscopic Features

Similar to all GI infections, the primary endoscopic abnormality is dictated by the infecting pathogen, and the severity of disease clinically and endoscopically depends on the presence and degree of immunodeficiency. *H. pylori* infection often results in no endoscopic findings or can be associated with a nodular (termed *chicken skin*) appearance due to the presence of lymphoid aggregates. *H. pylori* has also been associated with mucosa-associated lymphoid tumors which have a variable appearance, but typically ulcerated well circumscribed mass-like lesions or diffuse infiltration. CMV, the most common opportunistic gastric pathogen, generally manifests with a diffuse gastritis, characteristically with a hemorrhagic component (Fig. 41.5). Mucosal breaks are typical with focal or diffuse erosions or frank ulcerations (Fig. 41.6) that may be large, are usually well circumscribed, and may mimic a malignancy.<sup>50</sup> Ulcerations have also been described with other bacteria, fungi, and parasites.<sup>51–53</sup> The endoscopic features of gastric cryptosporidiosis and mycobacterial infection may appear as inflammation, polyps, or antral narrowing.<sup>53–55</sup>

**FIG 41.5** Cytomegalovirus gastritis. There is diffuse subepithelial hemorrhage, some of which is confluent in the gastric antrum. Several small erosions were also present in this patient.

**FIG 41.6** Pyloric channel ulcer resulting from cytomegalovirus. Hemicircumferential ulceration with a clean base in the pyloric channel. This lesion resembles a peptic ulcer.

In the normal host, gastric anisakiasis has been associated with ingestion of raw fish, and the *Anisakis* larvae may be visualized and removed at the time of endoscopy (Fig. 41.7).

### Small Intestine

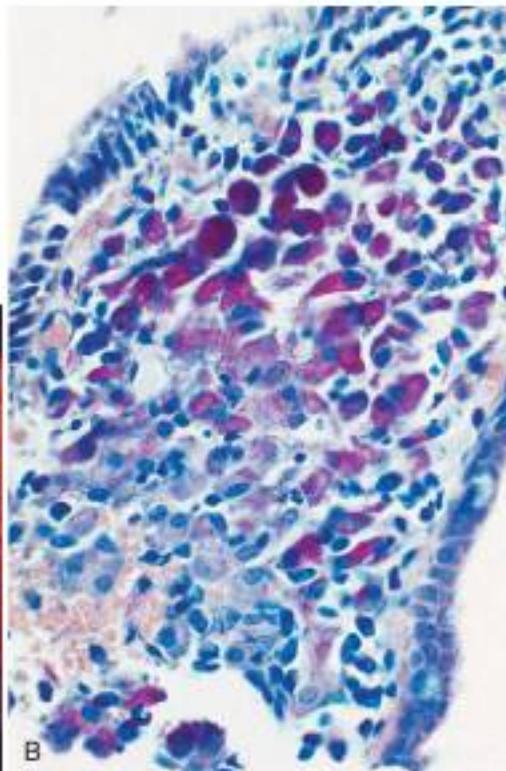

#### Clinical Features

The most common infections are viruses such as rotavirus and norovirus. The most common bacterial infection is enterotoxigenic *E. coli* (traveler's diarrhea), but epidemics of *Vibrio cholera* in endemic areas can have many affected patients with significant morbidity and mortality. Parasitic infections in the small bowel are mostly protozoa, with *Giardia lamblia* the most common, but include *Cryptosporidium*, *Cyclospora*, and *Cystoisospora*. The most common symptoms are diarrhea and abdominal pain. Diarrhea due to small intestinal pathogens is watery, and may be high volume when the organism impairs absorption or causes intestinal secretion like *Vibrio cholerae*. Diarrhea is not bloody as the organisms that infect the small bowel are generally not invasive or minimally so, with the exception of those bacteria that infect the ileo-colonic area, such as *Salmonella* and *Yersinia*. Associated symptoms include fever and crampy abdominal pain which is often perumbilical, and malaise. Dehydration and weight loss occur when the diarrhea is severe or chronic, and fat malabsorption may occur. Symptoms of fat malabsorption include greasy stools and symptoms of fat soluble vitamin deficiencies such as osteopenia/osteoporosis (vitamin D), night blindness (vitamin A), and easy bruising (vitamin K). With these illnesses, physical exam is usually normal unless there is volume depletion. Diagnosis is usually made by stool culture when appropriate or ova and parasite (O&P) exam. With O&P exam, three specimens over several days will give the optimal yield. There is rarely a role for radiologic imaging or even endoscopy. If CT imaging is done, it may show small bowel wall thickening with invasive pathogens but this is a nonspecific finding and can be seen with inflammatory bowel disease (IBD) and other inflammatory diseases, or even small bowel malignancy like lymphoma.

The situation is different with immune suppressed individuals. With the exception of CMV, opportunistic small bowel infections are uncommon in transplant patients, but they are a hallmark

**FIG 41.7** Anisakiasis. A well-circumscribed area of subepithelial hemorrhage is seen with a small worm emanating from the center of the hemorrhage. The worm was removed with biopsy forceps.

**FIG 41.8** Duodenal *Mycobacterium avium* complex (MAC). **A**, Multiple well-circumscribed papular lesions typical for intestinal MAC. **B**, Acid-fast staining of mucosal biopsy specimens shows numerous mycobacteria filling the lamina propria.

of AIDS, where *Cryptosporidium* and *Microsporidia* are frequent pathogens, causing watery diarrhea, which is often severe. Less common is MAC, a pathogen principally restricted to patients with AIDS that is usually widely disseminated at the time of diagnosis<sup>60</sup> (Fig. 41.8). A localized proximal small bowel infection can occur with CMV, and distal ileitis has been reported with CMV, bacteria, mycobacteria, fungi, and parasites.<sup>24,63-73</sup>

Severe watery diarrhea causing dehydration is characteristic of intestinal cryptosporidiosis, whereas less severe diarrhea is observed with most other pathogens. Although crampy abdominal pain may be observed with any diarrheal disorder, more constant abdominal pain would be most typical for CMV enteritis and MAC.<sup>65</sup> Because CMV generally causes focal mucosal ulceration sparing the intervening mucosa, abdominal pain and overt bleeding can be observed in the absence of diarrhea. An acute abdomen can result from intestinal perforation due to CMV.<sup>74</sup>

#### Endoscopic Features

Most patients with small bowel infections will not need endoscopy, with the exception of those who are immune suppressed or those in whom a diagnosis of IBD is entertained. The endoscopic findings of small bowel infections vary from normal to widespread hemorrhage and ulceration. Focal erosions and ulcerations are typical for a viral infection with CMV, whereas minimal mucosal changes, if any, are common with parasitic diseases. Small bowel atrophy is associated with some of these infections and endoscopically mimics celiac sprue.<sup>75</sup> MAC infection has a characteristic appearance of small to confluent nodular lesions, often with a yellow color resembling Whipple's disease (see Fig. 41.8). Disseminated fungal infections can also manifest with small

**FIG 41.9** Cytomegalovirus ileitis. There is well-circumscribed hemicircumferential ulceration at the ileocolonic anastomosis after heart transplant and right hemicolectomy.

nodular lesions.<sup>76</sup> Rarely, obstructive symptoms may predominate if there is an obstructive process. Stricture and ulceration of the ileum is typical for TB and rare for CMV (Fig. 41.9); these are best characterized by radiographic rather than endoscopic examination.<sup>77</sup> Ileitis can also be observed with some bacterial infections, including *Yersinia* species and *Salmonella* species. The endoscopic and radiographic features of any severe ileitis may mimic Crohn's disease and underscores the importance of ileal

examination with mucosal biopsy if colonoscopy is performed. Capsule endoscopy may also help characterize small bowel infections, although mucosal biopsy would require double-balloon enteroscopy.

## Colon

### Clinical Features

The most common symptoms are diarrhea and abdominal pain. In contrast to the large volume, watery diarrhea seen with small bowel pathogens, diarrhea due to colon pathogens tends to be smaller volume, can be bloody if the pathogen is invasive, and may be associated with tenesmus when there is rectal involvement, as is common with *Shigella* infection. Abdominal pain is most often left-sided unless there is right colon inflammation, as is seen with Shiga toxin *E. coli* (STEC). Other symptoms can include fever, malaise, and signs of volume depletion.<sup>73</sup> The physical examination is generally dictated by the infecting pathogen. With acute bacterial colitis, the patient may appear toxic and have significant abdominal tenderness suggesting an acute abdomen, and the pain may predominate over the diarrhea. The most common pathogens are, in order, *Campylobacter*, *Salmonella*, *Shigella* and STEC, both 0157:H7 strains and non-0157 strains. Rates of *C. difficile* infection have increased dramatically since the year 2000, and it should be considered in all acute diarrheal illnesses, not just as a consequence of antibiotics. CDI may complicate the illness in patients with IBD, especially in those with colonic involvement and with immune suppression. As the symptoms of IBD and CDI are the same, management can be challenging when CDI is adequately treated but the symptoms persist. Another challenge in management of IBD is the patient with ulcerative colitis (UC) who is severely ill and is refractory to immunomodulator therapy; in this situation, coinfection with CMV should be considered and endoscopy and biopsy can play an important role.<sup>74</sup> Less common bacterial pathogens are *Yersinia* (which has a predilection for the ileocolonic area and can thus mimic appendicitis and Crohn's disease), *Plesiomonas*, *Aeromonas* and noncholera *Vibrios*. Tuberculosis also has a predilection for the ileo colonic area.<sup>75</sup> The most common parasite to infect the colon is *E. histolytica*.

**Evaluation.** Recent American College of Gastroenterology guidelines (2016) on acute infectious diarrhea recommend microbiologic assessment of stool (i.e., stool culture for enteric pathogens) for immune competent individuals with dysentery (that is not travel related) and persistent diarrhea (14–30 days).<sup>76</sup> For travel-related diarrhea, empiric therapy was recommended, with the therapy depending on the severity of the illness. For diagnosis of CDI, most laboratories are moving to polymerase chain reaction (PCR) for detecting the toxin B gene in stools. Some still use enzyme-linked immunosorbent assay tests for toxin A and B.<sup>77</sup> Because PCR is very sensitive and 5% to 15% of individuals are carriers for *C. difficile*, only diarrheal stools should be tested. For diagnosis of TB, PCR of biopsy specimens is recommended as well as culture. For *Strongyloides*, serology and stool test combined give the best yield. In immune suppressed patients, the spectrum of pathogens includes the aforementioned, as well as opportunistic ones.

Depending on the clinical setting, CMV may be the most frequent opportunistic pathogen. Colonic CMV infection characteristically manifests as a chronic watery diarrhea; pain is often a prominent feature, and occult and overt bleeding may occur given the mucosal ulceration that is typical of colonic disease.<sup>78</sup>

When indicated, cross-sectional imaging may show colon wall thickening which is nonspecific. Cross-sectional imaging is reasonable to consider when there is severe abdominal pain and there are signs of toxicity. Colon wall thickening is nonspecific, and can be seen with invasive infections as well as ischemic colitis, and may be predominantly right-sided with STEC infection.<sup>79</sup>

Additional findings on CT may include small bowel thickening or lymphadenopathy.<sup>80,81</sup> Depending on the infectious cause, radiographic abnormalities may be either focal or diffuse. Barium enema examination, if indicated, should not be performed in patients with suspected colonic infection until all stool studies are collected.

### Endoscopic Features

Colonoscopy can be very helpful in diagnosis of colitis, where the endoscopic findings can range from normal to severe pan-colonic edema and ulceration. The colitis may be patchy, segmental, or diffuse. *Campylobacter*, *Shigella*, *Salmonella*, and *E. coli* 0157:H7 infections may appear similar endoscopically with mucosal edema, subepithelial hemorrhage, erosions, and ulcers of varying size<sup>82</sup> (Figs. 41.10 and 41.11). Distal disease is typical for *Campylobacter* and *Shigella* infections, whereas infections with *Salmonella* and *Yersinia* preferentially involve the right colon and ileum.<sup>83,84</sup> *Salmonella typhi* infection results in lymphoid hyperplasia leading to ulceration at the site of Peyer's patches; this may explain its location in the bowel.<sup>85</sup>

In mild cases of *C. difficile* the colon may be normal, or there may be colitis in more severe cases. In the most severe form, pseudomembranous colitis, there are the classic appearing yellowish plaque-like membranes that are typically confluent (Fig. 41.12). However, pseudomembranes may be absent in patients with IBD and CDI, which may make the diagnosis more challenging. Subepithelial hemorrhage is characteristic of CMV infection, as is ulceration of variable distribution<sup>86</sup> (Fig. 41.13). An appearance of IBD, either UC or Crohn's disease, has been described with bacterial and CMV infections. Colorectal biopsy will usually make the distinction between infection and IBD<sup>87</sup> but cannot usually distinguish acute infection superimposed on chronic IBD. HSV can rarely involve the colon, but generally only the distal rectum and anus are involved, given the tropism of HSV for squamous mucosa. Amoebic colitis may resemble a fulminant colitis or more commonly cause multiple ulcers that can be mistaken for Crohn's disease (Fig. 41.14).<sup>88</sup> The coloscopic findings of cryptosporidiosis may be minimal edema or normal-appearing colon. TB may manifest with a mass lesion or serpiginous ulceration and nodularity.<sup>89</sup> Fungi have rarely been reported to involve the colon, with histoplasmosis noted to cause ulceration or mass lesions resembling carcinoma.<sup>90,91</sup> Helminthic and other pathogens of the colon have also been described (Fig. 41.15).<sup>92,93</sup>

## PATHOLOGY

The pathologic features of GI infections depend on the infecting pathogen, and tissue tropism dictates the organ(s) of involvement.

### Esophagus

The gross pathologic appearance of esophageal candidiasis ranges from a few white or yellow plaques on the mucosal surface to a dense, thick plaque coating the mucosa and encroaching on the esophageal lumen. Although potentially misinterpreted as "ulcer,"

**FIG 41.10** *Campylobacter* colitis. **A**, Focal area of subepithelial hemorrhage and erosion in the cecum. **B**, Hematoxylin and eosin staining of cecal biopsy specimens shows preserved architecture, mucosal edema, subepithelial hemorrhage, and acute inflammatory cells. These findings are typical for acute, self-limited colitis resulting from a bacterial infection.

**FIG 41.11** *Yersinia* colitis. Marked edema, hemorrhage and ulceration in the colon.

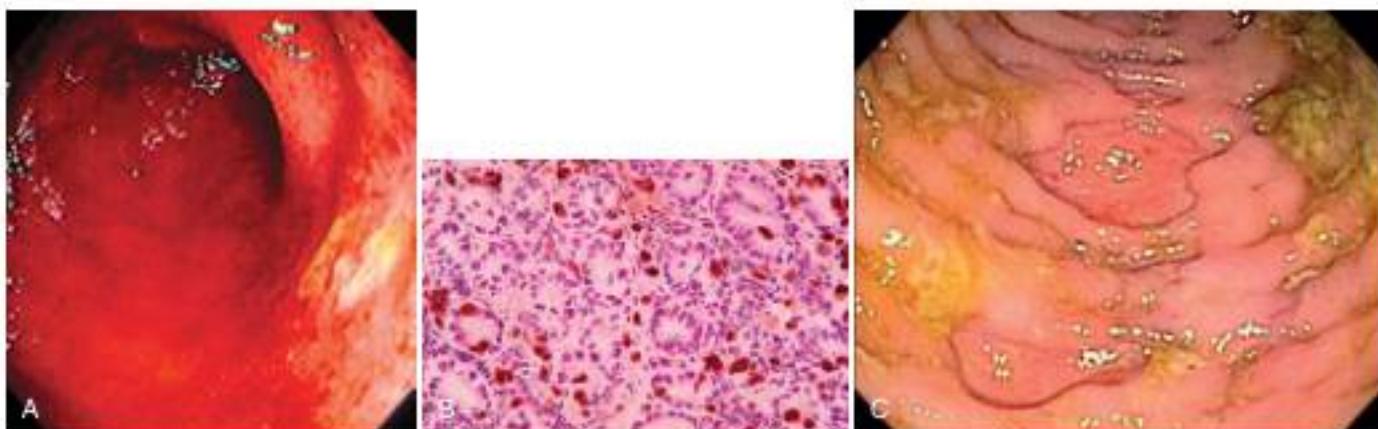

**FIG 41.12** *Clostridium difficile* colitis. Typical yellow plaques are in the distal colon.

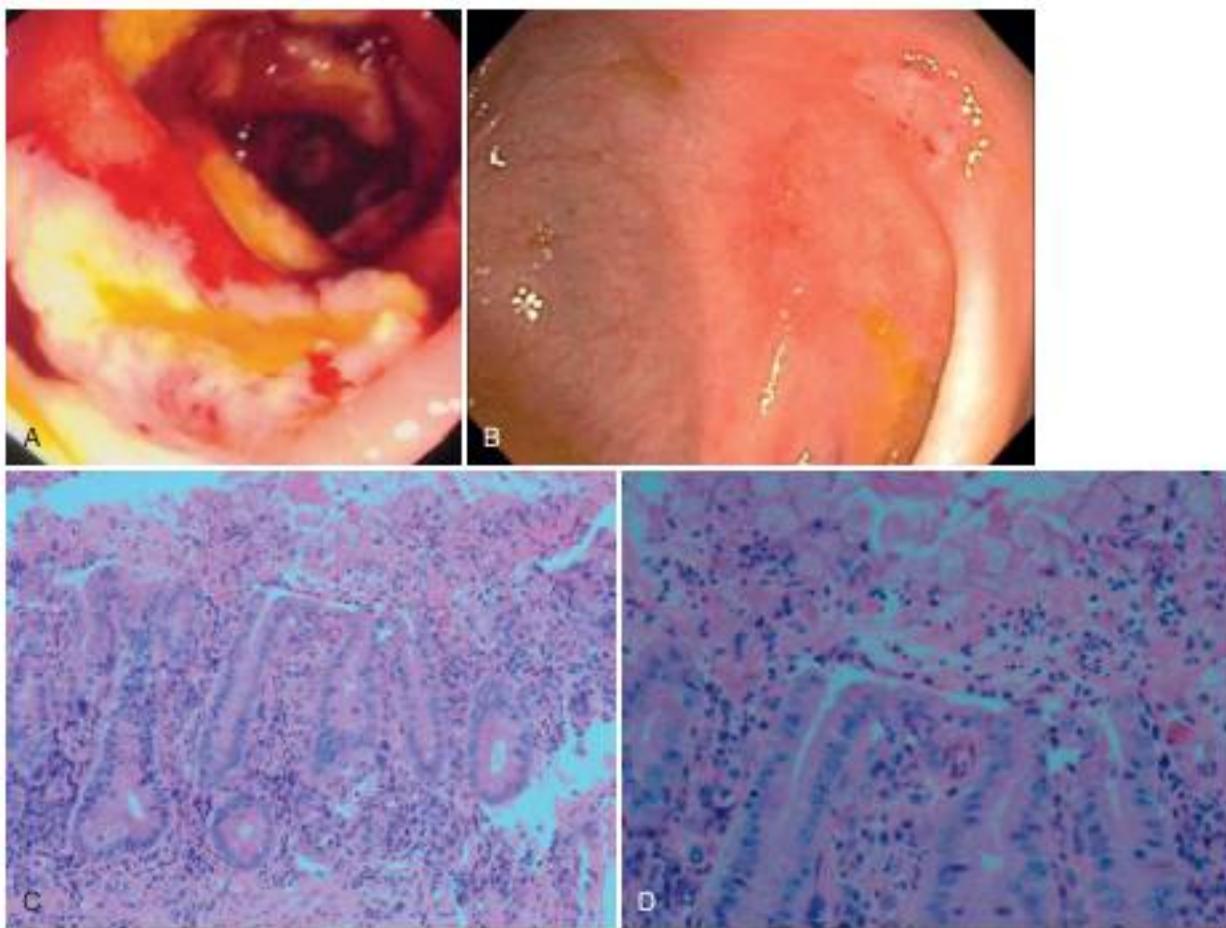

this plaque material is composed of desquamated squamous epithelial cells, admixed with fungal organisms, inflammatory cells, and bacteria.<sup>51</sup> True ulceration (granulation tissue) is rarely caused by *Candida* alone and has been documented most commonly in patients with profound granulocytopenia or when *Candida* is a coinfection with another cause of ulceration.<sup>52</sup> More deep-seated submucosal infections can occur with some fungi, and disseminated fungal infections can lead to ulceration.

Viral infection characteristically results in mucosal erosion and ulceration regardless of the site of infection. HSV infection is generally limited to squamous mucosa, where the earliest manifestation is a vesicle. As these vesicles enlarge and ulcerate, they coalesce to form larger, superficial lesions, which are typically focal, leaving the intervening mucosa normal. Microscopic examination of the squamous epithelial cells at the ulcer edge reveals multinucleation, ground-glass nuclei, and eosinophilic Cowdry's type A inclusion bodies that may take up half of the nuclear volume. With progression, these inclusion bodies may be surrounded by halos and may become more basophilic, filling, enlarging, and deforming the nucleus.

The histologic hallmark of CMV esophagitis is mucosal ulceration. Although variable, deep ulcers are very characteristic for disease in patients with AIDS, whereas in other immunocompromised patients, lesions tend to remain more superficial. Despite the depth of the lesions, perforation is rare. In contrast to HSV, the viral cytopathic effect of CMV is located in endothelial and mesenchymal cells in the granulation tissue of the ulcer base rather than in squamous cells. Inclusions are large (cytomegalic) and often have an eosinophilic appearance that may be located either in the nucleus or in the cytoplasm.<sup>53</sup> The inclusions can assume an atypical appearance, especially in patients with AIDS<sup>54</sup>; immunohistochemical stains play a valuable role in selected patients to confirm the presence of CMV, and they often highlight more infected cells than are appreciated by routine hematoxylin and eosin staining.<sup>55</sup> CMV may coexist with HSV or *Candida* or other pathogens in patients with AIDS. The gross pathologic appearance of bacterial esophagitis depends on the etiologic pathogen and ranges from diffuse, shallow ulcerations

**FIG 41.13** Cytomegalovirus (CMV) colitis. **A**, Diffuse subepithelial hemorrhage typical for CMV infection. **B**, Immunohistochemical stain for CMV antigens highlights the numerous infected cells. **C**, Large, well-circumscribed ulcerations potentially suggesting Crohn's disease.

**FIG 41.14** Amebic colitis. **A**, Patchy erosions and ulcer are suggestive of inflammatory bowel disease. **B**, Well circumscribed ulcer. **C**, Acute colitis with overlying inflammatory exudate which **D**, on close-up shows the typical amoebic structures. (**A**, Courtesy John L. Meisel, MD.)

to ulcers associated with erythema, plaques, pseudomembranes, nodules, or hemorrhage.

Microscopic examination reveals pseudomembranes and bacterial invasion that may be superficial and limited to squamous epithelium or may be invasive and transmural with infiltration of blood vessels (i.e., phlegmonous esophagitis). Esophageal

actinomycosis is characterized by ulceration and sinuses leading from abscess cavities with sulfur granules and filamentous gram-positive branching bacteria seen on tissue biopsy specimens.<sup>50</sup> In the one reported case, *R. henselae* esophagitis resulted in multiple nodules resulting from a lobulated proliferation of capillary vessels lined by plump endothelial cells.<sup>51</sup>

**FIG 41.15** Schistosomiasis of the colon. Solitary nodule in the descending colon.

### Stomach

Bacterial infection of the stomach is generally limited to *H. pylori* infection, which has the characteristic chronic active gastritis often with lymphoid aggregates.<sup>101</sup> These bacteria may be highlighted accurately by additional staining methods, including immunohistochemical stains. Phlegmonous gastritis, whose pathogenesis is not well understood, may involve gram-positive and gram-negative bacilli.<sup>102</sup>

### Small Bowel

Small bowel biopsy is helpful to detect parasites like *Giardia*, *Cryptosporidium*, *Cystoisospora*, and *Strongyloides*. When the lamina propria is filled with macrophages, a periodic acid-Schiff (PAS) stain will be positive in MAC infection, differentiating it from Whipple's disease. Rare findings include lymphoma or other obscure infections. Biopsy of normal appearing mucosa is indicated when looking for infections or a cause of chronic diarrhea.

### Colon

The main role of colorectal biopsy for the diagnosis of colitis is to distinguish infection from IBD. In the former, normal colonic architecture is usual, inflammation is predominantly acute, and there are no basal lymphoid aggregates. In UC, the inflammation is diffuse and limited to the mucosa. The hallmark is distorted crypt architecture, with acute and chronic inflammation and basal inflammation with plasma cells and lymphoid aggregates. In Crohn's disease, inflammation is typically patchy, but can be transmural. Granulomas can be found in up to 20% of biopsies, and can be found in biopsies of normal mucosa. However, granulomas are not specific for Crohn's disease, and can be seen with tuberculosis (they are typically more numerous though may not be caseating), *Yersinia*, schistosomiasis (surrounding the organism) and rarely in syphilis. Colorectal biopsy may also show ulcers with ameba on the surface (see Fig. 41.14).

Colorectal biopsy is also helpful to diagnose a CMV superinfection complicating IBD, especially UC, if typical inclusions are seen, but should be supplemented with another technique such

as culture or PCR testing. Biopsy cannot distinguish a bacterial infection superimposed on chronic IBD.

### Special Stains

Although generally an excellent stain, hematoxylin and eosin staining may not identify all pathogens. Various pathogen-specific stains are available to aid in the identification of nearly all common GI infections (with the exception of non-herpesviruses). These stains highlight infecting pathogens and make identification easier. Immunohistochemical stains for viral antigens are very helpful when examining for herpesviruses.<sup>103</sup> Because a battery of stains is not routinely performed on all biopsy specimens, communication with the pathologist is essential to ensure appropriate pathologic evaluation.<sup>104</sup> Intestinal TB and MAC may be hard to distinguish because both may have granulomas present in ulcer tissue, with mycobacteria identifiable by mycobacterial staining. MAC, in contrast to TB, may not result in well-formed granulomas. Staining for MAC with PAS stain characteristically yields an abundance of organisms (see Fig. 41.8B), whereas tuberculous bacilli may be few in number, even in patients with AIDS.

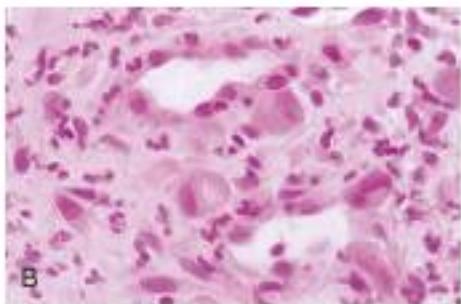

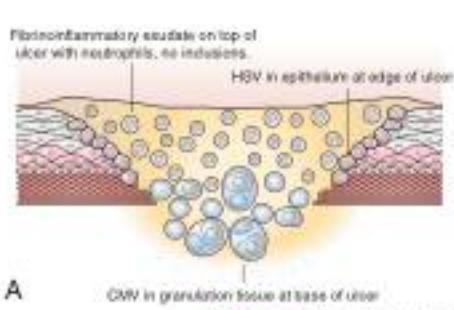

## DIFFERENTIAL DIAGNOSIS

Diagnostic considerations are determined by the clinical presentation, risk group, severity of immunodeficiency, and specific endoscopic findings. Although overlap is broad, some endoscopic abnormalities are typical for a specific pathogen and may be organ-specific (see Table 41.1). In the esophagus, CMV esophagitis and the idiopathic esophageal ulcer of AIDS are difficult to differentiate.<sup>105,106</sup> These two processes generally result in one or more large ulcers. Pill-induced esophagitis must be excluded by history because the pathologic findings of esophageal biopsy specimens are similar. Likewise, distal esophageal ulcer may suggest gastroesophageal reflux disease, and the histopathologic features cannot distinguish this from idiopathic esophageal ulcer. The clinical history is different, however, and the endoscopic appearance helps suggest gastroesophageal reflux. Small esophageal ulcers can be observed in the acute phase of HIV infection, which can mimic viral or pill-induced esophagitis.<sup>107</sup> Esophageal strictures can result from opportunistic infections.<sup>108</sup> The history coupled with mucosal biopsy helps differentiate infection from gastroesophageal reflux disease.

The appearance of the small bowel is similar in many infections and can be normal. The cause of bacterial colitis, with the exception of *C. difficile*, can rarely be differentiated by presentation or endoscopic appearance alone, although some infections may favor a proximal or distal location. In this setting, stool culture and blood culture may be diagnostic. In an immunosuppressed patient with chronic diarrhea, one or more colonic ulcers associated with subepithelial hemorrhage are highly suggestive for CMV, but this appearance can result from other disorders as well.<sup>109,110</sup>

### Description of Techniques

No specific techniques are generally required for the endoscopic evaluation of GI infection. Based on the suspected cause clinically, endoscopically, and pathologically, additional stains may be required, necessitating close collaboration with the pathologist to diagnose these infections accurately. Because most infections can be diagnosed on tissue biopsy alone, multiple biopsy specimens of endoscopic abnormalities should be obtained to increase

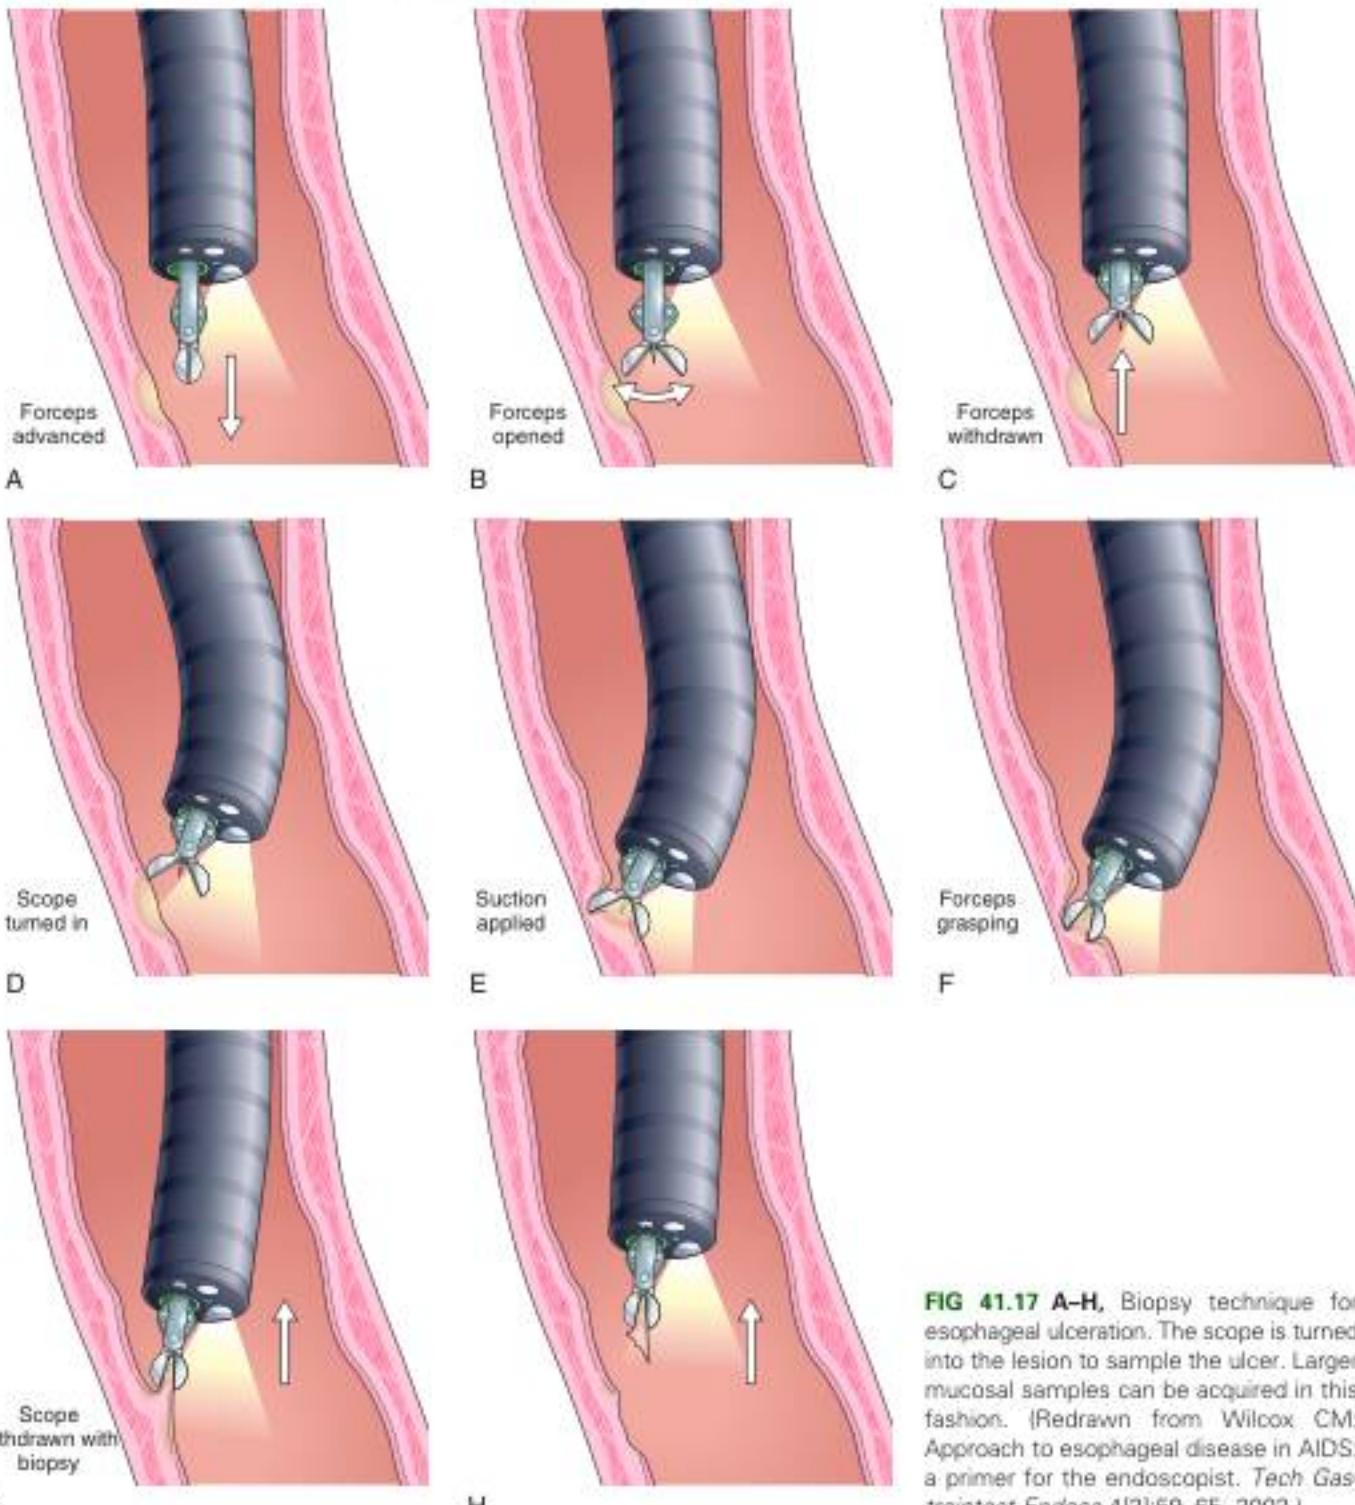

A

B

C

**FIG 41.16** **A**, Location of viral cytopathic effect in mucosal ulceration. Herpes simplex virus (HSV) can be found at the ulcer edge, whereas cytomegalovirus (CMV) is located in granulation tissue deep in the ulcer bed. **B**, Large cells with intranuclear inclusions typical for CMV. **C**, Multinucleated cells in squamous tissue typical for HSV. (From Lazenby AJ: Gastroenterologist/pathologist partnership. *Tech Gastrointest Endosc* 4(2):95–100, 2002.)

**FIG 41.17** **A–H**, Biopsy technique for esophageal ulceration. The scope is turned into the lesion to sample the ulcer. Larger mucosal samples can be acquired in this fashion. (Redrawn from Wilcox CM: Approach to esophageal disease in AIDS: a primer for the endoscopist. *Tech Gastrointest Endosc* 4(2):59–65, 2002.)

diagnostic yield. Even when the mucosa appears normal, multiple biopsy specimens should be taken when infection is suspected. During endoscopy, mucosal lesions can be brushed and submitted for cytologic evaluation, or biopsy specimens can be obtained for histologic diagnosis. Esophageal brushings with cytologic evaluation may be diagnostically helpful in certain diseases, such as those resulting from *Candida* and HSV, but are not helpful for diagnosis of CMV disease.

Viral culture of biopsy specimens may increase the diagnostic yield, although false-positive and false-negative results occur, and viral cultures are less sensitive than multiple biopsy specimens. Use of shell vial techniques improves the turnaround time for CMV culture to 48 hours. Bacterial culture of colonic biopsy specimens has been found in some series to enhance the diagnostic yield but is not typically done. Cytologic brushings and endoscopic mucosal biopsy specimens should be taken from the ulcer edge when HSV disease is suspected because the viral cytopathic effect is best identified in epithelial cells rather than in granulation tissue in the ulcer bed.<sup>106</sup> In contrast, a biopsy specimen of the ulcer base must be obtained when viral infection is suspected with CMV (Fig. 41.16). Multiple biopsy specimens (up to 10) may be required to establish the diagnosis in patients with AIDS and should be taken from the base of the ulcer.<sup>107</sup> Overall, mucosal biopsy for histologic diagnosis is the preferred method to distinguish the cause of ulcer.<sup>108</sup> Culture of an aliquot of stool obtained at colonoscopy and bacterial culture of mucosal biopsy specimens may increase the diagnostic yield.<sup>109</sup>

As mentioned previously, many histologic stains are available to identify pathogens. Immunohistochemical staining on biopsy samples using specific monoclonal antibodies to viruses such as HSV and CMV helps confirm the diagnosis when the viral cytopathic effect is difficult to appreciate. We generally rely on histology for the diagnosis of viral GI infections and use brushings and viral culture selectively. A technique first described for gastric biopsies, whereby the forceps are tilted into the lesion and the tissue is avulsed, is especially useful for taking samples from esophageal lesions (Fig. 41.17). Lastly, as noted previously, communication with the pathologist is essential so that appropriate attention can be drawn to specific pathogens and so that special stains can be performed.

### INTRODUCTION

Using the gut to provide nutritional therapy by the enteral route plays a pivotal role in patient outcome in the critical care setting. Failure to use the gut for nutrition results in the gut becoming a proinflammatory organ, and results in increasing oxidative stress and higher risk of complications.<sup>1</sup> Early enteral access and utilization of the gut in contrast, promote or support the mass of gut-associated lymphoid tissue (GALT), as well as mucosal-associated lymphoid tissue (MALT) at distant sites like the liver, lungs, and kidney.<sup>2</sup> This process accounts for the "nonnutritional benefits" of nutritional therapy, contributing to an appropriate immune response, downregulation of inflammation, and a reduction in the rate of long-term complications. The sicker the patient, the greater the need to maintain gut integrity. Enteral nutrition support becomes a therapeutic tool or pharmacologic agent capable of changing outcome by reducing nosocomial infection, multiple organ failure, and hospital length of stay.<sup>3,4</sup> Recent literature confirms that aggressive enteral tube feeding decreases the rate of complications when compared to "standard therapy," which is defined as patients who are allowed to advance to either an oral diet on their own as tolerated or parenteral nutrition (PN).<sup>5,6</sup>

However, obtaining enteral access early in the course of a critically ill patient may be difficult. Patients in this setting are at the height of the hypermetabolic response, often requiring high doses of narcotic analgesia and sedation; thus, they are prone to ileus, gastroparesis, and high gastric residual volumes. Transporting these patients to the radiology suite for placement of feeding tubes is difficult, as they are unstable. Such transport leads to delays in getting tubes placed and has been shown to increase the risk of complications (such as aspiration, hemody-

namic instability, and new cardiac dysrhythmias).<sup>7,8</sup> Bedside techniques to place feeding tubes are essentially blinded, which carries some additive risk. Although bedside techniques may be sufficient in a large number of patients in the critical care setting, the success rate for bedside placement decreases as disease severity increases, and there is greater need to place the tube lower in the gastrointestinal (GI) tract.

In long-term acute care and in the chronic management of patients recovering from stroke and neurologic injury, percutaneous endoscopic techniques provide a more reliable semi-permanent enteral access, affording a number of options in a variety of patients. Insertion of a feeding tube distal to the stomach and into the small bowel has been shown to reduce the incidence of regurgitation and aspiration.<sup>9,10</sup> In a 2016 meta-analysis performed in preparation for societal guidelines, small bowel feeding was shown to significantly reduce the incidence of aspiration pneumonia when compared with gastric feeding.<sup>11</sup> In patients with severe gastroparesis, percutaneous endoscopic techniques may provide a gastrostomy tube for decompression and a direct jejunostomy tube for continued enteral feeding. In patients with recurrent flares of chronic pancreatitis, placement of an endoscopic jejunostomy tube may provide therapeutic options which preserve nutritional status, decrease dependence on narcotic analgesia, and reduce the number of hospitalizations per year. In patients with dysphagia resulting from neurologic injury, these percutaneous endoscopic feeding tubes are easily removable should the patient recover function and resume adequate voluntary oral intake.

The role of the endoscopist in these settings is critical. One must have the skills to place the tube at the appropriate level in the GI tract, and most techniques can be performed at the bedside in the intensive care unit (ICU) without transport to the radiology

**Abstract**

Nutrition support teams depend on the skills of an endoscopist to deliver enteral tube feeding, especially when certain medical or surgical conditions require deep jejunal access. The need for short-term feeding (less than four weeks in duration) can be met by placement of a nasoenteric tube, but if longer periods of feeding are anticipated, a percutaneous device should be utilized. Mastering the many techniques described for achieving enteral access allows the endoscopist to adjust to the varying clinical scenarios and anatomic variations that may be encountered in general practice. Techniques which involve untethered endoscopy or placement of the tube over a guidewire are preferred over those which require dragging the tube itself down through in the gastrointestinal tract with the endoscope. Attention should be paid to securing the tube post placement. As the nutritional therapy is delivered, patients should be monitored for tolerance of their feeding regimen and the enteral access site should be examined regularly to avoid complications. Careful vigilance allows the identification of early problems, affords the opportunity for quick solutions, and avoids the more serious complications requiring endoscopic or even surgical intervention.

suite. The endoscopist has the expertise in gut physiology, thereby allowing for adequate monitoring of enteral nutrition therapy and distinguishing tolerance of feeds from intolerance. Endoscopists have the capabilities to provide simple techniques by which to manage complications. In the absence of such expertise for enteral access, the use of PN increases significantly, a change in management strategy that may negatively impact patient outcome.

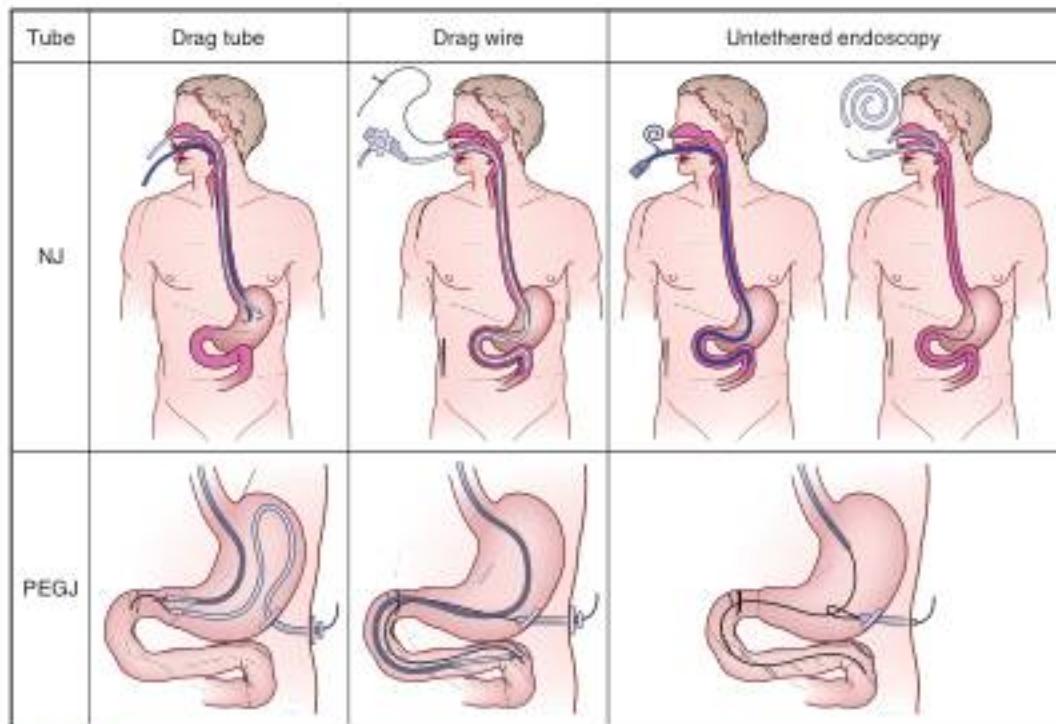

### HOW TO ESTABLISH AN ENDOSCOPY SERVICE FOR ENTERAL ACCESS

Several important steps should be taken to set up an effective endoscopic enteral "tube service." The nutrition literature is so strong regarding the beneficial effects of enteral feeding in the critical care setting that multidisciplinary nutrition teams are under significant pressure to get tubes in early and get feeds started quickly. The endoscopist should establish rapport with the multidisciplinary nutrition team and provide a timely response to consults for request for enteral access. This can be facilitated by flexibility with potential time slots in the endoscopy schedule to make room for add-on cases for enteral access. It is important to provide same-day service when a request for access is placed to deliver the best patient care. In general, it helps treat a request for enteral access for a patient in the ICU as one would respond to a request to evaluate a patient with GI bleeding.

The two most important endoscopes needed to outfit an endoscopic enteral tube service are a pediatric colonoscope and a small-caliber gastroscope with an insertion tube outer diameter

less than 6 mm. A pediatric colonoscope is usually the best choice for endoscopic nasoenteric tube (ENET), percutaneous endoscopic gastrojejunostomy (PEGJ), and direct percutaneous endoscopic jejunostomy (DPEJ) because of its length and relative stiffness. Although a push enteroscope is an adequate substitute for the pediatric colonoscope, the greater flexibility of the small bowel enteroscope promotes looping or curling in the stomach. The small-caliber gastroscope has the advantage that it can be passed via the transnasal route at the bedside with no sedation, making it an ideal choice in cases requiring ENET placement. The small-caliber endoscope can also be passed through a mature percutaneous endoscopic gastrostomy (PEG) tract ostomy for placement of a one-piece PEGJ. When a 28-Fr PEG is in place, this same endoscope may be passed through the PEG itself for purposes of conversion to a two-piece PEGJ. The endoscopist is encouraged to learn one technique well for each of the four procedures (ENET, PEG, PEGJ, and DPEJ), and then later experiment with many other techniques to find his or her personal favorite. When choosing an enteral access technique, priority should be placed on ones that allow "untethered" endoscopy to place a wire. Techniques which require dragging a wire down through the GI tract, or even worse, dragging the feeding tube itself, are less successful, more frustrating for the operator, and more likely to be displaced (Fig. 42.1).

Fluoroscopy is valuable early in the learning curve, but all these techniques may be performed easily at the bedside or in the endoscopy suite without fluoroscopy. The ability to come to the ICU and place these tubes endoscopically without fluoroscopy avoids the need to transport the patient out of the ICU, increases

**FIG 42.1** Prioritizing techniques for enteral access. Dragging a tube into place increases the chance for proximal displacement when the scope is withdrawn. Dragging a wire is better, but torsion on the wire still impedes endoscopy. "Untethered" endoscopy techniques allow placement of a wire and then delivery of the tube over that wire directly into the small bowel without the need to drag either into place using the endoscope. *NJ*, nasojejunal; *PEGJ*, percutaneous endoscopic gastrojejunostomy.

flexibility in scheduling, and avoids the cost and exposure to radiation involved with fluoroscopy. Having appropriate ancillary devices such as wires, biopsy forceps, and snares that are long enough (such that they can be passed out through the colonoscope and still have a workable length beyond the tip of the scope) and having key accessories such as a hemoclip (to secure the distal tube tip to the intestinal mucosa) or bandage clips (to secure the proximal end of the tube to the skin), all improve the efficiency and success rate for these procedures. It is important to maximize lubrication when working with feeding tubes, both by activating the hydrophilic lubricant on the inner surface of the tube by water infusion, and by applying a vegetable spray or surgical lubricant to the outer surface.

## ENDOSCOPIC NASOENTERIC TUBES

Endoscopic nasoenteric tubes (ENET) placement is most commonly required in the critical care setting. Severity of critical illness, complications of sepsis and multiple organ failure, and therapeutic strategies such as placement on mechanical ventilation are all factors indicating the need for early enteral access. Establishing enteral access and initiating enteral feeds is considered part of the basic resuscitation of these patients. ENET placement deep into the jejunum is specifically reserved for those critically ill patients who demonstrate intolerance to initial nasogastric feeding (due to poor gastric emptying, ileus, regurgitation, or aspiration) and those who are at high risk for aspiration. Several techniques have been described for ENET placement.

### Over-the-Guidewire Technique

The over-the-guidewire technique may be more difficult technically than other ENET procedures because of the oronasal transfer and wire exchanges (removing the endoscope from the wire and placing the feeding tube over the wire) (Fig. 42.2). However, this technique is the one ENET procedure that most reliably places the feeding tube at or below the ligament of Treitz. Before performing an endoscopy, the oronasal transfer tube is placed through one nostril, brought out of the mouth, and then clamped to the side using a hemostat. The pediatric colonoscope is passed through the mouth, down the esophagus and stomach, and into the small bowel. As the endoscopist traverses the duodenum, it is important to pay attention to landmarks of the duodenal bulb, and the C-loop. The long, straight segment immediately after the duodenal C-loop is the distal duodenum leading up to the ligament of Treitz. The ligament of Treitz is the first turn after this long segment. Paying attention to these landmarks helps assure the endoscopist as to the location of the tip of the endoscope within the GI tract. Passing the endoscope one to two loops below the ligament of Treitz helps anchor the tip of the wire during subsequent wire exchanges (see Fig. 42.2A). Once the endoscope has been passed as deep as possible, the wire is extended out from the end of the endoscope until it meets gentle resistance.

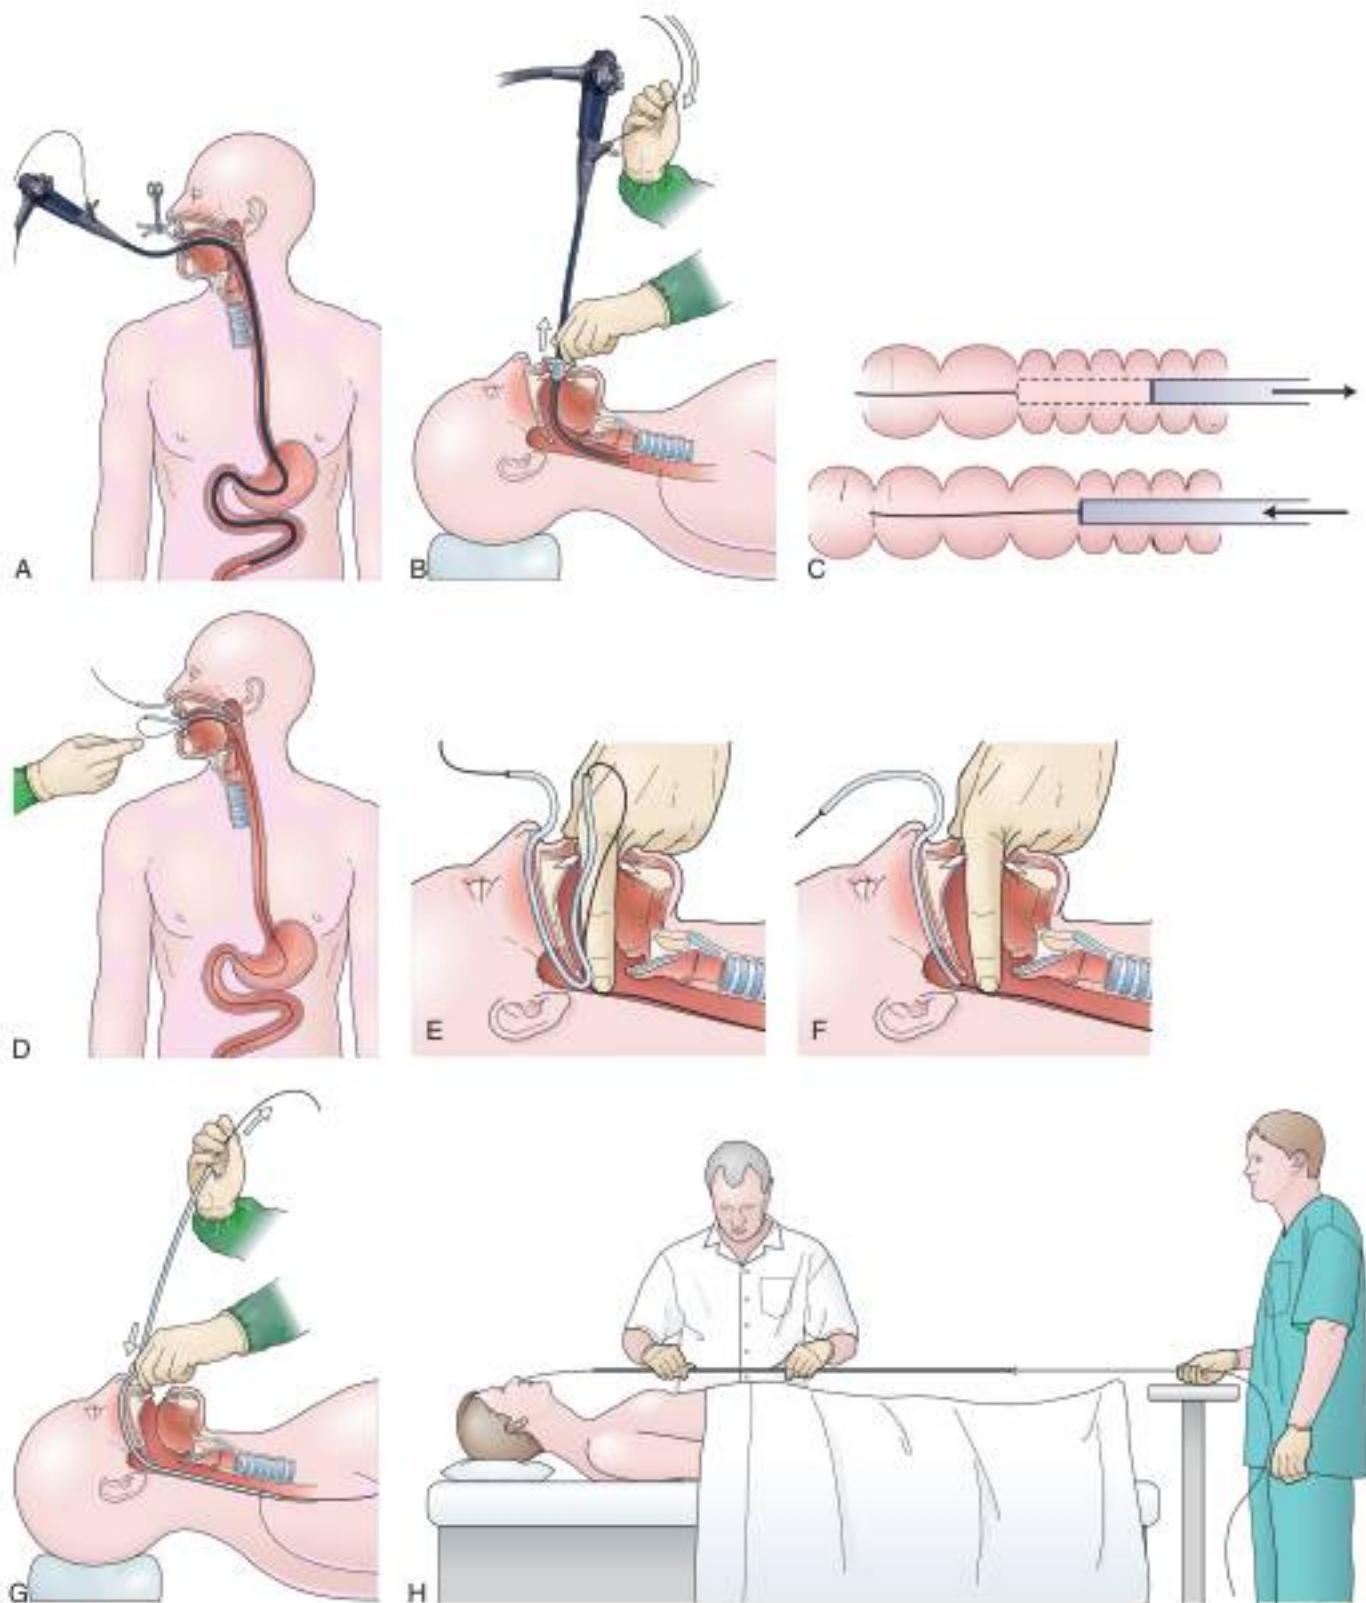

The first wire exchange involves removing the endoscope off the wire without displacing the tip. The key point to this aspect of the procedure is that the endoscopist places one hand on the endoscope as he or she removes it from the mouth and the other hand on the wire as it is passing into the operating channel of the endoscope at the other end (see Fig. 42.2B). An assistant may support the weight of the scope, keeping it from bowing in the middle during the wire exchange. As the endoscopist pushes the wire out the end of the tube with one hand, and withdraws

the scope with the other, a "keyhole technique" should be used. To keep the folds of the small bowel from passing off the end of the endoscope too quickly, a rolling motion should be used where the scope is withdrawn 5 cm and then pushed back in 2 to 3 cm (the same technique used to keyhole the pylorus in order to visualize the duodenal bulb as the scope is withdrawn from the small bowel on esophagogastroduodenoscopy). As a result, the bowel will come off the end of the scope in measured fashion 1–2 folds at a time (see Fig. 42.2C). The point at which the colonoscope has been withdrawn off the wire, the tip of the wire is protruding from the patient's mouth. The oronasal transfer of the wire, if done incorrectly, will cause a loop to form in the mouth and/or displacement of the tip of the wire from the small bowel back into the stomach. The tip of the wire is placed through the oronasal transfer tube, passing the excess wire out of the end of the transfer tube protruding from the nose (see Fig. 42.2D). Before the final loop protruding from the mouth is withdrawn or eliminated, the index finger is passed through the mouth, pinning the wire against the posterior wall of the oropharynx (see Fig. 42.2F). While firmly holding the wire against the posterior pharyngeal wall, traction is placed on the end of the wire protruding from the nose, completely eliminating the loop protruding through the mouth (see Fig. 42.2E). With the wire now protruding from the nose, the second and final wire exchange is made. This latter wire exchange may be accomplished using one of two different techniques. One technique involves carefully passing the feeding tube over the wire in a manner similar to the first wire exchange (see Fig. 42.2G). Again, the endoscopist is careful to place one hand at the nose as he or she inserts the tube, with the other hand at the opposite end of the feeding tube where the wire is being withdrawn. The rate of the tube passing down into the nose should match exactly centimeter for centimeter the rate of the wire being withdrawn at the other end, to avoid deflecting the tip of the wire (see Fig. 42.2G). An alternative technique for this second wire exchange involves pinning the end of the wire to a bed rail or bedside table establishing a "point in space" (see Fig. 42.2H). Assistants help keep the wire straight and level while the endoscopist slides the feeding tube over the fixed wire into final position.

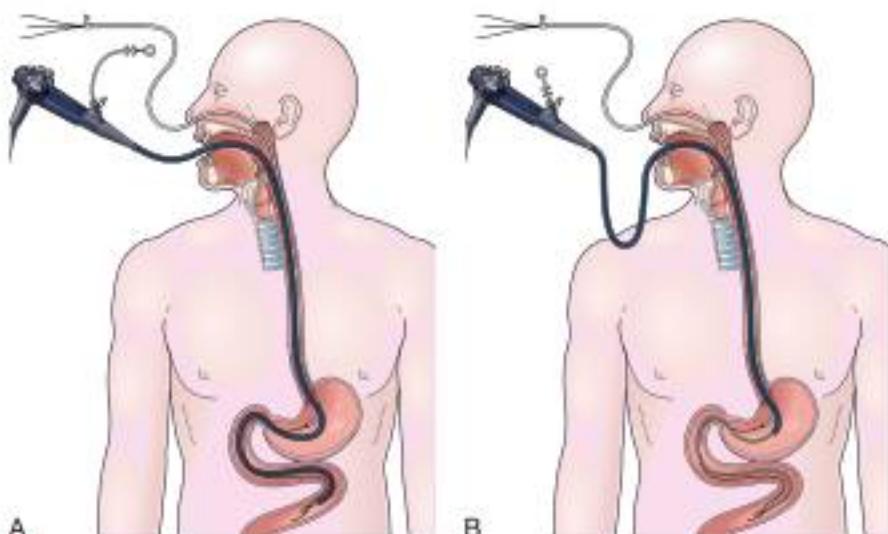

### Drag and Pull Technique

This technique is facilitated by placing one or two extra guidewires (for a total of 2 or 3) through the nasoenteric tube prior to placement. Two to three centimeters of the soft tip of one wire should protrude out through the distal end of the tube. This assembly is then passed down through the nose into the stomach, followed by passage of the endoscope alongside the tube, down through the mouth, and into the stomach. Once in the stomach, a long biopsy forceps is used to grab the soft tip of the wire protruding from the feeding tube. The endoscope holding the wire is then passed into the small bowel, hopefully down to or beyond the ligament of Treitz (Fig. 42.3A).

From the point of deepest insertion, the endoscope is then slowly withdrawn back toward the stomach as the biopsy forceps holding the wire is advanced, holding the tip of the wire in place in the small bowel. Once the endoscope is positioned back into the stomach, the feeding tube is advanced over the wire down to its tip, which is still being held by the biopsy forceps (see Fig. 42.3B). Only at this point are the biopsy forceps opened and the wire is released. The biopsy forceps are then withdrawn back into the endoscope and the endoscope is slowly withdrawn back out through the esophagus and mouth. The keys to success for

**FIG 42.2** Over-the-guidewire endoscopic nasoenteric tube (ENET) technique. **A**, The pediatric colonoscope is passed down below the ligament of Treitz and the wire extended out beyond the end of the scope. **B**, In the initial wire transfer, the scope is withdrawn out from the mouth at the same rate the guidewire is passed down through the operating channel, to prevent displacement of the wire tip from its position in the small bowel. **C**, The keyhole technique is used for withdrawing the endoscope off the guidewire. With the bowel pleated on the end of the endoscope, the endoscope is withdrawn 5–6 cm. By quickly pushing the endoscope back in 2–3 cm, the bowel comes off the end of the endoscope 1–2 folds at a time. **D**, With the wire protruding out through the oronasal transfer tube. **E** and **F**, The index finger is then used to pin the wire against the posterior pharyngeal wall while traction is placed on the wire protruding out through the nose, pulling on the wire until the wire is straight and tension is felt against the finger in the posterior pharynx. **G**, In one technique for the final wire transfer, the feeding tube is passed over the wire down through the nares at the exact same rate that the wire is withdrawn out from the distal end of the feeding tube, again to avoid displacing the wire tip. **H**, In an alternative technique for the final wire transfer, an assistant pins the wire to a “point in space” (using a bedside table), and the tube is then slid over the fixed wire into final position.

**FIG 42.3** Drag and pull endoscopic nasoenteric tube (ENET) technique. **A**, The feeding tube is stiffened with three guidewires and then passed into the stomach, where one of the three guidewires is passed out beyond the end of the feeding tube. This one wire is grabbed with biopsy forceps and the pediatric colonoscope drags the wire down below the ligament of Treitz. **B**, As the endoscope is withdrawn back into the stomach, the biopsy forceps are pushed out to hold the wire in position below the ligament of Treitz. With the endoscope still positioned in the stomach, the feeding tube is advanced over the wire until it meets the biopsy forceps at the distal end. The endoscope is then withdrawn out through the mouth before all the guidewires are removed.

this procedure are a pair of biopsy forceps that are long enough ( $\geq 240$  cm), and the stiffening of the feeding tube with extra guidewires (which facilitates removal of the endoscope without displacing the tube back into the stomach) (see Fig. 42.3B).

### Transnasal Technique

Availability of a small-caliber gastroscopy affords the endoscopist the opportunity for a simple technique for ENET placement. The key to success with this technique is the placement of a biopsy forceps or a Savary guidewire down through the operating channel, which serves to stiffen the instrument and increase the ease with which it may be passed through the bowel. Transnasal passage of the endoscope is tolerated well by the patient and sedation is not usually required. After intubating the esophagus and stomach, the endoscope is passed as far as possible, usually to the third or fourth portion of the duodenum. At this point, the stiffening device is withdrawn and a guidewire is placed down through the operating channel out as far as possible until meeting gentle resistance (Fig. 42.4). Using the wire exchange system described in the over-the-guidewire technique, the small-caliber gastroscopy is then withdrawn off the wire. Obviously, no oropharyngeal transfer of the wire is required, and the feeding tube may be immediately passed directly over the wire. Wire exchanges are somewhat more tenuous and difficult with this procedure because the wire is usually not passed as deep into the small bowel as in the over-the-guidewire technique described earlier, and the tip may be displaced more easily back into the stomach.

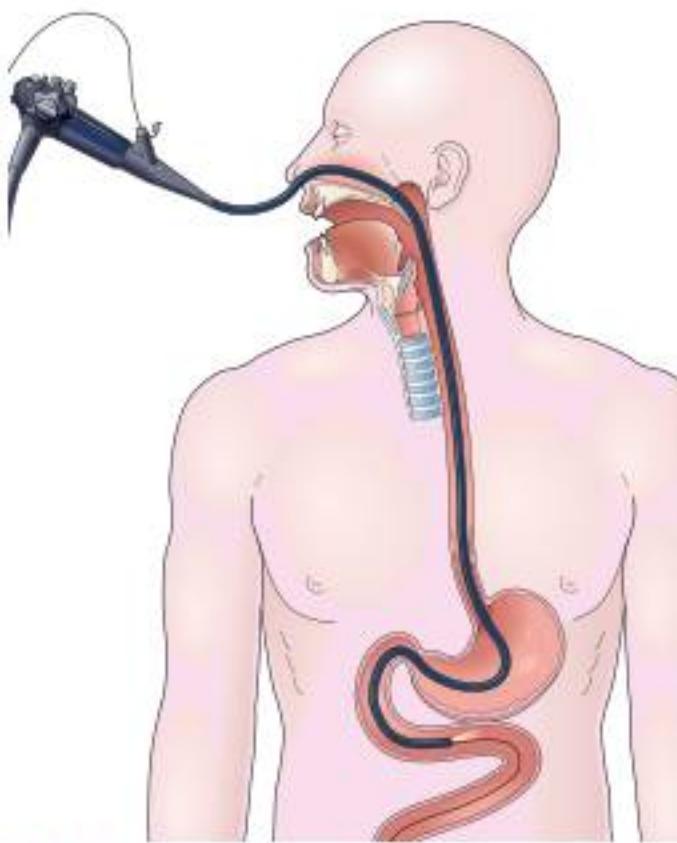

### Alternate Options

In a simpler version of the previously mentioned drag and pull technique, a knotted suture line is attached to the distal end of

the feeding tube, and then the tube is passed through the nares down into the stomach. The endoscopist passes the endoscope alongside the tube through the mouth, down into the stomach, grabbing the knotted suture with biopsy forceps (Fig. 42.5A). It can be surprisingly difficult and frustrating to drag the tip of the feeding tube through the pylorus and down into the duodenum. The success of this sometimes awkward procedure is improved by using a knotted suture line instead of a loop or single strand on the tip of the tube (see Fig. 42.5B), by adding a second guidewire to stiffen the tube to prevent displacement upon withdrawal of the endoscope, and by keeping the biopsy forceps 1 to 2 cm away from the tip of the endoscope to enhance visualization (see Fig. 42.5A).

Another alternate technique utilizes adding one or two extra guidewires (for a total of two or three) to the feeding tube to increase stiffness, and then passing the tube through the nares down into the esophagus and stomach. The endoscope is passed through the mouth alongside the tube down into the stomach, and the tip of the stiffened tube is simply pushed or nudged using open biopsy forceps through the pylorus into the duodenal bulb (see Fig. 42.5C). Continuing to watch endoscopically from the stomach, the endoscopist pushes the stiffened feeding tube from the outside proximal end in an effort to pass the distal tip around the C-loop and into the third and fourth portion of the duodenum (see Fig. 42.5C).

The most reliable of the three alternate methods uses an 8-Fr nasoenteric tube, which is passed through the operating channel of the endoscope after it has been passed through the esophagus and stomach into the small bowel. This procedure's success is enhanced by using a large channel therapeutic endoscope and a small-bore (8-Fr) nasoenteric tube which has a removable proximal feeding cap. Because the endoscope is passed through

**FIG. 42.4** Transnasal endoscopic nasoenteric tube (ENET) technique. After first placing biopsy forceps down through the operating channel to stiffen the endoscope, a small-caliber (< 6-mm diameter) gastroscope is passed through the nares down into the stomach and beyond the pylorus. A guidewire is passed through the operating channel out beyond the end of the endoscope, and then the endoscope is subsequently withdrawn. The final feeding tube is passed over the wire.

the mouth, it does require placement of an oronasal transfer tube and the subsequent transfer of the tube from the mouth out through the nose (see Fig. 42.5D), using the method described in the over-the-guidewire technique.

#### Securing Tube With Nasal Bridle

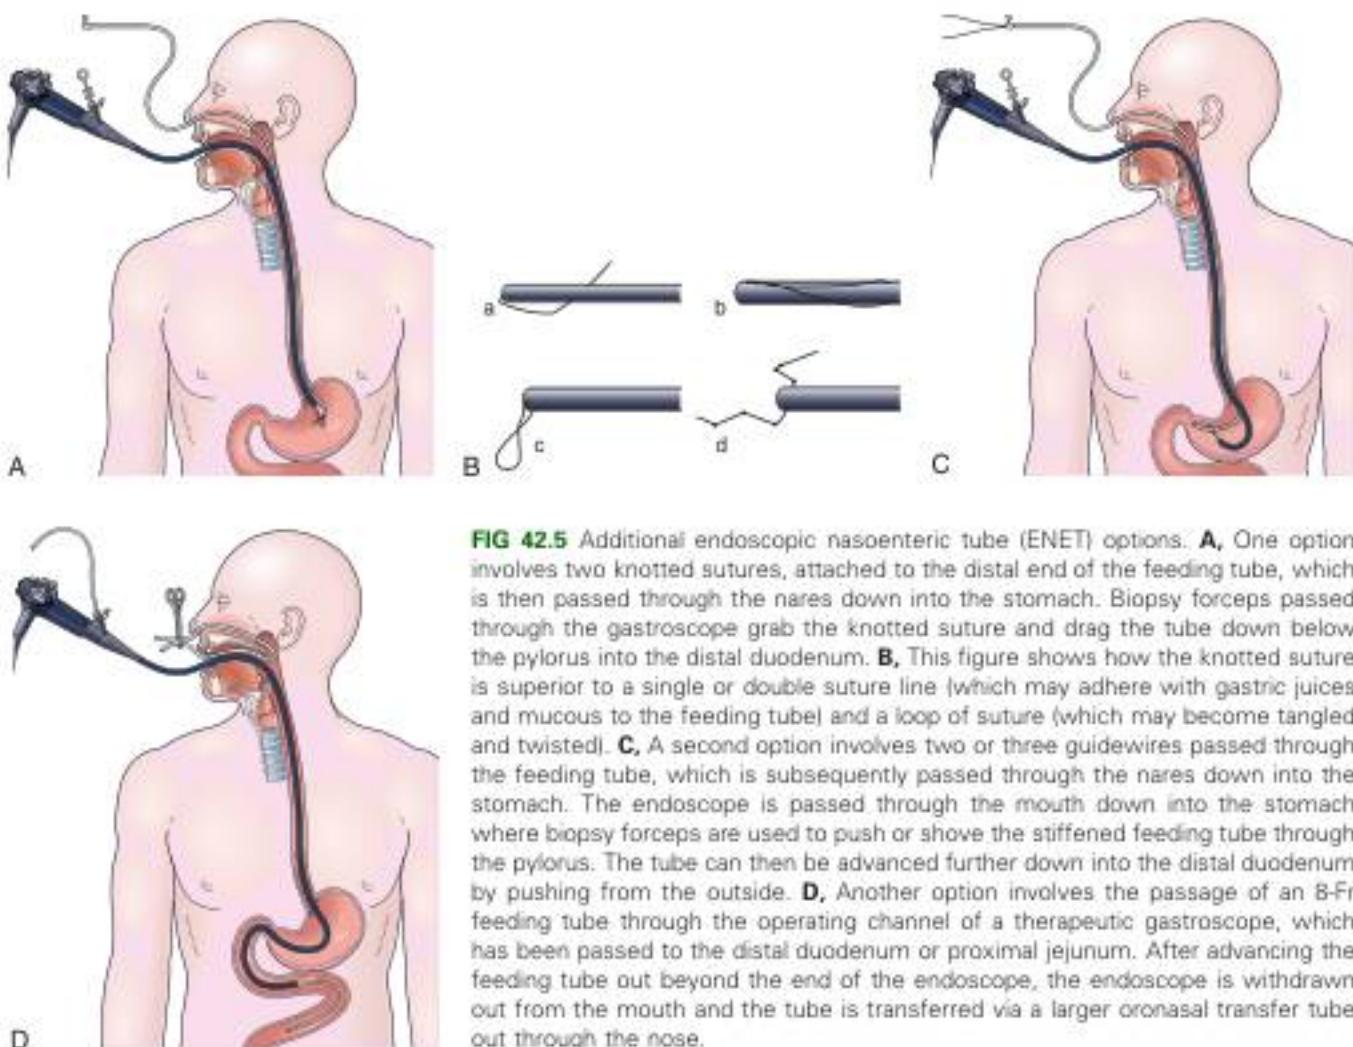

For any case in which the time and expense of endoscopic placement of a nasoenteric tube is required, consideration should be given to securing the tube with a nasal bridle. Although this technique may seem barbaric and somewhat punitive to the patient, selection of the proper tube for the nasal bridle results in a degree of discomfort that is no different than the presence of the nasoenteric tube alone. The timing of the nasal bridle placement is important, and should be done initially before endoscopy is performed (before the patient is agitated from the passage of the endoscope). Two separate but similar techniques may be used to establish a nasal bridle. In one technique, two 5-Fr neonatal feeding tubes are used (Fig. 42.6A). The first tube is passed through one of the nares and brought out through the mouth, while the second is passed through the other nare and likewise brought out through the mouth. The two ends protruding from the mouth are then secured together by a single suture, or are simply tied together by hand using a square knot. Traction

is placed on one end protruding from the nares, pulling the nasal bridle into place (pulling the knotted juncture out through the nares such that one of the tubes passes into the nares around the nasal septum and out the other nare) (see Fig. 42.6A). An alternate technique uses a commercial device with two flexible rubber sticks, each with a magnet at one end (see Fig. 42.6B). A cloth ribbon is attached to the opposite end of one of the sticks. Each stick is passed through a separate nare, allowing the magnetic tips to click together in the posterior hypopharynx. Traction is applied to one of the sticks to pull the cloth ribbon into final position in one nare, around the nasal septum, and then out the other nare (see Fig. 42.6B). The oronasal transfer tube is then placed and the rest of the ENET procedure commences thereafter. At the completion of the ENET placement, the feeding tube is taped to the 5-Fr nasal bridle tube (beginning 1 cm below the nose and wrapping the tape downward over the feeding tube and bridle until the bridle is completely covered; see Fig. 42.6A), or clipped to the cloth ribbon (see Fig. 42.6B).

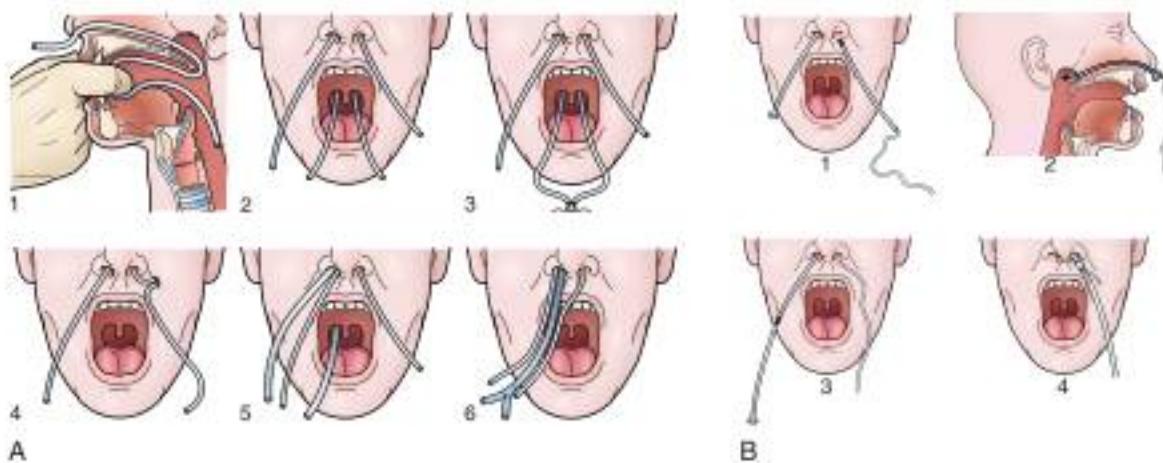

#### PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

Placement of a percutaneous endoscopic gastrostomy (PEG) tube provides a more reliable and semi-permanent enteral access compared to the ENET, and should be considered in any patient requiring specialized nutrition therapy for greater than 4 weeks' duration. Because an incision is made, those patients who are not already on antibiotics do need a single dose for antibiotic prophylaxis (a third-generation cephalosporin is appropriate) at the time of the initial procedure. Identifying landmarks with an indelible marker, such as the midline and the costal margins, provides good orientation during the procedure and avoids the possibility of lacerating the left lobe of the liver with placement too close to the costal margin. Antiplatelet or anticoagulant therapy is not a contraindication to these percutaneous techniques. Aspirin does not have to be stopped prior to the procedure. Patients on warfarin (Coumadin, Bristol-Myers Squibb Company, Princeton, NJ) may be switched to low molecular weight heparin (Lovenox, sanofi-aventis US LLC, Bridgewater, NJ) 1 week prior to the procedure (holding the dose on the morning of the procedure). If patients on clopidogrel (Plavix, Bristol-Myers Squibb) cannot be switched to aspirin alone 5 days before the procedure, the procedure may still be performed with caution (adding epinephrine to the anesthetic used for the initial skin incision to promote vasoconstriction, avoiding large superficial blood vessels in the skin or gastric mucosa, and setting the external bolster somewhat more firmly against the abdominal wall to achieve compression).

In the past, the traditional location for PEG placement has been in the left upper quadrant in the vortex formed by the midline and the left costal margin (Fig. 42.7A). Relocating the site of routine PEG placement down lower close to the umbilicus and even to the right of the midline should be considered for two good reasons. First, as shown on computerized tomography (CT) scan (see Fig. 42.7B), the area of greatest interface between the stomach and anterior wall that provides the shortest, most direct passage into the stomach, is located at this site. The traditional site in the left upper quadrant creates a tract that is longer and more tangential as it enters the stomach. However, even more importantly, this lower position on the abdomen places the PEG in the antrum, which facilitates conversion of the PEG to a PEGJ should the patient develop intolerance to gastric feeding later on. Site selection is further enhanced by

**FIG 42.5** Additional endoscopic nasoenteric tube (ENET) options. **A**, One option involves two knotted sutures, attached to the distal end of the feeding tube, which is then passed through the nares down into the stomach. Biopsy forceps passed through the gastroscope grab the knotted suture and drag the tube down below the pylorus into the distal duodenum. **B**, This figure shows how the knotted suture is superior to a single or double suture line (which may adhere with gastric juices and mucus to the feeding tube) and a loop of suture (which may become tangled and twisted). **C**, A second option involves two or three guidewires passed through the feeding tube, which is subsequently passed through the nares down into the stomach. The endoscope is passed through the mouth down into the stomach where biopsy forceps are used to push or shove the stiffened feeding tube through the pylorus. The tube can then be advanced further down into the distal duodenum by pushing from the outside. **D**, Another option involves the passage of an 8-Fr feeding tube through the operating channel of a therapeutic gastroscope, which has been passed to the distal duodenum or proximal jejunum. After advancing the feeding tube out beyond the end of the endoscope, the endoscope is withdrawn out from the mouth and the tube is transferred via a larger oronasal transfer tube out through the nose.

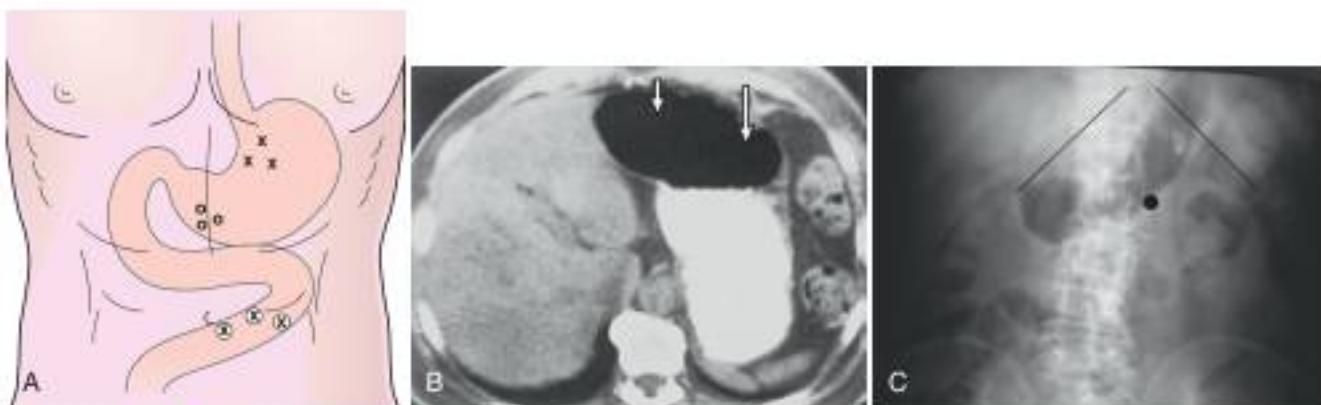

**FIG 42.6** Bridle technique for securing endoscopic nasoenteric tube (ENET) **A**, using two 5-Fr neonatal feeding tubes or **B**, a commercial device using two flexible sticks with magnetic ends. The numbers identify the sequential steps in each procedure.

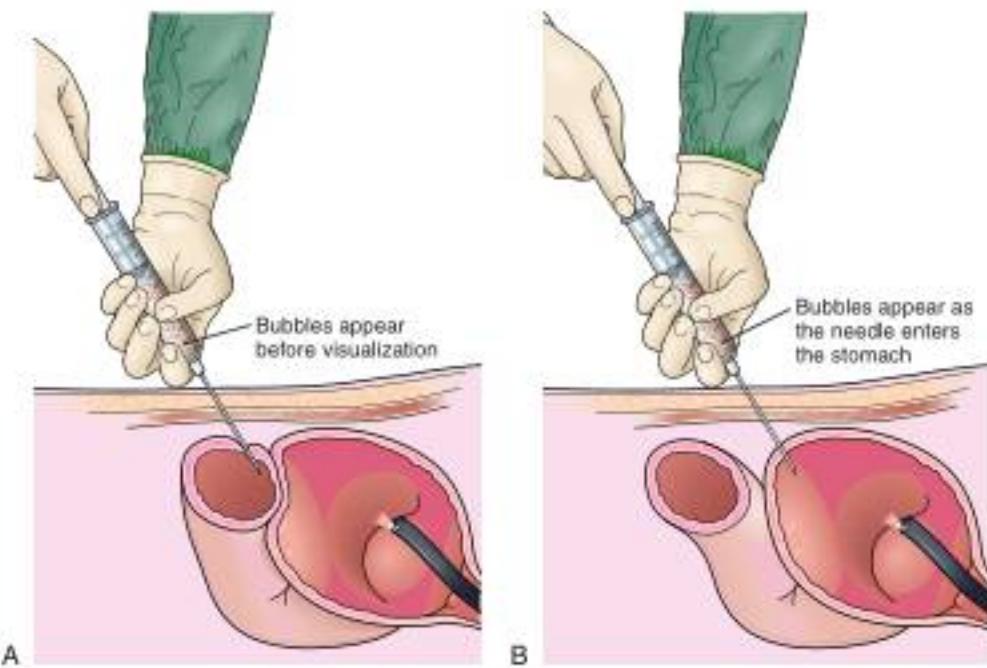

instilling 500 mL of air through the nasogastric tube into the stomach and obtaining an abdominal film in the hour prior to PEG placement. Putting a coin in the umbilicus serves as an obvious landmark on the abdominal film, the position of which can be compared to the costal margins. The position of the air

bubble with respect to the coin and the costal margins help select the specific PEG site. (see Fig. 42.7C).

Palpating the stomach and obtaining transillumination through the abdominal wall is a valuable reassurance for proper PEG site selection. If there is any question (especially in cases of obesity),

**FIG 42.7** Steps to localize percutaneous endoscopic gastrostomy (PEG), percutaneous endoscopic gastrojejunostomy (PEGJ), and direct percutaneous endoscopic jejunostomy (DPEJ) sites. **A**, The traditional PEG site is marked by the *x* in the left upper quadrant. Better placement is above the umbilicus, close to the midline, or slightly to the patient's right of midline position (circles). The PEG is in the gastric antrum, which is ideal should the patient require conversion later to a PEGJ. *X* with circles show the tremendous variability in the site for DPEJ placement, which can occur anywhere from the left costal margin down to the left iliac crest. **B**, Computerized tomography (CT) scan shows that the PEG site slightly above or to the patient's right of the umbilicus coincides with the area with the most direct, perpendicular, and shortest tract into the gastric antrum (*short arrow*). Traditional sites in the left upper quadrant have a longer, more tangential tract into the midbody or even lower fundus (*long arrow*). **C**, Placing a coin in the umbilicus (dark circle) and injecting 600 mL of air through a nasogastric tube before PEG placement helps identify the gastric antrum, easing selection of the PEG site.

**FIG 42.8** The safe tract technique for percutaneous endoscopic gastrostomy (PEG) placement helps **A**, avoid inadvertent tracking through an adjacent loop of bowel before **B**, passage into the stomach.

a safe tract technique may be utilized to assure that no intervening loop of bowel exists between the stomach and the anterior abdominal wall (Fig. 42.8). Using a 22-gauge spinal needle and a syringe with 1 to 2 mL of saline, the needle is passed through the abdominal wall at the proposed PEG site. If bubbles appear in the saline just as the needle passes into the lumen of the

stomach (as seen by endoscopy), there is some reassurance that the tract is appropriate. If bubbles appear before the needle passes into the stomach, there may be an intervening loop of bowel present (see Fig. 42.8). The length of the skin incision should be adequate just to accommodate the diameter of the feeding tube.

### Ponsky Pull and Sachs-Vine Push Technique

For PEG placement, the Ponsky pull and Sachs-Vine push techniques are virtually indistinguishable, provide no real advantage over the other, and may be selected based on personal preference of the operator. Once the PEG site is selected, the skin is anesthetized, a small incision is made, and the initial trocar is passed into the stomach. In the Sachs-Vine push technique, a single-stranded wire is passed through the trocar in the stomach and secured by a snare passed through the endoscope. With the Ponsky pull technique, a blue double-stranded wire loop is passed through the trocar and grabbed by the snare (Fig. 42.9A).

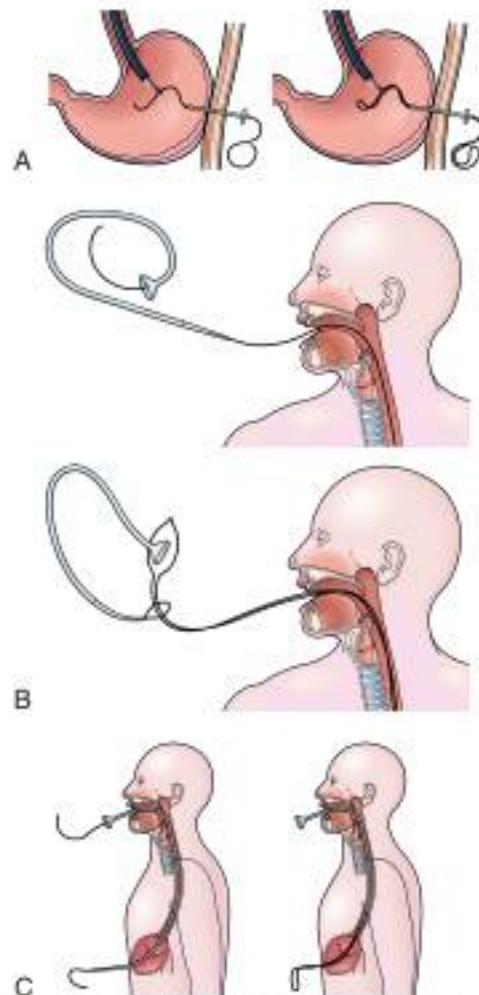

The wire passed by either technique is then brought out through the mouth. In the Sachs-Vine push technique, a long 2- to 3-foot plastic pointed leader is fused to the proximal end of the feeding tube, facilitating passage over the single-stranded guidewire. This assembly is pushed down the wire, through the esophagus, and out through the gastric and abdominal wall (see Fig. 42.9B). In contrast, the Ponsky pull technique involves a loop on the end of the feeding tube which is affixed to the double-stranded blue loop of wire protruding from the patient's mouth. Attaching the two wire loops is made easier by remembering the phrase "blue through," which describes the blue double-stranded wire being passed first through the silver loop on the end of the feeding tube (see Fig. 42.9B). Once the knot between the wire loops is secured, the feeding tube is then pulled down through the esophagus into the stomach and out through the abdominal wall into the final position (see Fig. 42.9C).

As a general rule when setting the external bumper, a close fit causes fewer subsequent complications than a tight fit, which can later lead to pressure necrosis and buried bumper syndrome. A quick and easy procedure to facilitate setting adequate tension between the bumpers involves following the PEG tube down through the esophagus by snaring the endoscope to the internal bolster (Fig. 42.10A). As shown in the top of Fig. 42.10A, snaring one-third of the internal bolster makes it easy to release the bolster once the endoscope is led down into the stomach. As the tube is pushed or pulled down through the esophagus and stomach, the endoscope is brought down easily with it into position into the stomach. Once the snare is released, the external bolster may be set with the internal bolster under direct endoscopic visualization (see Fig. 42.10B). Drawing a figure and marking the exact number on the tube for the position of the external bumper is a valuable aid for nursing care and may be placed on the chart for reference at any time (see Fig. 42.10B).

### Russell Introducer Technique

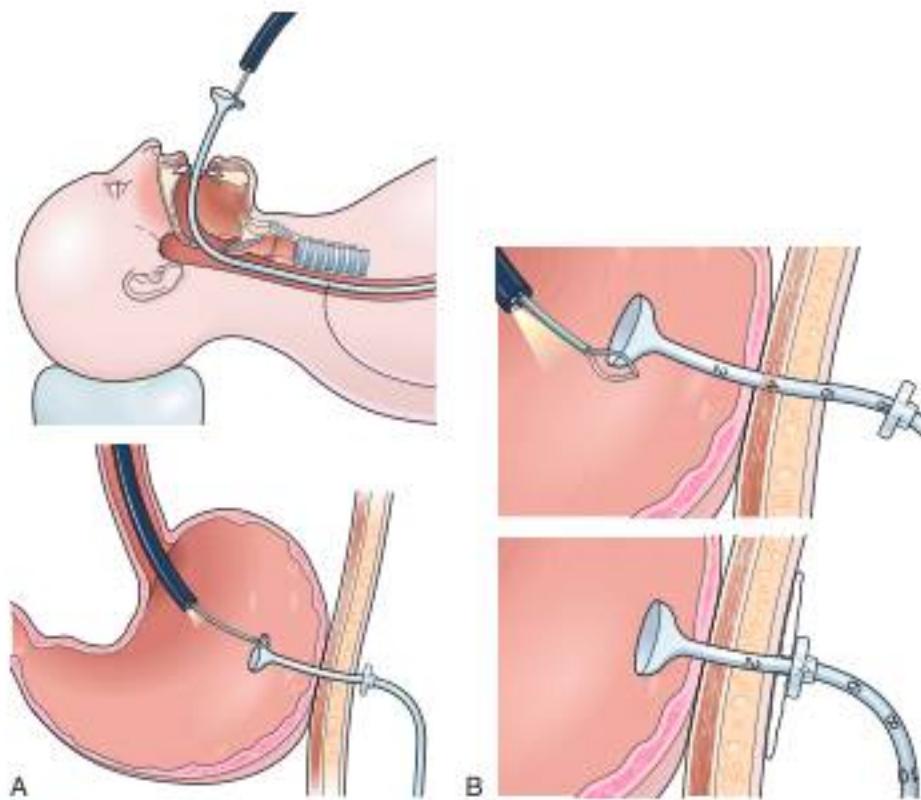

In patients with a large exophytic oropharyngeal or esophageal carcinoma, the Russell introducer technique should be considered to reduce the likelihood for tumor implantation of the PEG site. This is a technique commonly used by radiologists, but is easily performed by the endoscopist. Localization of the PEG site, position of the endoscope, and passage of the initial trocar are identical to the previous two techniques. With the trocar in place, a single-stranded guidewire is passed into the stomach and then held firmly by a snare protruding from the endoscope (Fig. 42.11A). Continuing to hold the wire throughout the procedure maintains a "safety line" of access to the gastric lumen.

The stomach has to first be secured to the anterior wall by T-fasteners (see Fig. 42.11A). Although a variety of commercial models of these fasteners exist, the design for deployment is

**FIG 42.9** Comparison of the Sachs-Vine push versus the Ponsky pull technique for percutaneous endoscopic gastrostomy (PEG) placement. **A**, In the Sachs-Vine technique, a single wire is passed through the trocar and grabbed with the snare, whereas a wire loop is passed through the trocar in the Ponsky pull technique. **B**, A long, 2-foot plastic leader attached directly to the feeding tube allows the entire ensemble to be passed or pushed over the wire in the Sachs-Vine push technique, whereas the blue wire loop can be attached to a wire loop on the end of the feeding tube in the Ponsky pull technique, allowing the tube to be pulled into position. **C**, In the Sachs-Vine technique, the tube attached to the plastic leader is pushed through the esophagus and out through the gastric wall, whereas in the Ponsky pull technique, the wire loop pulls the feeding tube down through the esophagus and out through the gastric wall.

similar. As shown in Fig. 42.11A, this particular technique involves a narrow-gauge introducer trocar in which the T-fastener is placed in a distal slot. A 22-gauge spinal needle is helpful as a sounding device to determine the appropriate tract for each T-fastener. After making a nick in the skin with a scalpel blade, the device is passed through the abdominal wall. The T-fastener is deployed in the stomach by a central canula. After removing the small trocar and canula for the T-fastener, a cotton roller ball and two metal fastening devices are cinched down until there is mild tension on the outer abdominal wall against the T-fastener on

**FIG 42.10** Following the percutaneous endoscopic gastrostomy (PEG) tube down into place and positioning the external bolster for appropriate tension. **A**, Just before the feeding tube is pushed or pulled down through the oropharynx and esophagus, a snare passed through the endoscope is snared to the internal bolster of the feeding tube, securing the endoscope to the tube. The endoscope is then pulled down through the oropharynx and esophagus as the PEG is brought down into position. **B**, Once in the stomach, the snare is released and the bumper is positioned gently up against the gastric wall. The external bumper is positioned with a single layer of gauze underneath. A final figure indicating the appropriate number on the feeding tube for position of the external bolster may be drawn and recorded on the patient's chart.

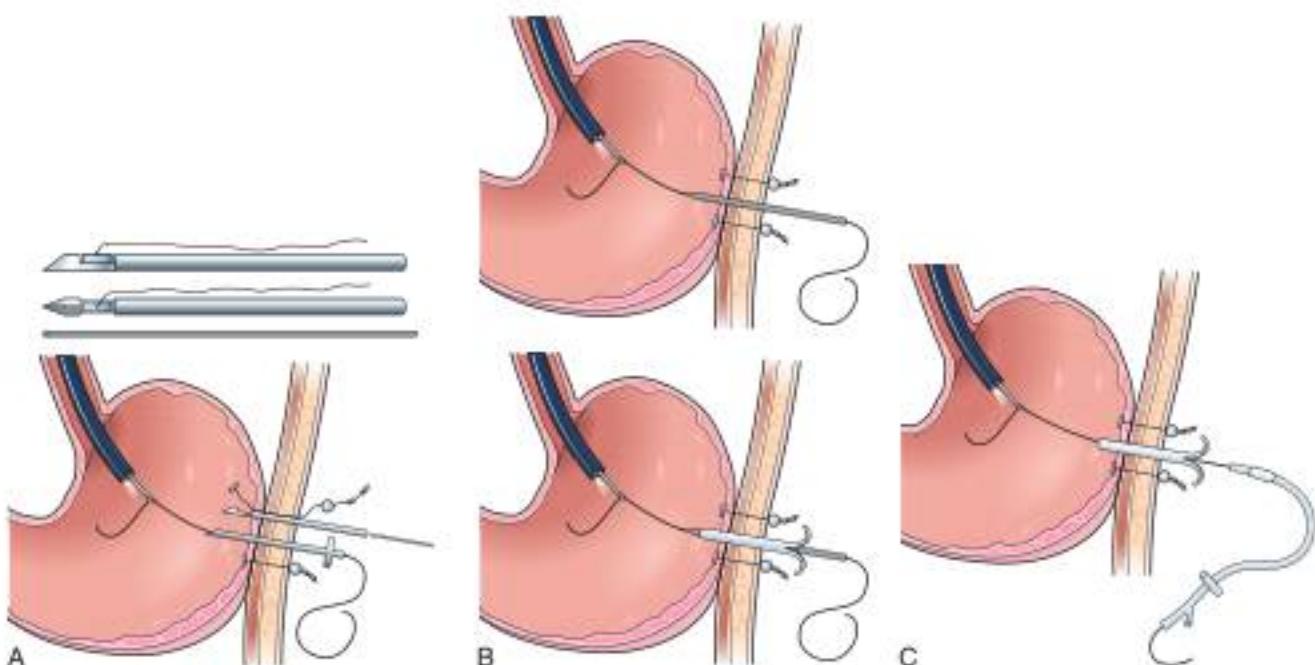

the inside of the stomach. Crimping the two metal fasteners holds the T-fastener in place. Anywhere from two to four T-fasteners should be placed circumferentially around the trocar before proceeding further (see Fig. 42.11A).

With the stomach affixed to the anterior wall by the T-fasteners, the tract over the wire is dilated by Seldinger-type dilators of increasing size. Three to five dilators are passed over the wire, with the snare holding the wire on the inside of the stomach (see Fig. 42.11B). Once the tract has been fully dilated, a peel-away sheet overlying a larger bore cannula is passed over the wire and into the stomach (see Fig. 42.11B, bottom).

Most of the Russell introducer kits do not come with an external bolster and are instead designed or anticipated to be sutured to the skin. A simple homemade external bolster may be created by a short segment from any small Salem sump, Foley catheter, or other larger gauge feeding tube, and placed over the feeding tube prior to passage into the stomach (see Fig. 42.11C). Once the external bolster is in place, the feeding tube may be placed over the wire through the peel-away sheet into the stomach. The internal balloon is then inflated, the peel-away sheet is removed, and the external bolster is then placed into position (see Fig. 42.11C).

## PERCUTANEOUS ENDOSCOPIC GASTROJEJUNOSTOMY

For patients with documented intolerance to gastric feeding with nausea, vomiting, high gastric residual volumes, or evidence of gastroparesis, the percutaneous endoscopic gastrojejunostomy (PEGJ) provides an easy, although somewhat less reliable, long-term access to the small bowel. The success of this procedure is related to a number of factors. Localization of the PEG in the antrum is most important. The PEG should be cut down to approximately 10 cm in length to afford a maximum length of the jejunal tube for passage into the small bowel. If the PEGJ is performed at the time of initial PEG placement, then antibiotic prophylaxis should be used. A site just to the right and above the umbilicus is the best site for placement into the antrum (see Fig. 42.7). A pediatric colonoscope is important to try to get one to two loops below the ligament of Treitz. Long biopsy forceps of greater than 350 cm in length are important to have a sufficient working length beyond the tip of the colonoscope (the accessory device must be twice the length of the scope plus 20 to 30 cm extra for a "working length"). The endoscopist should not use a snare to place wires in this procedure, as it can be

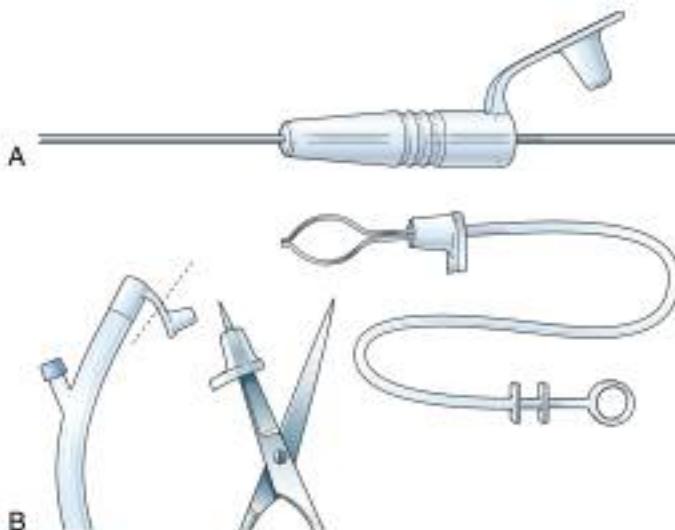

**FIG 42.11** The Russell introducer percutaneous endoscopic gastrostomy (PEG) technique. **A**, After initial placement of the trocar and passage of a single stranded wire, the wire is held with some tension against external traction by a snare passed through the endoscope within the stomach. T-fasteners are then passed to secure the stomach up against the anterior abdominal wall. The top of this figure shows how the T-fasteners (with attached suture) are released by the canula device. **B**, Once the stomach is secured to the anterior abdominal wall, the tract is dilated over the guidewire by three Seldinger dilators of increasing size. After the last dilation, a peel-away sheath over the final dilator is passed into position and the dilator is removed. **C**, After first preloading an external bumper on the feeding tube, the feeding tube is passed over the wire through the peel-away sheath into the stomach where the internal bolster is inflated, the peel-away sheath is removed, and the external bolster is positioned down against the skin.

difficult to extract the snare from the tip of the wire once it is positioned in the small bowel.

One of the most important elements in the success of this procedure is the function of an air retention valve (Fig. 42.12). Although a number of commercial models are available (see Fig. 42.12A), a homemade air valve can be made from the cap of the feeding tube (creating a hole with a pair of scissors) (see Fig. 42.12B). The air valve allows passage of a wire or a snare through the PEG into the stomach without losing air insufflation. Failure to use or create an air valve significantly prolongs the procedure and can make visualization very difficult when passing the endoscope from the stomach into the small bowel.

### Through-the-Snare Technique

This technique is the most reliable way to successfully place a PEGJ tube into the proximal jejunum at or below the ligament of Treitz. After cutting the PEG down to 10 cm, an air retention valve is fashioned and the snare is passed through the hole in the air valve positioned in the PEG into the stomach. The snare is opened, allowing the pediatric colonoscope to be passed down through the esophagus and stomach, through the snare, and on into the small bowel. Once the endoscope has been passed into the small bowel, the snare is closed once to make sure the endoscope has passed through the snare. The air valve may be backed out of the PEG at this point to decompress the stomach.

**FIG 42.12** Commercial and homemade air valves. **A**, The top figure shows a commercial air valve passed over the guidewire, which is used most often during percutaneous endoscopic gastrojejunostomy (PEGJ) conversions. **B**, A homemade air valve may be created by cutting off the valve plug on a feeding tube, coring the valve out with a pair of scissors, and then passing a snare or wire through the valve.

and prevent looping or curling of the endoscope. The endoscope is passed, hopefully, one to two loops beyond the ligament of Treitz. At its deepest penetration, a guidewire is passed out further into the jejunum until gentle resistance is met. The key to success of this technique is the selection of a very long 480-cm standard guidewire. The wire that comes with PEG and PEGJ kits is usually substantially shorter than this (Fig. 42.13A). Using proper wire exchange techniques, the endoscope is withdrawn back to the proximal stomach above the level of the snare, keeping the tip of the wire in position in the small bowel (see Fig. 42.13B). Once the endoscope has been brought back to approximately 45 cm (from the incisors), the air valve is placed back into the PEG to insufflate the stomach and confirm position of the endoscope above the snare (see Fig. 42.13B). The snare is then closed on the wire and a loop of the wire is pulled out through the PEG to the outside (see Fig. 42.13C). The endoscopist separates the loop with his fingers, and has an assistant pull on the proximal wire extending out from the proximal operating channel of the endoscope. The movement of one side of the loop helps identify that end of the wire coming from the endoscope (see Fig. 42.13C). This end of the wire is then pulled out through the PEG, resulting in a straightened single-strand guidewire passing through the PEG and down into the small bowel (see Fig. 42.13D). The jejunal tube is then passed over the wire (using good wire exchange technique) into position in the small bowel. Having an assistant provide a point in space above the abdomen secures or fixes the guidewire, facilitating passage of the jejunal tube into final position.

### Over-the-Guidewire Technique

Although this technique appears to be more simplified than the through-the-snare technique, it may be slightly more frustrating for getting proper placement of the jejunal tube well down into the small bowel. For this technique, an air retention valve is placed over a wire, and then the wire is passed through the PEG into the stomach. After passing the endoscope through the esophagus into the stomach, biopsy forceps are used to grasp the wire and walk it on down into the small bowel. The key to the success of this procedure is again using biopsy forceps that are greater than 350 cm in length, to afford a sufficient working length out beyond the end of the colonoscope. The colonoscope is hopefully passed down to a level at or below the ligament of Treitz (Fig. 42.14A). While still holding the wire in place at its distal tip, the biopsy forceps are slowly advanced as the endoscope is withdrawn back into the proximal stomach. The jejunal tube is then passed over the wire all the way down until it strikes the biopsy forceps still holding the tip of the wire in the small bowel (see Fig. 42.14B). Only at this point are the biopsy forceps opened, releasing the wire. The biopsy forceps are withdrawn back into the endoscope. It is important for the endoscopist to realize that if shorter biopsy forceps are used, the jejunal tube may strike the forceps holding the end of the wire while there is still a significant length of jejunal tube remaining outside the PEG. Although it is appropriate to open the biopsy forceps and release the wire at this point, the added length of the jejunal tube outside the PEG as the jejunal tube is pushed down and seated into position in the PEG often forms a loop in the stomach and the procedure has to be repeated.

### Trans-PEG Gastroscopy Technique

This technique may be performed with a small-caliber gastroscope, but is only feasible if the patient's original PEG is 28-Fr in

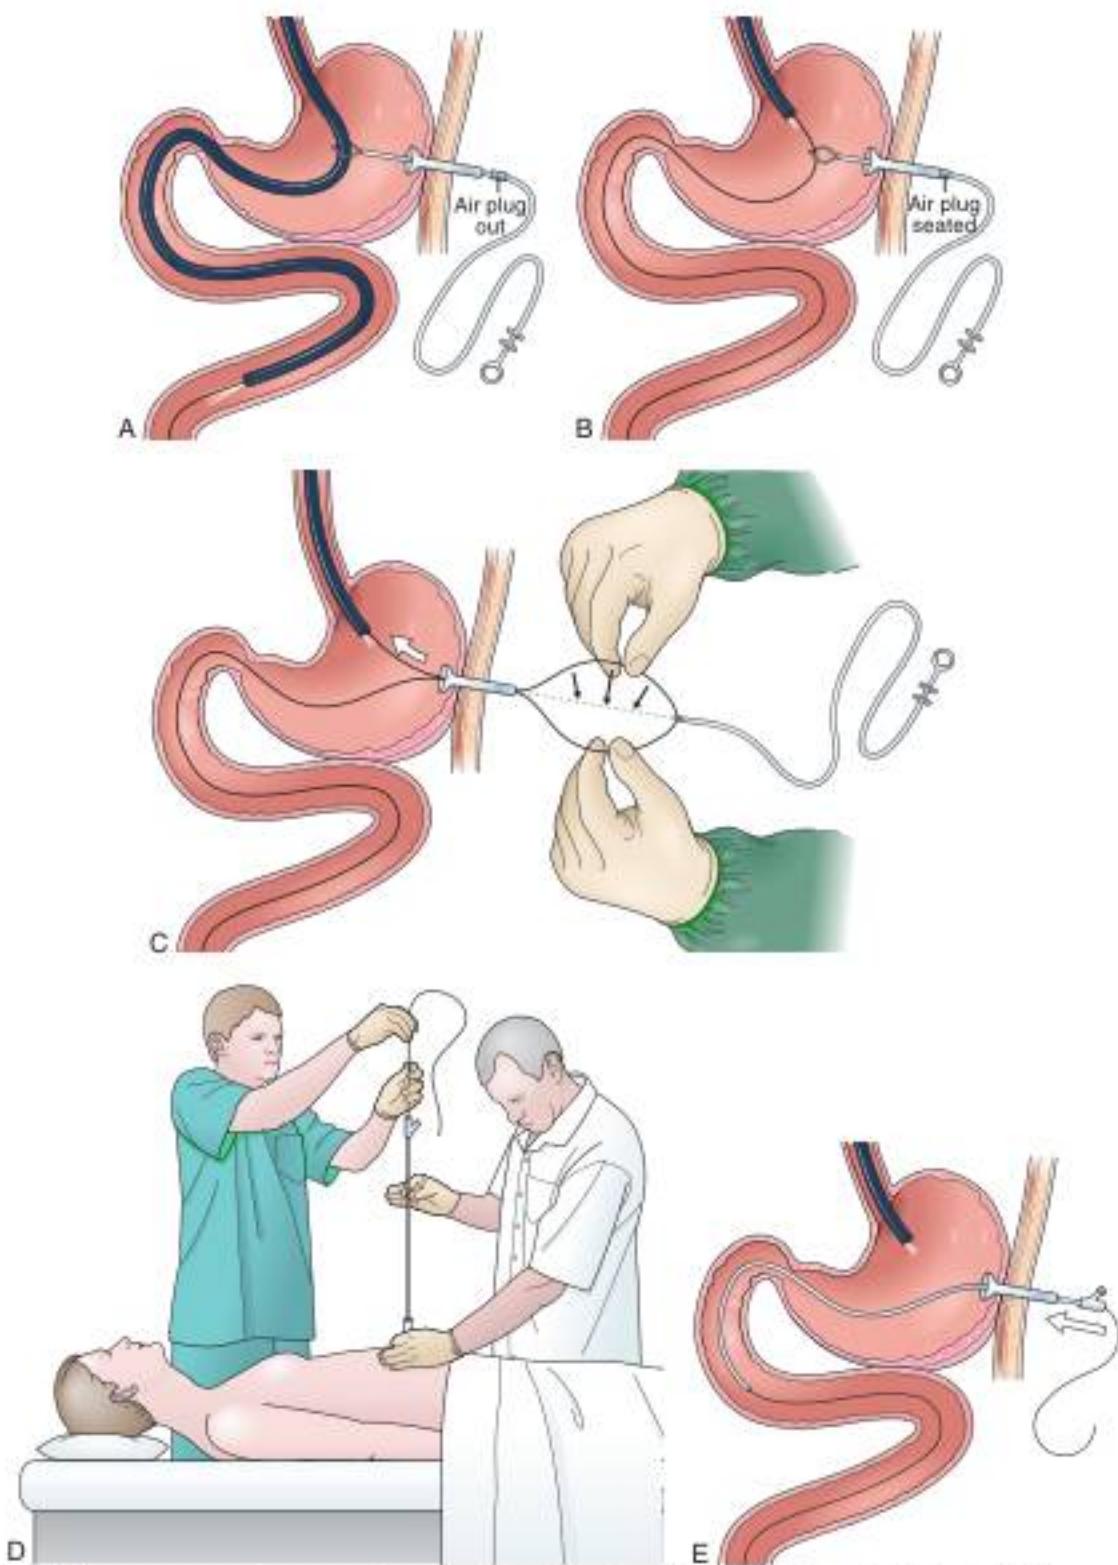

diameter. The technique can be performed through a PEG tube of smaller diameter, but a bronchoscope or ureteroscope may need to be substituted. The key to success with any of these small endoscopes is to stiffen the instrument by placing a biopsy forceps or a stiff guidewire down through the operating channel. Failure to do so will cause excessive looping or curling in the stomach and possible inability to transcend the pylorus. In this simple technique, the endoscope is passed through the PEG, down through the pylorus, and through the third and fourth portion of the duodenum. It is difficult to get beyond the ligament of Treitz with this endoscope alone, but passing the wire out through the end of the endoscope once it is positioned in the distal duodenum may allow passage of the wire into the proximal jejunum below the ligament of Treitz. The endoscope is then withdrawn and the jejunal tube is placed over the guidewire (Fig. 42.15).

If enough time has lapsed so a mature tract has already formed, a one-piece PEGJ can be placed through the existing PEG tract (Fig. 42.16). The original PEG should be removed in an atraumatic fashion. A small-caliber (< 6 mm) gastroscope is inserted through the PEG site and driven down below the ligament of Treitz. The soft-tipped end of the guidewire is fed through the scope and advanced as far as possible beyond the end of the endoscope, stopping when slight pressure is felt (see Fig. 42.16A). The scope is withdrawn, leaving the guidewire in place using the combination cm-by-cm and keyhole techniques described previously. The gastroscope is then reinserted through the nares or the mouth, passed down the esophagus, and positioned in the stomach to observe the position of the guidewire throughout the rest of the procedure. A one-piece PEGJ tube is fed over the wire, passing down into the small bowel while visualizing the wire and tube from the stomach to make sure a loop does not form in the process (see Fig. 42.16B). Once the tube has been passed far enough over the wire, the internal balloon bolster is inflated, the external bolster set, and the guidewire withdrawn. The key to success on this technique involves a long enough standard 0.035 wire (< 350 cm), thorough lubrication of the wire with silicone, and passage of the endoscope into the stomach the second time to watch out for looping of the wire or the tube.

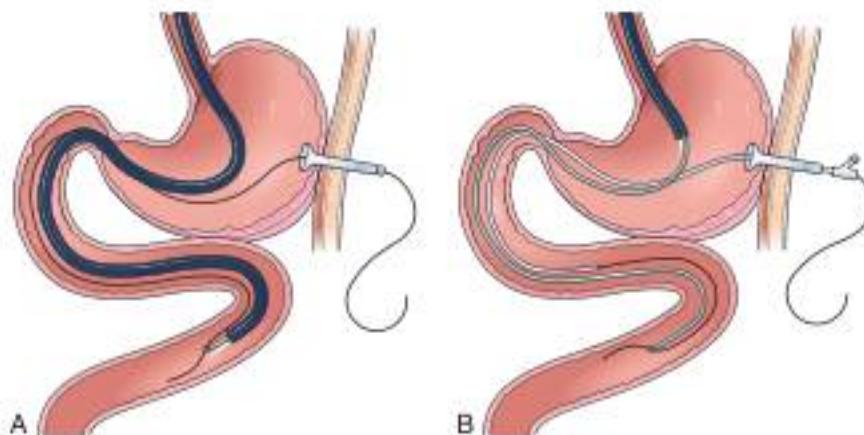

### Securing the PEGJ

The most frustrating aspect of the PEGJ procedure is that the jejunal tube frequently migrates back into the stomach. Two techniques may help prevent this. One is to use a rotatable endoscopic clip to clip a suture affixed to the distal end of the feeding tube to the intestinal mucosa. Although this is easy to perform, the clip may only hold the suture reliably in place for 7 to 10 days. A second technique is shown in Fig. 42.17, in which an anchor is created with a 1 cm segment from some other piece of tubing. A Salem sump, Foley catheter, or some other feeding tube may be used to create the 1-cm anchor. A 20-cm length of suture is affixed to the distal end of the feeding tube and then secured to the anchor. The anchor is placed over the guidewire ahead of the jejunal feeding tube in the final step of the PEGJ procedure, as the jejunal tube is passed over the wire into position in the small bowel (see Fig. 42.17).

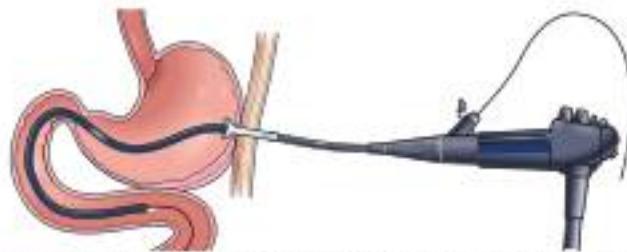

It is important, at the completion of the PEGJ procedure by any of these methods, that the operator confirms the proper position endoscopically. If the jejunal tube forms a loop up toward the gastroesophageal junction, the procedure may need to be repeated to achieve deeper positioning into the small bowel (Fig. 42.18). The natural action of this loop is to displace the tube

**FIG 42.13** Through-the-snare percutaneous endoscopic gastrojejunostomy (PEGJ) technique. **A**, After initial placement of the percutaneous endoscopic gastrostomy (PEG), the PEG tube is cut down short to approximately 10 cm, and then a snare placed through a homemade or commercial air valve is passed into the stomach. A pediatric colonoscope is passed into the stomach, through the snare, and then down into the small bowel below the ligament of Treitz (after which the wire is extended beyond the end of the scope). **B**, Using careful wire transfer technique, the endoscope is withdrawn back to the proximal stomach, keeping the tip of the wire in place below the ligament of Treitz. The air plug may be seated to allow visualization of the snare within the stomach. **C**, The snare is then closed on the wire, which is pulled out through the PEG. While the assistant holds the wire loop coming out from the PEG, the operator pulls on the wire extruding from the operating channel of the scope, to indicate which side of the wire loop represents the proximal end of the wire. That loop is then pulled out through the PEG. **D**, An assistant provides a "point in space" to secure or fix the guidewire as the operator passes the jejunal tube down through the PEG. **E**, The jejunal extension tube is passed down into final position, with the tip located well below the ligament of Treitz.

**FIG 42.14** Over-the-guidewire percutaneous endoscopic gastrojejunostomy (PEGJ) technique. **A**, A single stranded guidewire passed through a valve (which is seated in the percutaneous endoscopic gastrostomy [PEG]) is grasped by biopsy forceps (passed down through a pediatric colonoscope). The endoscope holding the wire (via biopsy forceps) is passed down into the small bowel below the ligament of Treitz. **B**, The endoscope is then withdrawn back into the stomach as the biopsy forceps are pushed outward through the end of the scope, holding the wire in place below the ligament of Treitz. Once the scope has been withdrawn back into the proximal stomach, the jejunal extension tube is passed over the wire until the distal end strikes the biopsy forceps at the end of the wire.

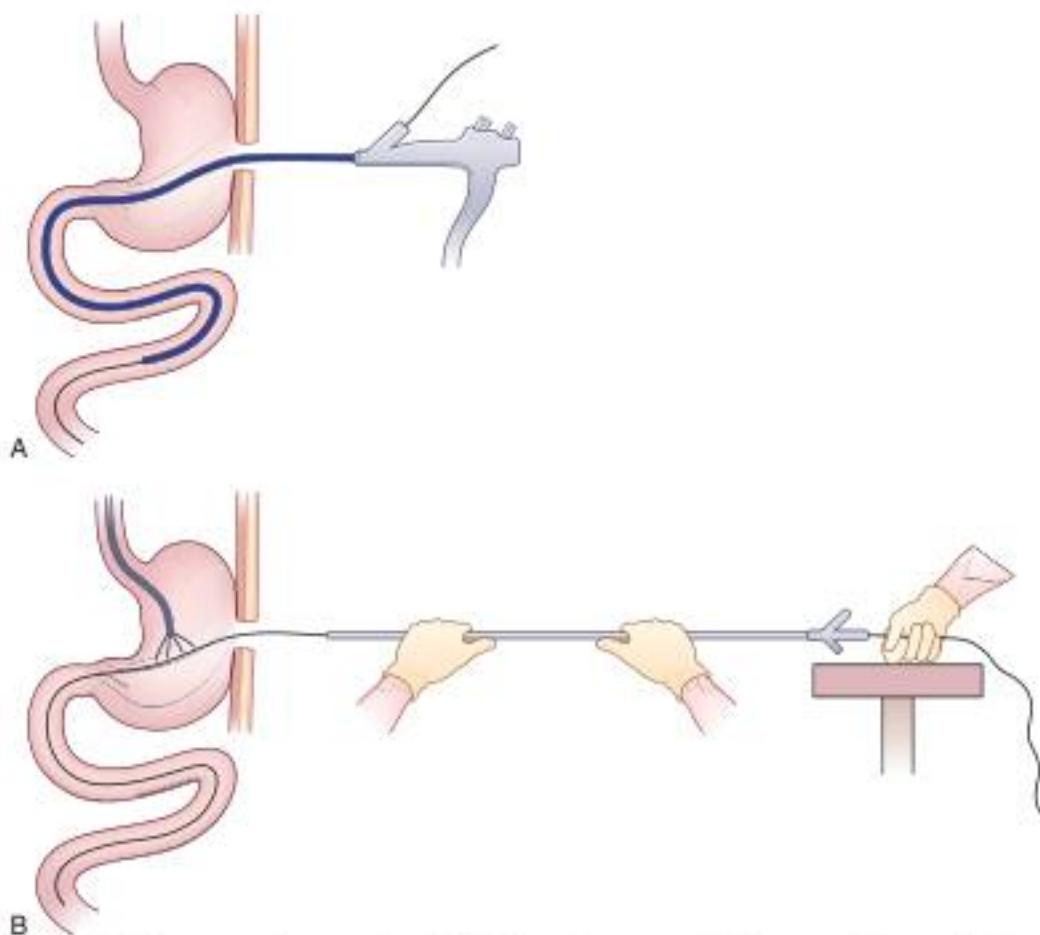

**FIG 42.15** Trans-percutaneous endoscopic gastrostomy (PEG) gastroscope percutaneous endoscopic gastrojejunostomy (PEGJ) technique. After first stiffening the small-caliber 5.5-mm gastroscope with a biopsy forceps, the endoscope is passed through the PEG down to the distal duodenum and proximal jejunum. After removing the biopsy forceps, a single-stranded guidewire is passed out through the end of the endoscope hopefully beyond the ligament of Treitz. After the scope is withdrawn, the jejunal extension tube is passed over the wire.

upward toward the fundus, out from the small bowel. Proper positioning instead should have the appearance that the jejunal tube passes from the PEG directly toward the pylorus and down into the small bowel (see Figs. 42.13E and 42.16B).

### DIRECT PERCUTANEOUS ENDOSCOPIC JEJUNOSTOMY

Although direct percutaneous endoscopic jejunostomy (DPEJ) may be the most technically demanding procedure for enteral access, it provides the most reliable semi-permanent access for the patient who has had difficulty with gastroparesis, nausea, vomiting, or previous intolerance to gastric feeding. Antibiotic prophylaxis is required for the DPEJ technique. Recommendations for the management of antiplatelet or anticoagulant therapy are similar to PEG placement. Although the DPEJ technique is very

similar to the Ponsky pull technique for PEG, a number of important differences exist. First, a much larger area of the abdomen from the costal margins bilaterally down to the iliac crests on both sides may need to be prepped because translumination may occur at more unusual sites anywhere over the abdomen. If the patient has had previous partial gastrectomy and rerouting of the GI tract, the DPEJ may end up being placed significantly to the right of the midline. The DPEJ is a two-person procedure, requiring an assistant at the level of the skin and a skilled endoscopist with the scope. The endoscopist should anticipate taking much longer time (anywhere from 5 to 30 minutes) to transluminate and to finger palpate the site. It is most appropriate to use a 22-gauge spinal needle as a sounding needle in attempts to intubate the small bowel. Again, the endoscopist should anticipate many more needle sticks with the spinal gauge needle compared to the PEG technique. The plastic leader on the Sachs-Vine push technique is not long enough to reach the small bowel site. Most importantly, a tube should be selected with a small internal bolster. A large balloon bolster may cause partial obstruction of the small bowel. A 14–16-Fr pediatric PEG tube with a flat or small mushroom internal bolster is ideal for this procedure. In passing the endoscope through the stomach and into the small bowel, it is important to pay attention to landmarks so that the endoscopist knows when the tip of the endoscope is below the ligament of Treitz. In a patient with Billroth II anatomy, it is important to document the efferent limb for DPEJ placement. The pediatric colonoscope is the instrument of choice in patients with intact anatomy or a “virgin abdomen.” A more flexible gastroscope may be better suited for the patient with a partial gastrectomy and a Billroth II reanastomosis. In patients with an intact stomach, the colonoscope may need to be passed its entire length into the small bowel and withdrawn back to the proximal duodenum several times before a site can be identified by translumination and finger palpation. Site selection is facilitated by searching for a site immediately beyond the ligament of Treitz,

**FIG 42.16** Placement of a one-piece PEGJ through a mature PEG tract. **A**, A small-caliber ( $< 6$  mm) gastroscope is passed through the PEG stoma down below the ligament of Treitz, and the guidewire is passed further still down the jejunum. The endoscope is withdrawn off the wire. **B**, The same endoscope is passed down from the mouth or nares to the stomach to watch out for looping of the wire as the tube is passed over the wire into final position.

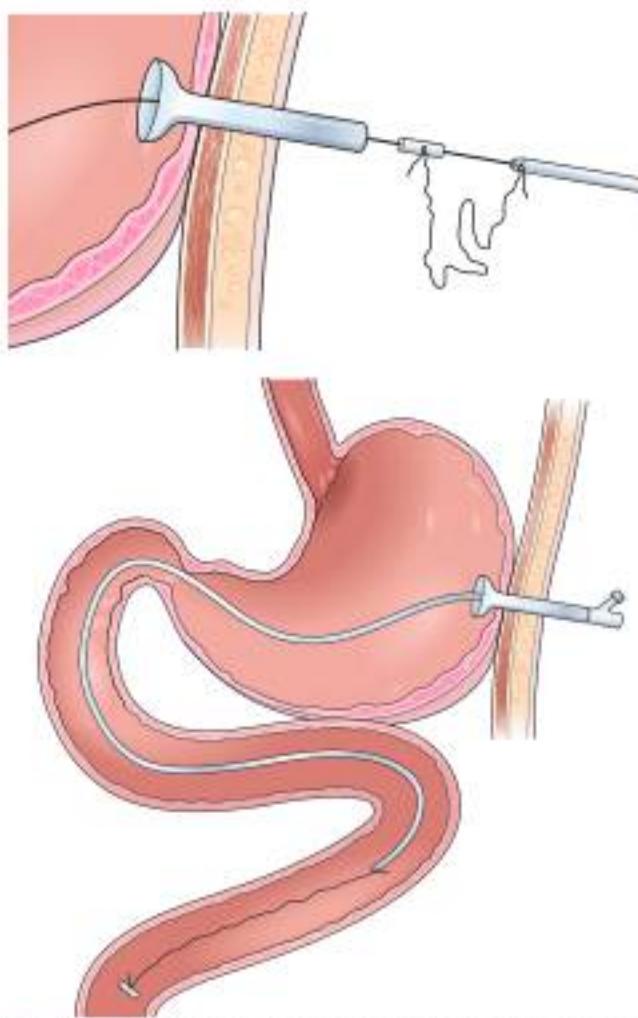

and subsequently passing into each successive length of bowel (moving distally) if unsuccessful.

At the beginning of the procedure, the assistant at the skin should have the anesthetic needle and syringe in one hand and the sounding needle in the other hand. As he or she visualizes an area of transillumination, a quick brief injection of the local anesthetic is followed by a quick abrupt puncture with the sounding needle. Care should be taken not to pass the sounding needle more proximally into the shaft of the endoscope. The endoscopist should place a snare through the instrument and out into the lumen, anticipating passage of the sounding needle into lumen of the small bowel (Fig. 42.19A). Once the small bowel is intubated, the sounding needle is grasped firmly with the snare and held in place by the endoscopist. The assistant at the skin then takes the trocar and passes alongside the sounding needle in the same axis to achieve intubation in the small bowel (see Fig. 42.19B). Glucagon may be given intravenously at this point to maintain a hypotonic bowel. Once the trocar is passed into the lumen of the small bowel, the snare is released from the sounding needle and repositioned on the trocar. The sounding needle is withdrawn and removed. Still holding the bowel in place with the snare affixed to the trocar, the double-stranded wire loop is passed through the trocar into the small bowel, and

the snare is slipped off the trocar, grabbing the wire loop within the lumen of the small bowel (see Fig. 42.19C). The wire is then fed through the trocar as the endoscopist removes the wire out through the stomach, esophagus, and the patient's mouth. Only at this point (see Fig. 42.19D) is further local anesthesia applied in the area of the wire, and an incision is made with the scalpel.

With the blue wire loop protruding out from the patient's mouth, the DPEJ tube is pulled down into position using the Ponsky pull technique. In comparison to the PEG (where passage of the endoscope post placement is optional), it is imperative to follow the internal bolster with the endoscope down through the stomach and small bowel into final position. The bolster has a tendency to pop down from one segment of bowel to the next. It is very difficult to confirm final position of the DPEJ by "blinded feel" alone, by measuring the distances (using the calibrated markings on the tube) between the skin and the internal bolster, or by palpating the internal bolster transabdominally with tension on the tube. Securing the end of the endoscope to the internal bolster with a snare (such as described earlier for the PEG procedure) will help facilitate this process.

Should the PEGJ tube need to be replaced because of deterioration, splitting, or shortening of the tube, an atraumatic technique should be utilized to protect the stomal tract and maintain wire

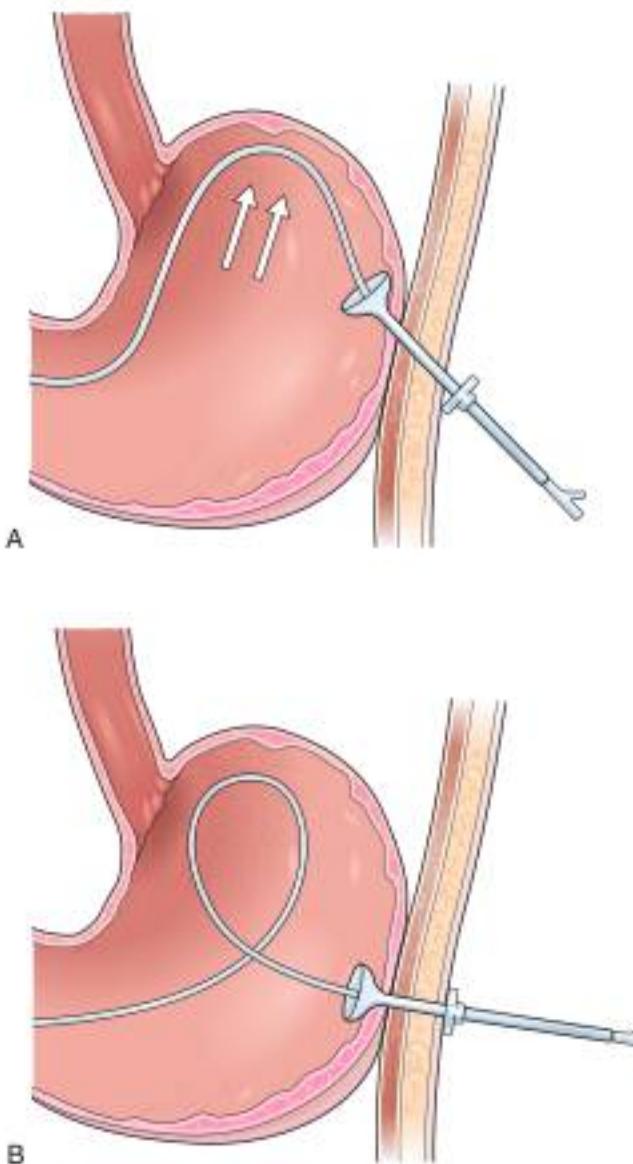

**FIG 42.17** Creation of a percutaneous endoscopic gastrojejunostomy (PEGJ) anchor. A single 1-cm section of tubing is created from any tube that is roughly the same diameter as the feeding tube, which is then attached to the distal end of the feeding tube via a 20-cm silk suture. The anchor segment is preloaded on the guidewire ahead of the feeding tube and then passed down into position in the distal duodenum and proximal jejunum. After removal of the wire, the anchor will hopefully pass distally and help hold the distal tip of the jejunal extension tube in place.

access with the gut lumen (Fig. 42.20). The blue double-stranded wire loop is passed through the DPEJ (after cutting it down to 3 to 4 cm in length). The wire loop is grabbed by the snare (see Fig. 42.20A), which is then pulled back into the DPEJ tube (see Fig. 42.20B). A scalpel incision is made along the length of the tube (1 cm long), the snare is pulled out through the incision, and the snare wire loop is opened (see Fig. 42.20C). A "luggage tag" connection is made between the blue double-stranded wire loop and the snare wire. As the DPEJ tube stump is brought back into the bowel and out of the mouth, the blue wire loop is pulled back with it, facilitating replacement with the new DPEJ tube (see Fig. 42.20D).

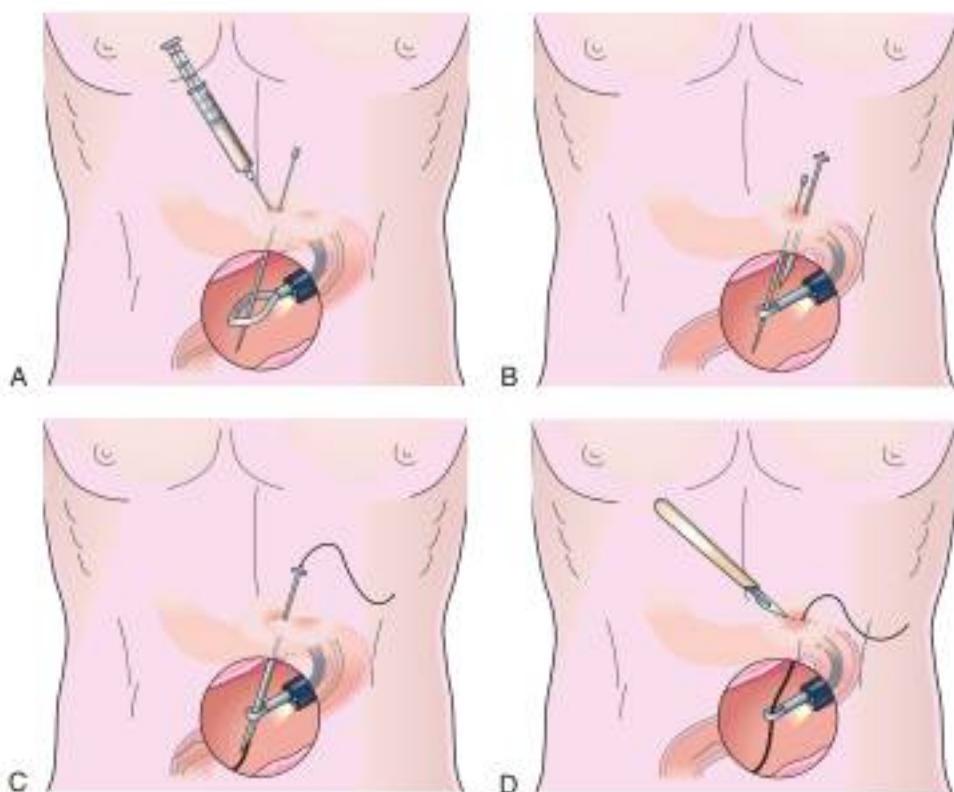

### POSTPROCEDURE CARE

Patient management and care of the enteral access site post placement is essentially the same for all the percutaneous

**FIG 42.18** Poor positioning of the jejunal extension tube after percutaneous endoscopic gastrojejunostomy (PEGJ) conversion. Poor placement is demonstrated by **A**, which shows that although the tip of the jejunal tube is well down past the stomach, the tube passes toward the gastroesophageal junction first before looping and then passing down to the pylorus. If the tube is left in this position after placement, this loop will serve to displace the tip of the jejunal tube back into the stomach. **B**, shows the jejunal extension tube looped back upon itself in the stomach following placement. Failure to correct this would also promote displacement of the tip back into the stomach.

techniques. Patients are generally held nil per os (NPO) for 3 to 4 hours following initial placement, after which feeds may be initiated. Starting at a lower infusion rate of 25 mL/hr, feeds may be advanced as tolerated quickly every 6 to 12 hours such that goal infusion rate is obtained within 24 to 48 hours. For the first 7 to 10 days, a mild cleansing agent should be used once per day to clean the access site. Use of hydrogen peroxide washes or scented soaps, which contain an alcohol base, should be avoided.

**FIG 42.19** Direct percutaneous endoscopic jejunostomy (DPEJ) technique. **A**, After quick initial skin anesthesia, a 22-gauge sounding needle is passed into the small bowel and grasped with a snare passed through the operating channel of the endoscope positioned in the small bowel. **B**, While holding the sounding needle in place with the snare, the trocar is passed at the same angle into the small bowel. The snare is opened, the sounding needle is withdrawn, and the snare is transferred to the trocar. **C**, A double-stranded guidewire is then passed through the trocar, the snare is opened enough to fall back onto the wire, and then the trocar is removed. **D**, Only after the wire has been grabbed firmly by the snare should the skin incision be made over the guidewire. Once the double-stranded wire loop has been withdrawn out through the mouth, the final placement is made using the Ponsky Pull technique.

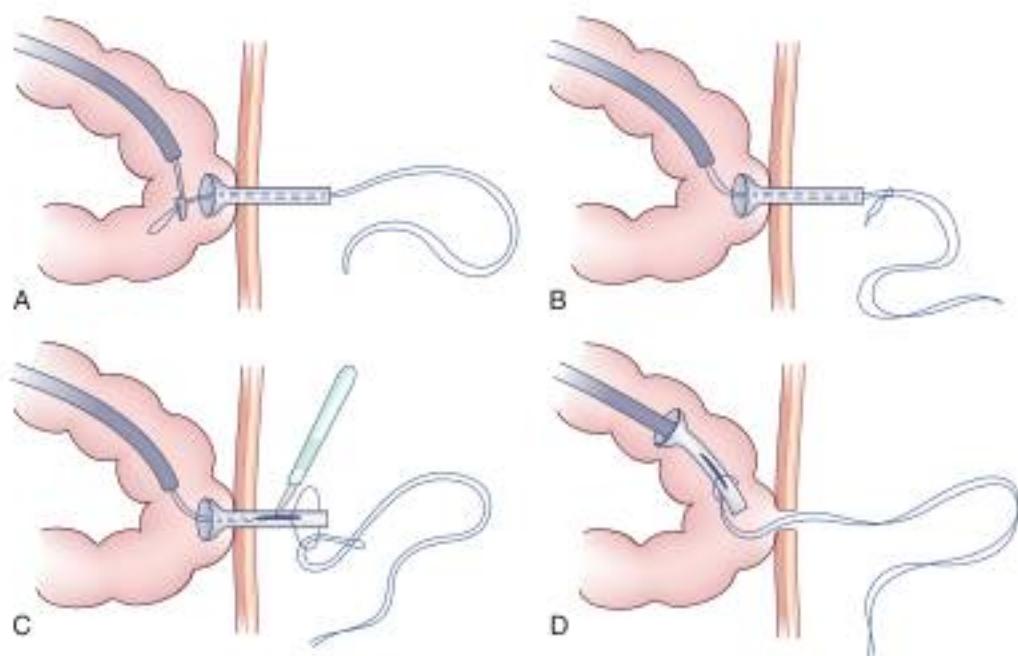

because they have a drying, desiccating effect on the tissue. Bandage dressings should be changed daily over this initial period. Four days after initial placement, the external bolster should be moved back to allow 0.5 to 1 centimeter of play between the skin and bolster. After 7 to 10 days, the frequency of dressing changes may be decreased.

### ENET Complications

The most common complication of the ENET procedure is postinsertion displacement. Tubes placed intentionally in the small bowel may be displaced back into the stomach in 3.7% to 7.0% of cases.<sup>12</sup> Inadvertent removal of the nasoenteric tube completely occurs in 21% to 41% of patients.<sup>13,14</sup> Surprisingly, inadvertent removal does not always occur in a setting with the typical profile of the patient with altered mental status. Most cases of inadvertent removal involve patients with normal mental status, occurring as a result of routine nursing duties (arising from bed, transport out of the unit, physical therapy) when there has been failure to secure the tube by proper methods.<sup>15</sup> Securing the distal end of the nasoenteric feeding tube by using a clip (securing a suture on the tip of the tube to the intestinal mucosa) will not prevent displacement of the tube manually by the patient.

Securing the proximal end with a nasal bridle or some kind of bandage-clipping device (securing the proximal end to the skin) is needed. Displacement of nasoenteric tubes upon initial placement occurs in 0.3% to 15% of cases (mean 3% to 4%), but this is related more to blinded, bedside techniques using aspirate pH and auscultatory methods.<sup>12,14,15</sup> In these cases, pneumothorax, bronchopleural fistula, and even empyema (resulting from infusion of formula into the lung) may occur.<sup>12</sup> These latter complications do not usually occur as a result of endoscopic placement.

Additional minor complications include epistaxis, persistent gagging, knotting, breaking and kinking of the tube, or occlusion of the tube from clogging of the formula. Clogged feeding tubes are best treated with a pancreatin (Viokase) tablet crushed in warm water with bicarbonate, placed in a 10-mL syringe, and used as an irrigating solution. This has been shown in formal testing to be superior to a variety of soft drinks and papain (or meat tenderizer).<sup>16</sup> If the clot fails to clear with this irrigating solution alone, an endoscopic retrograde cholangiopancreatography (ERCP) catheter should be placed down through the tube to the level of the clot and infusion of the irrigating solution should be delivered directly at the site of the clot. If the clogged

**FIG 42.20** Atraumatic replacement of a DPEJ. **A**, The blue double-stranded wire loop is passed through the DPEJ (after cutting it down to 3–4 cm in length) and grabbed by the snare. **B**, The closed snare is then pulled back into the DPEJ tube. **C**, A scalpel incision is made along the length of the DPEJ tube (1 cm long), and the snare is pulled out through the incision. The snare wire loop is opened and a “luggage tag” connection is made between the blue double-stranded wire loop and the snare wire. **D**, As the DPEJ tube stump is brought back into the bowel and out the mouth, the blue wire loop is pulled back with it, facilitating replacement with the new DPEJ tube.

tube persists, further efforts to clear the clot may be accomplished by a mechanical declogging device such as an endoscopy brush or spiral-shaped mechanical declogger that can actually be rotated or screwed through the obstruction.

Simusitis is a complication of prolonged nasoenteric tube placement, and should be a consideration in patients with such tubes who develop an unexplained fever. The incidence of simusitis based on opacification of sinuses on radiograph or CT scan tends to be overreported at approximately 25%, whereas needle puncture and culture of effluent from the sinuses more accurately places the incidence at approximately 11.4%.<sup>17</sup> Esophageal stricture is a theoretical complication of long-standing nasoenteric tubes, but the incidence is not clear and is probably underreported. A long-standing nasal bridle, in place for greater than 1 to 2 months' duration, may erode through the nasal septum.

### PEG Complications

Reports from the literature of overall complications related to PEG placement indicate that this minimally invasive procedure has low morbidity and negligible mortality.<sup>18,19</sup> Two large series published 15 to 20 years ago showed that the incidence of minor complications ranged from 4.9% to 13%, with major complications ranging from 1.3% to 3%.<sup>18,19</sup> Mortality in these two large series was only 0.2% to 1.0%.<sup>18,19</sup> Two other large series (2001) duplicated these results, showing that the rate of minor complications ranged from 10.3% to 10.7%, with major complications ranging from 1.0% to 2.4%.<sup>20,21</sup> There was no mortality in these more recent series. Minor complications described in these reports include peristomal wound infections, tube disintegration, clogging,

leakage, prolonged ileus, late inadvertent extubation, subcostal neuralgia, laceration of the left lobe of the liver, and delayed closure following removal. Major complications reported include aspiration, peritonitis, early premature removal, tumor implantation at the PEG site, buried bumper syndrome, gastrocolocutaneous fistula, necrotizing fasciitis, and hemorrhage.<sup>18–21</sup>

A benign pneumoperitoneum occurs in up to 40% of cases following routine PEG placement.<sup>22</sup> In the absence of peritoneal signs (e.g., rebound tenderness), this finding is innocuous and does not preclude feeding within 4 hours of tube placement. Pneumoperitoneum may or may not be accompanied by a large, air-filled, distended stomach, which can easily be decompressed by uncapping the newly placed PEG tube.<sup>23</sup> Prolonged ileus following PEG placement was described in 1% of patients in one large series.<sup>21</sup>

The incidence of aspiration following PEG placement is difficult to determine because of varying definitions (witnessed aspiration event vs. new infiltrate on chest radiograph vs. aspiration of gastric contents labeled with a radioisotope or fluoroscopic colorimetric microspheres). The risk of aspiration immediately related to the procedure of PEG placement itself has been reported to be less than 1% of cases,<sup>18,24</sup> and is thought to be related to oversedation, overinflation of the stomach, and performing the procedure in the supine position. Aspiration as a long-term complication of PEG placement has been reported in up to 18% of cases.<sup>25</sup> In one small prospective study, patients randomized to PEG placement had lower gastroesophageal reflux (as measured by 24-hour pH monitoring) compared to patients randomized to nasogastric feeding.<sup>26</sup> Risk for aspiration long term is related

to patient age (older than 70 years), reduced level of consciousness, history of neuromuscular disease, delayed gastric emptying, endotracheal intubation, trauma to the abdomen or pelvis, bolus versus continuous feeds, and nursing care.<sup>22,23</sup> Risk for aspiration increases fourfold when patients are moved from the ICU (low patient-to-nurse ratio) out to the medical or surgical floor (high ratio).<sup>23</sup> These studies reporting aspiration post-PEG placement do not usually differentiate aspiration of contaminated oropharyngeal secretions from regurgitation and aspiration of contaminated gastric contents. Three studies would suggest that the aspiration of contaminated oropharyngeal secretions is at least an equivalent if not greater factor in colonizing the trachea and upper-respiratory tree than aspiration of bacteria-laden gastric contents.<sup>24-26</sup> Poor oral health has been well defined as an additional risk factor for aspiration in patients on tube feeding.<sup>27</sup>

Buried bumper syndrome is an underreported complication ranging from ulceration underneath the internal bolster to total erosion of the PEG tube out through the gastric and abdominal wall. It most often occurs as a result of excessive tension between the external and internal bolster, but additional predisposing factors include smaller, stiffer internal bolsters (made from silicone compared to polyurethane), presence of malnutrition or poor wound healing, or a significant weight gain in response to feeding.<sup>24</sup> Buried bumper syndrome may present simply as increased leakage around the PEG, infection at the PEG site, immobility of the catheter, resistance to infusion, or abdominal pain occurring with infusion of formula.<sup>23,24,33,34</sup> A wide variety of techniques are described in the literature to manage this complication. Usually the PEG tube has to be removed either by pulling it back into the stomach and out through the mouth or pulling it out through the abdominal wall. In patients where the PEG tube has not been used from several weeks to months, the internal bolster may be completely buried within the gastric and abdominal wall. In this situation, a needle-knife thermocoagulation catheter may be required to cut down to the bolster to facilitate removal.<sup>23</sup>

Gastrocolocutaneous fistulas may occur because of inadvertent puncture of an overlying loop of bowel at the time of initial placement, or as a delayed complication occurring because of migration or erosion of the tube over time into the colon.<sup>24,25</sup> Insufficient transillumination, inadequate gastric insufflation at the time of initial placement, or previous abdominal surgery in which a loop of bowel may be tacked down by scar tissue are all risk factors increasing the likelihood for this complication.<sup>24,26</sup> Gastrocolocutaneous fistula may present acutely with peritonitis, infection, fasciitis, or obstruction to flow from infusion of the formula. More often it occurs chronically, presenting after several months with either stool appearing around the PEG tube or as insidious diarrhea in which the stool has the appearance of formula identical to that infused into the PEG. Frequently, this complication is not identified until the tube is removed and stool appears at the ostomy site. This complication is managed by first documenting the complication with radiographic contrast studies. Surprisingly, it is managed fairly easily by simply removing the PEG, placing a bandage over the defect, and allowing the site to heal. Operative takedown is only required if the fistula fails to close.<sup>23,24</sup>

PEG site infection is one of the most common complications of PEG placement. Risk for developing PEG site infection is related to patient factors (e.g., diabetes, obesity, malnutrition, or chronic use of steroids), factors involving technique (pull or push type PEGs vs. introducer PEGs, small incisions, and lack

of antibiotic prophylaxis), and nursing care (excessive traction on the bolsters). The incidence of wound infection around the PEG site ranges from 5.4% to 17.0%,<sup>25,30,37</sup> but the majority (more than 70%) are minor in degree.<sup>38</sup> Antibiotic prophylaxis at the time of initial placement is an important measure to reduce the incidence of this complication. In an older study, a single dose of antibiotic prophylaxis at the time of placement reduced the incidence of PEG site infection from 32% down to 7% ( $p < 0.05$ ).<sup>39</sup> In a more recent (1999) study, a single dose of one or two antibiotics at the time of placement reduced the incidence of PEG site infection significantly from 13.2% to 0.5% compared to controls receiving no antibiotic prophylaxis ( $p < 0.01$ ).<sup>30</sup> Patients already on concurrent antibiotics do not need additional prophylaxis at the time of PEG placement.<sup>40</sup> If infection develops around the PEG site, usually intravenous antibiotics and local wound care are sufficient to correct the complication. Surgical incision and drainage are rarely required. Actual peritonitis occurs less frequently in 0.4% to 1.5% of cases,<sup>18,24,35,41</sup> and is differentiated from simple PEG site infection by the development of peritoneal signs and rebound tenderness. Again, prompt broad-spectrum intravenous antibiotics are usually sufficient. But in the presence of peritonitis, contrast studies should be performed to rule out the presence of a leak. If there is leakage into the peritoneum, then surgical intervention is required.<sup>24</sup>

Hemorrhage is a rare complication involving less than 2.5% of cases.<sup>24,38</sup> A variety of etiologic factors may contribute to this complication, including direct puncture of a blood vessel or traumatic tearing of the esophagus or stomach upon initial placement, concomitant peptic ulcer disease, development of gastric ulcer underneath the internal bolster, or erosion of the posterior gastric wall opposite from the internal bolster of the PEG tube.<sup>24,35</sup> Management involves urgent endoscopy to document the source and appropriate steps to achieve hemostasis.

Leakage around the PEG site is reported in only 1% to 2% of cases,<sup>24,41</sup> but this probably represents underreporting of the incidence of this complication. Etiologic factors include corrosive agents (vitamin C ascorbic acid infused with formula, increased gastric acid arising from stop orders for prescribed acid-reducing agents, and continued hydrogen peroxide washes of the site following initial placement), cutaneous fungal infection around the site, development of granulation tissue, side-torsion on the tube creating ulceration on one wall of the tract, absence of an external bolster (allowing to-and-fro motion of the PEG tube through the tract), buried bumper syndrome, and PEG site infection. Management again depends on defining the exacerbating factors, which can usually be ascertained by careful examination of the PEG site. Initial physical exam should rule out PEG site infection, confirm there is no fixation of the tube (suggesting buried bumper syndrome), and make sure there is no ulceration of the tract indicating side-torsion. The patient's list of medications should be reviewed, a proton pump inhibitor should be added if this agent has not been ordered, ascorbic acid should be stopped, and consideration should be given to providing an antifungal cream or zinc oxide to the site. Side-torsion creating ulceration in the tract may require stabilization of the PEG tube with a vertical clamp (which prevents side-to-side motion). Granulation tissue around the PEG site may be treated with silver nitrate sticks. Options for those cases where there is no external bolster include replacing the PEG tube with a commercial replacement PEG set that contains an external bolster, or creating a homemade external bolster from the funneled end of a Foley catheter. PEG site infection should be treated, as should existence

of the buried bumper syndrome according to previously described methods. The tract may be damaged to the point that diverting the stream of infused formula down into the small bowel (by converting the PEG to a PEGJ) or completely removing the PEG tube and placing a nasoenteric aspirate/feed tube to allow the site to heal may be required in more severe cases.

Accidental extubation of the PEG tube occurs in anywhere from 1.6% to 4.4% of cases, half of which occur prematurely prior to complete maturation of the PEG site.<sup>20,21,22,37,42</sup> Normally the PEG site should mature over 7 to 10 days, at which point the gastric wall becomes fused to the anterior abdominal wall. Maturation of the PEG tract may be delayed up to 4 weeks in the presence of chronic steroid use, malnutrition, or ascites. Management is surprisingly simple, as long as no peritonitis is present.<sup>35</sup> The patient may be brought back down to the endoscopy suite immediately, and a new PEG may be placed through the same site on the abdominal wall (although there is no need to pass through the same site on the gastric wall). The placement of the trocar should be done quickly to avoid prolonged insufflation and a large pneumoperitoneum. If this strategy is unsuccessful, a nasogastric (NG) tube can be placed for decompression, a broad-spectrum antibiotic should be started, and the PEG may be replaced later within 7 to 10 days. Only if peritonitis develops is surgical intervention required.<sup>35</sup> Once the PEG tract is mature, simple bedside replacement with a PEG tube (or endoscopic placement if the site closes down) may be sufficient.

Less common complications of PEG placement include tumor implantation at the PEG site, development of a bronchoesophageal fistula, migration of the internal balloon bolster causing gastric outlet obstruction at the level of the pylorus, reversible apnea, subcostal neuralgia, and development of a gastroileocutaneous fistula.<sup>20,43–47</sup>

## PEG AND DPEJ COMPLICATIONS

For obvious reasons, patients requiring placement of a PEGJ are at risk for all the complications previously described for placement of a routine PEG tube. The most common additional problem encountered with PEGJ tubes is inadvertent migration of the jejunal tube from the small bowel back into the stomach, which occurs in 27% to 42% of cases.<sup>48–50</sup> A number of factors contribute to this complication, including a large dilated atonic stomach, failure to cut the PEG tube down to a shortened length, insufficient length of the jejunal tube, placement of the initial PEG high in the stomach, surgical PEG placement (in which the PEG tube is tunneled in a direction that points toward the gastroesophageal junction), as well as recurrent nausea and vomiting. Steps that can be taken at the time of initial placement to reduce this complication include positioning the PEG tube immediately above and to the right of the umbilicus so that the entrance is in the gastric antrum, cutting the PEG tube down to approximately 10 cm in length, selecting a jejunal tube with the greatest length, and making sure that there is no loop in the stomach as the jejunal tube passes from the PEG to the pylorus. As mentioned earlier in the section on technique of PEGJ placement, securing the distal end to the intestinal mucosa with a clip or placement of an anchor device may help hold the jejunal tube in place for a brief period.

Complications arising from DPEJ placement differ very little from those encountered by routine PEG placement. Of note is the fact that a jejunocolocutaneous fistula may occur. Intermittent small bowel obstruction may occur when a larger balloon-type

internal bolster is selected for the procedure. Volvulus leading to necrotic bowel has been described with DPEG.<sup>51</sup>

## CONCLUSION

Multidisciplinary nutrition teams across the country are pressured to obtain early enteral access, as the weight of the literature shows that early use of the gut and maintenance of gut integrity significantly improves patient outcome. These teams rely on a skilled endoscopist to obtain enteral access, monitor enteral tube feeding, and help troubleshoot problems when the issue of intolerance arises. When a short-term nasoenteric feeding is required, or more long-term percutaneous access is needed, a variety of techniques exist for almost any patient situation. Under each category of access, the endoscopist should learn one main technique well, and then experiment enough with other techniques to know which one suits him or her best. Proper choice of instrument, correct accessory devices, and selection of the appropriate technique for the individual patient needs should optimize the chances for success and minimize the risk of complications when performing endoscopic procedures to obtain enteral access.

Introduction, 488	Malabsorptive Procedures, 490
Endoscopic Options for Endoluminal Primary Treatment of Obesity, 488	Other Procedures, 492
Restrictive Procedures, 488	Conclusion, 493

## INTRODUCTION

Obesity is the pandemic of the 21st century and is associated with considerable morbidity and mortality.<sup>1</sup> Management of obesity depends on body mass index (BMI) and the presence of comorbidities, including heart disease, diabetes, hypertension, dyslipidemia, osteoarthritis, and sleep apnea.<sup>2</sup> Approximately 1.6 billion adults are overweight; at least 400 million adults are obese. The World Health Organization projected that by 2015, approximately 2.3 billion adults would be overweight, and more than 700 million would be obese. Previously considered a problem only in high-income countries, the number of overweight and obese individuals is now dramatically increasing in low- and middle-income countries, particularly in urban settings.<sup>3</sup>

At the present time, surgery is the only effective therapy for morbid obesity, defined as a BMI of 40 kg/m<sup>2</sup> or more, or as a BMI of 35 kg/m<sup>2</sup> or more in the presence of comorbidities.<sup>4</sup> Bariatric surgery has been shown to be effective in the long-term and significantly reduces the risk of mortality associated with morbid obesity. In the United States, the indications for bariatric surgery increased by 80% during the period 1998–2004.<sup>5</sup>

Bariatric surgery induces and maintains satisfactory weight loss while decreasing comorbidities in the overweight patient.<sup>6</sup> Efficacy varies with the type of procedure, which can be divided into restrictive (lap band, sleeve gastrectomy), malabsorptive (biliopancreatic diversion), or a combination of both (gastric bypass). Although very effective, laparoscopic and surgical bariatric procedures have complication rates of 3% to 20% and mortality rates of 1%.<sup>7</sup> Cardiopulmonary events and anastomotic leaks are the major sources of severe morbidities.

The demand for less invasive therapy for obesity led to the development of endoscopic technologies, potentially characterized by less invasiveness and fewer complications. Endoluminal surgery, performed entirely through a natural orifice, offers this potential for a less invasive weight loss procedure, possibly performed on an ambulatory basis, and might find its place in the current armamentarium for morbid obesity treatment, extending indications for treatment to patients with severe comorbidities and

older age and even to non-morbidly obese patients. We review the various endoluminal techniques that are either in routine use or in clinical evaluation and address the role of endoscopy in management of weight regain occurring after bariatric surgery.

## ENDOSCOPIC OPTIONS FOR ENDOLUMINAL PRIMARY TREATMENT OF OBESITY

Similar to surgical procedures, the different options for endoluminal treatment of obesity can be divided between restrictive and malabsorptive procedures (Table 43.1).

### Restrictive Procedures

#### Intragastric Balloons

The use of a fluid-filled intragastric balloon to induce weight loss in obese patients was first described in 1982.<sup>8</sup> Since then, numerous intragastric balloons have been in use worldwide, and several have been withdrawn from the market. The BioEnterics Intragastric Balloon (BIB; Allergan, Irvine, CA) or ORBERA (Apollo Endosurgery, Austin, TX) has a spherical shape and larger capacity than earlier models and has been the most extensively used device. Among the more recently improved minimally invasive procedures, the intragastric balloon has been one temporary nonsurgical option that can promote weight loss in obese patients by partially filling their stomach and inducing a sense of early satiety.<sup>9,10</sup> One of the major drawbacks of balloon implantation is weight regain after balloon removal. Two early studies help clinicians better understand what can be expected from balloon implantation.

In the first study, Mathus-Vliegen and Tytgat (2005)<sup>11</sup> included patients who had participated in a randomized controlled trial (RCT) comparing a balloon with a sham for a 3-month period in an additional trial which involved 9 months of balloon treatment and follow-up for 1 year after removal. The authors excluded 8 patients who had not met the weight loss goal during the first 3 months (5 patients) or who did not tolerate the balloon (3 patients). Although there was no difference between the sham and balloon during the first 3 months, after 1 year of balloon

**Abstract**

Morbid obesity is still a major health issue in western countries, for which the most efficient treatment is bariatric surgery. Nevertheless, expectations for a safer, less invasive and, hopefully, cheaper treatment persist. Different endoscopic techniques have been drawn up, implemented and studied. Some of the features of bariatric surgery have been reproduced, with both successes and setbacks. Some of these procedures could also be applied in situations where patients either fail to lose weight or regain weight after bariatric surgery. In this chapter we review the evolving developments in the field of bariatric endoscopy.

**TABLE 43.1 Available Bariatric Endotherapy Technology**

<b>Endoscopic Procedures</b>	<b>Mechanism</b>	<b>Human Applications</b>	<b>Limitations</b>
Intragastric balloon	Restrictive	Prospective crossover study; > 2000 cases reported	Patient tolerance Limited effect (6 mol)
Endoluminal vertical gastroplasty	Restrictive	One prospective study (64 patients)	Long-term efficacy Depth of suture
Transoral gastroplasty	Restrictive	Multiple human studies (> 150 patients), multicentric RCT completed unpublished	Long-term outcomes Complications
Endoscopic sleeve gastroplasty	Restrictive	Large postmarketing studies (> 200 patients), no prospective evaluation with ITT analysis	Long-term outcomes Patient selection biases
Endoluminal suturing device	Restrictive	Limited human study (11 patients) Universal triangulation platform Use of stitches; transmural stitching	Long-term efficacy
POSE	Restrictive	Two prospective studies (n = 161 patients)	Long-term efficacy Intraprocedural drop out of patients
Aspiration therapy	Malabsorptive	11 + 25 patients treated	Adherence to protocol Parietal complications
DJBS	Malabsorptive	32 patients investigated	Patient tolerance Long-term safety and efficacy Reversibility Liver abscesses
Gastroduodenjejunal bypass sleeve	Restrictive & malabsorptive	13 patients investigated	Tolerance at the level of the cuff inserted at the cardia Long-term efficacy

DJBS, duodenjejunal bypass sleeve.

treatment, a mean weight loss of 21.3 kg (17.1%) was achieved in all patients; 12.6 kg (9.9%) was maintained at the end of the second balloon-free year. Overall, 47% of patients sustained a 10% weight loss at the end of 2 years of follow-up. Although this study did not show an independent benefit of balloon treatment beyond diet, exercise, and behavioral therapy in the first treatment, balloon treatment for 1 year, in the patients who tolerated the treatment, resulted in substantial weight loss, a significant part of which was maintained during the first year after removal of the balloon.<sup>11</sup>

The second study looked at the long-term outcome after treatment with an intragastric balloon for 6 months, with no structured weight maintenance program after balloon removal. After BIB placement, 100 consecutive morbidly obese individuals were prospectively followed; 97 patients completed the final follow-up at a mean of 4.8 years. After 6 months, 63% of patients had more than 10% baseline weight loss, whereas there were only 28% at final follow-up. At that time, 35 patients had undergone bariatric surgery, and 34 patients had no significant weight change from baseline.<sup>12</sup>

Finally, a 2015 systematic review and meta-analysis performed by the American Society for Gastrointestinal Endoscopy (ASGE) Bariatric Endoscopy Task Force demonstrated that an intragastric balloon results in 25.4% of excess weight loss (EWL) and 11.3% of total weight loss 1 year after balloon insertion (6 months after balloon removal).<sup>13</sup> The main side effects consisted in upper gastrointestinal (GI) complaints (abdominal pain and nausea), which were responsible for early removal in approximately 7.5% of patients. Serious adverse events are rare, including 0.1% with GI perforation and 1.4% with balloon migration.<sup>13</sup>

Different technical modifications of the fluid-filled balloons have been brought to potentially improve its efficacy, tolerance, or safety profile. Currently, however, none of these have been

proven to be superior.<sup>14</sup> The Spatz adjustable Balloon system (Spatz FGIA, Inc., New York, NY) has an extractable inflation tube for adjustment after initial filling either in case of intolerance or decreased efficacy. It has been associated with specific complications related to catheter impaction requiring surgical extraction. However, it is approved for 1 year implantation and, in a case-controlled study that required adjustment in 22.5% of patients, had an efficacy similar to 2 consecutive BIBs left for the same period, with a similar tolerance and safety profile (Video 43.1).<sup>15</sup> The ReShape Duo (ReShape, San Clemente, CA) is the second intragastric balloon approved by the Food and Drug Administration (FDA). It consists of two separately attached filled balloons (450 mL each). In the REDUCE pivotal FDA trial (a prospective, randomized controlled pivotal trial of a dual intragastric balloon for the treatment of obesity), which enrolled 326 patients,<sup>16</sup> patients treated with Duo achieved significantly more weight loss than those with diet and exercise alone (27.9% vs. 11.3% EWL). Gastric ulcerations at removal were reported in 10% of cases. In Europe, the high cost of this device limits its clinical use.

Air/gas-filled balloons have been proposed as an alternative to classic fluid-filled balloons. The Heliosphere BAG balloon (Helioscopie, Vienne, France) was reported as having a similar efficacy to the BIB, with possibly less discomfort.<sup>17</sup> However, a high rate of spontaneous deflation, the absence of a marker allowing early identification of a possible rupture, and technical difficulties in its positioning have limited its routine use.

Other gas-filled balloons can be swallowed without the need for endoscopy but still require endoscopy for removal (Obalon Therapeutics, Carlsbad, CA), and some are even designed to be swallowed as a pill and inflated in the stomach, and contain a resorbable valve, which would allow spontaneous deflation and uneventful migration (Allurion Technologies, Inc., Wellesley,

MA). However, the clinical data available with these techniques are currently insufficient to make any recommendation on their use.<sup>18,19</sup>

In summary, balloon implantation may be helpful for long-term weight loss in select patients. It is a potential option for patients who are unwilling to undergo bariatric surgery or who are not suitable candidates for bariatric surgery. Balloon implantation could also be used as a temporary measure in superobese patients to induce weight loss and decrease the risk of complications associated with further bariatric surgery.<sup>20</sup>

### Suturing/Stapling Procedures

Another group of endoscopic procedures aims to offer a long-lasting reduction of gastric volume and decrease the distensibility of the stomach by suturing or stapling techniques. This endoluminal transoral restrictive surgery includes several techniques, the first one (EndoCinch) being performed with a device initially designed for treatment of gastroesophageal reflux disease (GERD).

**Endoluminal vertical gastroplasty.** The EndoCinch suturing system (C.R. Bard, Murray Hill, NJ) was initially designed for endoscopic treatment of GERD. This system allows the placement of a series of stitches in the lower esophagus to create a pleat at the level of the lower sphincter. Although associated with encouraging early results, use of the EndoCinch for the treatment of GERD has been called into question because of the lack of retention of plications in the long term.<sup>21</sup>

The device was then used to restrict the gastric cavity. The technique utilizes the deployment of seven sutures in a continuous and cross-linked fashion from the proximal fundus to the distal body. Again, despite initial encouraging results,<sup>22</sup> the latest development of the device (RESTORe Suturing system [Bard/Davol, Warwick, RI]), theoretically capable of full-thickness tissue apposition, found that sutures were not durable over time, leading to a lack of effectiveness.<sup>23</sup>

**Transoral gastroplasty.** Transoral gastroplasty (TOGa System; Satiety, Inc., Palo Alto, CA) used the first endoscopic stapling device to create a full-thickness plication in the proximal stomach with a strictly endoluminal approach.

The system consisted of the TOGa Sleeve Stapler, a flexible 18-mm diameter shaft device, which rides over a guidewire for introduction, and accommodates a standard endoscope up to 8.6 mm in diameter. It creates full-thickness plications of the anterior and posterior walls of the stomach, which are acquired using vacuum ports located parallel to the staple line (Fig. 43.1).

Two successive human pilot series<sup>24,25</sup> reported a mean EWL of 16%, 23%, and 25% at 1, 3, and 6 months, respectively, with the first design of the instrument, and 19%, 34%, and 46% at 1, 3, and 6 months, respectively, after some technical modifications. No severe adverse events were reported. A 1-year follow-up on a larger multicenter European study involving 53 patients has confirmed these data, with an EWL at 12 months of 39% in morbidly obese patients.<sup>26</sup> Although the technique was performed under general anesthesia, recovery was very fast, and the procedure could be performed within 30 to 45 minutes on an outpatient basis, suggesting that this technique might become an interesting first step for bariatric treatment strategy. A multicenter randomized sham-controlled study was performed in 11 centers comparing the active and sham procedure (2:1 ratio) in a series of more than 300 patients. This RCT showed significant but modest differences between the two groups, with two severe complications. The FDA required additional data. Due to a shortage of financing, the company closed and sold its assets. Interestingly, the company

that acquired these assets refused to provide the clinical data for publication of this RCT.

### Endoscopic Sleeve Gastrectomy

The Overstitch device (Apollo Endosurgery, Austin, TX) is an FDA-approved suturing device able to place full-thickness stitches across the gastric wall. Placement of multiple stitches from the antrum to the fundus is performed to reproduce a kind of restriction comparable to a sleeve gastrectomy. The first study published reported a mean percentage EWL of 54% and 21 kg of total weight loss at 1-year postprocedure in 22 patients out of 25 (3 dropped out).<sup>27</sup> During the follow-up, 1 patient underwent an additional intervention due to the loosening of the stitches. Interestingly, no major side effects were noted. A more recent study (2016) reported on 91 patients with a BMI above 30 treated in an open-access environment.<sup>28</sup> The authors reported a total body weight loss (TBWL) of 17.6% at 12 months, with a 76% follow-up rate and improvement of comorbidities. Only 1 severe complication (perigastric leak) occurred and was managed conservatively. Further data are needed to determine the long-term benefits of this technique.

**Primary obesity surgery endoluminal.** Using their Incisionless Operating Platform (USGI Medical, San Clemente, CA), the primary obesity surgery endoluminal (POSE) procedure places anchoring structures across the gastric wall, introducing an area of transmural plications within the corpus and the fundus, up to the gastroesophageal junction. Lopez-Nava et al (2015)<sup>29</sup> enrolled 147 patients in a prospective study over 1 year, with a highly controlled behavioral and nutritional follow-up. Thirty-one patients were lost to follow-up. In the 119 remaining patients, a mean of 44% EWL (15 kg of total weight loss) was observed without any serious adverse event.<sup>29</sup> A sham-controlled trial involving 332 patients (ESSENTIAL) has also been conducted. Results indicated 4.9% TBWL in the treatment arm and 1.38% in controls. The mean percent change in TBWL was 3.6 times greater in the active treatment group. The response rates were 41.6% for the active arm and 22% in the sham arm. However, the study did not reach its primary endpoint, which was defined as 5% TBWL at 12 months.<sup>30</sup>

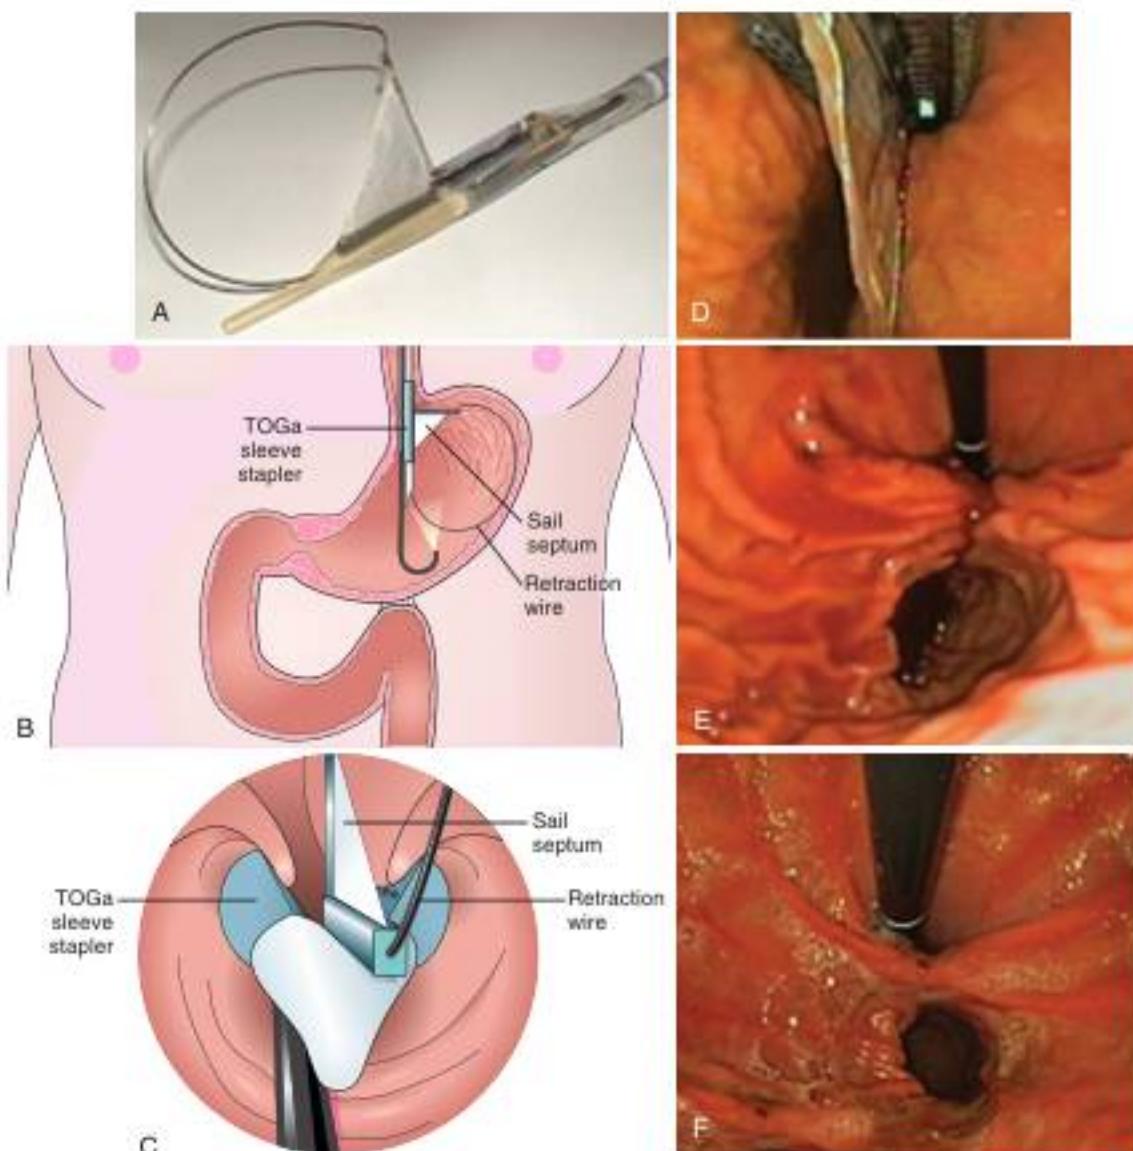

**Endoluminal suturing device.** More recently, Huberty et al (2016) reported the use of a new triangulation platform and endoscopic stitchers (Endo tools SA[ETT], Gosselies, Belgium), with which they could perform multiple double transmural plications along the greater curvature of the stomach to create a restrictive gastroplasty (Videos 43.2 and 43.3). No severe adverse events were recorded for the first 11 obese patients treated. The percentage of EWL was 41% at 6 months.<sup>31</sup> Again, broader experience and long-term technical and clinical outcomes will be necessary.

**Articulating circular endoscopic (ACE) stapling procedure.** The ACE stapling device (Boston Scientific, Marlborough, MA) is a rotatable device allowing eight plications at the level of the fundus, reducing the proximal gastric volume. In a pilot study, the investigators also added two plications at the level of the antrum. At 1 year of follow-up, plications persisted and the median EWL was 34.9%.<sup>32</sup>

### Malabsorptive Procedures

#### Aspiration Therapy

This procedure is based on a well-known endoscopic tool adapted for the purpose of inducing weight loss. It requires the implantation of a 30-Fr gastrostomy tube, called an *A-tube*, in obese

**FIG 43.1 A to F.** Transoral gastroplasty procedure.

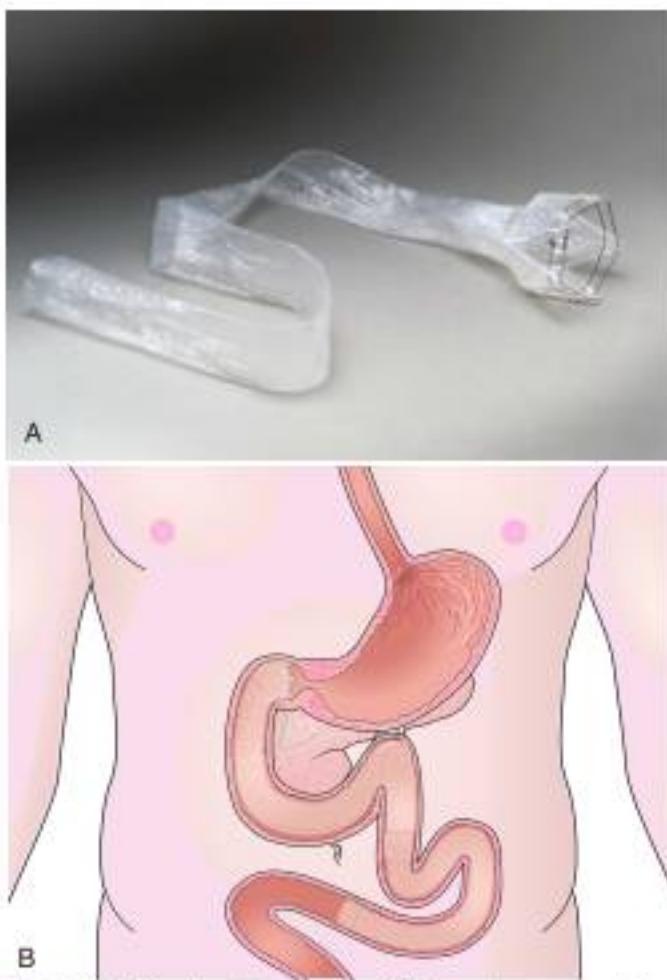

patients. The patient uses it 20 minutes after ingestion, to aspire 30% of each meal. The system is called the Aspire Assist (Aspire Bariatrics, King of Prussia, PA). There are two studies published. In the latest and largest one, including 22 out of 25 patients, mean EWL was 40.8% and TBWL was 14.8% after 6 months of use. Three patients dropped out because of time constraints (the system involves the evacuation of food three times daily). No nutritional deficiencies were reported.<sup>33</sup> A pivotal multicenter randomized study is ongoing in the United States.

#### Duodenojejunal Bypass Liner or EndoBarrier Device

The bypass technique has to be considered in line with the development of metabolic surgery and, particularly, with the clinical observation that bypassing the proximal bowel improves type 2 diabetes and induces weight loss, a feature that partly explains the greater improvement of diabetes observed in patients undergoing a laparoscopic Roux-en-Y gastric bypass (RYGB) for weight loss compared with a purely restrictive procedure.<sup>34</sup>

The first strictly endoluminal device used to bypass the proximal small intestine is the duodenojejunal bypass liner, also called the EndoBarrier (GI Dynamics, Watertown, MA). It is composed of a self-expanding implant that is placed in the duodenum and has antimigration features. It is attached to a 60-cm plastic sleeve that extends into the proximal jejunum and works by creating a physical barrier between food that has been ingested and the intestinal wall and biliopancreatic secretions (Fig. 43.2). The device is left in place for a maximum of 3 to 6 months and is removed with a dedicated and relatively easy system.

Three RCTs including 174 patients (90 received the EndoBarrier and 84 were the control arm) have been scrutinized by the ASGE Bariatric Endoscopy Task Force. This analysis demonstrated no statistical difference in terms of weight loss (%EWL) at 12 months after EndoBarrier insertion. On the other hand, this meta-analysis found a persistent effect 12 months after implantation on glycated hemoglobin, which had dropped by 1% (93 patients, 52 treated and 41 controls). More importantly, they

**FIG 43.2** **A**, Duodenojejunal sleeve. **B**, Schematic representation of the sleeve in place in the proximal jejunum. (**A**, Used with permission of GI Dynamics, Inc., Lexington, MA.)

also reported that the rate of early retrieval for intolerance of the device was as high as 18%.<sup>33</sup> In 2016, authors from Denmark found a modest effect of the EndoBarrier on weight loss, but did not find any glycemic improvement.<sup>34</sup> Finally, a 2015 report of liver abscesses (4 out of 325 patients) complicating the insertion of the EndoBarrier in the pivotal RCT in the United States precluded the actual development of the device.<sup>35</sup>

### Gastroduodenal Bypass Sleeve

The gastroduodenal bypass sleeve is another implantable device, potentially mimicking more closely RYGB (Valentx Inc., Carpinteria, CA). A plastic cuff with a 120-cm long sleeve is implanted endoscopically and laparoscopically at the level of the cardia. It reproduces not only the restrictive component of the surgical RYGB in its proximal part but also the malabsorptive component by ensuring that food has no contact with the bile and chyme coming from the papilla. This device was prospectively implanted in 12 patients. Early removal was necessary in 2 of them secondary to intolerance. Among the 10 remaining patients, the cuff partially detached from the cardia in 4. This detachment was presumed to explain a lower weight loss in that group of patients. Finally, the percentage of EWL at 1 year in the study was 36%. Interestingly, all comorbidities improved during the 12 months of the trial.<sup>36</sup>

### Other Procedures

#### Electrical Stimulation

Gastric electric stimulation can induce food intake reduction and gastroparesis, as well as modulate appetite-regulatory hormones. The Tantalusmeal activated device (MetaCure USA Inc., Orangeburg, NY) consists of 3 pairs of electrodes connected to a pulse generator that only delivers stimulation when eating starts. In a pilot study of 11 patients, an absolute weight loss of 5.3 kg and an improvement of diabetes control was reported after 6 months.<sup>37</sup>

#### Injections: Botulinum Toxin

Injection of botulinum toxin A (BoTox) into the gastric wall induces local and temporary paralysis of the muscle, which inhibits

**TABLE 43.2 Available Intragastric Balloons**

Balloon Type	Fluid or Air Filled	Particularities	Weight Loss
Orbera (Apollo Endosurgery, Austin, TX)	Fluid	Spherical silicone balloon Largest experience	Median % of Excess Weight Loss at six months –25% <sup>38</sup>

the release of acetylcholine at the neuromuscular junction. This can delay gastric emptying and also modulate local hormonal secretions. In an RCT, prolonged gastric emptying and significant weight loss (11.0 kg  $\pm$  1.0 vs. 5.7 kg  $\pm$  1.1) were reported 8 weeks after treatment, and a meta-analysis further confirmed the efficacy of this treatment. However, its high cost and the need to be repeated every 3 to 6 months limits its applicability.<sup>40,41</sup>

Table 43.1 summarizes current techniques of bariatric endotherapy for which clinical data are available. Further data are likely to become available, and the role of endotherapy in the management of obese patients undergoing bariatric surgery is likely to increase, rendering necessary the integration of endotherapy into the armamentarium of the multidisciplinary treatment of these patients.

Table 43.2 summarizes the different types of balloons evaluated in terms of particularities and their EWL effects.

## CONCLUSION

The role of endoscopy is expected to continue to evolve in the development of novel options for primary bariatric therapy, where endoscopy, in the setting of a multidisciplinary approach, is likely to represent a classic alternative within the upcoming years. Minimal thresholds have been defined for a technique to potentially be incorporated in clinical practice. They include an EWL of at least 25% at 12 months in patients with a BMI over 35. Obviously, not every technique will reach these thresholds, but if some do, and given the fact that a transoral approach has the major advantage of not compromising further surgery in the setting of a chronic, life-long disease, it is probable that primary endoscopic bariatric therapy will become part of the armamentarium for managing obese patients. In this case, it could become of particular interest as a first interventional therapy.

## INTRODUCTION

Obesity is a global epidemic, and has resulted in a substantial increase in the number of bariatric procedures performed worldwide.<sup>1–3</sup> As the field of bariatric surgery continues to grow with the increasing prevalence of obesity, a greater number of patients are referred for endoscopic evaluation after bariatric surgery. Despite improvement in the performance of bariatric surgery over the past decade, complications from the procedures are not uncommon. The type of complications and overall risk of adverse outcomes vary according to baseline patient characteristics, the duration of time since the operation, and the type of bariatric surgery performed.

A basic understanding of the anatomic changes and potential complications associated with bariatric procedures is essential for optimal assessment and appropriate treatment. A substantial number of these complications necessitate endoscopic interventions for accurate diagnosis and effective, minimally invasive management. This chapter will review the major complications, early and late, associated with the most commonly performed bariatric surgeries, and the endoscopic diagnosis and management of these complications.

## ROUX-EN-Y GASTRIC BYPASS (RYGB)

The RYGB has traditionally been the most common bariatric surgery procedure performed worldwide.<sup>1</sup> The surgery involves the creation of a small gastric pouch and an anastomosis to a Roux limb of the jejunum (Fig. 44.1A). The expected endoscopic findings following RYGB are therefore a normal esophagus and gastroesophageal junction leading into to a gastric pouch, typically 30 mL in volume at the time of bypass surgery. The gastrojejunal

anastomosis (GJA) is typically sized 10 to 12 mm, beyond which the efferent Roux limb is found, typically 75 to 150 cm in length. The jejunojejunal anastomosis leads to the common limb and the pancreaticobiliary limb (including duodenum and ampulla); however, intubation of the latter, for endoscopic retrograde cholangiopancreatography (ERCP) or assessment of the gastric remnant, is often technically challenging.

Although this altered anatomy leads to weight loss through a variety of mechanisms, there are several complications associated with this procedure, some of which are related to the altered anatomy, and others of which are specific to the surgical technique or approach (i.e., laparoscopic vs. open).

### Marginal Ulcerations

Marginal ulceration at the site of the GJA is not uncommon, and has been reported in up to 16% of patients after gastric bypass surgery (Fig. 44.2A).<sup>3–5</sup> The clinical presentation can range from being asymptomatic to having severe pain and obstructive symptoms or gastrointestinal bleeding, and, rarely, can present as perforation.

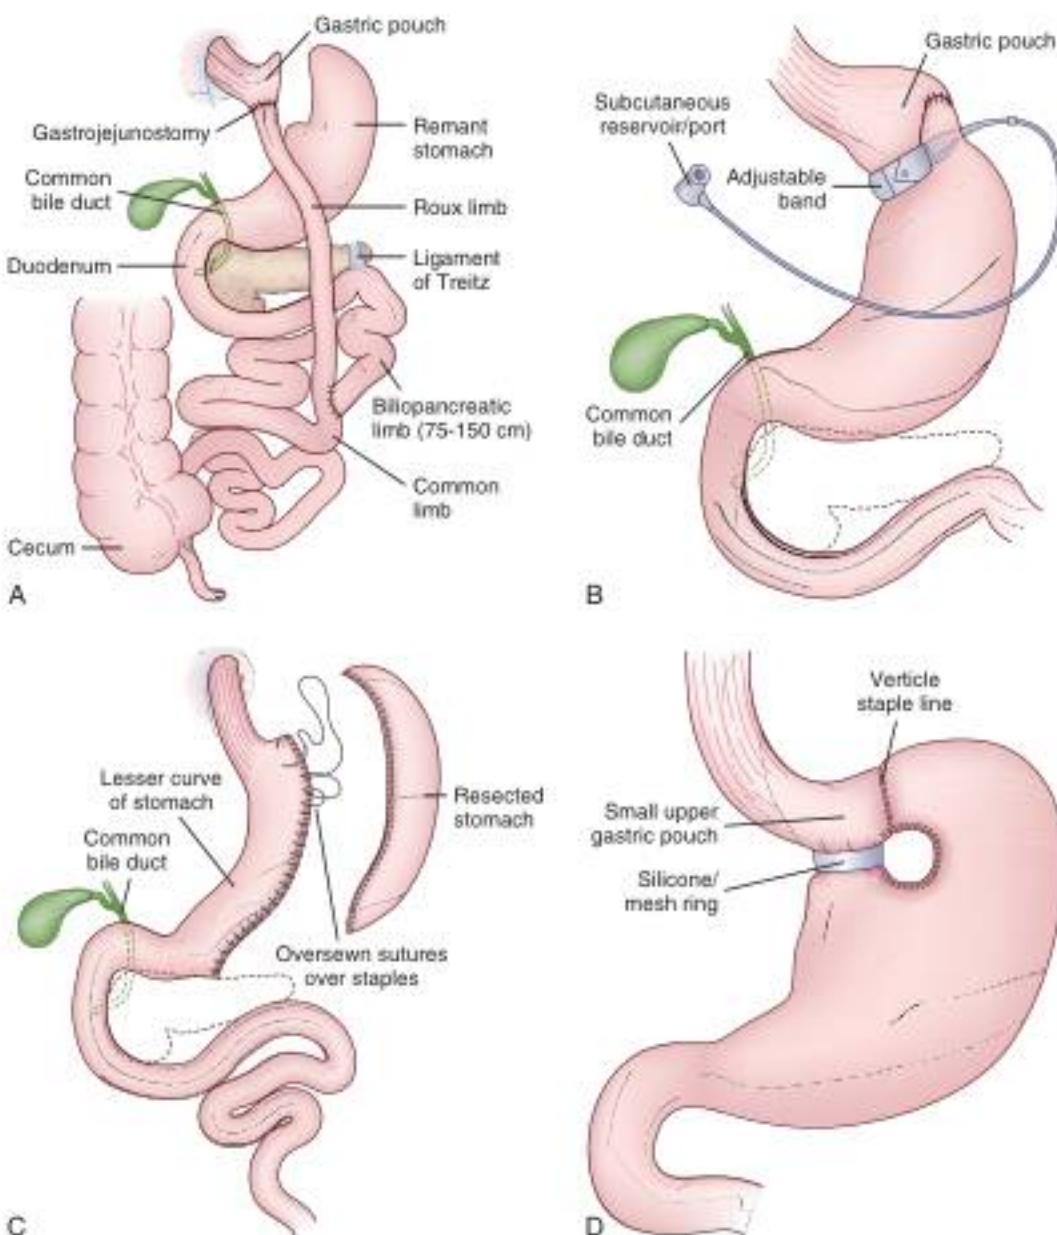

The mechanisms underlying the development of marginal ulceration have not been fully elucidated, and the etiology of this complication is likely multifactorial. There is substantial evidence that acidity plays a major role in the disease pathophysiology. Several potential inciting factors have been implicated including ischemia from the surgical creation of an anastomosis, foreign body materials (including staples or nonabsorbable sutures), gastogastric fistula (GGF) which lead to excessive acid exposure from gastric remnant, nonsteroidal antiinflammatory drugs (NSAIDs), immunosuppressive agents, smoking, and gastric pouch orientation or size.<sup>5–14</sup> The relationship between *Helicobacter pylori* (*H. pylori*) infection and the development of marginal

**Abstract**

Obesity is one of the most significant health problems worldwide, and the prevalence has been increasing over the past decade. Despite improvement in the performance of bariatric surgery, complications are not uncommon. These complications vary according to baseline patient characteristics, the duration of time since the operation, and the type of bariatric surgery performed. Endoscopy is the cornerstone in the diagnosis of postoperative complications after bariatric surgery, and may even be performed in the early postoperative course. With an increasing number of patients being referred for endoscopic evaluation following bariatric surgery, it is essential to develop an understanding of the anatomic changes for optimal assessment and appropriate treatment of these patients. In many cases, endoscopic intervention provides both diagnostic utility and a minimally invasive strategy for management. This chapter will review the major complications, diagnosis, and management of the most commonly performed bariatric surgical procedures including Roux-en-Y gastric bypass, sleeve gastrectomy, laparoscopic adjustable banding, and vertical banded gastroplasty.

**FIG 44.3** Suture material found in **A**, the gastric pouch and **B**, gastrojejunal anastomosis.

ulceration is controversial; however, a 2017 nationwide analysis suggests a strong association.<sup>13–17</sup>

During endoscopic evaluation, the gastric pouch should be closely inspected for a GGE. Endoscopic removal of foreign material, such as nonabsorbable suture or staples, should also be performed at the time of ulcer diagnosis<sup>22</sup> (Fig. 44.3). Pouch biopsies for *H. pylori* are less reliable, as most of the stomach where *H. pylori* resides is inaccessible.

The majority of patients with marginal ulcerations respond to medical therapy including high-dose proton pump inhibitor (PPI) therapy. PPI administration should be in soluble or open capsule form to enhance absorption, as recent evidence (2016) suggests it significantly decreases time to ulcer healing.<sup>23</sup> The addition of liquid sucralfate has also been advocated, in addition to smoking cessation and indefinite discontinuation of NSAIDs.

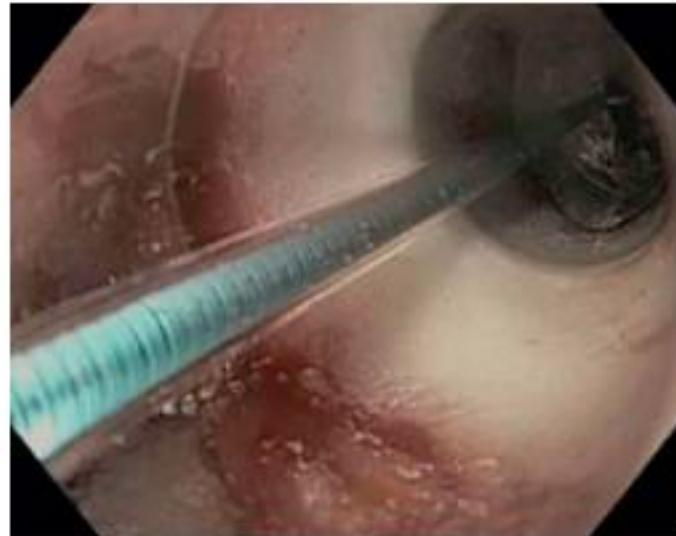

Endoscopic suturing techniques to oversew the ulcer have been described, with small case series demonstrating technical feasibility and efficacy.<sup>24</sup> Surgical revision of the gastrojejunostomy with truncal vagotomy has traditionally been performed in the small percentage of patients who do not improve. Reoperation, however, carries significant morbidity and a 7.7% recurrence rate.<sup>25</sup>

### Stomal Stenosis

Stricture of the GJA, also known as *stomal stenosis*, has been reported in up to one-fifth of patients undergoing RYGB, although the majority of studies report an incidence of less than 10%<sup>8,26–35</sup> (see Fig. 44.2B). Strictures can occur weeks to years after surgery. This complication is more common in patients undergoing laparoscopic RYGB, possibly due to the use of small-diameter circular staplers during the construction of the gastrojejunostomy. Tension or ischemia at the site of anastomosis, in addition to ulceration or anastomotic leak, may also contribute.<sup>34–36</sup>

Stomal stenosis often leads to symptoms of progressive dysphagia, nausea, vomiting, and inability to tolerate oral intake. Endoscopic visualization is the first diagnostic tool.<sup>37</sup> Although there is no clear definition for stomal stenosis, diagnosis is typically made when a patient is symptomatic and passage of a standard upper endoscope through the GJA is met with resistance.

Endoscopic balloon dilation of the stricture is used almost exclusively to treat this complication (Fig. 44.4). Serial dilation

**FIG 44.4** Endoscopic balloon dilation of stenosis of the gastrojejunal anastomosis.

using a through-the-scope balloon catheter should be performed with the goal of symptom resolution and target a stomal diameter of 8 to 12 mm, and rarely exceed 15 mm, as overzealous dilation may result in perforation or weight regain. The initial balloon size should be based on the estimated diameter of the anastomotic stricture, with effective dilation resulting in partial disruption of the GJA. A co-existent marginal ulceration may increase the risk of perforation, and dilation should be avoided or performed very carefully in this cohort of patients.

The majority of strictures can be effectively dilated in one or two sessions, with a 1- to 3-week interval between sessions. Other endoscopic interventions have also been reported with some success, including placement of a lumen-apposing metal stent (LAMS), needle-knife electroincision of the anastomosis, or steroid injection.<sup>38–40</sup> Surgical revision is required in a small percentage of patients who are refractory to endoscopic management, or in whom coexistent marginal ulceration precludes optimal treatment.<sup>41</sup>

### Leaks

One of the most serious complications of bariatric surgery is postoperative leak, which occur at multiple points along any staple line, and typically within days to weeks following the operation. The incidence ranges from 0.1% to 5.6%, and revision surgery predisposes to increased risk of occurrence.<sup>42–44</sup> The most common presenting findings are tachycardia, leukocytosis, and elevated inflammatory markers, but can also present as hemodynamic instability or sepsis.<sup>45</sup>

Identification of the location of the leak is critical, as that will dictate appropriate management. Leaks occurring at the pouch or GJA can be managed with endoscopic placement of self-expandable metal stents. To prevent both incomplete closure as well as stent migration or mucosal hypertrophy leading to increased difficulty of stent extraction, it has been proposed that the optimal time for stent removal is between 6 to 8 weeks.<sup>46</sup> Leaks at other sites may not be amenable to stenting, and other modalities have had variable results. Chronic leaks with a walled-off cavity should be treated like walled-off pancreatic necrosis. Surgical exploration is often required in patients who are unstable.

### Gastogastric Fistula

A GGF is an abnormal communication between the gastric pouch and the excluded stomach, or gastric remnant (see Fig. 44.2C). In the era of nondivided gastric bypass, GGFs were one of the most common complications, occurring in upward of half of all patients. With the advent of the divided RYGB, in which the gastrointestinal stapler simultaneously places rows of staples and transects the tissue between the rows, the incidence of GGF has declined to less than 6%.<sup>47–49</sup> Marginal ulceration, gastric leak, and foreign body erosion have all been additional postulated mechanisms for the development of this complication.<sup>45–48</sup>

The most common presenting symptom is weight regain or inability to lose weight, although pain, nausea, reflux, and emesis are often reported.<sup>50,51</sup> Endoscopy and upper gastrointestinal series should be performed to make the diagnosis, although GGFs can often be seen on abdominal computed tomography scan with oral contrast. On endoscopic evaluation, careful examination of the pouch should be performed, as GGF are often small and can be overlooked.

If present, maximum medical therapy should be instituted, with over one-third of patients experiencing symptom resolution. If the GGF is associated with a marginal ulcer, an initial conservative approach consisting of high-dose PPI therapy and liquid sucralfate may be sufficient to allow for fistula closure. NSAID use and smoking should be strictly avoided.

In a patient with persistent symptoms that are clearly attributable to the fistula, closure is indicated. Traditionally, procedural intervention has been accomplished via a surgical approach. However, endoscopic suturing symptoms should be considered, and these are especially effective when the fistula is less than 1 cm.<sup>51,52</sup> Use of over-the-scope clips have been described in small case series, but should be used with caution, as these may interfere with subsequent surgical intervention if it is required.<sup>53–55</sup>

### Gastrointestinal Bleeding

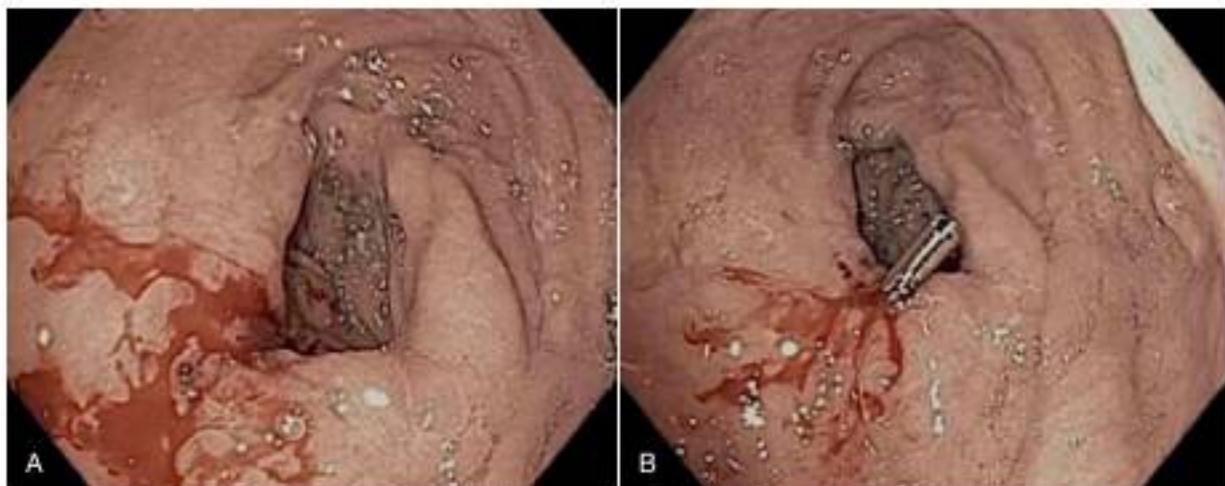

Gastrointestinal bleeding following RYGB is often seen at the gastrojejunostomy (Fig. 44.5). Hematemesis is the most common clinical presentation in early postoperative bleeds. Endoscopic management can be challenging because of the higher risk of perforation at the newly created surgical anastomosis. Carbon dioxide should be utilized instead of air insufflation, and the use of nonthermal devices such as clips is preferred for hemostasis.

Beyond the early postoperative period, endoscopic therapy can be achieved by standard hemostatic interventions such as injection of vasoconstrictors, thermal therapy, or mechanical modalities. Discontinuation of NSAIDs and smoking are advised. Balloon-assisted enteroscopy is often required to access the jejunoojejunostomy and enable retrograde examination of the bypassed stomach and duodenum.

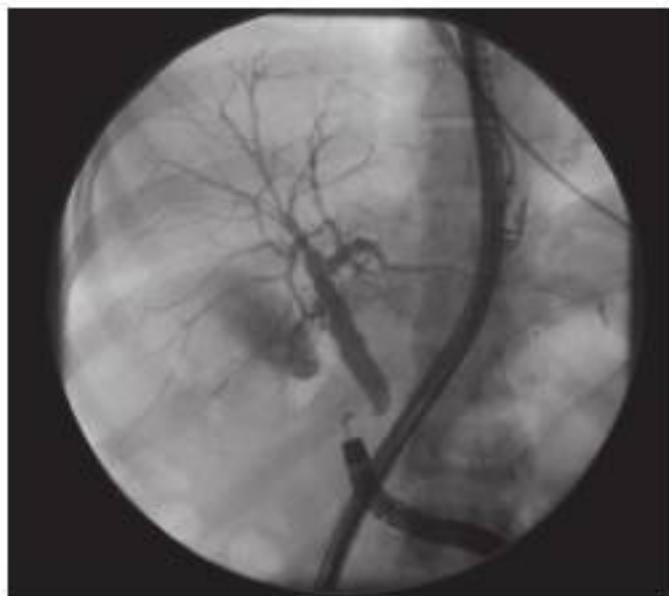

### Cholelithiasis and Choledocholithiasis

The development of cholelithiasis is not uncommon following RYGB, and is estimated to occur in 28% to 71% of patients within 6 months following surgery, with up to 40% of these patients becoming symptomatic.<sup>56</sup> Rapid weight loss has been shown to contribute to the formation of gallstones by increasing the cholesterol saturation in the bile and the gallbladder mucin concentration.<sup>56–61</sup>

Choledocholithiasis after RYGB can be particularly challenging to treat via ERCP due to the relative inaccessibility of the duodenum (Fig. 44.6). Use of a balloon-assisted enteroscope, pediatric

**FIG 44.5** **A**, Bleeding marginal ulceration. **B**, followed by endoscopic therapy.

**FIG 44.6** Use of balloon-assisted enteroscopy to perform endoscopic retrograde cholangiopancreatography in a Roux-en-Y gastric bypass patient.

colonoscope, spiral overtube, or duodenoscope back-loaded onto a guidewire is often required. If a GGF is present, the scope can pass directly through the remnant stomach and into the duodenum. Dilatation of the GGF may be performed if it is too small for scope passage, although subsequent closure is a concern. Placement of a prophylactic gastrostomy tube into the bypassed stomach, or endoscopic ultrasound (EUS)-directed gastrostomy, has also been described.<sup>62</sup> An alternative emerging procedure is the EUS-directed transgastric ERCP (EDGE) procedure that allows direct access through placement of a LAMS between the pouch and the gastric remnant,<sup>63,64</sup> although persistent GGF formation remains a theoretical concern.

### Dumping Syndrome

Early and late dumping syndrome occurs not uncommonly in patients who have undergone gastric bypass surgery when large quantities of simple carbohydrates are ingested. Early dumping typically occurs within 15 minutes of ingestion and has been attributed to rapid fluid shifts from the plasma into the bowel from hyperosmolality of the food. Late dumping occurs hours after eating and results from hyperglycemia and the subsequent insulin response leading to hypoglycemia. When hypoglycemia is severe, treatment with a low carbohydrate diet and an alpha-glucosidase inhibitor may be effective. Furthermore, restoration of gastric restriction using an endoscopic approach to reduce the aperture of the GJA has also demonstrated to be effective in management of this condition.<sup>65</sup> Symptoms of early and late dumping syndrome are shown in Box 44.1.

### Failure to Lose Weight or Weight Regain

RYGB is associated with 15% to 35% failure, defined as inability to achieve significant weight loss or excessive weight regain after initial adequate weight loss.<sup>66–70</sup> Whereas this may be due to progressive dietary noncompliance, anatomic changes may also predispose to weight regain. Dilatation of the GJA, development of a GGF, and enlargement of the gastric pouch also play a

### BOX 44.1 Symptoms of Early and Late Dumping

#### Early Dumping

- Gastrointestinal symptoms
  - Abdominal pain
  - Diarrhea
  - Borborygmi
  - Bloating
  - Nausea
- Vasomotor symptoms
  - Flushing
  - Palpitations
  - Perspiration
  - Tachycardia

#### Late Dumping

- Hypoglycemia
  - Perspiration
  - Palpitations
  - Hunger
  - Weakness
  - Confusion
  - Tremor
  - Syncope

From Thompson CC: *Bariatric endoscopy*. New York, 2013, Springer-Verlag.

significant role in weight regain, with the size of the GJA correlating linearly with the degree of weight regain.<sup>71</sup>

Endoscopic suturing, plication devices, and thermal therapy including argon plasma coagulation have been used to tighten the stoma and reduce pouch volume, with suturing demonstrating sustained weight loss at 3 years and level I evidence in a randomized controlled trial<sup>72</sup> (Fig. 44.7). These endoscopic therapies offer a less invasive option for management of post-bypass weight regain, with minimal morbidity.

### LAPAROSCOPIC ADJUSTABLE GASTRIC BANDING

Adjustable gastric banding is a restrictive procedure. Insertion of an adjustable, prosthetic band over the cardia of the stomach leads to formation of a gastric pouch with roughly 15 mL capacity (see Fig. 44.1B). The gastric band consists of a silicone ring connected to an infusion port, the latter of which remains in the subcutaneous tissue and can be easily accessed for saline injections to increase the degree of restriction. This type of procedure has the lowest peri-operative complication rate and mortality among all bariatric procedures; however, disadvantages include the presence of a foreign body.

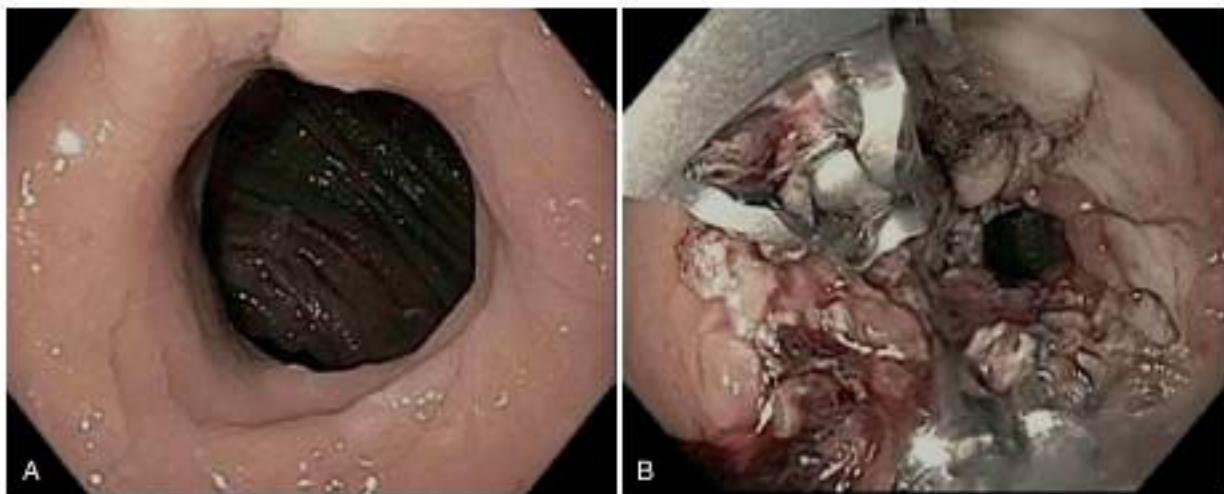

### Band-Related Complications

Band erosion is a severe complication of adjustable banding procedures and occurs in less than 10% of patients. Band erosion may occur early within weeks, or can be seen months and even years after operation.<sup>73,74</sup> Early erosions are usually secondary to undetected gastric perforations during surgery or early infection, whereas late erosions may be the consequence of gastric wall ischemia from an excessively tight band.

Clinical manifestations of this complication can range from weight gain to nausea and vomiting to life-threatening sepsis or massive hemorrhage, depending on the location of the erosion. Diagnosis can be made endoscopically, and depending on what portion of the band is visible, removal may be accomplished at the time of the procedure. Caution must be exercised if endoscopic removal of a gastric band is considered, especially when the penetration through the gastric wall is incomplete, as this endoscopic removal carries a high risk of gastric perforation.

### Esophageal-Related Complications

Reflux esophagitis are not uncommon following banding procedures, and typically require acid suppression therapy and

**FIG 44.7** **A**, Dilated gastrojejunostomy **B**, followed by endoscopic revision.

**FIG 44.8** Severe esophagitis following laparoscopic adjustable banding.

deflation of the band<sup>73,74</sup> (Fig. 44.8). Surgical revision is considered in patients who are unresponsive to maximum medical therapy.

Esophageal dilation proximal to the band can also occur if the band is excessively inflated. Symptoms include reflux, epigastric discomfort, and inability to tolerate oral intake. Typically, treatment involves deflation of the band and diet modification, but worsening esophageal dilation and inadequate weight loss mandate replacement of the band in a new location or conversion to an alternative bariatric procedure.

## SLEEVE GASTRECTOMY

Laparoscopic sleeve gastrectomy is a restrictive procedure in which a large portion of the greater curvature of the stomach is removed, with preservation of the pylorus and maintenance of physiological food passage (see Fig. 44.1C). Laparoscopic sleeve gastrectomy is increasingly being performed worldwide, and is now the most commonly performed bariatric surgery in the United States.

### Stenosis

Stenosis following sleeve gastrectomy occurs in up to 4% of patients. The site of stenosis is typically at the incisura angularis, and may be the result of over-sewing the staple line or using a bougie that is too small. Symptoms of obstruction can occur depending on the severity of the narrowing.

This diagnosis is typically made by upper endoscopy or with fluoroscopy using an upper gastrointestinal series, but can often be missed by upper endoscopy, as often there is no physical resistance to gastroscope passage. Successful balloon dilation of both the pylorus and incisura starting with a 20-mm hydrostatic balloon, followed by pneumatic balloon dilation from 30 mm to 40 mm at increasing pressures every 2 to 4 weeks, has been demonstrated to be safe and with high efficacy rates, with a small case series demonstrating 94% patients with resolution of symptoms.<sup>75</sup> This new method may offer a less invasive alternative to surgical revision.

### Anastomotic Leaks

Gastric leaks have been reported in up to 5.3% of patients, and usually occur along the superior aspect of the staple line just below the gastroesophageal junction. Leaks can be the result of inadequate healing of the gastric tissue from poor blood supply and oxygenation, or from heat generated from cautery during dissection of the greater curvature. This complication is one of the most serious. Endoscopic approaches have proven successful, and offer a less invasive first-line therapy to reoperation for many patients. If the leak occurs within 6 weeks, stent placement followed by dilation of the pylorus to treat distal obstruction should be performed. Leaks that occur more than 6 weeks following surgery require management similar to an endoscopic necrosectomy whereby pigtail stents are placed and tissue débrided. Endoscopic septotomy has also been described and used to facilitate healing of refractory leaks. This procedure is performed by incision and enlargement of the fistulous tract, thereby allowing direct communication with the gastric lumen and promoting internal drainage.<sup>76</sup>

## VERTICAL BANDED GASTROPLASTY

Vertical banded gastroplasty (VBG) involves the creation of a small proximal gastric pouch of less than 50 mL lined by a vertical

staple line and a tight prosthetic mesh that is sutured to itself but not the stomach (see Fig. 44.1D). This is a purely restrictive procedure and has the benefit of providing an outlet diameter that should remain constant.<sup>48</sup> Although this type of procedure has largely been replaced by other procedures, familiarity with the complications and the role of endoscopic management is still important.

### Staple Line Dehiscence

Staple line dehiscence can result in a fistula to the fundus, often leading to failure to lose weight or weight regain following the procedure. It is found in as many as half of all patients on routine postoperative endoscopy, but has also been described following blunt abdominal trauma. Endoscopy is helpful in diagnosing and evaluating the disruption, and endoscopic suturing systems may ultimately prove to be effective in treatment of this condition.

### Band Erosion

Band erosion develops in approximately 1% to 2% of patients with VBG, with clinical symptoms of weight regain and abdominal pain. Erosion of the mesh band is a late complication of this procedure, and can be removed via an endoscopic approach, but may ultimately require reoperation or conversion to RYGB.

### Obstruction/Pouch Dilatation

Obstruction from stomal stenosis can occur and be managed by endoscopic balloon dilation, although results are often short-lived and revision may be necessary when symptoms persist. Pouch dilation can occur as a consequence of stomal obstruction, band erosion, or staple line dehiscence. Endoscopy is the modality of choice for diagnosis.

## CONCLUSION

Obesity is one of the most rapidly emerging health problems worldwide. Although bariatric surgery is effective in achieving weight loss and resolution of comorbidities, complications are not uncommon. A basic understanding of the anatomic changes and potential complications associated with bariatric procedures is essential for optimal assessment and appropriate management.

### INTRODUCTION

Natural orifice transluminal endoscopic surgery (NOTES) is an evolving concept, combining minimally invasive surgery with flexible endoscopy, potentially representing a major paradigm shift to scarless surgery. Recently, NOTES went from few experimental reports to clinical series and multicentric studies.<sup>1,2</sup> Since the early concept, from pioneers such as Kalloo and Kantsevoy<sup>3</sup> in the United States, and Rao and Reddy<sup>4</sup> in India, NOTES has emerged as a promising new alternative to open and laparoscopic surgery for abdominal access. Potential benefits include decreasing surgical incision complications, such as incisional hernias, adhesions, intestinal obstruction, scars, and wound infection, together with better aesthetics. This evolution led to the first successful series of clinical applications in the literature for transvaginal (TV) and transgastric (TG) NOTES.<sup>5</sup>

Intramural surgery is an exciting new technical possibility, allowing for unimagined therapy for submucosal tumors, access for endoscopic techniques, and submucosal myotomy for achalasia. New tools and evolution of these techniques are changing the way many problems in gastroenterology are resolved. This chapter reviews early procedures and current clinical applications of intramural and transmural endoscopy.

### INTRAMURAL ENDOSCOPY TECHNIQUES

#### Techniques for Creation of a Submucosal Working Space

##### Submucosal Endoscopy With Mucosal Safety Valve Technique

The submucosal endoscopy with mucosal flap (SEMF) technique may offer safe access to the peritoneal cavity for NOTES surgery.

The submucosal space functions as a tunneled portal and the free overlying mucosa as a protective sealant flap, minimizing contamination of the extraluminal peritoneal cavity.

In the original SEMF technique, balloon dissection combined with high-pressure carbon dioxide (CO<sub>2</sub>) is used to dissect the submucosa.<sup>6</sup> A submucosal injection of saline is used to identify the submucosal tissue plane, then bursts of CO<sub>2</sub> are injected to create a gas-filled submucosal bleb, followed by injection of hydroxypropyl methylcellulose, which prevents gas escape. A mucosal incision is made with a needle-knife at one margin of the bleb/fluid cushion to allow entry below the mucosa. Balloon dissection can be performed to transform the submucosa into an intramural free space. Blunt dissection with grasping forceps can also be used (Fig. 45.1).

#### Chemically Assisted Submucosal Dissection Technique

Aiming to minimize mechanical trauma to the mucosal flap, mesna was discovered as a useful adjuvant to the blunt dissection, acting by chemically softening the submucosa. In this technique, mesna solution is injected into the saline submucosal bleb before initiating balloon dissection.<sup>7</sup>

#### Peroral Endoscopic Myotomy

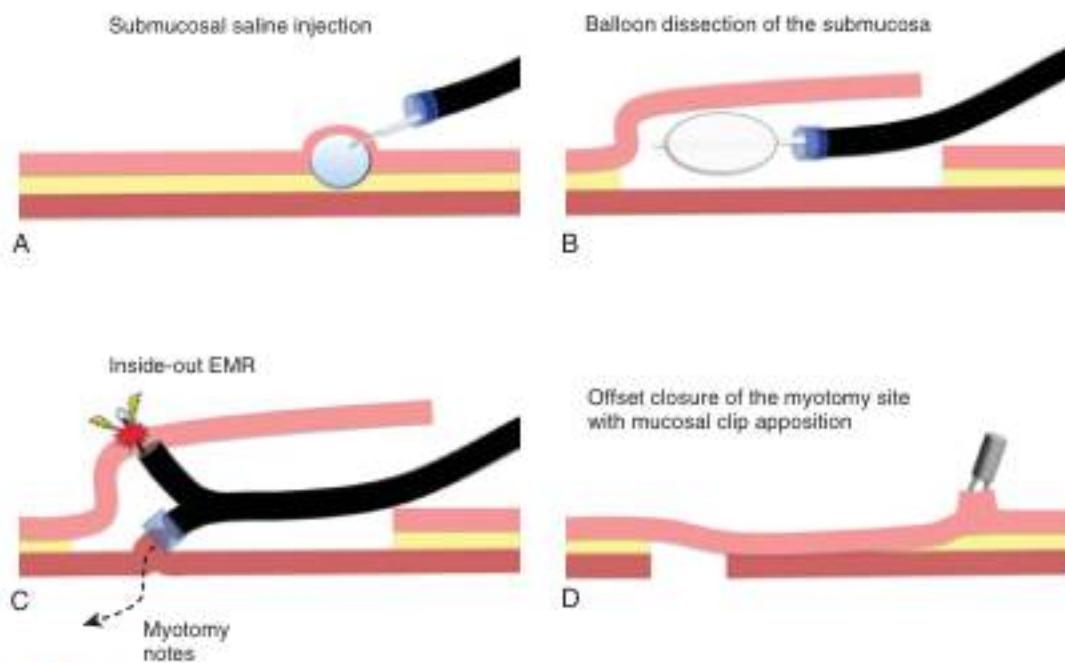

Achalasia is an esophageal motility disorder for which treatment, until recently, was restricted to pharmacotherapy, balloon dilatation, botulinum toxin injection, and surgical intervention (e.g., Heller myotomy) with the aim to reduce lower esophageal sphincter pressure. Conservative treatment has limited efficacy, frequently needing repeated procedures, whereas surgical treatment requires additional fundoplication to prevent gastroesophageal reflux. Due to this, novel technologies have been explored to treat this pathology. Peroral endoscopic myotomy (POEM)

**Abstract**

Transmural and intramural endoscopic surgery represents a new step in minimally invasive surgery and endoscopy, with the potential to be applied for similar indications as laparoscopic and open surgery to improve patient care. In recent years, experimental studies evolved to successful clinical series on natural orifice transluminal endoscopic surgery (NOTES). In this chapter, clinical applications on intramural endoscopy, especially for peroral endoscopic myotomy (POEM) technique and NOTES transgastric, transvaginal, and transanal (transrectal) access, are discussed and evaluated, with critical view of limitations, complications, and need for new technology.

**FIG 45.1** Submucosal flap construction. **A**, A small submucosal saline bleb is made to identify the submucosal tissue plane. **B**, After pretreatment of the submucosa with high-pressure carbon dioxide ( $\text{CO}_2$ ) or mesna, balloon dissection is performed to create an open space within the submucosal tissue plane. **C**, The submucosal space is used as a working space for interventions such as inside-out submucosal endoscopy with mucosal resection, intramural myotomy, and offset access for natural orifice transluminal endoscopic surgery (NOTES) procedures. **D**, The muscular defect after myotomy is sealed with an overlying mucosal flap, and the submucosal tunnel is closed with mucosal clip apposition. *EMR*, endoscopy with mucosal resection.

is a novel procedure, first performed in humans by Inoue et al (2010),<sup>7</sup> that has been established as safe, minimally invasive, and with expected long-lasting symptom control.

The technique involves four major consecutive steps: esophageal mucosal incision and entry into the submucosal space; creation of a submucosal tunnel; incision of the esophageal muscles (myotomy); and closure of the mucosal incision. It can also be used in patients with recurrence after other treatments have been performed.

### Technique

The procedure is carried out with the patient under general anesthesia, with positive pressure ventilation, using higher pressures than those generated by endoscopic  $\text{CO}_2$  insufflation. A submucosal injection is administered at the level of the mid esophagus, 13 cm proximal to the gastroesophageal junction (GEJ), followed by injection of saline with 0.3% indigo carmine. A 2-cm longitudinal mucosal incision is made on the mucosal surface to create an entry to the submucosal space. A long submucosal tunnel is then created, of approximately half the circumference of the tubular esophagus. Dissection of the circular muscle bundle is subsequently initiated. When the tip of the endoscope reaches the stomach region, the submucosal space becomes wider, and muscle layer cutting is continued for approximately 2 cm distal to the GEJ. Complete division of the circular muscle bundle is confirmed by endoscopic appearance. The mucosal entry is closed with hemostatic clips.<sup>7</sup>

### Results

In a series of 500 cases of patients who underwent POEM for achalasia, Inoue et al (2015) describe significant reductions in symptom scores and lower esophageal sphincter pressures.<sup>8</sup> Gastroesophageal reflux was noted in 16.8% of patients at 2 months and 21.3% at 3-year follow-up. Median total length of the endoscopic myotomy was 14 cm in the esophagus and 3 cm in the stomach. Median procedure time was 90 minutes (range: 70.8–119 minutes). Procedure-related adverse events were observed in 16 patients (3.2%). In all cases the POEM procedures were accomplished successfully, including those with adverse events. The overall success rate at 2 months, 1–2 years, and 3 years was 91.3%, 91%, and 88.5%, respectively.<sup>8</sup>

A meta-analysis evaluating studies using POEM for achalasia, comprising 1045 patients, concluded that there was no difference between POEM and laparoscopic Heller myotomy in reduction in Eckhart's score, postoperative pain and analgesic requirements, length of hospital stay, adverse events, and gastroesophageal reflux. Operative time was significantly lower for POEM. In the review, POEM was effective for achalasia, with similar outcomes as surgical myotomy.<sup>9</sup>

After several published series, POEM can be offered to almost all achalasia patients, with a low complication rate. According to Inoue et al, sigmoid esophagus, dilated esophagus, and long duration of symptoms do not appear to be a barrier to successful treatment with POEM.<sup>8</sup>

## TRANSGASTRIC ENDOSCOPIC SURGERY

TG NOTES was the first natural orifice access proposed by researchers, mainly because of familiarity of gastroenterologists and surgeons with upper flexible endoscopy, and the availability of endoscopic sets. TG procedures have the potential of completely avoiding incision complications, and may produce less pain.

### Technique of Transgastric Surgery

The patient is sedated with general anesthesia and placed in a Lloyd-Davies position. Pneumoperitoneum can be achieved using a Veress needle, followed by insertion of an umbilical laparoscopic optic, which allows peritoneoscopy to evaluate the feasibility of the procedure, safe transluminal entrance of the endoscope to the abdominal cavity, and facilitates closure of the gastric wound after the procedure.

The access technique starts by perorally passing a flexible endoscope into the stomach. The gastric contents are aspirated before advancement into the peritoneal cavity, and lavage with dilute chlorhexidine can be performed. Use of an esophageal overtube can protect against esophageal trauma due to instrumentation. The site of the gastric puncture is selected by laparoscopic guidance, with two relatively avascular areas in the stomach considered adequate for the approach: the proximal body, midway between the lesser and greater curvatures of the stomach, and a similar site in the distal antrum.<sup>4</sup> The gastric fundal region is avoided because of danger of damaging short gastric vessels and the spleen. A perforation of the wall is created by needle knife at the chosen site. The needle is withdrawn and an endoscopic balloon dilator is passed over the hole and positioned across the gastrotomy. The balloon is inflated completely and the endoscope is progressed into the peritoneal cavity.

Specimens can be extracted without special bags, and when the specimen diameter exceeds the diameter of the esophagus, open conversion by umbilical access and extraction is the solution.

An issue of the TG approach is reliable gastrotomy closure, as postoperative leaks for TG abdominal surgery cannot be tolerated. Tissue apposition and clipping have been widely used since

early reports, but the endoscopic clipping devices were developed for control of gastrointestinal bleeding and are therefore unreliable for NOTES closure.

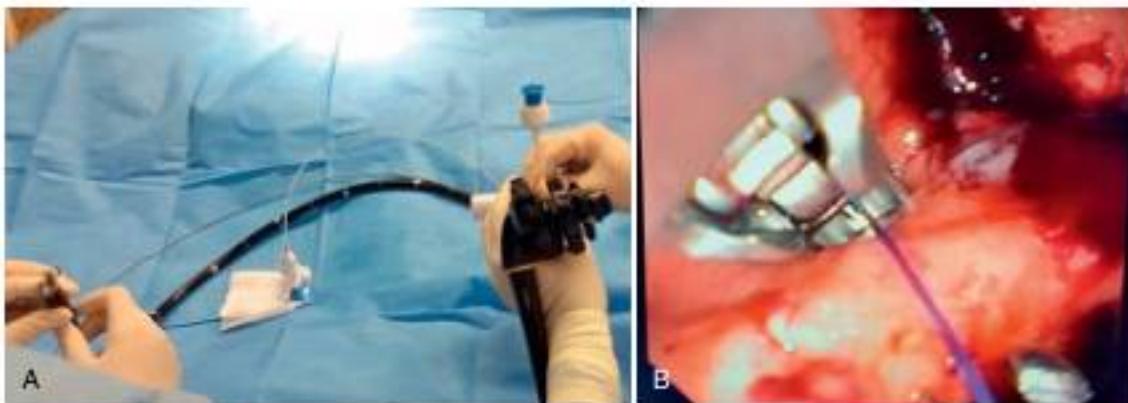

The use of endoscopic clips for closure was reported in most experimental studies and in the first casuistic of Rao and Reddy.<sup>5</sup> Differently from a gastric incision or an iatrogenic perforation, the gastrotomy created by the balloon dilation technique closes spontaneously after removal of the endoscope. Multiple clips can be applied to approximate and close the wound, starting from the periphery and moving to the center. However, most clips approximate only mucosa, and this can be an issue for further applications. Similar techniques have been used to close the gastric defects following endoscopic mucosal and submucosal resections.

In the laparoscopic closure, another 3-mm trocar can be inserted to aid in gastrotomy closure, using single-hand suture, by inserting a needle-holder through this trocar and a laparoscope through the umbilical trocar. This closure is also monitored by the endoscope, which is withdrawn and kept in the gastric lumen while the bites are taken.<sup>6</sup>

There are now several novel full-thickness closure devices, such as T-Tag tissue anchors (Olympus Corporation of the Americas, Center Valley, PA), the flexible linear stapling device (Power Medical Interventions, Langhorne, PA), the G-Prox (USGI, San Clemente, CA), the Eagle Claw (Olympus), the OverStitch (Apollo Endosurgery, Austin, TX), and the OTSC (Over The Scope Clip, Germany). Studies are under way to evaluate the efficacy of these new methods. Apollo Overstitch is currently the most reliable method of closing gastric defects, and there are growing applications in endoscopic sleeve gastroplasty for primary endoscopic therapy for obesity<sup>10</sup> (Fig. 45.2).

### TG Cholecystectomy

Usually, one 3- or 5-mm trocar is placed at the umbilicus for guiding the endoscope's safe TG exit, and later, for retracting the gallbladder fundus. Dissection can be performed either endoscopically or laparoscopically. In the series by Dallemande et al (2009), the umbilical trocar was also used to allow entry of a laparoscopic clip applier.<sup>11</sup>

**FIG 45.2** **A,** The Apollo Overstitch suturing device is currently used to close gastric and esophageal defects, fix gastroesophageal stents, and perform primary endoscopic therapy for obesity. Assembly of the Apollo Overstitch to the double-channel endoscope outside the patient. **B,** Internal view of endoscopic sleeve gastroplication (ESG) for morbid obesity. Six to nine sutures are placed in the greater curvature of the stomach for gastric reduction. The motility and emptying of the stomach are delayed, therefore producing restriction and feelings of satiety.

### TG Appendectomy

TG appendectomies are performed initially using a 3- or 5-mm umbilical trocar to guide peritoneal access by the endoscope. The same trocar can later be used for retracting the appendix. All the steps are usually performed without any other extra trocars until the extraction of the specimen. At that point, a 5-mm right pararectal trocar can be inserted to aid in gastrotomy closure.

### Clinical Transgastric Endoscopic Surgical Results

TG access was inspired by the initial description of Seifert et al (2000), who performed TG debridement of necrotizing pancreatitis using flexible endoscopy.<sup>12</sup> To date, there are only a few reports of clinical TG surgery for cholecystectomy, appendectomy, and cancer staging, with good results in a small number of cases.<sup>3,4,13–19</sup>

In the largest prospective multicenter database available in the literature, 362 patients were prospectively documented, including TG and TV cases, of which there were 29 TG cholecystectomies and 14 TG appendectomies.<sup>1</sup> The operative time for NOTES cholecystectomy did not differ significantly between TV (96.1 min) and TG access (110.93 min). In comparison to TV appendectomy, TG appendectomy had significant longer operative time (60.5 vs. 135.5 min). The main challenges were retroflexion of the endoscope, generating difficulty in orientation and restricted dissection possibilities, and gastric opening and closure. In one TG cholecystectomy case, the retrieval specimen was too large (a 2.4-cm gallstone) and could not be extracted through the oropharynx, requiring removal through an umbilical incision. In two cases where no overtube was used, large specimens also caused esophageal hematoma and laceration, and longer operative times.

Complications were recorded in 32 patients in general (8.84%). In one case of TG cholecystectomy, the patient was readmitted on the 5th postoperative day due to diffuse abdominal pain and distention. Laparoscopy was performed and diffuse peritonitis caused by *Streptococcus faecalis* was found, but without gastric fistula. Abdominal fluid aspiration and washing with saline solution was performed, with good postoperative course. In one patient, the passage of a large calculi with an inflamed gallbladder led to perforation of the proximal esophagus requiring a thoracic operation and longer intensive care unit admission.

A longer learning curve for TG surgery is expected. The lack of instruments to perform adequate dissection and retraction, the need for retroflexion and for flexible endoscopy skills, and the small size of the esophageal lumen contribute to longer operative times and complications than TV NOTES.

Large-specimen retrievals are not suitable for TG surgery, as the esophagus allows only a maximal instrumental (or specimen) diameter of approximately 2 cm. TV NOTES has less potential for complications such as fistula and peritonitis than other transluminal accesses. Potential disadvantages of NOTES surgery are the necessary use of antibiotics, possible trauma to the oropharynx, and risk of infection and morbidity of gastric, vaginal, and colonic access, still with longer operative times.

Currently, after all this clinical experience, TG abdominal surgery is limited to pancreatic endoscopy for debridement, pseudocyst drainage, and oncologic biopsies. Advanced flexible NOTES TG surgery is still waiting for technology to allow safe and effective applications.

### TRANSVAGINAL ENDOSCOPIC SURGERY

TV access has been established in gynecology for many years and is increasingly used in abdominal surgery. In 1813 the German surgeon C. Langenbeck performed the first TV hysterectomy.<sup>20</sup> In 1901 the Russian physician Dimitri von Ott published the first report about the so-called ventroscopy,<sup>21</sup> access to the abdominal cavity by colpotomy without using optics. Decker designed his "Culdoscope" and performed diagnostic culdoscopy.<sup>22</sup>

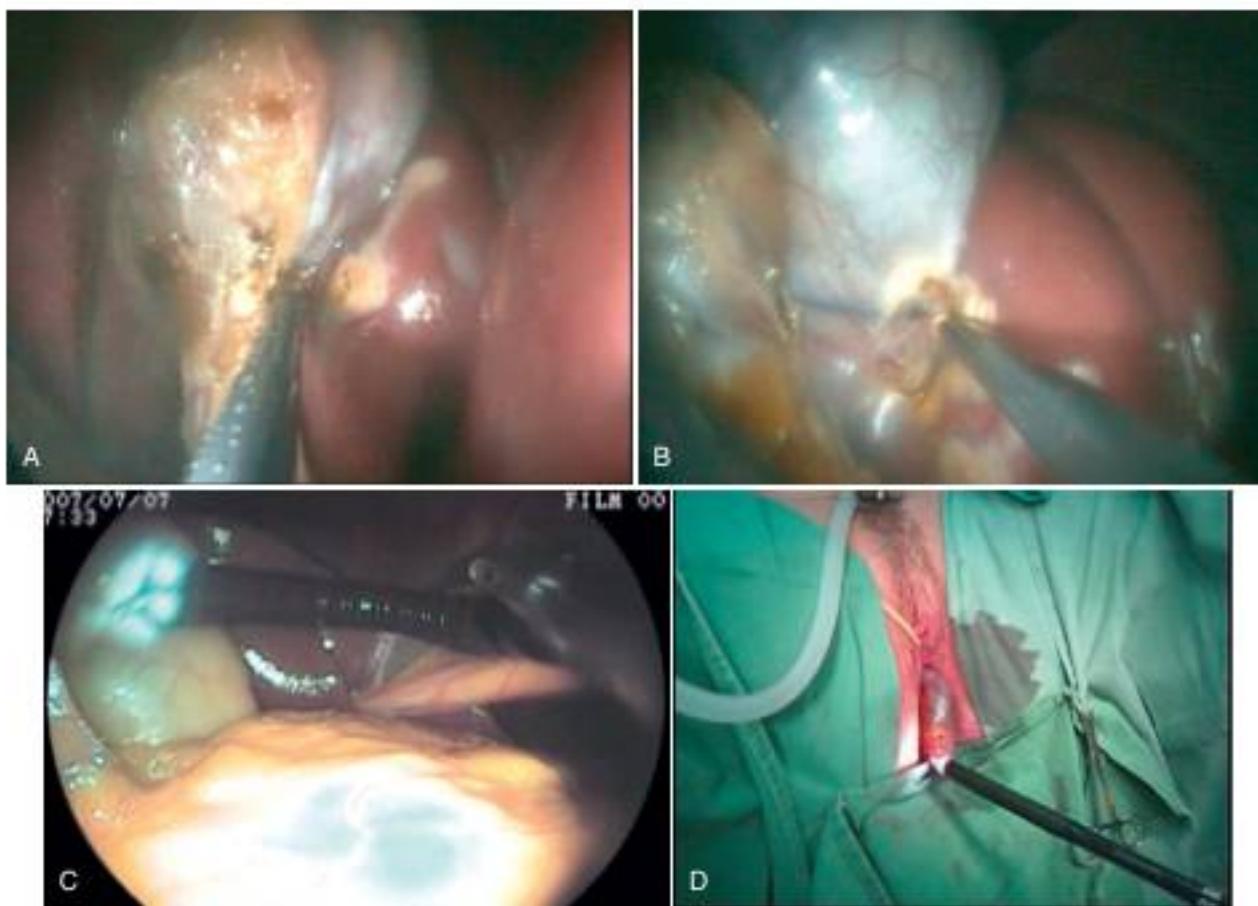

In 2007, Tsin et al published a review of 100 culdolaparoscopic cases, referred to by the authors as "mini-laparoscopy assisted natural orifice surgery" (MANOS).<sup>23</sup> Multiple procedures were reported: appendectomy, cholecystectomy, salpingo-oophorectomy, myomectomy, ovarian cystectomy, and culdolaparoscopy during vaginal hysterectomy. In 2007, Zorrón et al published the first cases of flexible NOTES TV cholecystectomy,<sup>24</sup> (Video 45.1) and soon other groups added more clinical experience.<sup>25–28</sup>

### Transvaginal Access Technique

In the majority of procedures, the patient is placed in the lithotomy position, and vaginal preparation is carried out with povidone-iodine or chlorhexidine gluconate solution. TV access can be obtained under laparoscopic view of the cul-de-sac or directly by colpotomy without guidance from a laparoscope. A speculum is inserted into the vagina to expose the posterior fornix and visualize the cervix, and its posterior lip is retracted to facilitate visualization of the cervicovaginal junction. A small incision is made in the posterior fornix, usually under visualization from a laparoscopic camera in the abdomen. The safest area to access the abdomen is known as the triangle of safety: after visualization of the cervix and posterior fornix, a clock located at the base of the cervix is envisioned, with the superior two corners of the triangle being the 4 o'clock and 8 o'clock positions.<sup>29</sup> Insufflation is commonly performed with a Veress needle placed in the umbilicus or abdominal wall. Alternatively, TV insufflation of the peritoneal cavity can be achieved either with a Veress needle placed in the posterior cul-de-sac, transuterine, or through a transvaginally placed port. If a flexible endoscope is used, insufflation can be established through one of the working channels. A wide variety of different ports and systems are currently used for TV NOTES. For colpotomy closure, absorbable suture in either an interrupted or running fashion using the directly visualized TV technique is recommended.

In a prospective multicenter study, the German Registry for Natural Orifice Endoscopic Surgery, a total of 551 patients were reported.<sup>2</sup> Cholecystectomies were the main procedure (85.3%), appendectomies were performed in 7.3%, and six patients received bariatric operations. All NOTES operations were performed transvaginally, with the hybrid technique (with an additional transumbilical trocar) being used in 99.3%. Rigid endoscopes were used in most cases for TV access. One appendectomy for chronic appendicitis was performed using the pure NOTES technique, with a flexible endoscope and no transabdominal trocars. The overall complication rate was low (2.9%), occurring only in cholecystectomies.<sup>2</sup>

In the International Multicenter Trial on Clinical Natural Orifice Surgery, two access methods were described.<sup>1</sup> Some centers performed abdominal insufflation by means of a Veress needle in the abdomen, and others achieved good results by directly accessing the cavity through a direct-view vaginal access. Different techniques for TV cholecystectomy were described. A total NOTES dual scope method used two endoscopes through the vaginal

**FIG 45.3** **A**, Transvaginal flexible cholecystectomy, dissection of gallbladder from the liver bed. **B**, Flexible endoscopic dissection of Calot's triangle by natural orifice transluminal endoscopic surgery (NOTES) transvaginal flexible cholecystectomy. **C**, Transvaginal introduction of two endoscopes (one gastroscope, one colonoscope) to perform total NOTES cholecystectomy. **D**, Transvaginal extraction of the specimen.

incision, with no use of laparoscopic instruments or camera (Fig. 45.3). A hybrid NOTES technique used the laparoscopy for safer access, visualization, and dissection, allowing a shorter operative time. Finally, TV trocars can also be used combined with mini laparoscopy instruments through the umbilicus. The complication rate for TV surgery was 6.9%. Mean intraabdominal CO<sub>2</sub> pressure did not show significant differences between the types of access and surgeries performed. Visualization of the cavity was mostly described to be of very good quality. When an abdominal trocar was inserted, insufflation through that trocar or Veress needle was preferred.<sup>1</sup>

In the series by Federlein et al (2010), satisfaction of patients with the result of the operation was high, and most would recommend TV access to others.<sup>31</sup> This painless access often requires very few postoperative analgesia. Dyspareunia has been mentioned as a possible complication of the TV approach, but it has not been recorded as a complication in most clinical series so far. On the contrary, TV access is used for diagnostic investigation of infertility, which in turn may be associated with sexual disturbance. The fornix of the vagina has very low sensible innervation. In our experience and from other authors, there is no detection of disturbance of sexuality in operated patients. The possibility of adhesion formation after incision of the posterior vault has thus far not been investigated.

Comparative studies on TV versus laparoscopic cholecystectomy have shown some advantages for the former.<sup>32</sup> In certain centers, TV cholecystectomy is no longer considered an experimental technique and may be routinely offered as a scarless option for cholecystectomy in female patients.

### TRANSRECTAL NOTES AND TAMIS TOTAL MESORECTAL EXCISION

Transanal NOTES surgery has been the subject of a few recent experimental studies, suggesting that this access route can be an attractive option for treating colonic and abdominal diseases.<sup>33–35</sup> Technical obstacles for colonic access include risk of infection and leaks, safe entrance into the abdominal cavity, and reliable colonic closure, which all hinder transcolonic clinical applications.

Intrarectal surgery seems to add the advantages of transanally endoscopic microsurgery (TEM) together with transanal extraction of the specimen (natural orifice specimen extraction, or NOSE<sup>33</sup>), and can be performed either with flexible or with rigid instruments. We can imagine that in a few years, most colorectal surgery will be performed predominantly through natural orifices using single ports, endoscopes, transluminal devices, and even one-arm robotics and miniature robots, and cameras. It will be

potentially possible to reach resections of any part of the colon as new technology becomes available.

Compared with TG access to the abdominal cavity, the transanal route offers potential advantages, by eliminating the need to retroflex the scope and other instruments in the upper abdomen. NOSE via TV and, more recently, transrectal access has been increasingly used to avoid larger incisions in laparoscopic surgery for large-organ extraction. NOTES TV sigmoidectomy, assisted by mini laparoscopy, was described by Lacy et al (2008), denominating the technique as MA-NOS in a patient with sigmoid cancer,<sup>36</sup> and Burghardt et al (2008) described the first case of NOTES TV right colectomy.<sup>37</sup>

#### **Human Transanal Down-to-Up TME**

The term *down-to-up total mesorectal excision* (TME) was coined in 2009 to describe the technique of cephalad progression of mesorectal dissection in transanal resections for rectal cancer.<sup>38</sup> Contrary to laparoscopic TME, this procedure allows easy identification of the distal limits of the tumor and promotes an excellent clearance of the distal resection margin. Our group published oncologic down-to-up TME (or transanal minimal invasive surgery TME [TAMIS-TME]) using a flexible colonoscope to enter the presacral plane and dissect the mesorectum (Fig. 45.4).

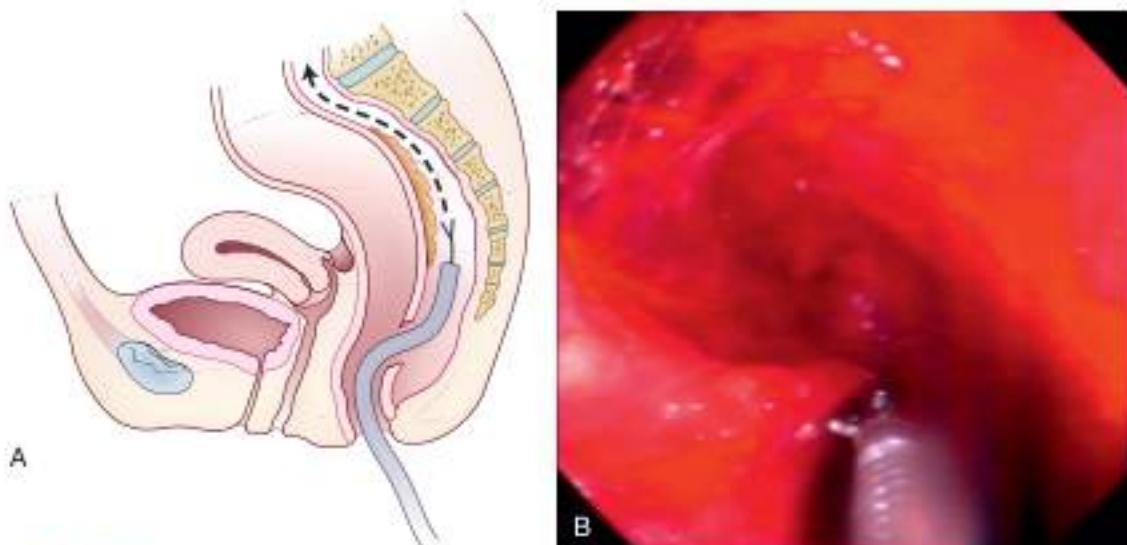

The current standard of care in the treatment of rectal cancer implies high ligation of the inferior mesenteric artery and total mesorectal resection with en bloc lymphadenectomy. The precise TME plane of dissection, described by Heald in the early 1980s, resulted in a better oncologic anatomical specimen without cell spillage, improving results and reducing the indication of abdomino-perineal resections.<sup>39,40</sup> From our experience with down-to-up TME, an adequate dissection with preservation of the mesorectal envelope can be achieved by flexible or rigid technique. Transanal NOTES TME is performed in the same anatomical plane but in the opposite direction (from anal to

rectosigmoid junction), beginning the dissection by gaining access to the presacral plane between the presacral fascia and the mesorectum. The progression of the cephalad dissection is improved by the retropneumoperitoneum inside this avascular plane.

The history and progress of transrectal NOTES is undoubtedly due to the pioneer efforts of Gerhard Buess, who in the early 1980s described TEM, which is still the standard therapy for most low-rectal benign lesions.<sup>41</sup>

#### **Down-to-Up Transanal NOTES TME Using a Single-Port Platform**

Down-to-up TME using rigid intrarectal laparoscopy and a single-port device implies initial low circular full-thickness access to the anatomic plane of presacral space, evolving the dissection cephalad and circumferentially.<sup>42</sup> The patient is placed in the Lloyd-Davies position, receiving a single dose of intravenous antibiotic prophylaxis. Transabdominal laparoscopic high ligation and left-colon mobilization can be performed at the beginning or after the mesorectal resection. When the procedure is started with the laparoscopic step, care must be taken to not dissect the upper rectum and posterior mesorectum, due to the risk of gas leakage when performing transanal TME. The rectal lumen is disinfected with iodopovidone solution, and a disposable single-port access device is inserted transanally. It has three channels for instrumentation, and one or two additional channels for CO<sub>2</sub> insufflation. A laparoscopic camera and instruments are inserted through the port to act intraluminally. The inferior limits of the tumor are identified, and the lower resection limit is chosen at the desired line of anastomosis. A purse-string suture is transanally performed at an adequate distance from the tumor margin. This unique characteristic of the down-to-up technique allows for adequate visualization of the tumor margin and resection line, which is different from laparoscopic TME. The

**FIG 45.4 A,** Diagram illustrating introduction of the endoscope in the presacral space for flexible natural orifice transluminal endoscopic surgery (NOTES) Down-to-Up total mesorectal excision (TME). The endoscope is inserted directly in the presacral space, 2–3 cm above the dentate line, allowing flexible dissection in the anatomic oncologic plane from below. **B,** Endoscopic view of flexible Down-to-Up TME for rectal cancer in a patient using a standard colonoscope. Total mesorectal resection is progressively accomplished using endoscopic monopolar scissors inside the ideal oncologic plane of dissection.

full-thickness circular incision reaches the plane between the presacral fascia and rectal fascia posteriorly, and the posterior wall of the vagina anteriorly, with cephalad progression. Transanal extraction of the specimen and section of the proximal colon is achieved. A transverse coloplasty can be performed in the proximal colon to improve functional results and hand-sewn or stapled coloanal anastomosis is performed.

### Flexible Down-to-Up NOTES TME

Perirectal NOTES access with flexible TME using a standard colonoscope implies an initial low posterior perforation to the anatomic plane between the presacral fascia and the fascia propria, evolving the dissection proximally and circumferentially.<sup>40</sup> Preparation of the patient is as described previously. The necessary equipment is a single-channel videocolonoscope and a laparoscopic set. An anoscope is transanally inserted, and the rectum lumen is closed by a circumferential purse-string suture above the limit of rectal section, and the distal rectum is disinfected. The anal verge is identified, and a small posterior incision is performed exactly at the planned line of rectal resection, using monopolar cautery under direct view. The access orifice is tested by digital exploration, and the colonoscope is inserted directly in the perirectal retroperitoneal space. Total mesorectal resection is progressively accomplished using endoscopic monopolar scissors in the oncologic plane between the presacral fascia and the mesorectal fascia (see Fig. 45.4), with posterior and anterior cephalad progression, finally reaching the peritoneal cavity. To provide high vascular ligation, a laparoscopic camera is inserted through the umbilicus, allowing high ligature of inferior mesenteric artery at the level of aorta insertion, using a standard three-trocar technique, and also mobilizing the splenic flexure. The specimen is grasped and transanally extracted, followed by transanal stapled anastomosis. Proximal loop ileostomy is performed in most cases to protect the low anastomosis.

The use of the transanal approach for TME is evolving. There is growing experience worldwide and published casuistic work with consistent oncologic results, with dedicated teams that incorporated the technique as a surgical solution for difficult lower tumors. Other centers have incorporated transanal TME as the standard therapy for middle- and low-rectal cancers. In the future, with the availability of long-term oncologic and functional results, it will be possible to evaluate the standard use of the technique as the primary indication for most rectal cancers with surgical indication.

### INTRAGASTRIC SINGLE-PORT SURGERY

An alternative method for transmural access of the stomach, intragastric single-port surgery (IGS) can be performed and allows for excellent exposition of difficult intragastric tumors, and to perform intragastric surgery when endoscopic therapy is limited.

#### Intragastric Single-Port Resection of Large Benign Tumors

Most benign intragastric tumors are treated endoscopically. In cases of tumors larger than 3 cm necessitating full-thickness resection involving a large gastric defect, IGS allows for safe and controlled resection even in difficult locations such as paraesophageal, using gastrointestinal laparoscopic staplers, coagulation, and sutures, without the need to previously enter the abdominal cavity laparoscopically.<sup>41</sup>

The technique involves the exteriorization of the gastric wall through the skin, fixation of the stomach to the skin, gastrotomy, and IGS (Fig. 45.5A–C). The tumor or bleeding lesion is localized, and successive intragastric stapling is performed to resect the lesion. In the case of gastric gastrointestinal stromal tumors, the resection can be performed intragastrically when more than 50% of the tumor is intragastric. When the tumor is exophytic to the abdominal cavity, a formal laparoscopic resection is indicated. Other indications are performing endoscopic retrograde cholangiopancreatography (ERCP) in altered anatomy after Roux-en-Y gastric bypass (RYGB), resection of recurrent Dieulafoy bleeding lesions (Video 45.2), and intragastric revision of pancreateo-gastro anastomosis.

#### Transgastric ERCP in Excluded Stomach for Altered Anatomy After Roux-en-Y Gastric Bypass

The incidence of gallstone disease is increased after RYGB, mainly in the first postoperative year, due to the rapid weight loss. Management of choledocholithiasis in these patients can be challenging due to difficulty in accessing the common bile duct (CBD) as a result of surgically altered anatomy of the stomach and duodenum.<sup>42</sup> A combination of laparoscopy and endoscopy can be used to perform a TG ERCP along with laparoscopic cholecystectomy.

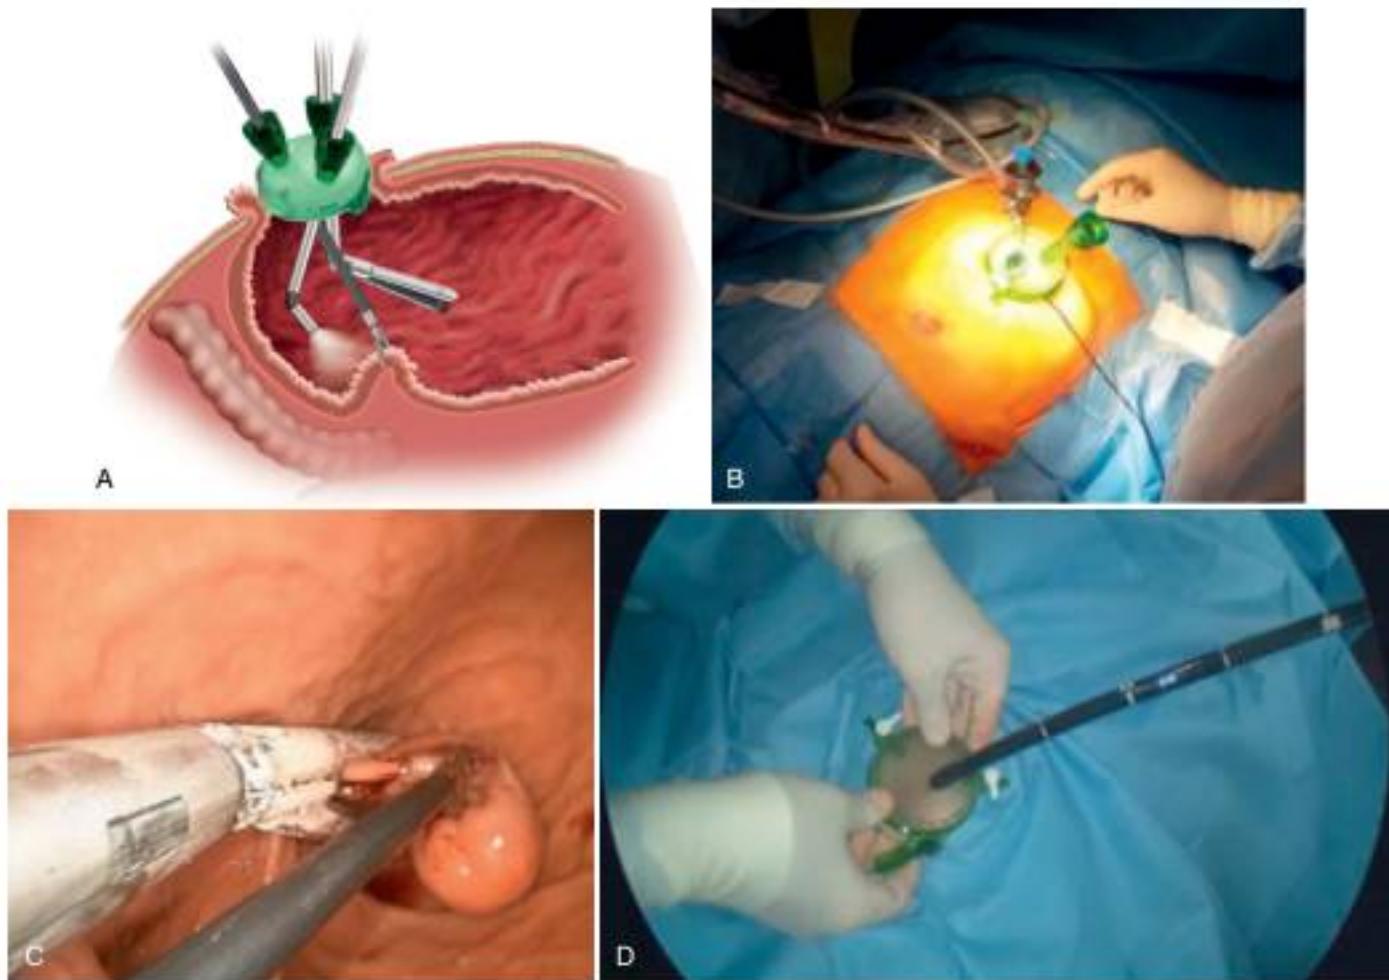

Access can be achieved by a 1-cm incision in the anterior wall of the remnant stomach and placement of a 15- to 18-mm trocar in the left abdomen, through which a side-view duodenoscope is passed, with the help of the surgeon, reaching the duodenum.<sup>43–46</sup> The procedure is then performed as a conventional ERCP.<sup>47</sup> In cases where this is technically difficult, an alternate technique can access the CBD via the jejunum, facilitated by a double-balloon enteroscope. This approach has a successful biliary cannulation rate of up to 60%.<sup>48</sup>

Falcão et al (2012) analyzed 20 patients submitted for TG laparoscopic ERCP, with papillotomy success in 100% of the cases without any serious complications. In a few cases the cystic duct was partially opened and a guidewire inserted that was exteriorized in the duodenal papilla, working as a guide for biliary catheterization.<sup>47,49</sup>

An innovative procedure can be performed using a single-port device inserted directly inside the excluded stomach, after its exteriorization through the abdominal wall (IGS). This method comprises the following technical steps: (1) insertion of the single port in one incision in the left upper abdomen; (2) adhesiolysis, cholecystectomy when indicated, localization and grasping of the excluded stomach; (3) removal of the single-port device; (4) exteriorization and fixation of the stomach to the skin; (5) gastrotomy and insertion of the single-port device, this time in an intragastric position; (6) progression of the endoscope through the single port, and ERCP and endoscopic papillotomy (see Fig. 45.5D). In our clinical series, ERCP was possible in all patients, and it is currently our standard technique for this common problem.

### EXPECTATIONS OF NATURAL ORIFICE SURGERY

NOTES appears to be evolving as a feasible, safe, and reasonable option for transabdominal surgery, with the potential to avoid incision-related complications. Preliminary results of clinical experience have demonstrated acceptable complication rates in main international centers, low postoperative stay, and good cosmetic and pain requirement results. More important than

**FIG 45.5** **A**, Schematic illustration of intragastric single-port surgery (IGS). The gastric wall is extracted and fixed to the skin. After this, an opening is made in the antrum to allow the introduction of a single-port device in an intragastric position. **B**, External view of IGS positioning for resection of a gastric gastrointestinal stromal tumor (GIST). **C**, Intraoperative view of IGS resection of a gastric GIST. Staplers and laparoscopic instruments can easily be introduced to perform full-thickness extraction of intramural tumors. **D**, Transgastric IGS-ERCP in excluded stomach for altered anatomy after Roux-en Y gastric bypass. The single port is intraabdominally inserted, then the excluded stomach is localized and exteriorized through the abdominal wall, and fixed to the skin. The endoscope is inserted percutaneously into the stomach and ERCP easily performed.

this, and perhaps crucial to indicate longevity for transluminal surgery, is the ability of surgeons and endoscopists to replace complex surgical procedures with simple endoscopic ones, and the identification of novel therapeutic targets.<sup>30</sup> Consistent advantages of natural orifice surgery over existing procedures are not evident yet, and future prospective clinical trials may be addressed to recognize the role of NOTES in surgery.

# Endoscopic Full-Thickness Resection of Subepithelial Lesions of the GI Tract

Jennifer Maranki and Stavros N. Stavropoulos

## CHAPTER OUTLINE

<b>Introduction, 510</b>	<b>EFTR of Subepithelial Tumors Arising From the Muscularis Propria, 510</b>	<b>Description of EFTR Technique, 512</b>
<b>Indications and Contraindications for EFTR, 510</b>	<b>Earlier EFTR Techniques, 511</b>	<b>EFTR Outcomes, 512</b>
		<b>Summary, 515</b>

## INTRODUCTION

Over the past 15 years, the role of endoscopy in the removal of large and subepithelial lesions has expanded greatly. Whereas expertise in endoscopic submucosal dissection (ESD) has been long established in Asia, the technique has become more widely available in the West. With expanding indications, including the removal of muscularis propria (MP)-originating subepithelial tumors (SETs), the need for a safe and effective method for performing endoscopic full-thickness resection (EFTR) is critical. Suzuki et al (2001) reported on the use of EFTR and endoscopic complete defect closure in one duodenal and two rectal carcinoids, the first English-language report of the technique.<sup>1</sup> Lesions were suctioned and ligated within the cap of the devices, and in the duodenal case, laparoscopic assistance was required for microperforation closure.<sup>1</sup> Since then, a variety of techniques have been reported including those that are laparoscopy-assisted, device-assisted, and those that employ a free-hand approach.<sup>2–4</sup>

## INDICATIONS AND CONTRAINDICATIONS FOR EFTR

Indications for EFTR are dependent on whether the lesion is in the upper or lower gastrointestinal (GI) tract. The most frequent indication for EFTR is SETs of 5 cm or less in diameter arising from or involving the MP based on endoscopic ultrasound (EUS) or computed tomography (CT) imaging.<sup>5</sup> These lesions are often gastrointestinal stromal tumors (GISTs), and National Comprehensive Cancer Network (NCCN) guidelines recommend removal of known or suspected GISTs that are symptomatic, have high-risk EUS features (including an irregular border, ulceration, cystic spaces, heterogeneity, and echogenic foci), or are greater than or equal to 2 cm in size.<sup>6</sup> Pathologic features that indicate a higher risk of metastasis or recurrence include mitotic index and Ki-67 status.<sup>7,8</sup> Another indication is recurrence of mucosal lesions following endoscopic mucosal resection (EMR) or ESD at a surgical resection site.<sup>9</sup> Any SET that is symptomatic should also be resected.<sup>9</sup>

Contraindications for EFTR can be divided into patient- and tumor-related factors. Patient-related contraindications include

the presence of high surgical risk due to severe comorbidities, including bleeding or coagulation disorders, and severe cardiopulmonary disease; pregnancy; inability to tolerate anesthesia; and anatomic issues that would preclude passage of the EFTR or suturing device. Tumor-related factors that are contraindications are the presence of a large extramural component; tumors with a high risk of lymph node spread or evidence of systemic spread; and features suggestive of aggressive behavior.<sup>1,9</sup> Notably, carcinomas should be resected with a pre-closure method of EFTR to prevent contamination of the peritoneal cavity with malignant cells.<sup>10–12</sup>

## EFTR OF SUBEPITHELIAL TUMORS ARISING FROM THE MUSCULARIS PROPRIA

EFTR allows for minimally invasive, "scarless," organ-preserving, en bloc resection of tumors ranging from 2 to 5 cm. Tumors less than 2 cm are rarely symptomatic and carry low risk of malignant transformation, whereas tumors greater than 5 cm in diameter typically have higher malignant potential<sup>13</sup> and are often difficult to extract from the mouth or the anus, making surgical resection a better option.

The most commonly encountered neoplastic SET is a GIST, and management decisions are based on size and mitotic rate. Whereas tissue acquisition via EUS-guided fine-needle aspiration or fine-needle biopsy is ideal, these techniques fail to obtain adequate histology in up to 40% of SETs.<sup>14–16</sup> Furthermore, assessment of mitotic index, a very important factor for risk assessment of GISTs,<sup>13</sup> frequently cannot be performed. NCCN consensus guidelines for known or suspected GISTs recommend resection for all lesions that are symptomatic, have high-risk EUS features (including irregular border, cystic spaces, ulceration, echogenic foci, and heterogeneity), or are greater than or equal to 2 cm in size.<sup>6</sup> Long-term annual surveillance is recommended for low risk GISTs less than 2 cm in size. This management plan is also utilized for other, indeterminate lesions or rare mesenchymal tumors for which there is a paucity of data to develop an evidence-based algorithm. As a result, a cumbersome, lifelong surveillance plan is undertaken, contributing not only to health care costs but also to substantial anxiety on the part of the patient.

### Abstract

As techniques for endoscopic removal of large and subepithelial lesion of the gastrointestinal (GI) tract have evolved, the need for safe and effective methods for endoscopic full thickness resection (EFTR) has increased substantially. The most frequent indication for EFTR is for the removal of subepithelial lesions less than 5 cm in size originating from the muscularis propria (MP) layer of the GI tract. Present techniques for EFTR have arisen out of endoscopic submucosal dissection (ESD) and natural orifice transluminal endoscopic surgery (NOTES) methods and have evolved into free-hand EFTR techniques or device-assisted approaches. Devices for EFTR include the GERDX device, over-the-scope nitinol clips (OTSCs), and a modification of the OTSC, the full-thickness resection (FTR) device. In expert hands, EFTR provides effective complete en bloc resection of subepithelial lesions in the esophagus, stomach, and colon with a favorable adverse event profile.

### Keywords

subepithelial tumors  
endoscopic full thickness resection  
gastric tumor  
muscularis propria  
over-the-scope clip  
natural orifice transluminal surgery

Frequently, these lesions are located in anatomic areas such as the gastroesophageal junction, pre-pyloric antrum, cardia, and esophagus where organ-preserving tumorectomy via standard surgical approaches is difficult or impossible, and thus require more extensive organ resection. Because of these circumstances, a technique that achieves minimally invasive, organ-preserving, complete resection of such lesions via natural orifices following the tenets of natural orifice transluminal endoscopic surgery (NOTES), preserving the natural anatomy and minimizing morbidity, is highly desirable.

There are several reasons why endoscopic resection of these tumors is favorable. Based on tumor biology, these lesions are rarely aggressive and, unlike epithelial malignancies, carry minimal risk of lymph node involvement. Furthermore, unlike cancer resections, they do not require a large margin of uninvolved tissue for resection because they have a low chance of local recurrence even in cases of R1 (microscopic margin positive) surgical resection.<sup>11</sup> Additionally, these lesions in the wall of the GI tract typically grow into the lumen of the GI tract, making them easily identifiable and often amenable to enucleation without the need for resection of uninvolved tissue.

## EARLIER EFTR TECHNIQUES

Although there is some overlap in terminology, the preponderance of recent literature utilizes the term EFTR to denote free-hand "pure NOTES" full-thickness resection of lesions with ESD-like technique and accessories. Later efforts incorporated a combined laparoscopic and endoscopic approach. A variety of techniques have been reported, with the role of endoscopy ranging from lesion and margin identification to almost complete endoscopic resection with laparoscopic defect closure.<sup>14,20</sup> The main drawback of these approaches is that they are more invasive and time-consuming than a purely endoscopic approach.

Device-assisted EFTR (DA-EFTR) utilizes devices to ensure serosal apposition prior to resection. DA-EFTR has been reported by means of tissue apposition devices that were designed for endoscopic anti-reflux procedures. Initially, the NDO Plicator device, which is no longer available, was used and, more recently, the GERDX device (G-SURG, Seeon-Seebruck, Germany) (Fig. 46.1), or over-the-scope nitinol clips (OTSCs) (Ovesco, Cary, NC) either via their original device designed for tissue apposition or a more recent adaptation by the same company (FTR device, Ovesco) specifically designed for DA-EFTR<sup>1</sup> have been used.

Potential advantages of DA-EFTR techniques include that they are easier and faster than free-hand EFTR and that pre-closure of the defect eliminates escape of luminal contents, which should decrease the risk of infection and potentially allow resection of epithelial malignancies without fear of disseminating malignant cells to the peritoneal or thoracic cavities. However, with current technology, DA-EFTR has significant limitations. The GERDX device is restricted to lesions less than 35 mm with a largely intraluminal growth pattern because of the progressive difficulty in placing full-thickness sutures as tumor size increases.<sup>1,21</sup> The GERDX device utilizes the placement of transmural resorbable sutures with serosa-to-serosa apposition underneath the SET followed by lesion resection. The OTSC method, even with the larger FTR device, is limited to epithelial lesions of less than 3 to 4 cm and subepithelial lesions less than 2 cm with intraluminal growth pattern only that are able to be suctioned completely into the device cap with subsequent clip deployment. Additionally, both the GERDX and OTSC devices are bulky and limited by the ability to advance the endoscope with the device to the area of interest, thereby making certain locations inaccessible to them. For example, the Ovesco FTR device, due to its very large size (outer diameter of 21 mm), is approved in Europe only for colonic lesions, although it has been used sporadically for selected upper gastrointestinal lesions by experts with significant experience.<sup>21</sup>

"Free-hand" EFTR represents an offshoot of ESD-based techniques utilizing the same knives but taking the plane of dissection deep to the submucosa, along the surface of the MP for submucosally located SETs (what has been termed endoscopic submucosal excavation [ESE]), or for MP-based SETs, taking the dissection INTO the MP (termed variably endoscopic muscularis dissection, endoscopic enucleation, or endoscopic muscularis excavation [EME], the term we will use in this review). Initial attempts at endoscopic resection of MP-based SETs employed the ESE or EME technique (for SETs arising from the submucosa or MP, respectively) to resect small subepithelial lesions in the range of 2 to 3 cm in size with intraluminal growth. The lesions are excavated en bloc using ESD techniques maintaining a plane of resection along the inner circular muscle or the surface of the MP, avoiding perforation or full-thickness resection. Complete resection rates range from 65% to 100%, with relatively low rates of perforation (0% to 13%) that can be managed endoscopically with minimal morbidity, as well as a favorable overall adverse event profile.<sup>22–24</sup>

FIG 46.1 GERDX. (Image courtesy G-SURG GmbH, Seeon-Seebruck, Germany.)

These techniques are limited to lesions with purely intraluminal growth (no tumor component extending beyond the MP towards the peritoneal or thoracic cavities), as is also the case with the DA-EFTR technique. Additionally, for MP-based lesions, as full thickness resection is not undertaken, EME may leave tumor cells in the MP or serosa.

Two main techniques, EFTR and submucosal tunnel endoscopic resection (STER), have been developed to address these disadvantages of EME. They represent pure NOTES techniques that can achieve complete full-thickness resection of MP-based tumors independent of growth pattern using ESD techniques and tools. Both techniques arose within a climate of renewed interest in NOTES in the form of juxtalaminal, short-range NOTES procedures, referred to as New NOTES procedures. This renewed interest was sparked by the remarkable success of Per Oral Endoscopic Myotomy (POEM), the prototypical New NOTES procedure that has been credited as the first successful NOTES intervention.<sup>31</sup> Although EFTR is widely applicable in any location of the GI tract, STER is limited to locations where a submucosal tunnel can be successfully created (esophagus, distal stomach or rectum). In this chapter, we will focus on the EFTR technique, because the STER technique is better addressed as an offshoot of tunnel-based interventions such as POEM. The EFTR technique involves full-thickness removal of a SET by creating an intentional perforation, with subsequent endoscopic closure using endoscopic suturing<sup>32</sup> or clips and endoloop techniques consisting of the use of several endoclips, with subsequent placement of the endoloop to fix and tighten the clips together.<sup>33,34</sup>

EFTR, using a free-hand approach with ESD techniques and tools, was first reported in 2011 by two Chinese groups.<sup>35,36</sup> Wang and colleagues reported EFTR of 66 nonintracavitory stromal lesions less than or equal to 3.5 cm in size, and compared their experience to 43 patients with similar tumors who underwent laparoscopic surgery. Median operating times and hospital costs were lower in the endoscopic group, both techniques achieved R0 resection in all cases, and postoperative complications were significantly higher in the endoscopic group, which correlated with tumor size (14% vs. 26%).<sup>37</sup> That same year, Zhou and colleagues reported on EFTR of 26 gastric submucosal lesions arising from the MP (16/26 GISTs), with size ranging from 1.2 to 4.5 cm. Complete resection was achieved in all cases, and there were no instances of significant adverse events or complications.<sup>38</sup>

## DESCRIPTION OF EFTR TECHNIQUE

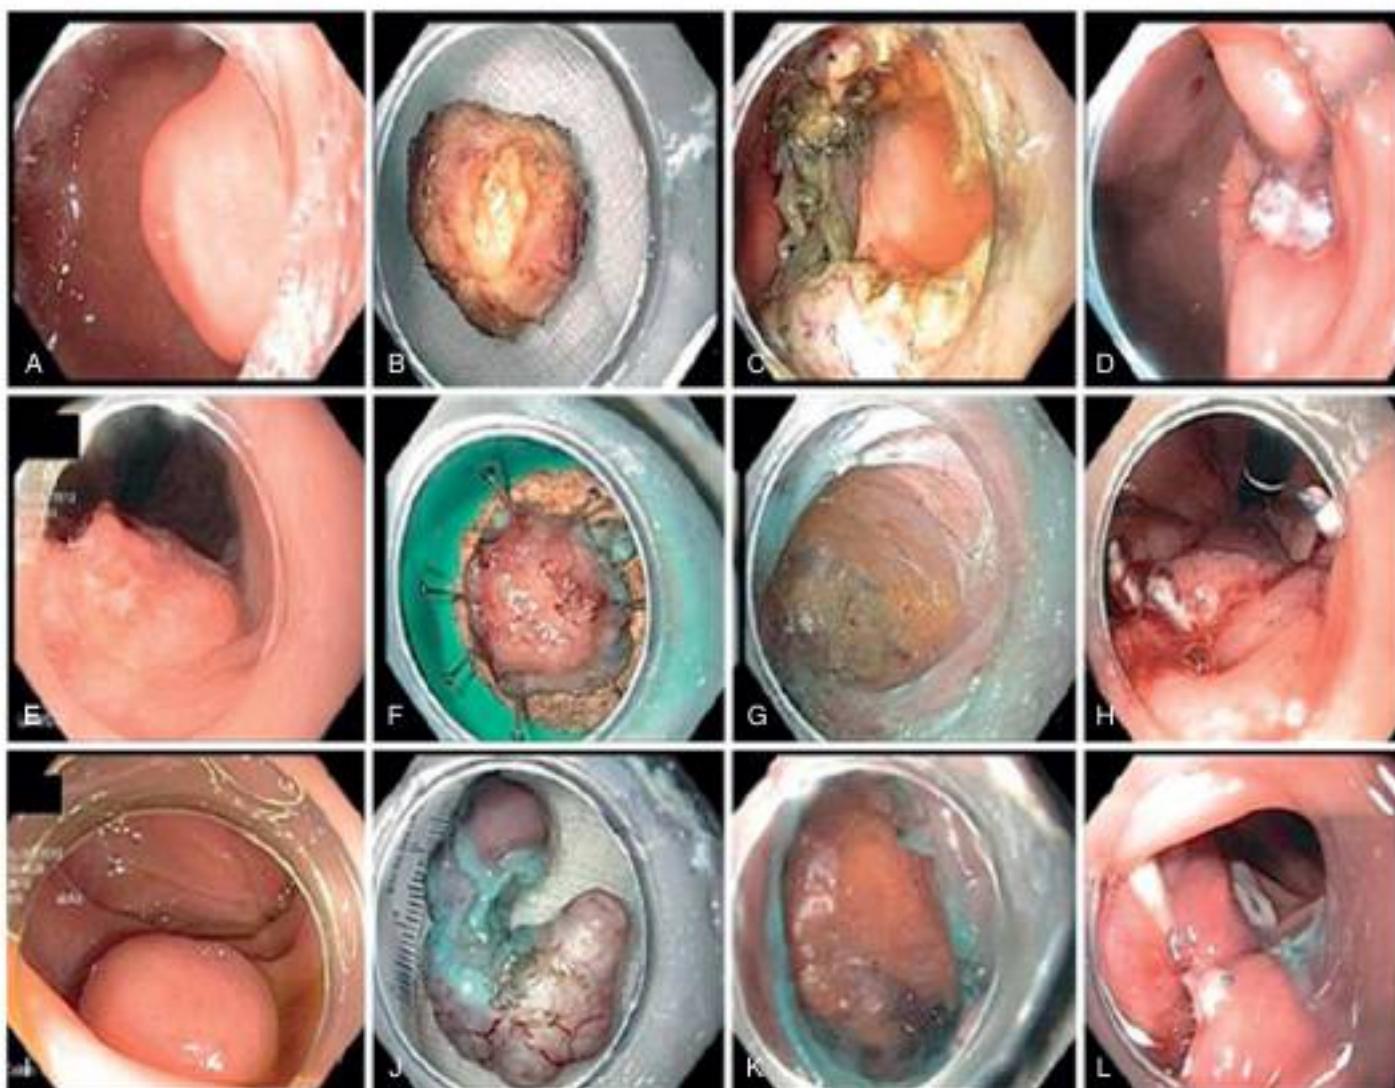

In accordance with NOTES protocols, as a breach of the GI lumen is expected, prophylactic antibiotics should be administered, and the target organ must be meticulously irrigated and cleaned of all debris. Furthermore, optimally, the patient should be positioned to ensure that the area of resection is non-dependent to avoid extraluminal escape of significant amounts of luminal secretions, irrigation fluid, and blood once a full-thickness defect is present and prior to its closure. Following the procedure, patients should take nothing by mouth (NPO) for at least 24 hours, and radiographic imaging to test for leaks must be performed prior to the initiation of a liquid diet. If there are any concerns regarding how secure a closure has been achieved (which is not usually the case if effective suturing is possible, but may be the case when endoclips/endoloop techniques are used), nasogastric suction should be applied and possibly more prolonged NPO status.

The critical steps of the EFTR procedure are as follows (Figs. 46.2 and 46.3):

1. Using a solution of blue dye (methylene blue or indigo carmine) and saline, or other standard solutions used in ESD and EMR, submucosal injection is performed along the margin of the tumor.
2. Using an ESD knife, circumferential margination of the tumor is undertaken. The type of knife used is operator-dependent, but the most commonly used ones include the ERBE T-type Hybrid Knife (ERBE USA, Marietta, GA), the IT2 Knife (Olympus America), and the Hook Knife (Olympus America). For a complete listing of ESD knives and accessories, refer to the American Society for Gastrointestinal Endoscopy (ASGE) ESD Technology Status Evaluation Report.<sup>39</sup> Margination is complete when fully circumferential mucosal and submucosal dissection has been achieved.
3. Resection of the MP is performed, with special attention to the avoidance of tumor capsule disruption, as damage to the capsule may result in dispersal of tumor cells. Tumors that are deep in the MP may be adherent to the serosa, which requires resection of the MP and serosa. For certain more superficial MP-based tumors it may be possible to preserve the serosa. In this deep dissection, a knife with an insulated tip is often preferred to prevent injury to adjacent organs. Key aspects of the technique are to avoid overinsufflation and to be able to detect and treat tension capnoperitoneum, which can be vented by placing an angiograph or Veress needle in the right or left upper quadrant.
4. In the final stages of the resection, care is taken to avoid pushing the tumor into the peritoneum through the defect. Some operators use a double-channel endoscope with a grasper to secure the tumor during the final incision. Alternatively, a snare is used to make the final cut, which enables capture of the tumor immediately on completion of the final incision.
5. Several devices may be used for closure of the full-thickness defect. Closure devices include the combination of endoclips and endoloops,<sup>32</sup> OTSCs (Ovesco),<sup>30</sup> and an endoscopic suturing device (Overstitch, Apollo Endosurgery, Austin, TX).<sup>39</sup> A unique approach to closure is the omental patch technique, which involves suctioning a patch of omentum through the defect and securing it with endoclips onto the defect to "plug" the defect and achieve secure closure.<sup>40</sup>

## EFTR OUTCOMES

Several case series using EFTR, mainly from China, have reported on the safety and efficacy for treatment of SETs, and are summarized in Table 46.1. Most lesions are between 15 and 30 mm in diameter, and are SETs in the upper GI tract, most of which are GISTs, followed by leiomyomas and smaller numbers of other mesenchymal tumors, such as glomus tumors and schwannomas. Procedure times range from 40 to 105 minutes, and en bloc resection is achieved in nearly 100%. Most common adverse events include localized peritonitis, pneumoperitoneum, abdominal distension or pain, fever, nausea and vomiting, and posterior pharyngeal pain likely due to minor trauma during peroral extraction of the larger tumors.<sup>41-48</sup> Of those with documented follow-up, none had evidence of recurrence. In a series of 48 patients from our center at Winthrop University, the only Western free-hand EFTR series to date, similar results using free-hand EFTR were achieved.<sup>33,45</sup>

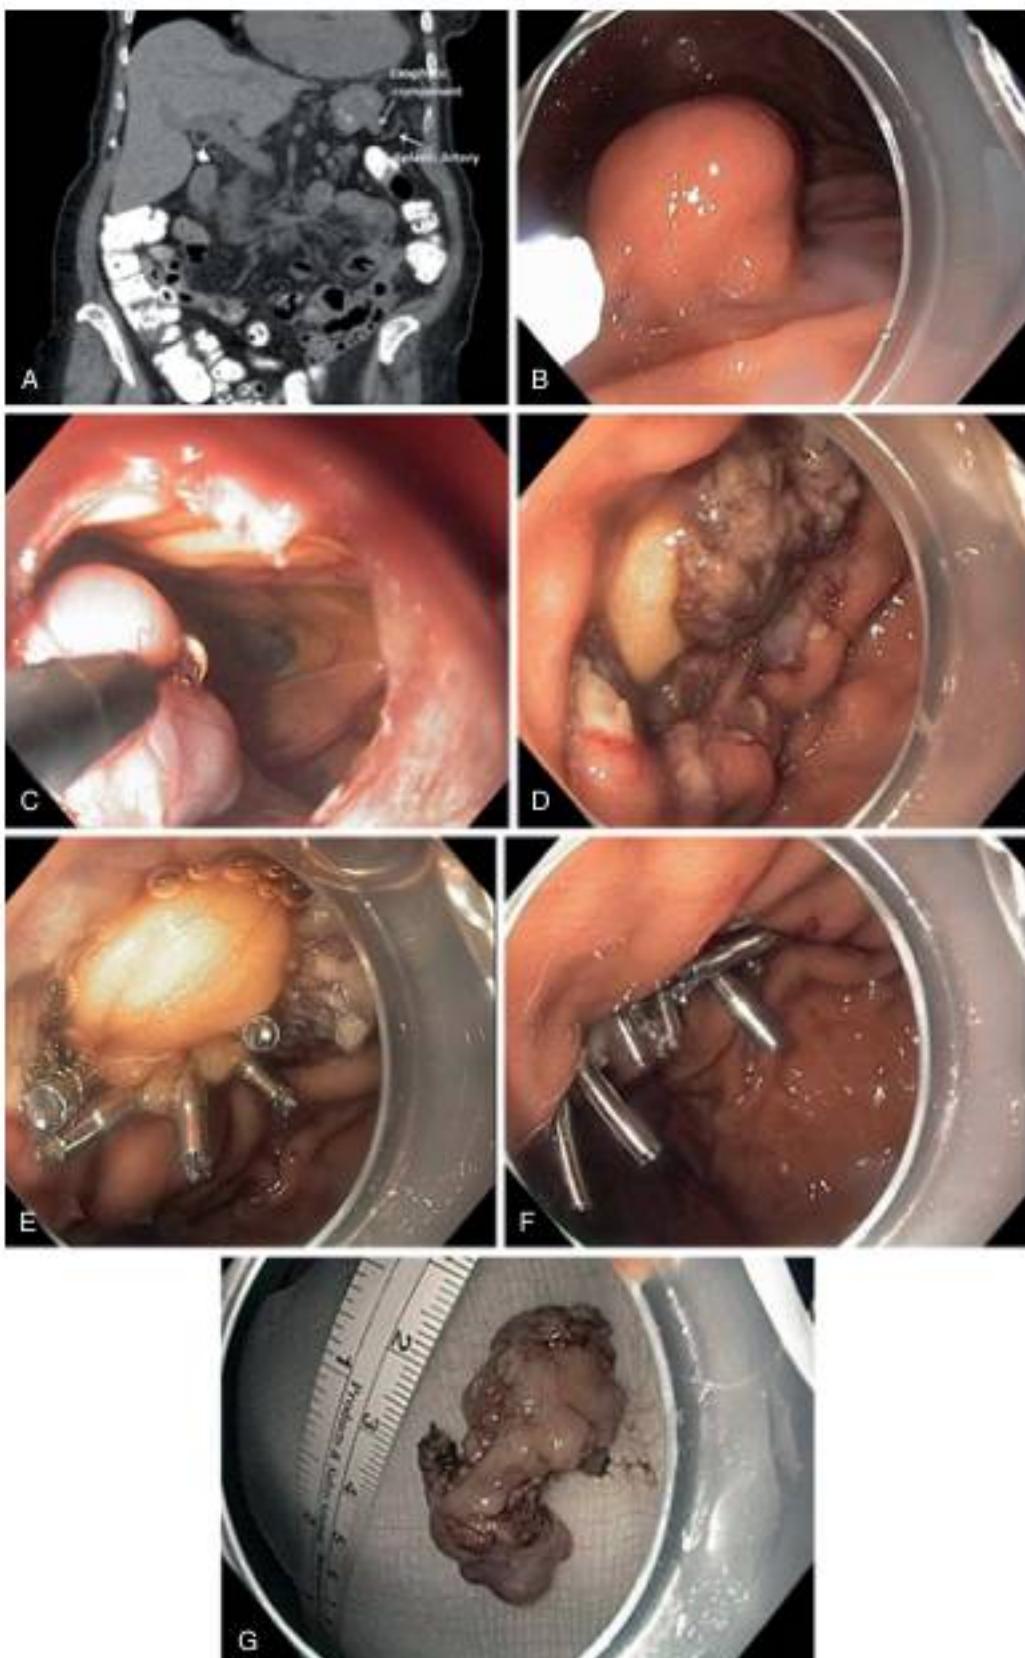

**FIG 46.2** Closure of intentional full-thickness perforations after subepithelial tumor removal with endoscopic suturing device. **A**, Endoscopic image of gastric muscularis propria based subepithelial tumor. **B**, 2.5 cm schwannoma. **C**, Resection crater showing transmural fat. **D**, Endoscopic sutured closure of defect. **E**, Endoscopic image of rectal carcinoma superficially extending to muscularis propria. **F**, 1.3 cm rectal low-grade adenocarcinoma. **G**, Resection crater showing perirectal fat, circular muscle layer, and longitudinal muscle layers. **H**, Endoscopic sutured defect closure. **I**, Endoscopic image of sigmoid muscularis propria based subepithelial tumor. **J**, 3 cm leiomyosarcoma. **K**, Resection crater demonstrating peritoneal fat. **L**, Endoscopic sutured closure of defect. (From Stavropoulos SN, Modayil R, Friedel D: Current applications of endoscopic suturing. *World J Gastrointest Endosc* 2015;7[8]:777-789.)

In comparing EFTR to laparoscopic-assisted resection of small SETs, few series have been reported.<sup>46</sup> Wang et al (2016) reported on 68 total patients who underwent EFTR or laparoscopic resection. EFTR was associated with fewer complications and favorable en bloc resection.<sup>46</sup>

A study by Tan et al (2016) compared outcomes of EFTR versus STER for the removal of gastric GISTs in 52 patients. No differences were found in tumor size, en bloc resection rate, operation time or complications, hospital stay, or cost.<sup>47</sup>

There is a paucity of data on the use of EFTR techniques for treatment of lesions located beyond the esophagus and stomach.

Pure EFTR is rarely applied to substantial duodenal lesions due to the technical difficulty in closing large defects in the duodenum and the high risk of leaks and bleeding complications that are difficult to treat, often resulting in significant morbidity. Abe and colleagues in 2012 reported on laparoscopy-assisted EFTR of a duodenal carcinoid.<sup>48</sup> More recently, Schmidt et al (2015)<sup>21</sup> reported on EFTR of four duodenal lesions (two non-lifting adenomas and two carcinoids) using the FTR device. Mean resection size was 28.3 mm (range 22–40 mm). There were two cases of minor bleeding and no perforations, and R0 resection was achieved in 3 of 4 cases.<sup>21</sup>

**FIG 46.3** **A**, CT scan demonstrating exophytic portion of the subepithelial tumor abutting splenic artery. **B**, Endoscopic view of the endophytic portion along greater curvature of stomach. **C**, Extraluminal portion of the tumor retracted with the endoscopic submucosal dissection knife to show omental fat and intraperitoneal organs, seen through the full-thickness defect. **D**, Resection crater with omental fat. **E**, Omental fat clipped to the resection rim to seal the full-thickness defect. **F**, Two-layer closure with endoclips to approximate mucosa **G**, "Dumbbell" shaped tumor  $4 \times 2.5$  cm with exophytic and endophytic lobulated components. Pathology: GIST (0 mitoses/50 hpf). (From Stavropoulos SN, Modayil R, Friedel D, Brathwaite CE: Endoscopic full-thickness resection for GI stromal tumors. *Gastrointest Endosc* 2014;80[2]:334-335.)

**TABLE 46.1 Selected Series of EFTR Cases**

Study	Year	Number of Cases	Lesion Location	Mean Tumor Size (cm)	Success Rate of en Bloc Resection (%)	Pathologic Diagnosis	Adverse Events

Schmidt, et al <sup>13</sup>	2016	106	Colonic	1.7	89	80 adenoma, 13 T1 carcinoma, 13 SETs	2 minor bleeds, 3 perforations (1 delayed)

EFTR has been used in the colon, with closure of the defect using clips. In a case series of 16 patients, two required laparoscopic assistance for defect closure, and two developed peritonitis.<sup>3</sup> DA-EFTR with the Ovesco FTR device may be an appropriate technique to remove epithelial lesions, such as advanced adenomas or intramucosal carcinomas, in the colon because pre-closure of the defect eliminates risk of extraluminal contamination (an important concern in the colon) and escape of malignant cells (which is a concern in epithelial neoplasms, unlike SETs). Even though these lesions are limited to the mucosa and thus amenable to EMR or ESD, DA-EFTR may facilitate resection of challenging lesions such as previously manipulated "non-lifting" lesions or lesions in difficult locations, such as near the appendiceal orifice. Salerno et al (2016) reported a case of EFTR using the FTR device to remove a 16-mm submucosal lesion of the right colon. Complete removal was achieved with no complications; pathology revealed a large B-cell lymphoma.<sup>10</sup> A large multicenter series from Germany reported application of DA-EFTR with the Ovesco FTR to 180 such lesions in the colon.<sup>12</sup> Outcomes were modest, and only lesions less than 3 cm were included. Complete R0 resection was only achieved in 78%. Full-thickness resection including MP was also only achieved in 78%. Significant adverse events, including events requiring emergency surgery (2 perforations [1 delayed], 1 appendicitis), occurred in 1.6%. Ten percent had residual/recurrent tumor even at limited 3-month follow-up. Seven percent required surgery within this 3-month interval. Hopefully, with continued device improvements, outcomes will improve.

In conclusion, in the hands of expert operators, EFTR appears to provide high rates of complete resection of SETs of 4 cm or

less, with favorable procedural times and adverse event profile. EFTR provides advantages over laparoscopy-assisted procedures by allowing for optimum organ-sparing resection with minimal invasiveness. For lesions of 4 to 5 cm in size, a combined approach with laparoscopy may be preferred, as it provides an effective method for tumor extraction. For lesions larger than 5 cm, given the increased risk for aggressive behavior and challenges in manipulating and endoscopically extracting such large lesions, including risk of rupture due to central necrosis in larger tumors, traditional surgery is recommended. It should be emphasized that, due to the skills required for secure closure, avoidance of severe bleeding, and control of insufflation, EFTR should be attempted by operators with ESD mastery, under institutional review board protocol at least initially, and with surgical backup.<sup>13</sup>

## SUMMARY

Current data indicate that EFTR in the hands of endoscopic resection experts represents a safe and effective pure NOTES approach for en bloc resection of SETs less than 5 cm in size, mainly located in the esophagus and stomach. Complete resection is achieved at high rates, with an acceptable adverse event profile. However, it should be emphasized that techniques for EFTR require a high degree of expertise, with mastery of ESD and submucosal tunneling techniques. Further improvements in closure devices such as the Overstitch system or other suturing devices in development, improvements in DA-EFTR devices such as the GERDX and FTR device systems, and the advent of novel devices, including robotic or lumen stabilization platforms currently under development (e.g., Lumen-R, Boston Scientific,

Marlborough, MA or DiLumen, Lumendi, Westport, CT), will likely push the field of EFTR forward and make it more widely accessible to advanced endoscopists beyond the current small group of resection experts.

### INTRODUCTION

The use of endoscopic ultrasound (EUS) has grown over the last 30 years, and it is now a well-established diagnostic method for the assessment of a range of gastrointestinal (GI) disorders, including the evaluation and staging of many types of endoluminal cancers. This chapter discusses EUS applications relating to extraintestinal structures, organs, and lesions. The objectives of this chapter are to review the utility of EUS for evaluating the mediastinum in both benign and malignant disease processes, including the detection of mediastinal lymph node metastases in lung cancer. Mass lesions in the paragastric and retroperitoneal organs (excluding the bile duct, gallbladder, and pancreas) are reviewed, including detection of lesions of the adrenal gland, liver, and kidneys. Ascites and pleural fluid are examined along with unusual extraintestinal lesions.

### LUNG CANCER

Lung cancer is the leading cause of cancer death in the United States in men and women, and has an overall 5-year survival rate of 15%.<sup>1,2</sup> Treatment decisions are based on the location and extent of the tumor. The presence of extrapulmonary metastasis is crucial because patients without mediastinal involvement are potential candidates for resection. The distinction between non–small-cell lung cancer (NSCLC), which accounts for 80% of tumors, and small-cell lung cancer (SCLC), which accounts for 20% of tumors, is important because of the more aggressive nature of SCLC. SCLC is usually classified as limited or extensive disease, although the criteria for these two categories remain controversial.<sup>3–5</sup> Although the TNM (primary tumor, regional nodes, metastases) staging system traditionally has not been used in staging SCLC, studies have suggested using the 7th

edition of the TNM classification scheme for clinical trials and registry information, to guide future management.<sup>6–10</sup> The forthcoming 8th edition of the TNM classification system has proposed changes to the T classification scheme, highlighting tumor size as a key feature.<sup>11</sup> Metastatic disease is detected in 80% of SCLC cases at the time of diagnosis and tends to spread quickly so that surgery is considered less often in SCLC compared with NSCLC. Although highly responsive to radiotherapy and chemotherapy, SCLC usually recurs within 2 years.

In comparison, half of NSCLC cases are localized or locally advanced and can be treated by surgery, the cornerstone of therapy for NSCLC, or with adjuvant therapy with or without resection.<sup>12–14</sup> NSCLC, which includes adenocarcinoma, squamous cell cancer, and large-cell cancer, was previously staged using the 2002 International Staging System.<sup>14–16</sup> Recently, NSCLC, has been staged using the 7th edition until December 31, 2017 (Box 47.1) and subsequently will be staged using the future 8th edition.<sup>11</sup> This section focuses on EUS applications in the diagnosis and staging of NSCLC, although much of what is covered can be applied to SCLC.

#### Staging and Staging Modalities

Mediastinal lymph node metastases are present in nearly half of all patients with NSCLC. Accurate staging of NSCLC is crucial in determining treatment options because the detection of mediastinal lymph node metastasis preoperatively has therapeutic implications. In the absence of distant metastasis, the documentation of mediastinal metastasis is probably the most common deterrent to cure.<sup>17–19</sup>

The TNM staging system used for lung cancer (see Box 47.1) designates metastasis to ipsilateral peribronchial or ipsilateral hilar lymph nodes, or both, and intrapulmonary nodes including involvement by direct extension of primary tumor as N1 disease;

**Abstract**

The use of endoscopic ultrasound (EUS) has grown over the last 25 years, and it is now a well-established diagnostic method for luminal and extraluminal disorders. This chapter discusses EUS applications relating to extraintestinal structures, organs, and lesions. The objectives of this chapter are to review the utility of EUS for evaluating the mediastinum in both benign and malignant disease processes, including the detection of mediastinal lymph node metastases in lung cancer. Mass lesions in the paragastric and retroperitoneal organs (excluding the bile duct, gallbladder, and pancreas) are reviewed, including detection of lesions of the adrenal gland, liver, and kidneys. Ascites and pleural fluid are examined along with unusual extraintestinal lesions.

**Keywords**

lung cancer staging  
endoscopic ultrasound of the mediastinum  
endoscopic ultrasound of the adrenal, renal, and liver lesions

**BOX 47.1 International Staging System for Lung Cancer, 2007****Primary Tumor (T)**

Tx: Primary tumor cannot be assessed

T0: No evidence of primary tumor

Tis: Carcinoma in situ

T1: Tumor &lt; 3 cm without bronchoscopic evidence of invasion more proximal than the lobar bronchus (not the main bronchus unless superficial tumor of any size with invasion limited to the bronchial wall, which may extend proximal to the main bronchus)

T1a: Tumor &lt; 2 cm in size

T1b: Tumor &gt; 2 cm but &lt; 3 cm in size

T2: Tumor &gt; 3 cm but &lt; 7 cm, or any size with any of the following:

Involves the main bronchus (at least 2 cm distal to the carina)

Invades visceral pleura

Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung

T2a: Tumor &gt; 3 cm but &lt; 5 cm

T2b: Tumor &gt; 5 cm but &lt; 7 cm

T3: Tumor &gt; 7 cm or directly invades any of the following:

Chest wall, diaphragm, mediastinal pleura, or parietal pericardium or tumor in the main bronchus &lt; 2 cm distal to the carina (without involvement of the carina)

Atelectasis or obstructive pneumonitis of the entire lung

Separate tumor nodules in the same lobe

T4: Tumor of any size that invades any of the following:

Mediastinum, heart, great vessels, trachea, esophagus, vertebral body, or carina

Separate tumor nodules in a different ipsilateral lobe

**Nodal Involvement (N)**

Nx: Regional lymph nodes cannot be assessed

N0: No regional lymph nodes metastasis

N1: Metastasis to ipsilateral peribronchial or ipsilateral hilar lymph nodes, or both, and intrapulmonary nodes including involvement by direct extension of primary tumor

N2: Metastasis to ipsilateral mediastinal or subcarinal lymph nodes, or both

N3: Metastasis to contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph nodes

**Metastasis (M)**

Mx: Distant metastasis cannot be assessed

M0: No distant metastasis

M1: Distant metastasis present

M1a: Separate tumor nodules in a contralateral lobe; tumor with pleural nodules or malignancy pleural or pericardial effusion

M1b: Distant metastasis

**Stage Grouping**

Occult carcinoma: TxN0M0

Stage 0: TisN0M0

Stage IA: T1a-bN0M0

Stage IB: T2aN0M0

Stage IIA: T1N1M0, T2bN0M0

Stage IIB: T2bN1M0, T3N0M0

Stage IIIA: T1N2M0, T2N2M0, T3N1-2M0, T4N0-1M0

Stage IIIB: T4 N2M0, Any TN3M0

Stage IV: Any T any N M1-b

Adapted from Goldstraw P, Crowley J, Chansky K, et al: The IASLC Lung Cancer Staging Project: proposals for the revision of the TNM stage groupings in the forthcoming (seventh) edition of the TNM classification of malignant tumours. *J Thorac Oncol* 21(8):706-714, 2007.

metastasis to ipsilateral mediastinal or subcarinal lymph nodes, or both, as N2; and metastasis to contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph nodes as N3. Although N2 disease is potentially resectable, most patients with N2 disease receive multimodality treatment (Table 47.1 and Fig. 47.1; see Box 47.1).

Various techniques are currently available to diagnose and stage lung cancer, including x-rays, computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), endobronchial ultrasound (EBUS), and EUS. CT scan of the chest is the current standard by which mediastinal lymphadenopathy is detected. Generally, lymph nodes larger than or equal to 1 cm on chest CT scan are considered abnormal. A review of previously published studies reveals an accuracy of CT staging of the mediastinum of 52% to 88%.<sup>18-20</sup> This variation has been attributed to the wide range of correlation of lymph node size to the presence of malignant involvement. Although the general trend is increased risk for metastasis correlating with increasing lymph node size, lymph node size is not an accurate criterion for assessing risk. Problems associated with size as a criterion include the inability to differentiate inflammatory or reactive lymph nodes from malignant involvement. In one study, 37% of mediastinal lymph nodes that ranged in size from 2 to 4 cm were benign,<sup>21</sup> and 40% of enlarged nodes in another series were not cancerous.<sup>22</sup> Similarly, normal-sized lymph nodes can contain foci of cancer. McKenna et al (1985)<sup>23</sup> found no correlation between the presence of mediastinal nodal metastases

and nodal size. Metastases may be found in 21% of normal-sized nodes.<sup>23</sup>

MRI may be slightly superior to CT in the detection of mediastinal disease,<sup>24</sup> and PET has been shown to be superior to CT for staging for the mediastinum.<sup>25,26</sup> PET does not rely on an arbitrary cutoff of size to diagnose malignant nodes but detects the increased glycolytic rate in metabolically active tumors. In a meta-analysis, PET had a sensitivity of 79% and a specificity of 91% compared with CT, which had sensitivity and specificity of 60% and 77%, respectively, for the detection of mediastinal disease.<sup>27</sup> In another meta-analysis by Toloza et al (2003),<sup>28</sup> the performance characteristics of CT, PET, and EUS for staging the mediastinum in NSCLC were compared. PET was more accurate than CT or EUS for detecting mediastinal metastases, with a sensitivity of 84% and a specificity of 89% for PET compared with CT (sensitivity 57% and specificity 82%) and EUS (sensitivity 78% and specificity 71%). However, PET is limited for small lesions ( $\leq 1$  cm), has false-negative results in tumors with low metabolic activity, and has false-positive results in benign lesions such as granulomatous disease. Although PET has a relatively high sensitivity, because of the importance and implications of staging, specificity is still too low, and pathologic staging is still generally sought.<sup>27-29</sup>

Fritscher-Ravens et al (2003)<sup>29</sup> performed a prospective comparison of CT, PET, and EUS for the detection of metastatic lymph nodes metastases in patients with lung cancer being considered for operative resection. After bronchoscopic evaluation,

**TABLE 47.1 Lymph Node Map Definitions**

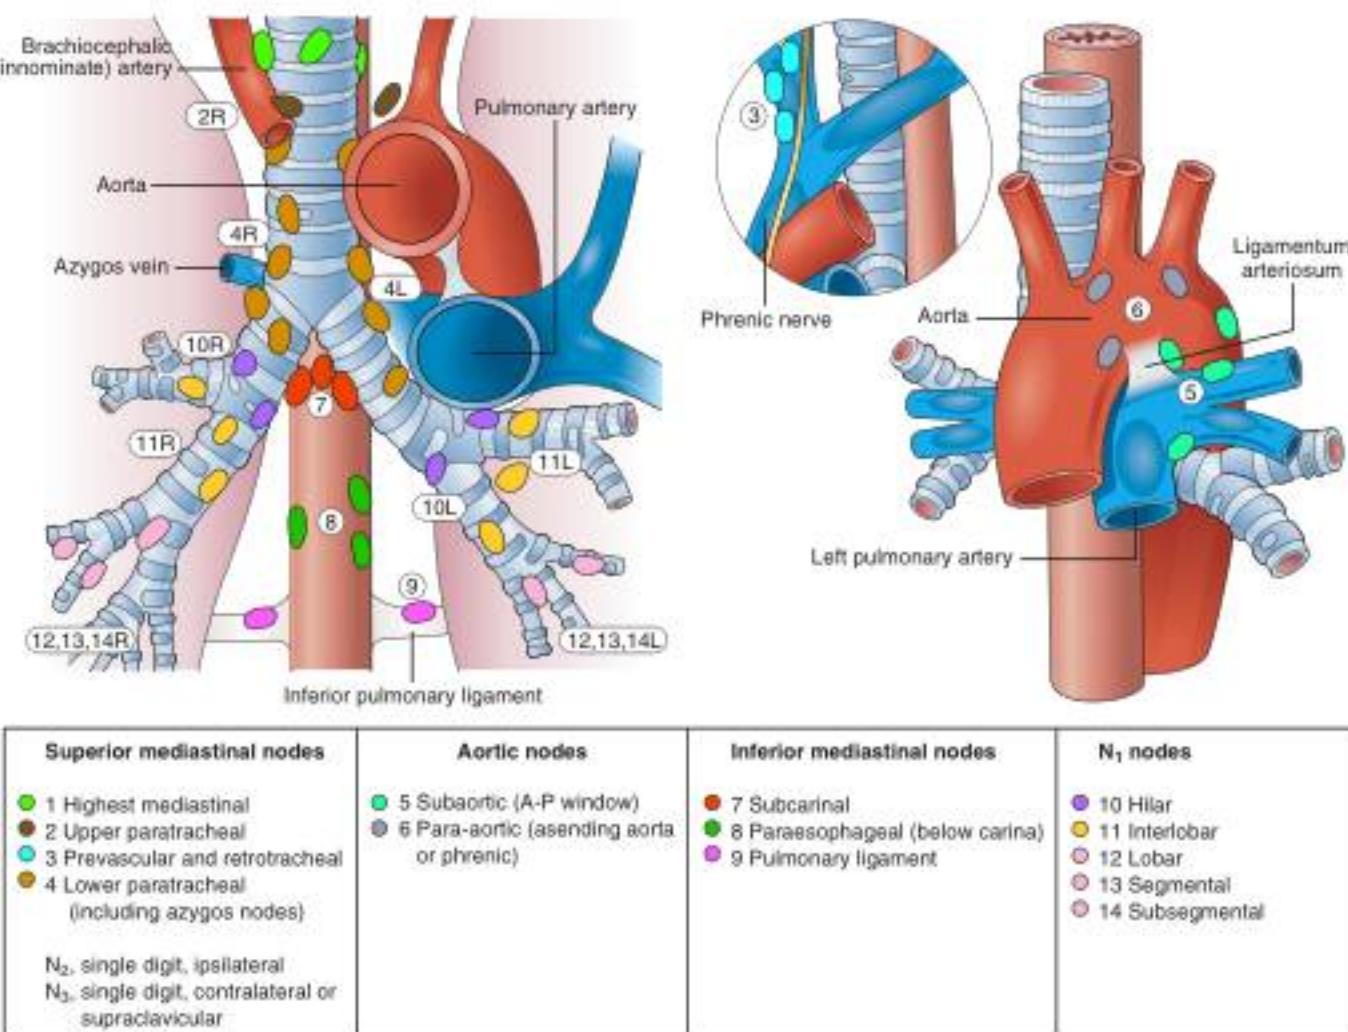

Nodal Station	Anatomic Landmarks
<b>N2 Nodes: All N2 Nodes Lie Within the Mediastinal Pleural Envelope</b>	
1. Highest mediastinal nodes	Nodes lying above the horizontal line at the upper rim of the brachiocephalic (left innominate) vein where it ascends to the left, crossing in front of the trachea at its midline
2. Upper paratracheal nodes	Nodes lying above the horizontal line drawn tangential to the upper margin of the aortic arch and below the inferior boundary of the No. 1 nodes
3. Prevascular and retrotracheal nodes	Prevascular and retrotracheal nodes may be designated 3A and 3B; midline nodes are considered to be ipsilateral
4. Lower paratracheal nodes	Lower paratracheal nodes on the right lie to the right of the midline of the trachea between a horizontal line drawn tangential to the upper margin of the aortic arch and a line extending across the right main bronchus at the upper margin of the upper lobe bronchus and contained within the mediastinal pleural envelope; lower paratracheal nodes on the left lie to the left of the midline of the trachea between a horizontal line drawn tangential to the upper margin of the aortic arch and line extending across the left main bronchus at the level of the upper margin of the left upper lobe bronchus, medial to the ligamentum arteriosum and contained within the mediastinal pleural envelope Researchers may wish to designate the lower paratracheal nodes as No. 4s (superior) and No. 4i (inferior) subsets for study purposes; No. 4s nodes may be defined by a horizontal line extending across the trachea and drawn tangential to the cephalic border of the azygous vein; No. 4i nodes may be defined by the lower boundary of No. 4s and the upper boundary of No. 4, as described previously
5. Subaortic (aortopulmonary window)	Subaortic nodes are lateral to the ligamentum arteriosum or the aorta or left pulmonary artery and proximal to the first branch of the left pulmonary artery, and lie within the mediastinal pleural envelope
6. Paraaortic nodes (ascending aorta or phrenic)	Nodes lying anterior and lateral to ascending aorta and the aortic arch or the innominate artery, beneath the line tangential to the upper margin of the aortic arch
7. Subcarinal nodes	Nodes lying caudal to the carina of the trachea but not associated with the lower lobe bronchi or arteries within the lung
8. Paraesophageal nodes (below carina)	Nodes lying adjacent to the wall of the esophagus and to the right or left of the midline, excluding subcarinal nodes
9. Pulmonary ligament nodes	Nodes lying within the pulmonary ligament, including nodes in the posterior wall and lower part of the inferior pulmonary vein
<b>N1 Nodes: All N1 Nodes Lie Distal to the Mediastinal Pleural Reflection and Within the Visceral Pleura</b>	
10. Hilar nodes	Proximal lobar nodes, distal to the mediastinal pleural reflection and the nodes adjacent to the bronchus intermedius on the right; radiographically, hilar shadow may be created by enlargement of both hilar and interlobar nodes
11. Interlobar nodes	Nodes lying between the lobar bronchi
12. Lobar nodes	Nodes adjacent to the distal lobar bronchi
13. Segmental nodes	Nodes adjacent to the segmental bronchi
14. Subsegmental nodes	Nodes around the subsegmental bronchi

From Mountain CF, Dresler CM: Regional lymph node classification for lung cancer staging. *Chest* 111(6):1718-1723, 1997.

CT, PET, and EUS were performed to evaluate potential mediastinal involvement with bronchoscopic biopsy and cytology-proven ( $n = 25$ ) or radiologically suspected ( $n = 8$ ) lung cancer before surgery. Surgical histology was used as the gold standard and revealed NSCLC in 30 patients, neuroendocrine tumor in 1 patient, and benign disease in 2 patients. With respect to the correct prediction of mediastinal lymph node stage, the sensitivities of CT, PET, and EUS were 57%, 73%, and 94%; specificities were 74%, 83%, and 71%; and accuracies were 67%, 79%, and 82%, respectively. Results of PET could be improved when combined with CT (sensitivity 81%, specificity 94%, and accuracy 88%). The specificity of EUS (71%) was improved to 100% by fine-needle aspiration (FNA) cytology. Furthermore, Redondo et al (2015) performed a comparative study for evaluation of mediastinal lymphadenopathy, directly comparing PET-CT with EUS-FNA. Endosonographers were blinded to PET-CT results. With tissue being the gold standard, the sensitivity and specificity of EUS-FNA was 91.3% and 100%, respectively, compared with 75% and 25%, respectively, for PET-CT.<sup>31</sup> Overall, across both

comparative studies, no single imaging method alone was conclusive in evaluating potential mediastinal involvement.

Whenever enlarged lymph nodes are seen in the mediastinum on chest CT scan, standard practice is to perform a lymph node biopsy for more accurate staging. The traditional methods for performing a lymph node biopsy are via CT or bronchoscopy, or both. Bronchoscopy with FNA is commonly used to evaluate suspicious paratracheal, hilar, and subcarinal lymph nodes seen on CT.<sup>32-35</sup> The role of bronchoscopy in the diagnosis and staging of NSCLC is well established and has a sensitivity of approximately 60%.<sup>36-42</sup> Bronchoscopy, however, is unable to access the aortopulmonary window or the inferior mediastinal nodes. CT-guided biopsy of the mediastinum is limited by overlying vascular and bony structures. When the lymph node status is not determined with CT or bronchoscopy or both, historically, mediastinoscopy, and in some cases limited thoracotomy, were performed to clarify the disease stage.<sup>30,43-45</sup> However, these procedures are significantly more invasive.<sup>46</sup> The advent of EUS and EBUS has made it possible to minimally invasively image the mediastinum with precise

**FIG 47.1** Lymph node stations. (From Mountain CF, Dresler CM: Regional lymph node stations for lung cancer staging. *Chest* 111:1718–1723, 1997.)

resolution, allowing for an accurate and safe method for staging lung cancer.<sup>47–51</sup>

### Endoscopic Ultrasound and Endobronchial Ultrasound

EUS-guided FNA can sample suspicious posterior mediastinal lymph nodes, including aortopulmonary window, subcarinal, and inferior (below carina) paraesophageal nodes. Tracheal air artifact generally precludes reliable assessment of the anterior mediastinum lesions, pretracheal nodes, and upper paratracheal nodes; however, the advent of EBUS technology seems to be minimizing this limitation.

Sampling of suspicious lymph nodes is essential except in N<sub>1</sub> nodes. EUS is best at accurately detecting mediastinal lymph node metastasis in the aortopulmonary window (station 5), subcarinal (station 7), and paraesophageal (station 8) regions (see Fig. 47.1). Several prospective studies evaluated the accuracy of EUS, EUS-guided FNA, and chest CT scan in detecting and staging mediastinal lymph node metastasis in patients with NSCLC based on correlation with surgical staging.<sup>52,53</sup> Gress et al (1997)<sup>54</sup> reported a study consisting of patients with NSCLC and enlarged mediastinal lymph nodes (>1 cm) seen on chest CT scan. EUS criteria used to differentiate benign from malignant

lymph nodes resulted in an accuracy of 84% compared with 49% for CT. The sensitivity (64%) and specificity (35%) of CT scan was compared to the sensitivity (93%) and specificity (100%) of EUS-guided FNA of lymph nodes. A 2008 meta-analysis of 76 studies (44 EUS, 32 EUS-FNA) evaluating mediastinal lymph nodes reported a sensitivity of 84.7% (EUS on criteria alone) and 88% (EUS-FNA), and specificity of 84.6% (EUS on criteria alone) and 96.4% (EUS-FNA).<sup>55</sup> The authors conclude that EUS-FNA should be the diagnostic test of choice in evaluating mediastinal lymphadenopathy, however recognizing the limitation of EUS in the anterior mediastinum.

In an attempt to view the anterior mediastinum, EBUS-guided transbronchial needle aspiration (TBNA) was developed. A systematic review of EBUS-TBNA showed that it was a safe and effective modality to aid in the staging of NSCLC with a sensitivity ranging from 85% to 100%.<sup>56</sup> Eapen et al (2013) performed a prospective study on 1317 patients undergoing EBUS staging with a 1.4% complication rate, with transbronchial lung biopsy being the only major risk factor.<sup>57</sup> In an early, large-scale study, Wallace et al (2008)<sup>58</sup> compared the use of TBNA, EUS-FNA, and EBUS-TBNA using pathologic confirmation of malignancy or benign disease as the diagnostic standard. This group found

EBUS-FNA to be more sensitive, with a higher negative predictive value than TBNA. More importantly, they found the combination of EBUS-FNA with EUS-FNA to have a sensitivity of 93%, a positive predictive value of 100%, and a negative predictive value of 97%. A recent meta-analysis in 2013 by Zhang et al evaluating eight studies further confirmed the conclusion that combined technique was more sensitive and specific than either alone.<sup>10</sup> Given the combined high sensitivity and specificity of EUS-FNA and EBUS-FNA, many investigators have been seeking to perform a complete "medical mediastinoscopy," with the hope of avoiding the more traditional, invasive staging, including mediastinoscopy, of NSCLC before operative intervention.

### Endoscopic Ultrasound Technique for Imaging the Mediastinum

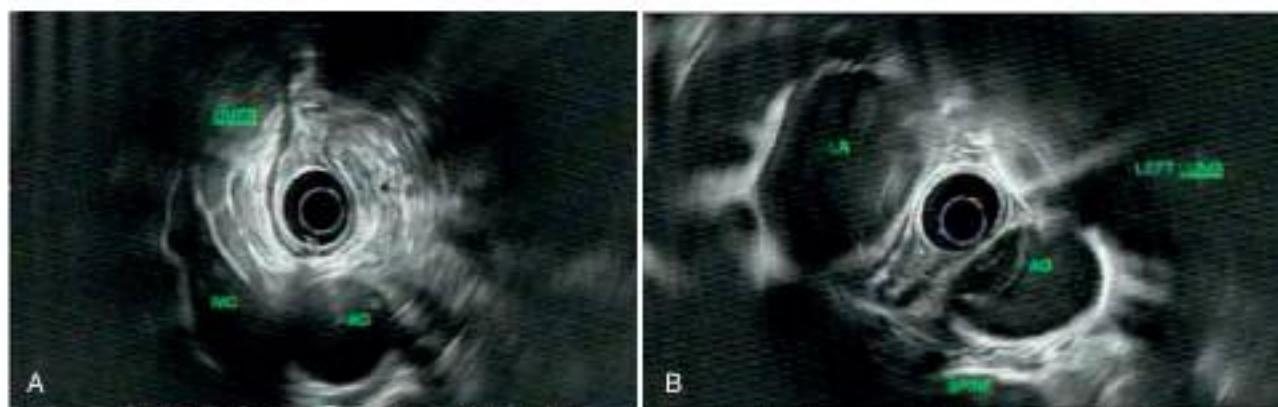

After informed consent is obtained, the patient is placed in the left lateral decubitus position. After sedation, the echoendoscope is passed to the gastroesophageal (GE) junction in a manner similar to the passage of a duodenoscope. Many endosonographers first perform staging with a radial scanning echoendoscope and then switch to a dedicated biopsy echoendoscope or a curved linear array echoendoscope if FNA is to be performed.

When imaging the mediastinum, a thorough understanding of mediastinal anatomy relative to the esophagus is essential to perform a complete examination. Scanning should begin distally below the GE junction while withdrawing the scope proximally because this limits scanning artifacts. It is useful to press the transducer with its balloon partially inflated against the gut wall to minimize air artifacts and to anchor the transducer. In addition, the suction port is depressed to maintain optimal imaging by minimizing intraluminal air.

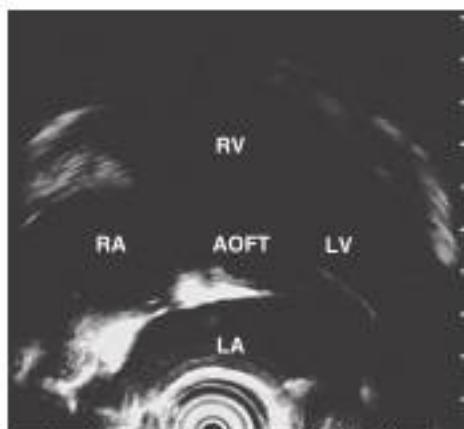

As the endosonographer withdraws the radial scanning echoendoscope, the aorta should be maintained in the 5 o'clock to 6 o'clock position in the ultrasound (US) field, which generally allows proper orientation of the paraesophageal structures. The aorta is easily recognized as a circular anechoic structure, approximately 1.5 to 2 cm in diameter, with a relatively bright border resulting from back wall enhancement (a normal artifact seen in vessels). As the echoendoscope is withdrawn into the distal esophagus, the aorta, spine, left lobe of the liver, inferior

vena cava, and heart can be seen. The spine is also easily identified in the 7 o'clock position next to the aorta and has irregular echo features with artifacts produced by poor penetration of echoes through bony structures. The left lobe of the liver appears at the 6 o'clock to 12 o'clock position, and often the hepatic veins and inferior vena cava can be seen as they course through the liver. Slightly more proximally, the beating of the heart is appreciated as the left atrium comes into view at the 12 o'clock position. The mitral valve leaflets can be seen as the valve opens from the left atrium into the left ventricle, and the pulmonary veins can be seen entering the left atrium. The left pulmonary artery arches posteriorly to the left of the ascending aorta and tends to be easier to view than the right pulmonary artery, which can be seen just below the carina. The left ventricle, right atrium, and right ventricle lie deep to the left atrium; it can be more difficult to visualize these structures completely. As the aorta moves toward the left, the spine and azygous vein are seen posteriorly. The aortic outflow tract can be appreciated as the endoscope is withdrawn further. The spine continues to be a useful landmark because it consistently appears as a hyperechoic structure located posteriorly throughout the chest. Careful inspection of this area may reveal the thoracic duct adjacent to the aorta and spine.

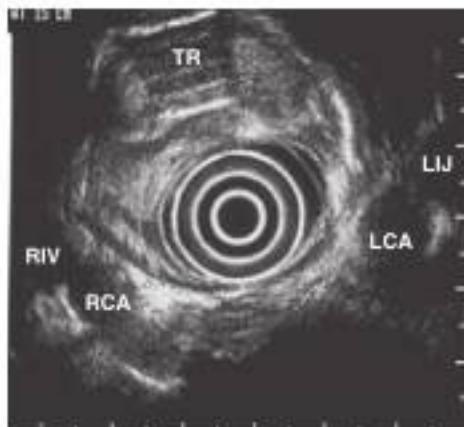

The right lung appears as hyperechoic rings emanating from the 9 o'clock position, whereas the left lung appears at the 2 o'clock position. In the midesophagus, the right and left bronchi are easily demarcated by the hyperechoic rings (echogenic air) seen at the 11 o'clock and 1 o'clock positions. The two bronchi join to form the trachea normally at 27–28 cm from the incisors. The azygous vein can be seen coming into position to the right of the aorta and moves anterior to the spine and toward the right lung. As the endoscope is withdrawn further, the azygous vein can be seen to move forward and extend anteriorly into the superior vena cava. The ascending aorta can be difficult to trace because this structure runs deep to the hilar structures (pulmonary vessels), and because of air within the bronchi and trachea, the ascending aorta is often not fully imaged. In the proximal esophagus, the aortic arch is identified on the left and moves rightward and anteriorly across the screen. In the cervical esophagus, above the level of the aortic arch, the carotid vessels and, occasionally, the thyroid gland can be seen (Figs. 47.2 to 47.4).

**FIG 47.2** **A**, Radial imaging at the distal esophagus showing the liver, inferior vena cava (IVC), and aorta (AO). The spine lies immediately deep to the aorta. **B**, Imaging slightly higher in the distal esophagus showing the right lower lobe of the lung (RLL), left lung (LL), aorta (AO), spine (SP), and a portion of the left atrium (LA).

**FIG 47.3** Radial endoscopic ultrasound (EUS) from the distal esophagus. The left atrium (LA), right atrium (RA), right ventricle (RV), and left ventricle (LV) can be seen. The leaflets of the mitral valve and the base of the aortic outflow tract (AOFT) are also visible.

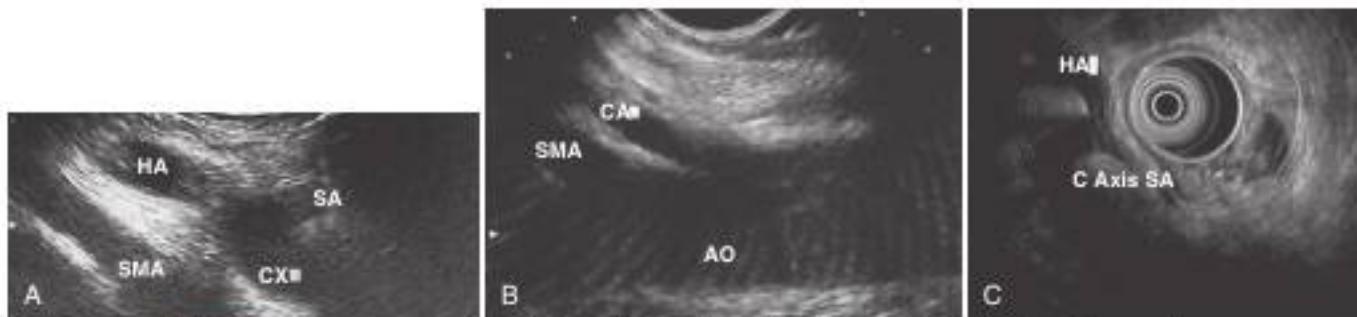

**FIG 47.4** Radial endoscopic ultrasound (EUS) from the most proximal aspect of the esophagus. The left common carotid artery (LCA), left internal jugular vein (LIJ), right internal jugular vein (RIV), and right common carotid artery (RCA) are seen. In addition, the thyroid gland is seen on either side of the trachea (TR). AOFT, aortic outflow tract.

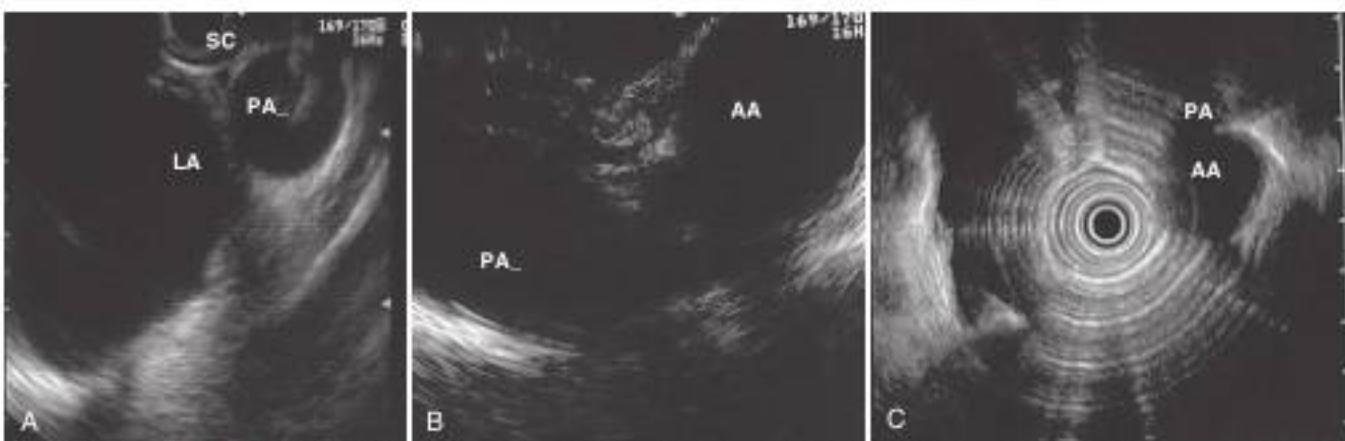

Evaluation of the mediastinum using linear EUS requires rotation of the echoendoscope every few centimeters for a thorough evaluation. As in radial EUS, vascular structures provide the major landmarks for orientation, and the home base structure is the descending aorta, which is first located approximately 35 cm from the incisors. The echoendoscope is rotated initially clockwise (right) bringing structures anterior to the esophagus into view and then counterclockwise (left) bringing posterior structures into view. The left atrium is found by rotating the shaft of the scope 180 degrees in the distal esophagus to midesophagus until a large, echolucent structure is seen within which the mitral valve leaflets are located. By tipping the scope upward and with slight withdrawal, the subcarinal lymph node station is located immediately beneath the endoscope at approximately 27 cm between the left atrium and right pulmonary artery. The aortopulmonary window is located by following the descending aorta cephalad to the arch and pushing the endoscope in again approximately 2 cm. The endoscope is turned 90 degrees clockwise and tipped up slightly until a cross-sectional view of the aortic arch and the more distally located left pulmonary artery are seen. The area between these structures is known as the AP window. Another potentially important area for FNA of lymph nodes is the celiac axis. This area is located by finding the abdominal aorta at the level of the GE junction and the takeoff of the celiac artery with the superior mesenteric artery just distal to this (Figs. 47.5 to 47.8).

### TECHNIQUES FOR STAGING NON-SMALL-CELL LUNG CANCER WITH ENDOSCOPIC ULTRASOUND

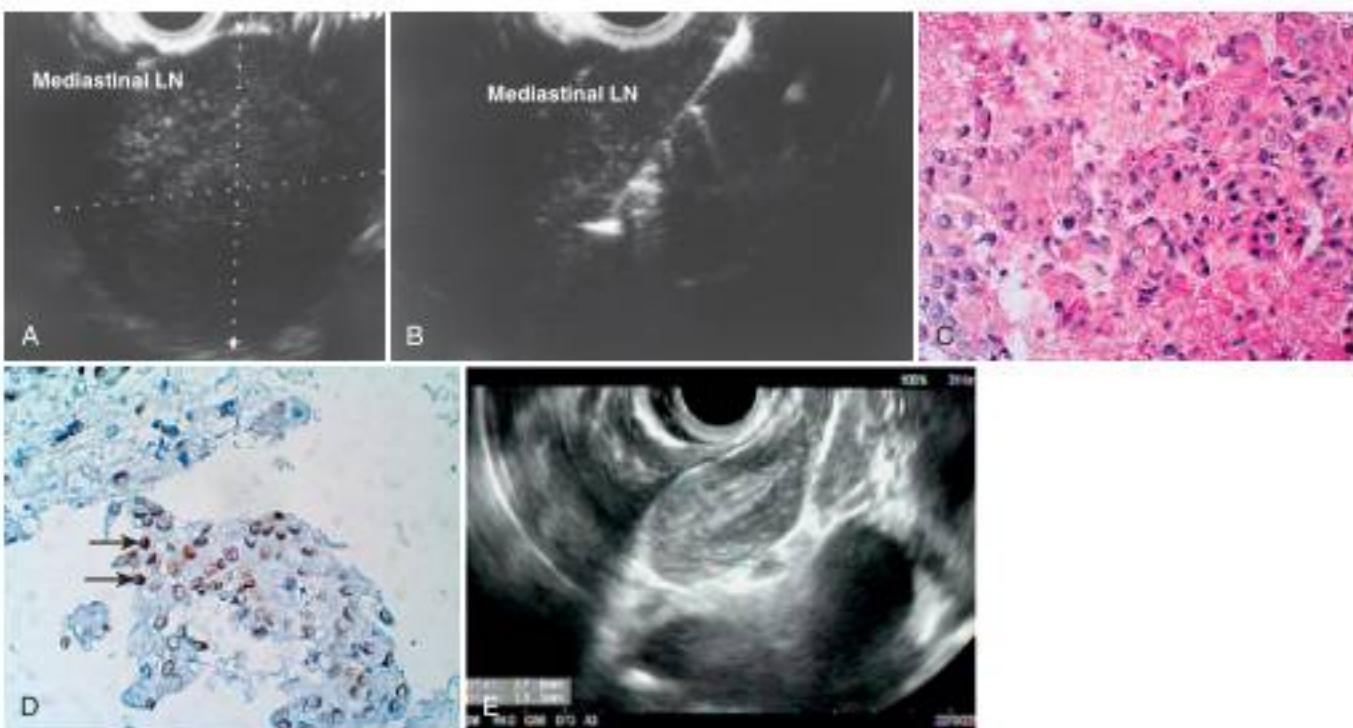

In experienced hands and with careful planning, EUS of the mediastinum can be performed quickly, regardless of the type of EUS technology used. Prophylactic antibiotics are not administered unless recommended by the American Heart Association or the American Society of Gastrointestinal Endoscopy because EUS-guided FNA of mediastinal lesions is not associated with significant bacteremia. However, prophylactic quinolone antibiotics are recommended for FNA of cystic mediastinal lesions, which is similar to the recommendations for pancreatic cystic lesions and perirectal lesions.<sup>83–85</sup> The instrument is advanced into the stomach, and the celiac axis is imaged. The probe is slowly withdrawn to the GE junction and then cephalad using radial scanning images generally obtained with 7.5-MHz frequencies at each 1-cm interval while keeping the aorta at the 5 o'clock

**FIG 47.5** **A**, Linear array imaging of the celiac axis is depicted showing the takeoff of the superior mesenteric artery (SMA) and celiac axis (CX) along with the hepatic artery (HA) and splenic artery (SA) branches. **B**, More typical linear images as seen from the proximal stomach. **C**, Radial imaging showing the CX, AO, Aorta.

**FIG 47.6** **A**, Curved linear array view through the midesophagus of the subcarinal (SC) region. The left atrium (LA) is next to the right pulmonary artery (PA) with the ascending aorta lying deep to these structures. **B**, Linear array view through the midesophagus of the aortic arch (AA) and the pulmonary artery (PA)—the “AP window.” **C**, Radial imaging of the area of the AP window.

**FIG 47.7** **A**, Mediastinal lymph node (LN) as imaged with the linear array endoscopic ultrasound (EUS) system. **B**, The fine-needle aspiration (FNA) needle is seen exiting the scope; the tip of the needle is seen to be in the center of the LN. **C**, High-power magnification of hematoxylin and eosin stain on cell block reveals metastatic adenocarcinoma. **D**, High-power magnification of immunoperoxidase stain on cell block. Tumor nuclei (arrows) are positive for TTF1 antibody consistent with non–small-cell lung carcinoma. **E**, Mediastinal lymph node as imaged with the linear array EUS system in a patient with prior history of Hodgkin’s lymphoma.

or 6 o’clock position, as described earlier. All mediastinal lymph nodes seen are “mapped” by location according to the American Thoracic Society classification scheme (see Box 47.1, Table 47.1, Fig. 47.1, and Video 47.1).<sup>14–15</sup>

An objective determination is made as to whether the mediastinal lymphadenopathy detected by EUS is consistent with benign or malignant status according to previously reported

studies using the same criteria.<sup>16,17–19</sup> EUS criteria used to diagnose malignant lymph nodes are round shape, sharp distinct borders, hypoechoic texture, and a short-axis diameter greater than 5 mm. Each of these parameters should be present for a lymph node to be considered as potentially malignant; however, FNA has significantly improved the sensitivity and specificity of detection of malignant lymph nodes.<sup>24,88,89,90,91,100</sup>

**FIG 47.8** Linear endoscopic ultrasound (EUS) reveals a hypoechoic mass within the mediastinum. EUS-guided fine-needle aspiration (FNA) was performed and revealed metastatic non–small-cell lung cancer (cytology favored a large-cell neuroendocrine-type lesion).

The liver and left adrenal gland are carefully inspected, and any ascites or pleural fluid that is unexpectedly detected is inspected. If suspicious lymphadenopathy or other suspicious findings are seen that may represent metastatic disease, the linear echoendoscope is introduced (if not already in use), and EUS-guided FNA is performed. Many centers have successfully used only linear technology for diagnostic imaging and for obtaining needle aspiration cytologic samples, and this may become the modality of choice after gaining more experience with the technique.

## TECHNIQUE FOR PERFORMING ENDOSCOPIC ULTRASOUND-GUIDED FINE-NEEDLE ASPIRATION

### Mediastinal Lymph Nodes

At the present time, several EUS catheter–FNA needle systems are available with various needle lengths (up to 14 cm) and gauges (19–25-gauge) available. We routinely perform EUS-guided FNA on all posterior mediastinal lymph nodes that are suspicious for malignant involvement by clinical suspicion or EUS criteria, or both. Many patients have more than one suspicious lymph node or finding. In our patients, we sample only the most suspicious lymph node or finding that would have the greatest impact on the clinical staging (i.e., contralateral or subcarinal).

The EUS-guided FNA technique was initially developed for use with the linear array instrument and has been described elsewhere.<sup>94–96,101,102</sup> The unique viewing angle of the linear array transducer allows for observation of the needle as it exits the

biopsy channel and enables direction of the needle tip into the target lesion. A similar technique using a radial scanning echoendoscope has been reported; however, serious complications have been described via this technique, and it is not recommended.<sup>93,103</sup>

EUS-guided FNA involves the insertion of the FNA catheter device through the accessory channel of the echoendoscope followed by deployment of the needle under EUS guidance into the lymph node to be sampled. The handle mechanism is secured to the accessory port, and if the instrument has an elevator, the elevator should be fully released into the down position to allow easy passage of the needle. The elevator can be used during the biopsy to direct the needle gently into the lesion. Doppler is used to identify surrounding vascular structures. The FNA needle is slowly advanced toward the target lesion. With certain needles, it helps if the stylet is withdrawn a few millimeters (2–3 mm), and the needle and the stylet are then directed into the target. When the needle has entered the lesion, the stylet is advanced (to clear the needle) and then removed. The endosonographer or assistant applies suction to the catheter system using a 5-mL or 10-mL Luer-Lok syringe. Suction is followed by in-and-out movements of the catheter after firmly locking the needle–catheter system to the appropriate depth so that the needle is not advanced beyond a desired depth. Typically, we make 7 to 10 gradual in-and-out movements within the lesion. Before removing the needle, the negative pressure is released slowly, the needle is removed from the lesion, and subsequently the needle system is unscrewed from the echoendoscope. It has been suggested to perform EUS-guided FNA of lymph nodes without the use of suction, as suction may result in a bloody sample that may be more difficult for the cytopathologist to examine.<sup>93</sup>

We recommend having a cytopathologist or cytotechnologist present during the EUS-guided FNA portion to improve the efficiency of the technique and potentially obtain preliminary cytology findings. If a cytopathologist or cytotechnologist is unavailable, two to three passes should be performed for lymph nodes (or liver metastases) and five to six passes should be performed for masses (similar to pancreatic masses) to ensure adequate cellularity in more than 90% of cases.<sup>93,103</sup> However, this approach is associated with a 10% reduction in definitive cytologic diagnoses, increased time and risk, and the potential need for additional needles.<sup>103</sup>

The FNA sample obtained is prepared for review using Diff-Quik stain (HARLECO; EMD Chemicals, Inc., Gibbstown, NJ) applied to the slide containing the deposited specimen or fixed with ethanol. Additional passes are made until a positive cytology or adequate tissue sample is obtained. When lymphoma is suspected, additional material is collected if possible and placed in a preservative solution for subsequent flow cytometry and immunocytochemistry as indicated.<sup>104,105</sup> If an infection is suspected, a culture media can be used.

### Other Malignant Mediastinal Disease

The most important indication for mediastinal imaging is the detection or staging (or both) of lung cancer. However, there are other indications for mediastinal EUS. There are several reports of EUS-guided FNA in the cytologic diagnosis and staging of mediastinal metastases from various extrathoracic malignancies. These include metastatic pancreatic, esophageal, gastric, colon, laryngeal, germ cell, renal cell, breast, and ovarian cancers.<sup>73,76,79–81,106–108</sup>

Devereaux et al (2002)<sup>104</sup> retrospectively reviewed a large, single-center experience with EUS-guided FNA for the diagnosis

**FIG 47.9** A 71-year-old woman with a history of breast cancer and melanoma was found to have mediastinal lymphadenopathy on chest computed tomography (CT). **A**, Radial endoscopic ultrasound (EUS) revealed a subcarinal 3.1 × 2.6-cm necrotic-appearing lymph node versus mass. **B**, Linear array imaging depicting fine-needle aspiration (FNA) of this lesion. **C**, High-power magnification of hematoxylin and eosin stain on cell block shows metastatic pigmented melanoma. *AO*, aorta; *AZ*, azygos vein; *LA*, left atrium; *LB*, left bronchi; *LN*, lymph node; *LV*, left ventricle; *PA*, pulmonary artery; *RB*, right bronchi; *TD*, thoracic duct.

of mediastinal mass or lymphadenopathy in the absence of known pulmonary malignancy. In this report, 49 patients were analyzed; a malignant process was diagnosed in 22 of 49 (45%), and a benign process was found in 24 of 49 (49%). These included four patients with previously undiagnosed lung cancer, whereas metastatic breast carcinoma was the most frequent (6 of 22 [27%]) lesion. EUS-guided FNA was diagnostic in 46 of 49 (94%) patients. Eloubeidi et al (2012) analyzed 116 patients with mediastinal lymphadenopathy of unclear etiology and found EUS-FNA sensitivity, specificity, and accuracy to reach almost 100% when on-site cytopathologist and special immunohistochemical stains were administered. Diagnoses ranged from lymphoma to solid-organ non-lung malignancies metastatic to the mediastinum.<sup>110</sup> This is consistent with recent studies that also support the use of EUS-FNA with flow cytometry for the diagnosis of mediastinal lymphoma.<sup>111–113</sup> In a multicenter study of 62 patients, Catalano et al (2002) found EUS-FNA to be diagnostic in 90% of cases, classified as benign, infectious, malignant pulmonary, and malignant mediastinal.<sup>108</sup> Panelli et al (2001) determined over a 5-year period that 2.5% ( $n = 33$ ) of upper EUS examinations involved evaluation for mediastinal lymphadenopathy.<sup>114</sup> EUS-FNA was performed in 25 of 33, of which 22 (67%) were determined to be malignant.

Overall, the authors for these studies suggest that EUS-guided FNA can be a useful and minimally invasive technique for the cytodiagnosis of extrathoracic cancers that are metastatic to the mediastinum (Fig. 47.9).<sup>111</sup>

### Nonmalignant Mediastinal Disease

Although commonly present in patients with suspected or known pulmonary malignancy, mediastinal lymph nodes are also present in patients with benign diseases such as histoplasmosis, sarcoidosis, and tuberculosis.<sup>108,115–118</sup> In addition, benign cystic structures such as congenital foregut cysts account for approximately 20% of mediastinal masses.<sup>119</sup>

Savides et al (1995)<sup>117</sup> described 11 patients with dysphagia who had a midesophageal submucosal mass or stricture. EUS findings consisted of large, matted posterior mediastinal lymph nodes in all patients. The diagnosis of histoplasmosis was

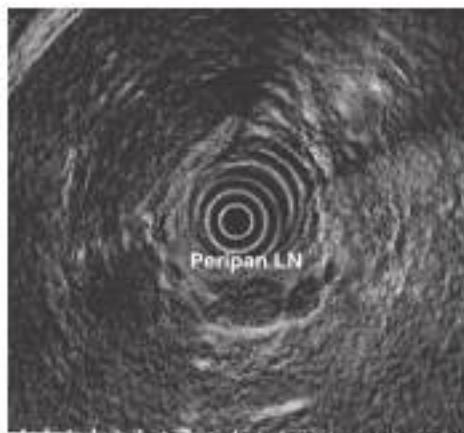

supported by the EUS finding of lymph node calcifications and response to treatment in seven of these patients without a malignancy in 20.5 months follow-up.

Sarcoidosis is a systemic granulomatous disease with a predilection for the lung and mediastinal lymph nodes. Historically, a transbronchial biopsy is carried out, which has a diagnostic yield of 40% with one biopsy and 90% when four biopsy specimens are obtained.<sup>115</sup> If the transbronchial approach is unsuccessful, more invasive diagnostic procedures such as mediastinoscopy or lung biopsy may be used. EUS has been reported to be an accurate and simple less invasive method for the diagnosis of sarcoidosis.<sup>105,106,119–120</sup> In two larger studies, Michael and colleagues<sup>120</sup> and Jamil and colleagues<sup>121</sup> reported a sensitivity greater than 80% in diagnosis sarcoidosis in patients with mediastinal lymphadenopathy, but failed to identify specific EUS characteristics (size, shape, echogenicity, or homogeneity) for sarcoidosis. The authors conclude that FNA is a vital part of the evaluation. A study reporting the results of EUS-guided FNA evaluation in 19 patients with suspected sarcoidosis revealed enlarged mediastinal lymph nodes (mean size 2.4 cm) located subcarinally ( $n = 15$ ), in the aortopulmonary window ( $n = 12$ ), and in the lower posterior mediastinum ( $n = 5$ ).<sup>108</sup> The nodes were described as isoechoic or hypoechoic, with "atypical" vessels in five cases. The aspirate obtained using EUS-guided FNA was adequate in all patients. Cytology showed epithelioid cell granuloma formation, and cultures for mycobacteria were negative in all of the patients except one, in whom the final diagnosis was tuberculosis. The specificity and sensitivity of EUS-guided FNA in the diagnosis of sarcoidosis were 94% and 100%. Furthermore, given sarcoidosis is a systemic disease, there is potential for EUS-guided FNA in the cytologic diagnosis of intraabdominal and pancreatic sarcoidosis, which is beyond the scope of this chapter (Figs. 47.10 and 47.11).<sup>110,120,123,124</sup>

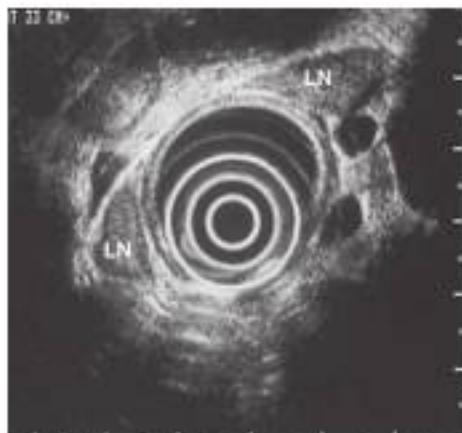

Tuberculosis must be on the differential in the evaluation of benign mediastinal lymphadenopathy. One study<sup>124</sup> found 2 patients with tuberculosis in 101 patients without a history of cancer who had EUS-guided FNA of mediastinal lymph nodes. This study highlights the need for acid-fast staining and culture to exclude tuberculosis in cases of noncaseating granulomas.

**FIG 47.10** **A**, Radial imaging of large hypoechoic, oblong, and teardrop-shaped mediastinal lymph nodes (measuring up to 3.7 cm × 3.4 cm) in a patient with fever and elevated angiotensin-converting enzyme level. **B**, Fine-needle aspiration (FNA) performed with linear array echoendoscope. **C**, High-power magnification of hematoxylin and eosin stain on cell block reveals a noncaseating epithelioid granuloma consistent with sarcoidosis. Special stains (acid-fast bacilli, Gomori methenamine silver) to rule out tuberculosis and fungal infections were negative. AO, aorta; LN, lymph node.

**FIG 47.11** Radial endoscopic ultrasound (EUS) from the body of the stomach in a patient with a history of sarcoidosis with peripancreatic lymphadenopathy that increased in size on serial transabdominal imaging. EUS revealed several hypoechoic lymph nodes. Fine-needle aspiration (FNA) yielded tissue with prominent granulomatous inflammation thought to represent abdominal sarcoidosis. LN, lymph node.

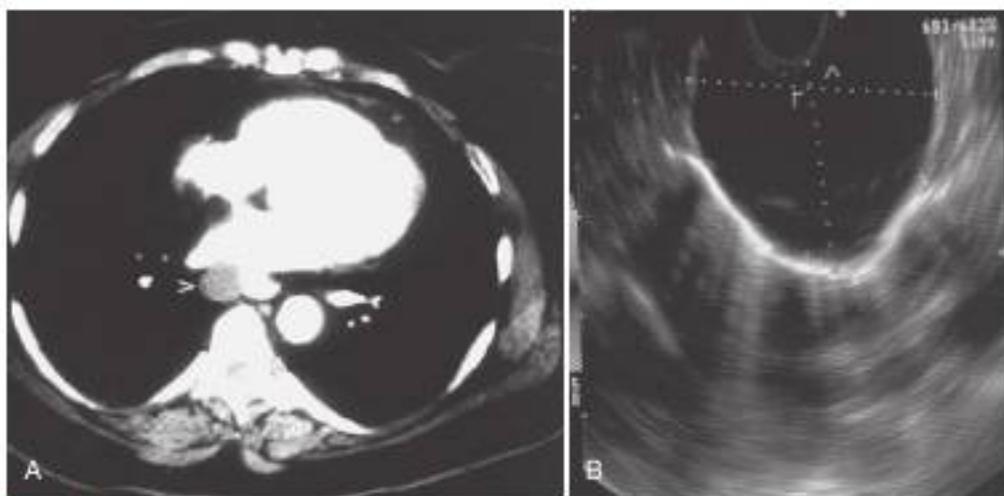

**FIG 47.12** Radial imaging of benign-appearing mediastinal lymph nodes (LN).

nodes for two expert reviewers. The interobserver agreement kappa was 0.84. The authors present elastography as a complement to guide biopsies, as the results still remain inferior to EUS-guided biopsies.<sup>127</sup>

EUS is often useful in distinguishing cystic lesions from solid lesions in the mediastinum, whereas chest CT scan can have limited utility in providing this distinction.<sup>128–133</sup> The features used to classify cysts were as follows: benign simple cysts appear as anechoic or hypoechoic smooth, spherical structures with well-defined thin walls; esophageal duplication cysts are adherent to the esophagus, whereas cysts originating from the airways are designated as bronchogenic cysts. Cysts that do not fall into either category are termed *nonspecific duplication cysts*. A layered wall structure supports the diagnosis of duplication cyst but is not mandatory. Simple cysts include mesothelial cysts, lymphangiomas, and thoracic duct cysts. Simple cysts do not have a layered wall and do not have a connection to the airways or esophagus and are termed *nonspecific simple cysts*. When solid tissue is seen within the fluid, the cysts are considered complex (e.g., benign cystic teratoma, thymic cyst), and the diagnosis of a benign simple cyst is excluded.

Approximately 4% of regional lymph nodes of carcinomas have noncaseating epithelioid granulomas. Therefore a presumptive diagnosis of sarcoidosis or another granulomatous disease should be made only after careful exclusion of malignancy and close follow-up.<sup>125</sup> Detectable mediastinal lymph nodes may also be present in normal subjects and are often found in patients undergoing EUS examinations for various indications, which may be indicative of prior histoplasmosis or other pulmonary infections (Fig. 47.12).<sup>127,128</sup> Given the difficulty in differentiating benign from malignant disease, Janssen et al (2007) tested the use of elastography to aid in the evaluation of lymph nodes in the posterior mediastinum. A total of 50 patients underwent EUS biopsies and each lymph node was characterized by their elastography patterns. Two expert reviewers analyzed the elastography patterns. The accuracy was 81.8% and 87.9% to detect benign lymph nodes, 84.6% and 86.4% to detect malignant lymph

**FIG 47.13** **A**, Chest computed tomography (CT) shows an ill-defined soft tissue density adjacent to the midesophagus. **B**, Linear array imaging of this lesion reveals a paraesophageal duplication cyst.

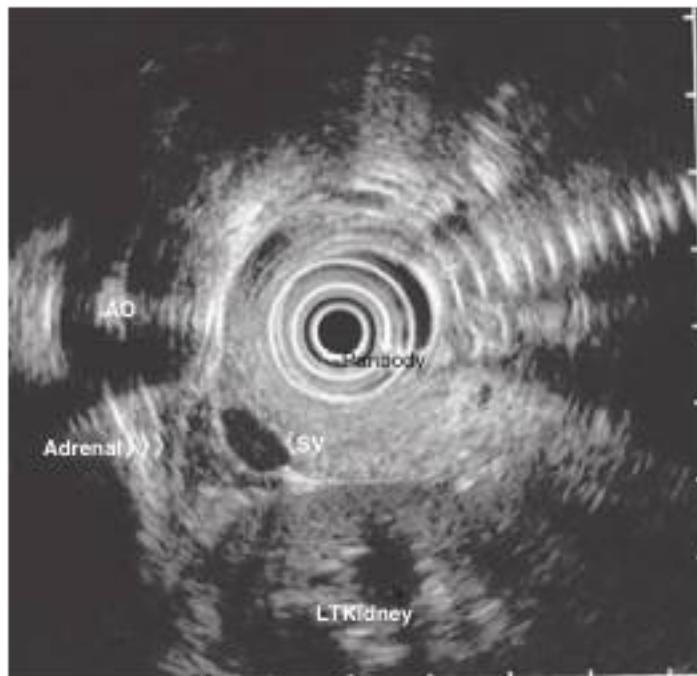

Posterior mediastinal cysts are usually benign; therefore obvious cysts should not be aspirated given the risks of mediastinitis (Fig. 47.13). FNA should be considered for hypoechoic lesions (when a cyst cannot be clearly distinguished from a solid tumor), but prophylactic antibiotics should be administered. Alternatively, an MRI or CT should be performed to confirm that there is a cyst. If FNA of a posterior mediastinal cyst is performed, intent should be for full drainage and a course of antibiotics.<sup>134</sup>

### Adrenal and Renal Lesions

EUS can provide early excellent images of the left adrenal gland. The right adrenal gland is also accessible by EUS, and its routine evaluation may be feasible, although it is more difficult to visualize than the left adrenal gland and the procedure is not routinely performed.<sup>135</sup> The left adrenal gland is more difficult to view than the right gland when imaging with transabdominal US.<sup>136–138</sup>

When imaging the left adrenal gland, the echoendoscope is advanced into the proximal stomach, and the aorta is identified just below the GE junction. The splenic vein is imaged by advancing the transducer forward with a clockwise rotation. Following the splenic vein laterally, the splenic hilum is found by further clockwise rotation and slight withdrawal. The left kidney is imaged by advancing the scope from the splenic hilum with a slight counterclockwise rotation. The left adrenal gland lies just below the splenic vein, between the left kidney (superior and medial to the kidney) and the aorta. In a study by Chang et al (1996),<sup>136</sup> the average long-axis dimension of the adrenal gland was 2.5 cm and the short-axis dimension was 0.8 cm. The adrenal gland as imaged on EUS is homogeneous and hypoechoic with two basic morphologic types: seagull shape and elliptical shape. Occasionally, the adrenal gland can appear as both shapes in the same patient with a slight change in the orientation of the EUS probe tip.<sup>136</sup> In some patients, the central region of the gland may appear more echogenic than the peripheral region (Fig. 47.14).

Incidental benign adrenal lesions are commonly found on CT scans performed for various indications. Unless unequivocally benign, biopsy of these lesions should be performed in certain scenarios. CT scans performed in the staging work-up of lung cancer reveal that more than 16% of patients have adrenal masses

**FIG 47.14** Radial imaging from the body of the stomach showing the left adrenal gland, aorta (AO), splenic vein (SV), left (LT) kidney, and body of the pancreas (Panbody).

on screening examination.<sup>139–142</sup> Metastasis to the adrenal glands as the cause of isolated mass lesions occurs in 32% to 93% of cases of NSCLC, as determined by FNA cytology.<sup>141,144</sup> In autopsy series of NSCLC, adrenal metastases are found in 59% of cases.<sup>143,146</sup>

EUS-guided FNA may provide an alternative to percutaneous aspiration technology in the evaluation of adrenal lesions. Chang et al (1995)<sup>147</sup> reported the identification of the left adrenal gland in 97% of 31 consecutive patients undergoing EUS for known pulmonary or GI malignancies, including one patient with a history of T1N0 lung cancer who was found to have metastatic disease with EUS-guided FNA. A more recent case series (2008)

also suggests that the right adrenal gland may be more accessible by EUS-guided FNA than previously believed.<sup>135</sup> Given the clinical impact of an adrenal metastasis, routine assessment of the left and possibly right adrenal glands in patients with lung cancer is recommended during the EUS evaluation.<sup>147</sup> A meta-analysis identified 17 studies evaluating 416 patients undergoing EUS-FNA of adrenal lesions. Only one complication was identified, adrenal hemorrhage, which required a brief hospital stay, demonstrating the relative safety of the procedure.<sup>148</sup>

EUS of the right and left kidneys is possible because of the immediate approximation between the GI lumen and the kidneys. The right kidney can be imaged by placing the transducer in the second portion of the duodenum and rotating laterally. The left kidney can be imaged from the body of the stomach, posterior to the spleen, as described previously. The left kidney is often easier to show than the right kidney. The kidneys have a hyperechoic central medulla, a hypoechoic outer cortex, and a thin echogenic capsule (Fig. 47.15).

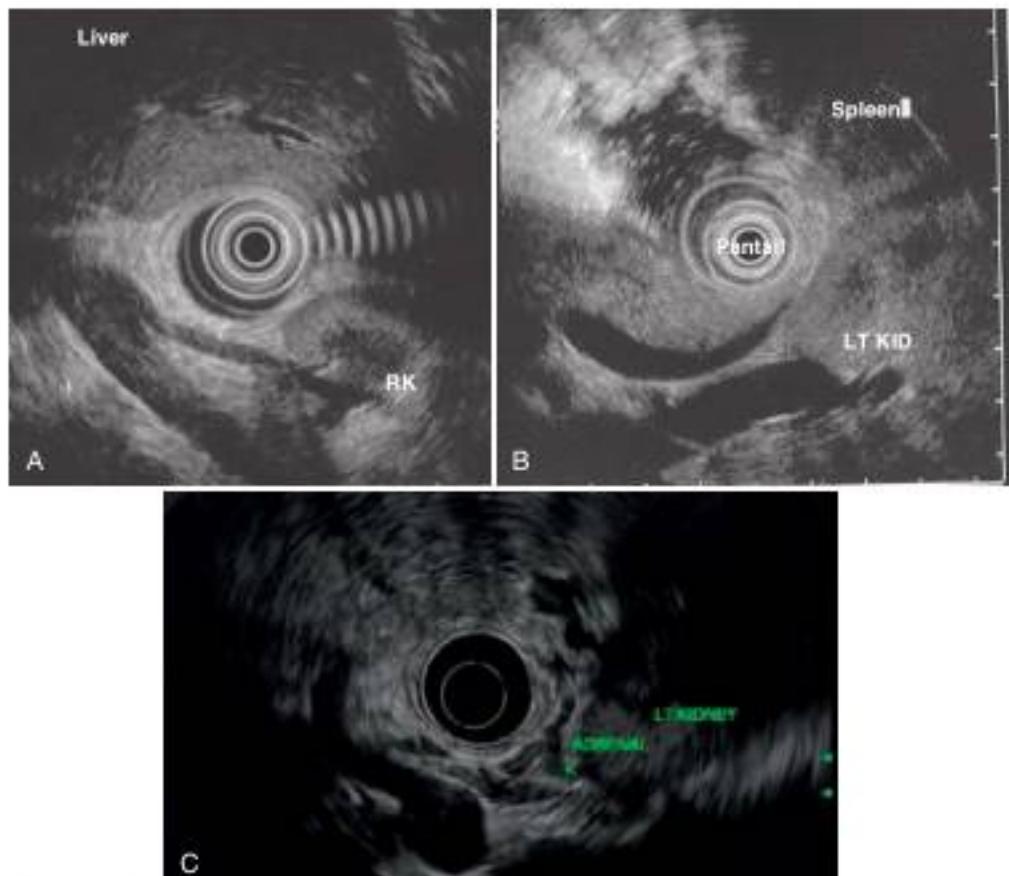

Approximately 85% of renal masses detected on CT are renal cell carcinomas, and 15% of CT-detected renal masses are benign lesions.<sup>149,150</sup> Biopsy of malignant-appearing masses that are resectable should not be routinely performed. Biopsy of a solitary renal mass is generally accepted in cases with a known primary

extrarenal malignancy when the presence of a metastasis would alter management.<sup>148,151</sup> Biopsy specimens of renal masses have traditionally been obtained under either transabdominal US or CT guidance.<sup>149,152</sup> A few case reports exist showing the possibility of making a diagnosis of renal cell carcinoma using EUS-guided FNA<sup>148,153</sup>; however, further experience is required before the establishment of EUS-guided FNA as a modality for performing renal biopsy.

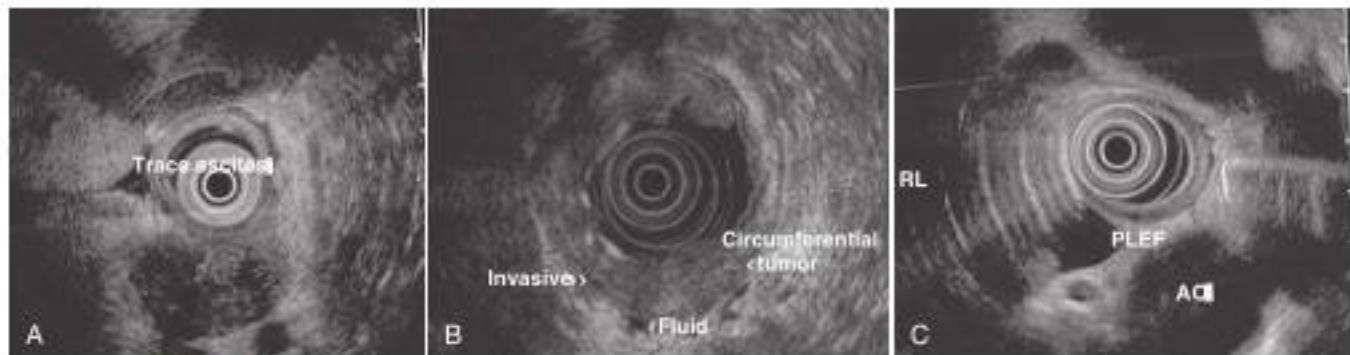

### Ascites and Pleural Fluid

The identification of malignant pleural effusion or malignant ascites is diagnostic of advanced disease in various malignancies. EUS seems to be more sensitive than CT in the detection of small amounts of ascites and pleural fluid. Drainage of pleural fluid or ascites at the time of EUS is possible and can be helpful if positive for malignancy. The technique of EUS-guided FNA of ascites or pleural fluid is similar to the technique applied to other lesions. Seeding of malignant cells into the fluid through the GI tract is a concern. The site of needle penetration in the GI lumen must not be involved with tumor (Fig. 47.16).

Chang et al (1995)<sup>147</sup> reported the utility of EUS for the detection of ascites and EUS-guided FNA in 571 consecutive patients who underwent upper EUS for various indications.<sup>154</sup>

**FIG 47.15** **A,** Radial imaging from the duodenum shows excellent images of the right kidney in this patient with malrotation of the right kidney (RK). The liver is seen in the upper portion of the image. **B,** Radial imaging from the body of the stomach shows the left (LT) kidney, spleen, body and tail of the pancreas (closest to the transducer) and above the splenic vein. The left renal vein is seen exiting the kidney. **C,** Radial imaging from the body of the stomach shows the LT kidney and adrenal gland.

**FIG 47.16** **A**, Radial imaging of trace ascites in a patient with pancreatic cancer. The pancreatic mass is seen below the ascites. **B**, Ascites in a patient with *linitis plastica*. **C**, Pleural effusion (PLEF) seen adjacent to the right lung (RL). AO, aorta.

EUS detected ascites in 85 (15%) patients, whereas CT-detected ascites in 14 (18%) of the 79 patients who underwent CT scanning before EUS. Of 85 patients, 31 underwent EUS-guided FNA paracentesis, and malignant ascites was diagnosed in 5 of these patients. Dewitt et al (2007) performed a retrospective study evaluating 60 patients undergoing EUS-FNA of ascites. Malignancy was revealed in 18 (30%) patients. Negative cytology did not exclude disease, as 3 (5%) patients ultimately were diagnosed with metastatic disease. Two patients experienced self-limited fever as a complication, suggesting the safety of EUS-FNA. The authors did find that EUS more readily identified ascites than CT, transabdominal US or MRI.<sup>155</sup>

### Liver Lesions

EUS provides very good imaging of the left lobe of the liver and a significant portion of the right lobe of the liver. The left lobe and hilum of the liver are examined from the gastric body and fundus. The tip of the echoendoscope is placed in the gastric antrum; then, slowly withdrawing the echoendoscope, the tip is deflected up and rightward. When the liver comes into view, the instrument is rotated to evaluate portions of the liver. The right lobe of the liver is best imaged from the duodenum but can also be seen from the antrum. Liver lesions near the second or third portion of the duodenum, peripheral lesions near the dome of the diaphragm, and lesions in the inferior portion of the right lobe of the liver can be difficult to visualize (see Figs. 47.2 and 47.15).<sup>156</sup>

CT-guided and US-guided FNA of liver lesions have been reported to have sensitivities of 83% to 93% for the detection of malignant disease.<sup>138,140–145</sup> However, although rarely, percutaneous FNA of the liver has been associated with tumor seeding, intrahepatic hematoma, and hemorrhage.<sup>157–161</sup> Nguyen et al (1999)<sup>156</sup> postulated that EUS-guided FNA has the possible advantage over the percutaneous route due to shorter insertion length of the needle if the liver lesion is deep to the skin surface. With EUS-guided FNA, there is continuous visualization of the needle tip, which helps minimize risk for bleeding when the procedure is performed in conjunction with color flow and Doppler US.

Early experience suggests that EUS-guided FNA is comparable to CT-guided FNA in terms of safety and diagnostic utility for hepatic lesions.<sup>156,162–166</sup> Nguyen et al (1999)<sup>156</sup> conducted a prospective study in which 574 consecutive patients with a history or suspicion of GI or pulmonary tumor who were undergoing

upper EUS examinations underwent EUS evaluation of the liver. They found small focal liver lesions that were undetected with conventional CT. Of these patients, 15 (2.6%) were found to have focal liver lesions (5 right lobe, 9 left lobe) and underwent EUS-guided FNA. The median largest diameter of the liver lesions was 1.1 cm (range 0.8–5.2 cm), and the mean number of passes per lesion was 2.0 (range 1–5 passes). Of the 15 liver lesions sampled via EUS-guided FNA, 14 were malignant and 1 was benign. Before EUS, recent CT depicted liver lesions in only 3 of 14 (21%) patients. In seven patients, the initial diagnosis of cancer was made by means of EUS-guided FNA of the liver. There were no immediate or late complications.

tenBerge et al (2002)<sup>166</sup> reported a multicenter study of 167 cases of EUS-guided FNA of the liver. Complications were reported in six (4%) cases, including death in one patient with an occluding biliary stent and biliary sepsis, bleeding (one case), fever (two cases), and pain (two cases). In 23 of 26 patients, EUS-guided FNA helped diagnose malignancy after a non-diagnostic percutaneous FNA. EUS was able to localize an unrecognized primary tumor in 17 of 33 (52%) cases after CT showed only liver metastases. This study highlights the fact that adequate biliary drainage is recommended in the setting of cholangitis before or coincident with the FNA procedure.

Dewitt et al (2003) performed a large single-center study to evaluate the clinical impact of benign and malignant solid liver lesions. The sensitivity for EUS-FNA for malignancy was 94% and malignancy was identified in 41% of patients who had negative prior CT or US. They reported a zero-complication rate.<sup>167</sup> EUS-guided FNA of liver lesions seems to be safe and effective and may become a more useful diagnostic method for liver lesions.

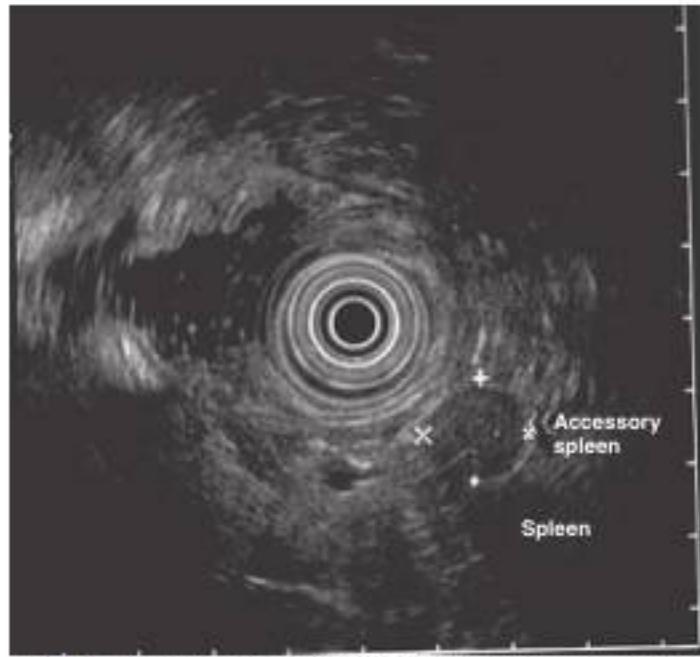

### Miscellaneous

The close proximity of the intestinal tract to abdominal organs raises the possibility of EUS-guided FNA of idiopathic abdominal masses. Catalano et al (2002)<sup>168</sup> retrospectively evaluated the diagnostic accuracy of EUS-guided FNA of abdominal masses of unknown cause and its impact on subsequent evaluation. From five tertiary referral centers, 34 patients with idiopathic abdominal masses underwent EUS-guided FNA after evaluation including CT or transabdominal US, or both. CT showed an intraabdominal mass in all patients. Four patients had a history of intraabdominal cancer (two cervical, one ovarian, one colon), but these cancers were considered to be in remission. A final

diagnosis for the mass lesions was established in all patients by various methods, including EUS-guided FNA, surgery, autopsy, or long-term follow-up. Abdominal masses were classified into three categories: infectious, benign or inflammatory, and malignant. EUS-guided FNA established a tissue diagnosis in 29 of 34 (85%) patients; infectious, 80% including abscess and infected pseudocyst; benign or inflammatory, 67% including hematoma or postsurgical inflammatory mass, leiomyoma, and sarcoidosis; and malignant, 91% including sarcoma, lymphoma, hepatoma, adenocarcinoma of unknown primary, ovarian cancer, transitional bladder carcinoma, uterine or cervical cancer, recurrent colon cancer, neuroendocrine tumor, paraganglioma, metastatic lung cancer, and prostate cancer. EUS-guided FNA was instrumental in directing subsequent evaluation in 29 (85%) patients and therapy in 26 (77%). The number of fine needle passes needed for adequate tissue sampling was lower for nonmalignant (2.2–3.2 passes) versus malignant diseases (4.6 passes). A perirectal abscess developed in one patient and was treated successfully with antibiotics.

Cases using EUS-guided FNA to diagnose a schwannoma of the mediastinum<sup>169</sup> and a retroperitoneal neurilemmoma have been described.<sup>170</sup> In addition, studies by Erickson and Tretjak (2000)<sup>171</sup> and Anand et al (2007)<sup>172</sup> have helped show that EUS-guided FNA is an effective method with a high sensitivity and specificity for diagnosing and altering patient management of nonpancreatic lesions adjacent to the GI tract.

Accessory spleen may be a potential cause of misinterpretation on EUS. Barawi et al (2003)<sup>173</sup> described the EUS features of accessory spleen in 10 (8 accessory spleen, 2 lobulated spleen) patients. The mean size of these lesions was 2.7 × 3.1 cm. Nine accessory spleens were round, and one was oval. All were located inferolateral to the pancreatic tail and medial to the spleen. All these lesions had a sharp and regular outer margin and homogeneous echo texture; four were hypoechoic and six were hyperechoic. CT scan may be helpful in confirming the presence of lobulated spleen and accessory spleen (Fig. 47.17).

**FIG 47.17** Radial imaging from the stomach of an accessory spleen.

One series described EUS-guided FNA of splenic lesions that were considered to be too small or dangerous for sampling with other modalities.<sup>174</sup> In this series, a positive diagnosis was made in 10 of 12 patients (83%) for lesions ranging in size from 0.8 to 4.2 cm (median 1.4 cm). Bacteriology was positive for *Staphylococcus aureus* and *Serratia* in one patient each and for *Mycobacterium tuberculosis* in two patients. Diagnoses included lymphoma, sarcoidosis, abscesses, tuberculosis, metastatic colon cancer, and infarction (in one patient). One patient experienced pain after the procedure, but no hematoma was shown on subsequent US examination. Since this study, other studies have been performed supporting the possibility that EUS-guided FNA of splenic masses is feasible and safe.<sup>175,176</sup>

### Complications

EUS-guided FNA is a relatively safe procedure compared with CT-guided FNA, bronchoscopy with transbronchial FNA, mediastinoscopy, or open or exploratory procedures. Generally, when complications occur, these are usually mild and self-limited. In reports and more recent prospective studies that have addressed complications of EUS-guided FNA, rare complications included endoscope-induced perforations, febrile episodes (after FNA of pancreatic cystic lesions), hemorrhage, pancreatitis, and pneumoperitoneum; false-positive diagnoses have been described.<sup>177</sup> As alluded to previously, the role of prophylactic antibiotics for EUS-guided FNA is unclear. The general practice has been to administer antibiotics to any patient undergoing FNA of cystic pancreatic or perirectal lesions. Barawi et al (2001)<sup>178</sup> studied 108 consecutive EUS-guided FNA cases that did not show bacteremia at 30 and 60 minutes after the procedure. However, the study by Van de Mierop et al (1999)<sup>179</sup> revealed a 19% incidence of bacteremia with EUS-guided FNA of solid lesions.

### CONCLUSION

Over the last two decades, EUS has played an increasingly important role as an accurate and safe method for staging patients with NSCLC. EUS is now integrated into the evaluation of non-GI pathology, especially in the assessment of mediastinal pathology. EUS-guided FNA should be considered in patients in whom a previous attempt at lymph node FNA was unsuccessful using CT or bronchoscopy. Depending on the local expertise, EUS may be considered the primary procedure for biopsy of lesions arising from the posterior mediastinum, especially at levels 5 (aortopulmonic), 7 (subcarinal), or 8 (periesophageal) because these are most readily accessed by EUS. EBUS may also be considered where available to evaluate lesions in the anterior mediastinum traditionally not visualized well with EUS alone. This consideration is of particular relevance for staging of NSCLC, in which contralateral mediastinal lymph node metastases preclude curative resection. Identification of ipsilateral mediastinal lymph node involvement may be helpful for identifying patients who could benefit from neoadjuvant therapy. Mediastinoscopy, thoracoscopy, or partial thoracotomy could be reserved for patients with enlarged anterior lymph nodes or patients with suspicious nodes not successfully sampled by CT, bronchoscopy, EBUS, or EUS. EUS-guided FNA has been shown to be a highly accurate modality for evaluating unknown mediastinal masses or lymph nodes including lymphoma, sarcoidosis, and histoplasmosis.

In patients with otherwise operable lung cancer, EUS-guided FNA may be a viable alternative to percutaneous aspiration biopsy

of a left adrenal mass. EUS can detect small focal liver lesions and small pockets of ascites or pleural fluid not detected by CT. Findings of EUS-guided FNA can confirm a cytologic diagnosis of metastasis and establish a definitive M stage that may change clinical management. EUS-guided FNA of renal masses may be a safe means of confirming the presence or absence of malignancy and may preclude the need for CT-guided studies. EUS-guided FNA provides minimally invasive tissue sampling and may obviate the need for exploratory laparotomy in cases of abdominal masses of undetermined origin.

### INTRODUCTION

Pancreaticobiliary endoscopy focuses on the diagnosis and therapy of conditions involving the pancreas and biliary tree, and distinguishes itself from luminal endoscopy by a greater use of side-viewing endoscopes and echoendoscopes and the use of fluoroscopy. As discussed in Chapter 1, endoscopic retrograde cholangiopancreatography (ERCP) was first performed in the early 1970s, and endoscopic ultrasound (EUS) was introduced in 1980 for transluminal evaluation of the pancreas. During those early years, both ERCP and EUS were primarily diagnostic modalities and lacked therapeutic capabilities. Since then, pancreaticobiliary endoscopy has grown rapidly within the field of gastroenterology, with the development of new endoscopic devices, improvements in endoscopic imaging, and innovation in endoscopic techniques. Concurrent advancements in noninvasive imaging with increased resolution of computerized tomography (CT) scans and the advent of magnetic resonance cholangiopancreatography (MRCP) have redefined the role of pancreaticobiliary endoscopy. In addition, as will be discussed later in this chapter, the therapeutic potential of EUS is increasingly being recognized, and innovative therapeutic procedures using combined EUS and ERCP techniques are being developed.

Though pancreaticobiliary endoscopy may utilize different equipment and devices relative to luminal endoscopy, the fundamentals of patient preparation, reporting, documentation, and risk management overlap and remain applicable to these patients. This chapter will highlight some of the specific preparations that may be required for patients undergoing pancreaticobiliary procedures.

### PATIENT-RELATED PREPARATION

#### Preprocedure Visit

Pancreaticobiliary diseases may range from relatively straightforward uncomplicated disorders such as choledocholithiasis or postoperative cystic duct leaks to more complex and challenging diseases such as primary sclerosing cholangitis, chronic pancreatitis, and disconnected pancreatic duct syndromes. In some cases, the availability of complementary diagnostic imaging (such as MRCP) and therapeutic procedures (interventional radiology, surgery) may impact management.

Therefore prior to performing pancreaticobiliary endoscopy, the indication for which the patient is referred must be carefully reviewed. This may or may not involve a clinic visit and physical examination. Typically, a comprehensive review of the laboratory and imaging data is required. For all patients, a frank discussion regarding the risks, benefits, and alternatives to the procedure must precede any endoscopic procedure. Clinic visits are more helpful for patients who will require multiple procedures and postprocedure admission to prepare them for periprocedural management. This provides an opportunity to establish a relationship and to prepare the patient for the sequence of events involved in their care.

Increasingly, endoscopists meet a patient for the first time in the preprocedure area on the day of endoscopy (open-access endoscopy).<sup>1</sup> Open-access endoscopy has gained popularity due to the increasing number of patients referred for screening colonoscopy who do not require a specialist visit prior to the procedure. With the increasing demand for endoscopic procedures, open-access endoscopy is also practiced in busy pancreaticobiliary

### Abstract

Pancreaticobiliary endoscopy focuses on the diagnosis and therapy of conditions involving the pancreas and biliary tree, and distinguishes itself from luminal endoscopy by a greater use of side-viewing endoscopes and echoendoscopes and the use of fluoroscopy. With advances in endoscopic equipment and growing experience, pancreaticobiliary endoscopy has evolved to encompass a wide range of diagnostic and therapeutic procedures of increasing complexity. Accordingly, the practice of pancreaticobiliary endoscopy requires meticulous preparation and training. This chapter reviews the various aspects of preparation for pancreaticobiliary endoscopy. These aspects are conveniently organized under patient-, physician-, and endoscopy unit-related preparation, with an emphasis on existing guidelines and published evidence. Preprocedure visits, the role of open-access endoscopy, informed consent, and interdisciplinary communication are discussed in the patient-related preparation section. Physician training, credentialing, and guidelines for the acquisition and adoption of new techniques are highlighted in the provider preparation section. Suggestions for unit layout, ergonomics, fluoroscopy, staff training, and postprocedure care are provided in the endoscopy unit-related preparation section. Attention to these often-overlooked details before and after the procedure increases the chance of a successful endoscopy and an excellent outcome for the patient.

### Keywords

pancreaticobiliary endoscopy

patient preparation

endoscopy units. The basic tenets of open-access endoscopy include appropriateness of referral, patient acceptance and preparedness for endoscopy, informed consent, diagnostic yield of the endoscopy, and assurance that appropriate follow-up will be adhered to. For pancreaticobiliary endoscopy, it is important to review these requests on an individual basis. In such cases, the endoscopist should review the pertinent patient data prior to meeting the patient and allow time for a discussion, as stated earlier. Patient dissatisfaction and communication lapses are the leading cause of medicolegal claims, and may be much more common than true malpractice or medical negligence.<sup>2</sup>

Most pancreaticobiliary endoscopy is now performed under anesthesiology supervision. Preprocedure consultation may also be useful for patients with comorbidities to allow a preprocedure anesthesia evaluation that enables the anesthesiology team to complete their assessment of the patient and obtain any additional testing, such as an electrocardiogram or cardiac evaluation. This process may decrease procedural cancellations on the day of the endoscopy and can facilitate flow in the endoscopy unit.

### Informed Consent

Consent is a voluntary agreement by a person with functional capacity for decision making, allowing a procedure to be performed on himself or herself. It is based on the principles of self-determination and autonomy, and requires that the provider or provider's representative provides the patient with substantive information necessary to make a reasoned decision.<sup>3</sup> In most circumstances, informed consent is also a requisite legal document, and failure to properly obtain informed consent can constitute medical battery and negligence.

It is especially important for pancreaticobiliary endoscopists to understand the concept of informed consent, as these procedures are frequently complex and may be associated with a higher rate of more serious adverse effects than other endoscopic procedures. Informed consent should be obtained after a detailed discussion of the nature of the proposed procedure, indication, and benefits, as well as potential risks and complications. Whenever possible, it is recommended that information in the form of non-technically worded handouts, fliers, or informational videos be shared with patients in advance of the procedure, giving them ample time to comprehend the planned procedure and allay their concerns.<sup>4</sup> A preprocedure visit or a well-documented preprocedure phone call can sometimes be utilized to help improve understanding of the procedure, and may allow time if there are additional concerns.

The consequences of not undergoing the procedure and the presence of alternatives to the procedure may also be very relevant to the discussion. Sometimes unanticipated procedures are needed in addition to the planned procedure, e.g., adding an unplanned EUS-guided rendezvous during a planned ERCP. Therefore some centers may require that these additional procedures be included as a part of the informed consent process. As a patient may withdraw consent at any time until the start of the procedure, it may be best if the consent is obtained on the day of the procedure. Often, the consent has a window of coverage within which the procedure must occur, or the consent will need to be repeated.

It is also recommended that a physician performing or participating in the procedure obtains the informed consent, thereby providing another opportunity to address any questions. Inadequacies in the informed consent process may impact patient-physician relationships, and are also one of leading

components of legal claims and lawsuits against pancreaticobiliary endoscopists.<sup>5</sup>

### Interdisciplinary Communication

In the area of pancreaticobiliary endoscopy, healthy and direct relationships with specialists in other disciplines are critical. Patients referred for pancreaticobiliary endoscopy often have complex neoplastic or inflammatory diseases and significant comorbidities. Very often, care is multispecialty, with patients frequently also receiving care from surgeons, oncologists, radiation oncologists, and/or interventional radiologists. Participation in multidisciplinary tumor boards with radiologists, medical and surgical oncologists, and pathologists is often helpful for outlining management plans for complex cases. Referral for pre-anesthesia evaluation for patients with significant comorbidities is frequently of benefit. Discussion with interventional radiologists and surgeons about the best approach for the management of the condition and complications, should they occur, is often of benefit if the presentation could be managed in several ways. Such collaboration may improve patient care and outcomes.<sup>6</sup> This is aptly illustrated in a 2014 single center study, where establishment of a multidisciplinary pancreatic cyst clinic led to a change in management of 30% of patients after a collaborative review of imaging features, cyst fluid analysis, cytology, and patient preference by gastroenterologists, pancreatic surgeons, radiologists, and cytopathologists.<sup>7</sup>

## PROVIDER-RELATED PREPARATION

### Provider Competence

Competence is the minimal level of skill, knowledge, and expertise required to safely and proficiently perform a procedure. Given the significant complications that may be associated with pancreaticobiliary endoscopy, it is very important that the endoscopist is competent and has the necessary skill set to perform the planned procedure. With the rapid pace of advancement, competence in pancreaticobiliary endoscopy requires not only adequate training but also an adequate case volume after training to maintain proficiency.

In 1996, a threshold of 100 ERCPs with 20 sphincterotomies was first proposed as a threshold for adequate training in ERCPs prior to independent practice. This threshold was soon challenged, and a more recent systematic review (2015) has suggested that 160–400 ERCPs may be required to achieve competency.<sup>8</sup> Similar numbers have also been proposed for EUS training.<sup>9,10</sup>

The increased scope and complexity of pancreaticobiliary endoscopy has led to a fourth year of advanced endoscopy training to achieve proficiency and certification in pancreaticobiliary endoscopy. It is, however, important to recognize that the number of procedures remains a surrogate for provider competence. Prospective multicenter studies on advanced endoscopy trainees have suggested that emphasis should be shifted to well-defined and validated competency thresholds for ERCPs and EUS rather than numbers alone.<sup>11,12</sup> It is important to recognize that, even if a provider is competent in performing the more common endoscopic procedures like stone extraction, stent placement, or fine needle aspiration, they may not have enough experience in the more complex procedures such as pancreatic necrosectomy or EUS-guided rendezvous. It has been demonstrated that high-volume endoscopists and centers have better outcomes than facilities where pancreaticobiliary endoscopy is performed less frequently (< 50 ERCP/year per endoscopist or < 87–200 ERCP/

year per center).<sup>13,14</sup> However, at this time, no guideline recommendations for case volume per endoscopist or center performing pancreaticobiliary endoscopy for maintenance of skills exist.

Another very important aspect of this field is the acquisition and safe adoption of new techniques and technology as they are introduced. The American Society of Gastrointestinal Endoscopy has published guidelines for the clinical application of these techniques that can be used by hospitals and practices for credentialing and granting privileges.<sup>15</sup> These guidelines recommend that emerging technologies can be stratified according to their complexity and general applicability. Training in minor new skills that are an extension of or advancement in a currently performed procedure or technique may be achieved by reading, viewing video recordings of the technique, or attending short courses. Training in major new skills that involve new techniques or procedures with a high level of complexity, interpretative requirements, and/or a new type of technology may require formal hands-on training under supervision, followed by documentation of competency.

Achieving competency in newer technologies depends on the individual endoscopist's skill set and prior training and the complexity of new technology. Therefore it is important for the endoscopist to adequately plan for the procedure prior to scheduling and to recognize if certain interventions or maneuvers are outside their skill set. In such cases, depending on the resources available, the provider may ask for supervision from a more experienced endoscopist or refer the patient to a center where such expertise is available. Representatives from industry may often provide assistance with training in the use of a particular accessory or endoscope, may provide case support, and may assist with materials and demonstration. This would not necessarily supplant training requirements for certain procedures that are high risk and represent a larger departure from procedures currently performed by the endoscopist.

## ENDOSCOPY UNIT-RELATED PREPARATION

### Endoscopy Unit Design

Ideally, the endoscopy suite for the performance of pancreaticobiliary endoscopic procedures should be 300 square feet or larger.<sup>16</sup> This is because pancreaticobiliary endoscopy requires additional equipment that may not be used for general endoscopy. This equipment may include EUS processors, electrohydraulic lasers, fixed table fluoroscopy, or portable C-arms. Frequently, these procedures also require anesthesiology support, and the presence of anesthesiology equipment, ventilators, and personnel requires additional space considerations. Equipment required for the procedures should be positioned to enable visualization, provider movement, and image transmission, all with the ultimate goal of facilitating a good procedural outcome for the patient.

Endoscopists are at increased risk for musculoskeletal injuries due to repetitive movements and possibly abnormal posture, and surveys of endoscopists have suggested musculoskeletal injury rates between 29% and 89%.<sup>17</sup> This risk may be greater in pancreaticobiliary endoscopists due to the longer duration of the procedures, thumb movement on the elevator of endoscopes, and the use of lead aprons, which leads to added strain to the neck and shoulders.<sup>18</sup> Therefore the endoscopy unit should be ergonomically designed and equipped to allow the endoscopist to stand on an antifatigue cushioned floor mat in a neutral position with video monitors positioned at eye level to minimize musculoskeletal stress and the risk of mechanical injuries.<sup>17</sup> Split

lead aprons are helpful in distributing the weight over the hips and less on the neck/lower back, and should be used if available.

A usual format that is followed is to center the room around the patient table and fluoroscopy equipment, such that adequate space is available at the head end for patient monitoring and anesthesia equipment, and for the endoscopist and the assistant to stand unencumbered on the side with access to control panels, monitors, and endoscopy devices. To achieve this, most high volume centers have dedicated pancreaticobiliary endoscopy procedure rooms with fixed table-mounted fluoroscopy equipment, boom- or wall-mounted video monitors, and storage for specialized endoscopic devices to efficiently and ergonomically perform these procedures. In lower-volume centers, where such dedicated fluoroscopy-enabled rooms are not present, portable C-arms may be brought in for performance of ERCPs. In such cases, it is important to remember the aforementioned principles and to position equipment prior to the start of the procedure, not only to allow for unobstructed and efficient conduct of the procedure but also to ensure that there is no impediment to accessing the patient or changing the position of the patient for resuscitation, should the need arise.

Pancreaticobiliary endoscopy requires frequent use of radiation, and may therefore expose the patient and endoscopy staff to the risk of radiation injury. Although most studies report that radiation exposure to providers and patients is well below the safety limits, the pancreaticobiliary endoscopy suite should be shielded to prevent radiation exposure outside the suite, and should have indicators for active fluoroscopy use. To mitigate the risk of radiation to endoscopy personnel, wraparound lead aprons, thyroid shields, and leaded eyeglasses should be provided and their use encouraged.<sup>19</sup> The endoscopy personnel should use dosimeters, and monthly evaluation of radiation exposure should be performed to keep track of cumulative radiation exposure for the endoscopy staff. Whereas some institutions require that nonradiologists undergo formal credentialing in the use of fluoroscopy, even if not mandatory, the pancreaticobiliary endoscopist and the endoscopy staff should at least have access to radiation safety information and be aware of the "ALARA" (as low as reasonably achievable) principle to decrease avoidable fluoroscopy use and radiation exposure.<sup>19,20</sup>

### Staff Training

Endoscopy practice is most commonly performed with support from nonphysician staff in the endoscopy unit. This staff may involve nurses, endoscopy technicians, nursing aids, anesthesia personnel, and administrative staff. Whereas adequate criteria have been set for physician training and maintenance of competence, most endoscopy staff undergo on-the-job training, and training certification is largely voluntary. Organizations such as the Society of Gastrointestinal Nurses and Associates offer training and certification courses for nurses and associates, as well as ongoing education through various local, regional, and national conferences, to provide a forum for staff exposure to new developments and techniques in endoscopy.

Another means of providing continuing staff training involves hands-on product demonstrations in the endoscopy unit to familiarize the staff with the use of available equipment, a process that is commonly referred to as an *in-service*. This may be applicable not only to new devices but also to periodic updates on equipment that is infrequently used (e.g., a mechanical lithotriptor) or complex devices (e.g., electrosurgical generators). This

may be facilitated by including industry representatives and training with the devices on animal explants or inanimate models. Such efforts are valuable in ensuring staff competency, facilitating the adoption of new technology, and eventually contributing to patient safety.<sup>21</sup>

### Preprocedure Checklist

Since their introduction, surgical safety checklists have been shown to decrease complications, length of hospital stay, and mortality, and are now used in most operating rooms.<sup>22</sup> These checklists were initially introduced for preprocedure verification of the patient, site of surgery, and antibiotic prophylaxis, as well as postprocedure sponge counts; however, an ancillary benefit involved increased communication within the operating room, further increasing efficiency and minimizing errors. Variations on these checklists are now used in most procedures outside the operating room, including endoscopy.<sup>23</sup>

As an extension of these checklists, the endoscopist can discuss the planned endoscopic procedure, and the anticipated devices and accessories can be pulled in advance. This helps team members prepare for the procedure, gives team members a chance to ask for guidance on the use of devices they may not be comfortable with, and ensures that all the required equipment is present prior to the start of the procedure. Doing a huddle and performing preprocedure verification of accessories may occasionally mean the difference between the success and failure of complex therapeutic pancreaticobiliary endoscopy procedures.

### Postprocedure Care

Increasingly complex therapeutic pancreaticobiliary endoscopic procedures are being performed on outpatients. Although the paradigm for most outpatient endoscopic procedures is early discharge after recovery from sedation, patients undergoing pancreaticobiliary endoscopy may require more prolonged postprocedure observation and aggressive postprocedure hydration, and occasionally have intraprocedural events or persistence of pain that may trigger further testing, procedures, or unplanned admissions.<sup>24</sup>

Frequently, complex pancreaticobiliary procedures are scheduled with a planned postprocedure admission. Therefore the unit should recognize that these patients may require close monitoring, and a protocol for postprocedure care should be developed by the physicians in conjunction with the postprocedure team and unit managers. Doing this allows the staff to assist with and facilitate the care of patients who may have unanticipated outcomes, and will ideally allow the busy outpatient endoscopy unit to run smoothly, without needing to divert staff or resources to attend to these patients.

### CONCLUSION

The field of pancreaticobiliary endoscopy continues to advance at a rapid pace. New developments such as interventional EUS, management of peripancreatic fluid collections, pancreatic necrosectomies, and submucosal endoscopic procedures such as endoscopic submucosal dissection and peroral endoscopic myotomy are permitting more advanced care to be performed in a minimally invasive manner. As these novel technologies and approaches are adopted, it is important that patients be advised of the options and alternatives in their treatment. At times, the higher procedural risk of a surgery must be weighed against a higher chance of recurrence if an endoscopic resection is not

complete. The necessity of interspecialty communication and collaboration has grown with the proliferation of treatment paradigms.

In what settings is an endoscopic procedure preferable to a minimally invasive surgery? What are the risks of repeated endoscopic procedures, compared to the morbidity of a single definitive procedure? In complex cases or gray areas, it is generally best to involve stakeholders prior to the procedure, allowing surgery, interventional radiology, and/or oncology to weigh in, as this increases the odds of obtaining the best outcome for the patient. Preparation for advanced endoscopic procedures becomes more important as higher risk procedures, novel procedures, and innovative approaches are implemented. Ultimately, attending to the details before and after the procedure increases the chance of a successful endoscopy and an excellent outcome for the patient.

## INTRODUCTION

Endoscopic cannulation of the major papilla with imaging of the biliary tree and the pancreatic ductal system (endoscopic retrograde cholangiopancreatography [ERCP]) was first successfully accomplished with an end-viewing duodenoscope and reported in 1968.<sup>1</sup> Subsequent development of side-viewing endoscopes with a catheter-deflecting elevator greatly advanced the technique. Diagnostic studies were supplemented by the first endoscopic sphincterotomies in the early 1970s.<sup>2,3</sup> Overall, these developments expanded the field of endoscopy and permitted the performance of less invasive diagnostic and therapeutic maneuvers in the pancreaticobiliary ductal system(s), which were previously limited to open surgical and percutaneous techniques.

In recent years, the refinement and proliferation of magnetic resonance imaging (MRI) and endoscopic ultrasound (EUS) techniques have changed the practice of ERCP. Now that quality diagnostic studies are readily available to the pancreaticobiliary endoscopist, ERCP has evolved from a stand-alone diagnostic procedure into an almost exclusively therapeutic endeavor. Although diagnostic indications for ERCP have now been displaced by the aforementioned less invasive, lower risk imaging modalities, the need for mastery of the radiographic findings of ERCP remains. Expert level execution and interpretation of

diagnostic ERCP is a crucial component for skillful, efficient deployment of therapeutic interventions. Diagnostic ERCP findings also complement (and, in a few scenarios, are superior to) noninvasive imaging modalities for establishing or excluding pathology (e.g., pancreatic ductal leaks and fistulae).

This chapter reviews the indications for ERCP, techniques involved in its performance, and frequently encountered normal and pathologic diagnostic findings.

## INDICATIONS AND CONTRAINDICATIONS FOR ERCP

Imaging of the pancreaticobiliary ductal system without anticipated therapy is appropriate in a narrow set of clinical circumstances. Patients requiring ductal imaging who are unable to undergo MRI/magnetic resonance cholangiopancreatography (MRCP) (e.g., those with implantable devices and/or a large body habitus) may require diagnostic ERCP as a first diagnostic test for ductography. However, conditions that indicate ERCP as purely a diagnostic modality are usually exceptional (e.g., cholestasis without dilated ducts, suspicion of early sclerosing cholangitis, confirmation of pancreatic fistula after nondiagnostic imaging if clinical suspicion persists), and it should only be performed in a setting of at least moderate pretest suspicion. In certain settings, such as clinical diagnosis of acute cholangitis

**Abstract**

Endoscopic retrograde cholangiopancreatography (ERCP) is no longer the first choice for diagnostic imaging for many conditions of the biliary tree and pancreas, due to relative risk for complications compared to current noninvasive modalities. However, ERCP remains a firmly established therapeutic modality that offers a wide range of interventions for pancreaticobiliary disease. Skillful execution of diagnostic ERCP remains crucial for the safe and effective deployment of endoscopic therapies. The pancreaticobiliary endoscopist must also master the interpretation of normal and pathologic radiographic findings encountered during ERCP to ensure the highest quality of care for patients. We present an evidence-based review of techniques for safe and efficient diagnostic ERCP. We also review radiographic features of a normal cholangiogram and pancreatogram, as well as findings associated with frequently encountered pathologies of the pancreas and biliary tree.

cannulation

with shock or sepsis, therapeutic ERCP is considered lifesaving, and need not be preceded by cross-sectional imaging. Overall, ERCP is indicated in clinical settings in which there is significant suspicion of pathology and a clear intention for therapeutics. A general list of indications is shown in Table 49.1.

Most contraindications to ERCP are relative, and the degree of risk must be balanced against the potential benefit.<sup>44</sup> In patients with necrotizing pancreatitis and low clinical suspicion for ductal stones, ERCP is relatively contraindicated, as pancreatography may result in bacterial contamination of the pancreatic bed and undrained fluid collections. Other relative contraindications

include unstable cardiopulmonary disease or severe coagulopathy. Patients with comorbid life-threatening conditions can have endoscopic retrograde cholangiography (ERC) performed in the intensive care unit (with or without fluoroscopy) if deemed medically necessary. ERCP with manometry and/or sphincterotomy is now generally not indicated in patients with type III sphincter of Oddi dysfunction, given the negative results of a 2014 high-quality, randomized study.<sup>7</sup>

## ENDOSCOPIC EQUIPMENT

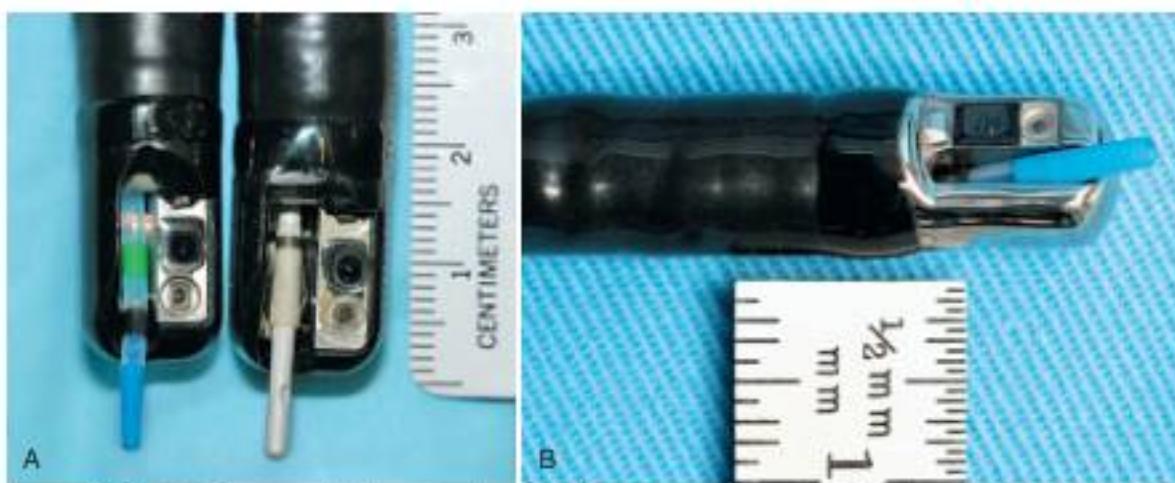

ERCP is performed using side-viewing instruments with video chip processors that provide high-quality images. Digital video systems (over fiberoptic) are now the standard, as they offer the advantage of television monitor viewing by all persons in the endoscopy suite, real-time teaching capabilities, and seamless coordination between the endoscopist and the ERCP team. Endoscopes have a working length of 120 cm and are generally categorized as diagnostic (11-mm distal diameter) or therapeutic (13.7-mm distal diameter). Some newer-generation endoscopes combine a large working channel diameter (up to 4.2 mm) with a standard 11-mm insertion tube diameter (Fig. 49.1). A pediatric duodenoscope with an outer diameter of less than 7.5 mm is available (Olympus America Inc., Center Valley, PA). Most ERCP examinations should now be performed with CO<sub>2</sub> insufflation. Data suggest that CO<sub>2</sub> insufflation reduces postprocedure abdominal distension and pain, and likely expedites recovery.<sup>5</sup>

Current-generation endoscopes are capable of undergoing submersion disinfection. After cleaning, endoscopes should be hung in vertical position to facilitate drying. However, in the setting of growing concern over carbapenem-resistant Enterobacteriaceae infections linked to contaminated duodenoscopes even after "standard" reprocessing procedures, enhanced techniques for disinfection and surveillance are now recommended.<sup>6</sup> Special attention should be given to the elevator mechanism during disinfection. Surveillance cultures of the duodenoscope instrument channel and its distal components are also recommended, with reprocessing of duodenoscopes if cultures are positive.<sup>6</sup>

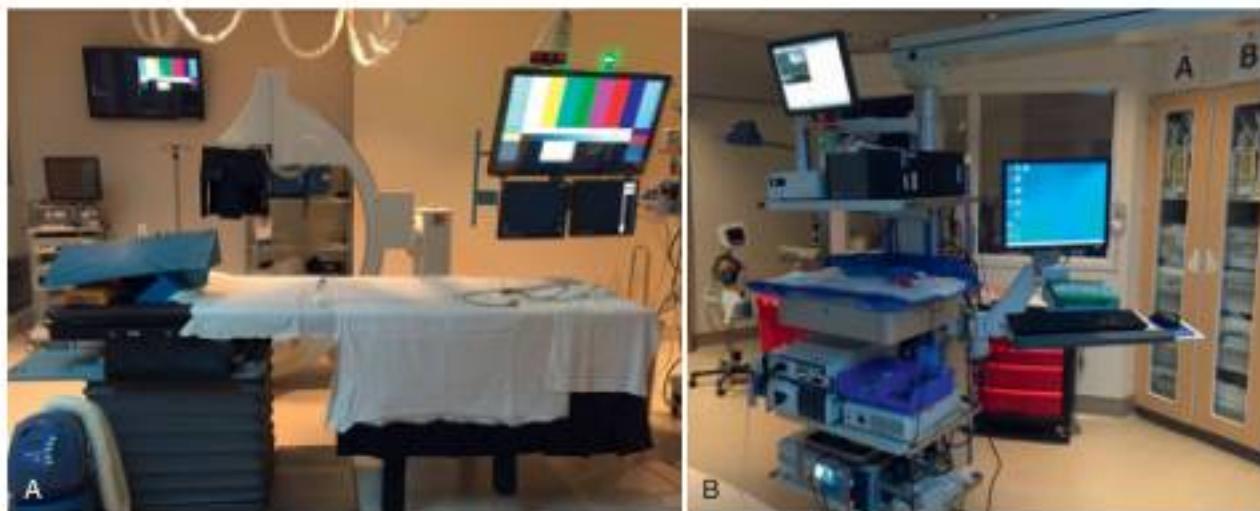

**TABLE 49.1 Indications for Endoscopic Retrograde Cholangiopancreatography**

Category	Biliary	Pancreatic
Diagnosis/ confirmation of suspected disorder	Obstructive jaundice/ cholestasis Ascending cholangitis Symptomatic choledocholithiasis Biliary lesion seen on other imaging test Biliary leak/fistula	Recurrent pancreatitis Main duct or mixed IPMN Chronic pancreatitis Pancreatic leak/fistula
Endoscopic therapy	Sphincterotomy Biliary drainage (stent) Bile-duct stricture therapy	Sphincterotomy Pancreatic drainage Transpapillary therapy for pseudocysts Pancreatic duct stones/strictures Pancreatic leak/fistula
Endoscopic tissue and fluid sampling	Biopsy, brush cytology, fine needle aspiration, bile collection	Biopsy, brush cytology, pancreatic juice collection
Preoperative ductal mapping	Malignant and benign bile duct strictures	Chronic pancreatitis
Manometry	Sphincter of Oddi dysfunction	Idiopathic pancreatitis

IPMN, intraductal papillary mucinous neoplasm.

Note lead apron drape from image intensifier and multiple high-resolution monitors. **B**, Tower with video recorder, video processor, and electrocautery unit. Note closet for storage of endoscopic accessories in the background.

### Digital Imaging and Radiation Safety

Endoscopists at high-volume centers often have dedicated suites for ERCP. However, many physicians in the community and/or at lower-volume centers must coordinate procedures with a radiology department and use general purpose or angiographic units. Manufacturers now market dedicated fluoroscopy units for ERCP. Flat tables with a fixed overhead carriage have limited versatility. Consequently, the preferred x-ray table configuration includes the ability to tilt the patient's head up and down 30 degrees and has a C-arm carriage, which allows axial, cranial, caudal, vertical, and horizontal movements, to create image vectors from multiple angles (Fig. 49.2). Because the patient is usually positioned prone with the head at the foot of the table, having the ability to reverse the viewing image in both the vertical and the horizontal axes is helpful. In the past, endoscopists used older-generation x-ray units, including portable C-arm units with limited image resolution. This practice is no longer acceptable because high-quality fluoroscopy and quality images are key to accurate diagnosis and management. High-quality ERCP imaging requires resolution equivalent to that for neuroradiology (brain blood vessels). Resolution of greater than 2.5 line pairs per millimeter is strongly recommended for both fluoroscopy and final images (Fig. 49.3). This resolution is best accomplished with image intensifiers that have smaller diameters (6–9 inches).

Radiation safety standards should be followed.<sup>11</sup> Monitoring levels of personal exposure, selecting the highest-quality equipment, using radiation shielding, and undergoing formal training in techniques to limit exposure are recommended to limit cumulative radiation dosage to the patient and the ERCP team (Box 49.1). Collimating to the area of interest rather than magnifying is good practice. Use of newer-generation pulse fluoroscopy gives intermittent viewing, which, although slightly jerky, is often adequate for the majority of maneuvers during a case and with a fraction of the radiation exposure. Appropriate lead aprons, lead glasses, and thyroid shields are recommended (Fig. 49.4).

**FIG 49.3** Phantom used in determining line pairs per millimeter resolution during fluoroscopy or image acquisition. Greater than 2.5-line pair resolution is recommended for optimal endoscopic retrograde cholangiopancreatography (ERCP) imaging. (Courtesy of Joe Edmiston, Indiana University Medical Center.)

### ENDOSCOPIC TECHNIQUE

#### Upper Gastrointestinal Endoscopy

Initially, a brief endoscopic examination of the esophagus, stomach, duodenum, and major duodenal papilla is performed with the duodenoscope. Whereas views of the lumen are limited,

### BOX 49.1 Strategies to Limit Personal Radiation Exposure During ERCP

#### Personal Shielding Protection

Full (wrap) coverage body aprons

Leaded glasses

Thyroid shield

Regular, systematic inspection of personal shielding for defects

#### Fluoroscopy Equipment

Under-couch x-ray tube preferred to over-couch and mobile C-arms

Leaded drapes, shielding between operator and collector

High-quality, digital systems

#### Operator Behavior

Use of collimation rather than magnification for enhanced images

Pulsed rather than continuous fluoroscopy

Use of "last image hold" over radiograph for reference

Use of endoscopic rather than fluoroscopic cues for appropriate ERCP maneuvers (e.g., exchange of endoscopic accessories within the duodenoscope channel)

#### Staff Monitoring and Education

Dual dosimeter monitoring with regular operator feedback

Displays with cumulative fluoroscopy time and radiation exposure

Structured training on fluoroscopy equipment and radiation safety

ERCP, endoscopic retrograde cholangiopancreatography.

**FIG 49.4** Endoscopy assistant with lead apron, thyroid shield, and lead glasses for optimal radiation safety.

a physician who is familiar with the endoscopic dynamics of operating a duodenoscope can often perform an adequate clinical examination of the patient's anatomy.

One should first attempt to exit the stomach with minimal residual intragastric air, as this permits *en face* papilla views and

**FIG 49.5** Plain x-ray film of right upper quadrant showing post-shock wave lithotripsy pancreatic calcifications (arrows) and residual biliary stent. This film serves as a background view for all subsequent contrast agent injections.

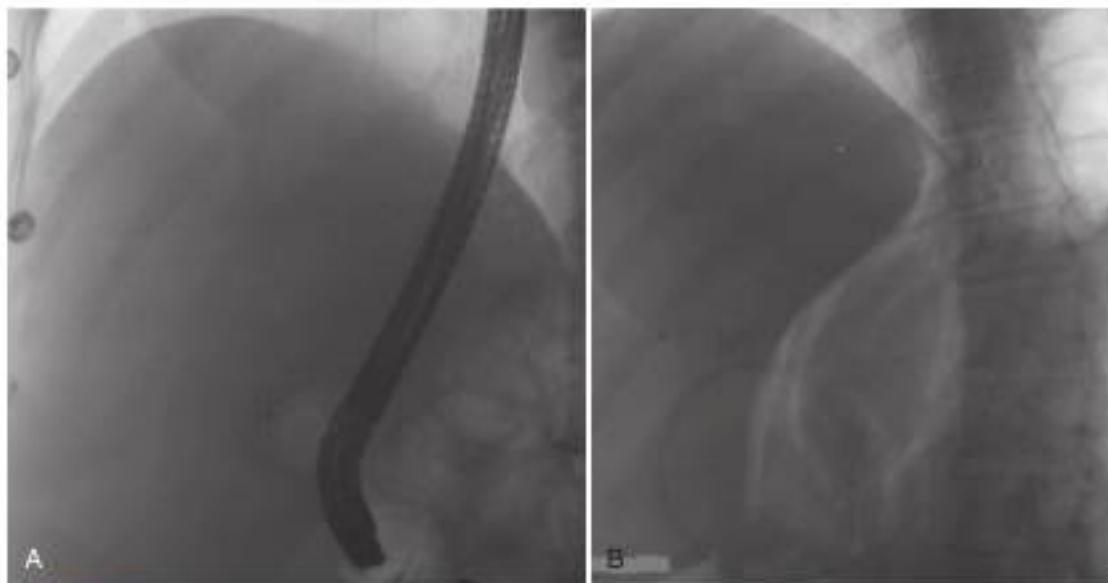

facilitates optimal fluoroscopic images. Encountering obstruction (malignant or benign) of the gastric outlet or otherwise should prompt the physician to consider switching to an end-viewing endoscope to assess the need for endoscopic dilation or any further maneuvers to complete the case.

Other findings, such as varices, external compression of the gut wall, or edema of the medial wall of the duodenum, help quantify or localize disease processes. The major papilla is usually located on the medial aspect of the mid-descending duodenum, but may reside anywhere from the duodenal bulb to the transverse duodenum. Care should be taken to look for major papilla abnormalities (e.g., tumor, edema, enlarged orifice from stone or mucin passage), as they may also have diagnostic value and import for planning your approach. The location of orifices should be noted. A brief examination of the minor papilla may be helpful if initial pancreatography via the major papilla fails and pancreatic access is intended.

If the major papilla is not initially evident, gentle lifting of folds, greater air distention, and use of glucagon to inhibit peristalsis will likely expose the structure. If duodenal diverticula are present, the major papilla is most often on the diverticular rim, but the papilla is within the diverticulum *per se* in approximately 5% to 10% of cases.

#### Selective Cannulation of the Desired Duct

Prior to attempting cannulation, fluoroscopic inspection of the field of interest should be performed to take note of the initial duodenoscope position, stents, calcifications, masses, extraluminal air, and residual contrast material from prior radiographic studies (Fig. 49.5). A still image should be indexed to document any findings and serve as a baseline for comparative purposes, if there is any question of complications during the case (e.g., retroperitoneal air associated with perforation) (Fig. 49.6). The choice of initial cannulation tool is a personal preference (similar

**FIG 49.6** **A**, Preprocedure radiograph. **B**, Postprocedure radiograph demonstrating retroperitoneal air and an air nephrogram suggestive of retroperitoneal perforation secondary to sphincterotomy.

to choosing a tennis racket or golf club). One may begin with a simple single-lumen 5-Fr polyethylene catheter or an extraction balloon in the setting of prior sphincterotomy. If the orifice appears small, or cannulation of the minor papilla is desired, a catheter with a highly tapered tip (to 3-Fr) or a sphincterotome is desirable. However, if sphincterotomy is anticipated, a sphincterotome is the most cost-effective tool, and is now the standard for most biliary endoscopists as they approach a native papilla. Two-lumen or three-lumen accessories are most advantageous, as they have dedicated channels for independent deployment of a guidewire and injection of contrast medium. A guidewire may be used at any point to aid cannulation or maintain intraductal stability.

For the purposes of cannulation, orientation of the catheter tip toward the 11 o'clock to 12 o'clock position (Fig. 49.7) is ideal to access the bile duct, and orientation of the catheter toward the 1 o'clock to 4 o'clock position is ideal for pancreatic duct entry. However, the biliary orifice location may vary from 10 o'clock to 2 o'clock, depending on patient anatomy. Pancreatic cannulation is often easier than biliary cannulation, as the vector for cannulation is often *en face*.

Cannulation may initially be attempted either by gently threading the guidewire 1 to 2 cm into the desired channel (wire-guided cannulation) or by gentle impaction of the catheter tip in the papillary orifice. Growing evidence supports initiating cannulation by threading or "feathering" the guidewire for access (wire-guided cannulation). Meta-analysis-level data suggest that this technique facilitates cannulation and is associated with lower rates of post-ERCP pancreatitis.<sup>12</sup> However, wire-guided cannulation must be performed carefully, as unintended passage of the guidewire into the pancreatic duct is common during biliary cannulation, and is associated with pancreatitis. Wire-induced pancreatic duct perforation through a side branch (often at the genu) can occur if the guidewire is advanced beyond 2 cm without contrast agent injection to confirm position<sup>13</sup> (Fig. 49.8). Deep cannulation (> 1 cm penetration of the catheter into the duct) should then follow for a more secure intraductal position. This

allows contrast agent injection, fluid aspiration, patient position changes, and endoscope position changes without loss of access to the duct.

For biliary cannulation, 0.025- or 0.035-inch diameter wires are preferred. An 0.021- or 0.018-inch guidewire may be desired for pancreatic access, especially if access through the minor papilla is anticipated. Soft-tipped wires have the advantage of inducing less tissue trauma (e.g., fewer submucosal or other extraductal dissections). Torsion with advancement of an angled wire with a hydrophilic tip may facilitate access across angulated ductal anatomy. Ultimately, the specific devices used are much less important than the experience and skill of the endoscopist and the ERCP team members (Fig. 49.9).

If the cannulation is not optimal for the desired duct, an advantage of a sphincterotome is the ability to orient further by "bowing" the instrument. Decompressing air from the stomach and/or transitioning to a long position (advancing the duodenoscope such that the shaft is along the greater curvature) may also achieve the necessary angles. In patients with a prominent major papilla (protruding well into the duodenal lumen), the path of the biliary lumen is nearly always stair-stepped. Cannulation is initially cephalad, then more perpendicular into the wall, and then more cephalad again. The cannulation is partially accomplished by pulling the endoscope more cephalad, lowering the elevator, and moving the viewing lens very close to the papilla. Gentle guidewire manipulations and more perpendicular catheter orientation are required.

When difficult anatomy, pathology (e.g., ventral duct obstruction), or pancreas divisum prevents performance of pancreatography from the major papilla, pancreatography can be accomplished via the minor papilla, with a reported rate of success of greater than 90%, regardless of divisum anatomy.<sup>14,15</sup> This technique allows for pancreatography of the dorsal and ventral pancreatic ducts (through antegrade filling) in most patients, and may be an effective approach for endotherapy.<sup>14</sup>

The minor papilla is a slightly raised structure that can display frond-like mucosa. However, it often lacks a clear os. Usually,

the minor papilla is located 2 to 3 cm proximal and slightly anterior and to the visual right of the major papilla; however, its location may vary along the duodenal wall. A gradual push of intravenous (IV) secretin (0.2 µg/kg body weight; 16 µg in most patients) over 60 seconds will frequently stimulate the flow of pancreatic juice into the duodenum and facilitate orifice identification. If the orifice is not detectable, methylene blue can be sprayed on the duodenal wall to facilitate visualization of the (relative clear) focal excretion of pancreatic juice. The minor papilla is best approached with an initial *en face* view facilitated by a long or semi-long duodenoscope position. Cannulation usually follows a slightly posterior and horizontal to mildly cephalad path.

Cannulation of the minor papilla can be achieved with a standard sphincterotome or with straight cannula accessories. However, due to the diminutive size of the os and the paradoodenal dorsal pancreatic duct, use of small-caliber tip accessories (3- or 4-Fr) and guidewires (0.018- or 0.021-inch) to facilitate deep cannulation with graded dilation of the os is preferred by experts.

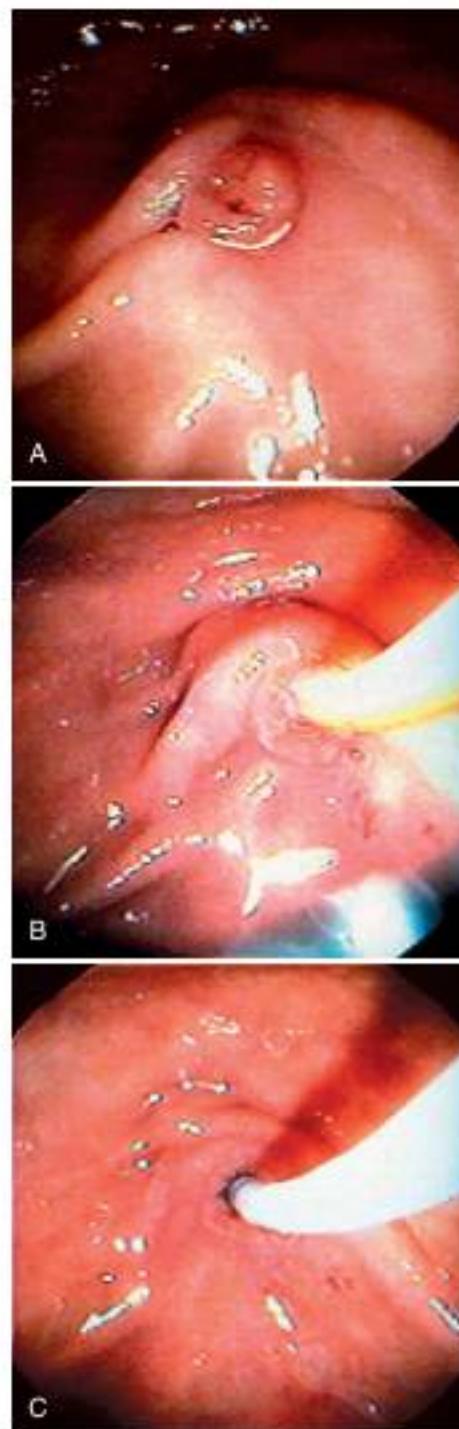

If cannulation of the biliary tree is mandatory and initial attempts fail, several options exist. Attempting cannulation alongside a pancreatic duct guidewire or stent has a significant rate of reported success.<sup>16</sup> Precut entry is also a reasonable next maneuver, and should ideally be performed after placement of a pancreatic stent. Literature now suggests that, if deployed early during a difficult cannulation by those with experience with the technique, precut needle knife access does not elevate the risk of complications.<sup>17-19</sup> Endosonographic rendezvous and drainage techniques may be deployed in expert hands. However, the endoscopist at this juncture must take inventory of his or her skill set and balance a decision for aggressive, advanced access techniques against transfer to a facility with high-level expertise, as the literature reports that subsequent success rates approach 95% in the setting of transfer to an expert center.<sup>20,21</sup> When cannulation fails in the setting of biliary obstruction, one may also consider percutaneous drainage.

#### Contrast Medium and Image Acquisition

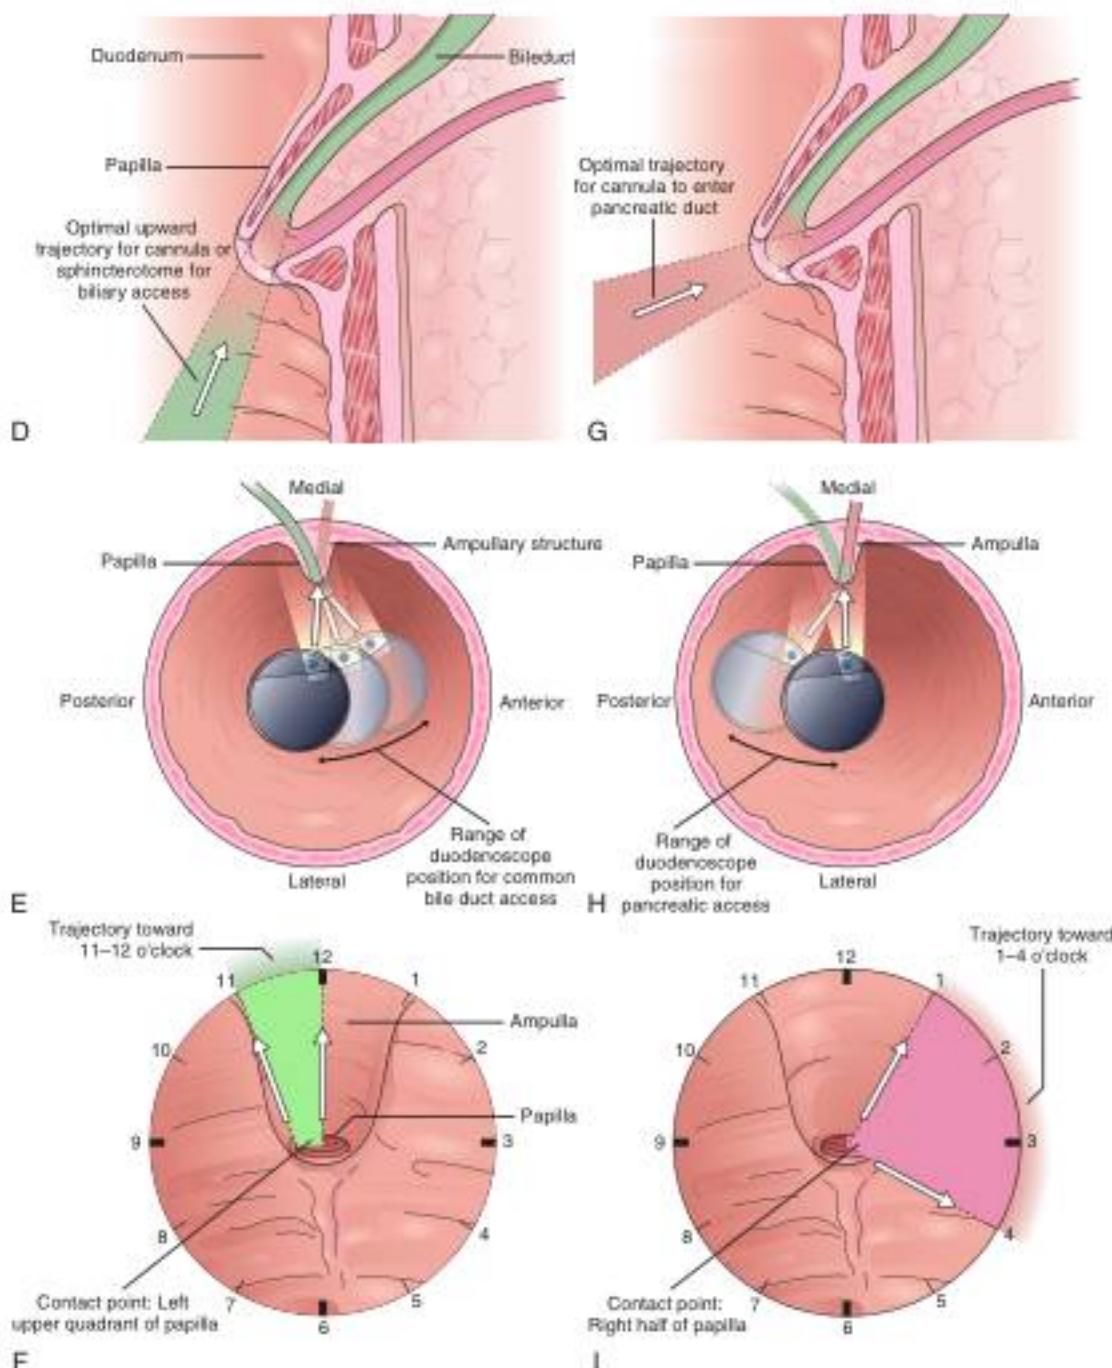

Standard ionic contrast medium (e.g., diatrizoate meglumine) at a 25% to 30% concentration is often called *half-strength*, and is most commonly used for cholangiography. Half-strength contrast medium permits adequate visualization of small ducts (2–6 mm in diameter) and allows filling defects (stones) to be seen in capacious, dilated ducts. However, biliary stricture detail, peripheral intrahepatic ducts, and pancreatic ducts are better defined with “full-strength” contrast medium (50%–60% concentration). Nonionic and lower osmolality contrast agents, which are more expensive, offer no safety advantage.<sup>22</sup> Many manufacturers have abandoned marketing of inexpensive ionic agents, making the use of nonionic agents necessary. Also of note, whereas a degree of absorption of contrast media has been reported, use of contrast media within the pancreaticobiliary system does not appear to elicit a clinical reaction, even in patients with a declared allergy to IV contrast media. Consequently, routine or even targeted prophylaxis for contrast media reaction is not recommended prior to ERCP.<sup>23</sup>

We prefer using 10- to 20-mL syringes for injection of contrast to decrease the need for frequent exchange of syringes (and the consequent potential to introduce air bubbles). The catheter should be preflushed with contrast prior to cannulation to avoid unnecessary injection of air from within the catheter lumen.

With each syringe exchange, one should aspirate back to remove any air bubbles from the Luer connector and flush to ensure that the contrast medium extends to the catheter tip. Contrast agent injection is performed with continuous fluoroscopic monitoring.

**FIG 49.7** **A**, Endoscopic view of 5-Fr catheter oriented toward the 11 o'clock position of the major papilla. **B**, The bile duct is entered, and bile aspiration is confirmed by the yellow color in the catheter lumen. **C**, The catheter is oriented more toward the 3 o'clock position to enter the pancreas. *Continued*

**FIG 49.7, cont'd D-I.** Optimal trajectories for cannulation of the bile duct (D, E, and F) and the pancreatic duct (G, H, and I), as projected in transverse (E and H), coronal (D and G), and sagittal (F and I) sections.

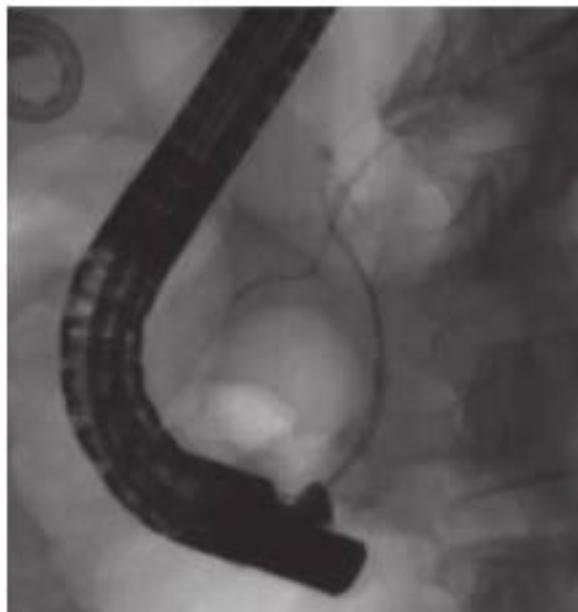

## CHOLANGIogram TECHNIQUE AND IMAGE INTERPRETATION

The density of contrast medium is greater than bile, and it flows along the most dependent route. The left lobe (lowest) fills quickest with the patient prone (Fig. 49.10A), the right lobe anterior segments fill next, and the right lobe posterior segments fill last (and may remain unfilled unless adequate volume and injection force are applied) (see Fig. 49.10B). However, injection

through a stone extraction balloon over a guidewire, inflated to prevent distal contrast flow targeting proximal portions of the biliary tree, allows for greater precision and control of contrast introduction.

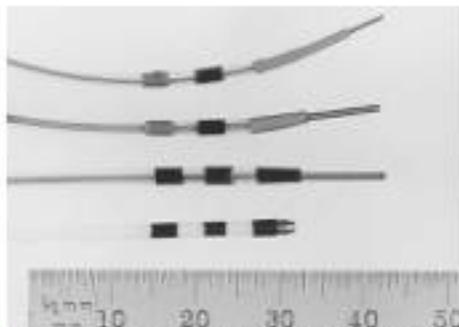

The extent of ductal filling should be considered in advance of ERCP, and should be based on clinical history, preprocedure imaging, and intentions for therapy. In settings of tight biliary strictures, contrast medium filling upstream should be limited until catheter access above the stricture is achieved (Fig. 49.11).

In patients with diseases with a high potential for residual contrast in undrained segments following cholangiography, limited filling of the biliary tree is of greatest importance. Such clinical scenarios include diseases with complex biliary strictures involving multiple segments (e.g., perihilar cholangiocarcinoma and intrahepatic

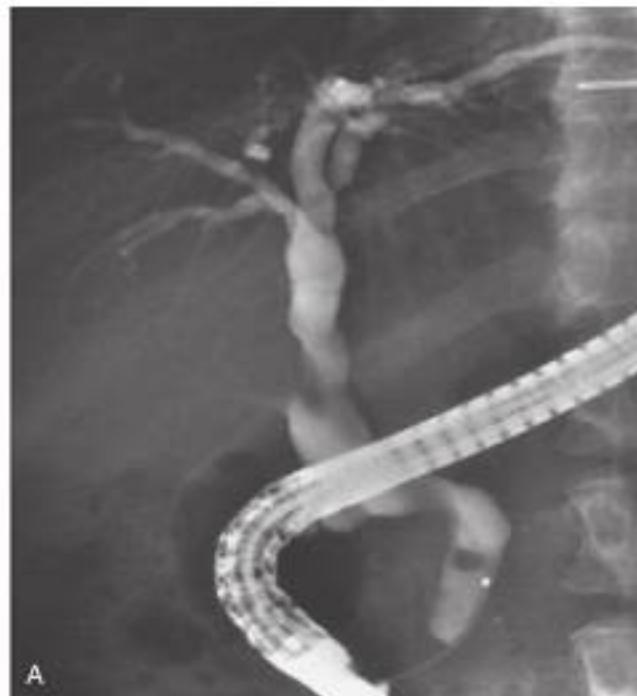

**FIG 49.8** Pancreatic duct leak from guidewire perforation at the genu of the pancreas. This was successfully managed with a bridging pancreatic duct stent.

primary sclerosing cholangitis [PSC]). To facilitate this approach, a preprocedure reference MRCP or high-quality computed tomography (CT) scan provides a critical "road map" for planning biliary opacification and access during ERCP. High-resolution fluoroscopy is also ideal to delineate fine detail and small ductal structures. A technique utilizing air/CO<sub>2</sub> insufflation via an intraductal catheter, rather than contrast for cholangiography during stent exchanges and placement, may be suitable in patients with complex hilar strictures. Although there are reported cases of fatal air embolism with direct air insufflation of the biliary tree during cholangioscopy, case series suggest that this event is rare. The use of CO<sub>2</sub> may decrease this risk, and is weighed

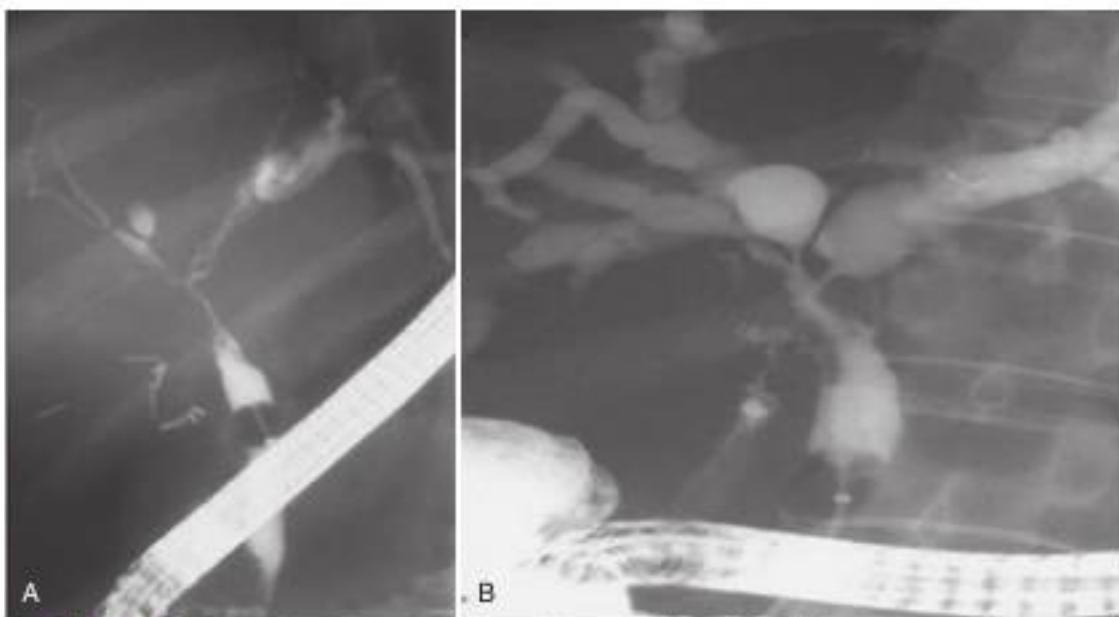

**FIG 49.9** A well-equipped biliary diagnostic unit contains a wide variety of guidewires with varying characteristics, different sizes (0.018-inch, 0.025-inch, and 0.035-inch diameter), variable hydrophilic tips, and some groomable wires whose tip shape can be changed. Also shown are 5-Fr catheters with variable tip tapers or metal tips (bottom).

**FIG 49.10 A,** Initial left lobe filling. This lobe fills preferentially because contrast medium is heavier than bile and flows down into the dependent left lobe with the patient prone. This could be mistaken for complete biliary filling. **B,** When the patient is tilted head-down 20 degrees and more volume is added, the right lobe can be viewed. Wire access and balloon occlusion of the right hepatic duct may facilitate right system cholangiogram as well.

**FIG 49.11** **A**, Cholangiocarcinoma involving the hepatic hilum. Only a limited amount of contrast medium is injected above the strictures to avoid contamination. More contrast medium should be injected only after the guidewire is advanced above the stricture. If additional upstream information is needed, magnetic resonance cholangiopancreatography (MRCP) or computed tomography (CT) scan is recommended. **B**, Excessive intrahepatic filling above hilar stricture. Unless subsequent bilateral drainage is achieved, the patient is at higher risk of postprocedure cholangitis.

against an advantageous decrease in the risk of cholangitis, which is a much more common sequela of ERCP when performed for complex hilar biliary strictures.<sup>24–27</sup> Finally, stent exchanges alongside or through (snare-over-the-wire technique) previously placed stents (before stent removal) ensure segmental wire access without the need for contrast injections (Video 49.1).

Multiple early views of the bile duct during filling are recommended to identify potential small filling defects (stones) that may be washed upstream (and then no longer be visible) or masked by dense contrast concentration in a dilated duct (Figs. 49.12 and 49.13). A “complete” cholangiogram requires filling of the peripheral intrahepatic radicles. The left lobe is more dependent in the prone position, and fills preferentially. Right lobe filling may require tilting the patient’s head down 15 to 20 degrees on the fluoroscopy table, administering a more forceful injection using a balloon occlusion catheter, employing selective right lobe cannulation, or turning the patient to the supine position. Positioning the C-arm in the left posterior oblique position is ideal for collecting images at the bifurcation, as it diminishes two-dimensional overlap of primary and secondary segmental branches (Video 49.2). Placing the duodenoscope in a long position is effective for inspecting portions of the middle bile duct often obscured by the superimposed instrument shaft (Fig. 49.14; see also Video 49.2). Table 49.2 provides a list of common technical problems and clinical challenges encountered during cholangiopancreatography, with suggested steps for troubleshooting.

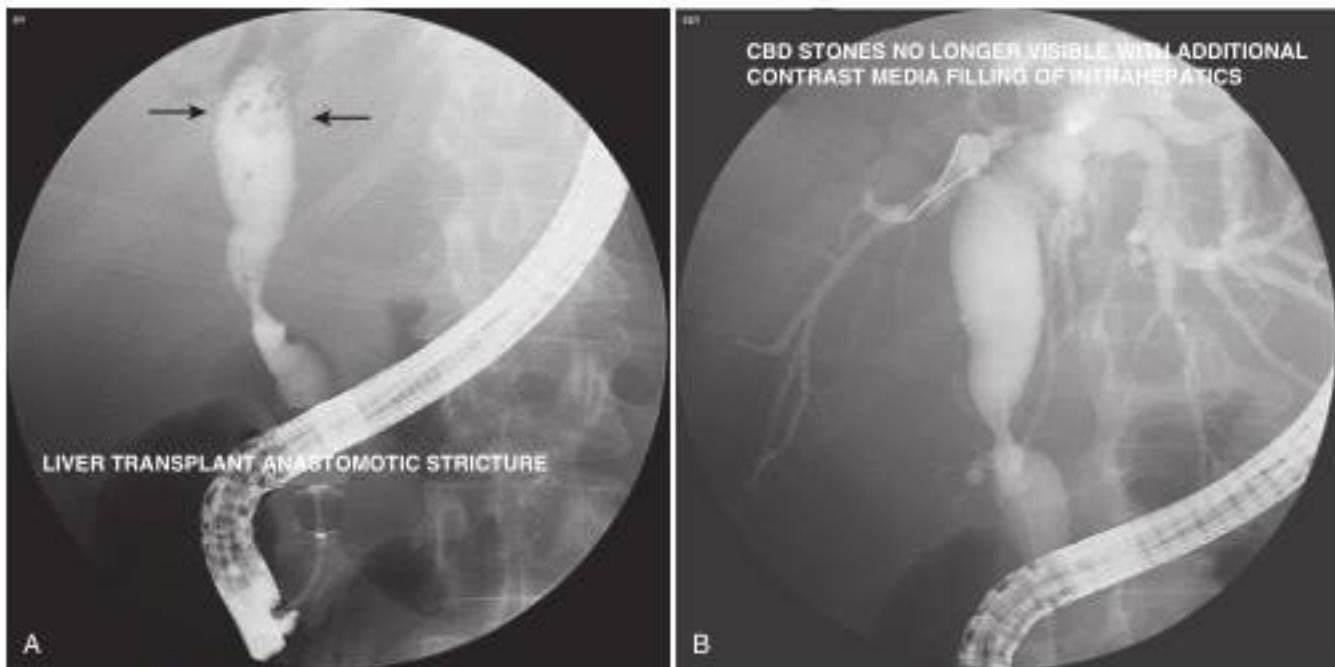

#### Features of a Normal Cholangiogram

A normal cholangiogram is shown in Fig. 49.15. Although controversial, there is evidence that indicates that the biliary tree

does not dilate significantly after cholecystectomy in the absence of obstructing pathology.<sup>28,29</sup> The diameter of the common hepatic and common bile duct on ERCP is commonly 2 to 3 mm greater than is seen on CT or ultrasound. This difference is accounted for by filling (or overfilling) the ductal system with extra fluid (contrast medium) under greater pressure than physiologic secretory pressure.<sup>30</sup> Many centers accept 10 mm as the upper limit of the normal diameter of the common bile duct in adults. The cystic duct typically joins the common duct approximately halfway from the hilum to the papilla, but the location of this junction may vary. The intrahepatic radicles have a leafless tree-like branch pattern with marked variation in distribution. An aberrant, low-insertion, right hepatic duct, which connects to right posterior hepatic segments, is seen in 5% of patients (Figs. 49.16 and 49.17). These may be transected during laparoscopic cholecystectomy and give rise to problematic bile leaks from the disconnected segmental branch. Because the transected duct does not fill on ERCP, MRCP may be more diagnostic.<sup>31</sup> Numerous other nonpathologic anatomic variants have also been reported (at a frequency of 20%–30% in MRI series), and should therefore often be encountered by the discerning biliary endoscopist.<sup>32,33</sup> A detailed review of anatomic variants of biliary anatomy requires discussion well beyond the scope of this chapter (Fig. 49.18).

#### Biliary Stones and Acute Pancreatitis

Relative consensus now exists regarding the role of endoscopic cholangiography for suspected choledocholithiasis and acute pancreatitis. Gallstone pancreatitis is a common outcome of small stone (< 5 mm diameter) passage (see Fig. 49.13). In this latter setting, more than 80% of patients spontaneously pass the

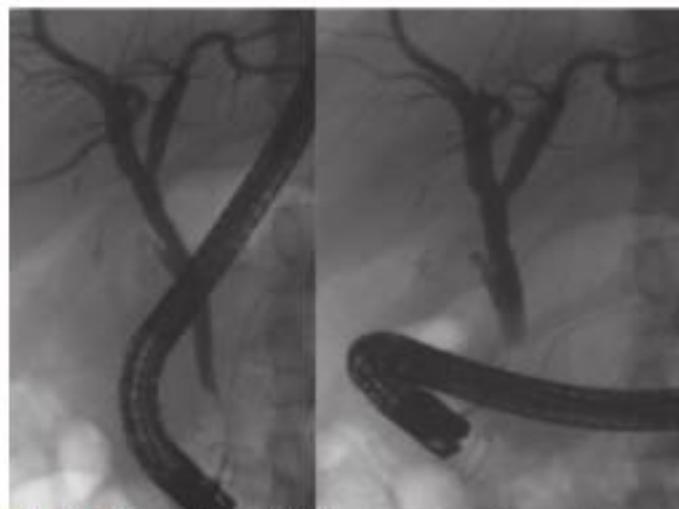

**FIG 49.12** **A**, Patients with suspected common bile duct (CBD) stones (especially patients with dilated ducts) should have multiple early-filling biliary films taken to observe stones (arrows). **B**, before the stones are potentially washed upstream or masked by dense contrast material. The patient has had a liver transplant with duct-to-duct anastomosis. There is stricture at the anastomosis.

**FIG 49.13** Small common hepatic duct stone (arrow) in a patient after cholecystectomy.

stones from the bile duct into the duodenum. Consequently, selective use of ERC is recommended. Guidelines support an approach that targets patients who present with predictors for a retained common bile duct stone based on biochemical and radiographic testing. These indicators include: persistent or worsening cholestasis, dilated extrahepatic bile ducts, or clinical

**FIG 49.14** Transition of the duodenoscope from a short to a long position. This maneuver reveals the middle portion of the bile duct that was obscured by the overlying duodenoscope insertion tube.

cholangitis.<sup>34</sup> Use of these predictors for decision making also applies in the setting of gallstone pancreatitis. This stems from meta-analysis-level data that confirm therapeutic ERCP to be beneficial in the setting of acute pancreatitis only in patients with high-level suspicion for choledocholithiasis (e.g. cholangitis or jaundice). Benefit does not correlate directly with the severity of pancreatitis.<sup>35,36</sup>

Whereas noninvasive imaging such as MRCP is helpful, it adds expense and should be reserved for patients who are at

**TABLE 49.2 Common General Problems and Challenges Encountered During Endoscopic Retrograde Cholangiography**

Cholangiographic Challenge or Clinical Suspicion	Potential Steps to Solve Problem
Obese patient	Increase kilo voltage Take extra exposures (a few are likely to be adequate) Review still images before deciding on therapy (i.e., do not rely only on fluoroscopy view)
Patient moves frequently	Take multiple exposures (one is likely to be clear) Increase kilo voltage to shorten exposure time
Terminal (presmpillary) CBD not well seen	If patient has cholangitis with risk of sepsis if greater filling is performed, pass stone retrieval balloon to mid-CBD, inflate balloon, and inject contrast agent downstream of balloon (need appropriate "below the balloon" injection port). Tilt head up 5–20 degrees. If moderate amount of contrast agent already upstream in intrahepatic ducts, place catheter tip 1 cm above sphincter. Aspirate nonopacified bile until upstream contrast agent flows back into terminal CBD.
Patient has typical postcholecystectomy pain, but ERCP (or MRCP) is normal	Perform manometry Do not initiate ERCP if ducts are not dilated by noninvasive imaging and liver serum chemistries are normal
Cannot find papilla	Check fluoroscopy to ensure endoscope tip is in descending duodenum. Be sure of surgical anatomy (Roux-en-Y gastrojejunostomy?). Bile present—follow trail. Gently lift folds in candidate area. Find minor papilla, and search left and inferior. Give cholecystokinin or secretin to stimulate fluid flow.
Left and right hepatic ductal systems overlap at hilum, not well-defined	Fix fluoroscopy table, roll patient to slight left posterior oblique position; use C-arm rotation to separate systems
Bile leak expected	Obtain multiple early images to locate leak site precisely before leak site contrast agent obscures view Limit injection to small amount of spilled contrast agent
Air bubbles introduced	Observe where bubbles went and where collected; if distal CBD, tilt head down and aspirate bubbles, bile, and contrast agent from terminal duct Consider tilting head up and observing bubble passage into intrahepatic ducts
Contrast agent or air in duodenum or stomach detracts from image quality	Aspirate all contrast agent and air from duodenum before imaging; do this routinely when injecting contrast agent
Endoscope repeatedly covers area of interest	Use C-arm (or patient positioning) to change angle Move the endoscope from short (lesser curve) to long (greater curve) position Place catheter upstream to hilum, slowly back endoscope into the stomach, aspirating air and spilled contrast agent as if a nasobiliary tube had been placed
Pyloric or duodenal narrowing precludes duodenoscope passage	Pass a stiff guidewire (Amplatz Super Stiff, Boston Scientific or SavaryWire) and catheter in to the transverse duodenum. Pass duodenoscope over the wire, paying attention to fluoroscopic alignment more than endoscopic view. Advance large (15–18 mm) balloon catheter over guidewire into transverse duodenum. Inflate extraction balloon and, with traction on the balloon catheter and duodenoscope reduction, advance duodenoscope beyond the stricture.

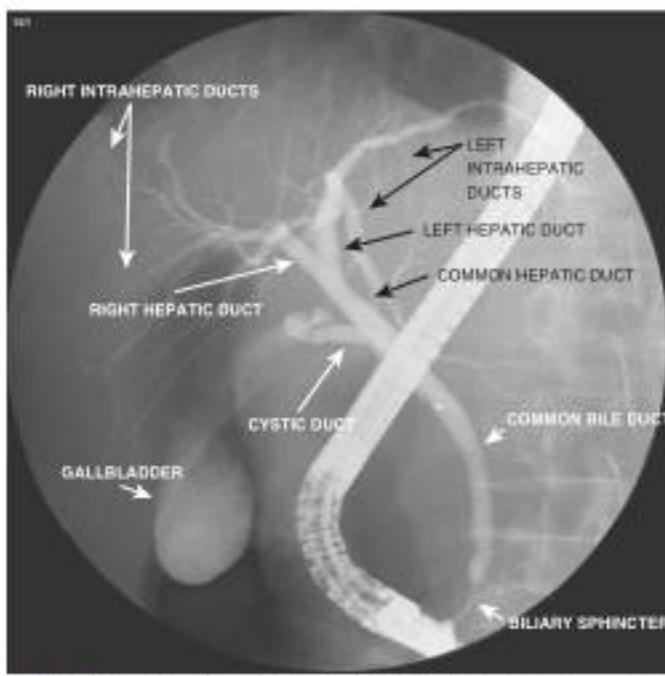

CBD, common bile duct; ERCP, endoscopic retrograde cholangiopancreatography; MRCP, magnetic resonance cholangiopancreatography.

high risk for adverse events linked to anesthesia, patients with altered foregut anatomy (post-bariatric surgery), and patients with moderate to low probability of ductal stones.<sup>34</sup> Patients with a very high or high probability for a retained bile duct stone should proceed directly to ERC. Patients with an intermediate probability for a retained bile duct stone should have a preceding MRCP or EUS, or should be considered for cholecystectomy with intraoperative cholangiogram if the gallbladder is in situ. A larger ductal stone in a patient following cholecystectomy is shown in Fig. 49.19A. Intrahepatic stones (with or without extrahepatic stones) are common in Asian populations, and may be associated with recurrent pyogenic cholangitis.<sup>35</sup> Fig. 49.19B shows right segmental branches with large fusiform stones. A stone impacted in the cystic duct may compress the common hepatic or common bile duct and cause obstructive jaundice (Mirizzi's syndrome). Cholangiogram may demonstrate only a common bile duct stricture in this scenario. Cross-sectional

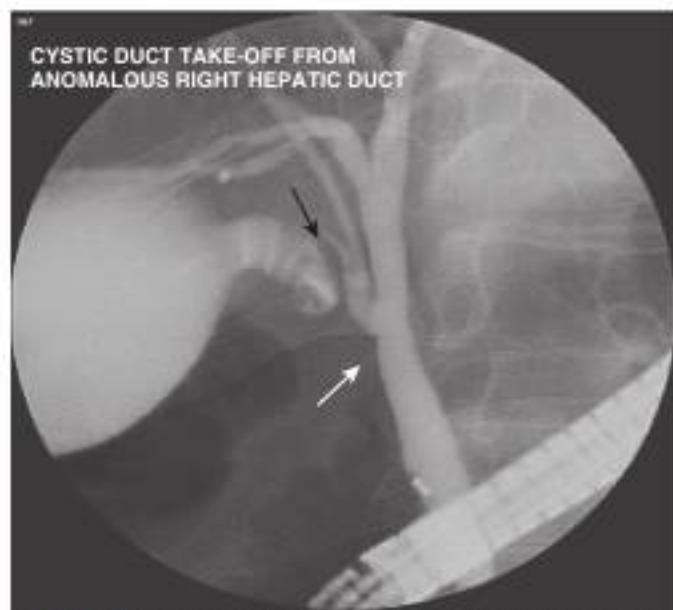

imaging or cholangioscopy may be necessary to confirm the diagnosis. Table 49.3 reviews problems encountered in biliary stone cases and ways to troubleshoot them.

### Biliary Strictures

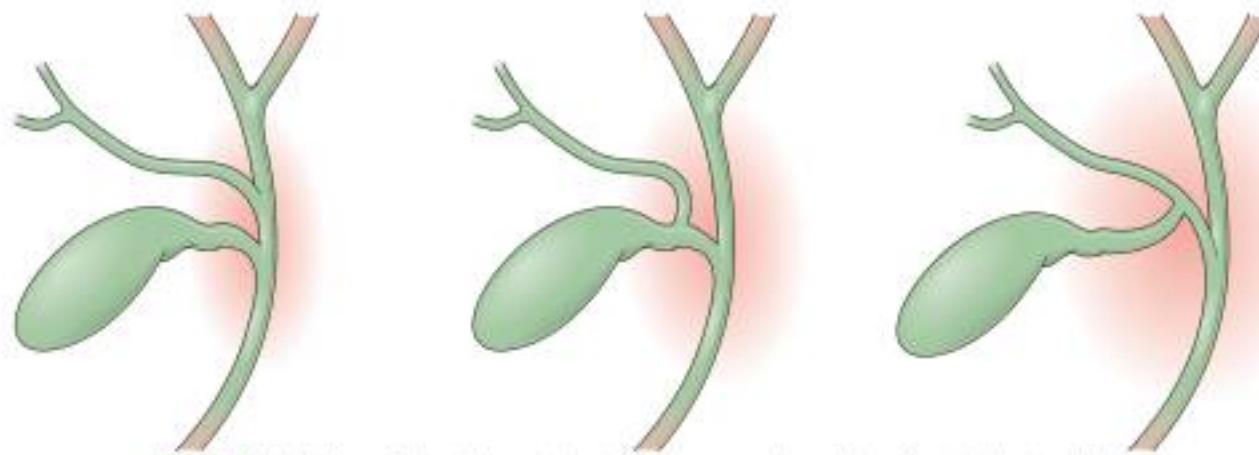

Biliary strictures are abnormal narrowings of the ductal system resulting from compression (e.g., chronic pancreatitis), scar formation (e.g., postoperative), autoimmune disease (autoimmune cholangiopathy, PSC), or neoplasm (e.g., cholangiocarcinoma, pancreatic duct adenocarcinoma, metastases).<sup>36</sup> These typically manifest clinically with cholestasis, obstructive jaundice, or cholangitis. The etiology of the stricture is usually evident from the history (e.g., recent biliary surgery, risk factors for chronic pancreatitis, or elderly patients with weight loss) and preprocedure cross-sectional imaging (e.g., pancreatic or perihilar mass). Table 49.4 reviews problems encountered during cholangiography for bile duct strictures. Fig. 49.20 shows a smooth, tapered, long

**FIG 49.15** Normal cholangiogram with ductal segments labeled. Colon gas overlaps the gallbladder, making viewing suboptimal.

**FIG 49.17** Aberrant posterior segmental hepatic branch arising from mid-extrahepatic duct (white arrow). The cystic duct take-off (black arrow) is from the aberrant right hepatic duct.

**FIG 49.16** Variations of the right posterior hepatic segment branch. Left, cystic duct and aberrant right hepatic duct are adjacent to each other, but both are attached to the main extrahepatic duct. Center, aberrant right branch arises from cystic duct. Right, cystic duct arises from aberrant right branch.

**TABLE 49.3 Challenges for Optimal Viewing of Stones**

<b>Cholangiographic Challenge or Clinical Suspicion</b>	<b>Potential Steps to Solve Problem</b>
Probable bile duct stones (most are in terminal CBD at beginning of examination)	Inject contrast agent with catheter tip in sphincter segment (not deeply cannulated) Inject contrast agent slowly Take film exposures early after only 1–2 cm of duct filled and again at each 1–2 cm further filling With patient prone, tilt table head up 5–20 degrees to keep contrast agent near papilla
Gallbladder stones	Take multiple early-filling gallbladder films If overfilled, advance guidewire and catheter into gallbladder and aspirate excess contrast agent Take delayed films supine in 4–24 hr
Probable sludge seen in terminal CBD on early films	Stop contrast agent injection; aspirate bile through a “see-through” (non-opaque) catheter and confirm granular material
Cholangitis manifesting with purulent bile (with or without sepsis)	Aspirate bile from CBD (send for culture) and replace aspirated bile (e.g., 30 mL with less than 1/3 volume [10 mL] of contrast media); limit intrahepatic filling; do definitive intrahepatic duct and stone evaluation later when cholangitis is resolved

CBD, common bile duct.

**FIG 49.18** Trifurcation of intrahepatic ducts at the hilum.

**FIG 49.20** Endoscopic retrograde cholangiography (ERC) showing long, smooth, tapered stricture within the pancreas with mild upstream dilation (the right lobe has not yet filled). Calcified stones (arrow) are seen in the head of the pancreas.

A

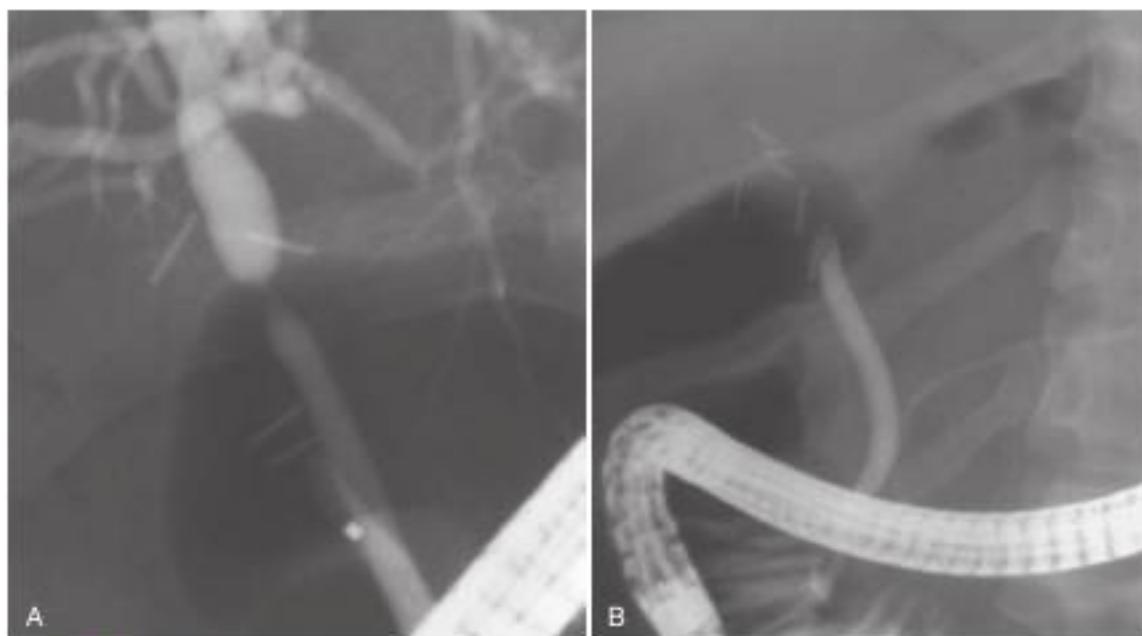

B INTRAHEPATIC DUCTAL STONES

**FIG 49.19** **A**, Large common bile duct stone. **B**, Large intrahepatic stones (arrows). Small common bile duct stones were also present. The gallbladder had been removed 5 years previously. These stones are much more common in Asian populations.

**TABLE 49.4 Challenges in Detection and Optimal Viewing of Strictures**

<b>Cholangiographic Challenge or Clinical Suspicion</b>	<b>Potential Steps to Solve Problem</b>
Hilar stricture	Take multiple early-filling views with varying degrees of angulation; especially obtain Y confluence view with left and right main hepatic ducts separated. Fill only a tiny amount of duct upstream initially, and pass guidewire upstream before filling more; avoid thorough upstream filling (only on MRCP or CT if that information is clinically needed) unless a guidewire and catheter have already been passed upstream and full stent drainage is certain.
Common bile or common hepatic duct stricture with obviously dilated upstream ducts (per CT or MRI); need definition of upper rim of stricture	Inject more contrast agent with greater force (unless purulent bile) Advance catheter into right duct Consider aspirating bile from near hilum to "empty" right lobe to make space for contrast agent If prior sphincterotomy, use balloon occlusion Tilt head down 5–20 degrees
Probable sclerosing cholangitis setting or other intrahepatic stricturing; contrast agent preferentially enters gallbladder	Limit gallbladder filling in primary sclerosing cholangitis, because post-ERCP cholecystitis may occur; inflate balloon catheter above cystic duct take-off and inject upstream; after more aggressive intrahepatic filling, patient should remain on broad-spectrum antibiotics for 5–7 days
Sphincter segment appears narrow	This is usually a normal finding; dilated duct upstream or abnormal liver serum chemistries present suggests pathology Measure length of segment: > 12 mm suggests scar or tumor narrowing; correlate with normal or abnormal appearance of papilla; brush cytology, manometry, sphincterotomy with viewing inside ampulla, or endoscopic ultrasound may be needed to clarify
Is postsphincterotomy biliary orifice adequate?	Do manometry, pull-through, stone retrieval balloon; size with hydrostatic balloon

CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; MRCP, magnetic resonance cholangiopancreatography; MRI, magnetic resonance imaging.

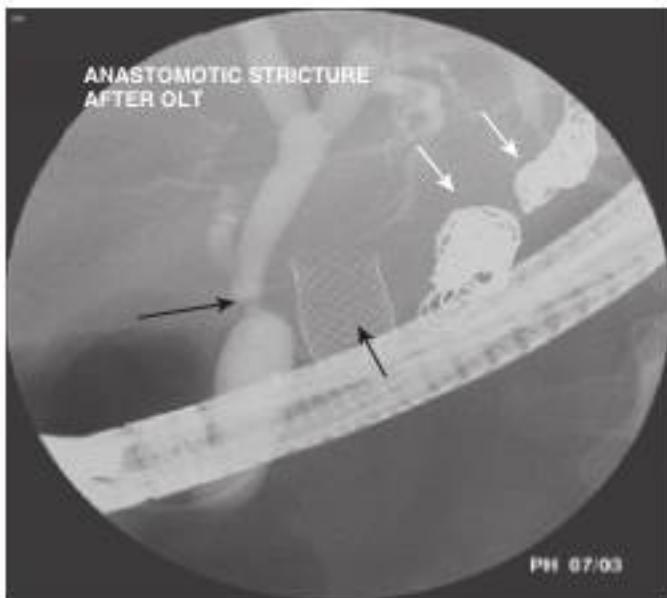

**FIG 49.21** **A**, Post-laparoscopic cholecystectomy. Short stricture of the common hepatic duct is seen, with upstream dilation. The stricture occurred near clips, and is probably due to a thermal injury. **B**, Unintentional clip transection of the common bile duct at the cystic duct junction, which occurred at open cholecystectomy in a patient with prior upper abdominal radiation for lymphoma.

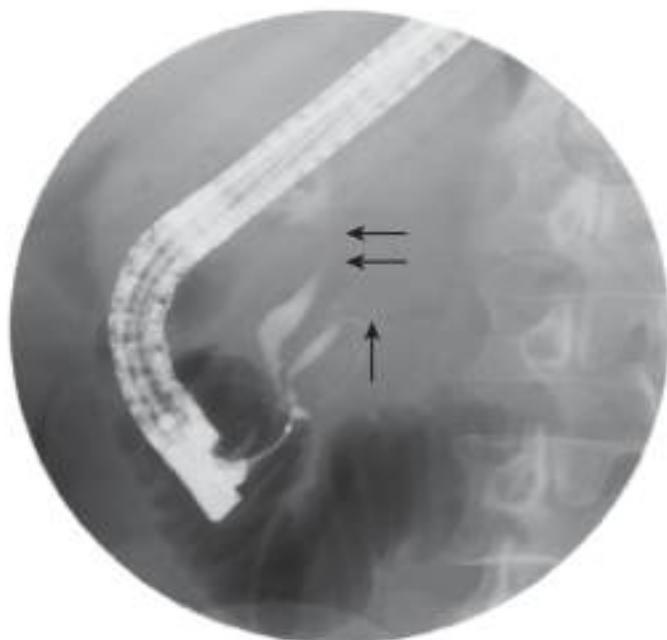

narrowing of the bile duct within the head of the pancreas in a patient with calcific chronic pancreatitis. Laparoscopic cholecystectomy is associated with thermal or mechanical injury, which results in stricture formation in 0.25% to 0.5% of patients.<sup>40,41</sup> Fig. 49.21A shows a typical postlaparoscopy stricture. Injuries during open cholecystectomy occur less frequently. Duct transections (see Fig. 49.21B) and duct resections are the most serious injuries.

Orthotopic liver transplant with duct-to-duct anastomosis results in pathologic narrowing at the anastomosis in 15% of patients (Fig. 49.22).<sup>42</sup> PSC is characterized by multifocal extrahepatic and/or intrahepatic strictures (Fig. 49.23).<sup>39</sup> The gallbladder and cystic duct are spared in this disease.

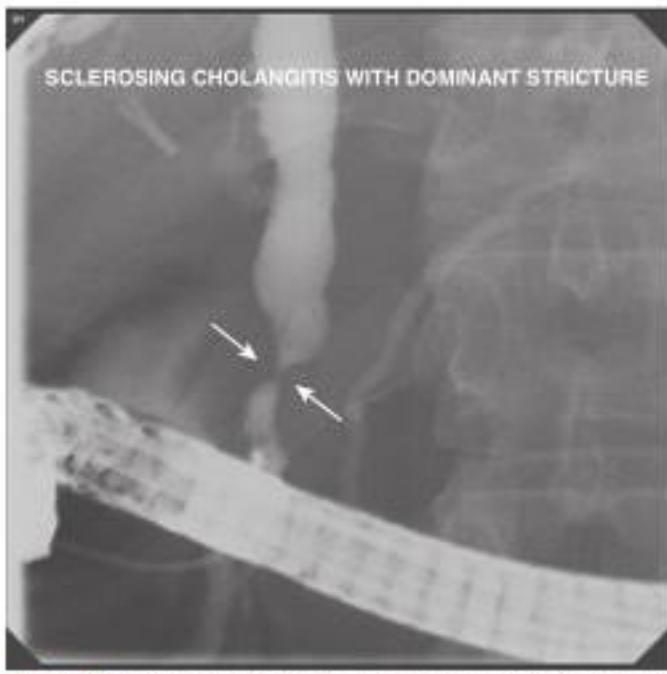

The goals of ERC in suspected PSC are to (1) treat dominant strictures, (2) guide sampling for diagnosis of cholangiocarcinoma,

**FIG 49.22** Orthotopic liver transplant (OLT) with duct-to-duct anastomosis. Narrowing of the anastomosis is seen just 10 days postoperatively (long black arrow). Note endovascular metal stent (transjugular intrahepatic portosystemic shunt) used to treat prior variceal bleeding (short black arrow) and endovascular coils in the duodenal arcade from bleeding duodenal ulcers (white arrows).

**FIG 49.24** Typical double-duct sign of pancreatic cancer. Double arrows indicate common bile duct narrowing. Single arrow indicates pancreatic duct obstruction. This sign may also be seen in chronic pancreatitis.

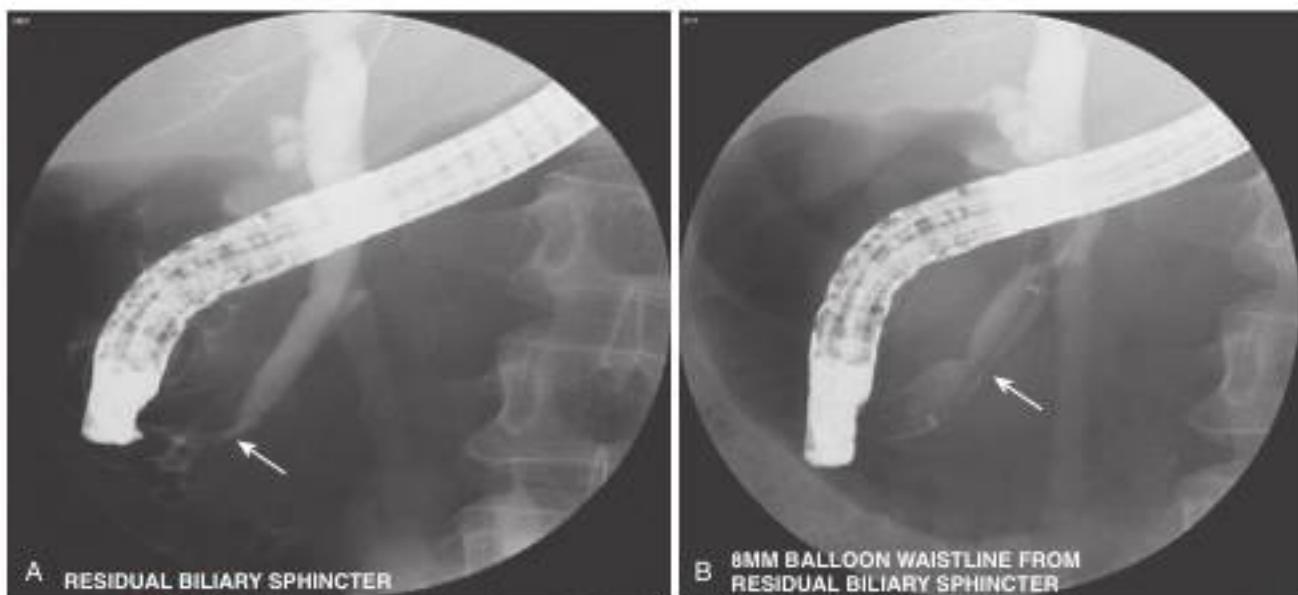

**FIG 49.23** Primary sclerosing cholangitis with dominant stricture. All diagnostic studies were benign.

prophylaxis.<sup>44,45</sup> Cholangiocarcinoma is of particular concern in this population, as the lifetime risk is 20% and approaches 40% in patients with advanced cases who go on to transplantation. Overall, the role ERC plays in routine screening and surveillance is an area of controversy.<sup>39,46</sup> Pancreatic ductal adenocarcinoma is the most common stricture of malignant origin encountered on ERC. Cancer of the pancreatic head often presents with the classic double-duct sign (Fig. 49.24). Although this sign is present in patients with chronic pancreatitis, the presence of jaundice creates a clinical scenario with a high pretest suspicion for ampullary and/or peri-ampullary malignancy.<sup>47</sup>

Tissue sampling should be done on strictures that have any clinical suspicion for neoplasia. Brush cytology is the easiest to obtain, but detects cancer when present in only 30% to 50% of cases. Additional sampling with a second brush, forceps, endoluminal needles, and/or fluorescence *in situ* hybridization increases the diagnostic sensitivity by approximately 10%.<sup>48,49</sup> Single operatory digital cholangioscopy site-directed biopsies and EUS fine-needle aspiration (FNA) (for distal bile duct strictures) have incremental value, in that they increase sensitivity for neoplasia to 85% and 81%, respectively.<sup>50,51</sup>

Beyond radiographic findings of upstream bile duct dilation, elevated basal sphincter pressure (> 40 mm Hg, as evaluated by manometry), and biochemical liver function test abnormalities, stenosis at the major papilla can also be assessed via dedicated cholangiography of the distal bile duct. Sphincter stenosis can occur *de novo* or as a late complication of prior biliary sphincterotomy. Discrete, abrupt, short segment narrowing of the intraduodenal bile duct segment is often observed. Following sphincterotomy, the true diameter of the biliary sphincter may be difficult to judge, and may best be assessed with the assistance of a hydrostatic balloon inflated with contrast across the sphincter segment, sized to the upstream bile duct (Fig. 49.25).

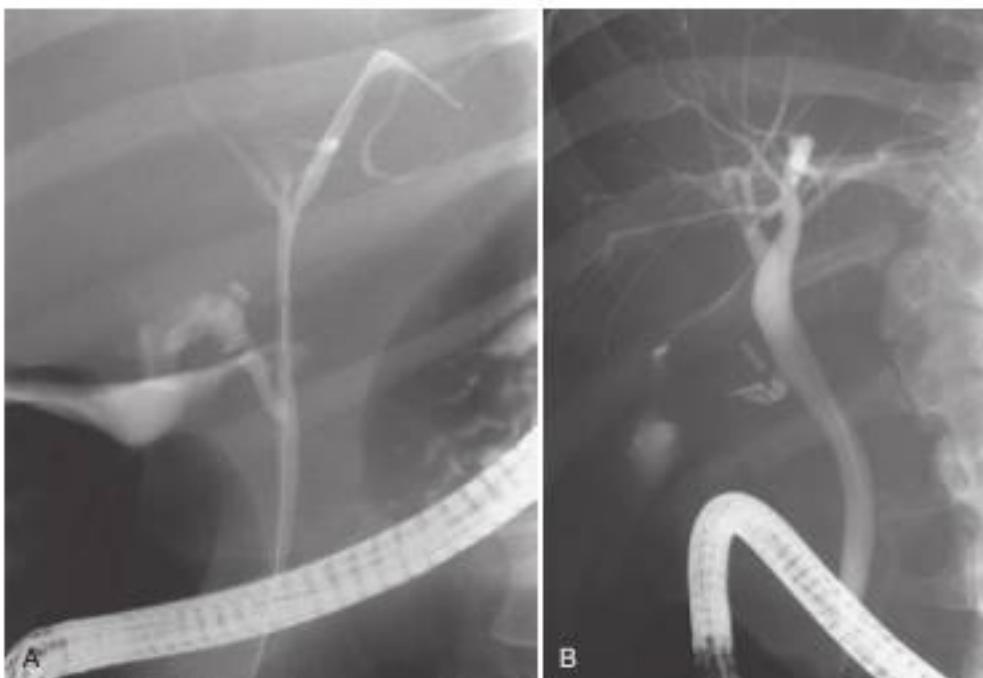

and (3) establish the diagnosis. However, with high-quality MRI/MRCP, performance of a "diagnostic" ERC for the sole purpose of establishing a diagnosis of PSC is no longer considered the standard of care.<sup>52</sup> The focus of ERCP in patients with PSC is endoscopic therapy and tissue sampling, given that the risk for bacterial cholangitis can range from 2% to 8%, despite antibiotic

A RESIDUAL BILIARY SPHINCTER

B 8MM BALLOON WAISTLINE FROM RESIDUAL BILIARY SPHINCTER

**FIG 49.25** After biliary sphincterotomy, the terminal bile duct may appear narrowed (**A**); however, true sphincter size is probably best determined by inflation of a hydrostatic balloon within the sphincter segment, observing the residual waistline (**B**).

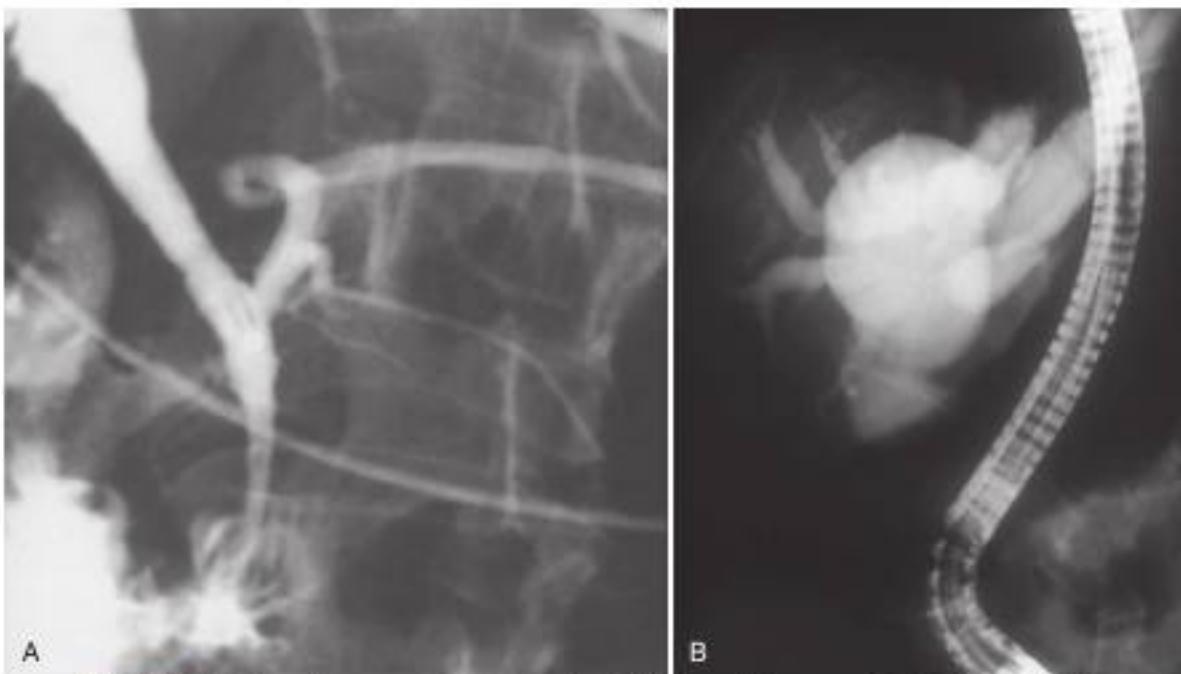

**FIG 49.26** **A**, Leak from cystic duct seen 2 days after laparoscopic cholecystectomy. **B**, Duct of Luschka leak seen 7 days after laparoscopic cholecystectomy. These ducts are in close proximity to the gallbladder bed, and are exposed with free dissection of the gallbladder.

### Biliary Leaks

Biliary leaks result from surgery complications or trauma (penetrating or nonpenetrating), or can be induced at the time of ERCP.<sup>11</sup> Laparoscopic cholecystectomy is most often associated with leaks from the cystic duct or the duct of Luschka (Fig. 49.26). Bile leaks typically cause right upper quadrant pain, fever, mildly abnormal serum liver chemistries, and leukocytosis. A typical duct of Luschka leak is seen in Fig. 49.26B, with the leak occurring from a small intrahepatic duct. A subhepatic contrast collection from

a cystic duct leak occurring after laparoscopic cholecystectomy is seen in Fig. 49.26A. A retrograde cholangiography-based grading system for the severity of biliary leaks after surgery has been reported. Based on the radiographic identification of a leak either before (high-grade) or after (low-grade) opacification of intrahepatic biliary radicals, this system may have practical applications for therapeutic decision making. A cohort study at a single center reported that more than 90% of patients with low-grade leaks and without additional, significant biliary pathology (e.g., bile duct stricture) were successfully managed

**FIG 49.27** **A,** Anomalous pancreaticobiliary ductal junction with pancreatic duct joining the bile duct well outside the duodenal wall. Note the long common channel of at least 15 mm in length. **B,** Type I choledochal cyst.

with biliary sphincterotomy alone.<sup>52</sup> In a separate retrospective study evaluating clinical factors associated with failure of the first endoscopic intervention for management of bile leaks after cholecystectomy, high-grade leak was found to be a statistically significant predictor on multivariate analysis (odds ratio [OR] 26.8,  $p < 0.001$ ).<sup>53</sup>

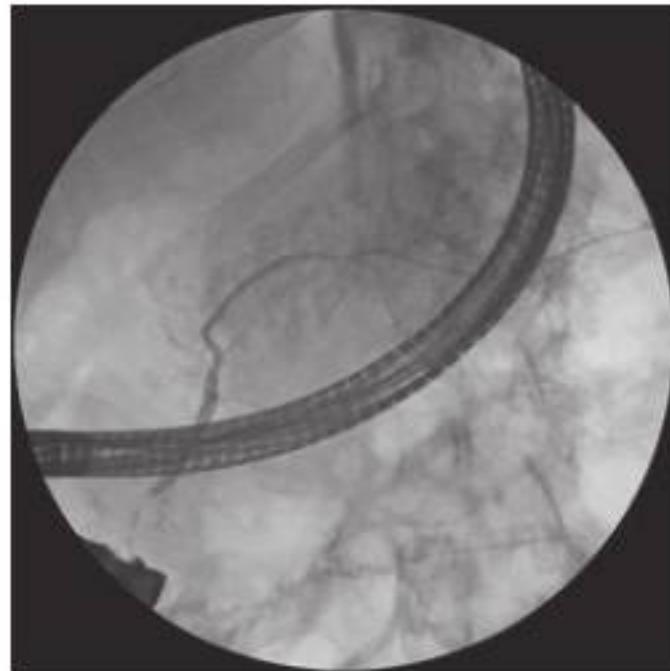

#### Anomalous Pancreaticobiliary Ductal Union

Anomalous pancreaticobiliary ductal union occurs in approximately 2% of people of Asian descent, but only 0.2% of Caucasian populations.<sup>54,55</sup> In this condition, the pancreaticobiliary junction occurs outside the duodenal wall, and simultaneous biductal filling occurs from major papilla injection through a common channel greater than 15 mm in length (Fig. 49.27A). Approximately one-third of these patients have an associated choledochal cyst (see Fig. 49.27B). Patients with an anomalous pancreaticobiliary junction are considered to be at high risk for gallbladder and bile duct cancer.<sup>55</sup>

#### PANCREATOGRAM TECHNIQUE AND IMAGE INTERPRETATION

Adjusting the C-arm for an anteroposterior (rather than a left posterior oblique) view to obtain images of the midline (head/genu of the pancreas) and left abdomen (body and tail) is optimal for acquisition of fluoroscopic and radiographic images of the pancreatic duct.

Safe imaging of the pancreatic ductal system necessitates the careful use of smaller volumes of contrast than are used to image the biliary system. This difference is crucial, as overfilling can occur with small volumes of contrast agent, and is an established risk factor for post-ERCP pancreatitis.<sup>56</sup> An approach of “feathering” contrast injections through gentle taps of pressure on the syringe is part of this subtle contrast injection technique. Overfilling is

**FIG 49.28** Acinarization of the pancreatic body from vigorous injection of contrast material.

best recognized as *acinarization*, which is the consequence of pressurized, densely opacified tertiary/quaternary and smaller pancreatic ductal structures. This appears as halos of fluffy radiographic structures along the pancreatic duct and its side branches (Fig. 49.28). Impaction of the catheter into a side branch, variant ductal anatomy, or injection downstream or upstream from a stricture/stone can cause segmental acinarization.

Caution is also advised in the setting of pancreatic fluid collections if formal drainage or surgery is not planned. Aggressive filling and consequent contamination of undrained cysts that follow pancreatitis (e.g., pseudocysts and walled-off necrosis) create a risk of infection. Antibiotic prophylaxis should be administered if this occurs.

## FEATURES OF A NORMAL PANCREATOGRAM

The goal of endoscopic retrograde pancreategraphy (ERP) is to collect contrast-enhanced radiographic images of the shape, caliber, course, and pattern of distribution of the main pancreatic duct (and in some cases its side branches) to guide therapy. Some diagnostic limitations of ERP are that it offers little information regarding the parenchyma, rarely provides dimensions for communicating cystic structures (in the setting of careful injection technique), and provides very limited information regarding the overall dimensions of the gland itself. The structures that comprise the first-order pancreatic ductal system include: the main (ventral) pancreatic duct of Wirsung extending through the head and genu, the (dorsal) accessory duct of Santorini in the head of the pancreas, and the dorsal pancreatic duct in the body and tail of the pancreas.

The main pancreatic duct is smooth and tapers in diameter from the head to the tail (Fig. 49.29). Its course of filling on anteroposterior images begins by ascending on the left of the spine (head, genu) and progresses in a horizontal-oblique fashion over (body) and to the right (body, tail) of the lower thoracic or upper lumbar spine.<sup>17</sup> Focal nonpathologic indentations are sometimes noted at the genu near the approximate junction

with the accessory duct, and in the body near the superior mesenteric vasculature.<sup>18</sup> Numerous postmortem and endoscopic studies have reported the length and diameter of the pancreatic duct. Postmortem values tend to be slightly higher than endoscopic values.<sup>17</sup> This may be due to the fact that, with age, the adult duct caliber appears to increase slightly, whereas the length is stable. The average length of a normal gland is approximately 17 cm, ranging from 9 to 24 cm. When the main duct is less than 9 cm in length, obstruction or atrophy should be suspected. The caliber of the pancreatic duct is most variable within the head of the gland. The normal diameter in the head is 3 to 4 mm (may range up to 6 mm), in the body 2 to 3 mm (up to 5 mm), and in the tail 1 to 2 mm (up to 3 mm).<sup>17</sup>

Visualization of side branches during pancreategraphy depends largely on technique and the force of contrast agent injection. Adequate visualization of side branches is by no means a routine maneuver in ERP, and it is often risky and irrelevant, as endoscopic therapeutic maneuvers are limited to the main pancreatic duct. Side branches are highly variable and asymmetric in the pancreatic head. However, they are regular and symmetric throughout the body and tail. A postmortem study reported a mean of 56 first-order branch ducts (range: 52–66).<sup>17</sup> Far fewer branches tend to be seen even with the most forceful pancreateogram.

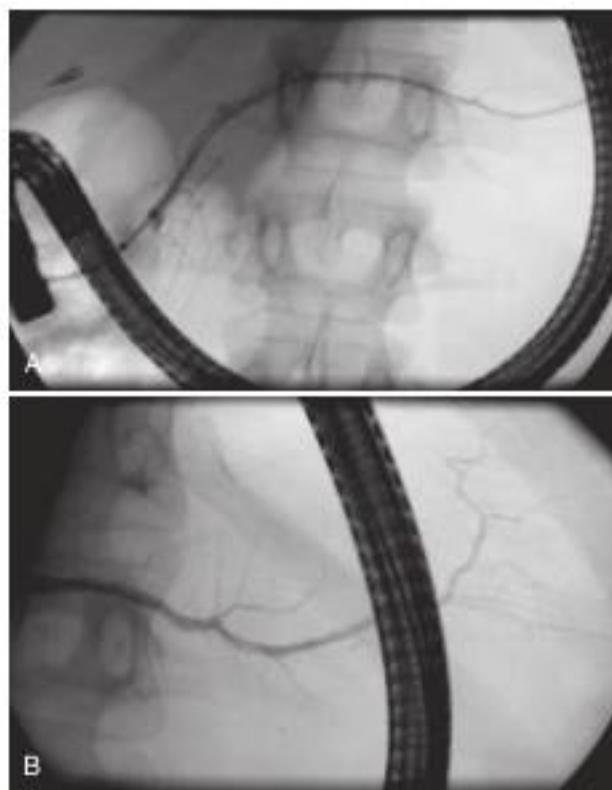

Normal ductal anatomy can vary greatly between individuals. A single large, inferiorly directed "uncinate" branch is seen in 55% to 62% of pancreateograms.<sup>18,19</sup> The accessory pancreatic duct (duct of Santorini) is also reported to have significant variability. This duct fills in only 43% of ventral endoscopic pancreateogram series, yet it communicates with the main pancreatic duct in approximately 90% of postmortem specimens.<sup>17</sup> The diameter, course, and patency for drainage through the minor papilla also varies greatly. Comparative pancreateogram series describe its patency to be 40% to 70% in general ERCP studies (without necessarily involving a targeted cannulation through the minor papilla). However, its patency is 17% to 21% in patients either being evaluated for biliary pancreatitis and/or ultimately presenting with post-ERCP pancreatitis, implying that when patent, the accessory duct may augment decompression of the main pancreatic duct and prevent pancreatitis.<sup>20,21</sup>

## ANATOMIC VARIANTS OF THE PANCREATIC DUCT

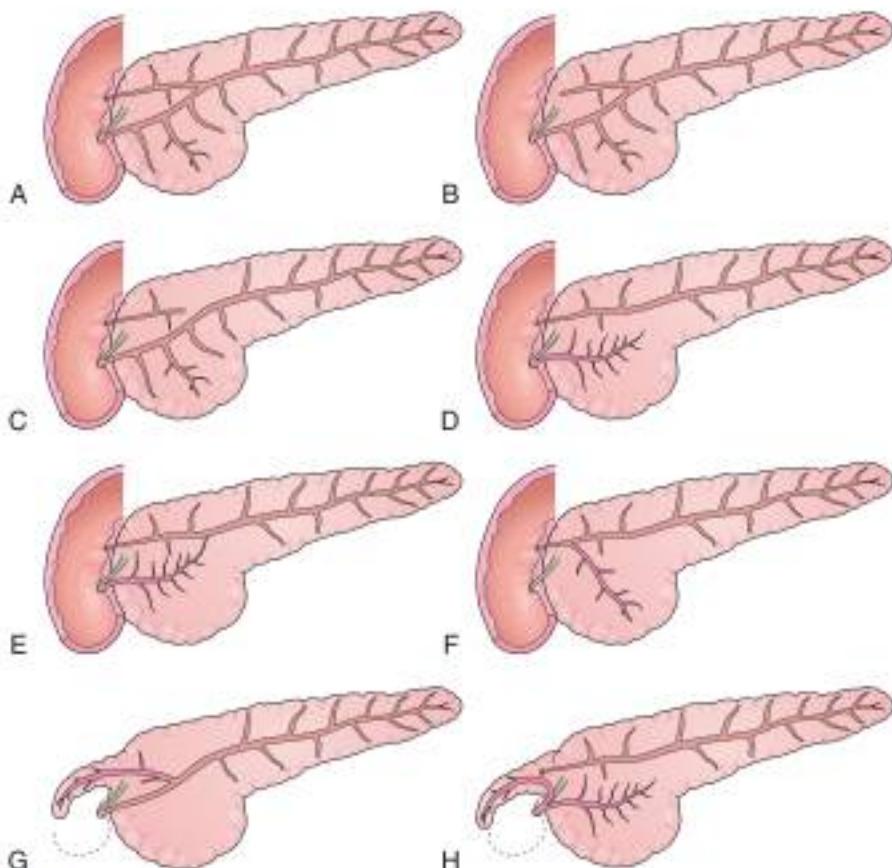

The pancreatic ductal system is subject to abnormal formation during embryogenesis (Fig. 49.30). The most important clinical variants develop between the sixth and eighth week of embryogenesis. The mechanism of their formation relates to either malrotation or malfusion of the ventral and dorsal embryonic pancreatic anlage and/or their respective ductal structures.

Failure of normal rotation and migration yields an annular pancreas, in which a portion of the ventral pancreatic anlage remains behind along the path of migration during organogenesis (Figs. 49.30 and 49.31). This band of incompletely migrated duct and parenchyma forms a partial or complete ring around the second portion of the duodenum, just proximal to the major papilla. Symptomatic variants can cause partial duodenal obstruction at any point during the lifetime of the patient. Annular pancreas may also cause episodic pancreatitis, but its association with other abnormalities makes interpretation of the exact etiology uncertain. For instance, approximately one-third of cases are associated with pancreas divisum.<sup>22</sup>

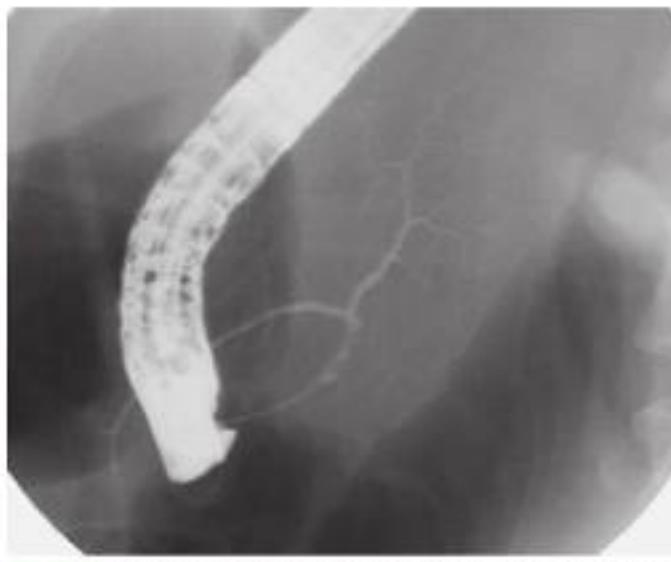

Pancreas divisum is the most common congenital variant (Fig. 49.32; see also Fig. 49.30). It occurs as a result of incomplete

**FIG 49.29** **A** and **B**, Normal dorsal duct pancreateogram of head (**A**) and body and tail (**B**) regions.

**FIG 49.30** Variations in dorsal and ventral duct migration and fusion. **A**, Normal. **B**, Normal with imperforate minor papilla. **C**, Normal with disjunction of the accessory duct. **D**, Pancreas divisum. **E**, Incomplete pancreas divisum. **F**, Pancreas divisum with no ventral duct. **G**, Annular pancreas with normal fusion of ventral and dorsal ducts. **H**, Annular pancreas with associated pancreas divisum.

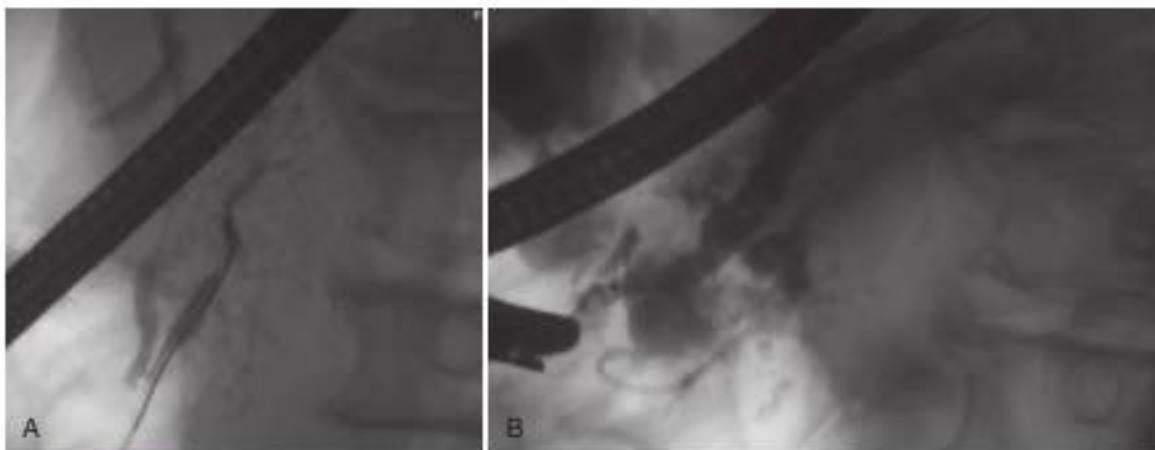

**FIG 49.31** Pancreatogram demonstrating pancreatic duct morphology consistent with annular pancreas.

fusion of the ventral and dorsal ducts after migration of the ventral anlage. Pancreas divisum is found in 7% of people in autopsy series. Approximately 15% to 20% of cases are "incompletely" divided, which is characterized by a persistent, tiny communication through side branches of the dorsal and ventral systems.<sup>63</sup>

Ductography via the major papilla in patients with pancreas divisum can reveal a normal, small diameter or a nonexistent (30%) ventral pancreatic duct. A "Christmas tree" pattern along the ventral duct of Wirsung with side branches that progressively diminish in size is often identified with ventral ductography. Dorsal ductography is also necessary to differentiate pancreas divisum from "pseudodivisum," as either may appear as an abrupt termination of the ventral pancreatic duct. Pseudodivisum is concerning, as the etiology may be a focal pancreatic lesion (e.g., pancreatic adenocarcinoma), yet it can be mistaken for pancreas divisum.<sup>63</sup>

Pancreas divisum is detected at a greater frequency in patients with recurrent acute and chronic pancreatitis (25%–30%) than in healthy individuals.<sup>64,65</sup> However, in symptomatic patients, pancreas divisum is often coincident with genetic mutations (*CFTR*, *SPINK1*) that also predispose to pancreatic disease. Studies and growing expert opinion now suggest that pancreas divisum is a complex condition that typically occurs in combination with

**FIG 49.32** Complete pancreas divisum and chronic pancreatitis: radiograph of a pancreatogram showing pancreas divisum. **A**, Ventral duct fills via injection into the duct of Wirsung at the major papilla. **B**, Dorsal duct fills via injection into the duct of Santorini at the minor papilla. Pathologic findings include parenchymal calcifications, dilated side branches, dilated dorsal and ventral pancreatic duct, and dorsal duct leak with filling of pseudocyst(s) in the pancreatic head.

other etiologies and/or exposures (e.g., tobacco and alcohol abuse), rather than a stand-alone etiology for recurrent acute and chronic pancreatic disease.<sup>60,61</sup> For this reason, the precise role of endoscopic therapy for symptomatic patients with pancreas divisum remains an area of controversy.

### OVERVIEW OF RADIOGRAPHIC PATTERNS OF PATHOLOGY SEEN DURING PANCREATOGRAPHY

During pancreatography, recognition of pathology requires differentiation between normal anatomy and patterns of abnormalities that suggest pathology. Categories of pathologic findings include (1) filling defects; (2) abnormalities in the main pancreatic duct or side branches (diameter and/or contour); (3) duct leaks, disruptions, or "disconnection"; and (4) filling of cystic spaces. Each abnormality has an associated differential diagnosis which should be considered carefully. Importantly, patients usually display multiple abnormalities that, in aggregate, offer a pattern that yields a diagnosis (e.g., chronic pancreatitis). Filling defects are often stones or mucus secreted by intraductal papillary mucinous neoplasm (IPMN). Ductal abnormalities include obstruction (partial or complete), duct dilation, and focal or diffuse contour irregularities, all of which may be secondary to benign inflammatory processes or malignancy. Leaks can be free, contained, or communicating with other organs as fistulas. They occur as a result of trauma, are iatrogenic (e.g., surgery, endoscopy), and/or occur as a local complication of acute or chronic pancreatitis (with or without necrosis). Filling of cystic spaces can be within or extrinsic to the pancreas, and may be associated with pseudocysts, pancreatic necrosis, or cystic neoplasms.

### Features of Pancreatic Neoplasia

ERP can identify neoplastic lesions of the pancreas. However, diagnostic ERP has been supplanted by cross-sectional imaging, magnetic resonance (MR) ductography, and endosonography to detect, diagnose, and (with EUS) sample malignancy of the pancreas. Pancreatic carcinoma does have characteristic ductal abnormalities. Individually, these characteristics are nonspecific,

**TABLE 49.5 Radiographic Features of Pancreatic Duct Strictures**

Attribute	Malignant	Benign (Chronic Pancreatitis, Autoimmune Pancreatitis)
Stricture length	Long (> 1–2 cm)	Long or short (focal)
Stricture contour	Blunt, abruptly pointed, or serrated	Smooth taper, concave (long), or web-like (focal)
Stricture severity	Usually complete with mass	Complete or partial
Side branches	Regionally absent	Present; dilated or ectatic
Upstream duct dilation	Always present	Present or absent
Multifocal strictures	Generally absent	Present

and overlap with ductal abnormalities caused by chronic and autoimmune pancreatitis. However, in aggregate, when taken as a pattern and interpreted in the proper clinical context, ERP ductal findings can elevate the suspicion for malignancy substantially and guide medical decision making (Table 49.5).

Again, the presence of concomitant neighboring strictures in both the pancreatic duct and the distal bile duct is highly suggestive of malignancy ("double duct" sign, see Fig. 49.24). The mechanisms for stricture of the neighboring, distal bile duct include: tethering by fibrosis, compression (mass or edema), and/or malignant effacement by a tumor, generally in the head, uncinate, or genu of the pancreas. Most often identified on preprocedure cross-section imaging, the presence of a double duct sign should substantially elevate suspicion for neoplasia.<sup>70,71</sup>

Of all the pancreatic neoplasms, ERP findings associated with main duct IPMN can be the most specific, but can also be difficult to identify.<sup>72</sup> The production of mucus by neoplastic epithelium

lining the main pancreatic duct or side branches can be identified in the form of dilated ductal segments on cross-sectional imaging or through symptoms caused by intermittent obstruction (pancreaticobiliary pain or pancreatitis).<sup>73</sup> When IPMN involves the main pancreatic duct, pancreatography typically shows main duct dilation. Soft, bulky, or linear filling defects that can be stripped from the lumen with an occlusion balloon are considered specific, and are caused by layering mucus. Gross papillary changes of the duct lining mucosa are infrequently evident on pancreatography, but, when present, can be sampled with a transpapillary approach using biopsy forceps and brushings to diagnose IPMN. Fluid can also be aspirated from the main pancreatic duct during ERP for carcinoembryonic antigen (CEA) biomarker testing and to assess for cytologic atypia. However, pancreatic duct fluid analysis for the diagnosis of neoplasia, although specific (97%), has limited sensitivity (35%).<sup>74</sup>

To opacify branched duct IPMN lesions, a forceful injection of contrast agent may be required to displace mucus. Consequently, this maneuver is rarely justified, given the increased risk for pancreatitis. Moreover, for branched duct lesions, a work-up comprised of high-quality cross-sectional imaging (MRI/MRCP, contrast enhanced CT) and/or EUS-FNA with collection of fluid for biomarkers (e.g., CEA) and/or integrated molecular analysis is now the recommended diagnostic approach, given the superior accuracy and lower risk profile compared to ERCP.<sup>75,76</sup>

Transpapillary pancreatoscopy and intraductal ultrasound have been described as useful in preoperative staging of the longitudinal spread of main duct IPMN.<sup>77,78</sup> Endoscopic visualization of thick mucus plugs extruding from a dilated papillary duct is pathognomonic, and is considered highly specific (Fig. 49.33) for main duct IPMN of either the bile duct or the pancreatic duct.<sup>79</sup> The latter (pancreatic) disease is far more common. During pancreatoscopy, mucus markedly distorts endoscopic views; however, intraductal abnormalities such as papillary "fish-eggs" or villous, mass-like projections of epithelium along the wall of

the main pancreatic duct are considered diagnostic and afford targets for intraductal sampling. Wire-guided intraductal ultrasound identifies both the mucus and papillary changes. However, none of these endoscopic tools are highly sensitive for confirming invasive malignancy.

### Acute Pancreatitis, Recurrent Acute Pancreatitis, and Pancreatic Duct Disruption

Pancreatography during an episode of acute pancreatitis is generally not indicated. Pancreatogram findings in the setting of acute pancreatitis tend to be nonspecific, and endoscopic interventions during the acute phase of pancreatitis are generally not recommended. Nonspecific ductal findings include irregularity in the contours of the main duct and side branches, delayed filling of side branches, and unorganized parenchymal staining before side branch filling; this last finding is likely to be associated with early pancreatic necrosis.

Additional ERP findings during acute pancreatitis include strictures, duct leaks, and/or disruptions. These findings, when identified close to the onset of acute pancreatitis, are associated with pancreatic necrosis.<sup>80,81</sup> Leaks can also indicate complications from pancreatitis caused by an "internal" fistula (e.g., pancreatic ascites, pancreaticopleural fistula) or an external (e.g., cutaneous) fistula. In the absence of clinical findings that suggest the presence of a fistula, leaks during acute pancreatitis correlate poorly with late pathology and/or a disease state that requires an endoscopic intervention.<sup>81</sup> Overall, there are no data to support either early diagnostic or therapeutic pancreatography in "all comers" with acute pancreatitis with or without necrosis. The risk for introducing a secondary infection of unorganized necrotic tissue and/or fluid collections through the use of contaminating contrast injections further diminishes the utility of ERP during the acute phase of pancreatitis in the absence of symptomatic pancreatic duct disruption with fistula.<sup>82</sup>

However, if acute pancreatitis is associated with clinical evidence of internal/external fistula (e.g., pancreatic ascites, pancreaticopleural fistula, cutaneous fistula), a combination of medical intervention (pancreatic rest with enteral or parenteral nutrition, somatostatin, and/or large-volume paracentesis) and pancreatography with associated therapies may be beneficial.

The timing of onset for duct leaks from "disruption" of the pancreatic duct remains incompletely defined. Following acute pancreatitis, leaks occur frequently near the genu, a region of pancreatic anatomy that is particularly vulnerable to necrosis due to watershed blood supply. Leaks from disruptions of the pancreatic duct that are identified within the first few weeks tend to lead to unorganized collections in the retroperitoneum. Leaks identified after longer intervals enter more circumscribed spaces of maturing fluid collections. They are diagnosed as extravasation (or leak) of contrast from the main pancreatic duct on ERP (Fig. 49.34). ERCP is considered to be the most accurate method of identifying leaks and ductal disruption.<sup>83-85</sup> A main pancreatic duct disruption can be categorized as incomplete (visualization of the upstream pancreatic duct) or complete (nonvisualization of the upstream pancreatic duct or "disconnected" pancreatic duct).

Literature related to the effectiveness of endotherapy is limited to case series, and is reported in combination with drainage procedures, nutrition support, and medical interventions for associated pseudocysts and free intrabdominal/pleural fluid collections. Rates of therapeutic success for disruption and associated fistula approach 75%.<sup>82,85</sup>

**FIG 49.33** Endoscopic image of mucus extruding from the minor papilla in a patient with intraductal papillary mucin-producing neoplasm (IPMN) of the pancreas.

**FIG 49.34** Pancreatogram showing a large pancreatic duct disruption with leak from the pancreatic duct in the region of the pancreas body. The pancreatic duct is in continuity, and the disruption is bridged with a guidewire. The patient presented with pancreatic ascites.

Smoldering pancreatitis is a disease state characterized by unrelenting pancreatic symptoms (> 7–10 days) in the setting of persistent pancreatic enzyme elevation and/or radiographic evidence of pancreatic/peripancreatic inflammation in the absence of pancreatic necrosis, pancreatic fluid collections, or organ failure. A single case series reported the use of therapeutic ERP in eleven patients. Eight of these patients demonstrated either duct irregularities or duct dilation on ERP. Pancreatic stent placement alleviated symptoms, resulting in discontinuation of parenteral nutrition and/or narcotics, in 10/11 patients.<sup>53</sup> A review article by Das et al (2015) reported outcomes for ERP in patients with smoldering pancreatitis. Pancreatic stent placement resulted in successful management of symptoms in 83% of patients (10/12) when used as first-line therapy, and in 100% of patients as second-line therapy ( $n = 4$ ) after pancreatic rest with nasojejunal feeds. However, the authors recommend that pancreatic stent placement should follow an attempt at management with post-ligation of Treitz feeds.<sup>54</sup>

Paraduodenal pancreatitis (also known as groove pancreatitis) is a disease entity characterized by persistent abdominal pain and biliary and/or gastric outlet obstruction from acute pancreatitis syndrome that has characteristic radiographic features. These include focal obstructing inflammation and/or fluid collections (linear or cystic) in the pancreaticoduodenal tissue interface (or groove) and in the apposing duodenal wall. A case series reported outcomes for 39 patients with paraduodenal pancreatitis managed with endoscopic therapy, which included varying combinations of pancreaticobiliary stenting and EUS-guided transduodenal drainage of periduodenal fluid collections with or without subcutaneous octreotide. A stricture of the main pancreatic duct and/or common bile duct was identified in 72.5% and 56.9% of patients, respectively. Features of chronic pancreatitis (calcifications, atrophy) were observed in more than 35% of patients. The authors reported a greater than 70% rate of clinical success with varying combinations of endoscopic and medical therapy. However, due to small numbers and heterogeneity in

the authors' management of the cohort, a clear algorithm for endoscopic therapy remains unclear.<sup>55</sup>

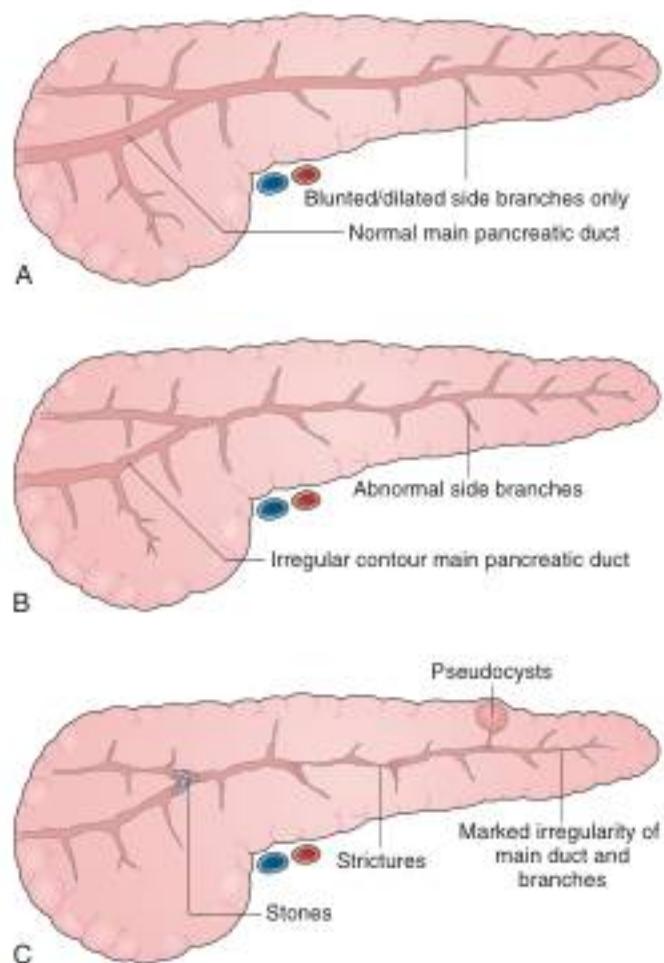

With reference to recurrent, idiopathic pancreatitis, Venu et al (1989) reported results for ERCP and sphincter of Oddi manometry in 116 patients.<sup>56</sup> A treatable cause of pancreatitis was identified in 37% of cases, with patients having anatomic abnormalities, stones, and sphincter hypertension. We examined diagnostic findings at ERCP in patients with idiopathic pancreatitis at our center. In patients with recurrent idiopathic pancreatitis, sphincter of Oddi (SOD) dysfunction (45%), chronic pancreatitis (35%), and pancreatic divisum (22%) were the most common findings. Chronic pancreatitis was identified more often (35% vs. 17%,  $p < 0.001$ ), and bile duct sludge and stones were identified less often (0.6% vs. 3.2%,  $p < 0.01$ ) in patients with idiopathic recurrent pancreatitis compared to those with a single episode of unexplained pancreatitis.<sup>57</sup> However, with the exception of SOD, the majority of morphologic and intraductal abnormalities can be identified using high-quality cross-sectional imaging, MR pancreatography, and EUS (alone or in combination).<sup>58</sup> This was elegantly demonstrated through a prospective study by Testoni et al (2009), in which patients with idiopathic pancreatitis underwent MRCP, EUS, and ERCP. Ultimately, the diagnostic yield of a non-ERCP approach was greater than 60%, and ERCP failed to identify pathology missed by the other two modalities. Hence, diagnostic ERCP for recurrent pancreatitis should be reserved for cases with a clear preprocedure intention for SOD manometry or a therapeutic maneuver (e.g., sphincterotomy, stone extraction, stricture therapy).<sup>59</sup> The approach to idiopathic pancreatitis will be covered in greater detail elsewhere in this volume (see Chapter 57).

### Chronic Pancreatitis

The indications for pancreatography in the setting of chronic pancreatitis, in order of appropriateness, include: (1) to confirm pathology and characterize the anatomy, with preprocedure intention to perform endoscopic therapy; (2) to characterize anatomy before surgical management of pathology; and (3) to establish a diagnosis. With reference to the latter indications, ERP for many years was the gold standard for diagnosing chronic pancreatitis and for preoperative planning. However, diagnostic ERCP is no longer considered a first-line test for diagnosis of chronic pancreatitis. MR pancreatography with contrast and secretin-stimulated images, EUS, and secretin-stimulated pancreatic function testing should be performed prior to consideration of diagnostic ERCP, given that they have similar (or even superior) accuracy and a more favorable risk profile.<sup>60–63</sup>

The Cambridge classification has remained the most widely utilized system for characterizing the severity of chronic pancreatitis since its inception in 1983. This sequential gradation of both main pancreatic duct and side branch findings, combined with the weight given to discrete, specific ductal abnormalities (e.g., stones, strictures) has an established accuracy (Figs. 49.35 and 49.36).<sup>64,65</sup> However, it should be noted that there is significant risk of pancreatitis with pressurized injection for opacification of normal side branches. Fortunately, this system can be extrapolated for diagnosis of chronic pancreatitis using MRCP.<sup>66</sup>

The main challenges in the interpretation of pancreatography for the diagnosis of chronic pancreatitis are the differentiation of normal from early (minimal change) disease, and the differentiation of focal strictures associated with pancreatic carcinoma and chronic pancreatitis (see Table 49.5). Of note, mild changes on pancreatography—blunting, dilation, or shortening

**FIG 49.35** Cambridge classification of chronic pancreatitis. **A**, Mild. **B**, Moderate. **C**, Marked.

**FIG 49.36** Pancreatogram showing advanced grade chronic pancreatitis.

of the side branches—are the least specific and most subjective observations, because they are highly dependent on technique and adequacy of filling, and can potentially be the result of age-related changes or transient effects of acute injury (e.g., acute pancreatitis, iatrogenic stent-induced changes).

Pancreatic duct morphology is best characterized by pancreatography (MRI or endoscopic), and this remains the procedure of choice for anatomic characterization before surgery and in patients with postsurgical pancreatic duct anatomy. With the exception of confirmation of fistula and leaks, MR pancreatography is now preferentially utilized for preoperative planning in patients with chronic pancreatitis. In patients with prior pancreatic surgery (e.g. pancreaticoduodenectomy, lateral pancreaticojejunostomy), MR pancreatography offers a distinct technical and safety advantage over diagnostic ERP, given the challenges of performing endoscopy in patients with altered anatomy.<sup>78</sup>

### CHOLANGIOPANCREATOGRAPHY IN PATIENTS WITH SURGICALLY ALTERED ANATOMY

The clinical success of ERCP performed in patients with a history of Billroth II hemigastrectomy approaches 80% in large case series, which is lower than that reported in the setting of native anatomy.<sup>104,105</sup> We generally start with a standard side-viewing duodenoscope; however, a recent study suggests that an approach using an end-viewing gastroscope fitted with a transparent cap may have a lower risk for perforation (< 5% vs. 5%–18%) and comparable rates of therapeutic success.<sup>106</sup>

A 160-cm pediatric colonoscope or a 220-cm enteroscope can reach the bile duct in a significant proportion of patients with a long Roux-en-Y gastroenterostomy or a choledochojejunostomy. Single- and double-balloon enteroscopy is now considered the standard endoscopic approach for ERCP in patients without Roux-en-Y anatomy. However, rates of overall therapeutic success with balloon-assisted enteroscopy vary widely, even across expert centers, and generally remain significantly lower than in patients with conventional anatomy (> 70% vs. > 95%).<sup>107–109</sup> The lack of a catheter-deflecting elevator and the limited spectrum of compatible (long) ERCP accessories are a further hindrance for end-viewing endoscopy in this setting.<sup>110</sup> Although Roux-en-Y gastric bypass patients may have the lowest rates of therapeutic success for ERCP performed in surgically altered anatomy, they are and will remain a common type of patient encountered by the ERCP endoscopist.<sup>111</sup> Consequently, duodenoscopic ERCP through a surgical gastrostomy in the excluded stomach may be preferable for patients with Roux-en-Y gastric bypass anatomy. Rates of therapeutic success with this technique are greater than 95%, and it affords access to the full spectrum of endoscopic accessories. The gastrostomy tract can be maintained if repeat procedures are anticipated. The disadvantages of this approach relate to morbidity in the postprocedure setting, either associated with surgical complications and/or longitudinal management of the larger (greater than 30-Fr) surgical gastrostomy tract required to allow subsequent passage of the duodenoscope for repeat procedures.<sup>112</sup>

Cholangiography and biliary therapeutics are successful in 60% to 90% of patients with pancreaticoduodenectomy (Whipple) anatomy, with balloon-assisted enteroscopy enabling higher rates of success.<sup>104,106,107</sup> However, when taken as a subgroup, pancreatography and pancreatic therapeutics are met with much lower rates of diagnostic and therapeutic success (< 10%).<sup>108,109</sup> In most patients with post-Whipple anatomy, a pancreatogram is more likely to be successful via a transgastric EUS-guided duct puncture (Fig. 49.37). This maneuver is also used as either an adjunct to retrograde cannulation or as a prelude to EUS-guided transgastric stent decompression of obstructed ducts.<sup>113</sup>

**TABLE 49.6 Approximate Frequencies of Complications From Endoscopic Retrograde Cholangiopancreatography (ERCP) and Sphincterotomy (%)**

Complication	AVERAGE-RISK PATIENTS		HIGH-RISK PATIENTS*	
	ERCP	Sphincterotomy	ERCP	Sphincterotomy
Pancreatitis	3	5	8	12
Bleeding	0.2	1.5	0.4	3.5
Perforation	0.1	0.8	0.3	1.5
Infection	0.1	0.5	2	2
Sedation reaction or cardiopulmonary	0.5	0.5	2	2
Total†	3.9	8.3	12.7	21

\*Certain patient characteristics and technical aspects of the procedure increase the risk of complications, including suspected sphincter of Oddi dysfunction, recurrent pancreatitis, difficult cannulation, precut sphincterotomy, coagulopathy, renal dialysis, cirrhosis, or advanced cardiopulmonary disease.

†Some patients have more than one complication.

Approximate severity of complications: mild, 70%; moderate, 20%; and severe, 10%.

**FIG 49.37** Transgastric pancreateogram utilizing endoscopic ultrasound.

## COMPLICATIONS OF CHOLANGIOGRAPHY AND PANCREATOGRAPHY

The complications of diagnostic cholangiopancreatography include perforation, infection, bleeding, and pancreatitis, with the latter being a much more common complication (Table 49.6).<sup>10</sup>

Pancreatography during ERCP is one of the most consistently identified risk factors in studies on procedure-related pancreatitis. Further details regarding preprocedure and technical risk factors are now well-described.<sup>10,11</sup> Numerous studies have now established both temporary pancreatic duct stent placement and rectal indomethacin as effective interventions that reduce the incidence and severity of post-ERCP pancreatitis.<sup>10,11</sup> An in-depth discussion of this literature is beyond the scope of this chapter.

Infection in the form of cholangitis is a risk of cholangiopancreatography, and occurs in 2% to 3% of patients. However, studies evaluating the effectiveness of routine preprocedure antibiotics have yielded mixed findings, with summative literature in the form of meta-analyses and systematic reviews suggesting significant benefit in only select populations of patients.<sup>12</sup> Consequently, in the era of multidrug-resistant bacteria and the consequent need for antibiotic stewardship, the weight of evidence does not

clearly establish a role for routine prophylactic antibiotics in the peri-ERCP period. Societal guidelines do support selective antibiotic prophylaxis in patients with pancreaticobiliary obstruction with the potential for incomplete drainage (e.g., PSC and cholangiocarcinoma), immunocompromised patients (e.g., liver transplant), and/or pancreatography cases with the potential for contamination of pancreatic/peripancreatic fluid collections.<sup>13</sup>

## ACKNOWLEDGEMENTS

We would like to acknowledge Dr. Glen Lehman, Dr. Bret T. Petersen, Dr. Lee McHenry, and Dr. James L. Watkins for their contributions to prior editions of this chapter (Diagnostic Cholangiography and Diagnostic Pancreatography, Editions 1 and 2). Portions of their contributions to *Clinical Gastrointestinal Endoscopy* Editions 1 and 2, in the form of images and writing, were used to construct this chapter.

## INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP) requires several years of dedicated training and continuous refinement of knowledge and skill.<sup>1–3</sup> Selective ductal cannulation is the sine qua non for diagnostic and therapeutic ERCP. General issues on cannulation have already been highlighted in Chapter 40. In a 2017 consensus report, difficult papillary access is defined as the inability to achieve selective biliary cannulation by standard ERCP techniques within 10 minutes or up to five cannulation attempts.<sup>4</sup> This chapter concentrates on variations of standard techniques to overcome challenges to standard cannulation, including in patients with anatomic variations, gastric outlet obstruction, and surgically altered anatomy. With the development of endoscopic ultrasound (EUS) and magnetic resonance cholangiopancreatography (MRCP), ERCP has moved from a diagnostic to an almost purely therapeutic procedure.<sup>5,6</sup> When used as a diagnostic procedure, image-guided tissue sampling with forceps biopsy, brush cytology, or cholangiography are performed. For this reason sphincterotomy is necessary for most cases of diagnostic or therapeutic ERCP.

## STANDARD ACCESSORIES

### Standard Cannulas

Cannulation catheters range in size from 5 Fr (French) to 7 Fr. They are usually made of Teflon. The tip can be straight, tapered, or rounded, and accepts up to a 0.035-inch guidewire. Tapered tip catheters probably confer a higher risk of submucosal injection.

### Sphincterotomes

Sphincterotome catheters are modified with an electrosurgical cutting wire at their distal end. Like cannulation catheters, they are usually made of Teflon. The cutting wire can be placed under

tension to “bow” the tip of the catheter, providing another articulation to facilitate cannulation. The tensed wire is also used to perform sphincterotomy.

To facilitate cannulation, double- or triple-lumen sphincterotomes are available. They allow the introduction of a wire to accomplish a therapeutic task, and in the case of a triple-lumen sphincterotome, allow injection of contrast with a guidewire in place. Due to the small size of the injection channel, contrast flow is slow, and the use of a small syringe is recommended to facilitate injection.

In general, sphincterotomes require a higher level of coordination between the endoscopist and the assistant controlling flexure of the device. Short-wire systems, in which the guidewire can be stripped external to the catheter, allow the endoscopist to control and lock the guidewire, reducing the need for coordination between the assistant and endoscopist.

### Catheter Versus Sphincterotome for Cannulation

A standard 6-Fr catheter with a 4-Fr tip accepting a 0.035-inch guidewire was the traditional first choice for cannulation. The advantage is high flexibility compared with a 6-Fr sphincterotome. The cannulation catheter could be used directly for deep cannulation (e.g., 0.035-inch J-tip with a hydrophilic Terumo guidewire [Terumo Medical Corporation, Tokyo, Japan]). For further intervention, the guidewire could be kept in place.

Sphincterotomes have largely supplanted the standard catheter in many institutions because they permit bowing of the catheter tip to facilitate alignment with the intraduodenal segment of the bile duct and because sphincterotomy is anticipated in the vast majority of ERCP procedures performed.

Data suggest an advantage of sphincterotome cannulation over standard catheter cannulation (84%–97% vs. 62%–75%),<sup>7–9</sup> but there is a great deal of heterogeneity in available studies, with variable criteria used to define cannulation failure.

**Abstract**

Endoscopic retrograde cholangiopancreatography (ERCP) requires several years of dedicated training and continuous refinement of knowledge and skill. With the dissemination of endoscopic ultrasound (EUS) and magnetic resonance cholangiopancreatography (MRCP), ERCP has evolved from a diagnostic to an almost purely therapeutic procedure. General issues on cannulation have already been highlighted in Chapter 40. This chapter concentrates on variations of standard techniques to overcome challenges to standard cannulation and sphincterotomy, including in patients with anatomic variations, gastric outlet obstruction, and surgically altered anatomy.

ERCP  
double-balloon ERCP  
sphincterotomy  
periampullary duodenal diverticula

**FIG 50.1** **A to C,** Reshaping of the distal end of a hydrophilic J-Tip of a 0.035-inch guidewire by means of an anatomical forceps in order to facilitate cannulation of an angulated duct.

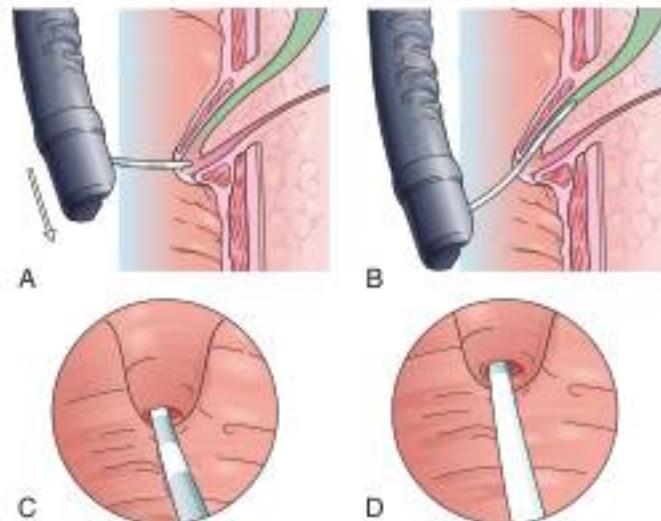

**FIG 50.2** Self-fixing torque aid for easy steering of J-shaped guidewire.

### Guidewires

Guidewires are frequently used for attaining and maintaining access to the biliopancreatic ducts.<sup>10</sup> Several studies have reported that wire-guided cannulation techniques increase cannulation success and may lower post-ERCP pancreatitis rates.<sup>11–13</sup>

The configuration of the guidewire tip can be straight or angled (J-shaped). Stiff shaft guidewires (e.g., monofilament guidewires) minimize lateral divergence and facilitate forward transmission of forces. To obtain access through biliary strictures, guidewires with activated hydrophilic coatings and flexible leading tips are generally recommended. For angulated accesses, the J-shaped distal end of a hydrophilic guidewire (e.g., Terumo 0.035-inch) can be customized by means of an anatomical forceps (Video 50.1 and Fig. 50.1). Guidewire tip steering is facilitated by a self-fixing torque aid (Terumo Corp.) (Fig. 50.2 and Video 50.2).

Currently available guidewire types include conventional, hydrophilic, and "hybrid," ranging from 0.018 to 0.035 inches in diameter and 260 to 480 cm in length. Enteroscopy length wires are available for balloon-assisted ERCP. Wire lengths greater than 400 cm are used for exchange of devices that are not compatible with the short-wire system. Only insulated (coated) wires should be used during electro-cautery applications to prevent aberrant transmission of electrosurgical energy.<sup>14</sup> Coated wires have a monofilament core of nitinol or stainless steel and an outer

**FIG 50.3** For primary cannulation of the common bile duct using a standard catheter and a therapeutic duodenoscope, it often helps to **A**, first intubate the papillary orifice with the catheter and then to **B**, change the angle of the catheter by gently advancing the endoscope. **C** and **D**, Alignment with the axis of the papilla is important for biliary cannulation. (Modified from Soehendra N, Binmoeller KF, Seifert H, et al: *Therapeutic Endoscopy: Color Atlas of Operative Techniques for the Gastrointestinal Tract*. New York, 1997, Thieme Medical Publishers.)

sheath of lubricious material (Teflon, polyurethane). Depending on the outer sheath, it is possible to improve radiopacity, slipperiness, and electrical insulation properties. To improve guidewire manipulation and accessory exchange, catheter lumens should be flushed with water to reduce friction with the guidewire.

### DIFFICULTIES IN CANNULATION OF THE PAPILLA

One should develop and employ a pragmatic step-up approach to cannulation. Each escalating technique may be tried several times before moving up to the next method until success is achieved. One traditionally preferred progression begins with a sphincterotome flushed with contrast. The ampulla is inspected for its anatomic features in an attempt to localize the desired duct orifice and to determine the optimal angle of ductal traverse of the ampulla. For biliary cannulation, the catheter tip should be directed toward the 11 o'clock orientation with the catheter tip bowed to parallel duct alignment (Fig. 50.3). The surface of

the ampulla should be gently stoked downward to the selected entry point (intended to deflect the fimbria separating the pancreatic and biliary orifices in the common channel) and the catheter tip advanced into the papillary meatus with an outward and upward deflection of the catheter. Gentle injection of contrast under fluoroscopic guidance will inform the catheter position as in the bile duct, pancreatic duct, common channel, or none of these. If the bile duct fills, further contrast should be injected and the catheter slid deeply into the common bile duct or, in the case of a triple-lumen catheter, the guidewire advanced. When the bile duct does not fill, bow the sphincterotome tip upward and tent the ampulla toward the endoscope and inject again. If still no filling, we employ a technique in which the sphincterotome is bowed and impacted into the papillary meatus at the 11 o'clock orientation, then the endoscopist deflects the endoscope toward and above the ampulla while slightly withdrawing the catheter within the accessory channel (so as to sustain a static depth of catheter tip entry into the papilla). This is performed concurrent with the assistant decreasing the tension on the bow of the sphincterotome. This maneuver helps direct the catheter into the location and orientation of the bile duct.

For selected pancreatic duct cannulation, the 5 o'clock papillary orientation is targeted, and with a straighter, as opposed to bowed, address (Fig. 50.4).

The guidewire cannulation technique is favored by many endoscopists. Herein, a straight or angled-tip guidewire is advanced to the tip of the catheter (standard or sphincterotome). The catheter tip is inserted into the desired location and angulation within the meatus, and the guidewire gently advanced under combined endoscopic and fluoroscopic guidance. Levels of resistance are appreciated, and we commonly "jiggle" the wire tip to seek out the desired ductal entry. Another approach is to advance the catheter into the papillary orifice with the

guidewire tip extending slightly from the tip of the catheter. Lastly, the catheter can be set to hover just before the papilla and the guidewire advanced into the desired location within the papilla.

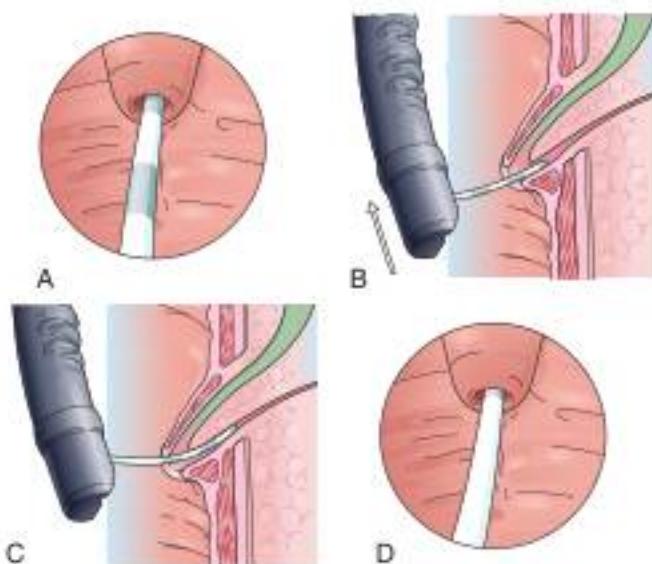

When there is repeated injection or guidewire advancement into the pancreatic duct, two techniques may be used to isolate it and facilitate selected bile duct cannulation. The first is to advance the guidewire into the pancreatic duct, exchange out the catheter, load it with another wire, and reinsert it alongside the pancreatic guidewire to attempt cannulation just above and to the left of the guidewire insertion point. This is known as the *double guidewire* technique. The second approach is to place a 3- to 5-Fr pancreatic duct stent and similarly cannulate just above and to the left. Both these approaches may be used to facilitate access prior to needle-knife sphincterotomy, detailed later.

### Access Sphincterotomy in Difficult Papillary Cannulation

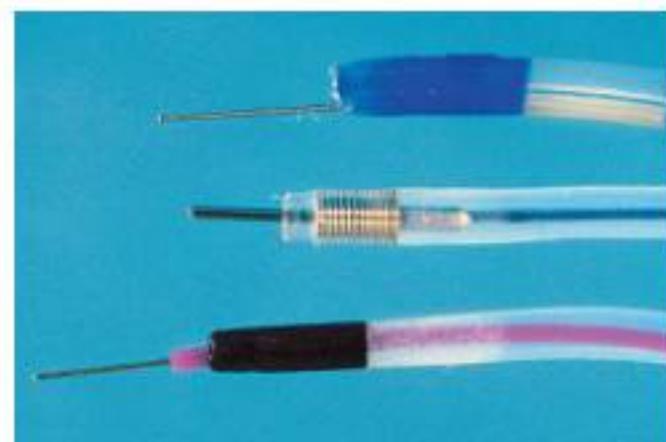

Standard cannulation techniques may fail even in the most experienced endoscopist's hands. A difficult anatomical position with inability to align the axis of the catheter and guidewire with the axis of bile or pancreatic duct may lead to failure of papillary cannulation. Other reasons may include impacted calculi, papillary stenosis, ampullary neoplasm, or duodenal inflammation.<sup>11</sup>

Access sphincterotomy (sometimes referred to as *pre-cut* sphincterotomy) commonly facilitates biliary cannulation safely and effectively in the hands of the experienced endoscopist. However, potentially severe complications may occur when performed by those who are inadequately trained.<sup>16,17</sup> The needle knife is the most common tool for access sphincterotomy (Fig. 50.5). Success rates vary widely according to the frequency of use and experience of the individual endoscopist, and range from 68.4% to 92.5%.<sup>18,19</sup>

There are two predominant access sphincterotomy techniques. For the conventional access sphincterotomy, the needle-knife tip is engaged within the papillary orifice and aligned with the presumed axis of the bile duct and papillary roof. Care has to be taken to modulate the cutting depth. Some advise beginning with a superficial cut of the papillary roof, starting at the papillary

**FIG 50.4** Pancreatic cannulation (A–D). **A**, Flat position of the catheter facing the papilla at the same level. **B** and **C**, If common bile duct cannulation was achieved first, pulling back the endoscope facilitates cannulation, as well as **D**, changing the direction of the catheter within the papilla. (Modified from Soehendra N, Binmoeller KF, Seifert H, et al: Therapeutic Endoscopy: Color Atlas of Operative Techniques for the Gastrointestinal Tract. New York, 1997, Thieme Medical Publishers.)

**FIG 50.5** Different types of needle-knives. Diameter and length of the cutting wire influences cutting properties: the thinner the wire knife, the faster and sharper the cut; the longer the wire, the potentially deeper the cut, with relatively high risk of bleeding and perforation.

orifice, transecting first the mucosa and incrementally cutting until the muscle layer of the common sphincter is visualized. The round or point-like aspect of the biliary orifice may be seen and then selectively cannulated with a hydrophilic guidewire exiting 2 mm from a cannula or sphincterotome. Even if 11 o'clock is a common position of the biliary sphincter, this may vary, and careful identification of the round structure of the biliary orifice and distal biliary sphincter muscle is the most important pathfinder. In the case of failed pancreatic cannulation, a biliary sphincterotomy, using standard or needle-knife technique, may be performed to better expose the pancreatic orifice, which is typically found in the 5 o'clock position. After selective deep duct cannulation, a guidewire sphincterotomy is often performed to also open the biliary or pancreatic sphincter and to achieve an optimal permanent access and drainage.

The alternative techniques for access sphincterotomy are starting suprapapillary and cutting downward toward the papilla face, or direct puncture fistulotomy into the roof of the papilla.<sup>20</sup>

Access sphincterotomy is used in 3.8% to 19.2% of ERCP procedures, with a success rate ranging from 75% to 99% and complication rates from 1.9% to 30%.<sup>18,21-24</sup> Complications of precut sphincterotomy are similar to those with conventional sphincterotomy, such as bleeding, perforation, pancreatitis, and cholangitis.<sup>25,26</sup> The complication rates reported in international studies are in the range of 7% to 13.3%.<sup>19,27,28</sup> Risk factors for complications include young age, an inexperienced operator, periampullary carcinoma, diverticulum, sphincter of Oddi dysfunction, and nondilated common bile duct.<sup>17,29</sup>

The timing of and decision to perform access sphincterotomy should be individualized based on the indication for the procedure, the ampullary characteristics, and the endoscopist's training and experience, with a continuous weighing of the potential procedural expectations, risks, and benefits, including the risks associated with failed cannulation.

### Periampullary Duodenal Diverticula

Duodenal diverticula are found in up to 15% of patients undergoing ERCP. They are defined as herniation of the mucosa or submucosa that occurs via a defect in the muscle layer. Some papillae are located on the edge of diverticula, others partially or completely within the diverticulum. Any of these locations may make access to the papilla for cannulation difficult or impossible. Due to the distortion, the pancreatic and biliary orifice locations can even be reversed. Depending on the position of the papilla and the distortion level, cannulation can be straightforward or extremely difficult. Thus, the challenge is to approach in the appropriate axis for access.

Success rates for cannulation in the context of periampullary diverticula versus no diverticulum are 62.4% versus 92.7%, respectively.<sup>30</sup> In contrast, Panteris et al (2008) reported similar success rates with or without diverticula, after excluding cases with undetectable papillae (94.9% vs. 94.8%).<sup>31</sup>

The most common problem in patients with periampullary diverticula is the inability of the endoscopist to detect the orifice of the papilla.<sup>32</sup> In a review article by Altonbary et al (2016),<sup>32</sup> the following tips are presented:

1. In most cases, the papilla is located on the lower edge of the diverticulum or just inside, somewhere between the positions of 3 o'clock and 8 o'clock.
2. Very large diverticula are usually divided by a ridge-like septum. This ridge typically overlies the bile duct and terminates inferiorly at the papilla.
3. A catheter can be used to straighten and evert the folds to identify a hidden papilla within the diverticulum.
4. Advancement of the tip of the duodenoscope into the sac is also possible, but care must be taken to avoid perforation.
5. Due to the altered anatomy, the biliary duct is often not acutely angulated superiorly, but runs more directly. Thus, acute angulation of the sphincterotome is not necessary.
6. In some cases, air aspiration shows the side of the diverticulum.
7. Changing patients' position to the abdominal (prone) position or pushing the upper right abdominal quadrant of the patient can help.
8. Instillation of saline solution on the contralateral side of the diverticulum may cause the papilla to protrude.

### Special Cannulation Techniques in Periampullary Duodenal Diverticula

Numerous techniques have been described to overcome difficulties in cannulation of an intra-diverticular papilla. Their use should be individualized based on specific indications and circumstances.

**Two devices in one channel method.** A biopsy forceps or thin caliber cannula is introduced through the working channel and used to retract the duodenal mucosa adjacent to the papilla. Thus, the papillary orifice can be drawn out of the diverticulum. Then a cannula or sphincterotome can be introduced alongside the forceps through the same working channel for cannulation.<sup>32</sup>

**Reversed guidewire method.** A cannulation catheter loaded with a guidewire is introduced through the working channel of the duodenoscope. A second guidewire is introduced through the working channel in reverse (stiff end forward) alongside the catheter. This second guidewire is now used to push the mucosa next to the papilla toward the duodenum. This results in straightening of the duodenal folds and an acceptable direction for cannulation is achieved.<sup>33</sup> We recommend using this technique with caution, as perforation of the thin duodenal wall by the stiff guidewire can occur.

**Endoscopic clip placement.** Commercially available through-the-scope clips can be used to evert the ampullary orifice from within the diverticulum and fix it in an orientation that will better facilitate cannulation. With the clip in the opened configuration, the mucosa is gored with one arm of the open clip. The endoscope is then torqued to evert the papilla. When the orientation is deemed optimal, the other arm of the clip is engaged with tissue and the clip is closed to fix the configuration. Cannulation is then undertaken in the usual manner.<sup>34</sup>

**"Clip and line"-assisted papillary cannulation (Video 50.3).** We recently described this technique deriving from endoscopic submucosal dissection (ESD).<sup>35</sup> In ESD, the so-called "clip and line" technique or "traction-assisted ESD" uses a conventional hemoclip attached to dental floss or a nylon string to exert traction and facilitate dissection.<sup>36</sup> For exposure of the papilla during ERCP, the endoscope is first removed from the patient in case of a difficult intra-diverticular papilla. A standard single-use hemoclip is advanced through the working channel of the duodenoscope. The clip is then slightly opened and dental floss of approximately 2 m length tied to one arm of the clip. The clip is then withdrawn back into the endoscope channel. The endoscope is then reinserted with the dental floss on its outside. The clip is then reinserted the mucosa of the papillary roof at the desired location. Traction can now be exerted by gently pulling on the string extracorporeally to expose the papillary orifice (see Video 50.3). Care must be taken to avoid unintentionally dislodging the clip.

**Double-endoscope method.** First a conventional gastroscope is introduced into the diverticulum. This allows better visualization of the papilla. Through this endoscope a forceps is used to grasp tissue next to the papilla to achieve a better orientation. The gastroscope with the instrument is placed on the left side to prevent a relapse of the papilla after opening of the forceps. Then a conventional side-view duodenoscope is introduced next to the gastroscope and a cannulation of the papilla is possible. This technique is potentially associated with increased risk of perforation at the level of the upper esophageal sphincter and the level of the duodenal bulb.<sup>36</sup>

**Balloon dilatation of the narrow diverticular neck.** Balloon dilatation with a 15-mm stone-retrieval balloon can be used in case of a narrow-necked diverticulum with the papilla situated in the fundus of the diverticulum.<sup>37</sup>

**Cap-assisted cannulation.** A transparent cap is mounted on the tip of a conventional gastroscope for better exposure of the papilla. If cannulation through the papillary orifice fails, an endoscopic fistulotomy can be attempted. Fistulotomy is performed between the lower two-thirds and the upper one-third of the papillary roof. After needle puncture, a soft-tipped guidewire is advanced through the fistulotomy.<sup>38</sup>

**Percutaneous transhepatic access and rendezvous.** First a percutaneous ultrasound-guided or often purely radiologic transhepatic biliary puncture is performed. A long guidewire is advanced through the biliary duct and papilla into the duodenum. With a snare, the guidewire is then grasped and an over-the-wire cannulation is performed.<sup>39</sup>

A limitation to this technique is the difficulty to grasp the guidewire without distortion or kinking.<sup>39</sup> A coated guidewire with a hydrophilic tip (e.g., Jag Wire 450 cm, Boston Scientific, Marlborough, MA) is best used and captured at the level of its soft distal end.

A small study on the percutaneous ultrasound-guided rendezvous technique involving 14 patients showed success in 13/14 (success rate 93%) with 1 complication (retroperitoneal perforation; complication rate 7%).<sup>39</sup>

**EUS-guided rendezvous technique.** In 3% to 5% of cases ERCP is unsuccessful because of previous surgery (surgical bypass, gastrectomy, or Whipple resection) or duodenal stenosis, for example, because of periampullary tumor infiltration or hilar cholangiocarcinoma. In these cases the endoscopist may choose between percutaneous transhepatic cholangiography or an EUS-guided approach. Wiersema et al described the first case of EUS-guided transduodenal cholangiography in 1996.<sup>40</sup> EUS-guided hepatico-gastrostomy with stent placement was first performed by Burmester et al in 2000.<sup>41</sup> This technique is described in detail in Chapter 52.

### ERCP in Surgically Altered Anatomy

In patients with surgically altered anatomy, access to the biliopancreatic orifices is usually more challenging than actual cannulation. ERCP in patients with surgically altered anatomy is associated with increased risk of perforation, particularly at the level of the anastomosis or the afferent limb.<sup>42</sup>

#### Billroth I

In this anatomic variant, the major and minor papillae are located more proximally than usual. The papilla is presented in an exaggerated clockwise orientation relative to the endoscope in the short position. Without the pylorus, anchoring of the endoscope is challenging. Thus, a stable position for cannulation

can be difficult. Sometimes working in the long-scope position is advantageous.

#### Billroth II

Due to the short distance to the papilla through the afferent loop, a standard duodenoscope may be used. Determining the afferent versus efferent limb may prove challenging, however. To access the afferent loop, the endoscope should follow the lesser curvature of the stomach. The upwardly oriented limb is usually the afferent loop. The efferent limb is usually easier to intubate because of the steep angle of fixation of the afferent loop that is sutured to the lesser curve.

In some cases the afferent loop is only visualized in the retroflexed position. In this case, suctioning gastric air may improve endoscope trajectory. Hand compression of the mid-abdomen or introducing a stiff guidewire or snare into the intended loop has been reported to possibly help.<sup>42</sup>

Once within the afferent loop and after advancing some distance, fluoroscopic confirmation that the scope has passed or is passing through the transverse duodenum is recommended. If it is found in the pelvis on fluoroscopy, then it is likely that the endoscope is in the efferent limb and should be withdrawn.<sup>43</sup>

Usually the major papilla is located near the duodenal stump at the 5 or 12 o'clock position. The minor papilla is usually located slightly further away from and to the left of the major papilla.<sup>42</sup> It is important to recognize that the orientation of the papilla will be inverted. The pancreatic duct is usually visualized at the 11 o'clock position.

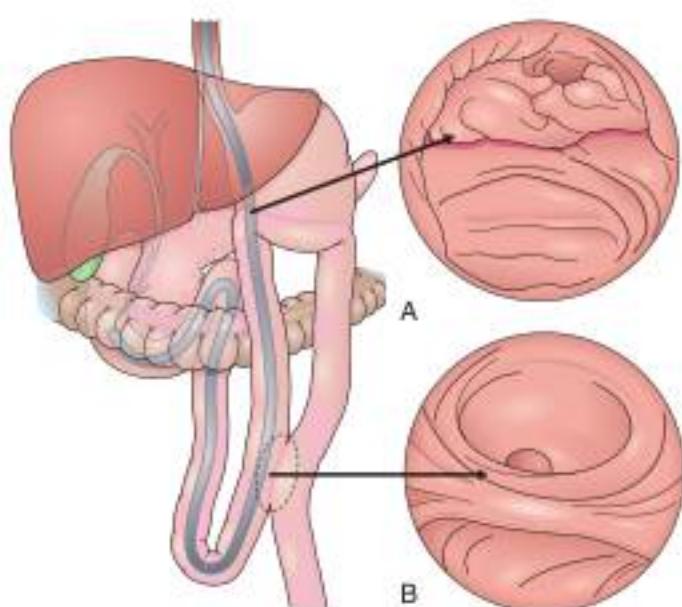

A forward-viewing endoscope may be needed to identify and traverse the afferent loop in some cases. Most experienced biliary endoscopists prefer the conventional side-viewing duodenoscope to take advantage of the elevator lever. However, in a randomized trial of 45 patients in Korea, no difference was noted between the side-viewing and end-viewing endoscopes in success of cannulation and sphincterotomy.<sup>44</sup> Nevertheless, cannulation in the Billroth II situation is challenging. In a study involving 185 Billroth II ERCP procedures, the failure rate was 34%.<sup>45</sup> Even in a tertiary biliary center, failure to enter the afferent limb has been reported to be as high as 10%<sup>46</sup> (Figs. 50.6 and 50.7).

**Sphincterotomy in BII cases.** It is important to recognize the upside-down configuration of the papilla in these cases. Several techniques have been described to perform a BII sphincterotomy. One technique is to place a bile duct stent first and then use a needle-knife to cut over the stent. The cut should be performed toward the junction of the intramural segment and the duodenal wall, which translates to the 5 to 6 o'clock position.<sup>47</sup>

Another option is the use of a reverse-type sphincterotome. This BII (shark fin) sphincterotome has a diathermy wire that is positioned at 6 o'clock, allowing sphincterotomy in the direction of the biliary sphincter. Unfortunately, reverse sphincterotomes do not always align correctly. Rotatable sphincterotomes are preferred by some experts for this purpose. In some situations, there is a need for needle-knife fistulotomy with subsequent antegrade passage of a wire across the ampulla.<sup>47</sup>

#### Roux-en-Y Gastric Bypass

A very short blind stump and a long, efferent limb are present due to the end-to-side gastroenterostomy anastomosis. Usually the efferent limb extends approximately 40 cm before the jejunoojejunostomy is encountered. At this point two or three lumens will be identified, depending on whether the two jejunal

**FIG 50.6** Billroth II anatomy: endoscopic access. Endoscopic view at **A**, the jejunal and **B**, enteroenteral (Braun) anastomosis. Intubate the afferent loop and stay to the same side of the enteral wall when you pass the enteroenteral anastomosis (oval). (Modified from Soehendra N, Binmoeller KF, Seifert H, et al: *Therapeutic Endoscopy: Color Atlas of Operative Techniques for the Gastrointestinal Tract*. New York, 1997, Thieme Medical Publishers.)

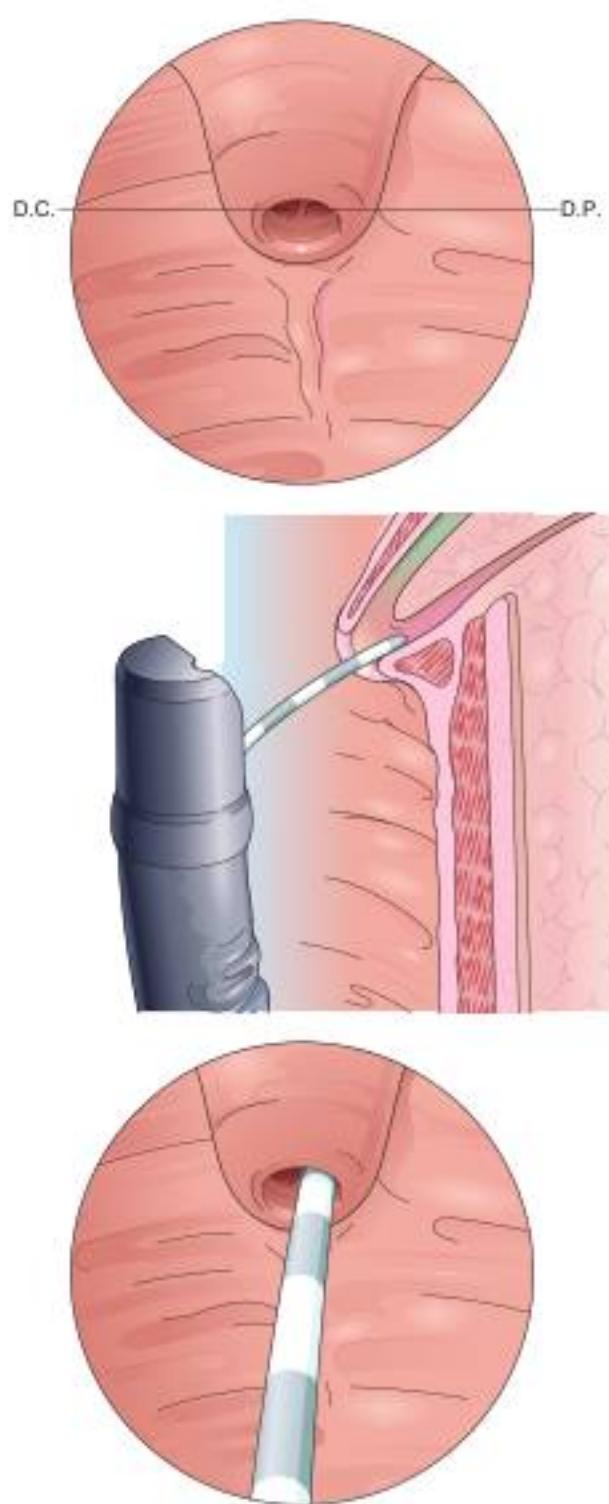

limbs are connected end-to-side or side-to-side. If side-to-side, one of the three outlets is a short, blind stump. If the pancreaticobiliary limb is engaged, the endoscope will travel to the proximal jejunum, traversing the ligament of Treitz, the transverse duodenum, and finally the descending duodenum. This long distance makes it nearly impossible for a 125 cm-long duodenoscope to reach the major papilla. Many longer length endoscopes have been used to perform ERCP in this setting, including pediatric or adult colonoscopes and push enteroscopes, but it has most commonly been performed with balloon-assist enteroscopy.<sup>47</sup>

Thus, the challenges of performing ERCP in a Roux-en-Y gastric bypass are not just to traverse a great length of small bowel and to recognize the proper intestinal lumen (usually through trial and error), but finally to cannulate selectively the bile and/or pancreatic duct from the reverse of normal trajectory, with a forward-viewing instrument and using accessories not necessarily designed for these purposes.

The major papilla is located along the interior part of the duodenal C-loop. Thus, forward-viewing endoscopes have difficulty in identifying and cannulating the papilla. To evaluate and treat a pancreatic condition is particularly problematic and largely ineffective.<sup>48,49</sup>

**Double-balloon enteroscopy for patients with Roux-en-Y anatomy.** End-viewing push enteroscopes or pediatric colonoscopes have often been reported to be inadequate in patients after partial or total gastrectomy such as Billroth II gastrojejunostomy, Roux-en-Y reconstruction, Whipple resection, or biliopancreatic reconstructions (pancreaticojunostomy, choledocho-choledochostomy, hepaticojunostomy).<sup>48-51</sup>

In a study by Raithel et al (2011), double-balloon enteroscopy (DBE)-ERCP was compared to push enteroscopy. DBE-ERCP

**FIG 50.7** Billroth II cannulation. View of the papilla from below with inverted anatomy. Schematic illustration of cannulating the pancreatic duct. D.C., Ductus choledochus; D.P., ductus pancreaticus. (Modified from Soehendra N, Binmoeller KF, Seifert H, et al: *Therapeutic Endoscopy: Color Atlas of Operative Techniques for the Gastrointestinal Tract*. New York, 1997, Thieme Medical Publishers.)

was performed successfully in 74.1% of cases via the enteroscope, whereas push enteroscopy reached biliary anastomoses or papilla in only 16.2% of patients. These results were in good agreement with recently published data for the approach by double- or single-balloon enteroscopy.<sup>30,32-34</sup> The push-and-pull method by DBE proved to be markedly more effective, because pushing and stretching of small intestinal loops is reduced by regular retractions of the DBE cycle.

The threading of the small intestine onto the DBE and the option to block the balloons at the enteroscope provides the enteroscope tip with a greater possibility of movement for identifying the biliary or pancreatic anastomoses or the papilla. In addition, sliding back of the enteroscope may be prevented by inflated balloons.<sup>35</sup>

Biliary cannulation is performed similarly to the technique employed in the Billroth II setting. Cannulation may be enhanced by placing a transparent cap on the tip of the endoscope to help anchor the papilla in place during attempts at cannulation. The enteroscope accessory channel length and small caliber limit the types and diameters of accessories and endoprostheses that can be used. Familiarity with these nuances is required for success. Only devices of 5 to 8 Fr may be passed through an operating channel of 2.8 mm.<sup>36</sup>

The double-balloon enteroscopy technique is successful in up to 70% of cases.<sup>37</sup> An alternative approach is intraoperative ERCP though a surgically created gastrostomy. This approach has a much higher success rate, albeit with the associated morbidity and cost of the operative approach.

#### Conventional Whipple Procedure

When an endoscope is passed into the mid-stomach, two small bowel orifices are seen in the conventional Whipple anatomy. One gastrojejunostomy opening ascends up the afferent limb and joins the bile duct and eventually the pancreatic duct. The other orifice leads to the efferent limb and the rest of the gastrointestinal tract. Fluoroscopy may occasionally be of benefit to confirm that the endoscope is within the afferent limb because it should be located in the right upper quadrant. Fluoroscopy may also help locate the pancreatic and biliary anastomoses, as they always come off the most cephalad portion of the bowel gas in the right upper quadrant.<sup>38</sup> A forward-viewing therapeutic channel gastroscope or colonoscope is commonly used to identify and access the choledochoenterostomy and pancreaticoenterostomy.

### CANNULATION OF THE MINOR PAPILLA

Cannulation of the minor papilla is performed in cases of complete or incomplete pancreas divisum. Due to the small diameter of the minor papilla (it is typically a <2-mm protrusion), cannulation is challenging. The usual position of the minor is 1.5 to 2 cm proximal and 5 to 10 mm to the right of the major papilla. We typically find that advancing the endoscope into the "long" position enables optimal visualization and access to the minor papilla. Cannulation is best achieved using a smallatraumatic catheter or mini-sphincterotome (Glo Tip 3/5-Fr catheter and 3/5-Fr Minitome; Cook Medical, Winston-Salem, NC) in combination with an 18- or 25-inch hydrophilic guidewire (e.g., Terumo Medical or Visiglide, Olympus Optical, Tokyo, Japan). Needle tip catheters may prove valuable for cannulation and injection of contrast for diagnostic purposes, but are not capable of transmitting a guidewire. The minor papilla cannulation success rate is up to 90%.<sup>39</sup>

### MAJOR PAPILLA SPHINCTEROTOMY

In most cases, a pull-type papillotome is used. Depending on the catheter used, the diathermy wire varies in length (range: 15–40 mm). A 25-mm cutting wire is most commonly used.<sup>1</sup> The aim of biliary sphincterotomy is to bisect the ampullary sphincter muscle as therapy for a number of conditions and to facilitate access for a variety of diagnostic and therapeutic accessories. Once free cannulation of the bile duct is achieved, the sphincterotomy is positioned under endoscopic guidance within the papillary orifice. Maintenance of cannulation and precise positioning are enhanced by guidewire placement. The alignment of the cutting wire should parallel the intraduodenal segment of the common bile duct and the direction of the sphincterotomy should ideally seek the 11 to 12 o'clock orientation. We position the sphincterotome such that approximately 3 mm of cutting wire is in contact with the tissue. The catheter position, tension on the cutting wire, and length of cutting wire contact are incrementally adjusted during the sphincterotomy in response to observed effect and the intended extent of cut. So too, the sphincterotomy direction and speed are influenced by maneuvering of the elevator lever, endoscope tip deflections, and torque. The sphincterotomy should bisect the sphincter of Oddi and may extend to the junction of the papilla and duodenal wall.

For some time there had been debate as to the ideal electro-surgical current for sphincterotomy with regards to associated risks of bleeding and pancreatitis. It had been suggested that pure cutting current is associated with a lower risk of pancreatitis, and that a blended current is associated with a lower risk of bleeding.<sup>40</sup> However, a meta-analysis by Kerma et al (2007) showed that the type of current used for sphincterotomy (pure cut vs. blended) does not clearly influence the incidence or severity of pancreatitis.<sup>41</sup> This debate has since been quelled by the near universal adoption of microprocessor-controlled "auto-cut" or "endo-cut" currents that modulate the coagulation and cutting currents to optimal effect. In the microprocessor-controlled mode of these electrosurgical units, the generator will automatically shut on and off, which maintains the cut in short stages.<sup>39,41,42</sup>

Current should usually be applied for 1 or 2 seconds. If no effect is observed within this time, one should consider decreasing the length of cutting wire in contact with the tissue. Uncontrolled rapid cutting (*zipper effect*) may result if the force applied on the sphincterotome is great, although the microprocessor-controlled modes largely mitigate against this.<sup>42</sup>

### PANCREATIC SPHINCTEROTOMY

The approach to pancreatic sphincterotomy is comparable to that of biliary sphincterotomy. A standard pull-type sphincterotome is typically used. An alternative is the use of a needle-knife after placement of a pancreatic duct stent.<sup>43</sup> The pancreatic duct is first cannulated with the pull-type sphincterotome with or without a guidewire. After confirmation of correct position with fluoroscopy, the incision is performed incrementally<sup>44</sup> toward the 1 to 2 o'clock position with the very distal extent of the cutting wire.<sup>44,45</sup> The cutting wire should not be inserted beyond 3 mm into the pancreatic duct to minimize the risk of perforation. In cases of larger duct diameter, longer cuts may be required.

In contrast to biliary sphincterotomy, in which the *cutting direction* is in the 11 to 1 o'clock position,<sup>46</sup> in pancreatic sphincterotomy the direction is more toward the right, along the floor of the papillary orifice.<sup>47</sup>

After pancreatic sphincterotomy, in addition to rectal indomethacin, prophylactic pancreatic stent placement has been shown to reduce the risk of procedure-related pancreatitis.<sup>68,70</sup>

In the needle-knife technique, after stent placement, the tip of the needle-knife is placed at the most proximal portion of pancreatic sphincter tissue that is overlying the top of the stent. The stent is used to direct the cut. The incision length is similar to the sphincterotomy in the pull-type style. Sometimes, a prior biliary sphincterotomy can help facilitate the needle-knife sphincterotomy.<sup>71</sup>

In a survey of 14 expert endoscopists in nine US centers, half "always" or "often" use the pull-type sphincterotome technique, whereas the other half "always" or "often" use the needle-knife technique.<sup>70</sup> Almost all endoscopists inserted a pancreatic stent after sphincterotomy. The type of stent (i.e., diameter, length, configuration, material, and duration of stenting) was not clearly defined.<sup>68,70</sup>

## MINOR PAPILLOTOMY

Minor papillotomy, or more accurately septotomy,<sup>72</sup> in patients with pancreas divisum has been shown to decrease the rate of recurrent pancreatitis in selected patients.<sup>72,73</sup> Recent evidence pertaining to genetic mutations associated with acute recurrent pancreatitis in patients with incidental pancreas divisum should prompt thoughtful consideration before recommending minor duct septotomy. Any of the aforementioned papillotomy tools and techniques may be used. Some endoscopists prefer an ultra-tapered tip papillotome in this setting (e.g., 3-Fr). Others employ a standard papillotome, but always with guidewire access. Still others perform an over-the-wire-push sphincterotomy (0.75-Fr Minitome) cut with max 4-mm insertion (better, 2–3 mm) in the 11 to 12 o'clock direction. Often, a 2-mm pre-cut over-the-wire is necessary in the 11 to 12 o'clock position to allow advancement of the catheter into the duct. Blended current or pure cutting current may be used.<sup>74</sup> Typically, sphincterotomy is performed in the short position. To force the guidewire upward to the roof of papilla, bowing of the sphincterotome and use of the elevator are necessary in most cases. Sphincterotomy in the long position requires less bowing. After cannulation is achieved, the endoscopist

can withdraw the sphincterotome to "tent" the minor papilla. Only 2 to 3 mm of the wire should be in contact with the papilla. The length of incision is based on the duct size, the surrounding anatomy, and indication, and is often in the range of 2 to 4 mm. The deeper the wire is in the papilla, the higher the risk of an uncontrolled zipper cut with retroperitoneal perforation.<sup>75</sup>

The needle-knife technique, as described earlier, may be performed over a previously placed pancreatic duct stent. The stent is generally maintained for 24 hours up to 2 weeks to reduce the risk of procedure-related pancreatitis. The overall complication rates are similar in those undergoing needle-knife and pull-type sphincterotomy.<sup>76</sup>

## INTRODUCTION

Endoscopic ultrasound (EUS) is a powerful technique that is integral to the management of many patients with biliary and pancreatic disease. EUS provides detailed images of the extrahepatic biliary tree and pancreas with very little risk to the patient, and is useful in the evaluation of obstructive jaundice, biliary or pancreatic ductal dilation, pancreatic masses, and pancreatitis. EUS and endoscopic retrograde cholangiopancreatography (ERCP) can be performed during the same sedation session, with EUS identifying patients likely to benefit from therapeutic ERCP. EUS-guided therapeutic interventions have an evolving role in selected patients, including celiac plexus block (CPB), fiducial placement, drainage of pancreas fluid collections, and EUS-guided drainage of inaccessible biliary and pancreatic ducts. EUS is an increasingly important tool for the biliary and pancreatic endoscopist. This chapter reviews the technique of pancreaticobiliary EUS and discusses its role in selected diagnoses. The role of EUS in patients with pancreatic malignancies, pancreatic cysts, and cholangiocarcinoma is discussed in other chapters.

### Linear Versus Radial Endoscopic Ultrasound Imaging

EUS imaging is currently available in two primary imaging planes: radial array and curved linear array. The imaging planes are determined by the orientation in which the individual piezoelectric

crystals are arrayed on the echoendoscope. The radial echoendoscope has the imaging transducer in a plane perpendicular to the long axis of the endoscope, thus producing a circular image with the endoscope shaft located at the center. With linear echoendoscopes, the imaging transducer is oriented to produce a sector-shaped image parallel to the long axis of the endoscope.

A major advantage of linear array imaging over radial is that a therapeutic device (such as a biopsy needle) that is advanced through the therapeutic channel of the echoendoscope will remain within the imaging beam. As a result, the biopsy needle can be followed continuously as it is advanced through the bowel wall into adjacent structures of interest and placed precisely within targets (such as masses) imaged in real time on EUS.

Most early endosonographers learned EUS using radial devices, as it was often assumed that radial EUS was easier to learn than linear EUS due to the radial images more closely resembling standard computed tomography (CT) imaging. It was also argued that all EUS cases should be initially performed using a radial echoendoscope, reserving linear devices until a need for a biopsy is identified on the radial exam. This may have largely been due to superiority of radial imaging at the time. In the past decade, this practice has changed dramatically. It has become increasingly more common to perform a majority of EUS exams entirely with the linear array echoendoscope. This trend likely reflects

**Abstract**

Endoscopic ultrasound (EUS) is a powerful technique that is integral to the management of many patients with biliary and pancreatic disease. EUS provides detailed images of the extrahepatic biliary tree and pancreas with very little risk to the patient, and is useful in the evaluation of obstructive jaundice, biliary or pancreatic ductal dilation, pancreatic masses, and pancreatitis. EUS and endoscopic retrograde cholangiopancreatography (ERCP) can be performed during the same sedation session, with EUS identifying patients likely to benefit from therapeutic ERCP. EUS-guided therapeutic interventions have an evolving role in selected patients, including celiac plexus interventions, fiducial placement, drainage of pancreas fluid collections, and EUS-guided drainage of inaccessible biliary and pancreatic ducts. EUS is an increasingly important tool for the biliary and pancreatic endoscopist. This chapter reviews the technique of pancreaticobiliary EUS and discusses its role in selected diagnoses.

an improvement in linear array imaging, an increasing acceptance of the clinical utility of EUS-guided tissue sampling, and an increase in percentage of cases in which a biopsy is needed. Furthermore, there are advantages to using linear EUS for pancreatic and biliary imaging. Because the linear echoendoscope visualizes tissues beyond the tip of the endoscope, the more proximal bile duct can be better visualized with a linear scope. In addition, a tandem study showed that linear EUS detects more pancreatic lesions than radial EUS in high-risk individuals undergoing pancreatic cancer screening.<sup>1</sup> At our institutions, the majority of pancreaticobiliary EUS examinations are performed solely with linear array imaging.

### Preparation for EUS Examination

Patient preparation for endosonography with either the radial or linear system is similar to preparation for routine upper endoscopy. Patients should be positioned in the left lateral decubitus position, as for most upper endoscopy procedures. Moderate or deep sedation is recommended for EUS examination, and moderate sedation is typically sufficient. For some cases, water filling of the stomach and esophagus can help optimize imaging; if this is anticipated, performing the procedure with general anesthesia and airway intubation should be considered.

### Esophageal Intubation

Prior to esophageal intubation, the balloon should be examined for air bubbles and water leakage to ensure optimal imaging during the examination. Lubricant gel should be avoided, as it may interfere with endoscopic or endosonographic imaging. Wetting the tip of the echoendoscope with water just prior to intubation is usually sufficient. If a lubricant gel is used, avoid the latex balloon and the optics of the scope. Intubation of the esophagus with an echoendoscope is similar to passing a duodenoscope, and is performed without endoscopic visualization. We often inflate the balloon slightly to aid with intubation and to minimize the risk for trauma and perforation. Placing the head in the sniffing position can aid in passage into the proximal esophagus.

### Principles of Linear and Radial Pancreatic and Biliary Imaging

Endosonographic imaging of the pancreaticobiliary system and vascular structures is via the stomach and duodenum with both the radial and linear system. An understanding of the anatomic

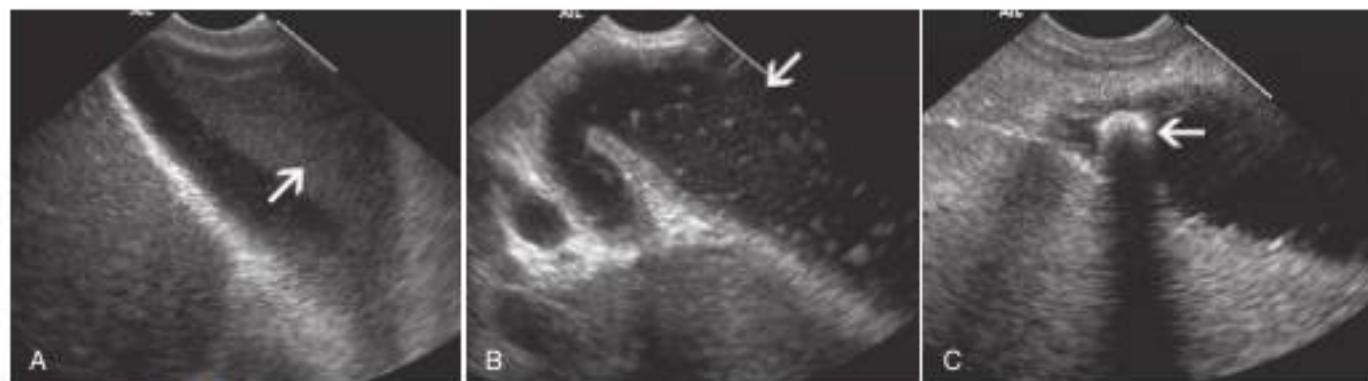

relationships of major blood vessels and the extraluminal organs of interest (primarily the gallbladder, liver, pancreas, bile duct, adrenal gland, and celiac axis) is essential for successful endosonography and EUS-guided fine-needle aspiration (FNA). The pancreas and the biliary system are best examined by beginning at three luminal stations: the proximal stomach, the duodenal bulb, and the second/third portion of the duodenum. The key principle in achieving efficient and complete linear EUS imaging in the pancreaticobiliary system is rapidly finding the "home base" anatomical landmarks, then using these locations to complete a systematic endosonographic examination.<sup>2</sup> Videos 51.1 and 51.2 detail the station-based technique for performance of pancreatic and biliary EUS using linear and radial imaging.

### GALLBLADDER STONES, SLUDGE, AND POLYPS

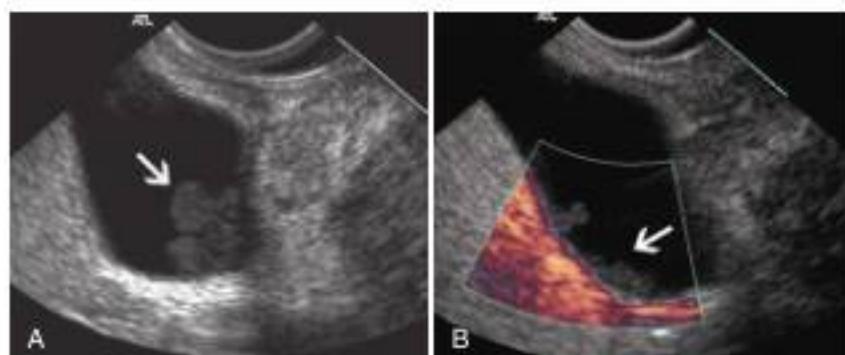

EUS is useful for diagnosis of gallbladder sludge or stones missed by transabdominal ultrasound, and is more sensitive than bile microscopy in patients with these conditions (Fig. 51.1).<sup>3,4</sup> It may be especially useful in obese patients and patients with stones in the gallbladder neck, settings in which transabdominal ultrasound is less sensitive for diagnosis. Sludge is visualized as echogenic, nonshadowing, layering material. It should not be confused with gain artifact or "ring-down artifact," which appears as circular bright lines parallel to the transducer. A clear-cut sludge/bile interface is helpful for diagnosis of sludge. Cholesterol crystals have straight edges and are highly echogenic; they appear as bright flecks in bile, sometimes casting "comet tails." Calcium bilirubinate granules are rounded and much less echogenic, and can be missed by EUS unless they are present in sufficient quantity to form layering sludge.

EUS has been used for differential diagnosis of gallbladder polyps. The best clinical studies have been reported from Asia, and their applicability to Western populations has not been well studied. Most gallbladder polyps are readily imaged, although the fundus and cap of the gallbladder may be difficult or impossible to visualize in some patients. Adherent sludge can mimic a gallbladder polyp, but sludge can usually be distinguished from polyp by gently shaking the patient's abdomen or turning the patient to the right decubitus position during EUS to determine whether the lesion moves (Fig. 51.2).

The differential diagnosis of gallbladder polyps is listed in Table 51.1. The size of gallbladder polyps is the single most important consideration in differential diagnosis. Neoplasm is

**FIG 51.1** Gallbladder findings in patients with recurrent acute pancreatitis and previous normal transabdominal ultrasound. **A**, Layering sludge (arrow). **B**, Echogenic cholesterol crystals in the gallbladder neck (arrow) casting bright "comet tails." **C**, Stone (arrow) in the gallbladder neck.

**FIG 51.2** Polypoid gallbladder sludge. **A**, Polypoid lesion of the gallbladder neck (arrow). **B**, When the patient is turned to the right decubitus position, the “lesion” moves to the gallbladder body and separates into several pieces (arrow).

Fibrous	Neuroendocrine tumor
Adenomyomatosis	

unlikely in polyps with a diameter of 5 mm or less, but is usually present in polyps greater than 15 mm in diameter, at least in Asian populations.<sup>7</sup> In patients with primary sclerosing cholangitis (PSC), neoplasia is likely in polyps of 8 mm diameter or greater, and cholecystectomy is recommended for gallbladder polyps in patients with PSC who have good liver function.<sup>8</sup> Particular ultrasound echofeatures that predict the type of polyp have been identified. Doppler evidence of vascularity has been associated with neoplasia in gallbladder polyps when evaluated by transabdominal ultrasound.<sup>9</sup> Neoplastic polyps may contain hypoechoic foci,<sup>10</sup> whereas cholesterol polyps often contain bright, echogenic spots or demonstrate comet tail artifacts caused by cholesterol crystals in the lesion. Adenomyomatosis typically appears as multiple small cystic or anechoic spaces, and may also show evidence of cholesterol deposits in the lesion. However, these features lack high predictive accuracy, particularly in polyps less than 10 mm in diameter.<sup>11</sup> When the distinctive findings of a non-neoplastic polyp are seen in a patient without risk factors for gallbladder cancer (such as stones or PSC), it may be reasonable to investigate larger gallbladder polyps, at least those that are less than 20 mm in diameter,<sup>7</sup> although neoplastic polyps containing EUS features of cholesterolosis or adenomyomatosis have been reported.<sup>12</sup> Neoplasm should be considered when the characteristic findings of a non-neoplastic lesion are absent and the lesion is greater than 5 mm, even in lesions confined to the mucosa. Loss of gallbladder wall architecture is suggestive of an invasive cancer.<sup>13</sup>

## BILE DUCT STONES

EUS is highly accurate for the diagnosis of choledocholithiasis. EUS is especially useful in patients with a low or intermediate

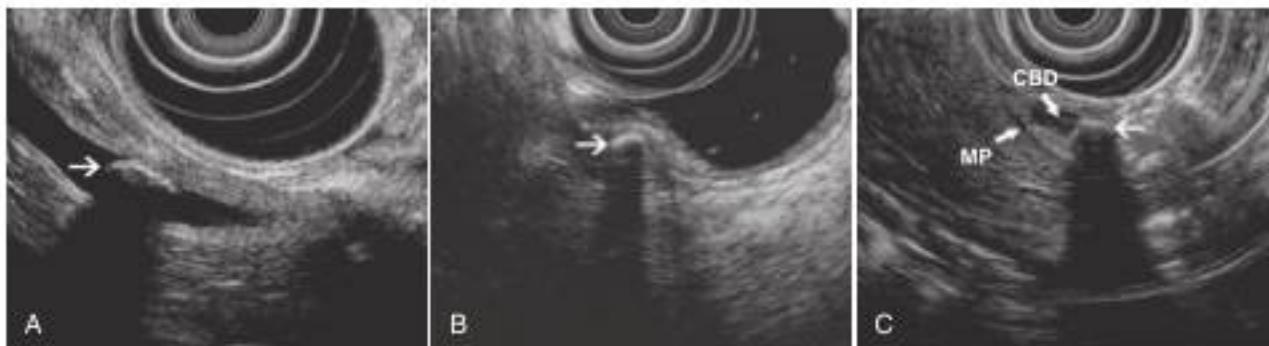

**FIG 51.3** Normal bile duct viewed from the duodenal bulb with a radial echoendoscope. *CBD*, common bile duct; *MP*, muscularis propria of the duodenal wall; *PD*, pancreatic duct.

risk of bile duct stones, refining the use of ERCP and decreasing the overall risks of an endoscopic approach.

The accuracy of EUS for the diagnosis of bile duct stones and sludge relies on both endoscopic and patient factors. The common duct is best visualized from the duodenal bulb, where it can be followed from the common hepatic duct to the periampullary region. The biliary confluence is sometimes visualized from the bulb, more often with linear array echoendoscopes. The bile duct is distinguished from adjacent vessels by identifying its convergence with the pancreatic duct as both ducts taper into the duodenal wall (Fig. 51.3). The cystic duct insertion is another useful landmark. In addition, the bile duct wall has an inner hypoechoic mucosal layer that is not present in adjacent vessels. Imaging should also be performed with the endoscope opposite the ampulla in the second duodenum for detection of stones in the ampulla or periampullary bile duct.

Stones are identified as echogenic structures casting dark acoustic shadows (Fig. 51.4). Air bubbles in the duct also appear as echogenic, rounded structures, but cast hyperechoic acoustic reverberations instead of shadows. Sludge or cholesterol crystals can be visualized in the bile duct, much as they are visualized in the gallbladder (see Fig. 51.1).

Diagnosis of ductal stones is easiest when small stones are present in a dilated duct, the very situation in which cholangiography can miss stones. Conversely, sonographic diagnosis may be challenging when a diminutive duct is present or when the common duct is completely filled with stones, obliterating a visible ductal lumen. Care should be taken to visualize the entire bile duct, not skipping over portions. It is important to recognize a technically inadequate or incomplete EUS exam, and to consider

**FIG 51.4** Bile duct stones (arrows) casting acoustic shadows. **A**, Common bile duct (CBD) stone. **B**, Ampullary stone. **C**, Ampullary stone with dilation of the obstructed intraampullary bile duct. MP, duodenal muscularis propria.

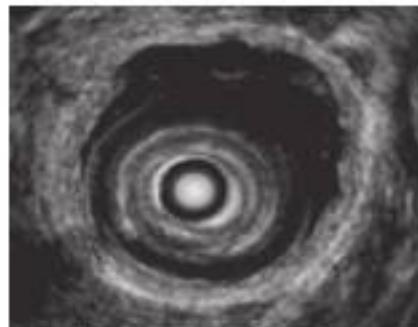

other imaging tests rather than concluding that no stones are present.

EUS (either radial or linear) has similar or superior sensitivity and overall accuracy for the diagnosis of bile duct stones compared to ERCP or magnetic resonance cholangiopancreatography (MRCP).<sup>14–16</sup> EUS appears to be more accurate for the diagnosis of stones less than 5 mm in diameter, and may also be preferable for the diagnosis of ampullary stones,<sup>17</sup> whereas MRCP diagnoses intrahepatic duct stones not visualized by EUS.

EUS can be used as the sole imaging study to exclude choledocholithiasis prior to laparoscopic cholecystectomy. When EUS showed no bile duct stones, recurrent symptoms due to ductal stones did not occur during almost 3 years of follow-up in a European cohort.<sup>18</sup> Several prospective randomized trials have compared clinical outcomes when either EUS or ERCP are used to evaluate the bile duct in patients at intermediate risk for bile duct stones, such as those with uncomplicated biliary pancreatitis or elevated serum liver tests.<sup>19–22</sup> Taken together, these studies show higher diagnostic accuracy, fewer overall complications, and less resource utilization in patients evaluated with EUS.<sup>17</sup> The majority of patients enrolled in the EUS arm of these studies did not have bile duct stones and did not require ERCP; those who did have ductal stones usually underwent ERCP immediately following EUS, under the same sedation. EUS has emerged as a preferred alternative to ERCP in patients at intermediate risk of bile duct stones, including many patients with a “positive” intraoperative cholangiogram.<sup>23</sup>

Biliary intraductal ultrasound (IDUS) is also accurate for diagnosis of bile duct stones and sludge. IDUS requires deep cannulation of the bile duct with the intraductal probe, which can be passed over a guidewire without sphincterotomy. Most investigators have performed IDUS after obtaining a cholangiogram during ERCP. To minimize trauma to the probe and extend its useful life, the operator should use as little elevator as possible and image only during slow probe withdrawal.

Because IDUS utilizes a high-frequency probe placed directly in the duct, it is probably the best available imaging technique for the diagnosis of small stones and ductal sludge. In one direct comparison of cholangiography and IDUS, the sensitivity of IDUS for stones was 97%, compared to 81% for ERCP.<sup>24</sup> Because it is performed during ERCP, IDUS is probably best used to clarify the diagnosis in patients with equivocal findings at cholangiography, such as small filling defects, possible air bubbles or polyps in the bile duct, or a dilated bile duct.<sup>25</sup> The use of IDUS improves diagnostic accuracy in approximately one-third

**FIG 51.5** Layers of the bile duct wall as visualized by intraductal ultrasound. The inner, hypoechoic layer is markedly thickened in this patient with cholangitis. An outer hyperechoic layer is also visible. Small amounts of sludge are present in the bile duct lumen.

of these patients.<sup>26</sup> The need to diagnose and treat small (< 5 mm) stones detected only with IDUS has been questioned, however, because such stones often pass spontaneously.<sup>23,28</sup>

Direct cannulation of the papilla via a linear array echoendoscope with endosonographic confirmation of deep bile duct cannulation and subsequent sphincterotomy and stone extraction is technically feasible and appears to have similar efficacy and complications as standard ERCP for sphincterotomy and stone extraction in patients with small bile duct stones.<sup>29</sup> This technique may be desirable in pregnant patients, as it avoids use of fluoroscopy.

## BILE DUCT STRICTURES

Biliary strictures may be of indeterminate etiology, particularly when cross-sectional imaging and intraductal biopsies and brushings obtained during ERCP are nondiagnostic. The cholangiographic appearance of a stricture and the patient's clinical history traditionally determined whether unexplained bile duct strictures should be resected on suspicion of malignancy. EUS and IDUS may be used to evaluate biliary strictures, and may aid clinical decision-making by suggesting a benign or malignant process. Endosonography can also be used for local staging of malignant biliary strictures.

The bile duct wall appears to have two or three layers on EUS and IDUS (Fig. 51.5). An internal, hyperechoic layer is sometimes seen, representing an interface echo. Deep to this layer is a

hypoechoic layer corresponding to the mucosa, subepithelial connective tissue, muscularis propria, and the fibrous layer of the subserosa. The amount of muscularis propria varies, with little or no muscularis propria in the proximal bile duct. Deep to this hypoechoic layer is an outer hyperechoic layer formed by the adipose layer of the subserosa, the serosa, and the interface with surrounding tissue.<sup>30</sup> The normal bile duct wall is less than 1 mm thick on EUS,<sup>31</sup> although the presence of a stent or drain in the duct may lead to thickening of the wall up to 2.8 mm.<sup>32</sup>

The bile duct wall layers can be identified with either EUS or IDUS. IDUS probes can be passed into the central intrahepatic ducts, visualizing portions of the biliary tree not usually accessible to transduodenal EUS, and IDUS also provides high resolution images of the bile duct wall and adjacent vessels and tissue. EUS with a dedicated echoendoscope can image the extrahepatic biliary tree, including Klatskin tumors,<sup>33</sup> and its deeper penetration depth permits a thorough assessment of the gallbladder, pancreatic head, and regional nodes. The two techniques are complementary.

Endosonography has been used for differential diagnosis of indeterminate bile duct strictures. During IDUS, malignant strictures typically appear hypoechoic with a thickened wall and irregular margins, whereas postoperative strictures are usually relatively hyperechoic with smooth edges.<sup>34</sup> Importantly, both PSC and IgG4-related sclerosing cholangitis (IgG4-SC) can mimic malignant strictures on IDUS. IgG4-SC typically presents with diffuse thickening of the wall of long segments of the bile duct, including regions with no cholangiographic stricture. Studies have shown IDUS and EUS to be more accurate than ERCP and intraductal tissue sampling for the diagnosis of malignant bile duct strictures,<sup>35–37</sup> although these were retrospective studies that included few or no patients with PSC or IgG4-SC. In a large prospective study, IDUS was as useful as advanced cytology techniques (including fluorescent in-situ hybridization) for the diagnosis of indeterminate strictures.<sup>38</sup> The combination of ERCP and IDUS is reported to have superior diagnostic accuracy for indeterminate bile duct strictures compared to EUS or CT.<sup>39</sup> Indeterminate strictures are discussed in further detail in a later chapter of this book.

Both EUS and IDUS have been used to stage cholangiocarcinoma. The two techniques have a similar T stage diagnostic accuracy of approximately 80%, and can differentiate T1 lesions confined to the bile duct wall (involving the hypoechoic layer) from T2 lesions invading beyond the bile duct wall (with disruption of the outer hyperechoic layer) (Fig. 51.6).<sup>32</sup> IDUS is more useful than EUS for lesions of the proximal biliary tree. IDUS has also been used to estimate the longitudinal extent of cholangiocarcinoma because cholangiography often underestimates

the longitudinal extent of ductal involvement. Unfortunately, nonspecific thickening of the bile duct wall due to the presence of a stent or drain limits the value of IDUS in previously drained patients.<sup>40</sup> Intravenous ultrasound contrast may improve the specificity of IDUS for malignancy, demonstrating hyperperfusion of inflammatory lesions and hypoperfusion of tumor.<sup>41</sup>

IDUS is probably a sensitive modality for the diagnosis of early cholangiocarcinoma in choledochal cysts. The technique should be considered in adult patients with choledochal cysts, especially if surgical resection of the cyst is not otherwise planned.

The diagnosis and staging of cholangiocarcinoma by EUS, IDUS, and EUS-FNA are discussed in detail in a later chapter.

## AMPULLA OF VATER

EUS provides detailed images of the papilla of Vater. The papilla is best located during slow withdrawal of the echoendoscope from the third duodenum, using sonographic rather than endoscopic landmarks. The ventral pancreas is visualized, and the bile duct and/or pancreatic duct lumens identified. The ducts can then be traced to the duodenal wall and papilla. Administration of intravenous glucagon and instillation of water into the duodenum may improve visualization once the periampullary region has been located.

The submucosal apparatus of the papilla can be visualized as a round hypoechoic structure in the duodenal submucosa, composed of the sphincter of Oddi and the intramural ducts. This normal submucosal structure is usually 4 to 7 mm in transverse cross-sectional diameter. The lumens of the bile duct and the pancreatic duct are usually not visible within the papilla; they generally taper and disappear from view as they reach the duodenal wall. The finding of a visible ductal lumen in the papilla suggests obstruction of the papilla by a stone (see Fig. 51.3), stenosis, or tumor, but can also be seen in choledochocele (type 3 choledochal cyst) and intraductal papillary mucinous neoplasm.

IDUS has been used to study the ampulla, and may aid in the local staging of some ampullary tumors. It identifies the sphincter mechanism and permits accurate measurement of its length. Sonographic features do not distinguish normal from hypertensive sphincters.<sup>42</sup>

## Ampullary Neoplasms

Adenomas of the papilla may occur on the duodenal surface of the papilla, within the papilla in the mucosa of the intraampullary ducts, or both. They may spread into or arise from the periampullary bile duct or pancreatic duct. EUS findings can include a mucosal mass on the duodenal surface of the papilla, enlargement of the submucosal ampullary apparatus due to intraampullary polyp, thickening of the periampullary duct walls, or the presence of an intraductal nonshadowing mass. These findings can be seen both in ampullary adenoma and in T1 ampullary cancer, and the two entities may be difficult or impossible to distinguish with EUS. We routinely perform EUS prior to ampullectomy to evaluate for intraductal extension.

The TNM staging of ampullary cancers is shown in Table 51.2 and illustrated in Fig. 51.7. T1 carcinoma may be limited to the mucosal surfaces of the ampulla and intraampullary ducts, but may also involve the sphincter mechanism of the ampulla. The presence of an irregular outer edge of the submucosal ampullary apparatus suggests a T2 lesion invading the duodenal submucosa or muscularis propria. T3 cancers invade the pancreas,

**FIG 51.6** T2 distal cholangiocarcinoma. The tumor thickens the bile duct wall and focally disrupts the outer hyperechoic layer of the duct wall (arrowheads). CBD, common bile duct; PD, pancreatic duct; T, tumor.

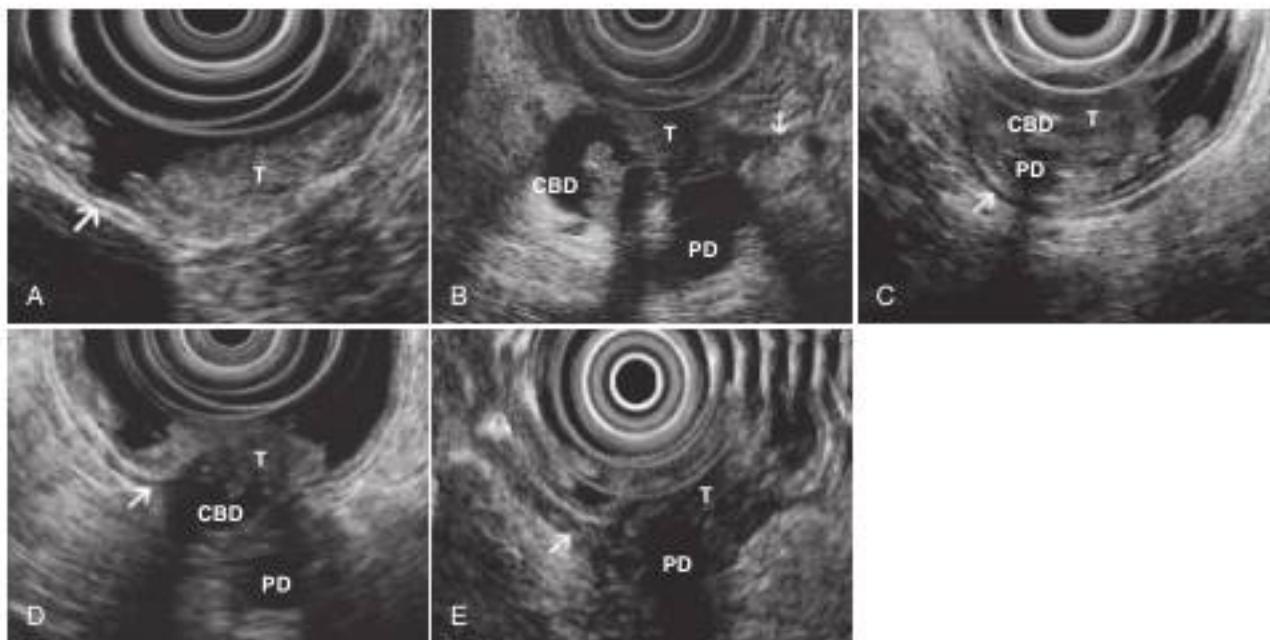

**TABLE 51.2 Staging of Ampullary Carcinoma**

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor limited to ampulla of Vater or sphincter of Oddi
T2	Tumor invades duodenal wall
T3	Tumor invades pancreas
T4	Tumor invades peripancreatic soft tissues or other adjacent organs or structures other than the pancreas
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Regional lymph node metastases
M0	No distant metastases
M1	Distant metastases
Stage 0	Tis N0 M0
Stage 1A	T1 N0 M0
Stage 1B	T2 N0 M0
Stage 2A	T3 N0 M0
Stage 2B	T1-3 N1 M0
Stage 3	T4 Any N M0
Stage 4	Any T Any N M1

extending either through the duodenal wall or else directly from the periampullary ducts. A T4 tumor extends into peripancreatic soft tissue or other adjacent structures. Regional lymph nodes include not only those adjacent to the pancreatic head but also the portal hepatic and celiac nodes.

In one large series, EUS accuracy for T staging of ampillary malignancies was 78%.<sup>43</sup> Adenomas were considered T1 lesions, highlighting the difficulty of distinguishing adenoma from T1 cancer with EUS. Most errors in staging involved overstaging of T2 lesions or understaging of T3 lesions, due to the difficulty of assessing the presence of invasion into the pancreas. The presence of peritumoral pancreatitis and edema, as well as shadowing and tissue thickening due to an indwelling biliary stent, were the major factors limiting the accuracy of EUS. Tumors may be difficult to distinguish from the normally hypoechoic ventral pancreas, and invasion of the duodenal muscularis propria may be difficult to detect because in normal anatomy the muscularis propria is interrupted by the ducts as they cross into the papilla. Despite these limitations, EUS is considerably more accurate than CT or magnetic resonance imaging (MRI).<sup>43-45</sup> Combined data from two centers reported the accuracy of ampillary tumor staging with multiple imaging modalities in patients with and without endobiliary stents.<sup>46</sup> Preoperative staging was performed in 50 consecutive patients with ampillary neoplasms by EUS plus CT (37 patients), MRI (13 patients), or angiography (10 patients) over a 3.5-year period. Of the 50 patients, 25 had a transpapillary endobiliary stent present at the time of EUS examination. EUS was shown to be more accurate than CT and MRI in the overall assessment of the T stage of ampillary neoplasms (EUS 78%, CT 24%, MRI 46%). No significant difference in N stage accuracy was noted between the

**FIG 51.7** Ampillary neoplasms. **A**, Adenoma on the surface of the ampulla. **B**, Ampillary tumor extending into the distal bile duct. **C**, T1 ampillary carcinoma involving the sphincter of Oddi. This lesion was mostly adenoma but contained foci of invasive carcinoma. **D**, T2 ampillary carcinoma invading the duodenal wall. **E**, T3 ampillary carcinoma invading the pancreas. three imaging modalities (EUS 68%, CT 59%, MRI 77%). EUS T stage accuracy was reduced from 84% to 72% in the presence of a transpapillary endobiliary stent. This was most prominent in the understaging of T2 and T3 carcinomas.

A study by Muthusamy et al (2001) demonstrated the role of EUS-guided FNA in the diagnosis and staging of ampullary lesions.<sup>47</sup> EUS-guided FNA was performed in 20 of 27 (74%) patients with suspected ampullary tumors, and made the initial ampullary tissue diagnosis in seven patients (adenocarcinoma in five patients, adenoma in one patient, neuroendocrine tumor in one patient). In addition, EUS-guided FNA resulted in a change of the diagnosis from adenoma to adenocarcinoma in one patient. In one patient, EUS-guided FNA detected a liver metastasis not seen on CT. Overall, EUS-guided FNA provided new histologic information in nine of 27 patients (33%). Another study of 35 patients who underwent EUS-guided FNA of ampullary lesions (with follow-up available in 27 patients) revealed 13 patients with adenocarcinoma, six with atypical cells (four suspicious for cancer and two consistent with reactive atypia), two with adenomas, one with carcinoid, and 13 with no evidence of malignancy. Three false-negative studies were identified, yielding a sensitivity of 82.4%, a specificity of 100%, a negative predictive value of 76.9%, and an overall accuracy of 88.8% for EUS-guided FNA in diagnosing ampullary lesions.<sup>48</sup>

A recent study by Ridtidid et al (2015) retrospectively evaluated 119 patients who underwent EUS for an ampullary lesion, 99 of whom had an adenoma or adenocarcinoma.<sup>49</sup> With surgical pathology used as the reference ( $n = 102$ ), the sensitivity and specificity of EUS were 80% and 93%, respectively, and the sensitivity and specificity of ERCP were 83% and 93%, respectively; therefore they were comparable. The overall accuracy for EUS for local T and N staging was 90%.

IDUS is probably more accurate than transduodenal EUS for T staging of ampullary neoplasms. In one large series, IDUS had an overall accuracy of 89%.<sup>50</sup> IDUS visualized small tumors missed by EUS and was more accurate than endoscopic biopsies for diagnosis of ampullary neoplasm. IDUS was also accurate for the differentiation of adenoma from T1 carcinoma. These results were achieved by experienced endosonographers, using IDUS at the patient's initial ERCP and before sphincterotomy, stent placement, or biopsy, which is an optimal algorithm for tumor imaging, but difficult to replicate in most EUS referral centers.

## ACUTE PANCREATITIS

Diagnostic EUS has two roles in patients with acute pancreatitis: the first is for timely diagnosis of common bile duct or ampullary stones in patients with acute gallstone pancreatitis, and the second is for differential diagnosis in patients with unexplained bouts of pancreatitis. In both cases, EUS can be used in place of diagnostic ERCP, and may identify those patients most likely to benefit from therapeutic ERCP.

The accuracy and cost effectiveness of EUS for the diagnosis of bile duct stones is discussed earlier in this chapter. When EUS is used to exclude ampullary stones, the ampulla must be examined from the second duodenum. A skilled examiner can perform a focused EUS of the extrahepatic bile duct in less than 10 minutes, and the patient can undergo therapeutic ERCP under the same sedation if a stone is demonstrated. This strategy allows patients with a suspected ductal stone to avoid the potential complications of ERCP if a stone is not present.

One prospective trial investigating EUS in gallstone pancreatitis reported that it was accurate for diagnosis of gallbladder and ductal stones, and predicted longer hospital stay in patients found to have peripancreatic fluid by EUS.<sup>51</sup> In another large series in which ERCP was used selectively on the basis of EUS findings, patient outcomes were favorable, and recurrent biliary pancreatitis was uncommon.<sup>14</sup>

EUS is also a useful tool in the evaluation of idiopathic pancreatitis, demonstrating abnormalities in the majority of patients.<sup>51–53</sup> Findings include missed biliary stones or sludge (see Fig. 51.1), chronic pancreatitis (CP), pancreas divisum, pancreatic or ampullary malignancy, and pancreatic duct stones. EUS does not diagnose pancreatic sphincter stenosis, but may nevertheless supplant ERCP by diagnosing or excluding previously unsuspected gallbladder pathology, CP, or pancreatic malignancy. EUS and MRCP appeared to have similar utility in one study, whereas others have suggested that EUS may be superior.<sup>54–56</sup> We feel it is best to wait until at least 4 weeks after an episode of acute pancreatitis, as acute inflammatory changes can make EUS interpretation and the detection of small tumors more challenging.

## CHRONIC PANCREATITIS

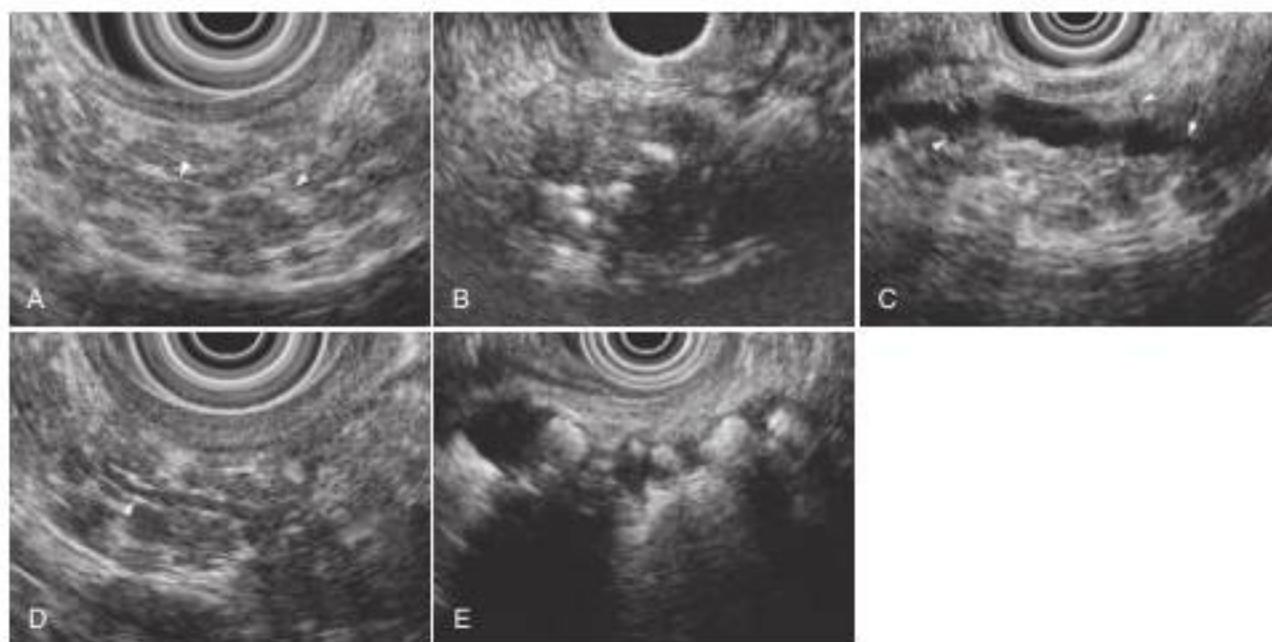

The traditional endosonographic features of CP are listed in Table 51.3 and illustrated in Fig. 51.8. This list of consensus criteria uses minimal standard terminology adopted by an international working group,<sup>57</sup> and good interobserver agreement has been demonstrated for these criteria among experienced American endosonographers.<sup>58</sup> Investigators have also described other features not included in this list, including honeycombing (in which contiguous lobularity of pancreatic parenchyma forms a honeycomb pattern), heterogeneous echotexture, focal areas of hypoechogenicity, tortuous pancreatic duct, thickened pancreatic duct wall, and narrowing of the main pancreatic duct. The traditional EUS approach to the diagnosis of CP gives each feature equal weight, and sums the number of features present. The Rosemont criteria, proposed in 2009, offer an alternative approach to diagnosis based on major and minor criteria (Table 51.4).<sup>59</sup> The Rosemont criteria likely have higher specificity and lower sensitivity than the traditional scoring system.<sup>60</sup>

Definitions vary for some criteria. Hyperechoic foci have been defined greater than as  $\geq 3$  mm by some investigators,<sup>61</sup> but as 1 to 2 mm by others.<sup>62,63</sup> Main pancreatic duct dilation has been variably defined, often as a diameter of greater than 2 mm in the body or greater than 1 mm in the tail.<sup>58</sup> The Rosemont criteria offer semiquantitative definitions for many criteria (see

**TABLE 51.3 Traditional Endoscopic Ultrasound Features of Chronic Pancreatitis**

Parenchymal Features	Ductal Features
Hyperechoic strands	Stones
Hyperechoic foci	Main duct irregularity
Lobularity	Hyperechoic main duct
Cysts	Visible side branches Main duct dilation

**TABLE 51.4 Rosemont Criteria for Diagnosis of Chronic Pancreatitis**

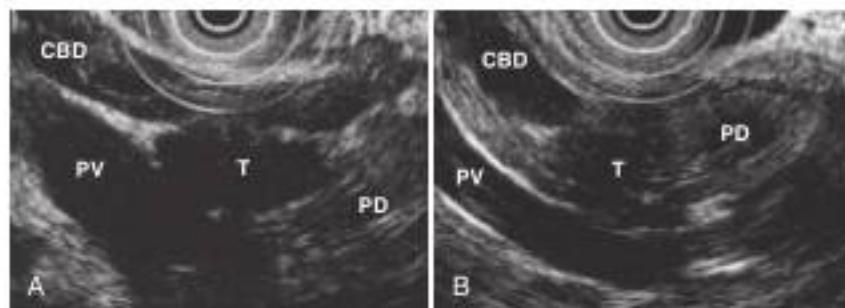

Criterion	Definition	Criterion Weighting	
Hyperechoic foci	With shadowing Without shadowing	Echogenic structures $\geq 2$ mm in length and width that shadow Echogenic structures $\geq 2$ mm in length and width with no shadowing	Major A Minor
Lobularity	With honeycombing Without honeycombing	Well-circumscribed, $\geq 5$ mm structures with enhancing rim and relatively echo-poor center, $\geq 3$ contiguous lobules Well-circumscribed, $\geq 5$ mm structures with enhancing rim and relatively echo-poor center, noncontiguous lobules Anechoic, round, or elliptical structures with or without septations	Major B Minor Minor
Stranding		Hyperechoic lines $\geq 3$ mm in length in at least two different directions with respect to the imaged plane	Minor
MPD calculi		Echogenic structures within main pancreatic duct with acoustic shadowing	Major A
Irregular MPD contour		Uneven or irregular outline and ectatic course	Minor
Dilated side branches		$\geq 3$ tubular anechoic structures each measuring $\geq 1$ mm in width, budding from the main pancreatic duct	Minor
MPD dilation		$\geq 3.5$ -mm body or $\geq 1.5$ -mm tail	Minor
Hyperechoic MPD margin		Echogenic, distinct structure $> 50\%$ of entire main pancreatic duct in body and tail	Minor
<b>Diagnostic Categories</b>			
Consistent with chronic pancreatitis		2 major A features, or 1 major A feature and major B feature, or 1 major A feature and $\geq 3$ minor features	
Suggestive of chronic pancreatitis		1 major A feature and $< 3$ minor features, or 1 major B and $\geq 3$ minor features, or $\geq 5$ minor features	
Indeterminate for chronic pancreatitis		1 major B and $< 3$ minor features, or $> 2$ and $< 5$ minor features	
Normal		$< 3$ minor features and no major features; dilated MPD and side branches, cysts	

MPD, main pancreatic duct.

From Cesolano M, et al: EUS-based criteria for the diagnosis of chronic pancreatitis: the Rosemont classification. *Gastrointest Endosc* 69(7):1251-1261, 2009.

Table 51.4). Criteria have been considered abnormal when visualized at either 12 or 7.5 MHz by some investigators, but at only 7.5 MHz by others. Findings must be interpreted with considerable caution when imaging the pancreatic head because some features (such as hyperechoic strands, lobularity, and visible

branch ducts) are often seen in the normal pancreatic head, whereas others (such as cysts and stones) are not. Diagnosis is best made based on features seen in the pancreatic body and tail. Visible duct side branches have been seen in the normal pancreatic body by some investigators.<sup>11</sup>

**FIG 51.9** Focal pancreatitis versus pancreatic cancer. Both lesions (T) caused biliary obstruction and were resected. **A**, Focal pancreatitis. **B**, T1 pancreatic adenocarcinoma. CBD, common bile duct; PD, pancreatic duct; PV, portal vein.

There are caveats regarding the specificity of EUS criteria for the diagnosis of pancreatitis. EUS features of CP have been reported in members of pancreatic cancer kindreds, in whom lobularity may correlate with the presence of pancreatic intraepithelial neoplasia (PanIN) in pancreatic branch ducts.<sup>64–66</sup> Focal areas of pancreatic hypoechoogenicity can be due to focal inflammation, but may also be due to neoplasm (Fig. 51.9). Acute pancreatitis may cause decreased parenchymal echogenicity (due to edema), accentuating the echogenicity of the pancreatic duct wall and the interlobular septa of the pancreas. When performed for diagnosis of CP, EUS should therefore be done after an acute episode of pancreatitis has resolved. Finally, some degree of ductal dilation and pancreatic fibrosis is common, and often occurs without clinical pancreatic disease.

Some EUS findings may be attributable to the effects of age, cigarettes, alcohol, and comorbidities on the pancreas, rather than CP. Although studies in healthy volunteers have generally demonstrated no parenchymal EUS abnormalities in young, asymptomatic people who do not use alcohol,<sup>61,63,67</sup> older patients with no history of pancreatic disease undergoing EUS for other indications had, on average, two EUS features of CP,<sup>68</sup> and EUS findings tend to correlate with the extent of alcohol ingestion and cigarette use.<sup>69</sup> Autopsy data show that pancreatic fibrosis is common in older persons, as well as in patients with diabetes, renal failure, or inflammatory bowel disease.<sup>70,71</sup> These histologic changes, which were termed *pancreatopathy* in the 1980s, are commonly found at autopsy in persons with no clinical history of pancreatic disease. In one small autopsy study, EUS showed CP in 90% of persons with no clinical history of pancreatic disease, and EUS findings were associated with histologic *pancreatopathy*.<sup>72</sup> A 2014 study of EUS elastography in persons with normal-appearing pancreases undergoing EUS for nonpancreatic indications found increasing pancreatic stiffness with increasing age, with overlap between age-related change and stiffness due to CP.<sup>73</sup> Improved methods of distinguishing *pancreatopathy* from CP are needed.

The accuracy of EUS for diagnosis of “early” or “minimal change” CP is debated, and EUS has been compared to pancreatography, functional tests, and histology. Early studies comparing EUS to pancreatography concluded that the presence of three or more traditional criteria was the best threshold for EUS diagnosis of CP.<sup>62–65,74</sup> These studies used pancreatography as a gold standard. However, the validity of pancreatography for the diagnosis of early CP is poorly established: the commonly used Cambridge criteria for pancreatogram interpretation are based on expert opinion, and autopsy studies have shown pancreato-

graphic abnormalities in the majority of persons without a clinical history of pancreatic disease.<sup>71,75</sup>

Histologic comparisons have reached conflicting conclusions, with retrospective studies of surgical specimens concluding that three or four EUS criteria are the best threshold for diagnosis,<sup>76</sup> and a prospective study of EUS fine-needle biopsy (FNB) concluding that histologic abnormalities were uncommon in persons with three or four traditional EUS criteria (see Fig. 51.9).<sup>77</sup> This discrepancy is most likely due both to differences in tissue sampling methods and differences in patient populations: the surgical studies included patients with pancreatic disease of sufficient magnitude to require surgery, some of whom had calcifications or pancreatic malignancies, whereas the EUS-FNB study enrolled patients with chronic abdominal pain and a paucity of other objective findings. More recently, a 2016 study of patients with presumed noncalcific CP treated with total pancreatectomy and islet autotransplantation demonstrated a poor correlation between preoperative EUS features and histologic extent of pancreatic fibrosis in the resected organ. Many subjects in that study had mild fibrosis that might be termed *pancreatopathy* rather than CP.<sup>78</sup>

EUS has also been compared to pancreatic function testing (PFT) and endoscopic PFT performed at the time of EUS. In populations of patients with either calcific CP or a low likelihood of CP, there is good overall correlation between the number of EUS features and the results of PFT; however, divergent results are common in patients with suspected minimal change CP. In those with divergent EUS and PFT results, it is unclear which test is more accurate.<sup>63,79–81</sup>

We conclude that, in some cases, EUS findings should be deemed indeterminate for CP. This category, introduced by the Rosemont criteria (which rate the presence of three or four minor criteria as indeterminate), reflects clinical and histologic realities and our current state of knowledge. In such cases, PFT, pancreatic biopsy, or repeat evaluation over time may be useful.

## AUTOIMMUNE PANCREATITIS

Type 1 autoimmune pancreatitis (AIP) is a common manifestation of IgG4-related disease, and may have a variable EUS appearance. Type 1 AIP is often characterized by extensive parenchymal lymphoplasmacytic infiltration, causing the pancreas to appear enlarged and hypoechoic on EUS, with loss of parenchymal lobulation and compression of the pancreatic duct. Long multifocal strictures of the pancreatic duct are common in Type I AIP, and may be apparent during EUS. In some cases, there is

prominent infiltration around or within the main duct wall, causing a hypoechoic halo around the duct on EUS. Type 1 AIP may also present as solitary or multiple pancreatic mass lesions. Type 2 AIP, which is associated with inflammatory bowel disease and is often seen in younger patients than Type 1 AIP, may present as a focal pancreatic mass or as a diffusely abnormal pancreas, with hypoechoic enlargement of some regions and CP elsewhere. Diffuse bile duct wall thickening may suggest biliary involvement by IgG4-related disease, although this may be due to other processes, such as PSC, cholangiocarcinoma, or the presence of a biliary stent.

EUS-guided tissue sampling is an important diagnostic tool for patients with suspected Type 1 AIP who do not otherwise meet clinical criteria for the diagnosis of IgG4-related disease. Although aspiration cytology has been deemed sufficient for diagnosis by some investigators, most favor core tissue biopsy, which allows histologic diagnosis using consensus pathologic criteria and includes quantitative analysis of tissue IgG and IgG4 immunostaining. EUS-FNB is also useful for the diagnosis of type 2 AIP, but the granulocytic epithelial lesion that is the pathognomonic histologic finding for this condition may be sparsely distributed in the lesion and missed by core biopsy samples.

## EUS-GUIDED FINE-NEEDLE ASPIRATION AND BIOPSY TECHNIQUE

The technique of EUS-guided FNA has been well described in the literature.<sup>42,43</sup> In general, the area of interest is visualized by EUS and placed within the center (or just slightly left of center on the monitor) of the imaging field. Doppler imaging is used as needed to identify vascularity of the lesion and to assess adjacent vascular structures. A standard FNA needle, with the stylet slightly withdrawn to provide a sharp tip, is advanced into the lesion under direct ultrasound visualization, avoiding any possible intervening vascular structures. The central stylet is advanced to remove any tissue that may be present in the needle tip as a result of the transluminal puncture. The following section covers specific aspects of the FNA and biopsy technique, with a focus on pancreatic and biliary lesions.

### Lesion Targeting

Generally, placing the FNA needle directly into the center of the targeted lesion is appropriate. However, this may not be the optimal technique for large tumors, especially tumors arising from the pancreas. The centers of large tumors may be necrotic, possibly from decreased oxygenation. If initial passes from the center show necrotic cells or acellular material, the endosonographer should realign the needle to target the periphery of the tumor. In addition, our experience suggests that targeting the precise site of obstruction of ductal structures provides a particularly high-quality cellular specimen.

### Prioritizing Lesions for Fine-Needle Aspiration

There are situations when more than one lesion in a patient may be targeted for EUS-guided FNA. The priority and sequence for multiple lesions in a patient with a pancreatic primary are summarized in Table 51.5. The sequence priority is predicated on the principle of confirming the most advanced stage and economizing the number of passes.

If a patient has a pancreatic mass, a suspicious mediastinal lymph node, a suspicious celiac lymph node, and a lesion in the

**TABLE 51.5 Sequence Priority for Endoscopic Ultrasound–Guided Fine-Needle Aspiration in a Patient With a Pancreatic Tumor**

Target Site	Average Number of Passes	Sequence Priority
Mediastinal lymph nodes	2 (range 1–5)	1
Ascites or pleural fluid	1	2
Liver	2 (range 1–5)	3
Distant (e.g., celiac) lymph node	2 (range 1–10)	4
Proximal lymph node	2 (range 1–10)	5
Pancreatic tumor	3–5 (range 1–19)	6

left lobe of the liver (no ascites), the endosonographer should approach the mediastinal lesion first. If this lesion is positive for cancer, this would give the most advanced staging information (although the liver lesion would also lead to M<sub>1</sub> stage), and biopsy of the other lesions would not be needed. However, if this lesion is negative, biopsy of the liver lesion, followed by the celiac node, and then the pancreatic mass itself would be needed to make the diagnosis and confirm the most advanced disease stage. This sequence is also the most efficient from a technical standpoint. The most difficult lesions to obtain adequate cytologic samples from are pancreatic tumors and submucosal tumors. Lymph nodes and liver lesions are relatively easier because fewer passes are generally required to obtain an adequate sample.

### Needle Selection

Needle selection for the endosonographer is often dictated by personal bias, but there are several guiding principles that should be kept in mind when decisions are being made about which needle to use for sampling a lesion. The first principle that should be considered, or the first question one should ask, is whether a good cytologic sample is desired, or if a histologic sample would better serve the patient. In most cases of pancreaticobiliary FNA, a sample that is sufficient for cytologic assessment is also sufficient to make a diagnosis and further direct the management of the patient. In several situations, however, cytologic assessment is not sufficient, and a sample that allows for assessment of both tissue architecture and cellularity is desired. Many have referred to this tissue acquisition technique as FNB, where a "core" specimen is achieved. EUS-guided FNB appears to allow improved diagnosis of AIP compared with standard EUS-FNA.<sup>44–46</sup> Other circumstances where using FNB to obtain a histologic core may be preferred over EUS-guided FNA include the diagnosis of well-differentiated neoplasms, lymphoma, subepithelial lesions, and neuroendocrine tumors.<sup>47</sup> Furthermore, it is increasingly apparent that histological core tissue is preferred over a cytological aspirate for the assessment of molecular markers that may facilitate risk stratification and tailored anticancer chemotherapy.

## EUS-GUIDED FNA FOR CYTOLOGY

### Needle Size

Studies regarding whether the choice of needle affects overall diagnostic yield or accuracy have had mixed results (Fig. 51.10). A study of 24 patients with solid pancreatic masses who underwent attempted tissue sampling with a 25-gauge, 22-gauge, and TruCut

**FIG 51.10** EchoTip Ultra with HD-FNA (high-definition fine-needle aspiration) (Cook Medical, Bloomington, IN). From top to bottom: 25-gauge, 22-gauge, 19-gauge, and handle. (Courtesy of Cook Medical, Bloomington, IN.)

Biopsy (TCB) (Becton, Dickinson and Company, Franklin Lakes, NJ) needle (discussed subsequently) showed similar diagnostic accuracy rates of 91.7%, 95%, and 91.7%, respectively, when technical success was achieved with each needle. However, technical success rates were significantly lower (50%) with the TCB, owing to the difficulty in accessing head and uncinate lesions using this needle, which led to overall accuracy rates of 91.7%, 79.7%, and 54.1%, respectively. These findings suggested that there is no statistically significant difference in overall diagnostic accuracy between the 25-gauge and 22-gauge needles, although the authors commented that the 25-gauge needle was easier to use and was associated with significantly higher technical success rates for uncinate lesions compared with the 22-gauge needle.<sup>67</sup> A similar study of 12 patients with pancreatic masses who underwent FNA with both 25-gauge and 22-gauge needles found no difference in cellularity with either needle, but three needle failures were seen in the 25-gauge group. A diagnosis was made in all cases.<sup>68</sup>

In contrast to these data, two larger studies have found significant improvement with the use of a 25-gauge needle in the diagnosis of solid pancreatic masses via EUS-guided FNA. The first study comprised 842 patients with pancreatic masses on EUS over a 6-year period who underwent EUS-guided FNA with a 22-gauge ( $n = 540$ ) or 25-gauge ( $n = 302$ ) needle. The sensitivity, specificity, positive predictive value, and negative predictive value were 84%, 100%, 100%, and 49%, respectively, for the 22-gauge group and 92%, 97%, 98%, and 89%, respectively, for the 25-gauge group. No complications were seen in the 25-gauge group; pancreatitis was reported in 2% of the 22-gauge group.<sup>69</sup> Our group reported on 100 patients with pancreatic masses undergoing EUS-guided FNA in two distinct time groups. The 22-gauge needle had a sensitivity, specificity, positive predictive value, and negative predictive value of 88%, 100%, 100%, and 67%, respectively, compared with 99%, 100%, 100%, and 93%, respectively, for the 25-gauge needle. In patients ultimately diagnosed with a pancreatic malignancy, 95% achieved a diagnosis within two passes using a 25-gauge needle compared with only 88% achieving a diagnosis after six passes with a 22-gauge needle. No complications occurred in either group.<sup>70</sup>

Both these latter studies and the randomized controlled trial suggest an 8% to 10% enhanced diagnostic yield with a 25-gauge needle. The specificity of the 25-gauge needle seems to be superior to that of the 22-gauge needle because of a reduction in the number of false negative FNA results. One theory related to this superiority for increased cytologic yield may be less blood contamination of the specimen.

### Number of Passes

Pancreatic adenocarcinoma, as compared to malignant lymph nodes or liver metastases, generally requires the greatest number of FNA passes to obtain an adequate specimen; typically, approximately three to five passes are required.<sup>71</sup> Pancreatic tumors may have extensive fibrosis (desmoplastic reaction) or necrosis, which decreases the cellularity of malignant cells. The number of passes required for pancreatic tumors may be related to the differentiation of the tumor. A study designed to assess prospectively whether any patient or EUS characteristics could predict the number of EUS-guided FNA passes needed for diagnosis of pancreatic malignancy has been performed.<sup>72</sup> Among 95 patients undergoing EUS-guided FNA of a pancreatic mass, the average number of needle passes into the mass (includes head, neck, body, and tail) was  $3.44 \pm 2.19$  (range 1–10). Tumors that were well differentiated required an average of 5.5 passes to obtain an adequate specimen; this is significantly different from the 2.7 passes needed for moderately differentiated tumors and the 2.3 passes needed for poorly differentiated tumors ( $p < 0.001$ ).

Based on this study, it was recommended that, without a cytopathologist in attendance, five to six passes should be made for pancreatic masses. However, this approach would still be associated with a 10% to 15% reduction in definitive cytologic diagnoses, extra procedure time, increased risk, and additional needles, compared with having "real-time" cytopathology interpretations. Lymph nodes and liver lesions generally require significantly fewer passes. In an earlier series of 171 patients, the median number of passes for lymph nodes was two (range 1–10).<sup>73</sup> One series showed that the average number of passes for liver lesions was also two (range 1–5).<sup>74</sup> Lymph nodes and liver metastases generally do not exhibit the desmoplastic or necrotic reaction that is common for primary tumors of the pancreas.

Ascites and pleural fluid on average require only a single FNA pass to obtain a specimen for cytologic diagnosis.<sup>75</sup> The endosonographer should try to obtain as much fluid as possible (preferably  $> 10$  mL). The fluid is spun down to concentrate the cells on a slide. Making the diagnosis of peritoneal metastasis from ascites fluid has a lower yield than solid lesions (approximately 50% false negative rate, especially with small amounts of fluid). However, a positive cytology result is still very helpful in staging the tumor as unresectable. Ascites fluid, if present, should be aspirated first before any other abdominal lesions, especially given the possibility of contamination of the ascites from other lesions if they were to undergo FNA first. In the presence of ascites, FNA of the primary pancreas tumor, lymph node metastasis, or liver metastasis theoretically could contaminate the fluid. In addition, the process of preparing cytology slides from ascitic fluid requires an additional step of concentrating the cells by centrifugation. To obtain the most relevant staging information and maximize the efficiency of FNA passes, the priority sequence for FNA is: suspicious mediastinal adenopathy, ascites, liver metastases, distant and local lymph nodes, and primary pancreatic tumor.

### Needle Insertion and Fanning

The technique of needle advancement can vary considerably from very fine motion of the needle handle using only the fine motor pincher muscles of the thumb and index finger, to very large motions using a full hand grasp on the needle handle with gross motor elbow and shoulder movements similar to a downward thrust with an ice pick. The optimal technique of advancing the needle varies according to three factors: (1) the consistency of the gastrointestinal (GI) wall (wall parameter), (2) the size and consistency of the lesion targeted (lesion parameter), and (3) the proximity of surrounding vessels (vessel parameter). Table 51.6 summarizes the needle advancement technique with respect to these parameters.

The "fanning" technique for EUS-guided FNA involves sampling multiple areas within a lesion with each pass. The needle is positioned at different areas within the mass using the "up-down" dial of the echoendoscope with minimal use of the elevator. In a study by Bang et al (2013), 54 consecutive patients with solid pancreatic mass lesions were randomized to undergo EUS-FNA using either the standard or the fanning technique. There was no difference in diagnostic accuracy (76.9% vs. 96.4%;  $p = 0.05$ ), technical failure, or complications. There was a significant difference in both the number of passes required to establish the diagnosis and the percentage of patients in whom a diagnosis was achieved on the first pass (57.7% vs. 85.7%;  $p = 0.02$ ) between the standard and fanning groups, respectively.<sup>55</sup> In alignment with this study, fanning is a technique that we routinely strive for when performing FNA of pancreaticobiliary lesions.

### Suction Methods

Two methods of needle suction are widely employed: syringe suction and the "slow pull" method. For syringe suction, typically, a 10-mL syringe is attached to the hub of the needle, and 5 cc of suction is applied as the needle is moved back and forth within the lesion (with typically 10–20 to-and-fro cycles used). The suction is slowly released, the needle is retracted into the catheter, and the entire assembly is removed from the biopsy channel.

Recently, a slow pull or "capillary" technique has emerged. With this technique, the slow withdrawal of the stylet from the needle serves to create negative pressure within the needle. The

stylet is withdrawn by the assistant at the same distance as the needle throw of the to-and-fro action of the endosonographer. Typically, to-and-fro movements are continued within the lesion until approximately two-thirds of the entire stylet has been removed from the needle.

A recent study by Nakai et al (2014) compared the slow pull and suction techniques in patients with solid pancreatic lesions.<sup>56</sup> A total of 367 passes (181 by suction and 186 by the slow pull technique) were performed during 97 EUS-FNA procedures for 93 patients with solid pancreatic lesions. The slow pull technique resulted in lower scores for cellularity, but scores for contamination with blood were also lower. The sensitivity for diagnosing malignancy was higher for the slow pull technique (90.0% vs. 67.9%,  $p < 0.01$ ) when a 25-gauge FNA needle was used. There were no significant differences between the two techniques when a 22-gauge needle was used.

Another technique recently described is the wet suction technique (WEST). WEST is carried out by flushing the needle with 5 mL of saline solution to replace the column of air within the lumen of needle with saline solution before needle aspiration. Attam et al (2015) conducted a study comparing the conventional technique with WEST on 117 lesions.<sup>57</sup> All lesions were sampled with the same needle by using alternating techniques. Patients were randomized to WEST versus the conventional technique for the first pass. If the first pass was made with WEST, the second pass was made with the conventional technique, and subsequent passes were made in an alternating manner using the same sequence. All FNAs were performed using 22-gauge needles. WEST yielded significantly higher cellularity in a cell block compared with the conventional technique, with a mean cellularity score of  $1.82 \pm 0.76$  versus  $1.45 \pm 0.768$  ( $p < 0.0003$ ). The WEST cell block resulted in a significantly better specimen adequacy of 85.5% versus 75.2% ( $p < 0.035$ ). There was no difference in the amount of blood contamination between the two techniques.

One important strategy to keep in mind when performing FNA is to adjust technique through the course of the passes to optimize the sample. After the first pass, one should assess the gross specimen and make adjustments based on the appearance of the sample yielded. For a specimen that is too bloody, consider using the slow pull technique or no suction at all. For a specimen that has too few cells, consider more to-and-fro movements, attempt more of a fanning technique, or switch to WEST.

**TABLE 51.6 Needle Advancement Technique for Endoscopic Ultrasound-Guided Fine-Needle Aspiration**

Wall Parameter	Lesion Parameter	Vessel Parameter	Needle Advancement Technique	Difficulty Level
Thin wall, taut (e.g., esophagus)	Small (e.g., lymph node)	Vessel immediately behind lesion	Very fine, slow pincer movements	Moderate
Thin wall, taut	Large (e.g., tumor)	No adjacent vessel	Slow, moderate movements	Easy
Thick wall, elastic (e.g., gastric fundus)	Small lesion or scant fluid	Vessel immediately behind lesion	Consider puncturing through stomach first (adjacent to lesion) with a very quick dartlike motion (or use spring-loaded device), then fine pincer movements to target lesion	Difficult
Thick wall, elastic	Large	No adjacent vessel	Very quick dartlike motion using wrist action directly into lesion	Moderate
Duodenum	Small	Adjacent vessel	Quick, pincer movement to avoid pushing scope tip away	Difficult
Duodenum	Large, firm tumor	No adjacent vessel	Very quick, hand grasp with elbow and shoulder "ice pick" motion	Difficult

## Rapid On-Site Evaluation and Macroscopic On-Site Evaluation

The importance of dynamic Real-Time On-Site Evaluation (ROSE) for cytologic interpretation has been debated recently. Earlier studies have emphasized its importance,<sup>13,87–99</sup> and showed that centers with an attendant cytopathologist had higher cytologic yield and diagnostic accuracy compared with centers that performed passes on an empiric basis. Increasing the number of empiric passes may increase cytologic accuracy, but at the expense of performing unnecessary passes with associated cost, time, and safety issues. One study described the experience of a single endosonographer practicing in two clinical sites, one with an attendant cytopathologist and one without.<sup>29</sup> In the site without an attendant cytopathologist, 17% of patients required repeat procedures, compared with 2% of patients requiring repeat procedures at the site where a cytopathologist was present ( $p = 0.015$ ). Recently, Wani et al (2015) conducted a multicenter randomized controlled trial in which 241 consecutive patients with solid pancreatic masses underwent randomization to EUS-FNA with or without ROSE. The number of FNA passes in the ROSE+ arm was dictated by the on-site cytopathologist, whereas seven passes were performed in ROSE- arm. There was no difference between the two groups in terms of the diagnostic yield of malignancy (ROSE+ 75.2% vs. ROSE- 71.6%,  $p = 0.45$ ) or the proportion of inadequate specimens (9.8% vs. 13.3%,  $p = 0.31$ ). Although procedures in ROSE+ group required fewer EUS-FNA passes (medians: 4 vs. 7,  $p < 0.0001$ ), there was no significant difference between the two groups with regard to the quality of the specimens, overall procedure time, adverse events, number of repeat procedures, or costs.<sup>100</sup>

A more recent concept for on-site evaluation of an FNA specimen is Macroscopic On-Site Evaluation (MOSE). With MOSE, the tissue adequacy is determined based on the macroscopic appearance of the specimen obtained, usually by the endoscopist. There is no cytology technologist needed, and there is no staining or microscopy performed in the room (as is done for ROSE). MOSE has the potential to decrease cost and time. Studies evaluating the feasibility of MOSE have yielded mixed results. A study by Nguyen et al (2009) evaluated MOSE performed by both experienced EUS technologists and cytotechnologists of 22-gauge FNA specimens of pancreatic tumors.<sup>101</sup> Only fair agreement was observed between cytotechnologists and EUS technologists versus final cytopathologic assessment of adequacy ( $\kappa=0.20$  and 0.19, respectively). More recently, however, Iwashita et al (2015) conducted a study to assess the efficacy of MOSE in estimating the adequacy of histologic core specimens obtained by EUS-FNA using a standard 19-gauge needle in 111 solid lesions. MOSE revealed macroscopic visible core (MVC) in 91.1% of lesions with a median length of 8 mm. Histologic core was confirmed in 78.9%. Comparisons of per-pass diagnostic yields showed significantly superior histologic, cytologic, and overall diagnostic yields in MVCs greater than 4 mm in length as compared to cores of less than 4 mm.<sup>102</sup> The difference in the results from these studies may be due to the different needles used and the ability of the larger needle to obtain a specimen where macroscopically visible cores were identified. Further study of MOSE is warranted.

## Specimen Handling

There is significant variation in how FNA specimens are processed. In general, for a cytologic specimen, the aspirated material is

expressed onto glass slides using an air-filled syringe or by reintroducing the stylet back into the needle. For each pass, a set of two slides is processed: a few drops of specimen are expressed onto a slide and smeared with a second slide. One slide is air-dried and evaluated using a Diff-Quik/modified Wright-Giemsa stain by a nearby cytopathologist in centers where ROSE is available. The other slide is wet-fixed in alcohol for later evaluation using the Papanicolaou stain. Residual material that is present within the needle is then expressed into a formalin container, which is collected and later processed into a cell block.

## EUS-FNB FOR HISTOLOGY

### Needle Type

The needles discussed thus far have been judged based on their ability to provide cytologic yield. In 2002, a new needle entered into the armamentarium: the TCB needle (Becton, Dickinson and Company) (Fig. 51.11). This needle, which contains an 18-mm tissue tray, allows for histologic, rather than cytologic, analysis owing to the ability of EUS-guided TCB to obtain tissue cores. Overall, EUS-guided TCB performance for pancreaticobiliary lesions has been poor, largely due to difficulties with deployment. As mentioned earlier, a comparative study of 25-gauge, 22-gauge, and TCB needles in 24 patients with solid pancreatic lesions showed that EUS-guided TCB achieved the lowest accuracy rates, a result almost entirely due to the fact that EUS-guided TCB was deployed successfully in only 11 of 24 patients and in only one of 12 patients with head or uncinate lesions.<sup>57</sup> The most recent and largest study (2009) of 113 patients undergoing EUS-guided TCB of pancreatic lesions also showed that EUS-guided TCB had a relatively poor sensitivity and overall diagnostic accuracy of 62% and 67.5%, respectively.<sup>103</sup>

To overcome some of the limitations encountered with the TCB design, new dedicated FNB needles have been developed. One such design includes reverse-bevel technology (ProCore; Cook Endoscopy, Bloomington, IN), and is currently available in three gauges: 19, 22, and 25 (Fig. 51.12). The needle has a lateral opening of varying lengths (depending on the gauge) in its shaft, as well as a reverse bevel that hooks and cuts the tissue and traps it in the needle during the FNA motion. However, unlike the TCB needle, the ProCore design does not rely on an

**FIG 51.11** Quick-Core (Cook Medical, Bloomington, IN) 19-gauge needle (tip, above; handle, below). (Courtesy of Cook Medical, Bloomington, IN.)

**FIG 51.12** ProCore (Cook Medical, Bloomington, IN) 19-gauge needle (handle, above; tip below). (Courtesy of Cook Medical, Bloomington, IN.)

in-built cutting mechanism, and is therefore less stiff and more maneuverable when performing FNA, especially within the duodenum. It was hypothesized that the ProCore needle design would yield a large piece of core tissue with preserved morphological (histological) architecture that would have significant advantages over the standard FNA (cytological) needle by resulting in superior diagnostic accuracy with possibly fewer passes.

A 2016 prospective multicenter randomized controlled trial evaluated the histologic diagnostic yield comparing a standard 25-gauge FNA needle with a 25-gauge ProCore needle for pancreatic masses.<sup>104</sup> Two hundred and fourteen consecutive patients with solid pancreatic masses who presented to eight Japanese referral centers for EUS-FNA were randomized to undergo sampling with a 25-gauge needle with a core trap (ProCore) or a standard 25-gauge needle. Tissue samples were fixed in formalin and processed for histologic evaluation. For the purposes of the study, only samples obtained with the first needle pass were processed for evaluation of diagnostic accuracy of malignancy, preserved tissue architecture adequate for histologic evaluation, and sample cellularity. Compared to the first pass with a standard needle ( $n = 108$ ), the first pass with the ProCore needle ( $n = 106$ ) provided samples that were more often adequate for histologic evaluation (81.1% vs. 69.4%;  $p = 0.048$ ) and had superior cellularity (rich/moderate/poor, 36%/27%/37% vs. 19%/26%/55%;  $p = 0.003$ ). There were no significant differences between the two needles in terms of sensitivity (75.6% vs. 69.0%,  $p = 0.337$ ) and accuracy (79.2% vs. 75.9%,  $p = 0.561$ ) for the diagnosis of malignancy.

A recent systematic review and meta-analysis was conducted by Bang et al (2016) to compare the performance of the ProCore and standard FNA needles when performing EUS-guided tissue acquisition of mostly pancreatic lesions, and showed slightly less favorable results.<sup>105</sup> Nine studies (including a total of 576 patients) met the inclusion criteria. There was no significant difference in diagnostic adequacy (75.2% vs. 89.0%, odds ratio [OR] 0.39,  $p = 0.23$ ), diagnostic accuracy (85.8% vs. 86.2%, OR 0.88,  $p = 0.53$ ), or rate of histological core specimen acquisition (77.7% vs. 76.5%, OR 0.94,  $p = 0.85$ ) between the ProCore and standard FNA needles, respectively. The mean number of passes required for diagnosis, however, was significantly lower when using the

**FIG 51.13** SharkCore needle (Medtronic, Dublin, Ireland). (Courtesy of Medtronic, Dublin, Ireland.)

ProCore needle (standardized mean difference: -1.2,  $p < 0.001$ ). Criticisms of the meta-analysis included the small number of studies that met the inclusion criteria, the heterogeneity in the definitions and design of the studies selected, and the inclusion of studies that did not use the 19-gauge ProCore needle.

More recently, another histology needle with a novel fork-tip needle, the SharkCore (SC) (Medtronic Corp., Dublin, Ireland), has been released for clinical use (Fig. 51.13). This needle does not have a side bevel, and its unique design is largely related to the six cutting edges on its tip. Early studies show promising results with improved histologic yield compared to standard FNA needles. Kandel et al (2016) conducted a retrospective case-control study whereby consecutive samples from EUS-FNB-SCs were matched in a 1:3 ratio by lesion site (e.g., pancreatic head) and needle gauge (i.e., 19-gauge, 22-gauge, 25-gauge) to recent random samples taken by EUS-FNA. The procedures were performed with ROSE. For study purposes, the specimen slides were evaluated by two cytopathologists for histologic yield using a standard scoring system (0 = no material, 1–2 = cytologic, 3–5 = histologic). The main objectives were to assess the histologic yield of the samples and to compare the median number of passes required to obtain core tissue by using EUS-FNB-SC and EUS-FNA needles. Of the 156 patients included in the study, 39 were in the EUS-FNB-SC group, and 117 were in the EUS-FNA group. According to standard scoring criteria for histology, the median histology score for EUS-FNA was 2 (sufficient for cytology but not histology), and the median histology score for EUS-FNB-SC was 4 (sufficient for adequate histology). Ninety-five percent of the specimens obtained from the EUS-FNB-SC group were of sufficient size for histologic screening, compared with 59% from the EUS-FNA group ( $p = 0.01$ ). The median number of passes required to achieve a sample was significantly lower in the EUS-FNB-SC group compared with the EUS-FNA group (two passes vs. four passes,  $p = 0.001$ ). There was a significant difference in the median number of passes made at all lesion sites and with all needle gauges.<sup>106</sup>

### EUS-FNB Technique

The optimal technique for acquiring a histologic sample using EUS-FNB is different from what has been described thus far for cytologic sampling. When a pancreatic lesion undergoes EUS-FNB, based on our experience, we believe the following technical aspects

should be kept in mind. The initial forward thrust into the lesion is very important and should be rapid and deliberate, whereas the repetitive to-and-fro movements may be of less importance. Fanning is often more difficult with EUS-FNB, and should not be the goal for EUS-FNB. Both high dry suction and WEST appear to be more effective than the slow pull technique for EUS-FNB.

### Complications of EUS-Guided FNA of Pancreaticobiliary Lesions

An important part of maximizing the yield of EUS-guided FNA is being aware of and avoiding potential complications. These complications include pancreatitis, bleeding, infection, seeding of malignant cells, and bile peritonitis. Initial data on the overall complication rates of EUS-guided FNA came from three large published series comprising more than 1000 patients.<sup>113,117,120</sup> One multicenter trial showed that complications associated with the procedure (457 patients) seem to arise predominantly from infectious or hemorrhagic events after puncturing pancreatic cystic lesions.<sup>113</sup> Five nonfatal complications occurred, for a rate of 0.5% (95% confidence interval [CI] 0.1%–0.8%) in solid lesions versus 14% (95% CI 6%–21%) in cystic lesions ( $p < 0.001$ ). Another single-institution study of 333 patients who underwent EUS-guided FNA reported only one complication (0.3%): streptococcal sepsis after puncture of a cystic pancreatic lesion.<sup>120</sup> A small risk (1 in 121 patients) of developing pancreatitis after EUS-guided FNA of the pancreas has been reported.<sup>113</sup> The overall risk with FNA is extremely low. Several more recent studies have reported on the specific risks of FNA of pancreaticobiliary lesions, and are discussed in the following sections.

The overall risk of pancreatitis from EUS-guided FNA appears to be less than 1%. A large retrospective series of 4909 patients undergoing EUS-guided FNA of solid pancreatic lesions from 19 centers over a 4-year period showed a 0.29% risk of pancreatitis.<sup>113</sup> This risk was 0.64% from the two centers that prospectively collected data and 0.26% from the 17 centers that retrospectively collected data, suggesting an underreporting of complications in the latter group. A subsequent prospective single-center study by the same lead author revealed a pancreatitis rate for solid pancreatic lesions of 0.85% (3 in 355).<sup>112</sup> The rates of pancreatitis are similarly low for cystic lesions; a large study of 603 patients with 651 pancreatic cysts undergoing EUS-guided FNA revealed only six cases of pancreatitis (0.92%) and an overall complication rate of only 2.2%.<sup>113</sup> Similarly, the complication rate from EUS-guided TCB is less than 2%, and is not significantly different from that for EUS-guided FNA.

Hemorrhage is a rare complication of EUS and EUS-guided FNA. Gress et al (1997)<sup>110</sup> initially reported two cases of hemorrhage (resulting in one death) in 208 patients who underwent 705 FNA passes using both radial and linear echoendoscopes. In both cases, EUS was performed using a radial echoendoscope, which precluded visualization of the needle tip during FNA. In one case, bleeding extended into the gastric lumen, whereas bleeding occurred in the pancreatic head region in the other case.

A 2005 study from Denmark reported on 3324 consecutive patients who underwent EUS procedures using curvilinear echoendoscopes over an 11-year period, of which 670 underwent EUS-guided FNA and 136 received EUS-guided interventions.<sup>114</sup> Only a single case of GI bleeding was reported in a patient with widespread pancreatic cancer who died 6 hours after EUS-guided FNA from massive GI bleeding. However, at autopsy, the FNA

puncture site showed no signs of bleeding and no vessels in the puncture route, and the cause of bleeding could not be established.

Limited data on extramural hemorrhage exist. One study reported that 3 of 227 patients (1.3%) undergoing FNA had extraluminal hemorrhage at the site of aspiration.<sup>115</sup> The bleeding lesions included a large pancreatic islet cell tumor, a benign lymph node in a patient with esophageal cancer, and a recurrent benign pancreatic cyst in a patient with a history of a mucinous cystadenoma that had been surgically resected. The authors described the bleeding as an expanding echo-poor region adjacent to the sampled lesions, although no clinically recognized sequelae of bleeding were noted. No predictive factors for bleeding were identified. The investigators applied pressure at the puncture site via balloon inflation and echoendoscope tip deflection for 15 to 25 minutes, although it is unclear if this had a tamponade effect on the extraluminal bleeding.

A case of self-limited retroperitoneal bleeding after EUS-guided FNA of the pancreas has also been reported.<sup>116</sup> Self-limited intracystic hemorrhage after EUS-guided FNA of pancreatic cysts has been reported to occur in 6% (3 of 50) patients in one series,<sup>117</sup> and clinically evident hemosuccus pancreaticus has also been observed after EUS-guided FNA of a pancreatic cyst.<sup>118</sup> However, a more recent and larger series of 651 cysts undergoing EUS-guided FNA revealed only a single retroperitoneal bleed.<sup>115</sup> These data indicate that clinically significant bleeding after EUS-guided FNA of solid or cystic pancreaticobiliary lesions is extremely uncommon with current techniques.

As stated previously, EUS-guided FNA seems primarily to be associated with infectious complications when cystic lesions are aspirated. Initial studies reported infectious complications in 14% (3 of 22) of patients undergoing EUS-guided FNA of pancreatic cystic lesions.<sup>113</sup> As a result, routine preprocedure and postprocedure antibiotic prophylaxis was adopted for FNA of such lesions. A single case of streptococcal sepsis after EUS-guided FNA of a pancreatic cystadenoma was reported in a large single-center report of 317 patients undergoing FNA of 327 sites<sup>107</sup>; this infection occurred despite the use of prophylactic antibiotics, and corresponded to an infectious complication rate of 0.3%. Fever, although infrequent, has also been reported in several studies after EUS-guided FNA. Chang et al (1997) reported one patient out of 44 (2%) undergoing EUS-guided FNA for pancreatic lesions who developed fever after sampling of a pancreatic cystic lesion.<sup>119</sup> This patient did not receive antibiotics before FNA.

Another series showed that two patients developed fever and infection out of 355 patients with solid pancreatic masses undergoing EUS-guided FNA, yielding an infectious complication rate of 0.56%.<sup>112</sup> One of these patients had cystic spaces within a pancreatic adenocarcinoma, and the other, who required surgical débridement, had acute pancreatitis with a focal lesion in the pancreatic tail. Bournet et al (2006)<sup>120</sup> reported 1 patient out of 224 undergoing EUS-guided FNA (0.45%) who developed fever and abdominal pain after aspiration of a mucinous cystadenoma, despite administration of antibiotics before the procedure. Similarly, Lee et al (2005)<sup>115</sup> reported 1 out of 603 patients undergoing aspiration of 651 pancreatic cysts who developed fever, pain, and leukocytosis, although it is unclear if this patient received antibiotics before the procedure. As a result of these data, current guidelines recommend the use of antibiotic prophylaxis for planned FNA of any cystic lesion, but not for solid pancreaticobiliary lesions.

The risk of malignant seeding from EUS-guided FNA is also believed to be very low. However, a case of focal gastric intramural

recurrence at the site of an EUS-guided FNA of a pancreatic tail lesion that underwent distal pancreatectomy was reported 21 months after a surgical resection with negative margins.<sup>121</sup> Although seeding may occur with this technique, EUS-guided FNA seems to have a significantly lower potential for peritoneal seeding (2.2% vs. 16.3%) compared with CT-guided FNA, as mentioned earlier in the section on EUS-guided FNA of pancreatic lesions.<sup>122</sup>

### Conclusions

EUS-guided FNA is extremely useful in the diagnosis and staging of pancreaticobiliary lesions such as pancreatic cancers (with associated lymph nodes, liver metastasis, and ascites), cystic tumors, neuroendocrine neoplasms, ampullary cancers, and cholangiocarcinomas. In addition, this technique has been extended via techniques such as EUS-guided fine-needle injection (FNI) into therapeutic modalities such as celiac plexus or ganglion block, cyst gastrostomy, achieving pancreaticobiliary access and drainage, assisting in or delivering radiation therapy, and delivering antitumor agents.

## EUS-GUIDED FINE-NEEDLE THERAPY

The advent of linear EUS in the 1990s transformed EUS from a purely diagnostic modality into a platform for advanced diagnostic and therapeutic applications. EUS-FNA has brought us the ability to access countless anatomic sites to sample tumors and lymph nodes, as well as drain cysts and fluid collections. The development of EUS-guided celiac ganglion neurolysis (CGN) started a new era in EUS-guided techniques, where the fine needle has become the vehicle for delivery of various ablative agents, chemotherapeutic agents, radio-opaque markers, and miniature devices. The following is a brief overview of some of the mainstream and upcoming applications of EUS-guided fine-needle therapy for pancreatic and biliary disease.

### EUS-Guided Celiac Plexus and Ganglia Interventions

Chronic abdominal pain is a common and debilitating symptom for patients with CP and pancreatic cancer. The etiology of pancreatic pain is multifactorial, and can be attributed to multiple causes, such as increased intrapancreatic pressure, pancreatic ischemia, fibrosis, pseudocysts, and neurogenic inflammation, as well as the invasion of pancreatic perineural space by cancer cells.<sup>123</sup> The current pharmacologic management for pancreatic pain involves starting with nonopioid analgesics, such as nonsteroidal antiinflammatory drugs, and progressing to increasing doses of opioid analgesics.<sup>124</sup> However, opioids often provide suboptimal pain relief, and their use is limited by side effects such as constipation, nausea, confusion, somnolence, addiction, and impaired immune function.<sup>125,126</sup> Sympathetic nerves innervating the pancreas pass through the celiac plexus, and celiac plexus neurolysis (CPN) can be performed with the goal of improving pain control, increasing quality of life (QOL), and reducing the risk of drug-induced side effects.

### Relevant Anatomy

The celiac plexus is comprised of a dense network of ganglia and interconnecting fibers, is located caudal to the diaphragm (in an anterocrural position), and surrounds the origin of the celiac trunk. Celiac ganglia vary in number (usually 1–5), size (0.5–4.5 cm) and location (T12–L2).<sup>127</sup> The celiac plexus transmits pain sensations from the pancreas and most of the abdominal

viscera, except for the left colon, rectum, and pelvic organs.<sup>128</sup> The neurons that innervate the pancreas can receive nociceptive stimulation and then transmit this pain information to the celiac plexus.<sup>129</sup>

### Non-EUS Methods for Celiac Plexus Neurolysis and Celiac Plexus Block

CPN and CPB can be performed percutaneously, surgically, or under EUS guidance. The retrocrural approach involves injecting the solution, which diffuses over the splanchnic nerves. The anterocrural approach, or "true" CPN, involves injection anterior to the diaphragm, thereby causing the solution to diffuse over the celiac ganglia.

Efficacy studies on percutaneous guided celiac plexus neurolysis (PQ CPN) for patients with pancreatic cancer have shown mixed results, but overall have demonstrated some benefit with fairly low risk. A 2011 Cochrane meta-analysis evaluated six randomized trials of 358 patients undergoing PQ CPN for pancreatic cancer pain.<sup>129</sup> At both 4 weeks and 8 weeks, patients in the treatment arm had significant improvement in pain compared with the control arm. Furthermore, opioid consumption was significantly lower in the treatment arm. In another meta-analysis by Eisenberg et al (1995) of 24 studies with 1145 patients treated with PQ CPN for palliation of cancer pain (of which 63% were pancreatic cancer patients), good to excellent pain relief was noted in 70% to 90% of patients up to 3 months after the procedure, regardless of which type of percutaneous technique was used.<sup>130</sup>

### Patient Preparation and Technique for the EUS-Guided Approach

Early on, linear array echoendoscopic imaging from the proximal posterior stomach was shown to demonstrate superb visualization of the aorta and the take-off of the celiac artery, which is often regarded as "home base" for novice endosonographers, given its reproducibility as a landmark in nearly all patients. As a result, development of an EUS-guided technique for celiac neurolysis became a logical next step.

EUS-guided CPN is usually performed in the outpatient setting, and sometimes during the index examination conducted for the purpose of pancreatic cancer diagnosis and staging. Contraindications to CPN in our practice include uncorrectable coagulopathy (international normalized ratio > 1.5), thrombocytopenia (platelets < 50,000/L), inadequate hydration, and altered anatomy prohibiting visualization or access to the celiac plexus/ganglia. Patients are initially hydrated with 500 to 1000 mL of normal saline to minimize the risk of hypotension. The procedure is performed with the patient in the left lateral decubitus position under moderate sedation or anesthesia. Continuous monitoring is necessary during and for 2 hours after the procedure. Before discharge, the blood pressure is rechecked in a supine and erect position to assess for orthostasis.<sup>125</sup> There is little evidence to support the administration of prophylactic antibiotics after CPN, thus we do not routinely administer postprocedure antibiotics in our practice.

The most widely performed approach to EUS-guided CPN involves diffuse injection into the region of the celiac plexus.<sup>131</sup> Linear array endosonographic imaging from the posterior lesser curve of the gastric fundus allows identification of the aorta, which appears in a longitudinal plane. The aorta is traced distally to the celiac trunk, which is the first major branch below the diaphragm. Targeting with CPN is based on the expected location of the celiac plexus relative to the celiac trunk, and Doppler

**FIG 51.14** EUS-guided direct injection of alcohol and Marcaine (Hospira, Inc., Lake Forest, IL) solution into two celiac ganglia in a patient with pancreatic cancer. FNA, fine-needle aspiration.

should be used to clearly delineate vascular structures. In our practice, a standard 22-gauge needle without stylet is primed with the injectate, advanced through the scope working channel, and affixed at the inlet. The needle is inserted under EUS guidance immediately adjacent and anterior to the lateral aspect of the aorta at the level of the celiac trunk. An aspiration test is performed to rule out vascular penetration prior to each injection. For patients with pancreatic cancer, typically a premixed 10 to 20 mL solution of 98% dehydrated alcohol and 0.75% Marcaine (Hospira, Inc., Lake Forest, IL) in a 70:30 ratio is injected (see Table 51.1). When performing CPN, we inject bilaterally with a modified technique, with half the volume on the left side of the celiac take-off and the remainder at the midline of the take-off. Our rationale for the modified technique is that the right side of the celiac artery is not as accessible, given the slight tilt of the artery relative to the scope position. Therefore left and midline are the preferred areas for injection. Some prefer to inject at a single site, usually midline. The practice of bilateral injection has been supported by several studies, including a 2009 meta-analysis that reported the proportion of patients with initial pain relief as 84.5% with bilateral injection compared to 45.9% for unilateral (midline) injection.<sup>132,133</sup> However, a 2013 study including 53 patients showed no difference in efficacy with bilateral versus unilateral injection.<sup>134</sup>

An alternative approach that has been described, which may be more applicable to advanced abdominal cancer, is EUS-guided broad plexus neurolysis (BPN). In this technique, the injection is performed at the level of the superior mesenteric artery, resulting in a broader distribution of neurolysis. A study by Sakamoto et al (2010) of 67 patients showed that BPN had significantly better 7-day and 30-day pain relief scores as compared to conventional EUS-CPN.<sup>135</sup>

#### EUS-Guided Direct Celiac Ganglion Neurolysis

Recently, it has been recognized that the individual celiac ganglia can be visualized and accessed by EUS, allowing for direct injection into the individual celiac ganglia to perform CGN. The celiac ganglia are typically oval or almond-shaped, range in size from 2 to 20 mm, and are most readily detected to the left of the celiac artery, anterior to the aorta. Compared to the surrounding retroperitoneal fat, the ganglia are echo-poor and often display similar echogenicity to the left adrenal gland. Central echo-rich strands and foci are often present within the ganglia, and the margins of the ganglia are irregular. Color Doppler demonstrates little to no flow within these structures. Ganglia are detected by

EUS in 81% to 89% of patients.<sup>136</sup> Our approach is to always perform CGN rather than CPN if ganglia are visualized.

All aspects of the procedure, including patient candidacy, sedation, antibiotic use, and follow-up, are the same as for standard CPN. The technique for CGN and the volume of solution injected have not been standardized. Our approach is to target as many ganglia as possible by injecting a total of 10 to 20 mL of premixed alcohol and bupivacaine (mixture as outlined previously) among all the ganglia in amounts relative to their size (Fig. 51.14). For example, if there are three ganglia visualized (small, medium, and large), we would typically inject 5 mL in the largest ganglion, 3 mL in the medium-sized ganglion, and 2 mL in the small ganglion. For larger ganglia, we typically advance the needle tip into the deepest point within the ganglion and then inject while slowly withdrawing the needle, creating an even distribution of injectate throughout the ganglion. For smaller ganglia, we usually target the ganglion's center. During injection, a clear "ballooning" of the ganglia should be visualized; otherwise, needle placement is considered suboptimal. Each ganglion can be injected until injectate is seen spilling from the ganglion into adjacent soft tissue. After injecting each visualized ganglion, the remaining injectate can be injected adjacent to the celiac or superior mesenteric arteries, as described earlier.

#### Clinical Trial Data

The clinical trial data for CGN and CPN for patients with pancreatic cancer are summarized in Table 51.7. There is great variability among studies in terms of injection technique, type of injectate and volume, definition of pain relief, and follow-up. Most studies are small retrospective studies with short follow-up.

For CPN, partial pain relief has been reported in 50% to 78% of patients within the first 4 weeks.<sup>131,133,137-139</sup> A meta-analysis including 119 patients found that EUS-CPN alleviated abdominal pain in 73% of patients.<sup>140</sup> In a randomized trial, 96 patients with inoperable pancreatic cancer were randomized to conventional pain management or EUS-CPN. At 3 months, patients treated with CPN had greater pain relief with a trend toward lower morphine consumption, although no difference was observed in QOL.<sup>141</sup>

For CGN, partial pain relief has been reported in 65% to 94% of patients.<sup>142-144</sup> In the only prospective trial to date comparing CGN to CPN, 68 patients with upper abdominal cancer (over 85% had pancreatic cancer) were randomly assigned to treatment using either EUS-CGN or EUS-CPN with one midline

**TABLE 51.7 Clinical Trial Data for Endoscopic Ultrasound-Guided Celiac Neurolysis**

Study	Design	n	Injection Site	Injectate	Pain Relief (% of Patients)	Complications
Doi et al. 2013 <sup>142</sup>	Prospective	68	Ganglia vs. plexus	1–2 mL bupivacaine 0.25–0.5% 10–20 mL alcohol	73.5% vs. 45.5% Partial 50% vs. 18.2% Complete	Hypotension 2.9% vs. 6.0% UGI bleed 2.9% vs. 0% Pain exacerbation 29.4% vs. 21.2%

SMA, superior mesenteric artery; UGI, upper gastrointestinal.

injection. The positive response rate was significantly higher in the EUS-CGN group (73.5%) than in the EUS-CPN group (45.5%). The complete response rate was also significantly higher in the EUS-CGN group (50%) than in the EUS-CPN group (18.2%). There was no difference in adverse events or duration of pain relief between the groups.<sup>142</sup> Follow-up was only 7 days, and much longer-term follow-up studies are needed, as well as comparison with bilateral EUS-CPN injections.

### Complications

Most complications related to CPN and CGN are transient, and serious complications are rare. The most common side effects reported are transient hypotension (up to 35%), diarrhea (up to 20%), and transient exacerbation of pain following the procedure, which are consistent with rates seen with the PQ approach.<sup>130</sup> Hypotension and diarrhea are related to sympathetic blockade and the relative unopposed visceral parasympathetic activity. Hypotension generally responds to intravenous fluid administration. The diarrhea related to this procedure is usually self-limiting, and typically resolves in less than 48 hours. CPN via a PQ approach has been associated with a 2% rate of serious complications, including neurologic complications (lower extremity weakness, paresthesia, paralysis), pain (pleuritic chest, shoulder), pneumothorax, and hiccupping.<sup>130</sup> A very small number of serious complications ( $\leq 0.6\%$ ), including fatalities and paralysis (mainly with alcohol injection), have been reported with the EUS approach in case report and abstract form.<sup>143,146</sup> Serious infections including retroperitoneal abscess and empyema have occurred, as well as severe ischemic damage to abdominal organs.

### EUS-Guided Radiofrequency Ablation

Image-guided radiofrequency ablation (RFA) is a well-recognized minimally invasive treatment modality in oncology, one that utilizes the generation of high-frequency electrical alternating current through target tissue to induce ion agitation and tissue friction, ultimately leading to thermal injury and consequent coagulative necrosis. Effective ablation is achieved by optimizing heat production and minimizing heat loss, with the objective of generating a clear tumor ablation margin while reducing potential side effects. The availability, safety, efficacy, and low cost of percutaneous RFA have facilitated its common utilization, in conjunction with ultrasound, CT, or MRI guidance, in the management of a variety of solid tumors, most commonly hepatocellular carcinoma, renal cell carcinoma, non-small cell lung cancer, and osteoid osteoma.

RFA has also been used to treat pancreatic cancer during exploratory laparotomy or laparoscopy; a 2014 systematic review identified five studies including 158 patients with a median survival after RFA of 3 to 33 months, 0% to 19% mortality, 10% to 43% overall morbidity, and 4% to 37% RFA-related morbidity, much of which was related to collateral injury to adjacent tissues.<sup>147</sup> Given its minimally invasive nature and superior imaging capabilities of the pancreas, EUS potentially provides an ideal vehicle for delivering RFA to pancreatic cancer, as well as other percutaneously inaccessible tumors.

### Animal Studies

Using a modified 19-gauge needle electrode connected to a monopolar radiofrequency generator, Goldberg et al in 1999

first demonstrated the feasibility of EUS-guided RFA of the pancreas in 13 pigs.<sup>118</sup> The maximum diameter of the ablated area was 10 to 15 mm by EUS and 12 mm by histology. Correlation between EUS or CT and gross pathologic findings for size of the ablated region was excellent for all areas larger than 5 mm; the size of the ablated zone at pathologic examination was within 2 mm of that visualized on imaging. Complications included three transmural gastric wall burns, an intestinal serosal burn, and an asymptomatic pancreatic fluid collection.

In an attempt to improve ablation efficiency while reducing collateral thermal injury, Carrara et al (2008)<sup>119</sup> used a hybrid cryotherm probe combining bipolar radiofrequency current with carbon dioxide cryotherapy to ablate the body of the pancreas in 14 pigs; they achieved a larger ablation zone (18 mm vs. 10 mm) with a 300-second application than that obtained with a 360-second application using the monopolar system from the Goldberg et al study. However, similar side effects (most reflecting longer application duration) were encountered, including two cases of pancreatitis (one necrotizing and the other asymptomatic), a gastric wall burn, and four cases of adhesions between the pancreas and the gut. The same group demonstrated the feasibility of using the CT probe in EUS-guided RFA of the liver and spleen in porcine models with no reported complications.<sup>120</sup> Ultrasound-guided RFA with the CT probe of 16 explanted human pancreatic tumors with a mean diameter of 29 mm produced ablation zone diameters of 10 to 20 mm, with the size of the ablated area correlating with the duration of ablation.<sup>121</sup>

Varadarajulu et al (2009) used an EUS-guided umbrella-shaped retractable monopolar electrode array to ablate five porcine livers, generating ablation zone diameters of 23 mm at EUS and 26 mm at histology without any complications.<sup>122</sup> Gaidhane et al (2012) deployed a 1-Fr RFA probe through a 19-gauge needle to ablate five porcine pancreata without complications; only histological evidence of focal pancreatitis was documented.<sup>123</sup> Kim et al (2012) used an 18-gauge saline pump-cooled RFA electrode to ablate the body or tail of the pancreas of 10 pigs; ablation zone diameters of 14.5 mm at EUS and 23 mm at histology were achieved.<sup>124</sup> Complications included three cases of asymptomatic retroperitoneal fibrosis or pancreatogastric adhesions.

### Human Studies

Human studies of EUS-guided RFA are limited. Arcidiacono et al (2012) ablated 16 unresectable stage 3 pancreatic cancers with a mean diameter of 35.7 mm using the CT probe.<sup>125</sup> RFA could not be deployed in six additional patients because of gastroduodenal wall or tumor stiffness. Complications included mild abdominal pain in three patients, one of whom had pancreatitis; a duodenal bleed requiring endotherapy; two cases of obstructive jaundice requiring stenting; a duodenal stricture treated with stenting; and an asymptomatic pancreatic cystic collection. Median postablation survival time was 6 months. CT imaging could clearly define the tumor margins in only 6 of 16 ablated patients, whereas no reduction or change in tumor size, however insignificant, was seen for up to 78 days.<sup>125</sup>

Song et al (2016) recently conducted a study to assess the technical feasibility and safety of EUS-RFA in six patients with unresectable pancreatic cancer using an 18-gauge RFA needle and the VIVA RF Generator system (STARmed, Koyang, Korea).<sup>126</sup> The length of the exposed tip of the RFA electrode was 10 mm. After insertion of the RFA electrode into the mass, the radiofrequency generator was activated to deliver 20 to 50 W ablation

power for 10 seconds. Depending on the tumor size, the procedure was repeated to sufficiently cover the tumor. EUS-RFA was performed successfully in all six patients (median age 62 years, range 43–73 years). Pancreatic cancer was located in the head ( $n = 4$ ) or body ( $n = 2$ ) of the pancreas. The median diameter of masses was 3.8 cm (range 3–9 cm). Four patients had stage 3 disease, and two patients had stage 4 disease. After the procedure, two patients experienced mild abdominal pain, but there were no other adverse events, such as pancreatitis or bleeding.

Early studies of EUS-guided RFA for neuroendocrine tumors and pancreatic cysts have also been performed.<sup>127–130</sup>

At present, EUS-guided RFA remains a tool that requires further assessment, refinement, and validation of its safety and efficacy in well-designed randomized controlled studies before it can be formally recommended for use in clinical practice. In particular, future studies will need to address the development of sharper probe designs, possibly equipped with cutting current to facilitate transluminal access; the appropriate radiologic modality and time interval for assessing tumor response; and the optimal settings for treatment duration, generator power, and gas coolant pressure for effective ablation of pancreatic cancer as opposed to healthy pancreatic tissue.

### EUS-Guided Fiducial Marker Placement

Fiducial markers are radiopaque coils or rods that assist in the targeting of cancer radiation therapy. Traditionally placed intraoperatively or percutaneously under radiology guidance, in more recent years EUS placement via an FNA needle has been preferred as a less invasive method for fiducial marker placement in GI malignancies, including esophageal tumors, cholangiocarcinomas, gastric cancers, and malignant lymph nodes.<sup>125–128</sup> In esophageal cancer, where there is a malignant lymph node far from the tumor, it is our practice to place fiducial markers into the lymph node to ensure radiation treatment to this region as well. There may be particular advantages for placement into the pancreas, with possibly a lower likelihood of peritoneal seeding, although recent protocols for pancreatic cancer have moved away from radiation therapy.<sup>122,124</sup>

Placement of fiducial markers allows accurate demarcation of the location and peripheral extent of the tumor in real time by image-guided radiotherapy (IGRT), which is a prerequisite to facilitating stereotactic body radiotherapy. The visualization of fiducial markers allows multiple beams of radiation to be delivered with extreme accuracy and consistency by quantifying respiratory motion and tumor extent, therefore maximizing radiation delivery to the tumor and minimizing collateral damage to the normal surrounding parenchyma.<sup>125</sup> This technique has also been used for intraoperative localization of small neuroendocrine tumors to allow parenchymal-sparing resections.<sup>126,127</sup>

### Fiducial Characteristics

Fiducial markers can be made of gold, carbon, or polymer.<sup>128</sup> Gold markers are more commonly used, as they are most easily visualized and provide the highest level of contrast. Gold fiducial markers can also produce more artifact, but fortunately this can be minimized by employing the metal artifact reduction methods to improve CT image quality.<sup>129</sup>

The size of fiducial markers can vary. The length is anywhere from 2.5 to 10 mm, and the diameter can range between 0.35 to 0.8 mm, which dictates the gauge of needle used for delivery. The shape of fiducials can be cylindrical (rod) or coiled. A 2012 comparison study demonstrated that rod-shaped fiducials were

significantly more visible than the coiled variety, without significant differences in the rate of migration.<sup>170</sup>

#### Technique for Fiducial Marker Placement

Fiducial markers can be delivered via a 19- or 22-gauge needle. The advantage of the 22-gauge delivery system is ease and success of deployment, especially when targeting more technically difficult locations such as the head or uncinate process of the pancreas. DiMaio et al (2010)<sup>163</sup> reported a 97% technical success rate with the 22-gauge system for GI-related malignancies, and Ammar et al (2010)<sup>162</sup> reported a 100% technical success rate in tumors and lymph nodes.

Up until recently, the technique for placement involved a single loading system whereby the sterile fiducial marker is loaded at the needle tip either anterograde<sup>162</sup> or retrograde<sup>171</sup> and secured with sterile bone wax placed at the very end of the needle. Once the lesion of interest is punctured, the stylet is pushed completely into the needle to deploy the fiducial marker. Saline flush is sometimes required instead of the stylet in situations where difficult stylet maneuverability is anticipated (e.g., uncinate process targets).<sup>172</sup> In general, this technique produces very high success rates of deployment with normal anatomy, but in the setting of altered or postsurgical anatomy, success rates decrease to 73%.<sup>173</sup> A new multifiducial system, the BNX needle aspiration system (Covidien, Dublin, Ireland), has been released for clinical use. It is engineered to improve the clinical workflow by facilitating the passage of multiple needles through a single delivery system without removing the delivery system between needle passages. It allows rapid exchange of the needles while keeping the needle sheath and catheter in the echoendoscope. Therefore having two or three preloaded needles can allow rapid deployment of multiple fiducials (this system allows placement of multiple fiducials through a single delivery system). This system was demonstrated to have a 95% success rate in porcine models, with four fiducials placed sequentially in under 1 minute.<sup>174</sup> This device has a narrowing or waist near the tip to provide the endoscopist tactile feedback indicating successful deployment of each individual fiducial marker. Cook Medical (Bloomington, IN) also manufactures a dedicated EUS needle, the EchoTip Ultra fiducial needle, which has four preloaded gold fiducial markers within a 22-gauge FNA needle.

#### Ideal Fiducial Geometry

Ideal fiducial geometry (IFG) is defined as having a minimum of three fiducials at least 2 cm apart and with interfiducial angles greater than 15 degrees (Fig. 51.15). Surgical placement has achieved IFG more consistently than EUS-guided methods, although IFG may not be necessary, as both surgical and EUS-guided methods achieve high visibility under Cyberknife (Accuray Inc., Sunnyvale, CA) imaging.<sup>175</sup> Placement protocols vary among centers, particularly regarding the actual number of fiducials placed. In most centers, three to four fiducial markers are inserted between 1.5 and 2 cm apart around the periphery of the tumor. The goal is to aim for IFG if the tumor is large enough to allow adequate spacing of the fiducials, regardless of the type of tumor. Smaller lesions may only allow one or two fiducials to be inserted.

#### Complications

Complications related to fiducial marker placements are rare. The most common is migration at 1 week postplacement, when IGRT typically commences. The median migration distance has been reported to be 1.3 mm<sup>170</sup>; however, total migration to the

**FIG 51.15** Fluoroscopic image of all three fiducial markers at the head of pancreas with a metal biliary stent coursing through the cancer.

extent whereby the fiducial marker is not seen at IGRT and the quality of IGRT is compromised has been reported in up to 7% of cases.<sup>173</sup>

Other reported complications include infection in two patients<sup>163,164</sup> who were managed without intravenous antibiotics or hospital admission. Given the overall low risk of infection with this procedure, we do not routinely administer antibiotic prophylaxis following EUS-guided fiducial marker placement for GI malignancy in our practice. There has been one report of postprocedural abdominal pain, which was ultimately diagnosed as mild pancreatitis.<sup>175</sup> Bleeding occurred on one occasion, although this was minor and did not require blood transfusion.<sup>172</sup>

In summary, fiducial markers play an integral role in the precise delivery of high intensity radiotherapy by Cyberknife. EUS-guided placement is particularly useful in deeper targets, particularly the pancreas, and has proven to be very safe and effective.

#### EUS-Guided Antitumor Agents

With CGN, EUS-guided FNI has demonstrated feasibility and safety in the delivery of a medication into a localized region and structure. As a result, EUS-FNI has received attention as a method for antitumor agent delivery, particularly for intratumoral and combination therapy for esophageal and pancreatic cancer. The evidence supporting the feasibility of EUS-FNI of antitumor agents has been expanding, with promising results. This topic is outside of the scope of this current chapter, but we feel it is important to mention that many remain optimistic that EUS-FNI will play an important role in future cancer therapy.

## INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP) has traditionally represented the optimal approach to the bile duct and the pancreatic duct. However, ERCP is not always successful because of the inability to achieve selective cannulation or because of inaccessibility of the papilla owing to gastric outlet obstruction (GOO) and surgically altered anatomy (e.g., Roux-en-Y gastric bypass). Recently, new endoscopic drainage techniques guided by endoscopic ultrasonography (EUS) have been developed, mainly for use in failed ERCP patients. However, such techniques are not yet fully established, and their usefulness is still debated. Herein, we focus on EUS-guided pancreaticobiliary drainage by describing the technique and its algorithm from the viewpoint of an interventional EUS expert.

## EUS-GUIDED BILIARY DRAINAGE (EUS-BD)

Percutaneous transhepatic biliary drainage (PTBD) is routinely used worldwide as an alternative biliary drainage technique in the case of failed ERCP. At present, EUS-BD is considered to be a viable second-line option for biliary decompression in case of failed ERCP, particularly at institutions with interventional expertise. This is because of its high technical success rate of 80% to 90% and its low adverse event rate of 10% to 20%,<sup>1,2</sup> and because its efficacy and safety are similar to those of PTBD.<sup>3,4</sup>

### Technical Considerations

Anatomically, the EUS-BD approach can be classified into two types: extrahepatic bile duct (EHBD) drainage and intrahepatic bile duct (IHBD) drainage.<sup>5</sup> EUS-guided hepatico-

ostomy (EUS-HGS) and EUS-guided choledochoduodenostomy (EUS-CDS) are typical transmural EUS-BD techniques. Other options, such as EUS-guided rendezvous (EUS-RV) and EUS-guided antegrade stenting (EUS-AS), have also been reported.

### EUS-Guided Extrahepatic Bile Duct Drainage

Puncture of the EHBD via the duodenum (EUS-CDS) (Fig. 52.1 and Video 52.1) is a common approach in EUS-guided EHBD drainage. The EHBD is visualized from the duodenal bulb using EUS in a long scope position. The direction of the needle in the long scope position is toward the hilar bile duct. A 19-gauge needle that has been prefilled with contrast medium is used to puncture the EHBD. After injection of contrast medium to delineate the IHBD, a 0.025-inch or 0.035-inch guidewire is placed. Tract dilation is performed using a standard ERCP catheter, a 6-Pr cautery dilator (Cyst-Gastro set, Mediglobe, Germany), and/or a 3- to 4-mm dilating balloon. Using a needle knife may increase the risk of adverse events. With regard to current, a high-frequency electrocautery setting such as AutoCut mode (100 W, effect 4, ICC200, ERBE Elektromedizin GmbH, Tübingen, Germany) is used. It is very important to keep the endoscope pressed against the duodenal wall (endoscopically, the so-called red spot) while taking ultrasonography images of the long axis of the bile duct and guidewire. It is also important to maintain the optimal scope position during radiography. In addition, it is critical to arrange the equipment that will be needed in advance to complete the procedure appropriately and in a short time. Finally, the type of stent used, such as a plastic stent (PS) or a self-expandable metal stent (SEMS) (including fully covered and partially covered SEMS), depends on the preference of the endosonographer, although SEMS appears to be more suitable for avoiding bile leakage and postprocedure bleeding.

**Abstract**

Endoscopic retrograde cholangiopancreatography (ERCP) has traditionally represented the optimal approach to the bile duct and the pancreatic duct. However, ERCP is not always successful. At present, endoscopic ultrasonography-guided biliary drainage (EUS-BD) is considered to be a viable second-line option for biliary decompression in case of failed ERCP, particularly at institutions with interventional expertise. This is because of its high technical success rate of 80% to 90% and its low adverse event rate of 10% to 20%, and because its efficacy and safety are similar to those of PTBD. EUS-guided pancreatic duct drainage (EUS-PD) as a same technique can be used to access a dilated pancreatic duct in cases in which the duct cannot be drained by conventional ERCP in cases with complete obstruction or without access. EUS-PD may also represent a viable second-line option for pancreatic duct decompression in case of failed ERCP because of its technical success rate of 70% to 100% and its low adverse event rate of 2% to 20%. Thus, therapeutic EUS-BD and EUS-PD represent an alternative to surgery or percutaneous biliary drainage when ERCP fails or is impossible (such as gastrectomy or Whipple resection). Although data have demonstrated that the procedure can be safe and effective, EUS-guided pancreatic duct drainage remains one of the most technically challenging therapeutic EUS interventions, as evidenced by the multiple considerations required for device selection and the risk of severe complications.

Thus far, conventional tubular biliary stents have been used for EUS-CDS. Recently, dedicated stents for EUS-BD have also been developed. The new, commercially available biflanged lumen-apposing metal stent AXIOS (Boston Scientific Corp., Natick, MA) (Fig. 52.2) is a safe and useful SEMS for EUS-CDS.<sup>67</sup> Furthermore, the Hot AXIOS stent (Boston Scientific Corp.), a cautery-enhanced delivery system for single-step EUS-guided

puncture and delivery of a lumen-apposing stent for EUS-CDS, has also been developed<sup>68</sup> (Fig. 52.3). When we use this one-step delivery system, freehand EUS-CDS can be performed without any needle puncture or tract dilation, although the bile duct must be dilated to a diameter greater than 2 cm for safe stent deployment.

### EUS-Guided Intrahepatic Bile Duct Drainage

Puncture of the IHBD via the stomach (EUS-HGS) (Fig. 52.4 and Video 52.2) is a common approach to EUS-guided IHBD drainage. Although rare, transjejunal IHBD drainage is possible in patients with altered anatomy such as total gastrectomy and Roux-en-Y reconstruction. The IHBD is small compared with the EHBD. If the IHBD is not dilated adequately, the use of a 22-gauge needle is also an option. However, in such cases, guidewire manipulation following puncture is not easy to perform.

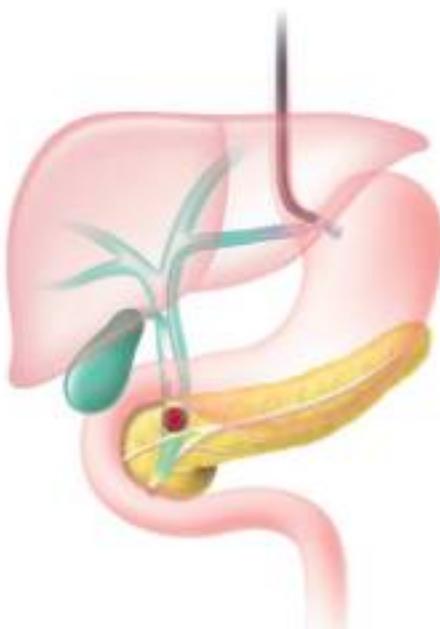

**FIG 52.1** Schema of EUS-guided choledochoduodenostomy using a lumen-apposing stent.

**FIG 52.2** Lumen-apposing biflanged metal stent (Hot AXIOS). (Courtesy Boston Scientific, Marlborough, MA.)

**FIG 52.3** EUS-guided choledochoduodenostomy using a Hot AXIOS stent. The distal flange is deployed in the common bile duct (CBD) as an anchor, under **A**, EUS guidance and **B**, fluoroscopic guidance. Finally, the proximal flange (endoscopic image, right lower corner) is deployed under endoscopic guidance in the duodenum (inset). PV, portal vein.

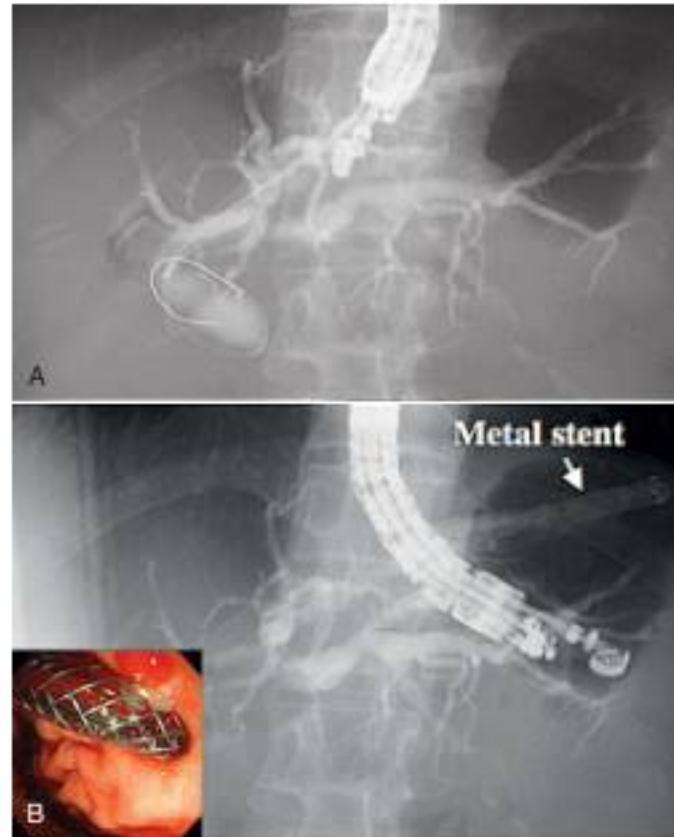

**FIG 52.4** Schema of EUS-guided hepaticogastrostomy using a metal stent.

After needle puncture, it is important to insert the guidewire into the bile duct as far as possible. Tract dilation of the fistula is achieved by basically the same procedure as is EUS-guided EHBD drainage. Finally, a PS or SEMS is placed in the IHBD. Similar to EUS-CDS, dedicated PSs<sup>9</sup> and SEMSs (including partially or fully covered SEMSs<sup>10</sup>) have been developed for EUS-HGS (Fig. 52.5).

When selecting the IHBD to puncture, is it better to puncture intrahepatic bile duct 2 (B2) or bile duct 3 (B3)? Although this depends on the patient's anatomy, B2 puncture may provide easier guidewire manipulation and stent delivery system insertion because the puncture is performed smoothly in a downstream direction toward the EHBD compared with B3 puncture. However, the B2 puncture site tends to be close to the esophagogastric junction, and stent deployment or re-intervention may be difficult. Moreover, there is a possibility of transesophageal puncture, leading to mediastinitis.

#### EUS-Guided Rendezvous<sup>11</sup>

There are three puncture routes for EUS-RV. The first route is transmural puncture of the IHBD, known as the IHBD puncture route. For the IHBD puncture route, transesophageal puncture of B2 and transgastric puncture of B2 or B3 can be performed; in addition, transjejunal puncture is possible in patients who have undergone reconstruction after total gastrectomy. B2 puncture appears to be the preferable puncture route for EUS-RV because guidewire manipulation is easier than in the case of B3 puncture. On the other hand, there are two methods for transduodenal puncture of the EHBD: EHBD puncture via the proximal duodenum (D1) and EHBD puncture via the second portion of the duodenum (D2). For EHBD puncture via D1, the scope is in a push position (long position), whereas for EHBD puncture via D2, the scope is in a short position. When performing the EHBD puncture via the duodenum, the stomach antrum is rarely punctured.

**FIG 52.5** EUS-guided hepaticogastrostomy using a partially covered metal stent. In this case, needle puncture was performed via the B2 intrahepatic bile duct. **A**, After tract dilation using a cautery dilator, a partially covered metal stent was placed (**B**, fluoroscopy; lower endoscopic image, inset).

After needle puncture, an angled tip hydrophilic-coated guidewire is passed into the duodenum as far as possible through the stenosis and papilla. Then, the EUS scope is switched to a duodenal scope for standard ERCP, leaving the guidewire in place. Biliary cannulation by ERCP is performed alongside the guidewire emerging from the papilla (parallel rendezvous), or the guidewire is grasped with snare or biopsy forceps and passed through the accessory channel, and the ERCP catheter is then advanced into the bile duct over the guidewire.

#### EUS-Guided Antegrade Stenting

EUS-AS (Fig. 52.6) is usually performed via the EUS-guided IHBD route. After needle puncture, an angled tip hydrophilic-coated guidewire is passed into the duodenum as far as possible through the stenosis and papilla, similar to EUS-RV. After the tract is dilated to the size needed for the stent delivery system (6-Fr to 8-Fr), a covered or uncovered metal stent is inserted antegrade and placed across the stenosis through to the duodenum via or above the papilla (Fig. 52.7). Some endoscopists perform simultaneous stent placement via the EUS-HGS route to avoid bile leakage in case of possible antegrade stent dysfunction.

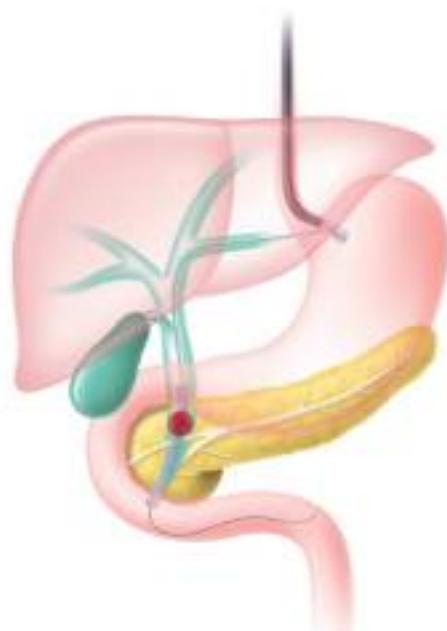

#### Clinical Outcomes

Numerous studies have reported on the success of EUS-BD to date. The outcomes for each procedure type are summarized in Table 52.1.<sup>12</sup> The technical success rates of EUS-CDS (n = 340),

EUS-HGS (n = 153), EUS-RV (n = 267), and EUS-AS (n = 39) were 92%, 95%, 81%, and 77%, respectively, and the adverse event rates were 15%, 17%, 11%, and 5%, respectively. These results suggest that transmural drainage provided a high technical success rate, whereas transpapillary procedures showed a low

adverse event rate. Regarding stent selection for EUS-HGS, a previous review showed that the technical success, clinical success, adverse event rates, and mortality rates did not differ significantly between PS (n = 26, 100%, 94.7%, 15.4%, and 0.038%, respectively) and SEMS (n = 147, 95.2%, 91.6%, 91.6%, 16.3%, and 0.007%, respectively). There was no significant difference of clinical outcomes between PSs and SEMSs. Based on these data, the use of either type of stent seems safe, but there could be publication bias because most of these data were collected retrospectively and from centers that perform a high volume of interventional EUS procedures. Notably, a Spanish survey showed that the technical success rates of EUS-HGS and EUS-CDS performed by various skilled endoscopists were 64.7% (22/34) and 86.3% (19/26), respectively.<sup>13</sup>

Although PTBD is the standard method used for draining a malignant biliary obstruction after failed ERCP, a 2016 randomized clinical trial comparing PTBD and EUS-BD showed that

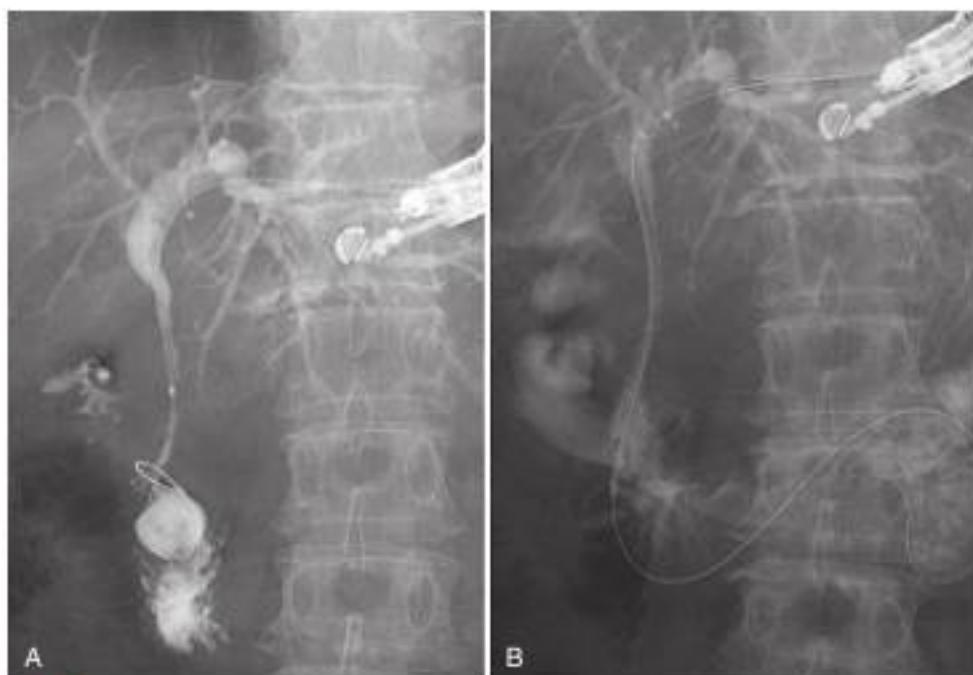

**FIG 52.6** Schema of EUS-guided antegrade stenting using a metal stent.

**TABLE 52.1 Summary of EUS-Guided Biliary Drainage**

	TRANSMURAL PROCEDURES		TRANSPAPILLARY PROCEDURES	
	EUS-CDS	EUS-HGS	Rendezvous	Antegrade
No. of cases	340	153	267	39
Technical success (%)	92	95	81	77
Early adverse events (%)	15	17	11	5

EUS-CDS, endoscopic ultrasound-guided choledochoduodenostomy; EUS-HGS, endoscopic ultrasound-guided hepatocholecystostomy.

**FIG 52.7** EUS-guided antegrade stenting using a metal stent. **A**, The guidewire was advanced into the duodenum across the stricture and papilla. **B**, After tract dilation, an uncovered metal stent was placed.

both techniques had similar levels of efficacy in patients with unresectable malignant distal biliary obstruction and inaccessible papilla, based on technical and functional success rates and quality of life.<sup>14</sup>

The use of EUS-guided right IHBD drainage has been reported in patients with complicated hilar obstruction.<sup>15</sup> Although its application is limited, EUS-guided right IHBD drainage should be considered as an alternative to PTBD in selected patients.

### Clinical Algorithm

Which of the several EUS-BD techniques that have been developed thus far is the optimal procedure? The technique selected depends on the endoscopist's preference and experience. At present, the real issue is the unavailability of a perfect technique that can accomplish biliary drainage in a wide range of patients. For example, the intrahepatic (IH) approach is difficult or impossible in the case of a nondilated IHBD. In contrast, the extrahepatic (EH) approach can be used in the case of a distal bile duct stricture, but is not possible in cases of complete GOO or nearly complete blockage of the EH bile duct. Therefore, selection of the EUS-BD technique must be flexible and based on patients' anatomies, such as those who have undergone Whipple resection or the Roux-en-Y procedure, as well as patient conditions, such as GOO.<sup>16</sup>

Tyberg et al (2016) proposed a novel algorithm for individualizing technique selection based on patient anatomy.<sup>17</sup> Patients with a dilated IHBD, as determined by cross-sectional imaging and confirmed by EUS visualization, received an IH approach with AS or HGS stent placement if anterograde placement was not feasible. Patients with a nondilated IHBD, as determined by cross-sectional imaging and confirmed by EUS visualization, underwent an EH approach with an RV technique, or a transenteric stent placement if RV was not feasible. If the IHBD approach was attempted but unsuccessful, an EH approach was performed. A similar algorithm for guidewire manipulation was proposed by Park et al in 2013.<sup>18</sup> These two algorithms suggest that guidewire manipulation is the most difficult part of the procedure, and is a key factor for performing a successful EUS-BD procedure. An optimal algorithm for EUS-BD is thus required, with the progressive development of dedicated devices in the near future. Until then, all techniques (i.e., EUS-HGS-/CDS-/RV-/AS) should be adequately learned to be able to accommodate various patient situations.

The timing for performing EUS-BD is not clear. We recommend obtaining consent for possible EUS-BD at the time of ERCP in patients at high risk for failed biliary cannulation.<sup>19</sup> This means that the endoscopist must ensure that adequate time, as well as skilled staff and appropriate back-up staff, is available for performing EUS-BD and managing its possible complications. Obtaining consent for possible EUS-BD at the time of ERCP avoids the need for repeated endoscopic interventions, as well as allowing for timely biliary drainage and the initiation of chemoradiation, if needed.

### Conclusion

EUS-BD is an effective alternative to PTBD or surgery in patients with failed ERCP as evidenced by previous data. Nevertheless, we advocate that this procedure should only be performed in appropriately selected patients and by experienced endoscopists trained in both EUS and ERCP, together with an available, well-trained radiologic and surgical back-up staff, after obtaining informed consent.

## INTERVENTIONAL EUS-GUIDED PANCREATIC DUCT DRAINAGE

The development of interventional EUS has provided better access to the pancreas. Just as pancreatic fluid collections (such as pseudocysts) can be successfully drained from the stomach or duodenum by endoscopic cystenterostomy or cystgastrostomy, the same technique can be used to access a dilated pancreatic duct in cases where the duct cannot be drained by conventional ERCP because of complete obstruction.

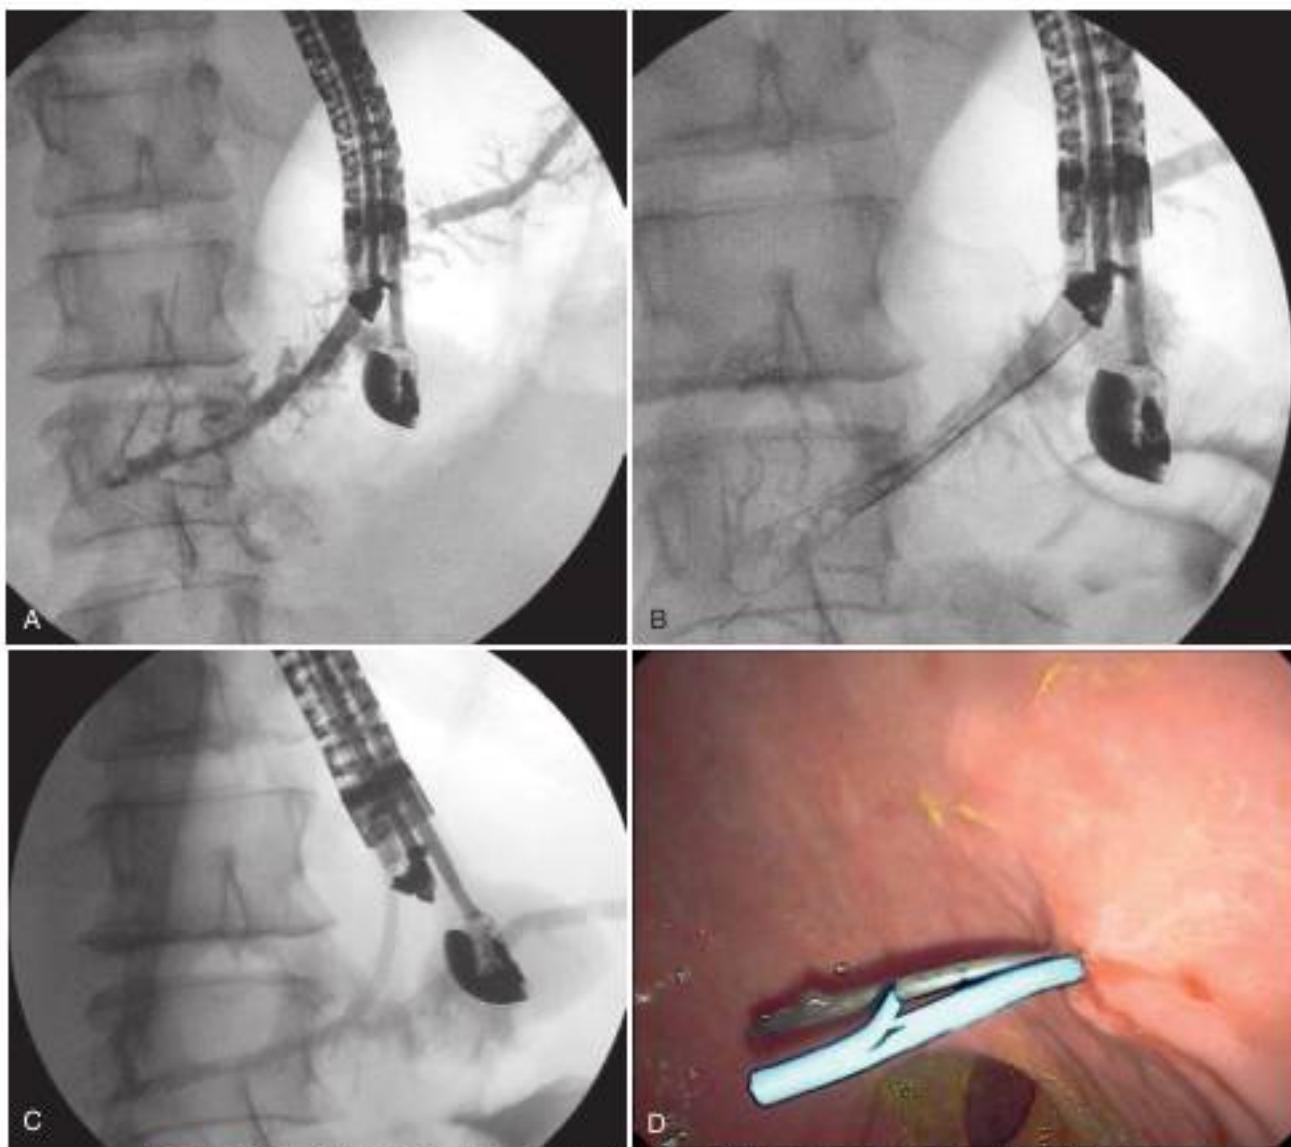

The main indications are stenosis of the pancreaticojejunal or pancreaticogastric anastomosis after Whipple resection (which induces recurrent acute pancreatitis [AP]), main pancreatic duct (MPD) stenosis due to chronic pancreatitis (CP), post-acute pancreatitis, or post-pancreatic trauma after ERCP failure. The pain associated with CP is caused, at least in part, by ductal hypertension. Both surgical and endoscopic treatments can relieve pain by improving ductal drainage. Endoscopic drainage requires transpapillary access to the pancreatic duct during ERCP. EUS-guided pancreaticogastrostomy (Fig. 52.8) or bulbostomy (Fig. 52.9) offers an alternative to surgery. Despite the advances in endoscopy, EUS-guided pancreatic duct drainage remains a technically challenging procedure. Technical success rates are greater than 70%; however, the average rate of adverse events is nearly 20%, and increases to 55% when stent migration is included. Until recently, a significant challenge associated with this technique was the absence of dedicated devices.

### Technical Considerations

The dilated MPD is visualized using a linear interventional EUS scope. Endoscopic papillotomy (EPG) is then performed under combined fluoroscopic and ultrasound guidance, with the tip of the echoendoscope positioned such that the inflated balloon is in the duodenal bulb while the accessory channel remains in the antrum. A 19-gauge needle is inserted transgastrically or through the bulb into the proximal pancreatic duct, and contrast medium is injected. Opacification is verified via a pancreatogram. A guidewire (0.025- or 0.035-inch) is introduced through the needle. At this point in the procedure, there are two options.

Option 1: The guidewire passes the stenotic area and goes through the papilla into the duodenum. A rendezvous technique (Fig. 52.10) should be performed by exchanging the EUS scope for a duodenoscope, and "classic" pancreatic endotherapy can then be performed. This technique should be the first choice when the patient's anatomy is intact because the complication rate is very low.

Option 2: The guidewire does not pass the stenotic area, or the patient has had a previous surgery (Whipple or gastrectomy). The needle is passed over a guidewire (0.025- or 0.035-inch) with a 6.5-Fr or 8-Fr diathermic sheath (prototype Cysto-Gastro set, EndoFlex, Voerde, Germany), which is then used to enlarge the tract between the stomach and the MPD. The sheath is introduced using cutting current. After exchange over a guidewire (rigid, 0.035-inch diameter), a 7-Fr, 8 cm-long pancreaticogastric stent is positioned. This stent is then changed for two 7-Fr or one 8.5-Fr stents 1 month after the first procedure. This EUS-guided MPD technique was first reported by François et al (2002).<sup>20</sup> Other authors have reported different techniques that have similar first steps (i.e., puncture of the MPD, pancreatogram, and guidewire insertion)<sup>21,22</sup> but a balloon dilatation is used instead of a cystostome, as reported in the original study,<sup>20</sup> and also by Tessier et al (2007).<sup>23</sup>

**FIG 52.8 A to D,** Pancreaticogastrostomy. Stenosis of the wirsungojejunostomy after Whipple surgery for a pancreatic neuroendocrine tumor of the head of the pancreas. **A,** Endoscopic ultrasonography-guided pancreatic ductography. **B,** Guidewire insertion. **C,** Stent placement to create a pancreaticogastrostomy. **D,** Endoscopic view of plastic stent.

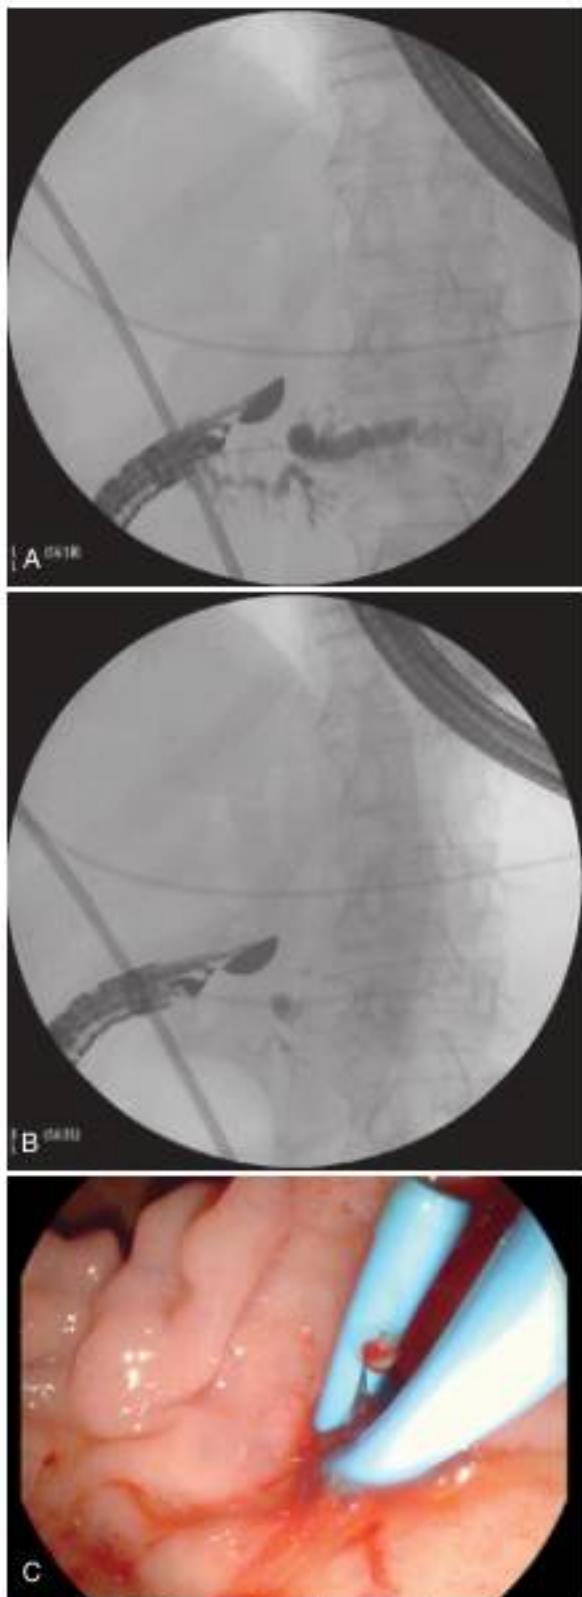

More research is needed on how to prevent pancreatic juice leakage using a diathermic technique versus balloon dilation. In our experience, peripancreatic collection occurs more frequently when we use balloon dilation than when we use the diathermic catheter, which prevents the leakage of pancreatic juice by creating fibrosis around the puncture tract.

### Clinical Outcomes

The results from several published case series<sup>21–27</sup> do not recommend wider use of EPG (Table 52.2), which in any case should be restricted to tertiary centers specializing in biliopancreatic therapy. Pain relief was achieved in 70% of cases. However, the complication rate is high (approximately 15%); adverse events include bleeding, pancreatic collection, and perforation. Nevertheless, the possibility of draining the MPD into the digestive tract through an endoscopically created fistula, with patency maintained by stent placement, might be interesting as an alternative method

of drainage without the complication of stent occlusion that is associated with transpapillary drainage.

The first large series (of 36 patients) was published by Tessier et al (2007)<sup>21</sup>. Indications were CP with complete obstruction (secondary to tight stenosis, a stone, or MPD rupture) in patients with inaccessible papilla or impossible cannulation ( $n = 20$ ); anastomotic stenosis after a Whipple procedure ( $n = 12$ ); complete MPD rupture after AP; or trauma ( $n = 4$ ). EPG or endoscopic pancreatic biopsy was unsuccessful in three patients; one was lost to follow-up. Major complications occurred in two patients, and included one hematoma and one case of severe AP. The median follow-up was 14.5 months (range: 4–55 months). Pain relief was complete or partial in 25 patients (69%, intention-to-treat). Eight patients had no improvement of their symptoms (four were subsequently diagnosed with cancer). Stent dysfunction occurred in 20 patients (55%) and required a total of 29 repeat endoscopies.

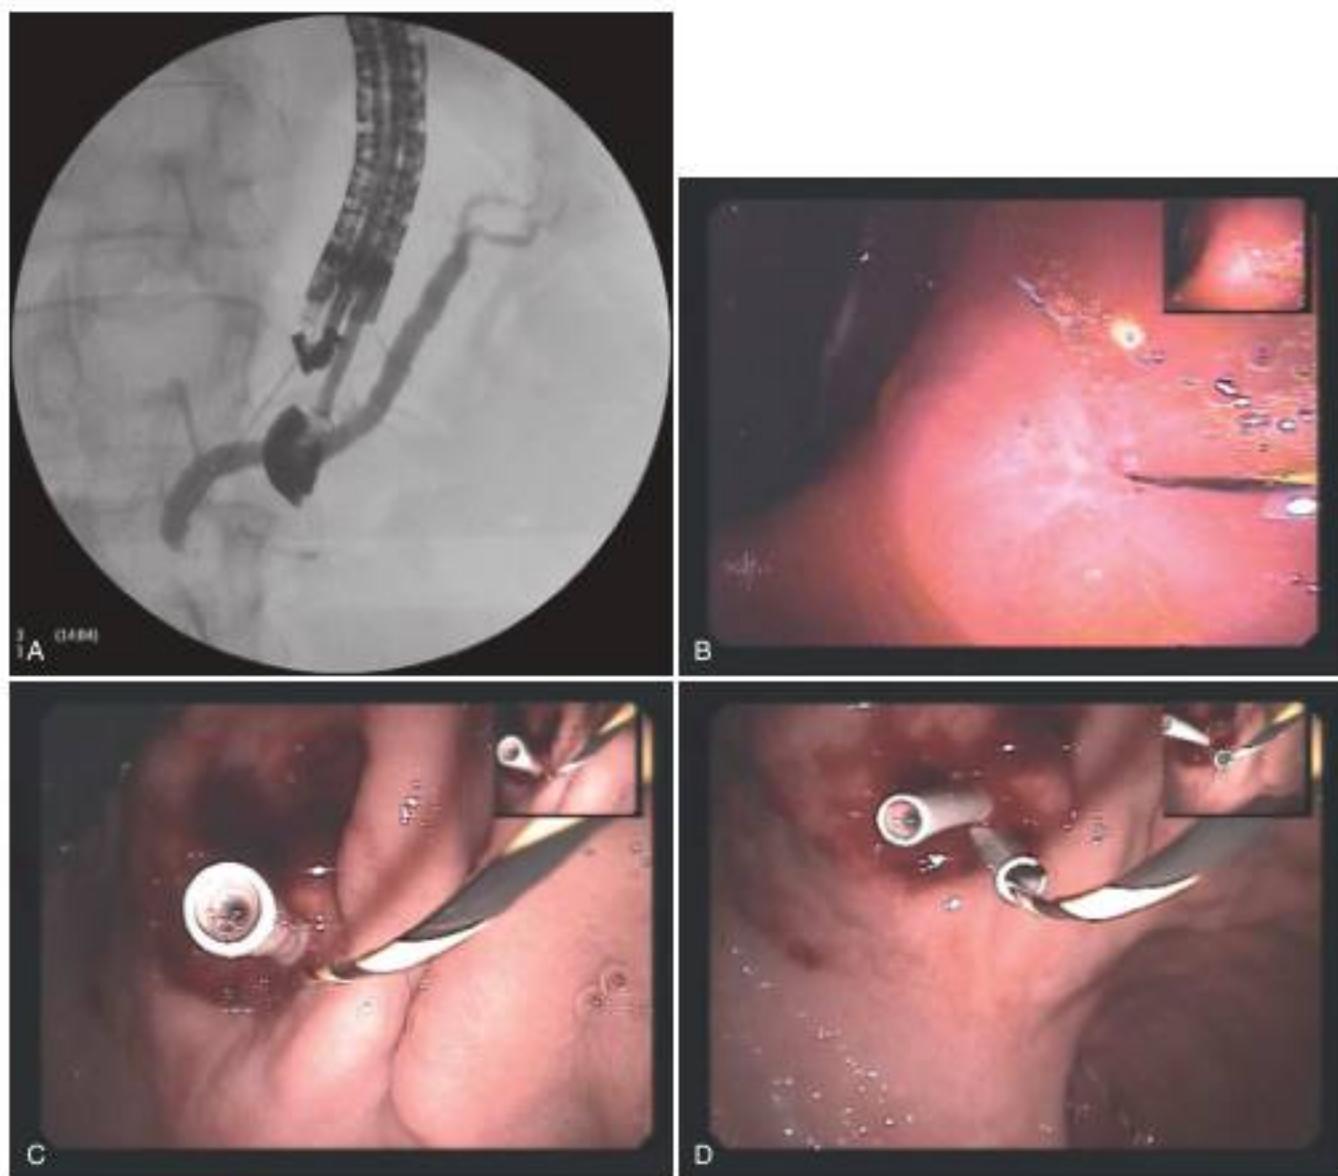

**FIG 52.9 A to C.** Pancreaticobulbostomy/chronic pancreatitis with a high degree of stenosis of the main pancreatic duct in the head of the pancreas. ERCP failure. **A**, Endoscopic ultrasonography-guided pancreatic ductography. **B**, Guidewire insertion. **C**, Endoscopic view of two plastic stents creating the pancreatogastrostomy.

Fujii et al (2013)<sup>22</sup> reported their experience with 45 patients, 37 of whom had undergone failed ERCP, and 29 of whom had surgically altered anatomy. Median follow-up after initial EUS-guided intervention was 23 months. Two underwent EUS for stent removal, and EUS-guided MPD stent placement was attempted in 43. Technical success was achieved in 32/43 (74%), with antegrade ( $n = 18$ ) or retrograde ( $n = 14$ ) stent insertion. Serious adverse events occurred in 3 patients (6%). Patients underwent a median of 2 (range: 1–6) follow-up procedures for revision or removal of stents, without complications. Complete symptom resolution occurred in 24/29 patients (83%) while stents were in place, including all six with nondilated ducts. Stents were removed from 23 patients, who were then followed for an additional 32 months (median); four had recurrent symptoms. Among the 11 failed cases, most had persistent symptoms or required surgery.

A larger study was reported by Will et al (2015).<sup>23</sup> This study enrolled 94 patients who underwent EUS-guided pancreatectomy and subsequent placement of a drain. In all, 94 patients underwent 111 interventions with one of three different approaches: (1) EUS-guided endoscopic retrograde drainage with a rendezvous technique; (2) EUS-guided drainage of the pancreatic duct; and (3) EUS-guided internal, antegrade drainage of the pancreatic duct. The technical success rate was 100%; in all cases, puncture of the pancreatic duct was accomplished successfully with the aid of pancreatectomy. Initial placement of a drain was successful in 47/83 patients (56.6%) requiring drainage. Of these, 26 patients underwent transgastric/transbulbar positioning of a stent for retrograde drainage; plastic prostheses were used in 11, and metal stents in 12. A ring drain (antegrade internal drainage) was placed in three of these 26 patients because of anastomotic stenosis after a previous surgical intervention. The remaining 21 patients with successful drain placement had transpapillary drains placed using the rendezvous technique; the majority ( $n = 19$ ) received plastic prostheses, and only two received metal stents (covered SEMSs). Clinical success, as indicated by reduced or no pain after the EUS-guided intervention, was achieved in 68/83 patients (81.9%), including several who improved without drainage, but with manipulation of the access route.

In 2015, Fujii-Lau and Levy (2015)<sup>24</sup> summarized the current literature on EUS-guided pancreatic duct drainage, reviewing the published experience of 222 patients. Including both antegrade and rendezvous techniques, technical success was achieved in 170/222 patients (76.6%). A similar review by Itoi et al<sup>25</sup> in 2013 reported a technical success rate of more than 70% in 75 patients using the antegrade technique, and a range of success rates from 25% to 100% in 52 patients with the rendezvous technique.

More recently, Oh et al (2016)<sup>26</sup> reported the use of pancreatic fully covered self-expanding metal stents (FCSEMS). Twenty-five consecutive patients with painful obstructive pancreatitis underwent EUS-guided MPD drainage with a FCSEMS after failed ERCP. EUS-guided MPD drainage was successful in all 25 patients (technical success rate: 100%), and symptoms improved in all patients (clinical success rate: 100%). EUS-guided pancreaticogastrostomy ( $n = 23$ ), pancreaticoduodenostomy ( $n = 1$ ), and pancreaticojejunostomy ( $n = 1$ ) were performed. Pain scores improved significantly after FCSEMS placement ( $p = 0.001$ ). Early mild-grade adverse events occurred in five patients (20%): four had self-limited abdominal pain, and one had minor bleeding. No other adverse events related to FCSEMS, including stent migration, stent clogging, pancreatic sepsis, and stent-induced ductal stricture, were observed during follow-up periods. The

Oh et al*, <i>Gastrointest Endosc</i> , 2016	25	100%	20%	5 months

\*FCSEMS, Fully covered self-expanding metal stent

mean duration of stent patency was 126.9 days during a mean follow-up period of 221.1 days.

### Clinical Algorithm

Regarding the three techniques, rendezvous<sup>28</sup> should be used preferentially because the complication rate is very low. EUS-guided pancreaticobulbostomy is recommended for stenosis of the MPD in the head of the pancreas because the EUS scope position is very stable. EUS-guided pancreaticogastrostomy is indicated when the patient's anatomy is altered (Whipple or gastrectomy), and mainly in the case of stenosis of the wirsungojejunostomy anastomosis, but this technique is the most difficult, with a high percentage of complications due to the instability of the EUS scope in the stomach.<sup>28</sup>

### CONCLUSION

Therapeutic EUS-guided pancreaticogastrostomy and EUS-guided biliary drainage represent an alternative to surgery or percutaneous biliary drainage when ERCP fails or is impossible due to previous surgery (such as gastrectomy or Whipple resection). Although data have demonstrated that the procedure can be safe and effective, EUS-guided pancreatic duct drainage remains one of the most technically challenging therapeutic EUS interventions, as evidenced by the multiple considerations required for device selection and the risk of severe complications. At this time, we recommend that this procedure should only be performed in appropriately selected patients by experienced endoscopists trained in both EUS and ERP with well-trained surgical back-up available.

### INTRODUCTION

Symptomatic gallbladder disease is one of the most common conditions encountered by the gastrointestinal endoscopist. It accounts for over 225,000 hospital discharges per year and over 2 billion health care dollars spent per year.<sup>1</sup> Whereas gallbladder disease can manifest itself in a variety of forms, it is the development and presence of gallstones which is responsible for the majority of disease. Typically, the presence of gallstones can result in intermittent and acute obstruction of the cystic duct, resulting in distention of the gallbladder, ischemia, inflammation, and infection. In addition, gallstones may enter the common bile duct (CBD) via the cystic duct, leading to symptomatic biliary obstruction. Impaction of stones at the level of the major papilla, or passage across it, can result in infectious complications such as ascending cholangitis, as well as induce pancreatitis, presumably via obstruction of flow of pancreatic ductal secretions.

The development of endoscopic retrograde cholangiopancreatography (ERCP) was spurred by the need for a minimally invasive approach to manage diseases of the biliary tree. The proven safety and efficacy of ERCP led to widespread adoption of this modality as a first-line approach for biliary interventions, and has nearly eliminated the need for complex surgical approaches for managing benign biliary tract disease. As such, on a global level, management of choledocholithiasis and gallstone pancreatitis remains the most common indication for ERCP. Traditionally, surgery has been the mainstay for management of gallbladder disease. However, advances in ERCP techniques and accessories have led to the ability to safely access the gallbladder itself, thus allowing for transpapillary drainage of

the gallbladder in select patients who may not be candidates for surgery. Further advances in endoscopic ultrasound (EUS)-guided transmural access to the gallbladder have gained attention in the past 5 years and are allowing the gastrointestinal (GI) endoscopist an opportunity to be all things for all biliary disease.

This chapter will focus on the endoscopic management of cholecystitis, choledocholithiasis, and gallstone pancreatitis.

### BILIARY STONE DISEASE

Cholelithiasis refers to gallbladder stones and choledocholithiasis refers to stones in the bile ducts. Choledocholithiasis can be further classified as either primary stones, which develop within the bile ducts, or secondary stones, which occur as a result of passage from the gallbladder into the bile duct. Stones come in a variety of forms. Non-crumbling concretions greater than 2 mm in diameter are considered stones, whereas particles less than 2 mm in diameter are typically referred to as microlithiasis. Biliary sludge is a suspension of cholesterol monohydrate crystals or calcium bilirubinate granules in bile and has been implicated to act as a causative factor in acute pancreatitis and other biliary stone-related disease.<sup>2</sup>

#### Stone Types

Cholesterol stones are the most common type of stone encountered in the biliary system, accounting for approximately 80% of gallstones.<sup>3</sup> These stones form through an interplay of altered gallbladder absorption and secretion, bile stasis related to gallbladder dysmotility, cholesterol supersaturation in bile, and precipitation of calcium. Cholesterol stones are typically yellow in color

**Abstract**

Symptomatic gallbladder disease is one of the most common conditions encountered by the gastrointestinal endoscopist. Common gallstone related diseases include acute cholecystitis, choledocholithiasis, cholangitis, and gallstone pancreatitis. Endoscopic retrograde cholangiopancreatography (ERCP) has an important role in the management of gallstone-related diseases, and its indications have become broader with advancements in technology and minimally invasive techniques. Endoscopic ultrasound (EUS)-guided treatment for acute cholecystitis is an emerging therapy, particularly for patients who are poor candidates for surgery. This chapter will focus on the endoscopic management of cholecystitis, choledocholithiasis, and gallstone pancreatitis.

and nodular (Fig. 53.1). There are numerous well-established risk factors for the development of cholesterol stones. Modifiable risk factors include diet, sedentary lifestyle, rapid weight loss, obesity, and dyslipidemia, whereas nonmodifiable risk factors include ethnicity, genetics, advanced age, and female gender. In addition, certain medications have been associated with increased risk of cholesterol stones due to their effect of increasing bile concentrations of cholesterol (e.g., oral contraceptives, estrogen, clofibrate) or by leading to biliary stasis by inhibiting gallbladder contraction (e.g., octreotide). Cholesterol stones typically present as cholelithiasis or secondary choledocholithiasis.

Pigment stones account for approximately 20% of gallstones.<sup>3</sup> Pigment stones can be further classified into brown pigment stones or black pigment stones (Fig. 53.2). Brown pigment stones

**FIG 53.1** Cholesterol stones removed from the bile duct.

**FIG 53.2** Brown and black pigment stones removed from bile duct.

are largely composed of calcium bilirubinate, and contain cholesterol and fatty acid soaps as well. Major risk factors that can precipitate the formation of brown pigment stones include any process resulting in biliary stasis and/or an infectious process. Examples include primary sclerosing cholangitis (PSC), chronic biliary obstruction from non-PSC strictures, and bacterial infections of the biliary tree, such as seen in recurrent pyogenic cholangitis. Other risk factors include conditions allowing for colonization of the biliary tree with enteric bacteria, such as indwelling biliary stents, prior biliary sphincterotomy, biliary-enteric anastomosis, and periampullary diverticula. As such, brown pigment stones typically present as primary choledocholithiasis. Black pigment stones consist of calcium bilirubinate with mucin glycoproteins. They form in the gallbladder and thus present as either cholelithiasis or secondary choledocholithiasis. Major patient risk factors include a history of hemolytic disease, such as sickle cell disease, or chronic liver disease.

## CHOLECYSTITIS

The vast majority of patients with cholelithiasis will be asymptomatic, with the stones being found incidentally on imaging studies performed for other reasons. When symptomatic, gallstones typically exert symptoms by becoming lodged in the cystic duct, thereby preventing emptying of the gallbladder. Gallbladder obstruction in and of itself may produce symptoms of post-prandial right upper quadrant pain in a crescendo-decrescendo pattern, otherwise known as biliary colic. The classical presentation is a few hours after eating, at the time when the gallbladder is stimulated to contract by cholecystokinin. Acute cholecystitis occurs when the cystic duct obstruction does not spontaneously resolve, leading to the development of subsequent inflammation and infection of the gallbladder, manifesting as right upper quadrant pain, fever, and leukocytosis.

Approximately 10% of cases of cholecystitis are actually acalculous cholecystitis, in which gallstones are not implicated as the cause, and there is no cystic duct obstruction. Acalculous cholecystitis typically presents in patients who are hospitalized and severely ill. Other comorbidities associated with this disease include diabetes mellitus, end-stage renal disease, immunocompromised states, coronary artery disease, congestive heart failure, cardiac surgery, and history of trauma. Acalculous cholecystitis typically occurs as a consequence of gallbladder stasis and ischemia, leading to local inflammation, followed by secondary infection by enteric flora. In approximately 50% of cases, gallbladder necrosis and gangrene can develop with subsequent perforation, occurring in as many as 10% of patients.<sup>4</sup> Given these risks and the associated underlying comorbidities, acalculous cholecystitis is associated with mortality rates as high as 33% to 41%.<sup>4,5</sup>

Patients with gallstones may also present with choledocholithiasis and subsequent bile duct obstruction, cholangitis, and pancreatitis. These topics will be covered later in this chapter.

## Diagnosis

The clinical presentation of acute cholecystitis typically manifests as right upper quadrant abdominal pain with associated fever and leukocytosis. The classic physical exam finding is that of Murphy's sign. To assess for Murphy's sign, the examiner places their hand at the patient's right upper quadrant and palpates deeply, in the region of the gallbladder fossa under the liver edge. The patient is then asked to inspire deeply. As the diaphragm

descends on inspiration, the inflamed gallbladder will approach the examiner's hand, resulting in increased pain and discomfort and typically resulting in the patient quickly halting the inspiratory effort.

No one piece of clinical, physical, or laboratory finding is sufficient to make a diagnosis of acute cholecystitis.<sup>5</sup> Thus, imaging is typically utilized to support the clinical suspicion and diagnosis of acute cholecystitis. Transabdominal ultrasound (TAUS) is an easy, noninvasive, and cost-effective tool in the evaluation of patients with suspected cholecystitis. Typical findings of acute cholecystitis on TAUS include gallbladder wall thickening and edema, pericholecystic fluid, and distention or hydrops of the gallbladder. In addition, a sonographic Murphy's sign can be elicited with the ultrasound transducer. A large systematic review reported a sensitivity for TAUS in diagnosing acute cholecystitis 88%.<sup>7</sup> TAUS is particularly sensitive in detecting the presence of cholelithiasis, with reported sensitivity as high as 98%.<sup>8</sup> Another imaging modality commonly employed in the evaluation for possible acute cholecystitis is a nuclear scintigraphy test called cholescintigraphy. In this test, technetium-labeled hepatic iminodiacetic acid (HIDA) is injected intravenously and acts as a radiolabeled tracer. The HIDA is taken up by hepatocytes and excreted in the bile. The tracer can then be visualized as it fills the bile ducts and gallbladder. Failure of the gallbladder to fill implies cystic duct obstruction, as would be expected when cholecystitis is suspected. Multiple studies demonstrate the superiority of cholescintigraphy to TAUS in diagnosing acute cholecystitis, with reported sensitivities ranging from 90% to 97%.<sup>7,8-11</sup>

### Other Gallstone-Related Conditions

Aside from cholecystitis, gallstones can result in a number of other gallbladder conditions. When gallstones are impacted in the gallbladder neck or cystic duct, they may cause extrinsic compression of the adjacent common hepatic duct. The resulting bile duct obstruction typically presents as obstructive jaundice, with dilation of the upstream biliary tree (common hepatic duct and intrahepatic bile ducts), a condition referred to as Mirizzi syndrome. Type I Mirizzi syndrome occurs when there is external compression on the common hepatic duct, whereas Type II Mirizzi occurs when the impacted stone erodes through the gallbladder wall, creating a cholecysto-choledochal fistula (Figs. 53.3 and 53.4). Recognition or suspicion of Type II Mirizzi syndrome is key, as this condition requires surgical repair of the bile duct injury in addition to a cholecystectomy, and thus traditionally is managed via an open surgical approach.

Large gallstones (typically ≥2 cm) that erode into the luminal GI tract by means of a cholecysto-enteral fistula can lead to mechanical intestinal obstruction. Bouveret syndrome is a rare condition characterized by a large, often single, gallstone eroding through the gallbladder wall into the proximal duodenum by way of a cholecysto-duodenal fistula. Once present in the lumen, the stone can result in a mechanical gastric outlet obstruction (Fig. 53.5). Furthermore, should the stone subsequently dislodge and pass to the deep small bowel, it may again become impacted at the ileocecal valve with subsequent small bowel obstruction, thus resulting in a condition termed gallstone ileus. These conditions whereby cholecysto-enteral fistulas form are classically preceded by cholecystitis, with formation of adhesions between the gallbladder and small bowel, followed by pressure necrosis of a large gallstone, resulting in fistula formation and erosion of the stone in the GI lumen. In fact, there are numerous case

FIG 53.3 Type 1 Mirizzi syndrome.

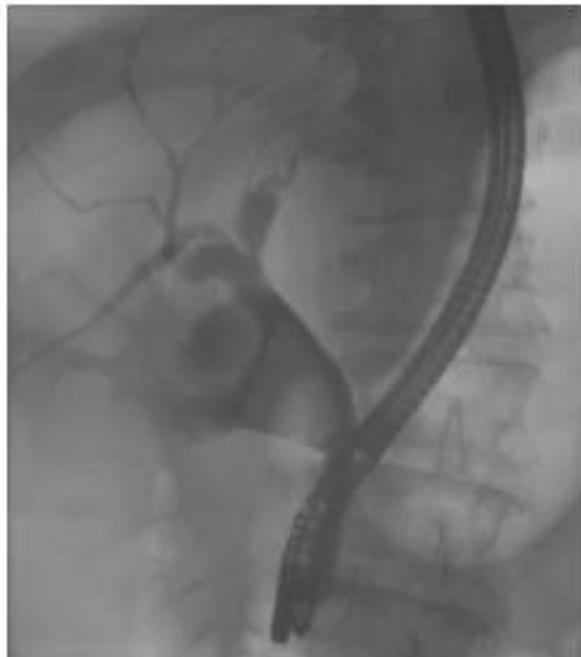

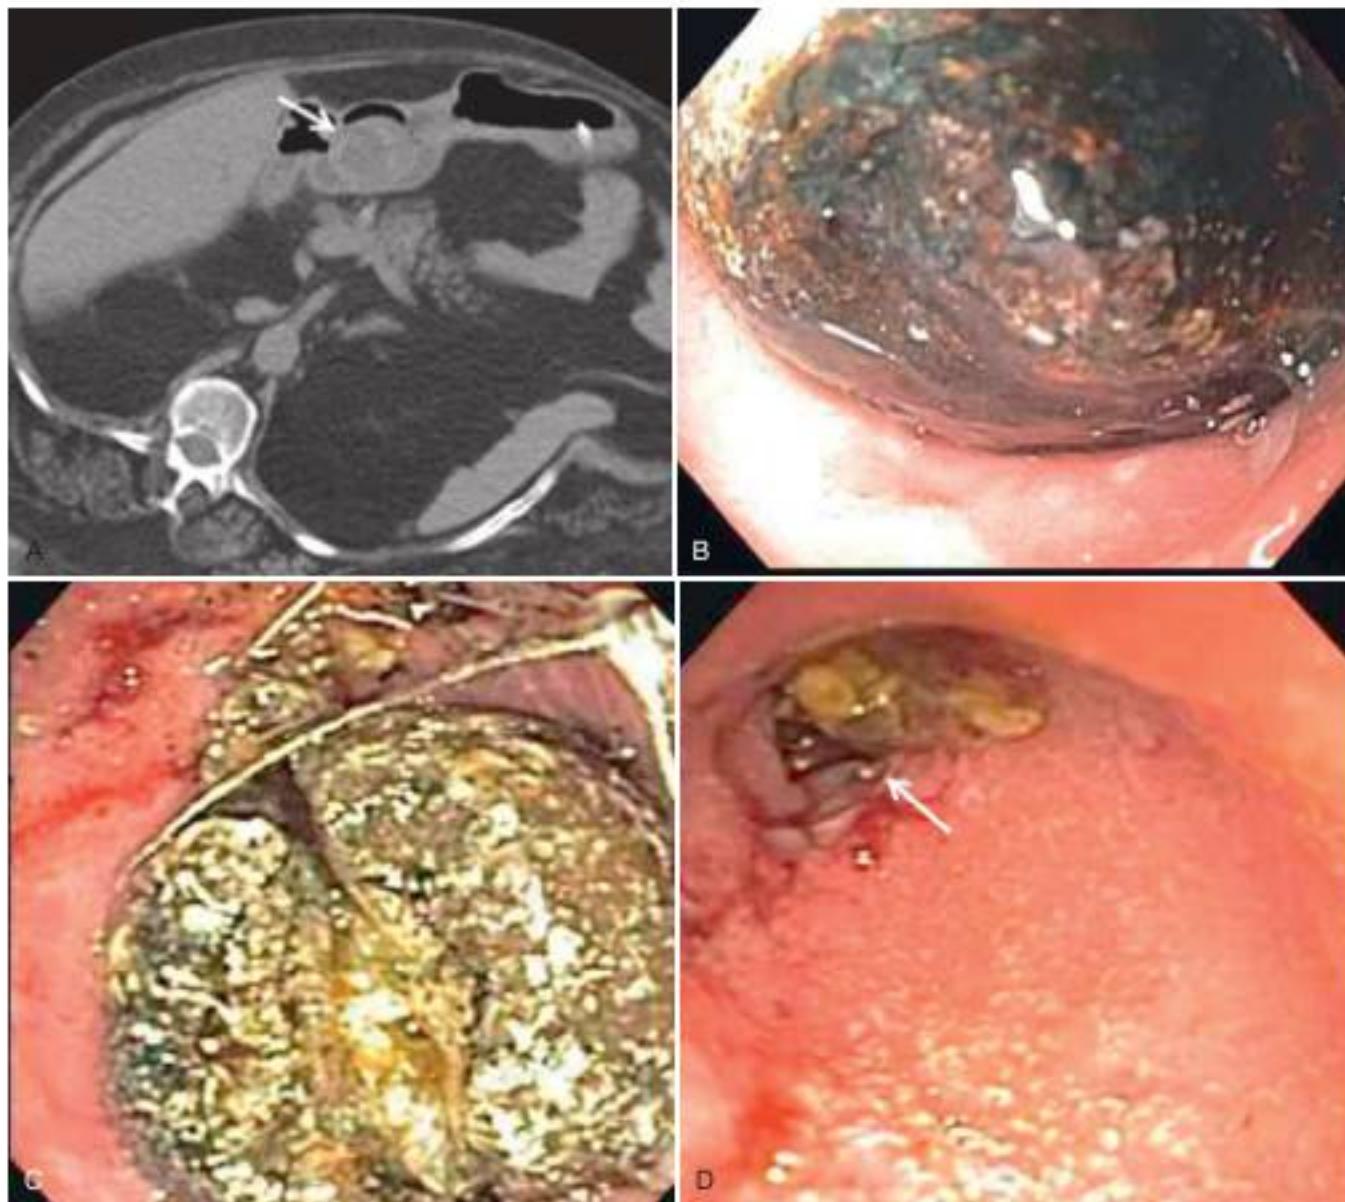

FIG 53.4 Type 2 Mirizzi syndrome.

reports of cholecysto-colonic fistula development resulting in gallstone erosion directly into the colon, with subsequent colonic obstruction.

The presence of cholelithiasis has long been recognized as a risk factor for the development of gallbladder cancer. Gallstones are present in up to 90% of cases of gallbladder cancer. Numerous epidemiologic studies demonstrate that the presence of gallstones can increase the risk for subsequent gallbladder cancer.<sup>12-14</sup> Fortunately, the incidence of gallbladder cancer remains quite low (approximately 1%) in patients with a history of cholelithiasis.<sup>15</sup> Factors that confer an increased risk of developing

**FIG 53.5** Bouveret syndrome. **A**, Computed tomography image of a gallstone impacted in the duodenal bulb (arrow). **B**, Endoscopic image of the impacted stone. **C**, Partial fragmentation of the stone following mechanical lithotripsy with basket wires around stone. **D**, Cholecystoduodenal fistula (arrow).

gallbladder cancer include stones larger than 3 cm and longer duration of cholelithiasis.<sup>16–18</sup> However, given the high prevalence of gallstones and very low incidence of gallbladder cancer, screening is currently not recommended.

#### Therapy for Cholecystitis and Symptomatic Cholelithiasis

The mainstay of treatment for the vast majority of patients with cholecystitis and symptomatic cholelithiasis is surgical cholecystectomy. Since its introduction in the mid 1980's, laparoscopic cholecystectomy has become the standard first-line treatment for cholecystitis. Laparoscopy allows for a less invasive approach, with associated fewer overall adverse events, reduced cost, decreased length of hospital stay, and increased patient satisfaction, compared to its predecessor of open surgical resection.

In the subset of patients who may not be suitable for surgery, such as those with sepsis, hemodynamic instability, or other comorbidities precluding safe administration of anesthesia, a nonsurgical approach to managing cholecystitis is required. Percutaneous drainage of the gallbladder is a technique that is widely available and effective for rapid drainage of an inflamed and/or infected gallbladder. Two percutaneous approaches exist. Percutaneous cholecystostomy involves the use of radiologic imaging (either TASU or computed tomography [CT]) to locate the gallbladder, identify an avascular window for puncture, and allow for the placement of a percutaneous drainage catheter directly into the gallbladder. Technical success rates are typically at or near 100% and clinical success rates of 78% to 95% have been reported.<sup>19–25</sup> Percutaneous drainage placement does have a number of associated downsides. Major procedural-related

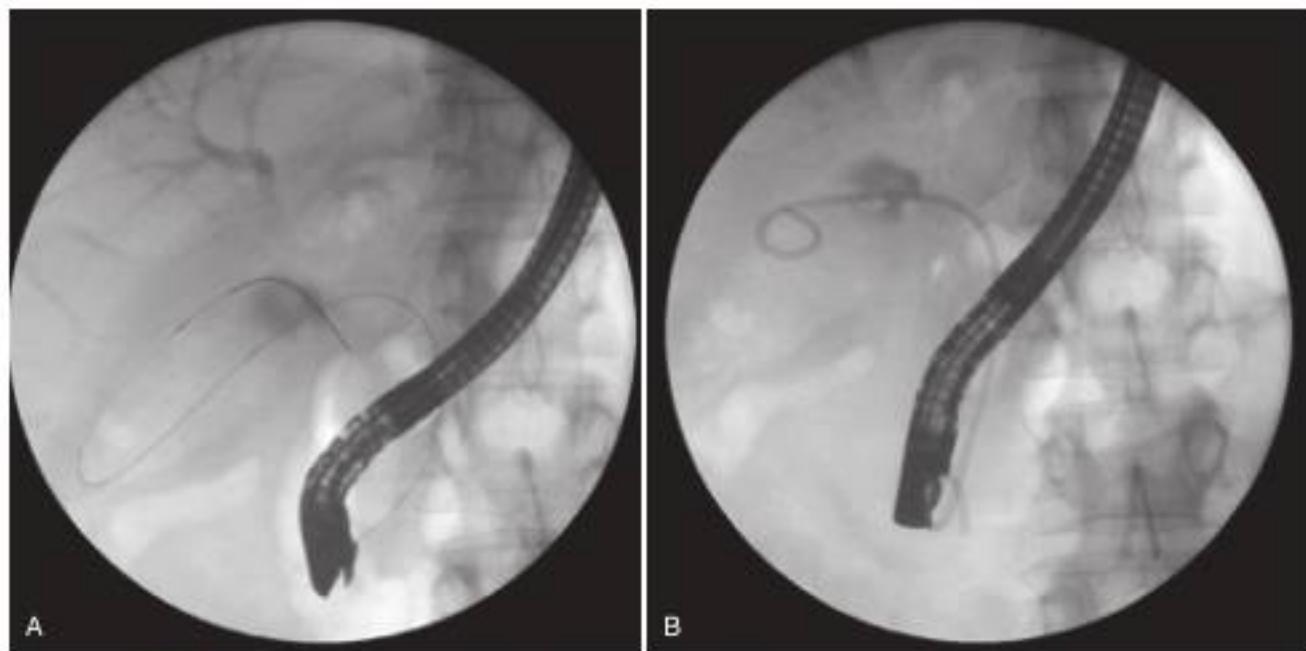

adverse events include bleeding, pneumothorax, bile peritonitis, and inadvertent displacement of the drainage catheter occur in up to 12% of patients.<sup>19–27</sup> Lastly, long-term indwelling drainage catheters are associated with diminished quality of life in patients unfit for surgery.<sup>28</sup> An alternative percutaneous approach involves simple aspiration of the gallbladder, without placement of a drainage catheter, and thus avoidance of its attendant risks. This has the advantage of being able to be performed bedside, with smaller gauge needles, fewer adverse events, and the ability to repeat the intervention if necessary. Overall, the percutaneous approach to emergent drainage of the gallbladder allows for stabilization of the severely ill patient, as well as resolution of local inflammation in severe cases, thus potentially avoiding the need for emergency surgery in high-risk individuals and/or avoidance of open surgical resection in patients with extensive pericholecystic inflammation.

A number of endoscopic options exist as an alternative to the traditional surgical or percutaneous approaches to managing cholecystitis and symptomatic cholelithiasis. These include transpapillary drainage of the gallbladder, EUS-guided transmural drainage of the gallbladder, and natural orifice transluminal endoscopic surgery (NOTES).

Endoscopic transpapillary nasogallbladder drainage involves the use of ERCP to gain transpapillary wire access to the gallbladder, followed by placement of a nasogallbladder tube, allowing for both drainage and irrigation of the infected gallbladder. The technique involves standard biliary cannulation, followed by selective guidewire cannulation of the cystic duct and the gallbladder. Given the varied locations of the cystic duct take-off, as well as the small caliber and tortuosity of the cystic duct, a variety of tools and techniques have been described to successfully achieve gallbladder access. These include the use of standard cannulating catheters, standard sphincterotomes, and sphincterotomes with the ability to rotate and/or "swing" in opposite directions to

allow for directed wire placement both into the cystic duct orifice, as well as navigating the wire across the cystic duct.<sup>29–31</sup> There is no favored guidewire size, as the use of 0.035-, 0.025-, and 0.018-inch guidewires with a hydrophilic tip have been reported.<sup>28–32</sup> Itoi et al (2010) reported using either a 0.025- or 0.018-inch guidewire in patients with left-sided distribution or deformation of the cystic duct.<sup>29</sup> Once gallbladder access is achieved, a 5-Fr or 7-Fr nasogallbladder drain can be placed over the wire. Multiple large retrospective series have been published, reporting a technical success rate of 71% to 89% and a clinical success rate of 69% to 89%.<sup>33–38</sup> Two prospective series demonstrated a technical success of 82% to 91.9% and a clinical success of 70.6% to 87%.<sup>31,40</sup> Overall, adverse events associated with endoscopic transpapillary nasogallbladder drainage occur in up to 14% of cases.<sup>30</sup> Reported adverse events associated with this technique include cystic duct perforation, gallbladder perforation, cholangitis, sepsis, inadvertent removal of the nasogallbladder drain, as well as post-ERCP pancreatitis, and sphincterotomy-related bleeding.<sup>30,33,34–45</sup>

Endoscopic transpapillary gallbladder stenting is similar to nasogallbladder drainage, with the exception that it has the advantages of internal placement of drainage tubes, allowing for physiologic drainage, and no risk of inadvertent dislodgement of the drain (Fig. 53.6). Wire guided cannulation technique is similar to that for nasogallbladder drainage. Most series report the use of 5-Fr or 7-Fr double-pigtail plastic stents. Glessing et al (2015) described the use of the Johlin pancreatic wedge stent (Cook Medical, Bloomington, IN), which is made of a softer polyurethane material compared to standard double-pigtail stents.<sup>41</sup> In addition to being softer, these stents are fenestrated, available in 8.5-Fr and 10-Fr sizes, as well as lengths up to 22 cm. Multiple large retrospective series report technical success rates ranging from 90% to 100%, and clinical success rates of 64% to 100%.<sup>30,32,42–45</sup> Lee et al (2011) reported their prospective

**FIG 53.6** **A**, Endoscopic transpapillary gallbladder drainage by selective cannulation and placement of a guidewire across the cystic duct into the gallbladder lumen, followed by **B**, placement of a transpapillary double pigtail stent.

experience of transpapillary gallbladder stent placement in 29 patients, using a 7-Fr × 15-cm double pigtail stent. Technical success was 79% and clinical success was 100% in the group with successful stent placement.<sup>40</sup> Median follow-up was 586 days, during which time 20% of patients developed late adverse events including distal stent migration, cholangitis, and recurrent biliary pain. Overall, adverse events associated with gallbladder stenting have been reported in up to 16% of cases.

Two prospective randomized trials compared endoscopic transpapillary nasogallbladder drainage to transpapillary gallbladder stenting in patients with acute cholecystitis. Itoi et al (2015) studied 73 patients, reporting a clinical success of 86.5% in the nasogallbladder drain group compared to 77.8% in the stenting group ( $p > 0.05$ , nonsignificant [NS]), in their intention-to-treat analysis.<sup>39</sup> Adverse events included one post-sphincterotomy bleed and one post-ERCP pancreatitis in the nasogallbladder drain group, and one post-ERCP pancreatitis in the stent group. The authors did note patients receiving the gallbladder stent reported a significantly lower patient discomfort score compared to those receiving the nasobiliary drain. Yang et al (2016) studied 35 patients, demonstrating a clinical success rate of 70.6% in the nasogallbladder drain group compared to 83.3% in the stenting group ( $p > 0.05$ , NS), in their intention-to-treat analysis.<sup>41</sup> Adverse events included one cystic duct perforation, one severe post-ERCP pancreatitis, and one inadvertent drain pull in the nasogallbladder drain group, and one mild post-ERCP pancreatitis in the stent group.

Overall, in expert hands, endoscopic transpapillary nasogallbladder drain placement and gallbladder stent placement appear to be equivalent in terms of technical and clinical success rates. One potential downside to gallbladder stenting is that gallbladder irrigation to dissolve/remove blood and debris is not feasible, unlike in nasogallbladder drain placement. As such, this can potentially increase the risk of subsequent recurrence of cholecystitis and biliary symptoms. Recurrent cholecystitis after transpapillary gallbladder stenting has been reported to occur in 0% to 11.8% of patients.<sup>38,42–45</sup> One potential strategy to minimize this risk is to place a nasogallbladder drain at initial endoscopy to allow for optimal drainage, irrigation, and possibly clearance of debris in the gallbladder, and then convert this drain to a stent once the acute inflammation resolves.

One advantage of transpapillary gallbladder stents is that they can remain in place indefinitely. In contrast to plastic CBD stents, which should be changed every 3 months to decrease the risk of cholangitis secondary to stent occlusion, there is no evidence that routine drainage of transpapillary gallbladder stents decreases the risk for recurrent biliary type pain or acute cholecystitis. Our practice has been to change the stents on an as-needed basis for the recurrence of symptoms regardless of etiology (calculous vs. acalculous). Additionally, despite lack of prospective data demonstrating an advantage of biliary sphincterotomy, we routinely perform biliary sphincterotomy in conjunction with stent placement with the thought that this may facilitate biliary drainage around the stent even in the setting of stent occlusion.

One potential challenge with attempting transpapillary gallbladder drainage pertains to the potential difficulty in achieving gallbladder access in the setting of cholecystitis. This may be secondary to the inability to identify the cystic duct on cholangiogram, and/or due to cystic duct obstruction and inability to advance a wire into the gallbladder. An emerging solution to this conundrum is the use of direct cholangioscopy to identify

the cystic duct takeoff and simultaneously guide placement of a wire across the cystic duct into the gallbladder. A handful of case reports and one case series have demonstrated the feasibility and success of this technique using single-operator cholangioscopy systems.<sup>31,38–32</sup>

The next evolutionary step in the endoscopic management of cholecystitis has been the development of EUS-guided transmural gallbladder drainage (EUS-GBD). First described in 2007, this technique mirrors that of EUS-guided transmural pseudocyst drainage and has the advantages of placement of internalized, larger diameter stents.<sup>33</sup> EUS is used to first locate the gallbladder, followed by EUS-guided puncture of the gallbladder, typically with a 19-gauge needle in a transgastric or transduodenal approach. A guidewire can be placed through the needle into the gallbladder lumen. Once the needle is removed, various devices such as bougies, balloons, or electrosurgical knives can be placed over the guidewire to dilate the newly created cholecysto-gastric fistula or cholecysto-duodenal fistula. Finally, biliary endoprostheses such as double pigtail stents, covered metal biliary stents, or dedicated lumen-apposing metal stents (LAMS) can be placed across the tract to allow for gallbladder drainage into the GI lumen.

Initial reports described the placement of nasogallbladder drains and/or plastic double-pigtail stents across the fistulous tract.<sup>33–35</sup> One early concern with this technique however, is that unlike most pancreatic pseudocysts that are amenable to transmural endoscopic drainage, the gallbladder is typically not adherent or apposed to the GI lumen wall. This poses the potential risk of leakage of pus and bile around the stents into the peritoneum, as well as risk of stent migration as the two lumens move away from each other with peristalsis and respiration. As such, to mitigate this risk, the use of covered metal biliary stents has become the favored approach. Widmer et al (2014) described the use of a fully covered self-expanding metal stent with antimigratory fins in three patients with symptomatic gallbladder obstruction secondary to underlying pancreatic cancer.<sup>36</sup>

The true breakthrough in EUS-GBD drainage came with the development of dedicated endoprostheses designed specifically for transmural drainage. These devices, dubbed LAMS, are short (1 cm long) and have dumbbell shaped flanges. Upon expansion, the two flanges catch and appose their respective lumen walls, allowing for fistula development. Currently available LAMS are fully covered, thus preventing spillage of luminal contents across the tract. In addition, they are specifically designed to fit through the working channel of a therapeutic linear echoendoscope. Lastly, the lumen of the LAMS is wide enough (10 mm or 15 mm) to allow insertion of standard endoscopes through the stent and into the gallbladder lumen, facilitating further intervention such as irrigation, debridement, and stone removal.

In 2011, Jang et al reported their experience with a modified covered self-expandable metal stent (SEMS) (BONA-AL Standard Sci Tech Inc, Seoul, Korea).<sup>37</sup> This stent is a partially covered metal stent, 10 mm in diameter, and 4 to 7 cm in length. The flares on the end of each stent were modified by enlarging them to 22 mm external diameter and placing them at a 90-degree angulation to prevent migration once in place. In 15 patients with acute cholecystitis, technical success rate was reported in 10/10 cases from a transgastric approach, and 5/5 cases from a transduodenal approach. All patients had a clinical response as well. Two patients experienced pneumoperitoneum. Choi et al (2014) reported long-term outcomes in 63 patients who underwent gallbladder drainage with this device.<sup>38</sup> Technical and clinical

success was reported in 98% of cases. Adverse events included one patient with a perforation, and two patients with pneumoperitoneum. Long-term outcome data was available in 56 patients, with a median follow-up of 275 days. There was no recurrence of biliary symptoms or cholecystitis in 54/56 (96%) cases over this time frame. Late adverse events were encountered in four (8.4%) patients, which included stent migration and stent occlusion. Overall, cumulative stent patency was 86% at 3 years. The authors concluded that EUS-GBD with a SEMS for acute cholecystitis showed excellent long-term outcomes and may be considered a viable definitive treatment in patients who are not surgical candidates or are suffering from advanced malignancy. Of note, the BONA-AL stent used in these two studies is not available in the United States.

The Axios stent (Boston Scientific, Marlborough, MA) is the only LAMS device available in the United States. The standard "cold" Axios device comes preloaded on an EUS needle-like delivery catheter. The standard technique for transmural gallbladder stent placement involves the identification of the gallbladder on EUS, transduodenal or transgastric puncture of the gallbladder using a 19-gauge needle, followed by passage of a 0.035-inch Jagwire through the needle and into the gallbladder lumen (Fig. 53.7). The needle is then exchanged over the wire, leaving the wire in the gallbladder. The cholecysto-enteric fistula is then dilated, typically with a 6-Fr bougie dilator and/or a 4 to 6 mm biliary dilating balloon. Finally, the Axios delivery catheter is advanced over the wire, through the accessory channel of the therapeutic linear echoendoscope, and locked into place, similar to a standard EUS needle. The delivery catheter is then advanced across the fistulous tract under EUS guidance, followed by stepwise deployment of the inner distal flange, and then the outer proximal flange. Following deployment, the stent can be dilated to its final diameter using standard CRE dilating balloons (Boston Scientific); however this step is not always necessary, as the LAMS is a self-expanding type stent (Video 53.1).

Small, retrospective case series have been published describing the use of the Axios stent for EUS-GBD. A 2013 report demonstrated technical success in 11/13 (84%) and clinical success in 11/11 (100%) patients.<sup>50</sup> Ten of the eleven cases were transgastric. In 4/11 (36%) of patients, a tubular SEMS was placed in a coaxial fashion through the LAMS to ensure adequate drainage. During the same session, an endoscope was inserted through the stent lumen into the gallbladder to perform lavage and/or stone

extraction. A total of two adverse events were noted in this series, one patient with hematochezia and another with right upper quadrant abdominal pain. There was no recurrence of cholecystitis during a median follow-up of 100 days. Irani et al reported on a multicenter experience in 15 patients.<sup>51</sup> In this series, a transduodenal approach was favored in 14 cases, compared to one transgastric deployment. Technical success was 14/15 (93%) and clinical success 100%. One adverse event (fever) was noted. During a median follow-up of 160 days there was recurrence of cholecystitis in this group. It is noted that in six patients, an additional double-pigtail plastic stent was deployed through the LAMS to decrease the risk of hyperplastic tissue overgrowth at either end of the stent.

Walter et al (2016) reported the results of a multicenter prospective trial of the Axios stent in 30 patients with acute cholecystitis.<sup>52</sup> Technical success was achieved in 27/30 (90%) of patients and clinical success in 26/27 (96%) patients. Recurrent cholecystitis due to stent obstruction was encountered in 7% of patients. Adverse events were encountered in 15/30 (50%) of patients, but the authors state that only 4 (13%) were possibly related to the stent or procedure. The 30-day mortality was 17% and the overall mortality was 23%. The authors state that 30-day mortality rate is comparable with that of percutaneous gallbladder drainage (15%). Their conclusion was that the high overall rate of adverse events was attributable to the overall morbid patient population of their study, as none of the patients were considered surgical candidates due to underlying comorbidities.

In 2015, a modified version of the Axios stent was released with an electrocautery-enhanced tip. By allowing for direct puncture across lumen walls without the need for prior tract dilation, this "hot" Axios device allows for essentially a one-step delivery system without the need for multiple device exchanges (Video 53.2). As such, the electrocautery-enhanced Axios can be placed without a guidewire.

Given the relatively widespread adoption of EUS-guided transmural pancreatic fluid collection drainage, the prospect of routine EUS-GBD with LAMS holds promise. However, the gallbladder is a hollow organ rather than a collection and thus once the inflammatory/infectious issues are resolved it will not shrink or collapse as would be expected in a pancreatic fluid collection. As a result, there are unique issues related to LAMS use. One issue is that of impaction of the gallbladder and/or stent with food, particularly when a transgastric approach is

**FIG 53.7** Endoscopic ultrasound-guided gallbladder drainage. **A**, A lumen-apposing metal stent is inserted under EUS-guidance into the gallbladder via **B**, a transgastric approach, with **C**, subsequent drainage of purulent bile.

utilized. Mechanical friction of the LAMS against the mucosal surface of the gallbladder can induce bleeding (Todd Baron, personal communication). Epithelial overgrowth of the intraluminal portion of the LAMS has been reported as well.<sup>63,64</sup> This "buried LAMS" phenomenon can result in stent occlusion and recurrent cholecystitis. In addition, this may result in technical difficulty in removing the buried stent.<sup>62</sup> It is postulated that buried LAMS is most likely to occur when the stent is placed in the prepyloric antrum, as gastric motility in this location may result in traction on the stent and a hypertrophic tissue reaction, similar to that seen with the formation of inflammatory polyps of the stomach.<sup>65</sup> One maneuver that has become adopted at some centers to minimize the risk of buried LAMS is to place one or two double pigtail stents inside the lumen of the LAMS. This may also decrease the risk of bleeding or food impaction.

Perhaps the biggest question remaining regarding the technique of EUS-GBD with LAMS is whether the creation of a cholecystoduodenal fistula or cholecysto-gastric fistula will have a major impact on future cholecystectomy in any one patient.<sup>64</sup> It has been shown that the transmural placement of a small caliber 5-Fr drainage tube did not result in any significantly higher need for open cholecystectomy (9%) compared to patients undergoing percutaneous gallbladder drainage (12%, NS).<sup>66</sup> However, LAMS are much larger in diameter (10 mm or 15 mm) and will produce a larger fistula. As such, it remains unclear if the creation of a larger fistula will lead to difficulties in performing laparoscopic resection, or if new, unanticipated challenges will be created. Baron et al (2015) reported a case of a patient with end-stage liver disease who underwent transduodenal placement of a 10-mm LAMS for management of acute cholecystitis.<sup>67</sup> Five months later, when the patient underwent liver transplantation, a large duodenal defect was encountered upon take-down of the fistula and stent. Despite oversewing the defect, placing an omental patch, leaving in surgical drains, and keeping the patient on nasogastric tube suction for 2 weeks, a leak and abscess developed at the site. Ultimately, a large hepatic artery pseudoaneurysm developed at the site of the abscess necessitating aggressive vascular intervention and ultimately surgery.<sup>67</sup>

EUS-GBD remains an emerging technique. Regardless of whether plastic stents, SEMS, or LAMS are chosen, the overall adverse event rate remains moderate at 12%.<sup>68</sup> In a 2016 multicenter retrospective study involving 90 patients with acute cholecystitis, EUS-GBD had similar technical and clinical success with percutaneous transhepatic gallbladder drainage.<sup>69</sup> It should be emphasized that EUS-GBD should be reserved as an option for nonsurgical candidates. Optimal patient selection—ideally within a multidisciplinary approach involving surgeons, endoscopists, and interventional radiologists—remains key in predicting the overall success of this intervention.

The final frontier in the minimally invasive approach to acute cholecystitis is that of natural orifice transluminal endoscopic surgery, or NOTES. In this technique, the abdominal cavity is accessed through a small incision of an internal organ, such as the stomach, rectum, or vagina, and the endoscopic surgical tools are advanced through this incision. Thus far, this technique has been performed in a limited number of centers throughout the world, with the majority being performed via a hybrid transvaginal approach with the use of a small transumbilical port to facilitate visualization. The major potential advantages of a NOTES approach are less pain, faster recovery time, and decrease in risk of wound healing, as well as the avoidance of a

visible scar.<sup>70</sup> However, two prospective trials comparing NOTES cholecystectomy to laparoscopic cholecystectomy failed to demonstrate any advantage to NOTES in terms of postoperative pain, recovery, length of stay, or complications.<sup>71,72</sup> Further studies are needed to better identify the role of NOTES in the management of gallbladder disease.

## CHOLEDOCHOLITHIASIS

### Epidemiology/Incidence/Risk Factors/Pathophysiology

Choledocholithiasis refers to the presence of stones within the extrahepatic bile duct. This is a common clinical problem, with an estimated incidence of 5% to 20% at the time of cholecystectomy in patients with cholelithiasis.<sup>73</sup> Choledocholithiasis can be primary or secondary. Secondary stones are those that originate within the gallbladder and migrate into the CBD via the cystic duct. In Western countries, secondary stones are much more common than primary bile duct stones. Primary stones refer to stones that form directly within the bile duct. Risk factors for primary bile duct stones include IgA deficiency, chronic infections of the biliary tree, and biliary dyskinesia. Primary bile duct stones can also occur in patients who have undergone biliary sphincterotomy, particularly in patients who have sphincterotomy stenosis. In this setting, duodenal contents can reflux into the bile duct and serve as a nidus for stone formation. Primary bile duct stones are usually soft and brown.

### Symptoms

Patients with choledocholithiasis can be asymptomatic. Symptomatic patients can present with liver function test abnormalities, jaundice, cholangitis, or gallstone pancreatitis, with severity ranging from mild abdominal pain to sepsis.

Choledocholithiasis can cause ascending cholangitis, or bacterial infection within the biliary tree which develops behind an obstructing stone in the distal bile duct. The classic presentation for cholangitis is Charcot's triad (fever, right upper quadrant pain, and jaundice) and Reynold's pentad (renal dysfunction and mental status changes) which indicates more severe disease.

The Tokyo Guidelines (TG) for the management of cholangitis provide diagnostic criteria consisting of signs of systemic infection (fever, rigors, laboratory evidence of inflammatory response), cholestasis, and imaging findings consistent with biliary obstruction (biliary duct dilation, stone, stricture). The diagnosis of cholangitis is "suspected" in patients with evidence of systemic infection and either abnormal liver enzymes or imaging suggesting biliary obstruction. The diagnosis of cholangitis is considered "definite" in patients with evidence of systemic infection and both laboratory and imaging evidence for biliary obstruction. These were initially reported in 2007 and then revised in 2013. Within the retrospective cohort of patients with ascending cholangitis, Charcot's triad had excellent specificity (95%) but poor sensitivity (26%) for the diagnosis of cholangitis. This compared to TG13 criteria, which were 92% sensitive and 78% specific for the diagnosis of ascending cholangitis.<sup>74</sup>

Chronic or recurrent choledocholithiasis is frequently associated with chronic infection and inflammation within the bile ducts. This can predispose an individual to strictures within the biliary tree, or secondary biliary cirrhosis. It is also a risk factor for cholangiocarcinoma, presumably due to chronic inflammation progressing to neoplasia. Choledocholithiasis can also cause gallstone pancreatitis, which will be discussed in more detail later in this section.

### Diagnosis

The diagnosis of choledocholithiasis can be suspected on the basis of abnormal liver enzymes. Early in the course of the disease, patients with choledocholithiasis may have elevations in transaminases only. Later in the course, patients may develop an obstructive pattern with elevations in direct bilirubin and alkaline phosphatase. A meta-analysis revealed that elevated bilirubin was 69% sensitive and 88% specific for choledocholithiasis, and elevated alkaline phosphatase was 57% sensitive and 86% specific.<sup>75</sup> Given the wide range of liver enzyme abnormalities which can occur in patients with choledocholithiasis, abnormal liver function tests (LFTs) are not specific for the diagnosis. However, the negative predictive value for bile duct stones in patients with normal liver enzymes is 97%.<sup>76</sup>

In cases of suspected choledocholithiasis, the least expensive and most available imaging modality is TAUS. TAUS is very specific for choledocholithiasis, but sensitivity is limited. In a meta-analysis of five studies, the sensitivity and specificity for choledocholithiasis was 73% and 91%, respectively.<sup>77</sup> The distal CBD may be obscured by intervening bowel and artifact from bowel gas or not visualized at all due to body habitus, which further decreases the sensitivity of the test. CBD stones appear as round, shadowing structures within the bile duct. In the setting of nonvisualization of the distal bile duct, the presence of bile duct dilation of greater than 6 mm is suggestive of distal obstruction, and the probability of a stone increases with increasing duct diameter.<sup>78</sup>

A strategy to assign risk of choledocholithiasis was created based on laboratory and TAUS parameters was proposed by the American Society for Gastrointestinal Endoscopy (ASGE) in a 2010 guideline.<sup>79</sup> The presence of a CBD stone on US, bilirubin greater than 4, and clinical signs and symptoms of cholangitis are considered "very strong" predictors. "Strong" predictors include a dilated CBD (> 6 mm with gallbladder in situ) and bilirubin 1.8–4. "Moderate" predictors include age greater than 55 or any abnormal liver biochemistry. Patients are considered high risk for choledocholithiasis in the presence of any very strong predictor or presence of both strong predictors. Patients are considered low risk if none of the predictors is present. All others are considered intermediate risk.

Patients who are considered intermediate risk should undergo additional studies prior to therapy directed at biliary drainage. The most commonly used modality for intermediate risk patients is magnetic resonance cholangiopancreatography (MRCP). MRCP allows for three-dimensional reconstruction of the bile ducts and is very sensitive and specific for choledocholithiasis; however, the sensitivity of MRCP decreases for stones greater than 6 mm.<sup>79</sup> EUS is the most sensitive test for the detection of choledocholithiasis with greater than 95% sensitivity and 100% specificity<sup>80</sup> (Fig. 53.8). A decision analysis suggested that for patients with low (< 40%) probability of choledocholithiasis, MRCP should be the test of choice, but in cases where choledocholithiasis is suspected despite a negative MRCP, EUS should be performed; for patients with a 40% to 91% probability, EUS should be performed, preferably in a setting where same-session ERCP can be performed if EUS is positive. Patients with a higher probability should undergo ERCP.<sup>81</sup> However, there are data suggesting that this guideline overexposes patients to ERCP with an overall accuracy of 63%.<sup>82,83</sup> Therefore it is important to recognize that current guideline lacks accuracy and should not replace clinical judgment. Additionally, large, multicenter studies are needed to

**FIG 53.8** Endoscopic ultrasound identification of a common bile duct stone, represented by a bright, hyperechoic focus with shadowing.

further clarify appropriate risk stratification in patients suspected of choledocholithiasis.

In patients with an intact gallbladder suspected of having choledocholithiasis, cholecystectomy with intraoperative cholangiogram (IOC) or intraoperative ultrasound (IOUS) can be performed instead of MRCP or EUS, though practice varies among surgeons and institutions. These modalities can be useful in the detection of retained CBD stones and for bile duct injury. Data from a randomized controlled trial suggest that initial cholecystectomy with IOC may be preferred to endoscopic bile duct assessment and clearance (via EUS or ERCP) in patients with intermediate probability of having common duct stones with regard to length of stay, number of bile duct evaluations, without change in morbidity.<sup>84</sup> A prospective blinded study among patients with a positive IOC found that EUS had a positive predictive value (PPV) of 95% in detecting choledocholithiasis, and only 65% of patients who had a suspicious IOC had CBD stones at the time of ERCP.<sup>85</sup> Thus, in patients referred for a "positive" IOC, a reasonable approach, particularly in asymptomatic patients, is to perform an EUS to confirm the presence of choledocholithiasis prior to performing ERCP.

There is an approximate 5% to 15% incidence of silent choledocholithiasis at the time of cholecystectomy. Routine evaluation for choledocholithiasis intraoperatively, either with IOUS or IOC, is institution-dependent. However, data from a cost-analysis study, with a set incidence of choledocholithiasis of 9%, found that IOUS was more cost-effective than IOC or a watchful waiting approach.<sup>86</sup> Additionally, even among patients who undergo preoperative ERCP, approximately 12% will have retained stones on IOC during subsequent cholecystectomy.<sup>87</sup>

In select patients, especially in an increasingly cost-conscious environment, there may also be a role for no biliary imaging. In a study of 668 patients presenting with elevated but downtrending LFTs who did not undergo pre- or intraoperative biliary imaging and underwent same-admission cholecystectomy, only 38 required postoperative imaging and only 22 had definite choledocholithiasis.<sup>87</sup>

## Treatment

### ERCP

Patients with documented choledocholithiasis or those at high risk for choledocholithiasis based on the criteria described previously should have an ERCP for further evaluation. Typically, this is performed in conjunction with biliary sphincterotomy and stone extraction. For smaller stones, it is possible to perform ERCP with biliary sphincteroplasty instead of biliary sphincterotomy,<sup>33</sup> but this is generally discouraged due to the concern for possible higher risk for post ERCP pancreatitis (PEP).

In the majority of cases of choledocholithiasis, biliary sphincterotomy followed by use of an extraction balloon or retrieval basket is sufficient treatment (Fig. 53.9). Biliary sphincterotomy treats the principal barrier keeping the stone within the bile duct. Sphincterotomy should be complete, which decreases the risk for subsequent sphincterotomy stenosis and facilitates stone extraction. A blended current is usually used for biliary sphincterotomy, and there are no data to support the use of pure cut versus blended current. However, pure cut may increase the risk for postsphincterotomy bleeding but decrease the risk for PEP when compared to blended current. When performing extraction of multiple stones, the most distal stone should be removed first, progressing proximally. During stone extraction, it is useful to periodically inject contrast to identify the next stone to target for removal. Attempts at removing a stack of stones on one sweep can result in impaction of stones in the distal duct which can decrease the success of stone clearance and increase complications. There may be an advantage of using baskets instead of balloons in dilated bile ducts with multiple stones because balloons may slip by the stones.

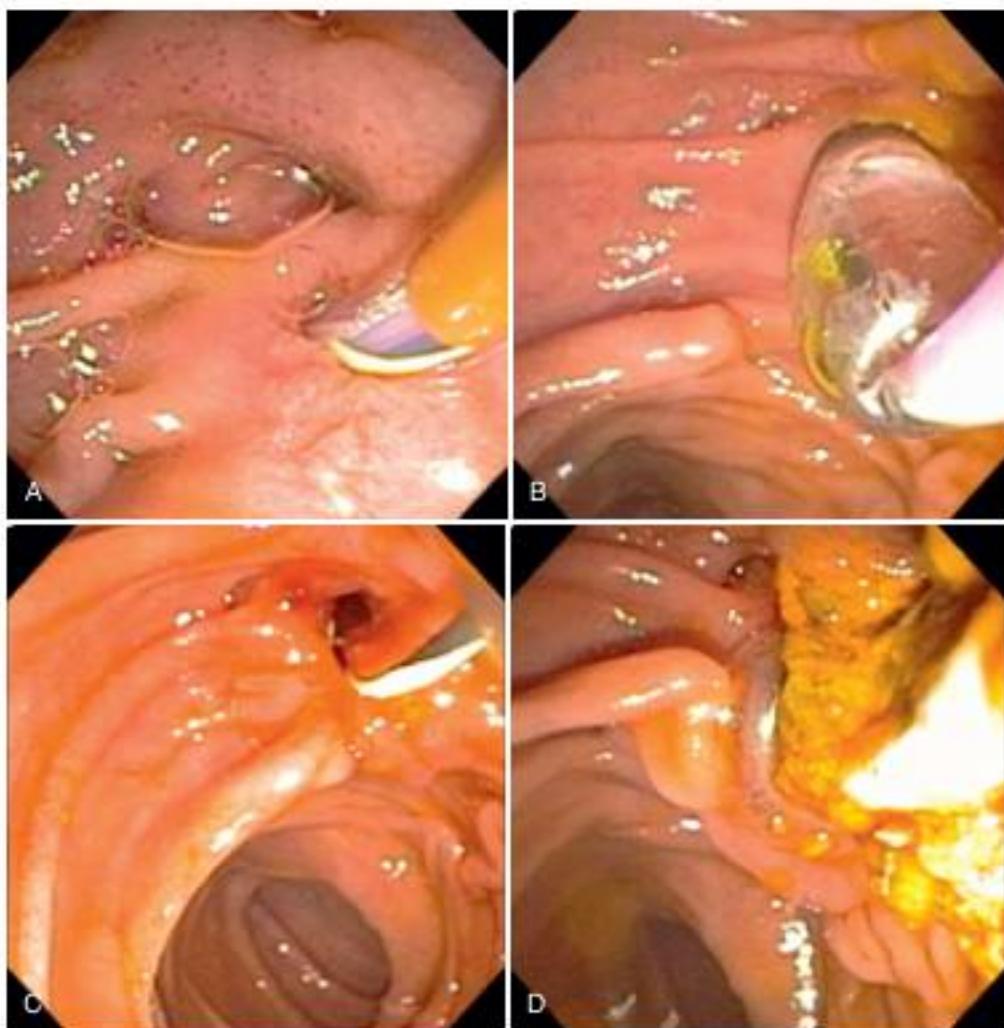

For larger stones (generally > 15 mm) or in which a stone is larger than the distal duct, biliary sphincterotomy and sweep may be insufficient<sup>34</sup> (Fig. 53.10). There are several therapeutic options for larger bile duct stones, including large balloon sphincteroplasty,<sup>35,36</sup> mechanical lithotripsy, and cholangioscopy-directed stone fragmentation techniques such as electrohydraulic lithotripsy (EHL) and laser lithotripsy. Typically, these can and should be performed at the same setting, but one may choose the option of placing a biliary stent to ensure biliary drainage and refer to a tertiary care facility for more advanced techniques.

Balloon sphincteroplasty following biliary sphincterotomy is extremely effective and is the least labor- and time-intensive

**FIG 53.10** Large intraductal bile duct stone with distal narrowing of the common bile duct.

therapeutic maneuver for management of large bile duct stones. An over-the-wire dilation balloon should be used to ensure its proper placement within the bile duct. The choice of balloon size should be based on the diameter of the upstream duct and size of the stone. Dilation is performed under both endoscopic and fluoroscopic guidance to visualize both the apex of the sphincterotomy and waist of the balloon (Fig. 53.11). The balloon should be kept inflated until obliteration of the waist. There are data suggesting that for an intact papilla, the longer the balloon is inflated, the lower the risk for PEP,<sup>37</sup> though usually dilation to balloon effacement is sufficient. The balloon is then carefully deflated and withdrawn over the wire while evaluating for bleeding and perforation. The stones are then swept into the duodenum through the sphincteroplasty with an extraction balloon or basket (Video 53.3). A meta-analysis of six trials, including 835 patients,

**FIG 53.11** **A** and **B**, Performance of endoscopic papillary balloon dilation on a stenotic papilla to facilitate **C** and **D**, removal of large common bile duct stone burden.

concluded that biliary sphincterotomy plus large balloon sphincteroplasty was associated with fewer complications than biliary sphincterotomy alone.<sup>33</sup>

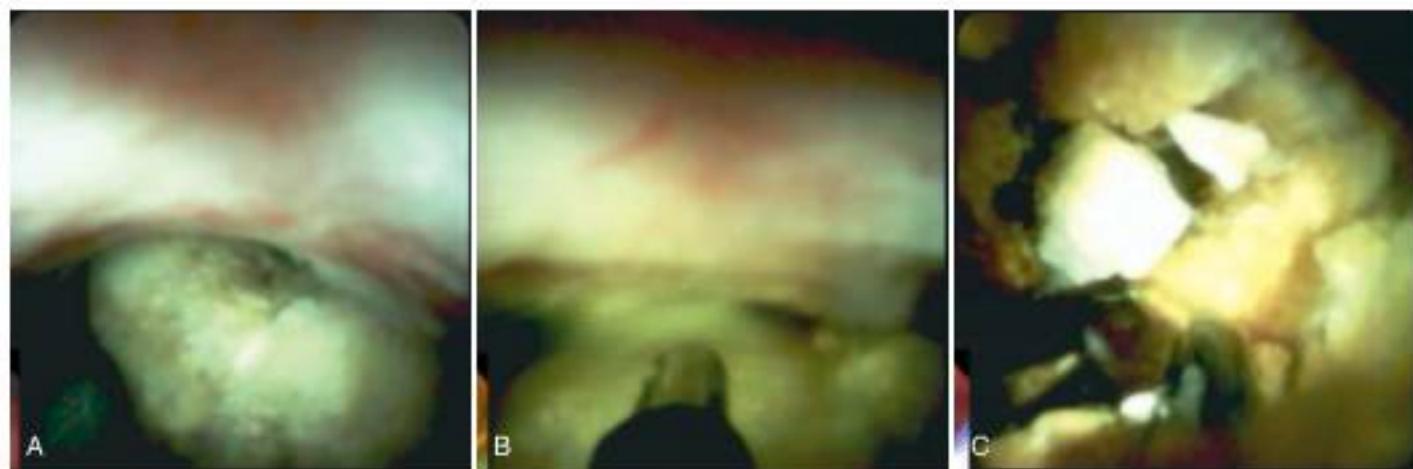

Usually, large balloon sphincteroplasty is performed following biliary sphincterotomy. However, a single retrospective study involving a small number of patients suggested that duct clearance could be achieved via balloon sphincteroplasty alone without biliary sphincterotomy, suggesting that biliary sphincterotomy is not mandatory, even in the management of large stones.<sup>34</sup> However, there are no prospective randomized data, and biliary sphincterotomy is routine for management of choledocholithiasis in clinical practice. Additionally, failure to perform sphincterotomy may increase the risk for PEP, which may be severe. In the setting of planned balloon sphincteroplasty for management of large bile duct stones, some experts recommend leaving room at the apex of the sphincterotomy prior to balloon sphincteroplasty. Doing so may decrease the risk of retroperitoneal perforation should there be extension of the sphincterotomy on performing balloon sphincteroplasty.

Mechanical lithotripsy involves use of large stone retrieval baskets attached to a crank mechanism. These are available either through the scope or outside of the scope, the former being used more commonly in clinical practice. Some retrieval baskets do

not come prepackaged with the lithotripter components but are lithotripter compatible in situations in which a stone becomes impacted in a basket and cannot be extracted; this is known as *rescue lithotripsy*. Rescue lithotripsy, if needed, is an outside of the scope device. It is extremely important to recognize which baskets are lithotripter compatible and choose these baskets if lithotripsy is at all anticipated, because use of baskets that are not lithotripter compatible can lead to basket impaction and operative intervention.

Some baskets come prepackaged with a lithotripter setup. This is more labor-intensive to set up and use but can be very effective to fragment large stones, making them amenable to extraction through a biliary sphincterotomy. Hard stones can be very difficult to fragment and, not infrequently, wires of the basket can slip off the side of the stone, resulting in little to no fragmentation. Additionally, baskets tend to become easily misshapen and difficult to mold back into working condition.

In a single trial, 90 patients with large bile duct stones (12–20 mm) were randomized to mechanical lithotripsy or large balloon sphincteroplasty following sphincterotomy.<sup>35</sup> Overall, the rate of stone clearance was greater than 91% in both groups and without a statistically significant difference. However, there was a statistically significant increase in complications among

**FIG 53.12** **A**, Use of single operator digital cholangioscopy to identify large common bile duct stone, and **B**, use of electrohydraulic lithotripsy to **C**, fragment to stone into smaller pieces.

the patients in the mechanical lithotripsy group (4.4% vs. 20%).<sup>95</sup> Thus, when possible, biliary sphincterotomy followed by large balloon sphincteroplasty should be attempted prior to mechanical lithotripsy for management of large bile duct stones.

Cholangioscopy directed stone fragmentation is another advanced technique for clearance of large bile duct stones. Common techniques include EHL and laser lithotripsy. Each requires direct visualization of the stone using cholangioscopy. Typically, cholangioscopy is performed using a mother-daughter scope system. A disposable digital cholangioscope is available in clinical practice. Direct peroral cholangioscopy can also be performed using an ultra-slim upper endoscope. Once the cholangioscope is within the duct, the duct is filled with sterile saline to improve visualization and serve as a medium for transmission of EHL. The EHL probe is then advanced close to, but not touching, the stone, and the energy is then delivered, initially at low power (Fig. 53.12). The power can be titrated up based on initial fragmentation. Once the stones are fragmented, standard retrieval with a basket or balloon is then performed. Patients should be given a dose of antibiotics intraprocedurally to decrease the risk of cholangitis. Cholangioscopy-guided laser lithotripsy is another option, but its use is dependent on operator expertise and availability varies by institution.

Biliary stenting may be required. The most common reason in the setting of choledocholithiasis is for incomplete stone clearance. This temporizes the condition, allowing for biliary drainage around the residual stones. Additionally, the stents may serve to fragment residual stones, making subsequent stone extraction easier, though there are no data to support this. Typically, plastic biliary stents are sufficient, but there are two situations where off-label use of fully covered biliary stents may be beneficial. One is for postsphincterotomy bleeding or suspected/confirmed retroperitoneal perforation. The other is to attempt progressive dilation of a narrow CBD with large stones proximally. Following complete stone clearance, there is no proven benefit for biliary stent placement to protect against biliary obstruction due to papillary edema, though anecdotally, this is not uncommon in clinical practice.

#### Percutaneous Transhepatic Biliary Drainage (PTBD)

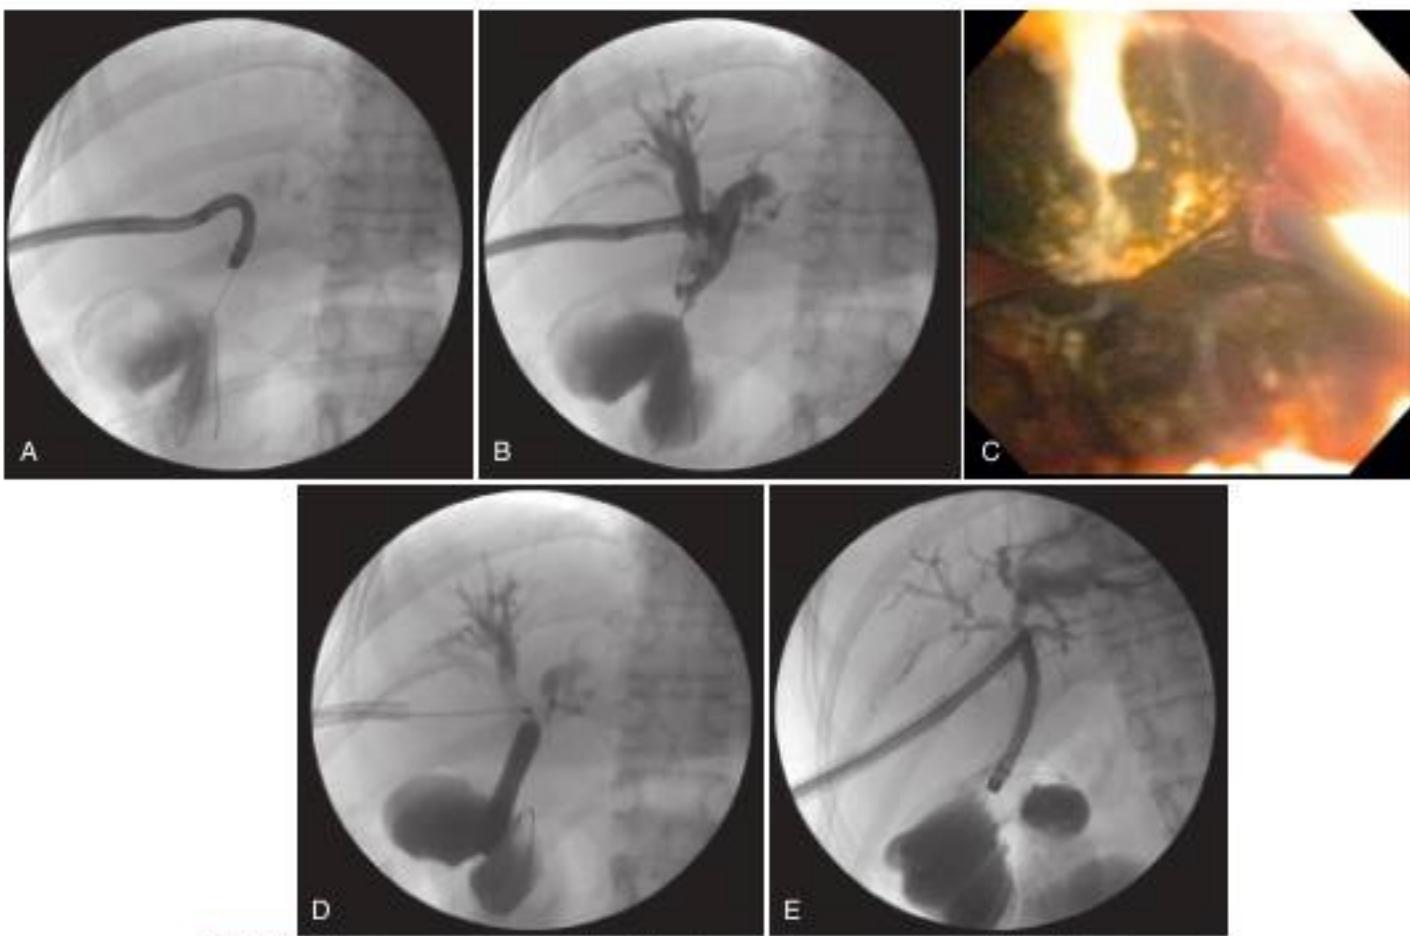

Percutaneous transhepatic biliary drainage (PTBD) is an alternative to endoscopic management of choledocholithiasis. PTBD

is performed by interventional radiologists and may be chosen in patients who have a contraindication for ERCP, who have had a failed ERCP, or in those with altered anatomy in whom ERCP is not attempted or unsuccessful. PTBD usually requires placement of a percutaneous transhepatic cholangiography drain. Approximately 6 weeks following initial drain placement, patients return for stone management. Techniques include antegrade balloon sphincteroplasty with a standard dilation balloon followed by attempts to push the stone into the duodenum. A "cutting balloon" may also be used to perform antegrade sphincterotomy. Additional devices including retrieval baskets, mechanical lithotripters, and choledochoscopes can be passed percutaneously through the PTBD tract to perform stone fragmentation and extraction (Fig. 53.13).

#### Surgery

In patients with concurrent choledocholithiasis and cholelithiasis with or without cholecystitis, the decision to perform ERCP pre- or postoperatively is largely institution- and provider-dependent. In most cases, patients with established choledocholithiasis undergo ERCP first, followed by cholecystectomy. Another option in these patients is to perform a laparoscopic CBD exploration (LCBDE) at the time of cholecystectomy, though data from a randomized controlled trial suggest that intraoperative ERCP is better than LCBDE at bile duct clearance.<sup>96</sup>

CBD exploration, either laparoscopic or open, is rarely performed. In patients undergoing laparoscopic cholecystectomy, meta-analysis revealed that single-stage cholecystectomy plus LCBDE was equivalent to two-stage cholecystectomy followed by ERCP.<sup>97</sup> Another study revealed that the surgical plus endoscopic approach was equivalent in morbidity and mortality, but that ERCP resulted in higher rates of duct clearance.<sup>98</sup> Although studies have demonstrated comparable efficacy between the two approaches, there are clinical scenarios in which the laparoscopic cholecystectomy and LCBDE may be a superior option, including patients presenting with choledocholithiasis and cholelithiasis with altered anatomy, particularly Roux-en-Y gastric bypass. This may be the preferred option to laparoscopic cholecystectomy followed by intraoperative ERCP, in which surgical access to the excluded stomach is obtained followed by transabdominal transgastric passage of the duodenoscope to the major papilla.

**FIG 53.13** Percutaneous transhepatic cholangioscopy for management of bile duct stones in a patient with an inaccessible bilioenteric anastomosis in post Roux-en-Y hepaticojejunostomy anatomy. **A**, An endoscope with a 6-mm diameter is placed into the biliary tree via a mature percutaneous track. Multiple stones are visualized on both **B**, fluoroscopic and **C**, endoscopic examination. **D**, Papillary balloon dilation is performed via an antegrade approach. **E**, allowing for clearance of the biliary tree.

### Special Situations

#### Cystic Duct Stones and Hepatolithiasis

Cystic duct stones and stones proximal to the common hepatic duct (hepatolithiasis) present a challenge for the endoscopist because treatment of these conditions usually requires more advanced ERCP techniques.

Cystic duct stones may masquerade as common duct stones, particularly given the limitations of fluoroscopy. A clue that one is dealing with a cystic duct stone and not a common duct stone is that the balloon or basket repeatedly slips by the stone. In reality, the stone is within the lumen of the cystic duct, which overlies the common duct on fluoroscopy. Rotation of the fluoroscopy unit (or patient) may splay the two ducts and delineate the problem. Once a cystic duct stone is identified, its retrieval can be problematic for several reasons. One is the limited space in the cystic duct in the postcholecystectomy patient; this may prevent balloon or basket passage proximal to the stone. In this situation, cholangioscopy with electrohydraulic or laser lithotripsy may be required. Another problem is the spiral valves of the cystic duct, which may impede retrieval of the stone. Again, lithotripsy may be required to fragment the stone prior to retrieval.

In extreme cases, extracorporeal shock wave lithotripsy (ESWL) may be utilized to fragment the stone, but a stent may be needed to localize the stone for targeting by ESWL if it is not radiopaque.

There are several considerations when dealing with hepatolithiasis. The first is whether ERCP is the best treatment modality. In patients with recurrent pyogenic cholangitis (formerly Oriental cholangiopathy) segmental hepatectomy may be the preferred option. The second is the reason the patient has hepatolithiasis. Is it due to a migrated stone or is there an underlying cholangiopathy or malignancy? When performing ERCP for hepatolithiasis, it is critically important to keep these questions in mind. Again, given its location proximal to the hilum, cholangioscopy with electrohydraulic or laser lithotripsy is often required.

#### Treatment of Choledocholithiasis in Surgically Altered Anatomy

Performing ERCP in patients with surgically altered anatomy is challenging. Knowledge of postoperative anatomy in general, and of each patient in particular, is crucial in determining choice of scope, instruments, and ultimately having a successful outcome. Additionally, developing a plan with a surgeon is important in

determining the best approach for these patients. For example, in patients with Roux-en-Y gastric bypass with concurrent choledocholithiasis and cholelithiasis, options include preoperative peroral ERCP followed by cholecystectomy, intraoperative ERCP through the excluded stomach, and cholecystectomy with bile duct exploration.

When performing peroral ERCP in patients with surgically altered anatomy, the choice of scope is usually determined by the type of surgery. In patients with Billroth II anatomy, advancement of a duodenoscope to the major papilla is often successful. In postpancreatoduodenectomy patients, a pediatric or adult colonoscope is usually utilized. In patients post-Roux-en-Y gastric bypass, the length of the Roux limb is critical in determining likelihood of success. For patients with short Roux limbs (< 75 cm), a colonoscope can usually be successfully advanced to the papilla. For patients with a long Roux limb, frequently balloon-assisted enteroscopy is required. It is important for the endoscopist to realize the limitations of non-duodenoscopes in performing ERCP, such as lack of an elevator and scope channel length and width, which will limit the types of instruments that can be used in the case (Fig. 53.14).

When peroral ERCP is unsuccessful or not pursued due to high likelihood of failure, EUS-guided biliary drainage (EUS-BD) is an alternative emerging technique for the management of choledocholithiasis. In this procedure, a therapeutic linear echoendoscope is used to visualize the intrahepatic ducts in the left lobe of the liver. A 19-gauge fine-needle aspiration needle is used to access an intrahepatic duct, followed by advancement of a standard ERCP wire through the needle, which is advanced antegrade across the papilla into the duodenum. A dilation balloon is then used to perform antegrade balloon dilation of the papilla (balloon sphincteroplasty) followed by pushing the stone(s) into the duodenum. Case series describing this technique have demonstrated high technical and clinical success rates with low complication rates comparable to PTBD and can be performed successfully during the same session as a failed ERCP. From a technical standpoint, it is more advantageous if the intrahepatic ducts are dilated, which facilitates biliary access.

#### Treatment of Choledocholithiasis in Pregnancy

Pregnancy is a risk factor for the development of cholelithiasis. The complications of gallstones, including cholecystitis, choledocholithiasis, and gallstone pancreatitis, appear to occur in the same incidence as patients who are not pregnant. Patients presenting with choledocholithiasis in the setting of pregnancy can safely undergo ERCP with particular attention to timing (delaying until the second trimester if possible), radiation exposure to the fetus, and sedation risks to the fetus.

Performing ERCP safely during pregnancy involves pre-, intra-, and postprocedural considerations. As with nonpregnant patients, the necessity of the procedure should be a strong preprocedure consideration. Diagnostic ERCPs should be avoided, and definitive documentation of a stone, usually by MRCP, should be obtained prior to performing ERCP. When possible, intervention should be delayed until the second trimester due to lower surgical risk and apparent lower risk for adverse radiation-associated complications in the fetus. Obstetric involvement should be sought and a plan for fetal heart rate monitoring during the procedure versus pre- and postprocedural documentation of fetal heart sounds should be discussed. Early in pregnancy, patients can be placed in a high prone position with the right leg bent significantly to take pressure off the uterus. Later in pregnancy, prone position

is not possible and patients should be placed in a left lateral decubitus position.

Use of fluoroscopy during pregnancy appears safe, with no data suggesting adverse effects on the fetus from radiation exposure. Nonetheless, steps should be taken to limit radiation dosing to the fetus. The uterus should be shielded with lead aprons. Scout films and "hard copies" should be avoided due to higher radiation doses. Magnification should be avoided as this generally increases the radiation dose.

Despite the lack of evidence for fetal harm from radiation exposure during ERCP, there have been a number of studies looking at fluoroscopy-less ERCP. One technique involved wire-guided or free cannulation followed by aspiration in six patients. If bile was aspirated, the procedure was continued without the use of fluoroscopy.<sup>109</sup> In all six patients, there was resolution of jaundice and no maternal or fetal complications. Another technique involves EUS-guided ERCP. In a study involving 31 patients, EUS-guided cannulation and successful completion of the procedure was accomplished in 26 (84%) of patients.<sup>108</sup> Yet another technique involves cholangiography-assisted ERCP, not only to confirm entry into the bile duct without fluoroscopy but also to confirm duct clearance.<sup>110</sup>

Postprocedure considerations include documenting fetal heartbeat, standard approaches to fluid management, monitoring for complications, and surgical consultation regarding timing of cholecystectomy. Biliary sphincterotomy is usually protective against recurrent choledocholithiasis and gallstone pancreatitis through pregnancy such that cholecystectomy can be performed postpartum.

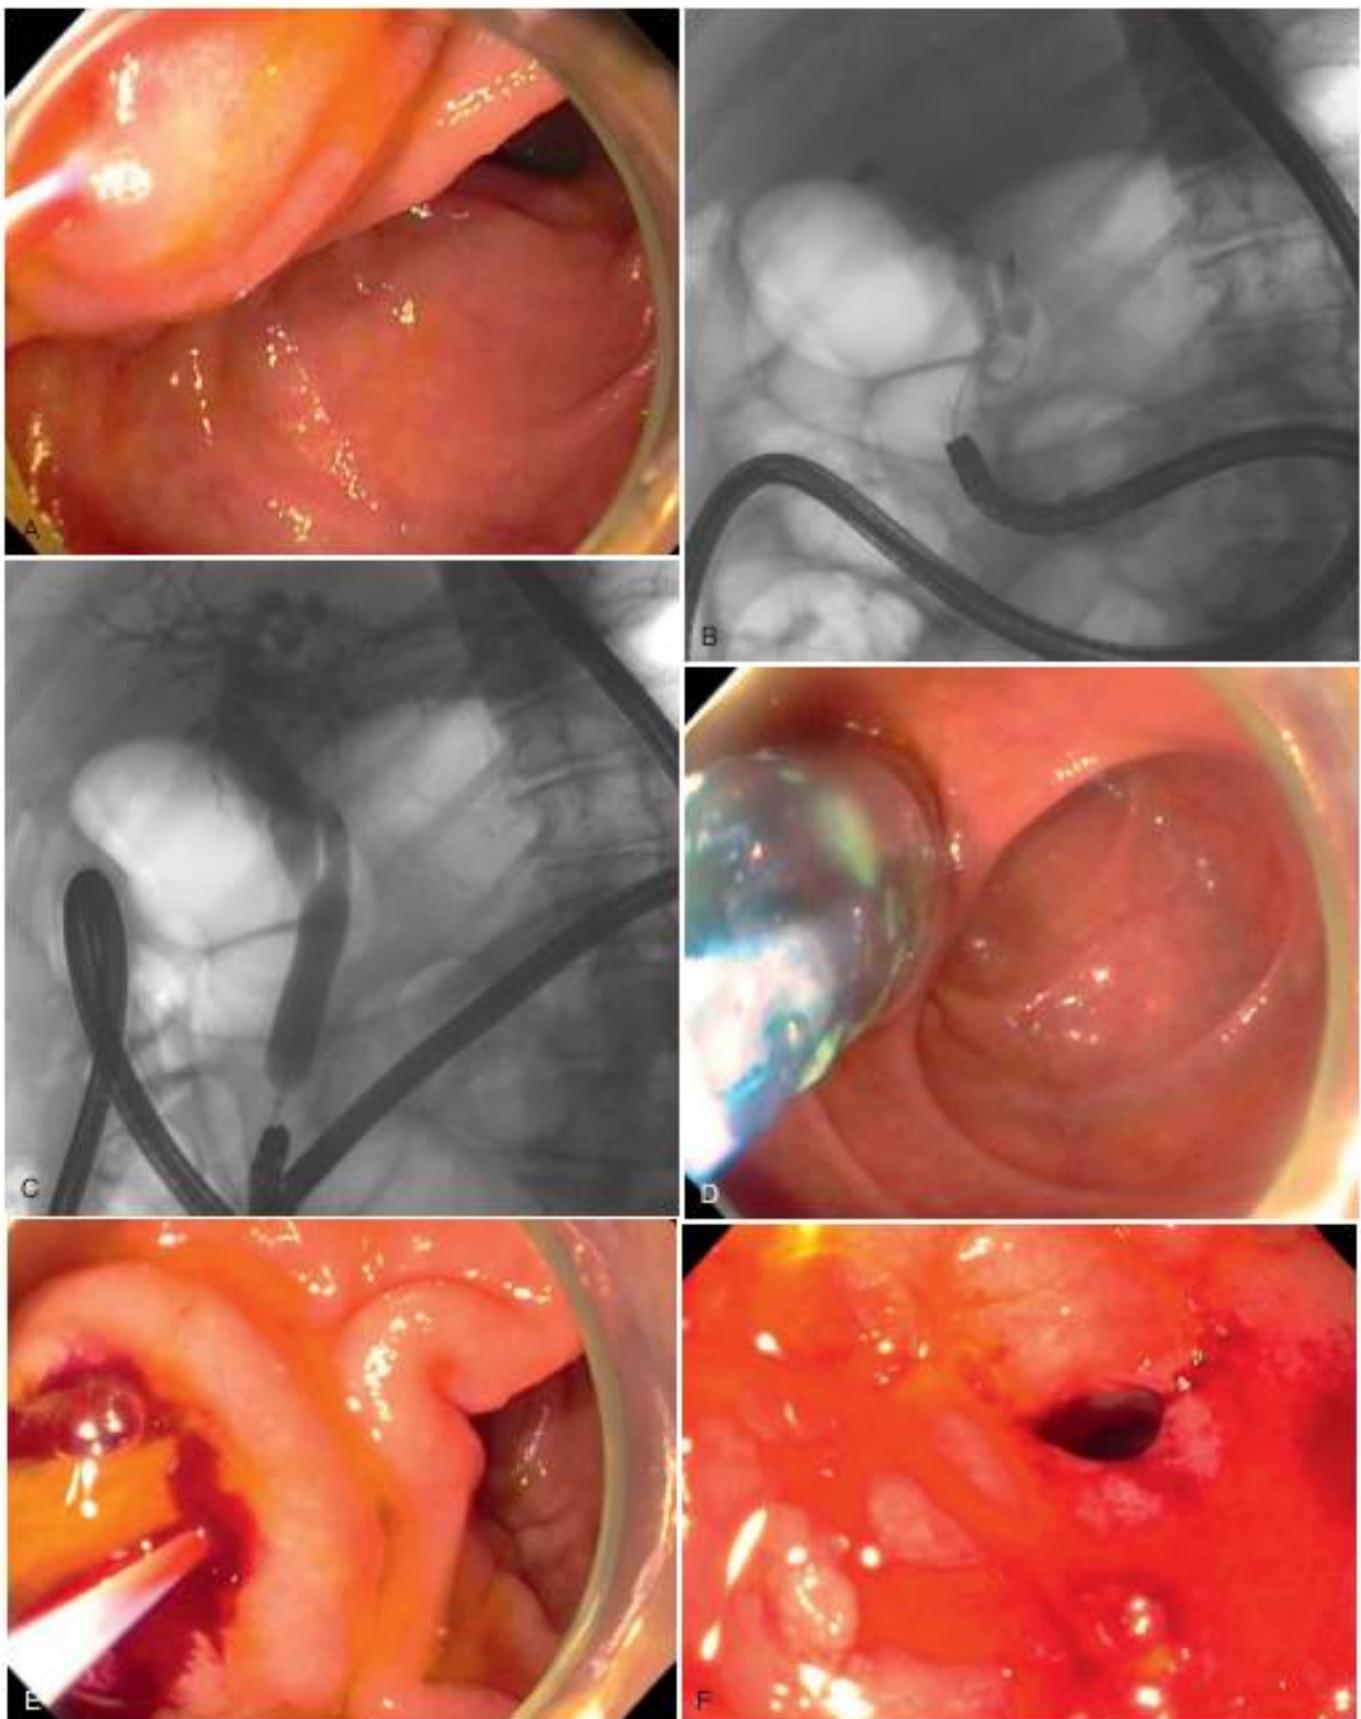

#### Posttreatment Recurrence

It is likely that a considerable proportion of recurrent choledocholithiasis is, in fact, not recurrence but failure to achieve duct clearance on the initial ERCP. Cholangiography alone has limited sensitivity for detection of duct stones, and the sensitivity decreases in larger caliber ducts where small residual stones can be missed. Use of dilute contrast may increase the sensitivity for detecting residual stones. Cholangioscopy is another modality to ensure complete ductal clearance, but this approach is costly and adds procedure time and complexity, so its use should be individualized.

The most important way to prevent recurrent choledocholithiasis is to ensure patients are referred promptly for cholecystectomy. In patients who do not undergo interval cholecystectomy, recurrent choledocholithiasis occurs in up to 11% patients.<sup>111</sup> However, there are data suggesting that elderly patients do not benefit from cholecystectomy,<sup>112</sup> so comorbidities and life expectancy should be considered when making recommendations regarding subsequent cholecystectomy in the elderly.

Some patients develop recurrent primary bile duct stones. Risk factors include sphincterotomy stenosis, biliary dyskinesia, IgA deficiency, and possibly the presence of a periampullary diverticulum.<sup>104</sup> Patients with recurrent primary bile duct stones have a higher rate of duodenal-biliary reflux.<sup>113</sup>

A variety of medical treatments, endoscopic treatments, and surgical treatments have been used to decrease the rate of bile duct stone reaccumulation. In a 2016 small randomized controlled trial, patients receiving ursodiol had a lower risk of recurrent choledocholithiasis; however, this was not statistically significant and the study was likely underpowered.<sup>105</sup> Additionally, case reports of ursodeoxycholic acid (UDCA) stones have been published suggesting that UDCA can exacerbate this problem

**FIG 53.14** ERCP for choledocholithiasis in a patient status post Roux-en-Y gastric bypass. **A**, Endoscopic image of wire through major papilla which was reached via cap-assisted single balloon enteroscopy. **B**, Cholangiogram revealing choledocholithiasis with stones in the cystic duct and extrahepatic bile ducts. **C**, Fluoroscopic and **D**, endoscopic images of primary balloon sphincteroplasty to perform stone extraction; **E**, image of soft brown stone being extracted and **F**, biliary orifice following balloon sphincteroplasty and stone extraction.

in some patients.<sup>107</sup> However, UDCA is a reasonable option for those that have recurrent cholesterol or brown pigment stones given the relative safety profile despite the lack of data from large, randomized controlled trials. Likewise, there are no data regarding use of antibiotics, lipid-lowering agents, and biliary bypass in the prevention of recurrent primary bile duct stones.

Prophylactic biliary stenting and scheduled ERCPs with balloon sweep are options to manage recurrent primary bile duct stones. Data from a prospective comparison study suggest that patients with recurrent choledocholithiasis who undergo routine stent exchanges approximately every 3 months versus as-needed have a lower rate of cholangitis.<sup>108</sup> Another approach for which there is no data is to perform scheduled ERCPs periodically to clear the ducts. Our approach has been to perform ERCPs as-needed for signs and symptoms attributable to choledocholithiasis.

## GALLSTONE PANCREATITIS

### Incidence/Epidemiology

Gallstone, or biliary, pancreatitis is the most common cause of pancreatitis in the Western world, accounting for approximately 40% to 70% of all cases of acute pancreatitis.<sup>109</sup> However, only approximately 3% to 7% of patients with gallstones develop acute pancreatitis.<sup>110</sup> Additionally, a patient with acute pancreatitis and an intact gallbladder should not be assumed to have gallstone pancreatitis, particularly if the gallbladder is normal and if there is no significant elevation in liver enzymes.

### Pathophysiology

The exact pathophysiologic mechanism of gallstone pancreatitis is unknown. Smaller stones are more likely than large stones to cause gallstone pancreatitis because smaller stones are more likely to traverse the cystic duct and enter the CBD. Additionally, smaller stones are more likely to migrate into the common channel or traverse the sphincter of Oddi than larger stones. It is thought that acute pancreatitis occurs by several possible mechanisms: a stone obstructs the common channel causing reflux of bile into the pancreatic duct, a stone obstructs the pancreatic duct causing ductal hypertension, or a stone causes periampullary inflammation.<sup>111</sup>

### Diagnosis

The diagnosis of gallstone pancreatitis should be suspected in any patient presenting with acute pancreatitis and an intact gallbladder. However, not every patient with an intact gallbladder presenting with acute pancreatitis should be assumed to have gallstone pancreatitis. In patients with a normal-appearing gallbladder on TAUS, other etiologies for acute pancreatitis should be explored. In patients with recurrent unexplained pancreatitis with a normal-appearing gallbladder, performing empiric cholecystectomy or endoscopic biliary sphincterotomy are controversial and should be individualized.

The presence of sludge or gallstones within the gallbladder makes the diagnosis of gallstone pancreatitis more likely, particularly if associated with concurrent liver enzyme abnormalities or evidence for choledocholithiasis or recently passed stone (i.e., extrahepatic biliary duct dilation). Data from a meta-analysis revealed that elevated alanine aminotransferase (ALT) was the most useful predictor of gallstone pancreatitis with a value greater than 150 IU/L ( $> 3 \times$  upper limit of normal) having a PPV of 95%.<sup>112</sup>

A TAUS should be a part of the work-up for any patient presenting with acute pancreatitis. However, additional cross-sectional imaging is usually not necessary unless there is a question of the diagnosis, complications associated with pancreatitis, or indeterminate probability of a retained stone. Patients with an indeterminate probability for choledocholithiasis (see earlier section on *Choledocholithiasis* diagnosis) should undergo MRI/MRCP or EUS.<sup>113</sup>

### Treatment

The management of gallstone pancreatitis begins with conservative management that is standard for pancreatitis of any etiology. This includes goal-directed fluid resuscitation, monitoring of hemodynamics and standard laboratory parameters, pain management, and nil per os. Antibiotics are not recommended, unless there is concern for concurrent ascending cholangitis.

### ERCP

Not all patients with suspected gallstone pancreatitis should undergo ERCP. Patients with pancreatitis and concurrent cholangitis should undergo ERCP, preferably within 24 hours of admission.<sup>114</sup> Patients with confirmed choledocholithiasis who do not have evidence for cholangitis can undergo ERCP for stone removal when stable from a pancreatitis standpoint. In the absence of cholangitis, the clinical course will be dictated by the evolution of pancreatitis that is not altered by performing an ERCP. Nearly 75% patients with biochemical or imaging evidence for choledocholithiasis on admission will spontaneously pass the stone into the duodenum within 3 days,<sup>114</sup> so rushing to perform ERCP in patients without cholangitis is ultimately unnecessary in a large majority of patients.

There have been several studies looking at whether ERCP with biliary sphincterotomy can reduce the severity, complications, and mortality of predicted severe acute pancreatitis. A study from the late 1980s looked at 121 patients with acute biliary pancreatitis and found a benefit of early ERCP (within 72 hours of admission) in decreasing complications associated with acute pancreatitis even when excluding the patients with obvious biliary obstruction.<sup>115</sup> However, there was no mortality benefit from early ERCP. Another study published several years later looked at another heterogeneous group of patients with biliary pancreatitis and showed a decrease in complications but no mortality benefit of early ERCP.<sup>116</sup> Another trial was performed several years later which excluded patients with a bilirubin greater than 5.<sup>117</sup> This study did not find a morbidity or mortality benefit of early ERCP with papillotomy in these patients.

Based on these studies and lack of subsequent data showing a mortality benefit from early ERCP with sphincterotomy in patients with severe biliary pancreatitis without concomitant biliary obstruction, ERCP should not be performed unless there is evidence of ongoing biliary obstruction. Performing ERCP with biliary sphincterotomy does not alter the mortality of acute biliary pancreatitis but may decrease the morbidity and mortality from concomitant cholangitis.

Patients with acute biliary pancreatitis and indeterminate evidence for choledocholithiasis (see earlier section on *Choledocholithiasis*) should undergo additional tests such as MRCP or EUS prior to ERCP. If such patients are not candidates for cholecystectomy, an ERCP with empiric biliary sphincterotomy should be performed to decrease the risk for recurrent biliary pancreatitis.

A validated protocol used five equally weighted parameters (CBD > 9, gamma-glutamyl transferase > 350, Alk phos > 250, direct bilirubin > 2, and total bilirubin > 3) to assign a score of 0 to 5 for each patient presenting with gallstone pancreatitis.<sup>118</sup> In this protocol, which enrolled 84 patients, patients with a score of 0 underwent cholecystectomy, patients with a score of 1 to 2 underwent cholecystectomy with IOC, patients with a score of 3 to 4 underwent MRCP, and patients with a score 5 underwent ERCP. This protocol had an overall accuracy of 88% for CBD stones and avoided unnecessary ERCPs in all patients in the protocol.

### Cholecystectomy

Patients without ongoing biliary obstruction and uncomplicated biliary pancreatitis should undergo cholecystectomy during the same admission. A large, multicenter prospective randomized controlled trial (Pancreatitis of biliary origin: Optimal timing CHOlecystectomy [PONCHO]) from the Netherlands confirmed that failure to perform a same-admission cholecystectomy increases the risk for subsequent recurrent biliary pancreatitis, readmission, and pancreatitis-related complications.<sup>119</sup>

Patients with biliary pancreatitis undergoing ERCP with biliary sphincterotomy should fall into one of three groups: (1) patients who have documented, or a high suspicion for, choledocholithiasis and (2) those in whom cholecystectomy will be delayed or (3) those who are not candidates for cholecystectomy either due to comorbidities or refusal to undergo surgery.

In patients undergoing preoperative ERCP with biliary sphincterotomy, does this obviate the need for cholecystectomy? In these patients, the risk for development of recurrent pancreatitis appears to be similar to those undergoing cholecystectomy; in other words, biliary sphincterotomy appears to be similar to cholecystectomy in protecting against recurrent pancreatitis, particularly in elderly patients. The protective effect of biliary sphincterotomy is likely due to the disruption of the common channel and enlargement of the biliary orifice, which decreases the risk for pancreatic duct obstruction and increases the likelihood of atraumatic passage of gallstones. However, in young patients, biliary sphincterotomy should not be considered definitive therapy due to risk of sphincterotomy stenosis and biliary obstruction in the setting of a migrated gallstone and lifetime risk for acute cholecystitis.<sup>120</sup> Furthermore, patients who do not undergo interval cholecystectomy have a statistically higher mortality rate, incidence of biliary type pain, and cholecystitis.<sup>120</sup>

For patients who cannot undergo cholecystectomy or in whom cholecystectomy is going to be delayed, ERCP with empiric biliary sphincterotomy should be performed to protect against recurrent pancreatitis. Performance of neither cholecystectomy nor biliary sphincterotomy leads to the highest rate of readmission within 2 years from recurrent pancreatitis.<sup>121,122</sup>

Again, patients who lack gallbladder sludge or stones and significant liver enzyme abnormalities should not be assumed to have biliary pancreatitis, and cholecystectomy in these patients should not be uniformly recommended. Data suggest that patients with a normal gallbladder on ultrasound and lack of significant liver enzyme elevation had a 50% chance of developing recurrent pancreatitis following empiric cholecystectomy.<sup>123</sup> Given this finding, patients with unexplained recurrent acute pancreatitis with an intact, normal-appearing gallbladder should be counseled that cholecystectomy may not prevent recurrent pancreatitis and the decision to pursue cholecystectomy in this setting should be individualized.

## INTRODUCTION

Accidental injuries of the bile ducts leading to biliary leaks and strictures may occur during any surgical procedure involving the biliary tract. However, the main causes of injury of the bile ducts at the present time are laparoscopic cholecystectomy (LC) and after liver transplantation (LT). Although LC has proved to be superior to open cholecystectomy in terms of shorter hospitalization, lower overall morbidity, faster recovery, and better cosmetic outcome, the risk of bile duct injury during LC is two to six times greater compared with open cholecystectomy.<sup>1,2</sup> Bergman et al (1996)<sup>3</sup> described four types of postoperative bile duct injuries, as follows:

- Type A: Cystic duct leaks or leakage from aberrant or peripheral hepatic radicles (minor lesions)
- Type B: Major bile duct leaks with or without concomitant biliary strictures (major lesions)
- Type C: Bile duct strictures without bile leakage (major lesions)
- Type D: Complete transection of the duct with or without excision of some portion of the biliary tree (major lesions)

Biliary strictures in patients with LT are classified as anastomotic strictures (ASs) and nonanastomotic strictures (NASs). AS are by far the most common. In most centers, a biliary duct-to-duct anastomosis is preferred over a Roux-en-Y choledochojejunostomy as it offers the advantage of easy endoscopic access to the biliary system and preservation of the sphincter of Oddi. The type of LT and biliary reconstruction has some implications in the development of biliary strictures. Due to the small diameter of the anastomotic bile duct, biliary strictures are known to be more common in living-donor LT (LDLT) than in deceased-donor LT (DDLT). The type of biliary reconstruction (duct-to-duct choledocho-choledochostomy vs. Roux-en-Y choledochojejunostomy) in DDLT has been suggested as a risk factor for biliary complications; however, it is now generally agreed upon that the rate of complications is similar with the Roux-en-Y choledochojejunostomy.

## EPIDEMIOLOGY

LC was first performed by Mouret in France in 1987. The technique was standardized by two other French surgeons, Dubois in Paris and Perissat in Bordeaux.<sup>4,5</sup> This new technique spread very rapidly around the world; in the United States, the percentage of cholecystectomies done laparoscopically grew from zero in 1987 to over 90% in 2010.<sup>6</sup> The advent of LC also induced an estimated increase of at least 25% in the overall number of cholecystectomies performed,<sup>7,8</sup> so that the likely number of cholecystectomies performed at the present time in the United States is 800,000 per year.<sup>1,9</sup> The number of iatrogenic injuries to the bile duct has increased accordingly.<sup>10</sup>

There are many reasons that may explain the increased incidence of biliary complications at the beginning of the laparoscopic era, most related to the new technical skills required to perform laparoscopically what had previously been done by open surgery: bidimensional vision, loss of tactile sensations, different visual approach of the hepatic pedicle, difficult hemostatic maneuvers, abuse of electrocoagulation, and lack of confidence with the new instrumentation.<sup>11</sup> The rate of injuries seemed to be related to the surgeon's learning curve and his or her personal experience. An inversely proportional relationship between the number of cholecystectomies performed and the rate of injuries was suggested by earlier reported series.<sup>1,12</sup> In a review of 77,604 LCs performed in the United States, the incidence of biliary injuries decreased from 0.6% to 0.4% ( $p < 0.001$ ) for surgical teams having an experience of more than 100 LCs.<sup>1</sup> A Belgian survey<sup>13</sup> suggested the number of 50 LCs as the threshold of a completed learning curve; however, the same authors emphasized that one-third of the biliary injuries in their country had occurred with surgeons with an experience of more than 100 LCs. When reviewing several multicenter series published before 1995, totaling 198,267 LCs, the incidence of biliary injuries was 0.55% in 13 European series and 0.49% in 17 series outside Europe.<sup>13</sup>

### Abstract

Accidental injuries of the bile ducts leading to biliary leaks and strictures may occur during any surgical procedure involving the biliary tract, especially during or after laparoscopic cholecystectomy and after liver transplantation. These injuries can lead to external biliary fistula, choleperitoneum, biliary strictures, and cholestasis, with or without the features of acute cholangitis. Endoscopic retrograde cholangiopancreatography (ERCP) has a pivotal role in the management of postsurgical biliary complications. Bile leaks or fistulas in most cases are easily managed with endoscopic sphincterotomy and plastic stent placement. For biliary strictures, progressive stricture dilation with placement of multiple plastic stents and exchange of stents every 3 months during a period of 1 year has become the standard treatment of choice. Placement of uncovered self-expandable metal stents (SEMS) in benign strictures is strictly forbidden due to the inability of removal related to hyperplastic ingrowth. Fully covered SEMS have raised significant interest for benign biliary strictures and a number of studies show similar efficacy to plastic stents. Drug-eluting, self-expandable stents have been used in the vascular system to inhibit endothelial growth; it is conceivable that this technology might become available for use in the biliary system. Local release of antiinflammatory drugs able to control the fibrogenetic process that occurs during healing of a biliary injury may be valuable in this setting.

### Keywords

benign biliary strictures

laparoscopic cholecystectomy  
liver transplantation  
plastic biliary stents  
self-expandable metal stents

In the mid-1990s, the incidence of biliary injury seemed to be three times higher for LC than for open cholecystectomy. However, these figures most likely underestimated reality because there was a tendency not to declare all the lesions, as revealed by the low rate of reply to most surveys and by the increasing number of reported lesions in direct proportion with the collected replies.<sup>14</sup> At the present time, the incidence of biliary injuries has not substantially changed, even if a trend toward reduction has been reported by some authors.<sup>6,9,15</sup> The estimated overall incidence is 0.25% to 0.74% for major biliary lesions (Table 54.1) and 0.1% to 1.7% for minor biliary lesions (Table 54.2).<sup>15-18</sup> These figures are only partially explained by the still increasing number of LCs performed around the world and by the activity of young surgeons at the beginning of their learning curve. However, at least one-third of biliary injuries may be ascribed to technical mistakes during surgery.<sup>16</sup> The learning curve is not the only risk factor for LC.

Bile duct strictures after LT account for approximately 40% to 50% of all biliary complications after LT.<sup>16,21</sup> The incidence of AS in various reports ranges between 10% and 15%.<sup>21,23</sup> Strictures that occur early after LT are mainly due to technical problems, whereas late strictures are mainly due to vascular insufficiency, ischemia, and problems with healing and fibrosis. Patients with Roux-en-Y choledochojejunostomy may also develop strictures at the anastomosis with the bowel, and in most cases

percutaneous therapy by interventional radiology is performed in these individuals. In some centers with experienced endoscopists, endoscopic retrograde cholangiopancreatography (ERCP) can be successfully performed in patients with a Roux-en-Y choledochojejunostomy with small bowel enteroscopy.<sup>24</sup>

## PATHOGENESIS

An unintentional lesion of the bile duct also may occur during an "easy" cholecystectomy performed by an experienced surgeon. Intuitively, the likelihood of injuring the bile duct should increase when the cholecystectomy is difficult and the surgeon is inexpert. Any cholecystectomy may become unexpectedly difficult during surgery; however, clinical and morphologic criteria exist that may be useful in predicting a cholecystectomy at higher risk of bile duct injury. Clinical criteria are obesity; previous abdominal surgery; cirrhosis; portal hypertension; age of the patient; and previous cholecystitis, cholangitis, or pancreatitis. Morphologic criteria revealed by preoperative abdominal ultrasound (US) are related to the gallbladder status (sclerotic/gallbladder, thickening of the gallbladder wall, gallbladder distention resulting from a stone in the infundibulum) and to the liver (hepatomegaly, atrophy or hypertrophy of the liver lobes). The presence of several criteria raises the chances of being confronted with a difficult cholecystectomy and the risk of concomitant common bile duct (CBD) stones.

In patients who have undergone LT, a number of factors play a role in the development of ASs and NASs. In most instances, the major underlying risk factor is ischemic due to problems with the hepatic artery, mainly stenosis or thrombosis (HAT). As the biliary system receives blood supply mainly via the hepatic artery, low flow of the hepatic artery can lead to complex ASs and hilar strictures. Hepatic artery stenosis can also lead to both ASs and NASs, particularly when associated with long, cold ischemia time.<sup>25</sup> T-tube placement in LT is controversial. Originally T-tubes were routinely placed as a prophylactic measure for AS development. However, the results of several comparative studies, systematic reviews, and meta-analysis suggest no major differences in the incidence of biliary complications, and the current trend has favored the abandonment of the use of T-tubes after LT in most centers.<sup>26-28</sup> Other factors include concomitant bile leak, technical factors during surgery (tight anastomosis, excessive dissection and electrocautery during the reconstruction, redundant bile duct), mismatched size between donor and recipient bile ducts, ischemia/reperfusion injury, presence of cytomegalovirus infection, donation after cardiac death, ABO blood group mismatch, older age of donor, graft, steatosis, prolonged cold and warm ischemia times, and primary sclerosing cholangitis.<sup>29-34</sup>

Unrecognized CBD stones are one of the major risk factors of cystic duct leakage after LC. The mechanism and the cause of a biliary injury remain unexplainable in at least one-third of cases.<sup>15</sup> In more than 50% of cases, the injury occurs during the dissection of the cystic duct or during separation of the gallbladder neck from the CBD. Misinterpretation of the cystic duct and the CBD is the most common cause of injury.<sup>12</sup> Excessive traction on the gallbladder neck, especially if the tissues are not inflamed, may facilitate the injury of the CBD. Conversely, when the area is acutely or chronically inflamed or when a stone is trapped in the gallbladder infundibulum, the risk of CBD injury is higher during the dissection of the gallbladder neck from the hepatic pedicle. Other common reasons for bile duct injury are related to incorrect hemostatic maneuvers in the case of bleeding from

the cystic artery; inappropriate use of electrocautery; and other specific maneuvers, such as intraoperative cholangiography, which is used in cases of suspected CBD stones or difficult anatomy, cystic duct dilation, and transcystic CBD instrumental exploration.

An anatomic anomaly is often reported by the surgeon as having caused a biliary injury. Variations of the biliary anatomy, especially at the level of the main hepatic confluence, are present in 50% of patients (see the later section on interpretation of intrahepatic cholangiography). Surgeons must be aware of such variations and must keep in mind the danger of injuring aberrant ducts originating in the right liver during dissection of the gallbladder pedicle. Aberrant ducts must not be interpreted as accessory ducts because the biliary distribution within the liver parenchyma is of a terminal type; this implies that there are no intrahepatic anastomoses between the ducts and that every injury of an aberrant duct would determine functional exclusion of the corresponding liver area. Injury to a small aberrant duct may still be considered a minor lesion; however, it would cause a bile leak into the peritoneal space with all the related consequences. Another cause of injury is clipping or ligation of an aberrant duct. This injury does not involve a bile leak but entails the functional exclusion of the corresponding liver area leading to its progressive atrophy and hypertrophy of the remaining liver parenchyma. This possible event may be clinically totally asymptomatic and noted only by an increase in biochemical parameters of cholestasis and cytology (Fig. 54.1). Although there is no indication of treatment in asymptomatic cases, if the obstructed ducts become infected, recurrent cholangitis is the typical clinical manifestation often requiring operative reestablishment of an adequate bile flow.

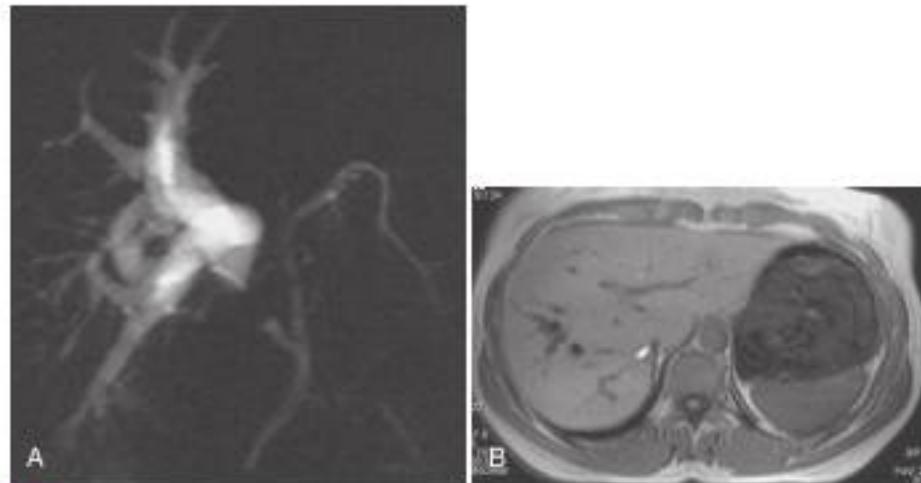

## CLINICAL FEATURES

Schematically, three main clinical pictures are characteristic of a bile duct injury: (A) external biliary fistula, (B) choleperitoneum, and (C) cholestasis with or without the features of acute cholangitis. Various combinations of these clinical pictures may also be present. Most important, although some of the clinical manifestations, such as mild jaundice or well-drained external bile leakage, do not require any emergency treatment, the presence of infection must be regarded as an important criterion that requires intensive care and rapid decisions to treat sepsis. Septic complications are the main reason for mortality in these patients in the postoperative period. External biliary fistula and choleperitoneum are both typical features of the immediate postoperative period, whereas obstructive jaundice may occur either immediately after surgery or later, within days to several years. When symptoms arise late after surgery because of a slow progression from injury to stricture, overt jaundice may be absent, and the clinical picture is typically that of anicteric cholestasis, with or without itching, and recurrent bouts of acute cholangitis.

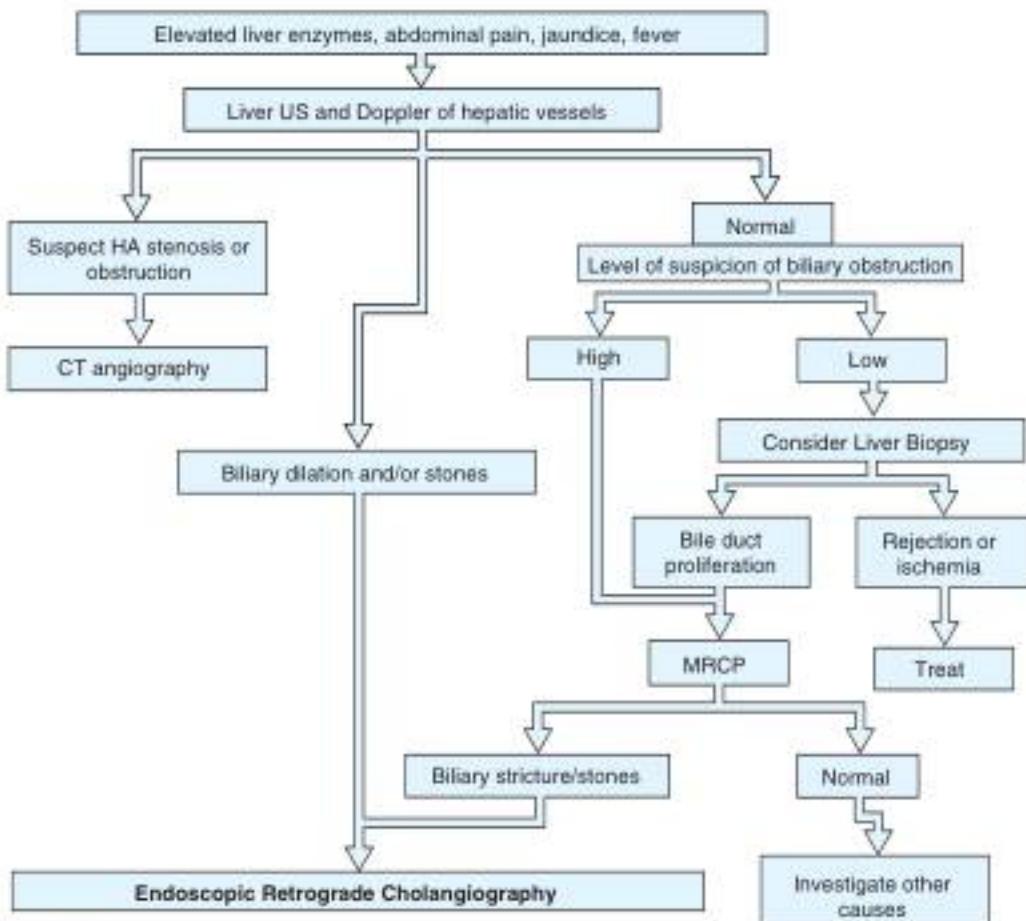

The suspicion of bile duct injury after LC injury is not always straightforward. When subtle symptoms such as dull abdominal pain, abdominal distension, low-grade fever, and nausea arise in the first days after LC, one should always suspect a possible complication. Intraperitoneal bile collections may initially produce very little or no specific symptoms, but they should be quickly suspected and eventually confirmed to identify the cause and to plan the best treatment for the individual patient. Hemobilia is a rare but alarming clinical presentation of a bile duct injury. The mechanism by which a biliary injury may be associated with hemobilia is often the perforation of a pseudoaneurysm of the right hepatic artery or one of its branches into the bile ducts. These pseudoaneurysms are the result of an inadvertent intraoperative injury of the artery produced by hemostatic maneuvers during a difficult cholecystectomy and cause hemoperitoneum. In patients with an external biliary drainage or fistula, the bleeding may become suddenly and massively apparent through the drain and may occasionally require emergency treatment.

In individuals who undergo LT, the clinical presentation is variable according to the type of lesion. In many cases, patients will have nonspecific symptoms such as malaise and anorexia.

Others may present with pruritus, jaundice, or associated bile

**FIG 54.1** This patient presented 2 years after laparoscopic cholecystectomy (LC) with only occasional minor right upper quadrant pain and slightly elevated liver function tests. **A**, Magnetic resonance cholangiography shows complete obstruction and dilation of the right biliary ductal system with normal common bile duct (CBD) and left biliary ductal system. **B**, Abdominal magnetic resonance imaging shows hypotrophy of the right liver and compensatory hypertrophy of the left liver.

ascites and abdominal pain. In most instances, a biliary stricture is usually first suspected in asymptomatic LT recipients who have elevations of serum bilirubin, alkaline phosphatase and/or gamma-glutamyl transferase levels. Although strictures usually present as asymptomatic cholestasis, some patients can present with cholangitis, especially if the patient has concomitant bile duct stones.

## DIAGNOSTIC APPROACH AND DIFFERENTIAL DIAGNOSIS

In all cases of a suspect biliary stricture, the initial evaluation should include an abdominal US. In those with LT, a Doppler evaluation of the hepatic vessels to rule out hepatic artery thrombosis or stenosis and/or portal or hepatic vein occlusion must also be performed. Unfortunately, abdominal US may not be sufficiently sensitive (sensitivity 40% to 66%) to detect biliary obstruction in many patients.<sup>23</sup> Thus, the absence of bile duct dilation on US should not preclude further evaluation with more sensitive tests if there is clinical suspicion of a biliary stricture. In such cases, a magnetic resonance cholangiopancreatography (MRCP) is considered an optimal noninvasive diagnostic tool for the assessment of the biliary strictures. Although ERCP or percutaneous transhepatic cholangiography are the gold standard, MRCP has gained acceptance as the most reliable noninvasive

study for the evaluation of the bile ducts, particularly in patients after LT (sensitivity 96%, specificity 94%).<sup>26</sup> The preferred approach is to perform an MRCP first; however, proceeding with a diagnostic invasive procedure such as ERCP without an MRCP can be an acceptable clinical strategy in some patients because of the high likelihood that a therapeutic intervention will be required.<sup>27</sup> An algorithm depicting the diagnostic approach for patients with suspected AS is shown in Fig. 54.2.

Strictures occurring long after surgery may need to be distinguished from malignant strictures and other benign conditions such as primary sclerosing cholangitis, autoimmune cholangitis, or sclerosing cholangitis in critically ill patients among others. The clinical history may be helpful only in cases in which the biliary injury had been recognized and eventually treated at the time of surgery. In this setting, the stricture is usually the result of progressive scarring at the site of surgical repair. In all other circumstances, the relationship with cholecystectomy or LT should be questioned. However, clinical presentation may be helpful in discriminating postoperative and malignant stenoses; painless jaundice is in favor of a malignant disease, whereas development of overt jaundice in benign strictures is often heralded by a long period of anicteric cholestasis and relapsing attacks of mild to severe acute cholangitis. Stricture morphology may be very helpful in discriminating scars from neoplastic involvement of the bile duct. Postoperative strictures are usually short, with sharp, often

**FIG 54.3** Biliary anastomotic stricture after liver transplantation. The structure is quite short and in the area of the anastomosis. These strictures are amenable to endoscopic therapy with biliary dilation and subsequent plastic stent placement across the stricture.

asymmetric edges, close to the cystic duct stump, and clips may be seen lying over the bile duct or located medially to it. ASs after LT are defined as a dominant short narrowing at the anastomotic site without free or effective passage of contrast material as demonstrated by cholangiography (Fig. 54.3).

## TREATMENT

In recent years, ERCP has acquired a pivotal role in the management of postsurgical biliary complications. Both the major typical clinical presentations occurring in this setting may be addressed by ERCP: (A) biliary leak into the peritoneal cavity or external leak and (B) obstructive syndrome with cholestasis, cholangitis, or jaundice. ERCP confirms the clinical suspicion of biliary injury and provides detailed morphologic information of the lesion. ERCP is currently considered a first-line therapeutic tool in complications that are amendable to endoscopic treatment.

### Endoscopic Retrograde Cholangiopancreatography and Biliary Leak

The presence of a bile leak invariably indicates a break in the continuity of the biliary system. However, the severity of the injury (i.e., ranging from simple leakage of the cystic stump to complete transection of the bile duct) and the complexity of its repair are extremely variable. The magnitude of the bile output of abdominal drains does not usually help in identifying the origin and the size of the leak. A direct cholangiogram is of utmost importance for accurate anatomic depiction and to classify the type of injury to plan therapy. The usefulness of MRCP in the delineation of postoperative biliary leaks<sup>30</sup> and of iatrogenic strictures<sup>31</sup> has been reported. However, in contrast to ERCP, MRCP has no therapeutic capability. MRCP may be recommended in anatomic situations in which the endoscopic approach is presumably difficult or occasionally impossible, such as in patients with a Billroth II anatomy and with Roux-en-Y hepaticojejunostomy. In LT recipients, bile leaks occur in 2% to 25% of patients.<sup>32,33,40</sup> An important thing to consider is that the presence

of a bile leak is an independent risk factor for the development of early or late strictures and requires prompt therapy.<sup>31</sup>

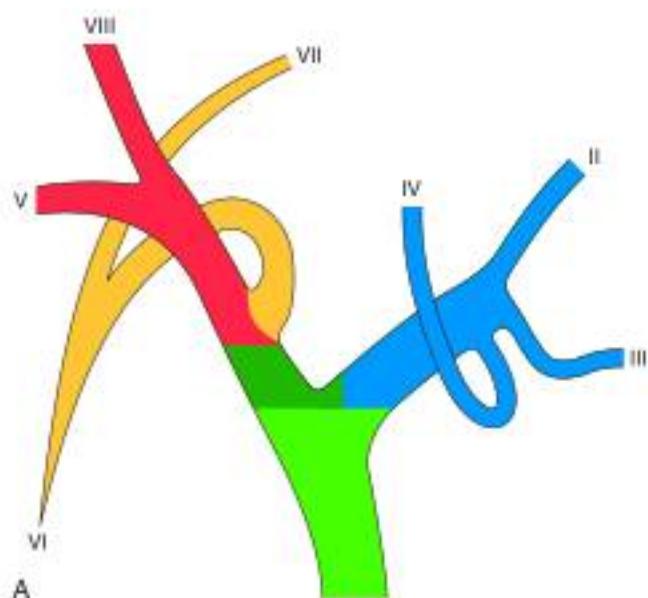

ERCP provides a detailed morphologic picture of the biliary tree and, when indicated, offers immediate therapeutic options during the same procedure. In cases of biliary leaks, ERCP is usually required in the early postoperative period when the patient has fresh surgical scars (which are potentially painful, especially if surgery has been converted to laparotomy) and has one or more external abdominal drains placed during surgery or in the postoperative period under US or computed tomography guidance; this is why the supine position is often preferred to the usual left lateral or prone position in performing ERCP. The supine position, although a little more demanding for the operator, is also preferable for interpretative purposes, especially in the case of complex hilar lesions. The anteroposterior radiologic projection, with the liver lying on the spine, substantially helps in identifying the anatomy of the main biliary confluence and of the segmental intrahepatic ducts. Use of the supine position also allows for the changing of the patient's position obliquely in the case of superimposition of the biliary branches, which may create difficulties in interpretation.

In the case of an external biliary fistula through an abdominal drain, it is not advisable to start the procedure by injecting contrast medium through the drain (fistulography). In most instances, especially in minor lesions, the contrast medium freely flows into the peritoneal space without depicting the biliary tree. The presence of contrast medium overlapping the area involved by the lesion may hinder the correct interpretation of subsequent cholangiography and occasionally disguise the picture entirely. In contrast, fistulography is indicated whenever endoscopic cholangiography shows an incomplete filling of the biliary system resulting from a complete transection of the main bile duct or lack of visualization of a sectorial or segmental intrahepatic branch. As an alternative to contrast medium, which occasionally might not fill the missing branch, air or CO<sub>2</sub> may be used to obtain a pneumocholangiogram.<sup>41</sup>

The technique of ERCP in the setting of a suspected biliary injury does not substantially differ from the routine examination. Special attention should be paid to the injection of contrast medium, however, which should be slow and careful to allow precise delineation of the lesions. Massive injection of the biliary tree should be avoided. Minimal injection and early filling x-ray films are also important in detecting small residual CBD stones, which are present in 13% to 20% of patients with biliary leakage originating from the cystic duct stump.<sup>42</sup> If the suspected lesion is located in an intrahepatic biliary branch, it is of paramount importance to obtain a complete intrahepatic cholangiogram, and to achieve an adequate pressure of injection, especially if a sphincterotomy has been previously performed, in which case the use of an occlusion balloon catheter is advisable. Intrahepatic biliary anatomy is better shown by multiple x-ray films taken in different projections. Percutaneous transhepatic cholangiography and MRCP should be reserved for patients in whom ERCP fails technically or fails to show the intrahepatic biliary anatomy because of proximal ductal disruption.<sup>43</sup>

### Interpretation of Intrahepatic Cholangiography

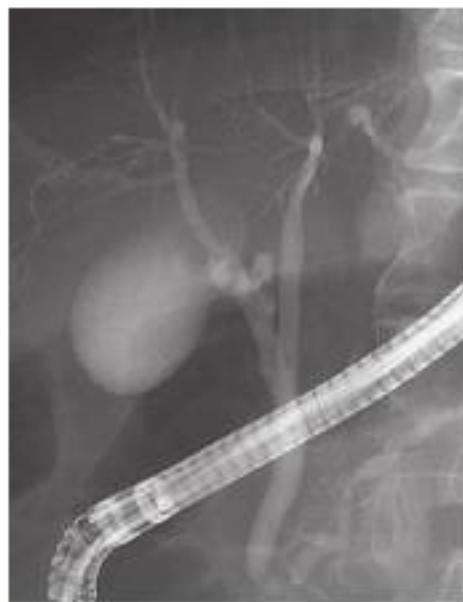

The main biliary confluence is formed by the union of the right and left hepatic ducts, which drain the bile originating in the right hemiliver and the left hemiliver. The main confluence is often incorrectly called *bifurcation* in the English literature; actually, although the portal vein and the hepatic artery carrying

**FIG 54.4 A and B.** Normal distribution of intrahepatic bile ducts: common hepatic duct (light green), left hepatic ducts (blue), right hepatic duct (dark green), right anteromedial duct (red), and right posterolateral duct (yellow).

the blood to the liver have bifurcations, the fusion of ducts collecting the bile from the liver with a flow directed toward the CBD generates a confluence. According to the segmental liver anatomy described by Couinaud,<sup>44</sup> the left hepatic duct collects the bile originating from segments II and III (left anatomic liver lobe or left lateral sector) and from segment IV (quadrant lobe). One or more small ducts originating from segment I (caudate lobe) also join the left hepatic duct close to the main confluence. The anatomic variations occurring in the left hepatic system are rare and are irrelevant in this perspective. The right hepatic duct is shorter than the left hepatic duct and follows the same axis of the common hepatic duct. The right hepatic duct originates from the confluence of the right anteromedial sectorial duct (segments V and VIII) and of the right posterolateral sectorial duct (segments VI and VII). The right anteromedial duct is recognizable thanks to its orientation, which follows the same axis of the right hepatic duct, whereas the right posterolateral duct joins the right anteromedial duct on its medial aspect with a typical umbrella handle-like shape.

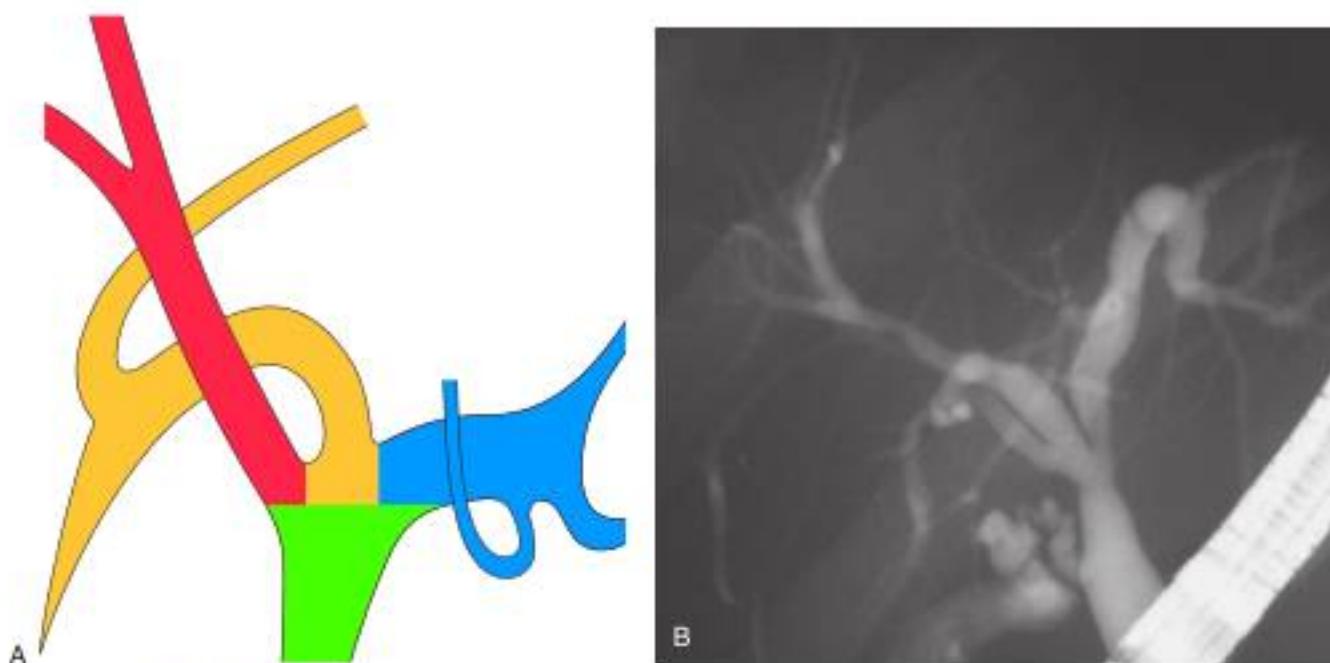

This normal anatomy (called *modular* by Couinaud) is present in approximately 60% of the population (Fig. 54.4).<sup>44,45</sup> The main hepatic confluence is usually located high in the hilar region. A lower position at the level of the hepatic pedicle may also occur, causing a much closer proximity to the insertion of the cystic duct into the hepatic duct (Fig. 54.5). The main variations of the main hepatic confluence are the absence of the right hepatic duct with the anteromedial and posterolateral right ducts joining independently to the left duct to form the confluence (Fig. 54.6), or with one of the two right sectorial ducts joining the main bile duct at a more distal level closer to the insertion of the cystic duct (Fig. 54.7). More rarely, an isolated segmental or subsegmental duct may join the CBD away from the main confluence, usually on the lateral aspect of the CBD close to the insertion of the cystic duct. Most aberrant ducts arise from the right liver and drain into the common hepatic duct or cystic duct within

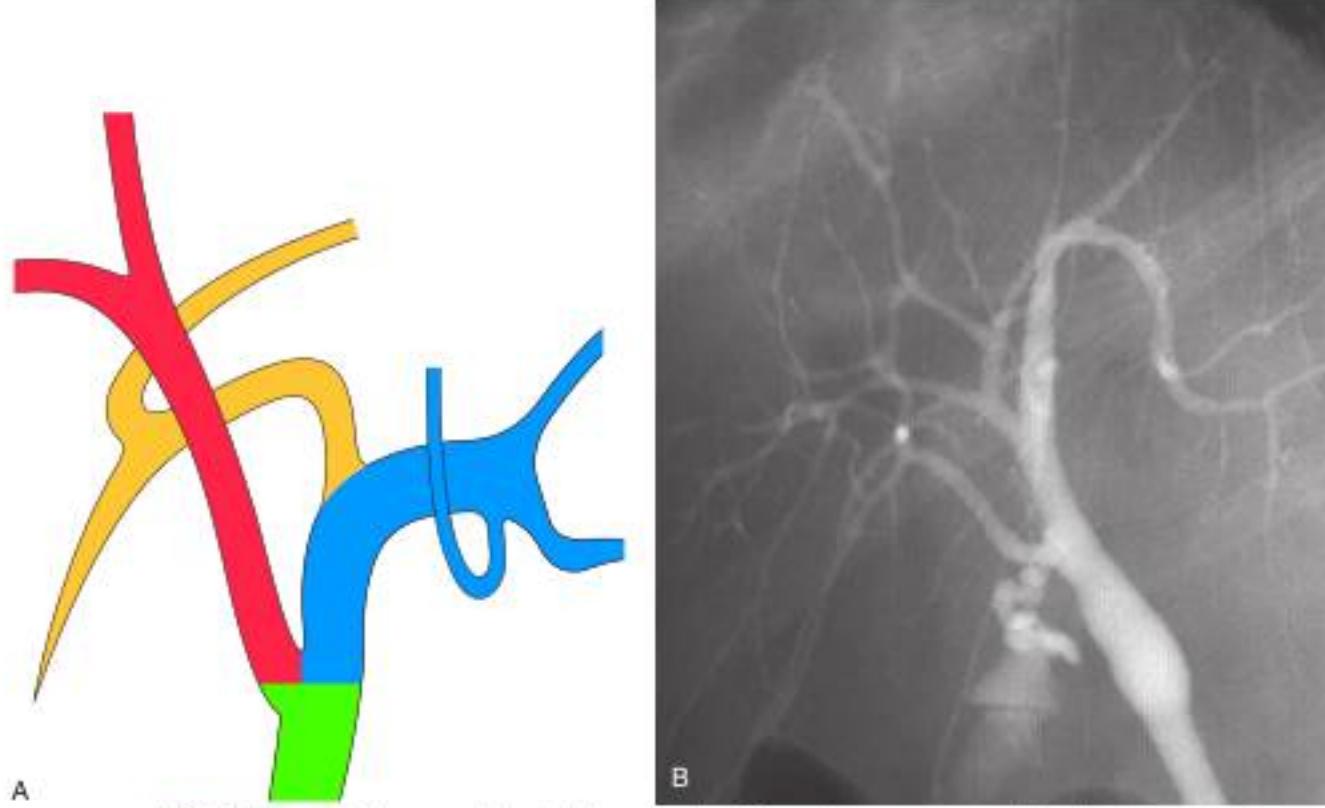

**FIG 54.5** Endoscopic retrograde cholangiopancreatography (ERCP) shows low main confluence with the cystic duct joining the right hepatic duct on its medial aspect.

30 mm of the hepatocystic angle.<sup>46</sup> These are the most dangerous anatomic variations for the surgeon during the dissection of the gallbladder pedicle. Apart from complete transection of the CBD (type D of the Bergman classification) (Fig. 54.8), which is typically an indication for open surgical repair, an attempt at endoscopic treatment may be envisaged in all other circumstances of biliary injury with concomitant bile leak.

The basic principle of endoscopic treatment is diminishing the transpapillary pressure gradient, equalizing the bile duct and

duodenal pressures, and allowing preferential flow of bile into the duodenum.<sup>47</sup>

#### Endoscopic Treatment of Minor Lesions

The largest part of biliary leaks from minor lesions originates from the cystic duct stump (Fig. 54.9), or the biliary anastomosis in the case of LT recipients. Bile leakage from the cystic duct stump may be due to stump dehiscence resulting from defective technique in clips positioning, inadvertent injury to the cystic wall below the closure, or partial disruption of the cystic duct implantation into the bile duct resulting from excessive traction. Biliary hypertension resulting from temporary impaction of a residual bile duct stone into the sphincter of Oddi in the early postoperative period is most likely the cause of cystic duct stump dehiscence in almost one-fifth of patients. Bile leakage in LT recipients can occur from the anastomosis, the cystic duct, the T-tube tract, or (in the case of living-donor or split liver LT)

from the cut surface of the liver. Many bile leaks can be resolved nonoperatively with early endoscopic intervention. Bile leaks after LC can also originate from severed ducts of Luschka (small peripheral ducts connecting the intrahepatic system with the gallbladder lumen) (Fig. 54.10), small subsegmental ducts running in the gallbladder bed, and segmental or subsegmental aberrant branches joining the CBD in the proximity of the cystic duct.

Treatment of these latter leaks does not differ from treatment employed when the leak arises from the cystic duct stump or the biliary anastomosis (Table 54.3). The transpapillary pressure gradient can be equalized by endoscopic sphincterotomy (ES) alone,<sup>48,49</sup> ES and stent or nasobiliary drain (NBD) placement,<sup>50</sup> and stent<sup>51,52</sup> or NBD placement alone<sup>53</sup> without prior ES (Fig. 54.11). All methods seem to be equally effective in facilitating the closure of the biliary leak, usually within 1 to 2 weeks of treatment in cases of LC<sup>54-56</sup> and 4 to 6 weeks in cases of LT.<sup>51,55</sup> If stones are present in the CBD, ES and stone extraction with

**FIG 54.10** Postoperative endoscopic retrograde cholangiopancreatography (ERCP) after laparoscopic cholecystectomy (LC) in a case of subhepatic bile collection. The common bile duct (CBD) is normal. Two clips are visible on the cystic artery and the cystic duct. A leak of contrast medium into the gallbladder bed originates from a duct of Luschka connecting a subsegmental branch that joins the CBD lower than the main confluence.

**TABLE 54.4 Endoscopic Options to Treat Postoperative Bile Leaks (Type A According to Bergman)**

Procedure	Advantages	Disadvantages
ES	Treatment of associated CBD stones	Complications
Nasobiliary drain (days)	Avoids ES Allows check cholangiography	Uncomfortable Prolongs hospitalization
Stent placement (wks)	Avoids ES	Repeat ERCP required Clogging, dislocation

CBD, common bile duct; ERCP, endoscopic retrograde cholangiopancreatography; ES, endoscopic sphincterotomy.

or without stent or NBD placement seems the preferred approach. However, each option has specific limitations. ES is associated with inherent immediate and potential long-term complications; stent placement requires a second procedure to remove the stent, which can also become clogged or can migrate; and NBD requires a prolonged hospital stay, is uncomfortable for the patient, and may be accidentally displaced. Advantages and disadvantages of the different options are summarized in Table 54.4.

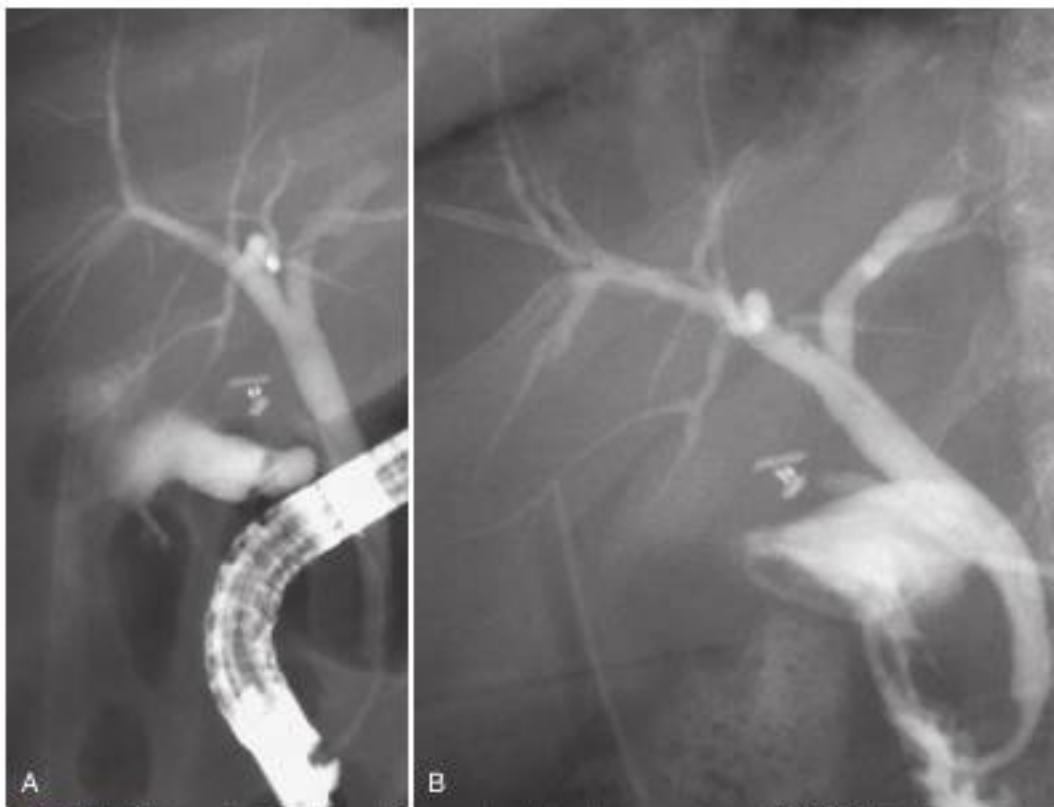

To select the optimal endoscopic therapy, Sandha et al (2004)<sup>30</sup> proposed classifying the bile leaks after LC by ERCP into two categories: low-grade (identified only after intrahepatic opacification) and high-grade (observed before intrahepatic opacification). Of 104 low-grade leaks, 75 were treated by ES alone with a success rate of 91%. Of 100 high-grade leaks, 97 were treated by stent insertion with a final success rate (4 patients had to undergo retreatment) of 100%. The investigators concluded that this simple, practical endoscopic classification system might be clinically relevant in the choice of endoscopic therapy. Endoscopic local injection of botulinum toxin in a canine model (Botox) to decrease the transpapillary bilioduodenal pressure gradient has also been reported.<sup>31</sup> Injection of 100 IU of botulinum toxin into the sphincter of Oddi was shown to lower CBD pressure significantly within 24 hours. This effect lasted for 2 weeks on average in the animal model. Postoperative bile leaks from minor lesions (type A) are usually amendable to endoscopic management with plastic stents and biliary sphincterotomy with a very high success rate. All methods seem to be equally effective in facilitating the closure of the leak within a few days.

In cases of LT, bile leaks in the first month after LT usually occur at the anastomotic site and are usually related to technical problems of the surgery or severe HAT.<sup>32</sup> Late bile duct leaks are usually related to the removal of the T-tube, resulting from delay in T-tube tract maturation due to immunosuppression. A bile leak should be suspected in patients who develop pain when the T-tube is removed. In cases where a T-tube is in place, small anastomotic leaks can be diagnosed with a T-tube cholangiogram and can be managed by leaving the tube open without further intervention. In patients without a T-tube, endoscopic retrograde cholangiography (ERC) is considered the gold standard diagnostic method in detecting bile leaks. Therapy also includes placement of a plastic stent with or without sphincterotomy, as described earlier.<sup>21,25,33–36</sup>

#### Endoscopic Treatment of Major Lesions

Bile leakage in major lesions originates from a tear on the CBD or on one of the biliary branches that form the main hepatic confluence (type B). In both instances, ES alone may be inadequate to diminish the leak. It is preferable to insert at least one large-bore plastic stent (10-Fr to 11.5-Fr), long enough to bypass the site of injury. The secondary intent of stent placement is to prevent the development of stricture at the site of the injured bile duct wall. For this purpose, the stent should be left in place for at least 8 to 12 weeks to allow the healing process to stabilize. In case of secondary stricture formation at the site of injury, the presence of a stent already in place facilitates successive endoscopic maneuvers to dilate the stricture. Therapeutic success may be obtained in 71% to 90% of cases (Fig. 54.12 and Video 54.1).<sup>33,34</sup>

Biliary stents have also been successfully used to reestablish the continuity of disrupted segmental branches at the level of the main hepatic confluence<sup>34</sup> and for leaks from aberrant bile ducts.<sup>35,36</sup> In major biliary injury with bile leakage, the primary therapeutic objective, if there is no transection, is to bypass the leak with the stent to divert bile flow to the duodenum and convert an acute problem into a stable condition. The high efficacy of the endoscopic approach in this setting justifies its use as a first-line treatment whenever possible. Treatment of postoperative bile duct strictures in the prelaparoscopic era was traditionally surgical. The role of ERCP was limited to the diagnostic phase and particularly to the definition of the level and extent of the lesion (Video 54.2).

**FIG 54.11** Postoperative endoscopic retrograde cholangiopancreatography (ERCP) after laparoscopic cholecystectomy (LC) in a case of external biliary fistula through a subhepatic drain. **A**, Leak of contrast medium originating in the gallbladder bed (duct of Luschka) is seen. **B**, Check cholangiography performed 3 days after endoscopic sphincterotomy and nasobiliary drain placement. The leakage is no longer visible.

In LT recipients, placement of a plastic biliary stent (10-Fr to 11.5-Fr), with or without biliary sphincterotomy, across the leak is successful in treating 90% to 95% of bile leaks.<sup>21,55,58–60</sup> As a result, if there is a strong clinical suspicion, ERC is the treatment of choice. In contrast to postcholecystectomy leaks, where the stent can be removed in 4 weeks, in post-LT leaks it is preferred that the stent be left in place for approximately 2 months because of problems with delayed healing that may arise due to immunosuppression.<sup>21,60</sup> Stents are not changed during this period unless there is a clinical suspicion of obstruction. At the end of this period, the leak has typically healed and no other stent is needed.

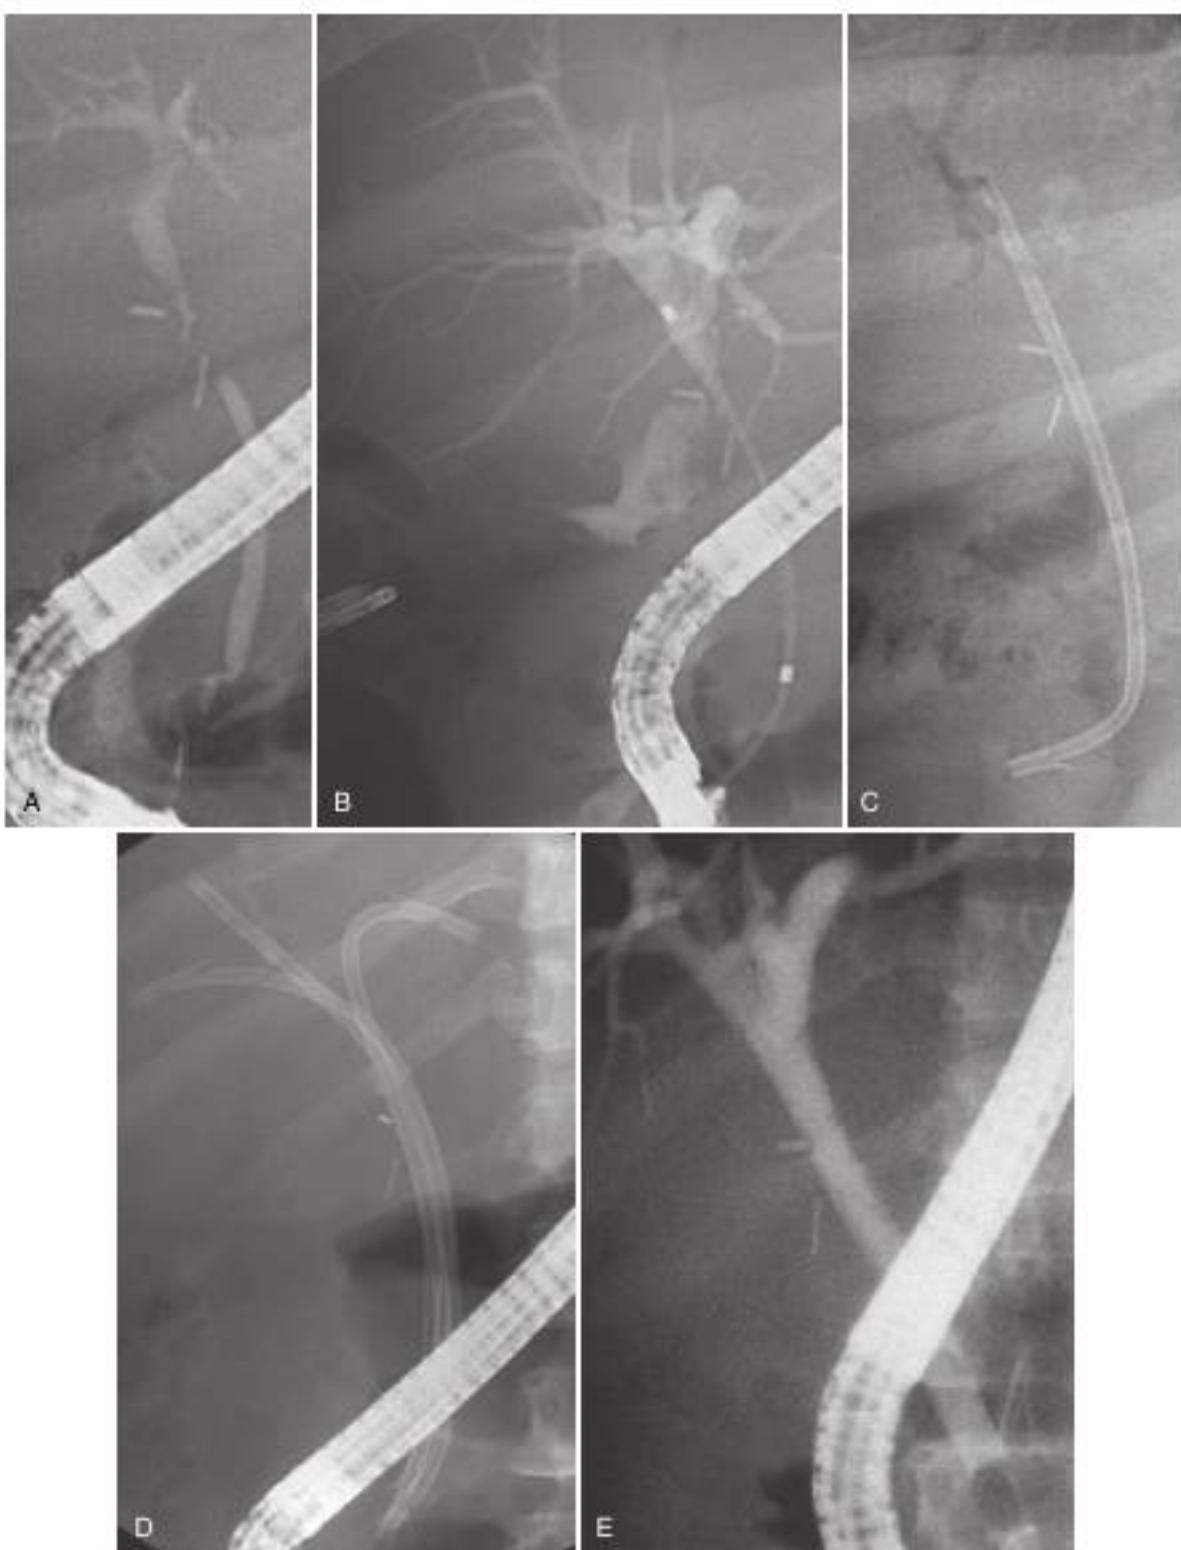

Aside from this approach (sphincterotomy with plastic stent placement), some authors now advocate the use of fully covered self-expandable metal stents (FCSEMS) for patients with bile leaks (mainly postcholecystectomy leaks) given the high resolution rates (93%–95%).<sup>64,65</sup> It is the clinical experience that FCSEMS are useful in some LT recipients with large or refractory bile leaks. However, information is limited.

## BILIARY STRICTURES

Along with the increasing use of ERCP in the evaluation and treatment of acute complications of LC and LT, therapeutic ERCP has been increasingly employed to manage postoperative biliary strictures. The first nonoperative alternative in the management of bile duct strictures was the percutaneous transhepatic approach.

After establishment of percutaneous access to the intrahepatic bile ducts, the stricture is crossed with a guidewire, and pneumatic balloon dilation is performed. Although instantly very effective, this approach has a very limited value in the longterm because of the high rate of stricture recurrence.<sup>66</sup> Approximately one-third of patients undergoing this treatment modality experience complications, and stricture recurrence develops in at least 25% of cases during follow-up.<sup>67,68</sup> In another series published by the group at The Johns Hopkins University, the success rate of these procedures was only 55%, with 20% of patients having significant hemobilia.<sup>69</sup> The high recurrence rate after percutaneous pneumatic dilation is most likely due to the forceful disruption of the scar, which can add further traumatic damage to the tissue and consequential development of new local fibrogenic reaction.

The percutaneous approach has been progressively replaced by the endoscopic approach. The endoscopic approach avoids the need for liver puncture, which is the main cause of complications of the percutaneous approach; it is not more difficult when the intrahepatic bile ducts are not dilated or only slightly enlarged, which is often the case in postoperative strictures; and it is also feasible in case of liver cirrhosis, ascites, or coagulopathy. The endoscopic approach avoids the need for long-standing percutaneous internal-external catheters, improving the patient's comfort and compliance. At the present time, the endoscopic approach is considered the first-line, nonoperative alternative to surgical treatment; in addition, it never hinders the option of a surgical

**FIG 54.12** Postoperative endoscopic retrograde cholangiopancreatography (ERCP) after laparoscopic cholecystectomy (LC) in a case of peritoneal bile collection and cholestasis. **A**, Stricture of the common bile duct (CBD) with clips overlapping. **B**, A catheter has been passed over the stricture using a guidewire; injection of contrast medium through the catheter clearly shows the site of biliary injury and the correspondent leak. **C**, A 10-Fr plastic stent has been placed. **D**, During the following months, three 10-Fr stents were inserted to dilate the stricture, one in each main biliary territory (anteromedial right, posterolateral right, and left biliary ducts). **E**, Balloon-occluded cholangiography after removal of the three stents. The stricture has completely disappeared.

approach as a rescue therapy in case of failure.<sup>70</sup> Both surgery and endoscopic treatment may obtain good results. However, the two alternatives have never been systematically compared in a prospective randomized trial. It is also very unlikely that such a study will ever be conducted in the future because of the relatively low incidence of this pathology, its dispersion in several centers, and the heterogeneity of its clinical and morphologic presentation, which would make it very difficult to gather cases in homogeneous groups large enough for any comparison.

### Description of Technique

Endoscopic treatment of postoperative biliary strictures is based on three steps: (A) traversing the stricture, (B) dilation of the stricture, and (C) stent placement.

#### Traversing the Stricture

The morphologic requirement that allows the traversing of the stricture is the continuity of the CBD. In the case of complete transection or complete obstruction of the bile duct, the endoscopic option alone is applicable in only a very few cases. A combined percutaneous and endoscopic approach with an aim at reconstructing the missing segment of the bile duct can be performed.<sup>71</sup> A similar combined approach has also been described in the case of complete obstruction of the distal biliary stump; percutaneous puncture of the distal stump was performed under radiologic guidance with a device designed for nonbiliary use (a set marketed for placing transjugular intrahepatic portosystemic shunts).<sup>72</sup> However, because of the lack of standardization, these approaches cannot be recommended on a routine basis.

In most cases, and especially when symptoms develop a long time after surgery, the CBD is accessible by endoscopy, and the stricture is incomplete, traversing the stricture is the mandatory and preliminary step before performing dilation. This maneuver is often much more difficult in postoperative strictures than in neoplastic strictures because the stenosis, even if commonly very short, may be asymmetric and irregular. The fibrosis makes it especially thin and tightened. It is often necessary to use thin hydrophilic guidewires (0.021 inch or 0.018 inch) with a straight or J-type extremity; their manipulation requires patience, skill, and optimal x-ray control.

The morphology of the stenosis has to be respected, and forceful maneuvers with stiff guidewires that may create false routes leading to the failure of the procedure should be strictly avoided. Changing the position of the patient may help in radiologically identifying the right pathway to follow with the guidewire. Pulling on a stone retrieval balloon inflated under the stricture may help in stretching the bile duct and in modifying the axis of the guidewire. Manipulation of bendable catheters or papillotomes may also be used to change the direction of the guidewire. When the stricture is passed, the hydrophilic guidewire is exchanged for a stiffer and more stable one to proceed to dilation.

#### Dilation of the Stricture

Dilation of the stricture has two objectives: (A) to reopen the bile duct to achieve a regular bile flow, and (B) to secure a larger diameter to avoid restenosis in the long-term. In the beginning of endoscopic treatment, only the first objective was pursued; in the percutaneous approach, the mainstay of treatment was pneumatic dilation alone.<sup>73</sup> However, it soon became clear that even if immediately very effective, pneumatic dilation alone was ineffective in granting good results in a long-term follow-up. At

the present time, pneumatic dilation is mainly used as a preliminary step before placement of one or more plastic stents (Fig. 54.13). The role of stent placement is to keep the stricture open for a long time (months to years, according to different treatment strategies), while allowing scar modeling and its consolidation.<sup>74</sup>

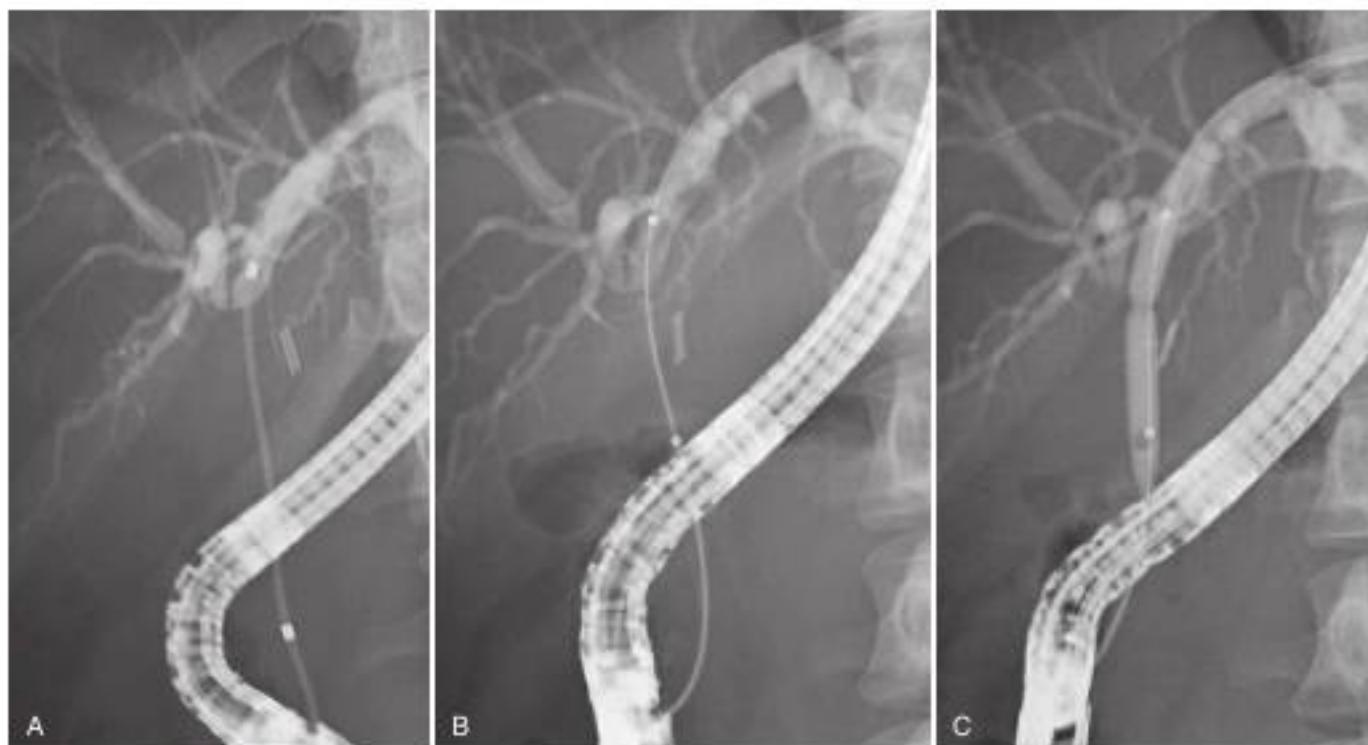

#### Strictures After LC

Typically, two 10-Fr stents are placed, exchanged every 3 months to avoid cholangitis resulting from stent occlusion, and left in place for 1 year. In a retrospective study from the Amsterdam group reporting on the multidisciplinary experience obtained during a decade (1981–1990), the long-term results of endoscopic treatment were compared with the long-term results of surgery.<sup>75</sup> Surgery (Roux-en-Y hepaticojejunostomy) was performed in 35 patients, and endoscopic treatment was performed in 66 patients. Patient characteristics, type of initial injury, and level of obstruction were not significantly different in the two groups. At a mean follow-up of 50 months and 42 months for the surgical and the endoscopic groups, 83% of patients in both groups had an excellent (asymptomatic patient with normal or stable laboratory parameters) or good (single episode of cholangitis) result. Immediate complication rate was in favor of endoscopic treatment (8% vs. 26% for surgical treatment), whereas 21% of the patients had at least one episode of cholangitis resulting from stent malfunction during the stent period (two 10-Fr stents for 1 year with stent exchange every 3 months).<sup>75</sup>

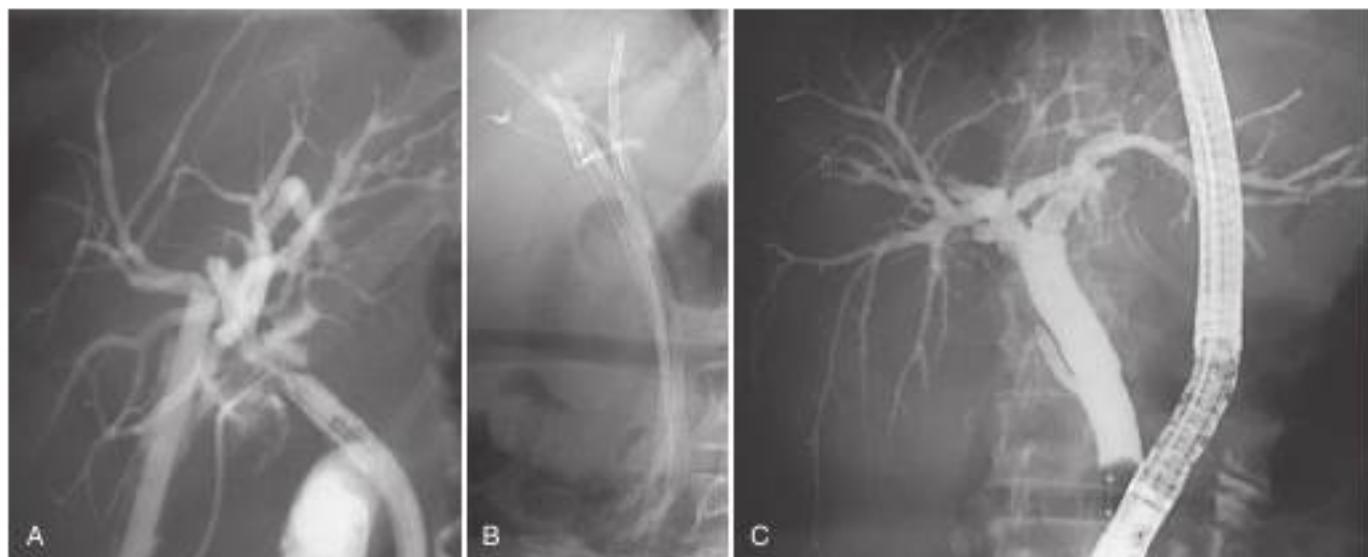

When analyzing the long-term results, it becomes immediately evident how the time interval between the end of treatment and the symptomatic recurrence of the stricture is much shorter in the group with endoscopic treatment compared with the surgical group (on average  $3 \pm 11$  months vs.  $40 \pm 11$  months), indicating possible undertreatment in the endoscopy group.<sup>75</sup> However, this important study showed that endoscopic treatment may be considered at least as effective as surgical treatment in terms of long-term results, having the major advantage of not hindering any further surgery if necessary. Several other experiences of endoscopic treatment with plastic stents of postoperative biliary strictures have been published in recent years.<sup>76–85</sup> From the analysis of the available data, however, this treatment modality still seems far from standardized; the published experiences differ in terms of number of stents placed, their caliber, exchange intervals, and definition of treatment objectives and of outcomes. Examples of two different methodologic approaches follow:

- The treatment protocol used by the Amsterdam group (74 patients) is the classic one, entailing placement of two 10-Fr stents, exchanged every 3 months for 1 year (the period of stent placement).<sup>75</sup> Preliminary pneumatic dilation had been performed in approximately one-fourth of the patients before stent insertion. A combined percutaneous-endoscopic approach to bypass the stricture with a guidewire was required in only three cases. Stents were removed after 1 year.
- The protocol described by the Italian group (55 patients)<sup>79</sup> involved the placement of the maximum possible number of stents (ideally 10-Fr) in relation to the tightness of the stricture and diameter of the CBD at every treatment session with a trimonthly interval. Treatment was continued until complete morphologic disappearance of the stricture at cholangiography (Fig. 54.14).

Preliminary balloon dilation was performed in 40% of the patients, almost always at the first treatment session. A combined percutaneous-endoscopic approach was required in three cases.

**FIG 54.13** Postoperative stricture after laparoscopic cholecystectomy (LC) converted to open cholecystectomy. **A**, At the level of the main confluence, a very tight stricture has been overcome by a catheter and guidewire. **B**, A balloon dilator has been passed through the stricture over the guidewire. **C**, Balloon dilation is performed. Notice the waist on the balloon indicating high stricture firmness.

**FIG 54.14** Postoperative cholangiography through a T-tube drain placed at cholecystectomy to repair complete transection of the common bile duct (CBD) at the hilum. **A**, Stricture and leak of contrast medium around the CBD are visible. **B**, At the end of the fifth treatment, 10-Fr stents have been placed. **C**, Balloon-occluded cholangiography after stent removal. The stricture has disappeared completely.

The mean number of stents inserted was 1.7 (range 1 to 4) at the first session and 3.2 (range 1 to 6) at the end of the treatment. Disappearance of the stricture was checked 24 to 48 hours after removal of the stents by check cholangiography through NBD. Early complications developed in four (9%) patients (three cholangitis, one pancreatitis), and stent occlusion that required early stent exchange occurred in eight (18%) patients. Mean duration of treatment was  $12.1 \pm 5.3$  months (range 2 to 24 months). Follow-up included clinical evaluation, laboratory parameters, and liver US every 3 months during the 1st year and every 6 months in the following years.<sup>79</sup>

- In the Amsterdam series,<sup>71</sup> the technical success of stenting was 80%; however, only 44 patients (59% of the initial cohort and 75% of patients in whom an initial technical success had been obtained) concluded the 12-month stent period for different reasons. At a median follow-up of 9 years, 9 out of 44 patients (20%) developed recurrent strictures. In eight of nine cases, recurrent strictures developed within the first 6 months of follow-up (median 2.6 months). On an intention-to-treat basis, this protocol was able to resolve definitively the bile duct stricture in 47% of the initial cohort. The results of this study suggest that endoscopic stent placement is not the best treatment option for patients with low compliance to repeated treatment sessions. Similar results, with 81% of patients symptom-free at a mean follow-up of 9.5 years, were reported in an abstract form by the Toronto group by using the same treatment protocol.<sup>76</sup>
- In the Italian study, 42 out of 55 patients initially considered were evaluable at a mean follow-up of 49 months after the end of treatment.<sup>70</sup> Ten patients were excluded from the protocol because of complete CBD section ( $n = 5$ ) or use of self-expandable metallic stents (SEMSs) ( $n = 5$ ). Another three patients were not evaluable for different reasons. Two patients died of unrelated causes during follow-up. Among the remaining 40 patients, there was no recurrence of symptoms caused by relapsing biliary stricture. One patient sustained two episodes of cholangitis but without stricture recurrence. By an intention-to-treat analysis, the success rate was 89% (40 of 45). Although the follow-up period in this series is shorter compared with the Amsterdam series, it is longer than the typical period during which all the recurrences after endoscopic treatment have been described (2 years). This more aggressive approach to endoscopic treatment with stents seems to improve long-term results for patients with postoperative biliary strictures. The authors reported on the very long-term results of this aggressive approach in the same cohort of patients<sup>76</sup>; of 35 evaluable patients after a mean follow-up of 13.7 years, seven (20%) had recurrent cholangitis owing to relapse of the stricture in four patients (all successfully retreated with stents) and newly formed bile duct stones in three patients. The remaining 28 patients remained completely asymptomatic with normal liver function tests and abdominal US.

At the present time, multiple stent placement is a well-accepted strategy adopted for postoperative bile duct strictures.<sup>80-84</sup> According to the published data, endoscopic treatment with stents of major bile duct injuries and strictures is at least as effective as surgical treatment. The advantages of endoscopic treatment are its simplicity, reversibility, and minimal invasiveness. Endoscopic treatment should always be considered, whenever available, in the therapeutic algorithm of most patients with major bile duct injuries. For most patients, it may be the only treatment required. Endoscopy and surgery should be considered as complementary

treatments. This complex and difficult pathology is best managed in centers in which a multidisciplinary approach is available.

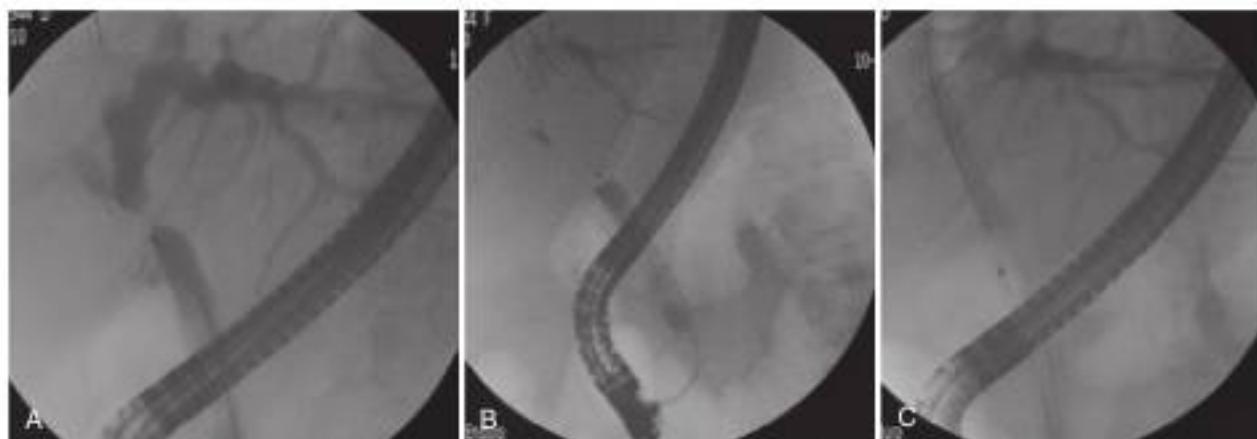

## STRICTURES AFTER LT

The majority of ASs occur within the first year after LT.<sup>85</sup> ASs identified within the first 6 to 12 months after LT usually have a good response to stenting every 3 months.<sup>81</sup> However, patients require long-term surveillance because strictures often recur. One study demonstrated that patients with biliary strictures after LT and who were initially treated endoscopically with balloon dilation and plastic stents had a recurrence rate of 18% with a mean time to recurrence of 3.7 months.<sup>82</sup> In a second study, the recurrence rate following endoscopic treatment was 34%, with a mean time to recurrence of 14.5 months.<sup>83</sup>

The characteristic cholangiographic appearance of an AS is that of a thin narrowing in the area of the biliary anastomosis (see Fig. 54.3). In some patients, a transient narrowing of the anastomosis may become evident within the first 1 to 2 months after LT due to postoperative edema and inflammation. This type of narrowing responds to endoscopic balloon dilation and plastic stent placement; in most patients, it will resolve within 3 months, and the anastomosis will remain patent without further intervention.<sup>84</sup>

Most patients with ASs after LT require ongoing ERC sessions every 3 months with balloon dilation and long-term stenting (for 12 to 24 months). This technique consists of placing a guidewire across the stricture (Fig. 54.15), followed by a dilation of the AS using balloon diameters of 6 to 8 mm, and, finally, placing 10-Fr to 11.5-Fr plastic stents with an increasing diameter and number if possible in each session (see Fig. 54.15). The standard technique requires sphincterotomy of the papilla before stent placement. Plastic stents need to be exchanged every 3 months to avoid occlusion and bacterial cholangitis. This approach has been reported to be more effective than dilation alone.<sup>85</sup> Increasing the number of stents in each session improves success rates and thus placing the maximal number of stents possible in each session is recommended; in general up to 5 or 6 stents are needed. In a retrospective study of 83 LT recipients with ASs, treatment success was associated with the number of stents placed (8 in the success group vs. 3.5 in those in whom treatment failed).<sup>86</sup> Another study found that among 56 patients at a large academic hospital who underwent ERC for LT-related biliary complications between July 1994 and March 2012, resolution of AS was seen in 50 out of 51 patients (98%), and mean duration of endoscopic treatment was 11.5 months, with a median of 4 ERCS per patient.<sup>87</sup> After a median follow-up of 5.8 years from stent removal, 3 out of 50 patients (6%) had recurrence of ASs. All three were successfully treated again endoscopically and were asymptomatic after a further median follow-up of 5.6 years. This approach usually requires several interventional sessions (mean of 3 to 5 sessions per patient) in order to achieve long-term success rates of 70% to 100%.<sup>85-88</sup> Table 54.5 describes the findings of different studies evaluating the outcome of dilation and plastic stent placement of biliary ASs.

There is some clinical experience in temporary (approximately 3 to 12 months) placement of covered SEMS to reduce the need for repeated stent exchanges. In a systematic review that included 200 patients treated with SEMS, stricture resolution rates of 80% to 95% were seen when the stent duration was 3 months or longer.<sup>89</sup> However, the stent migration rate was 16%. By comparison, the stricture resolution rate was 94% to 100% for patients

**FIG 54.15** Biliary anastomotic stricture after liver transplantation (LT). **A**, A guidewire is pushed across the anastomotic stricture. **B**, The guidewire allowed the dilation of the stricture and afterward, **C**, The placement of two plastic stents across the stricture. Once placed, the stents allow drainage of bile and contrast.

ERCP, endoscopic retrograde cholangiopancreatography; SEMS, self-expandable metal stent.

who were treated with plastic stents for 12 months or more.<sup>103</sup> A 2014 multicenter prospective study that included 187 patients with benign strictures analyzed the role of FCSEMS. In the study, 42 LT recipients with ASs were treated with FCSEMS. There was a resolution rate of only 68% with a significant complication rate (38%), mainly due to cholangitis.<sup>104</sup> Finally, a randomized trial with 112 patients with benign biliary strictures (from LT, chronic pancreatitis, or other postoperative injury) found a resolution rate by 12 months of 93% with SEMS and 85% for plastic stents.<sup>105</sup> Stricture recurrence was seen in 14% of the patients treated with SEMS and 5% of patients treated with plastic stents. However, in the subgroup of 73 patients with biliary strictures after LT, there was no difference in stricture resolution rates (95% each) or number of days (371 SEMS vs. 367 plastic) to resolution among both groups. Currently, there are not enough data to support the systematic use of SEMS over plastic stents in the treatment of ASs. The use of SEMS may be beneficial in patients who fail therapy with plastic stents and dilatation; however, data are scarce, and migration rates in this setting are also high.<sup>106,107</sup>

## COMPLICATIONS

Complications may occur during the first treatment session and are related to ES (acute pancreatitis, retroperitoneal perforation, and bleeding), which is usually performed to gain access to the bile ducts, or occur during the stent period. ES-related complications in this setting do not differ in frequency, severity, and management from complications encountered in other, more common situations, such as treatment of CBD stones. In LT recipients, the rate of these complications is not very different from that of the general population. There is up to a 9% complication rate per procedure.<sup>108</sup> The most common complications are pancreatitis, cholangitis, and postsphincterotomy bleeding. Other complications include bile leak, subcapsular hematoma, perforation, and stent migration. Complications arising during the stent period are mostly due to stent dysfunction (i.e., obstruction, migration, dislocation, and impaction). Acute cholangitis is the typical clinical manifestation of stent dysfunction. Cholangitis is usually mild and often self-limited in this setting, but requires prompt endoscopic evaluation and reestablishment of correct bile drainage by stent repositioning.

A typical complication of long-term stent placement is the development of biliary sludge and stones above the stricture. This condition may cause cholangitis, but it may also be totally asymptomatic. In addition, liver function tests may be completely normal. The lack of symptoms and normal liver function tests may lead to unintentional prolongation of the planned stent period. Removal of all stones and sludge by basket or balloon extraction or both is mandatory before placement of a new stent or stents to avoid potential early reocclusion. To avoid stone formation, the trimonthly time schedule of stent replacement should not be prolonged. Patient compliance is crucial when dealing with postoperative bile duct stricture, and patients should always be fully informed of the inherent risks of not following the planned treatment program.

## FUTURE TRENDS

The main limitation of endoscopic treatment of postoperative bile strictures with the current method of multiple plastic stent placement is the need for repeat interventions over a long time

(1 year on average). The ideal stent would allow progressive dilation of the stricture during weeks or months and would dissolve once the goal had been reached. Uncovered SEMS have proved to be a bad alternative to plastic stents for several reasons. First, SEMS invariably induce a hyperplastic response of the inflammatory tissue at the level of the stricture. This hyperplastic reaction ultimately leads to occlusion of SEMS, on average less than 1 year after their placement. Second, SEMS are usually not removable; treatment of secondary stricture resulting from hyperplastic reaction requires repeated balloon dilations and plastic stent placement. Third, biliary SEMS have been developed to produce abrupt recanalization of a stricture resulting from neoplastic invasion; the radial force exerted by the stent is much higher than the force desirable to induce progressive dilation of a scar, such as the scar of postoperative bile duct strictures.

Partially covered SEMS have the advantage of avoiding ingrowth of hyperplastic tissue at the level of the stricture and of often being removable; however, no clinical experience is available. The advent of fully covered, removable SEMS has raised new interest concerning their potential use in benign conditions. These stents, although effective, are not superior to plastic stents, and there is not enough information to recommend the systematic use of SEMS over plastic stents in the initial treatment of biliary strictures. The use of SEMS may be beneficial in patients who fail therapy with plastic stents and dilatation; however, data are scarce, and migration rates in this setting are also high.<sup>103-107,109</sup> Drug-eluting, self-expandable stents have been used in the vascular system to inhibit endothelial growth; it is conceivable that this technology might become available for use in the biliary system.<sup>110,111</sup> Local release of antiinflammatory drugs able to control the fibrogenetic process that occurs during healing of a biliary injury may be valuable in this setting.

## INTRODUCTION

The word *cholangitis* is a pathologic term that means "inflammation of bile ducts." It is a broad term and does not imply any specific diagnosis. In clinical practice, cholangitis is defined on the basis of symptoms and signs of systemic sepsis originating in the biliary tract.<sup>1</sup>

The most important predisposing factor for infections of the biliary tract, including the common bile duct (CBD) and gallbladder, is obstruction to the flow of bile. By far, gallstones remain the most common cause of obstruction and infection of biliary tract (cystic duct or CBD). Other causes of cholangitis include biliary strictures (benign or malignant), recurrent pyogenic cholangitis (RPC), iatrogenic (post-endoscopic retrograde cholangiopancreatography [ERCP]), parasitic (Ascaris, liver flukes, echinococcal), viral (HIV cholangiopathy), etc. (Box 55.1). In this chapter, we shall discuss biliary tract infections (cholangitis and cholecystitis) due to various etiologies and their management.

## ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

### Indications

The primary indication for ERCP in infectious cholangitis is to decompress the obstructed biliary system.

### Contraindications

Contraindications to ERCP in biliary tract infections are similar to other endoscopic procedures. Patients who are unable to tolerate conscious sedation because of cardiopulmonary disease require an anesthesia assessment. The risk of adverse reaction to iodine containing contrast media is very low, and prophylactic premedication for contrast allergy is usually not required.<sup>2</sup>

ERCP in pregnancy is apparently safe for both the mother and the fetus compared with the risk of delay in definitive treatment of cholangitis, which may be life-threatening.<sup>3</sup>

Radiation to the fetus can be minimized by external shielding with a lead apron placed under the lower abdomen, limiting fluoroscopy time, collimating the beam to the area of interest, using brief "snapshots" of fluoroscopy, and avoiding hard copy x-ray films.<sup>4</sup>

### Equipment

To perform ERCP, a side-viewing endoscope (duodenoscope) and fluoroscopy are required. Cannulation with a sphincterotome is recommended because most cases of biliary tract infection require a sphincterotomy. A guidewire is essential for selective cannulation of the intrahepatic ducts and the cystic duct and for accessing the biliary tree proximal to a stricture. To extract intraluminal debris, a biliary extraction basket and/or balloon

### Abstract

Biliary tract infections are encountered frequently in gastrointestinal (GI) practice. Cholangitis is a clinical syndrome comprising fever, pain, and jaundice. Obstruction and stasis in the biliary tract leads to raised intrabiliary pressure, which subsequently results in bacteremia. There are various etiological factors for cholangitis, such as biliary calculi, strictures, parasites, post-endoscopic retrograde cholangiopancreatography (ERCP), postoperative, etc. In contrast to other causes, biliary parasitoses is more common in Southeast Asia. Common parasites involving the biliary tract include *Ascaris lumbricoides*, liver flukes, and *Echinococcus*. The incidence of acquired immune deficiency syndrome-related cholangiopathy has decreased after the availability of potent antiretroviral regimens. More recently, improper reprocessing of the endoscopes has been implicated in outbreaks of multidrug-resistant organisms. With the availability of excellent less invasive or noninvasive modalities like endoscopic ultrasound and magnetic resonance cholangiopancreatography, ERCP is now mainly performed with therapeutic intent. Irrespective of the etiology, the mainstay of management of an infected biliary tract is drainage of infected biliary system. The availability of endoscopic ultrasound (EUS)-guided biliary drainage and enteroscopy-assisted ERCP has allowed safe and easy access to the biliary tree in cases of inaccessible papillae. Therefore, most cases of biliary tract infections can be managed nonoperatively. However, a multidisciplinary approach involving endoscopists, interventional radiologists, and surgeons may be required in some cases, such as recurrent pyogenic cholangitis and hydatid disease of liver.

AIDS, acquired immunodeficiency syndrome; ERCP, endoscopic retrograde cholangiopancreatography.

must be available. Mechanical lithotripsy may be necessary before extraction of larger stones. Dilating catheters or a biliary dilation balloon, or both, and a selection of plastic and metal biliary stents are required to manage cholangitis secondary to a biliary stricture. A cytology brush and biopsy forceps are used to sample the stricture before stent insertion. Nasobiliary tubes are needed for biliary instillation therapy in certain forms of parasitic cholangitis. Duodenoscope-assisted cholangioscopy may be required to identify completely obstructed intrahepatic ducts, place a guidewire across a stricture, perform directed biopsies of a biliary stricture, and perform electrohydraulic lithotripsy (EHL) or laser lithotripsy (LL).

**Preparation**

The patient should be kept nothing per mouth (NPO) after midnight the day before ERCP. In urgent situations this may not be possible. Coagulopathy should be corrected if possible. A decision to discontinue anticoagulants or antiplatelet agents should be individualized. There is insufficient evidence to support routine discontinuation of aspirin and nonsteroidal antiinflammatory drugs before therapeutic ERCP procedures. Antibiotics should be administered for prophylaxis of post-ERCP cholangitis if indicated, but patients with established cholangitis will already be receiving antibiotics.

**Postprocedure Care**

If complete endoscopic drainage is not achieved during the initial procedure, antibiotics should be continued until definitive therapy is performed by repeat endoscopic, percutaneous, or surgical biliary decompression. Biliary obstruction resulting from hilar strictures and intrahepatic duct strictures, particularly multiple strictures as seen in sclerosing cholangitis, often require antibiotics after the procedure. Antibiotics, however, are not a substitute for adequate biliary drainage.

The duration of antimicrobial therapy for acute cholangitis is a subject of debate. As per the Tokyo guidelines, patients with

**TABLE 55.1 Acute Cholangitis and Sepsis After ERCP: Risk Factors and Mechanisms**

	<b>Risk Factors</b>	<b>Mechanism</b>
1. Disease-related	Complex hilar strictures; PSC, post liver transplant	Incomplete biliary drainage
2. Instrument-related	Contaminated duodenoscopes/accessories Faulty scope design	Improper scope disinfection
3. Host defense	Immunocompromised patient	Impaired host defense

PSC, primary sclerosing cholangitis.

moderate or severe acute cholangitis (see later sections in this chapter) should receive a minimum duration of antibiotics for 5 to 7 days. In patients with mild cholangitis or after successful endoscopic therapy, a duration of 2 to 3 days is sufficient.<sup>3,4</sup>

**Complications**

Complications of ERCP include the complications inherent to any endoscopic procedure, including reactions to medications, cardiopulmonary complications, infection, perforation, hemorrhage, and complications specific to ERCP, such as pancreatitis, postsphincterotomy hemorrhage, and biliary infection. Infectious complications of ERCP are post-ERCP cholangitis and long-term postsphincterotomy cholangitis. However, delayed and unsuccessful ERCP are the two major factors associated with complications and worse outcomes in patients with acute cholangitis.<sup>7</sup> Endoscopic sphincterotomy may be avoided in patients with acute severe cholangitis due to increased risk of bleeding.<sup>8</sup>

**ERCP AND BILIARY TRACT INFECTIONS (IATROGENIC CHOLANGITIS)**

ERCP is the mainstay of endoscopic drainage of the biliary tract. Asymptomatic bacteremia is common after diagnostic or therapeutic ERCPs. However, it is rarely significant clinically and routine antibiotic prophylaxis is not recommended after ERCP. Biliary tract infections after ERCP include acute cholangitis, acute cholecystitis, and cholangitic abscesses (Table 55.1).

The most important risk factor for acute cholangitis after ERCP continues to be incomplete drainage of an obstructed biliary system. ERCP in patients with complex hilar strictures (Bismuth type III/IV), post live donor liver transplant, and primary sclerosing cholangitis (PSC) are associated with higher risks of incomplete biliary drainage and subsequent cholangitis. Therefore, antibiotic prophylaxis should be considered in these situations.

Another important risk factor for post-ERCP sepsis is improper reprocessing of the endoscopes. Failure of adherence to the endoscope disinfection guidelines along with difficulty in cleaning the elevator of the duodenoscope has resulted in recent outbreaks of multidrug resistant organisms like *E. coli*, *Klebsiella*, and *pseudomonas*.<sup>9,10</sup> Therefore, newly designed endoscopes should be subjected to strict premarketing validation of the reprocess ability and post-marketing surveillance.<sup>11</sup>

Acute cholecystitis may occur in 1.9% to 12% of patients after ERCP.<sup>12</sup> It is usually associated with metal stent placement for malignant biliary obstructions. Obstruction of the cystic duct

orifice by the stent, tumor involvement of the cystic duct, and introduction of nonsterile bile or contrast agent are the proposed factors that predispose to acute cholecystitis in these patients.<sup>15</sup>

### Prevention

Iatrogenic cholangitis after ERCP should be prevented when possible. Delineation of biliary anatomy with prior magnetic resonance cholangiopancreatography (MRCP) will provide an anatomical road map for ERCP. Prophylactic antibiotics should be used in patients at high risk of incomplete biliary drainage. Contrast agents must not be instilled into obstructed segments prior to securing a guide wire beyond obstruction. The use of air cholangiogram is an attractive strategy to prevent cholangitis in hilar strictures and deserves further evaluation in randomized trials.<sup>16</sup>

In the case of incomplete drainage, biliary drainage with an alternate modality (percutaneous, endoscopic ultrasound [EUS]-guided, or surgical) should be promptly carried out to avoid morbidity and mortality. Adequate reprocessing of duodenoscopes and strict adherence to the guidelines for disinfection are mandatory.

## ACUTE CHOLANGITIS

Acute cholangitis is a clinical syndrome defined by the triad of right upper quadrant pain, fever, and jaundice (Charcot's triad). The presence of altered sensorium and hypotension in addition defines Reynold's pentad. Although the presence of this pentad is uncommon, it portends a poor prognosis in these patients. The basic predisposing factors of cholangitis include stasis (due to biliary obstruction) and disruption of the anatomical barrier (i.e., sphincter of Oddi) due to previous surgery, sphincterotomy, or placement of biliary endoprostheses. This leads to bacterial infection of the biliary tract. Infected bile with elevated intrabiliary pressure, exceeding the cholangiovenous reflux pressure leads to translocation of bacteria into systemic circulation, eventually leading to sepsis. Cholelithiasis, biliary strictures, and previous biliary instrumentation are relatively common causes of cholangitis (see Box 55.1). In contrast, cholangitis is relatively uncommon in malignant biliary strictures due to complete obstruction, which limits the chances of ascending infection.

### Diagnosis and Grading of Severity

The Tokyo guidelines for the diagnosis and management of acute cholangitis were initially published in 2007 and updated in 2013. The diagnosis of cholangitis is based on the presence of systemic inflammation (clinical, laboratory data), cholestasis (abnormal liver function tests), and imaging (biliary dilatation/stone/stricture, etc.). Ultrasonography is a reasonable initial imaging modality in patients with suspected acute cholangitis. The sensitivity of ultrasonography is only 50% for detection of CBD stones due to the proximity of the duodenum and interference with bowel gas. In the authors unit, EUS or MRCP is performed prior to ERCP if the clinical suspicion of cholangitis is not strong. Unnecessary ERCPs and associated complications can be avoided with this approach. Moreover, MRCP can provide an anatomical road map for subsequent ERCP, which may be especially useful in the case of hilar or intrahepatic obstruction. However, ERCP is performed without delay in cases of strong suspicion of severe cholangitis based on clinical and laboratory features.

Three grades of severity of cholangitis in the Tokyo guidelines are based on the presence or absence of organ dysfunction, age, and laboratory parameters (white blood cell count, bilirubin level, serum albumin). In moderately severe cholangitis, at least two of the following conditions are present: abnormal leucocyte count ( $> 12,000/\text{mm}^3$  or  $< 4000/\text{mm}^3$ ), fever ( $\geq 39^\circ\text{C}$ ), age ( $> 75$  years old), high bilirubin ( $> 5 \text{ mg/dL}$ ), and low albumin ( $< 0.7 \times \text{lower limit of normal}$ ). Presence of at least one organ dysfunction defines severe cholangitis.<sup>17</sup>

### Management

Irrespective of the underlying etiology of cholangitis, the mainstay of management is drainage of the infected biliary system. However, initial stabilization of the patient is of paramount importance before any therapeutic intervention is contemplated. Intravenous antibiotics should be administered as per the local antimicrobial sensitivity trends. Antibiotic coverage against anaerobes should be considered in cases with prior history of bilioenteric surgery.

The modalities of drainage include endoscopic (ERCP and EUS-guided), percutaneous, and surgical. Initial medical treatment may be sufficient for patients with mild cholangitis, whereas urgent biliary drainage is indicated for those with moderate or severe cholangitis (organ dysfunction/elderly)<sup>18</sup> (Fig. 55.1).

Endoscopic biliary drainage is the preferred modality in most patients. ERCP may be performed with a palliative intent initially in patients with severe cholangitis. After resolution of cholangitis, a more definitive ERCP can be performed. Initial aspiration of infected bile under pressure before instilling contrast in the bile duct is a wise practice, and repeated injections of contrast into the bile duct should be avoided. Excessive injection of contrast into an obstructed biliary system may further increase the intrabiliary pressure leading to cholangiovenous reflux and aggravation of sepsis. The aspirated bile may be sent for culture and sensitivity. In the author's unit, a nasobiliary tube (NBT) is placed initially to drain the infected bile. In the subsequent days, a cholangiogram is obtained and definitive ERCP is carried out. Plastic biliary stents may also be used instead of NBT to avoid discomfort to the patient. Both approaches are equally effective in relieving acute cholangitis.<sup>17,18</sup> Initial stent placement may also be accomplished in experienced hands in the intensive care unit setting without fluoroscopy in those patients too sick for transport.

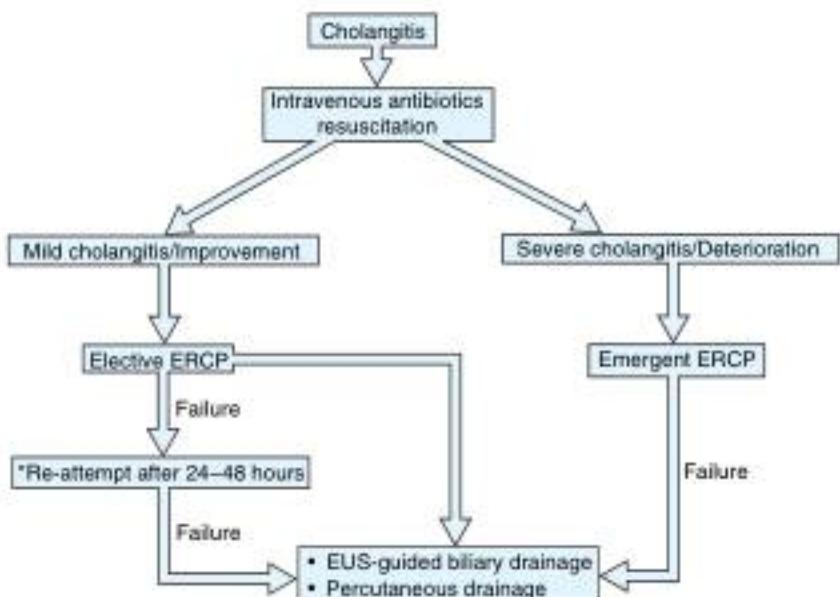

In the following section, we shall discuss the endoscopic management of acute cholangitis caused by different etiologies.

### Postoperative Cholangitis

Various surgical procedures which are potentially associated with postoperative cholangitis include postcholecystectomy bile duct injury, hepatojejunostomy, post liver transplant biliary strictures, afferent limb syndrome, and choledochoduodenostomy (sump syndrome).

The endoscopic management of postoperative benign biliary strictures includes either serial placement of multiple plastic stents or a fully covered metal stent for optimal results (Fig. 55.2). Balloon or catheter dilatation may be required to facilitate stent placement. In a multicenter randomized trial, the stricture resolution was higher with covered metal stents as compared to multiple plastic stents (92.6% vs. 85.4%).<sup>19</sup>

In afferent limb syndrome, long-standing afferent loop obstruction (stricture, kinking, or adhesions) results in pancreaticobiliary obstruction and may present as obstructive jaundice, cholangitis,

**FIG 55.1** Algorithm for management of cholangitis. ERCP, endoscopic retrograde cholangiopancreatography; EUS, endoscopic ultrasound.

**FIG 55.2** **A** and **B**, Patient with cholangitis resulting from a benign postoperative bile duct stricture shown by endoscopic retrograde cholangiopancreatography (ERCP) (**A**) and after placement of three 10-Fr plastic stents (**B**).

or liver abscess.<sup>21</sup> It usually occurs after subtotal gastrectomies, Billroth II surgeries, or other gastrojejunostomies. The management options include endoscopic, surgical, and percutaneous. Endoscopic treatment includes balloon dilatation and stenting across the afferent

loop stricture. Limited data suggests that endoscopic management is safe and effective in these patients.<sup>21</sup>

Sump syndrome is an uncommon entity that occurs after creation of choledochojejunostomy to manage retained CBD stones in a dilated bile duct. The distal bile duct between the papilla and the anastomosis becomes a stagnant reservoir or sump into which sludge, calculi, and food can accumulate. The clinical presentation includes recurrent pain, cholangitis, hepatic abscess, or pancreatitis. Management with endoscopic sphincterotomy (ES) and extraction of debris from the bile duct is successful in most patients.<sup>21</sup> However, a repeat sphincterotomy may be required in some cases due to restenosis of the sphincter.<sup>21,22</sup>

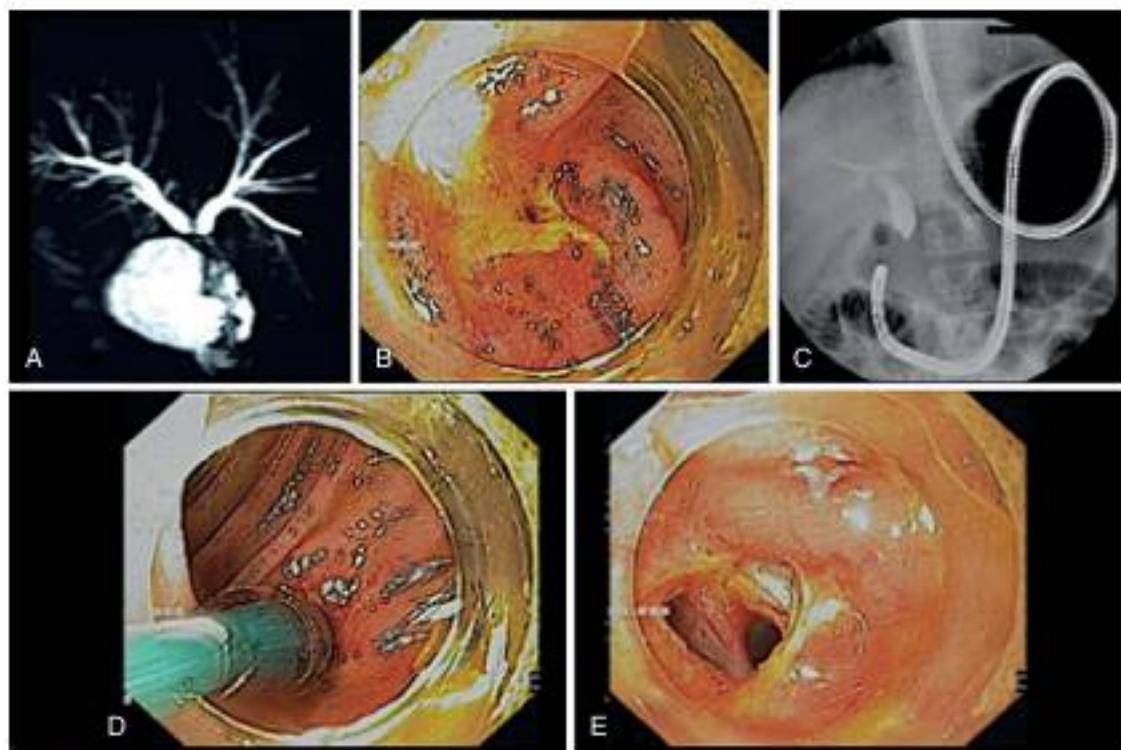

ERCP may be difficult in patients with bilioenteric strictures like hepatojejunostomy (Fig. 55.3). Treatment options include balloon enteroscopy-assisted ERCP, EUS-guided biliary drainage, and percutaneous biliary drainage.<sup>23–26</sup>

### Biliary Strictures (Chronic Pancreatitis Related and Malignant)

Chronic pancreatitis related biliary strictures are often resistant to standard endoscopic management. However, stricture resolution of up to 90% has been reported with multiple plastic stents or covered metal stents.<sup>27</sup> Therefore, endoscopic treatment should be the preferred initial treatment in such patients and surgery should be reserved for refractory cases.

Malignant biliary strictures are usually not associated with cholangitis unless previous instrumentation has been done. If present, cholangitis is a definite indication for preoperative biliary drainage in these patients. Metal stents provide superior results and are preferred over plastic stents irrespective of the resectability status.<sup>28</sup>

In hilar strictures (Type III), bilateral stenting should be done (Y or parallel) with the goal of draining greater than 50% of liver volume.<sup>29</sup> In patients with duodenal narrowing due to tumor infiltration or altered anatomy, EUS-guided biliary drainage is often successful.

**FIG 55.3** Patient with cholangitis and stricture at hepatojejunostomy anastomosis site. **A**, Magnetic resonance cholangiopancreatography (MRCP) image revealing stricture at hepatojejunostomy site with upstream dilatation of biliary tree. **B**, Endoscopic image of stricture site. **C**, Enteroscopy assisted cholangiography showing anastomotic stricture with upstream dilatation. **D**, Endoscopic dilation of anastomotic stricture with balloon. **E**, Endoscopic image of stricture site after dilatation (**A** to **D**, Courtesy of Dr. Hrushikesh P. Choudhary, Hyderabad, India.)

### Choledocholithiasis

CBD stones remain the most common cause of cholangitis. CBD stones act as nidus for the colonization of bacteria. More than 90% of CBD stones can be removed with standard ERCP techniques. In a sicker patient, the biliary system may be drained first by placing a biliary stent or NBT, followed by a more definitive procedure of clearing the bile duct (Fig. 55.4). A wire-guided approach is preferred for biliary cannulation to reduce the chances of post-ERCP pancreatitis. In cases of difficult biliary cannulation (> 5 attempts at cannulation, > 5 minutes spent at cannulation, or > 1 unintended pancreatic duct cannulation or opacification), the double wire technique or precut fistulotomy can be utilized to facilitate the cannulation.<sup>31</sup>

An endoscopic sphincterotomy is required for removal of CBD stones. Primary balloon dilation (often incorrectly termed *sphincteroplasty*) may be preferred for patients with coagulopathy as it is associated with a lower risk of bleeding. Recently, partial sphincterotomy followed by balloon sphincteroplasty has been successfully used, especially for large stones (> 1.5 cm). The procedure time was significantly shorter and the requirement of mechanical lithotripsy significantly lower in the combined technique as compared to endoscopic sphincterotomy alone in one study.<sup>31</sup> The rate of post-ERCP pancreatitis is not higher with this approach as the direction of papillary tearing is directed away from the pancreatic sphincter due to prior biliary sphincterotomy.<sup>32</sup>

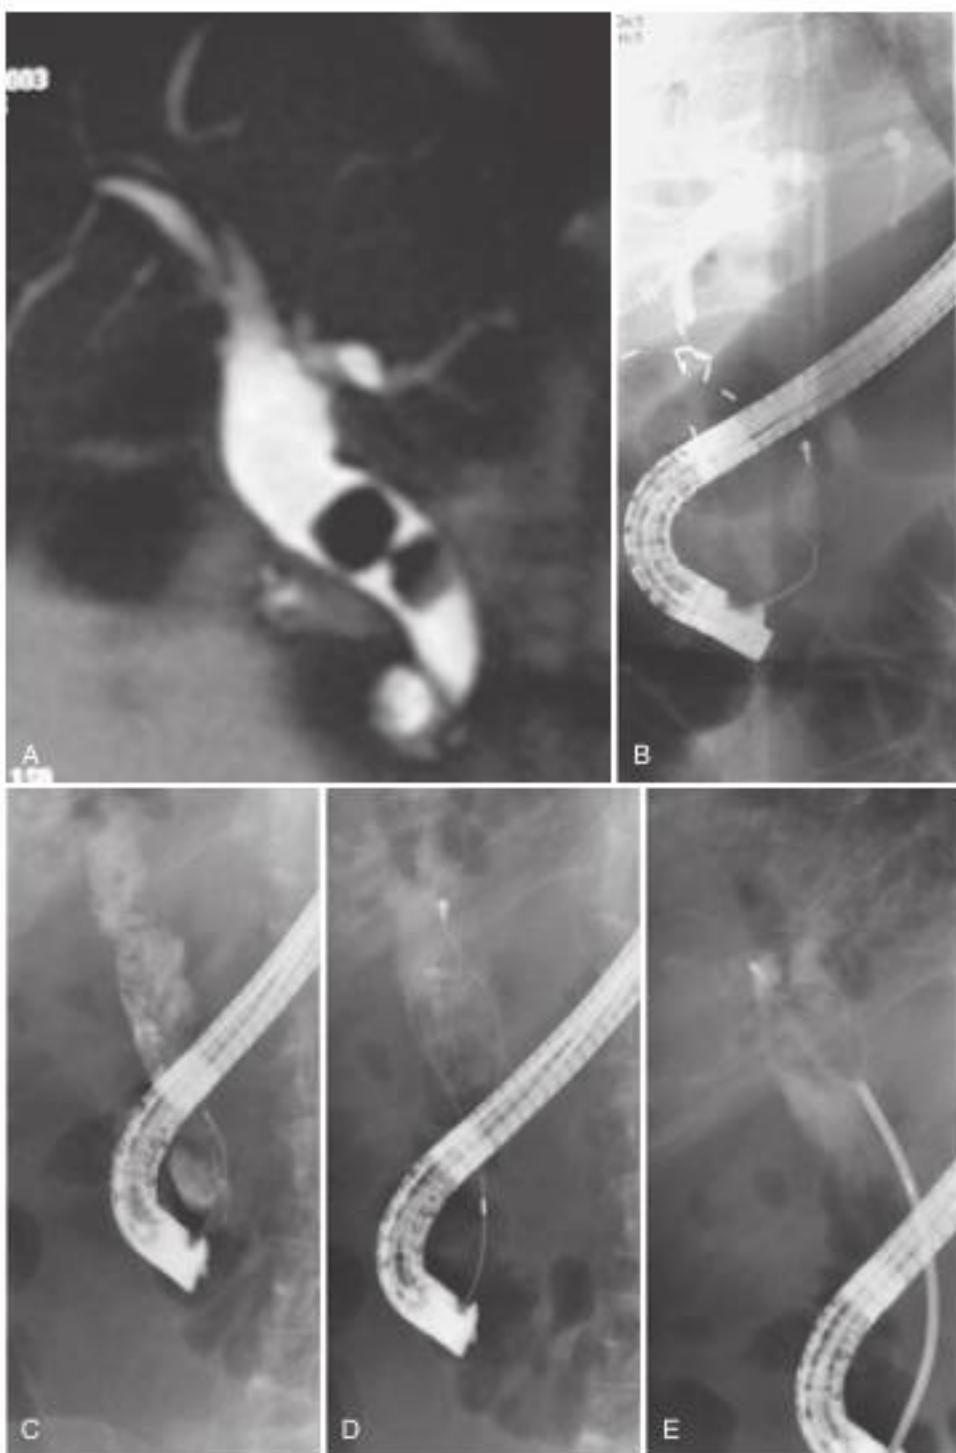

Extraction devices include a balloon or basket and depends on the operator's preference. Other approaches for large CBD

stones that are difficult to remove by standard techniques include mechanical lithotripsy, EHL, LL, and extracorporeal shock wave lithotripsy (Fig. 55.4).

### RECURRENT PYOGENIC CHOLANGITIS

RPC is characterized by the triad of biliary calculi (intrahepatic and/or extrahepatic), biliary strictures, and recurrent cholangitis. The presence of biliary calculi, which are typically intrahepatic, and strictures result in biliary stasis and predispose the patient to recurrent bouts of cholangitis (Fig. 55.5). The pathogenesis of RPC is incompletely understood. The disease predominantly occurs in middle-aged individuals (4th decade) residing in Southeast Asia. Low socioeconomic status and biliary parasitosis (*Ascaris lumbricoides* and *Clonorchis sinensis*) are thought to predispose one to the development of RPC. Therefore, the disease is more prevalent in countries where gastrointestinal parasites are endemic.<sup>33</sup>

RPC typically involves intrahepatic ducts with focal stricturing and dilatation of the intrahepatic biliary tree along with intrahepatic pigmented stones. The left hepatic duct is involved more often than the right because of the more acute angulation of the former. The clinical presentation can be quite variable. RPC can present as acute cholangitis with right upper quadrant pain, fever, and jaundice. However, often the symptoms are subtle and the disease goes unrecognized in the initial period for months to several years. The long-term complications of RPC include cholangiocarcinoma (3% to 5%) and secondary biliary cirrhosis (7%) with portal hypertension.<sup>34</sup>

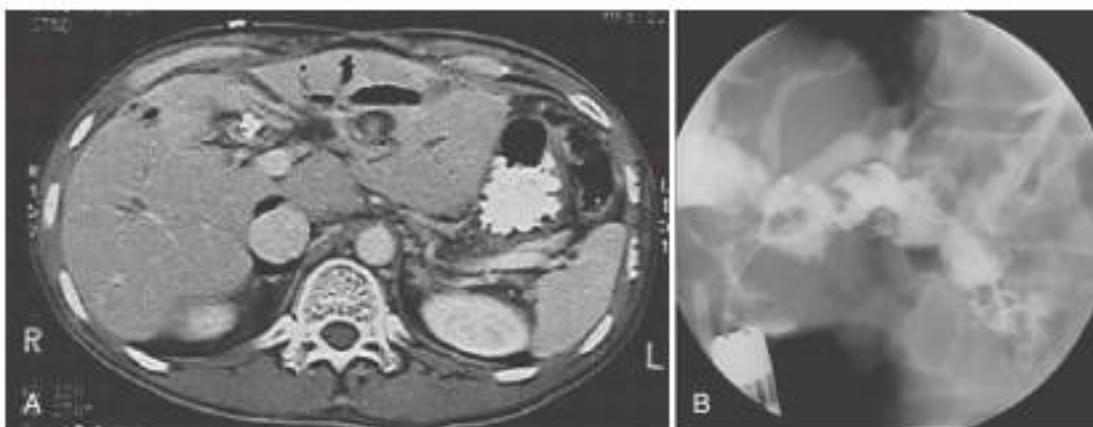

**FIG 55.4** **A**, Magnetic resonance cholangiopancreatography (MRCP) shows two large bile duct stones in a patient with cholangitis. **B**, Endoscopic retrograde cholangiopancreatography (ERCP) in the same patient with basket extraction of one of the stones. **C**, ERCP shows dilated bile duct packed with stones. **D**, Basket extraction. **E**, Mechanical lithotripsy.

### Diagnosis

The diagnosis of RPC relies on a combination of clinical features and imaging. Abdominal sonography is often the initial imaging modality revealing dilated intrahepatic ducts with calculi. It may also reveal associated cholangitic abscesses if present. Other imaging

modalities include computed tomography (CT), ERCP, and MRCP. However, MRCP remains the imaging modality of choice for the initial evaluation of patients with RPC. The advantages of MRCP over ERCP include the ability to reveal ductal anatomy proximal to stricture or stone, its noninvasive nature, and no risk of aggravating biliary sepsis.<sup>35</sup>

**FIG 55.5** Patient with recurrent pyogenic cholangitis. **A**, Computed tomography (CT) scan shows dilated air-filled left intrahepatic ductal system with stones and two stents. **B**, Endoscopic retrograde cholangiography (ERC) shows multiple lucent stones in the same system.

Several classification systems have been proposed to characterize the phenotype of disease in patients with RPC.<sup>20–22</sup> These classifications broadly classify the disease into several grades of severity based on laterality of the disease (unilateral or bilateral), order of bile ducts involved (first, second, or third order) and presence or absence of concomitant parenchymal liver disease. Unfortunately, none of these classification systems have been validated in subsequent studies.

### Management

The goal of treatment is not only to relieve cholangitis, but also to prevent or minimize the long-term consequences of the disease (e.g., biliary cirrhosis and cholangiocarcinoma).

The management of RPC includes drainage of obstructed biliary ducts by endoscopic, percutaneous, and surgical approaches. Often a combination of these modalities is required to achieve optimum biliary drainage. There has been no direct comparison among these modalities to demonstrate the superiority of any one approach over the other. A multidisciplinary approach involving gastroenterologists, interventional radiologists, and hepatobiliary surgeons appears to be rewarding in these patients.

### Endoscopic Management

The primary goal is to relieve acute cholangitis by administering broad-spectrum antibiotics and placing a biliary plastic stent or NBT. Subsequently, a more definitive management is planned after the stabilization of the patient, which includes dilatation of the stricture and clearance of biliary calculi.

It is of paramount importance to select appropriate candidates for endotherapy. Strictures or stones in the CBD or main intrahepatic ducts can be managed with ERCP. A percutaneous approach may be more appropriate when the strictures/stones are located in peripheral biliary ducts, whereas surgery is more appropriate for patients with predominantly left-sided disease along with atrophy of the left lobe of the liver.

The endoscopic management of RPC can be divided into the following steps:

- Biliary decompression and control of sepsis by placing a stent or nasobiliary drainage catheter
- Accurate localization of the disease (stones and strictures) by cholangiogram

- Securing the guidewire across the stricture
- Dilatation of the stricture using biliary balloons
- Brush cytology of suspicious strictures
- If required: breaking the stone with either mechanical lithotripsy/EHL or laser probe
- Retrieval of stones and placement of plastic biliary stent, if required

As a rule, broad-spectrum antibiotics should be administered in all patients undergoing endotherapy for RPC. Aggressive injection of contrast into the obstructed intrahepatic ducts should be avoided, and a prior MRCP should help in guiding through the location of strictures or stones.

Several sessions of endoscopic treatment are often required to achieve complete clearance of bile ducts. Regular follow-up is mandatory, as intrahepatic strictures and stones frequently recur after initial resolution.<sup>23</sup>

The major limitation of ERCP is its inability to achieve complete ductal clearance in a significant proportion of cases. Recurrent cholangitis is obviously more common in patients with residual intrahepatic stones. In a retrospective series, complete ductal clearance could be achieved in only 18 out of 57 patients (32%).<sup>24</sup> However, complete clearance of intrahepatic stones was achieved in approximately 67% of patients in two recently published series.<sup>25,26</sup>

The factors associated with negative outcomes include tortuous or sharply angulated duct, presence of intrahepatic stricture, and multiple stones scattered in many ducts.<sup>27</sup>

### Role of Cholangioscopy

Cholangioscopy plays an indispensable role in the management of hepatolithiasis. With the recent availability of digital cholangioscopy, high-quality images of the biliary tract can be obtained. Moreover, any suspicious biliary stricture can be biopsied to rule out malignancy.

Therapeutic cholangioscopy can be performed perorally, via the percutaneous route, or intraoperatively via choledochotomy. In general, peroral cholangioscopy (POCS) is appropriate for stones in main intrahepatic ducts, whereas the percutaneous approach may be required for more peripheral disease. In some cases, a combination of both routes is required for complete ductal clearance.

In POCS, endoscopic sphincterotomy is performed and a cholangioscope is advanced through the accessory channel of a therapeutic duodenoscope. Calculi are then extracted via balloon or a basket. Large intrahepatic stones can be fragmented by either EHL or LL (Nd:YAG). Intrahepatic strictures are dilated with a balloon or biliary dilating catheters, followed by stent placement. In one study, POCS was found to be safe and effective for management of hepatolithiasis with complete and partial ductal clearance in 64% and 11% of patients, respectively.<sup>43</sup>

#### Percutaneous Approach

In the percutaneous approach, initially a percutaneous transhepatic drainage (PTBD) is performed. Subsequently the tract is dilated up to 18 Fr to facilitate the passage of a cholangioscope and the removal of stones. Intrahepatic strictures can be dilated by balloon or dilating catheters. Complete stone clearance is achieved in 80% to 85% of patients with percutaneous transhepatic cholangioscopy.<sup>44,45</sup> Complete clearance of stones is hampered by the presence of severe intrahepatic strictures, as with the endoscopic approach.

#### Role of Surgery

Surgery can provide definitive treatment for patients with unilateral disease (usually left-sided). Both stones and strictured segments of the biliary tree can be removed. The major advantages of surgery are a lower recurrence of intrahepatic stones and a significantly less incidence of complications (biliary cirrhosis, cholangiocarcinoma) as compared to nonoperative treatment.<sup>46</sup> The laparoscopic approach has been utilized with promising results in patients with hepatolithiasis, with the advantage of a shorter hospital stay.<sup>46,47</sup>

In patients with bilateral disease, a combined approach is useful (i.e., removing the more severely affected lobe and creating a hepaticojejunostomy in the remaining lobe for endoscopic management in future)<sup>48</sup> (Fig. 55.6). A Hutson access jejunal loop between the skin and the hepatic ducts has been used in the past to provide access for repeated interventions.

In patients who are not candidates for hepatectomy, laparoscopic bile duct exploration in conjunction with choledochoscopic lithotripsy has been shown to be safe and effective.<sup>49</sup>

## PARASITIC CHOLANGITIS

*Ascaris lumbricoides* is a nematode or roundworm that matures within the small intestine and causes cholangitis by entering the bile duct across the major papilla. The trematodes *Opisthorchis sinensis*, *Opisthorchis viverrini*, *Opisthorchis felineus*, and *Fasciola hepatica* mature to adulthood within the human bile duct and are collectively known as liver flukes. *A. lumbricoides* and liver flukes cause inflammation of the bile duct and secondary bacterial cholangitis by allowing ascending bacterial contamination of bile, obstructing the bile duct and stimulating choledocholithiasis. Hepatic infection by *Echinococcus* species frequently involves the biliary tract by hydatid cyst compression or rupture and direct extension of alveolar echinococcosis.

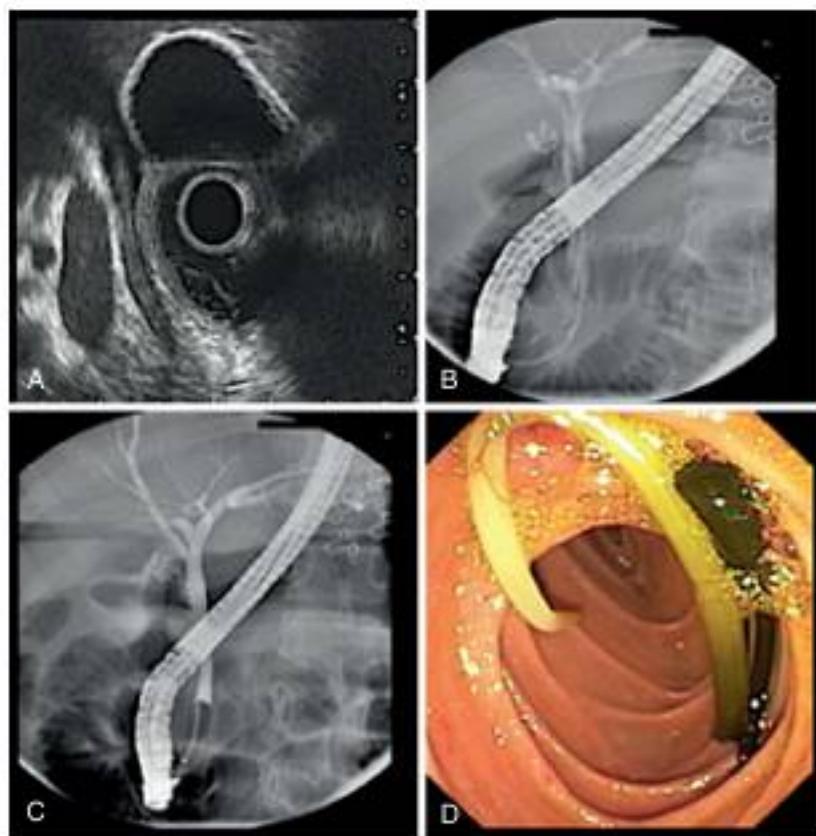

#### Ascaris Cholangitis

*A. lumbricoides* exists worldwide but is most prevalent in Asia, Africa, and South America as a result of the crowded living conditions and poor sanitation. Ova are passed in human feces and are ingested on contaminated fruits or vegetables. Hepatobiliary ascariasis (HBA) may manifest as biliary colic, cholangitis, cholecystitis, liver abscess, and, rarely, hemobilia. Previous cholecystectomy, sphincterotomy, sphincteroplasty, choledochotomy, or biliary enteric anastomosis favor biliary tract migration, whereas low insertion of cystic duct facilitates gallbladder involvement.<sup>50</sup> *A. lumbricoides* causes inflammation of the bile duct and secondary bacterial cholangitis by allowing ascending bacterial contamination of bile, obstructing the bile duct, and stimulating pigment stone formation. Therefore, it is not surprising that HBA predisposes to RPC as well. Over 5% of patients with HBA develop RPC, and 10% of patients with RPC have a definite evidence of ascariasis.<sup>50</sup>

Ultrasound is the imaging modality of choice for diagnosis and follow-up of patients with HBA. Characteristic sonographic findings include thick echoic stripe with a central, longitudinal anechoic tube (gastrointestinal tract of the worm, inner tube sign), thin nonshadowing strip without an inner tube (strip sign), overlapping longitudinal interfaces in the main bile duct (spaghetti sign), and the characteristic movement of these long echogenic structures within the bile duct.<sup>51</sup>

**FIG 55.6** Patient with recurrent pyogenic cholangitis, previously treated surgically with the creation of a cutaneous-jejunal-hepatic duct conduit. **A**, Gastroscope passed through the conduit shows a large left intrahepatic duct stone. **B**, After electrohydraulic lithotripsy and extraction of fragments.

**FIG 55.7** **A**, Endoscopic ultrasound image shows *Ascaris lumbricoides* as a hyperechoic linear structure within the bile duct. **B**, Endoscopic retrograde cholangiography in the same image shows a long linear filling defect in the common bile duct and left hepatic duct. **C**, Cholangiogram after balloon sweep and clearance of the bile duct. **D**, Endoscopic view of extracted adult *Ascaris*. (**A**, Courtesy of Dr. Sundeep Lakhtakia, Hyderabad, India; **B** to **D**, Courtesy of Dr. Zaheer Nabi, Hyderabad, India.)

In cases where ultrasonography is nondiagnostic, EUS and MRCP may be performed. On EUS, the worms appear as long linear hyperechoic structures without acoustic shadowing (single-tube sign) or with a central hypoechoic tube (double-tube sign)<sup>32</sup> (Fig. 55.7).

#### Indications of ERCP

Conservative management (intravenous fluids, antibiotics, anthelmintic medications, and analgesics for pain) is successful in 60% to 80% of cases.<sup>33,34</sup>

ERCP is indicated in severe cholangitis, failure of conservative management, and persistence of worms in the bile duct (indicating dead worms). Dead worms can incite inflammatory reaction leading to stricture formation or can act as nidus for stone formation. Therefore, dead worms should be extracted as well.<sup>35</sup>

**Preparation.** All patients with *Ascaris* cholangitis should receive antibiotics and anthelmintic therapy. Close contacts of infected individuals should submit stool specimens for analysis and be treated if positive.

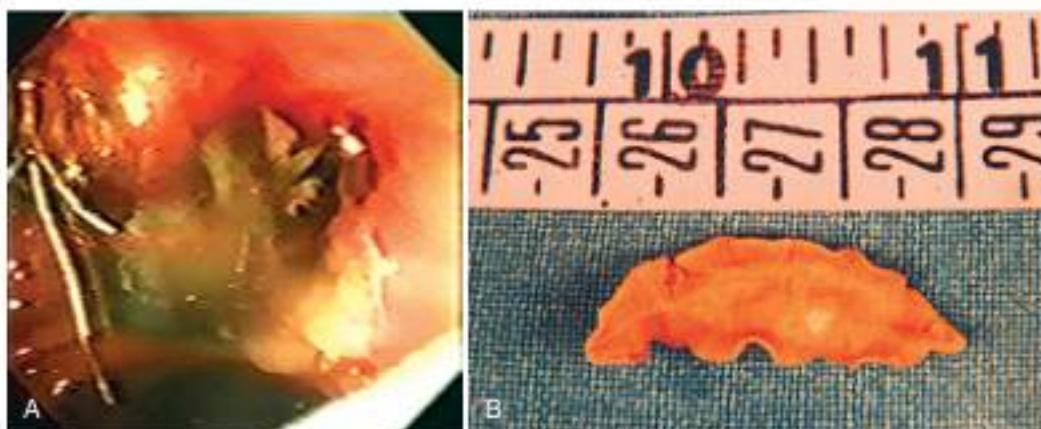

**Procedure.** The goal of therapy is complete removal of the parasite and secondary stones or strictures if present. At duodenoscopy, the adult worm is seen as a long pale white or reddish yellow tubular structure, either within the lumen of the duodenum or crossing the major papilla. Worms across the papilla can be

grasped with a biopsy forceps and then withdrawn along the endoscope by holding the worm near the accessory channel of the scope.

Worms located completely within the biliary tract appear as a tubular filling defect with tapered ends and may show the erratic motility pattern typical of *A. lumbricoides* on real-time fluoroscopy (see Fig. 55.7). Injection of contrast material may stimulate the worm to migrate distally into the duodenum. Otherwise, intrabiliary worms can be removed with a biliary extraction balloon or basket. Major papilla is often patulous in these patients due to frequent worm migrations, facilitating worm extraction and avoiding the need for a sphincterotomy. Moreover, sphincterotomy facilitates future biliary tract involvement by the worm and should be avoided when possible. Instead, papillary balloon dilatation can be done if required.<sup>36</sup>

The worm should be brought to the papillary orifice and grasped using the biopsy forceps as described previously. Polypectomy snares should be avoided as they are liable to transect the worm and complicate extraction.

**Complications.** In addition to infecting the biliary tree, *A. lumbricoides* parasites also burrow through the bile duct wall into the liver parenchyma to form hepatic abscesses. Acute pancreatitis has been reported secondary to worms obstructing the pancreatic duct.<sup>37</sup>

**FIG 55.8** **A**, *Fasciola hepatica* being extracted at endoscopic retrograde cholangiopancreatography (ERCP). **B**, Adult worm after extraction. (**A**, Courtesy of Dr. Claudio Navarette, Santiago, Chile; **B**, courtesy of Dr. Alok Gupta, Kanpur, India.)

**Outcomes.** Endoscopic extraction of biliary *A. lumbricoides* is successful and safe in 99% of patients.<sup>33</sup> Approximately 15% of patients will experience symptomatic reinvasion of biliary tree, and 4% to 5% may develop biliary lithiasis in endemic regions.<sup>33,34</sup>

Therefore, antihelminthic therapy should be repeated at regular intervals in endemic zones. The indications of surgery include cholecystitis, failure of endoscopic bile duct clearance, and intrahepatic strictures or stones.

### Liver Fluke Cholangitis

The most important liver fluke species include *Clonorchis sinensis*, *Fasciola* spp., and *Opisthorchis* spp. More than 750 million people across the globe are at risk of infection. Liver flukes are endemic in Southeast Asia and the Western Pacific region.<sup>35</sup>

Human infection occurs from eating uncooked or undercooked freshwater fish or plants such as watercress, alfalfa, and parsley that harbor the infective metacercarial cysts of liver flukes. *Opisthorchis* enter the biliary tree through the major papilla, whereas *Fasciola* penetrate the intestinal wall into the peritoneal cavity and enter the biliary tree transhepatically. Adult liver flukes most commonly reside in the intrahepatic branches but may be observed in the distal biliary tract.

### Indications for ERCP

The hepatic phase of *Fascioliasis* can be managed with the antiparasitic drug triclabendazole (10 mg/kg body weight) alone. Praziquantel is the drug of choice for clonorchiasis (75 mg/kg in three divided doses). ERCP is indicated for the diagnosis and management of liver fluke cholangitis and associated secondary bile duct strictures and stones. ERCP enables the sampling of bile to show the presence of ova, which may be more sensitive than stool microscopy.<sup>31</sup>

**Procedure.** The goals and techniques of the endoscopic treatment of liver fluke cholangitis are similar to *Ascaris* cholangitis. The most characteristic cholangiographic finding of hepatic clonorchiasis in ERCP is filamentous or elliptic filling defects of the biliary tract.<sup>31</sup> Cholangiographic findings in patients with biliary phase fascioliasis include radiolucent, crescent-shaped shadows in the bile ducts with or without dilatation.<sup>32</sup> Other cholangiographic findings include diffuse saccular dilation of the intrahepatic ducts with blunted terminal ends.<sup>33</sup>

Endoscopic sphincterotomy is usually required for liver fluke extraction. Extraction of flukes is undertaken with a biliary extraction basket or balloon. Because liver flukes frequently inhabit the proximal biliary tree, complete clearance can be challenging. Placement of a NBT to perform biliary infusion of povidone-iodine has been described in the management of *F. hepatica* cholangitis.<sup>34</sup> At duodenoscopy, flukes appear as brownish, flat, leaf-shaped organisms 1 to 2 cm long and usually less than 1 cm wide<sup>33</sup> (Fig. 55.8).

**Complications.** The major hepatobiliary diseases associated with liver flukes include: cholangitis, cholecystitis, choledolithiasis, hepatocellular carcinoma, RPC, portal hypertension, and cholangiocarcinoma.<sup>36</sup>

**Outcomes.** Medical management with anti-parasitic drugs is sufficient for asymptomatic hepatobiliary fluke infections. Endoscopic extraction is required for patients with acute cholangitis and failure of conservative management. Surgical intervention is indicated for biliary or pancreatic obstruction after unsuccessful endoscopic therapy and for cholecystitis.

### Echinococcal Cholangitis

*Echinococcus granulosus* accounts for up to 95% of all human echinococcal infections and is particularly prevalent in regions where dogs are used to raise livestock. *E. granulosus*, *Echinococcus vogeli*, and *Echinococcus oligarthus* form a unilocular hydatid cyst within the liver. However, *Echinococcus multilocularis* cysts are not contained by an outer fibrous membrane and extend through the liver and into adjacent structures. The cyst is composed of three layers: an outermost layer of granulation and fibrous tissue, a middle layer of laminated membrane, and the innermost germinal layer of the parasite, which forms the daughter cysts and protoscolices. Biliary disease results from compression by the cyst or rupture of the cyst into the biliary tree. Larger cysts (>7.5 cm) are more likely to harbor cyst-biliary communication.<sup>37</sup>

### Indications for ERCP<sup>38</sup>

The indications for ERCP in biliary echinococcosis are listed in Box 55.2.

### Procedure

The goals of ERCP are to document suspected *Echinococcus* cholangitis and treat biliary obstruction.

ERCP is performed in the usual manner. Duodenoscopy may show glistening, white membranes within the duodenum or protruding from the papilla, which can be removed with biopsy forceps (Fig. 55.9). On cholangiography, three patterns of filling defects have been reported. The membranes appear filiform, the daughter cysts round, and hydatid sand as debris.<sup>68</sup>

Endoscopic sphincterotomy is usually required prior to the removal of the filling defects with a biliary extraction balloon or basket.<sup>69</sup>

Saline irrigation facilitates the removal of hydatid cyst material.

#### BOX 55.2 Indications for Endoscopic Retrograde Cholangiopancreatography in Hepatic Echinococcosis

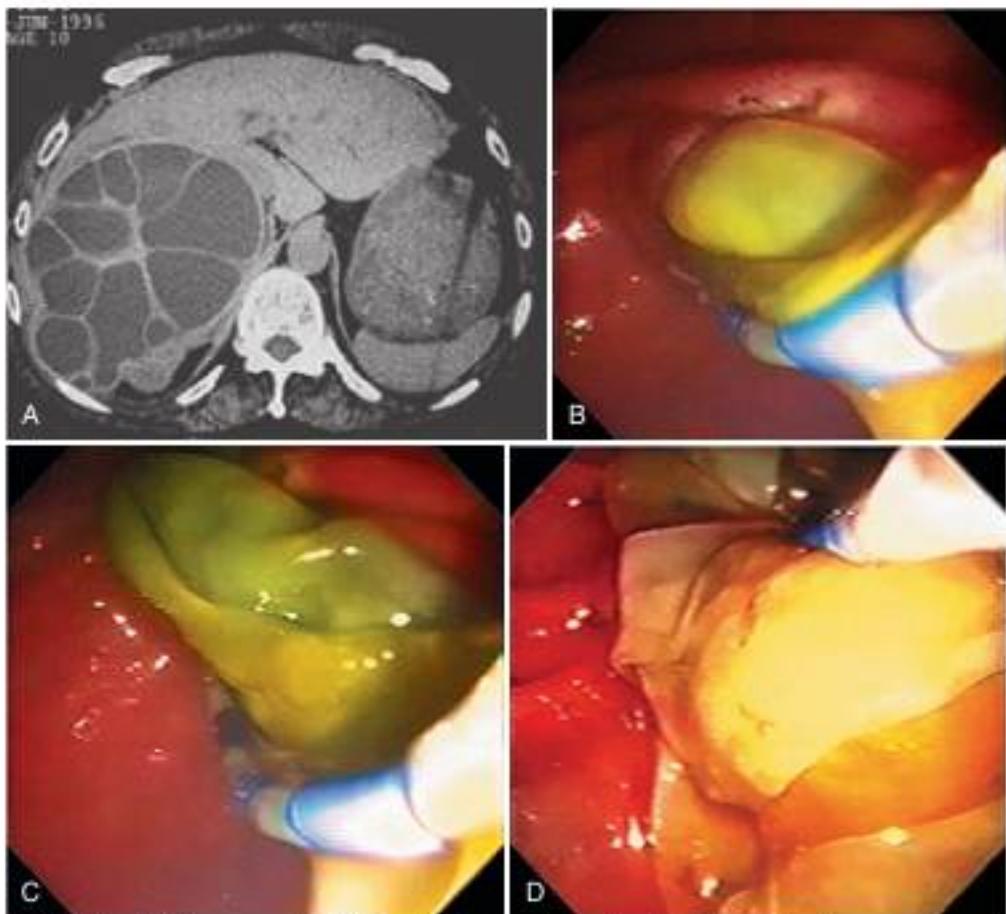

- Bile duct obstruction
- Extrinsic compression by hydatid cyst
- Hydatid cyst rupture into the biliary tract
- Biliary tract invasion by alveolar echinococcosis
- Before protoscolicide administration
- Postprotoscolicide biliary stricture
- Postoperative bile leak

In case of frank intrabiliary rupture, it is preferable to coil a hydrophilic guidewire into the cystic cavity, followed by the placement of a NBT. Subsequently, periodic irrigation of the cystic cavity with saline is carried out for several days, to ensure complete clearance of the cyst cavity.<sup>67,70</sup>

Some authors use a specially designed NBT (10-Fr) with additional holes on both duodenal and biliary ends.<sup>67</sup> Encouraging results with the NBT approach suggests that it should be attempted prior to surgery in the case of major intrabiliary ruptures.

Biliary strictures resulting from hydatid cyst compression or alveolar echinococcosis invasion can be managed with stent insertion.

Endoscopic therapy in the postoperative period may be required to manage external biliary fistulas, clear the hydatid remnants causing biliary obstruction, or biliary strictures from scolicidal agents.<sup>67</sup> In biliary fistulae, ERCP is indicated only if fistula output is high (> 300 mL/day), persistent, or rising each day. Endoscopic sphincterotomy alone may be sufficient in some cases. However, biliary stent placement may be required in cases of failure with ES alone or incomplete clearance of hydatid material in the bile duct. Stenting is also preferred to ES alone in those with chronic high output fistulae and if fistulae are accompanied by a biliary stricture.

**FIG 55.9** **A**, *Echinococcus* (hydatidosis) infection shown in right lobe of the liver on computed tomography (CT) scan. **B** to **D**, Sequence of cyst wall extraction at endoscopic retrograde cholangiopancreatography (ERCP) after sphincterotomy. (**A**, Courtesy of Dr. Nageshwar Reddy, Hyderabad, India; **B** to **D**, Courtesy of Dr. Claudio Navarette, Santiago, Chile.)

### Complications

*E. multilocularis* may invade into the portal venous system resulting in portal hypertension.<sup>71</sup>

### Outcomes of Endoscopic Therapy

Endoscopic management of biliary obstruction secondary to *E. granulosus* infection through extraction of hydatid debris or biliary endoprosthesis placement is successful at alleviating patient symptoms.<sup>65</sup> Endoscopic therapy alone is curative in approximately 25% of cases with frank intrabiliary rupture.<sup>67</sup>

In the postoperative period, endoscopic therapy is required for biliary fistulae, stricture, and remnant hydatid material in the bile duct. Overall, more than 80% of patients can be successfully managed with endoscopic therapy alone.<sup>72</sup> External biliary fistulae respond well to ES with or without placement of a biliary stent. In one study, 75% of biliary fistulae responded to ES alone.<sup>73</sup> In patients with high output external biliary fistulae, larger stents are preferable to ES alone or 7-Fr stents. In a multicentric study, the time to fistula closure was significantly shorter in the 10-Fr stent group as compared to ES alone and 7-Fr stent group.<sup>74</sup>

### Other Therapies (Medical, Percutaneous, and Surgical)

Medical therapy with albendazole should be given for greater than 3 months and is curative in less than 60% of patients.<sup>75</sup> Small and simple cysts are more likely to get cured with medical therapy alone. Albendazole is also administered before surgery, as it results in a higher number of nonviable cysts and may decrease the risk of local recurrence or intraperitoneal seeding should spillage of cyst contents occur.<sup>75</sup>

Percutaneous evacuation with ultrasound-guided puncture-aspiration-injection-reaspiration (PAIR) is widely used to treat unilocular *E. granulosus* cysts. Scolicidal agents employed for PAIR include 95% ethanol and hypertonic saline. PAIR is equally effective, with fewer complications and shorter hospital stays as compared to surgery.<sup>76</sup>

Complications of PAIR include hypersensitivity reaction, infection, intraabdominal seeding, and fistula formation to adjacent organs. ERCP should be performed before protoscolicide administration to ensure there is no communication between the cyst and biliary tree because contact with protoscolicidal agents produces sclerosing cholangitis.

Surgical management, which includes excision by cystectomy, pericystectomy, or partial hepatic resection, is usually curative in *E. granulosus* infection. Surgical mortality is 1% to 2%.<sup>77</sup> Complications include infection, bile leak, and leakage of cyst contents with hypersensitivity reaction and dissemination of disease.

## ACQUIRED IMMUNODEFICIENCY SYNDROME CHOLANGIOPATHY

AIDS cholangiopathy is a syndrome of right upper quadrant pain, elevated alkaline phosphatase, and typical cholangiography findings associated with the human immunodeficiency virus (HIV) infection. Elevation in serum bilirubin is minimal or absent in AIDS cholangiopathy unless a concomitant hepatobiliary disease is present. Opportunistic infections of the biliary tract implicated in AIDS cholangiopathy include *Cryptosporidium* (most commonly *Cryptosporidium parvum*),<sup>78</sup> *Microsporida*, cytomegalovirus, *Isospora*, *Cyclospora*, and *Mycobacterium*

*avium intracellulare*.<sup>79,80</sup> Cholangiopathy is the AIDS-defining illness in few patients, but most of these have had AIDS for at least 1 year.<sup>81</sup>

The characteristic bile duct abnormalities in AIDS cholangiopathy can be divided into four groups, including: (1) papillary stenosis, (2) sclerosing cholangitis involving extrahepatic and intrahepatic bile ducts, (3) combined papillary stenosis and sclerosing cholangitis, and (4) long extrahepatic strictures. AIDS cholangiopathy usually develops in patients with advanced disease and is rare in patients with CD4+ greater than 200. Therefore, its incidence has reduced after the introduction of highly active antiretroviral therapy (HAART). In fact, non-HIV-related biliary diseases (like choledocholithiasis, calculous cholecystitis, ampullary malignancies, etc.) may be more common in these patients.

### Indications

ERCP is the gold standard in the diagnosis and management of AIDS cholangiopathy (Fig. 55.10). However, MRCP may be a good noninvasive alternative prior to ERCP for the evaluation of both the intrahepatic and extrahepatic biliary tree in these patients.<sup>82</sup> Bile duct abnormalities on MRCP in AIDS cholangiopathy include dilatation, dilatation with beading and strictures, distal stricture, and contrast enhancement.<sup>83</sup> Cholangiographic abnormalities may resolve with HAART and can be followed with MRCP. Therefore, with the availability of MRCP, ERCP should be reserved for carrying out therapeutic procedures like ES in papillary stenosis or balloon dilatation/stenting in symptomatic biliary strictures. The differential diagnosis of AIDS cholangiopathy and the management approach are shown in Box 55.3 and Fig. 55.11, respectively.

### Precautions

Protease inhibitors decrease benzodiazepine metabolism and increase their serum levels, which may potentially cause respiratory depression.<sup>84</sup> Therefore, benzodiazepines such as diazepam and midazolam should be used cautiously for sedation in these patients.

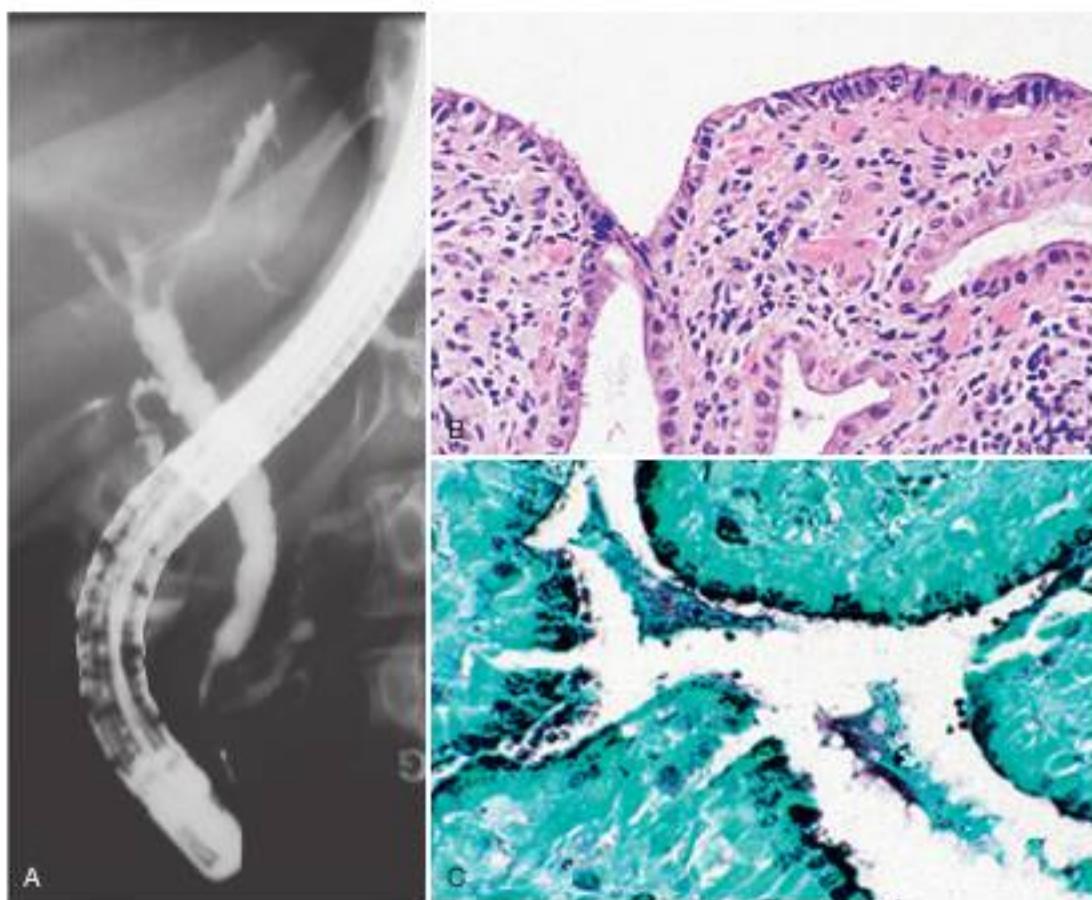

### Procedure

ERCP should be performed only in symptomatic patients with abdominal pain, cholestatic jaundice, or fever. The cholangiography findings in ERCP include papillary stenosis, with or without intrahepatic strictures (51%) (most common), and

### BOX 55.3 Differential Diagnosis of Acquired Immunodeficiency Syndrome Cholangiopathy

Non-HIV-Related	HIV-Related
Choledocholithiasis	Medication hepatotoxicity
Cholecystitis	Opportunistic Infection
Primary sclerosing cholangitis	
Viral hepatitis	
Chronic pancreatitis	

CMV, cytomegalovirus; HIV, human immunodeficiency virus; MAI, *Mycobacterium avium-intracellulare*.

**FIG 55.10** **A**, Acquired immunodeficiency syndrome (AIDS) cholangiopathy shown by endoscopic retrograde cholangiopancreatography (ERCP) with narrowed distal bile duct and irregular bile duct walls. **B**, Relatively normal bile duct epithelium on biopsy and standard hematoxylin and eosin staining. **C**, Microsporidia shown on the surface as black with silver staining. (Courtesy of Dr. Richard Tilson, Boston, MA.)

**TABLE 55.2 Cholangiography Findings in Acquired Immunodeficiency Syndrome Cholangiopathy**

Finding	Frequency (%)
Papillary stenosis and intrahepatic duct strictures	33
Papillary stenosis alone	21
Papillary stenosis and intrahepatic and extrahepatic duct strictures	20
Intrahepatic duct strictures alone	12
Intrahepatic and extrahepatic duct strictures	8
Extrahepatic duct strictures alone	5
Papillary stenosis and extrahepatic duct strictures	1

isolated or combined intrahepatic and extrahepatic biliary strictures (25%)<sup>70,80,83</sup> (Table 55.2). Other reported cholangiography abnormalities include adherent polypoid filling defects; biopsy specimens of these defects show granulation tissue.<sup>80</sup>

Recently, single-operator cholangiscopy has been reported in a patient with AIDS cholangiopathy. Cholangioscopy showed fibrotic-appearing stricture of the common hepatic duct (CHD) with pseudodiverticula and multiple nonobstructing rings in

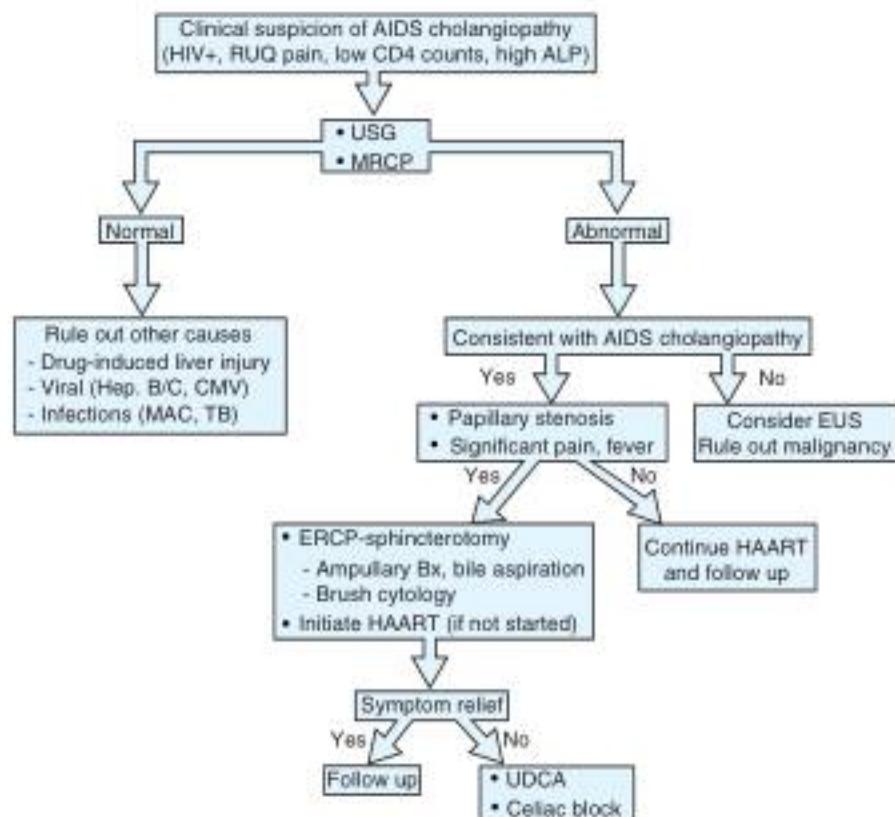

the distal CHD.<sup>87</sup> Interestingly, pancreatography is abnormal in one-half of patients with AIDS cholangiopathy, revealing pancreatic duct strictures in the head of the pancreas.<sup>79,88</sup>

The standard ERCP procedure consists of an ES if papillary stenosis is present. ES is not beneficial in the absence of papillary stenosis. Dominant strictures should be sampled for cytology with a cytology brush or biopsy forceps to exclude cholangiocarcinoma or another malignant process. In a symptomatic patient, balloon or catheter dilation of the stricture may be performed, but long-term stent placement should be avoided to limit the migration of enteric pathogens into the biliary tract.

During ERCP, the duodenum should be inspected for mucosal abnormalities such as erosions or ulcerations that may indicate enteric infection. Duodenal/ampullary biopsy specimens and bile aspiration samples should be obtained and sent for microbiologic and cytologic analysis. Aspiration of bile for culture and multiple biopsy specimens of the duodenum and papilla reveal an underlying pathogen in up to 92% of cases.<sup>80,89</sup>

### Complications and Outcomes

The complications of untreated non-HIV-related sclerosing cholangitis include secondary biliary cirrhosis and cholangiocarcinoma.

**FIG 55.11** Algorithm for management of suspected acquired immunodeficiency syndrome (AIDS) cholangiopathy. ALP, alkaline phosphatase; CMV, cytomegalovirus; ERCP, endoscopic retrograde cholangiopancreatography; EUS, endoscopic ultrasound; HAART, highly active antiretroviral therapy; Hep. B, hepatitis B virus; Hep. C, hepatitis C virus; HIV, human immunodeficiency virus; MRCP, magnetic resonance cholangiopancreatography; RUQ, right upper quadrant; UDCA, ursodeoxycholic acid; USG, ultrasonography.

However, except for a rare case report of development of cholangiocarcinoma in a patient with AIDS cholangiopathy, these complications have not been reported in AIDS cholangiopathy.<sup>91</sup>

The mainstay of treatment in patients with AIDS cholangiopathy is restoration of immunity with HAART. The median survival in these patients has increased significantly after the introduction of HAART. In a 2010 series, the median survival was 34 months after the diagnosis of cholangiopathy as compared to 4 to 9 months in previous case series.<sup>91</sup> The development of cholangiopathy in patients on HAART is associated with a drop in CD4+ counts and may indicate resistance to antiviral drugs.

ERCP does not prolong survival in these patients and is intended only to provide symptom relief.<sup>91,92</sup> ES in patients with papillary stenosis results in improvement of abdominal pain in 32% to 100% of patients.<sup>88,89,93</sup>

Elevation in liver enzymes (especially ALP) may persist and should not be used as a criterion for successful endotherapy.<sup>93</sup> In patients with refractory pain after endotherapy, ursodeoxycholic acid (10 mg/kg) and celiac plexus block have been reported, with good results.<sup>93,94</sup>

Unfortunately, the treatment of pathogens implicated in AIDS cholangiopathy (cytomegalovirus, *C. parvum*, and *Microsporidium*) has not been found useful in reducing patient's symptoms, liver enzymes, and cholangiography abnormalities.<sup>78,88,95</sup>

## ROLE OF ERCP IN ACUTE CHOLECYSTITIS

Acute cholecystitis is an inflammatory injury to the gallbladder mucosa from bile stasis, ischemia, or infection. Bile stasis usually results from cystic duct obstruction by a gallstone or from decreased gallbladder motility. Less common causes of cystic duct obstruction are worms, hemobilia, and tumor. Decreased gallbladder motility and ischemia are implicated in the development of acalculous cholecystitis in critically ill patients. Infection of the gallbladder complicates cholecystitis in approximately 50% of cases but is not usually the causative factor, with the exception of parasitic and AIDS cholecystitis.

### Indication

ERCP is indicated for gallbladder drainage in patients who are medically unfit for surgery and in whom percutaneous drainage is contraindicated or unsuccessful. The advantages of transpapillary drainage of gallbladder (EDGB) over percutaneous drainage are that coagulopathy and the presence of ascites are not contraindications, there is no risk of bile leak, there is less pain, and there is the option of removing coexisting bile duct stones.

### Preparation

Antibiotic coverage is directed against *Enterobacteriaceae* and *Enterococcus* species until directed therapy can be instituted against specific organisms identified in blood or bile cultures.

### Procedure<sup>101</sup>

ERCP is performed in the usual manner. EDGB is achieved by transpapillary placement of a NBT or double pigtail stent into the gallbladder (Fig. 55.12). Biliary sphincterotomy is not required unless coexisting bile duct stones are to be removed. After cannulating the bile duct, a hydrophilic guidewire (0.025- or 0.035-inch) is advanced into the cystic duct and subsequently into the gallbladder.

Either a sphincterotome or a flexible tip catheter can be used. A rotatable sphincterotome may be especially helpful in some patients with left-sided cystic duct takeoff. In case the cystic duct is not opacified by contrast due to cystic duct edema or calculus, a guidewire along with a catheter are gently manipulated to enter the cystic duct. An occlusion cholangiogram with balloon inflated just below the expected cystic duct takeoff may also help in opacifying the cystic duct. If the previous methods fail, cholangioscope can be used to place the guidewire under direct vision. Once the guidewire is in position, a NBT (5- or 6-Fr) or double pigtail stent (5- or 7-Fr) can be fashioned into the gallbladder. Nasobiliary lavage with saline or N-acetyl cysteine is carried out in case thick pus is aspirated from the gallbladder.

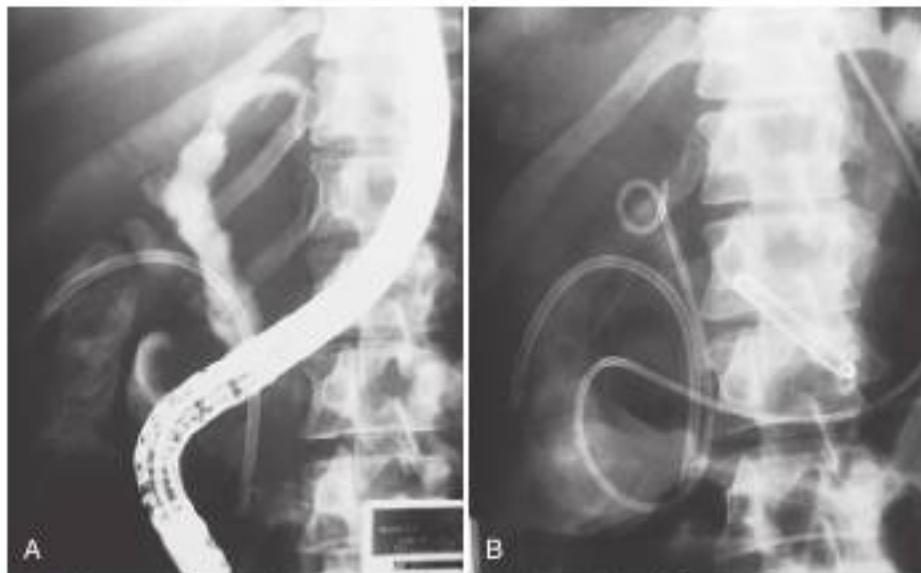

### Outcomes

The outcomes of EDGB are encouraging and at par with percutaneous drainage. Technical and clinical success in recent studies range from 77% to 100% and 72% to 98%, respectively<sup>101-103</sup> (Table 55.3). There is no difference in success rates and adverse events between NBT or double pigtail stents.<sup>101,102</sup> The major reasons for technical failure are the inability to pass a 7-Fr stent or NBT due to impacted cystic duct stones or stenosis of cystic duct. Smaller catheters (5 Fr) may be useful in this situation but carry the risk of getting clogged readily due to the thick, purulent bile. However, the stent may act as a wick, and bile may flow within as well as alongside the stent into the duodenum. Therefore, the risk of recurrent cholecystitis appears small.<sup>104</sup>

The relapse of acute cholecystitis occurred in 20% of patients after a median follow-up of 17 months in one study.<sup>105</sup> Therefore, these patients should undergo cholecystectomy, once stabilized.

### Complications

The incidence of procedure-related complications ranges from 0% to 14% and includes post-ERCP pancreatitis, perforation of the cystic duct or gallbladder, cholangitis, and sepsis<sup>106</sup> (see Table 55.3).

**FIG 55.12** Concomitant calculous cholangitis and cholecystitis. **A**, Endoscopic retrograde cholangiopancreatography (ERCP) shows a plastic stent draining the gallbladder. **B**, Radiograph obtained after ERCP shows addition of a nasobiliary tube draining the common bile duct (CBD).

**TABLE 55.3** Endoscopic Drainage of Gallbladder

Study	No. of Patients	Drainage Model	Technical Success (%)	Clinical Success (%)	Complications (%)
Pannala et al <sup>101</sup>	51	NBT	100	98	8
Maekawa et al <sup>102</sup>	40	7 Fr-DPTS	77.5	72.5	None
Itoi et al <sup>103</sup>	73	NBT - 37 DPTS - 36	91.9 86.1	86.5 77.8	4.1

Winston Churchill 1939

## INTRODUCTION

Functional disorders of the biliary tree and pancreas are controversial topics, with insufficient scientific evidence to provide clear guidelines for clinical practice. This chapter attempts to summarize what is known, what is unclear, and what studies need to be done. One author (PBC) was recently involved in the comprehensive Rome IV process, conclusions from which have been published.<sup>1</sup> One recommendation was to change the names of the clinical syndromes, to functional biliary sphincter disorder (FBSD), and functional pancreatic sphincter disorder (FPSD).

## THE SPHINCTER: STRUCTURE AND FUNCTION

The anatomy and physiology of the sphincter zone have been well described in standard texts. It is a complex of muscle fibers 4 to 10 mm in length, surrounding the distal bile and pancreatic ducts (Fig. 56.1). Although often subdivided into three sections (biliary, pancreatic and ampillary), the fibers are intertwined and the distinction probably has little clinical significance. The sphincter has a resting basal pressure, and phasic contractile activity, closely associated with the migratory motor complex. Its role is to control the flow of bile and pancreatic secretions into the duodenum, under both neural and hormonal control.

## FUNCTIONAL BILARY SPHINCTER DISORDER (FBSD)

The concept that disordered function of the sphincter can cause pain is based on the fact that many patients have "biliary" pain in the absence of recognized organic causes, and that some apparently are cured by ablation of the sphincter. The hypothesis is that it fails to relax sufficiently when the bile is flowing, thereby causing the pressure to rise in the bile duct to a level sufficient to produce biliary pain.

### Postcholecystectomy Pain

FBS is commonly considered in the 10% to 20% of patients who have persistent or recurrent pains after cholecystectomy. Loss of the gall bladder reservoir aggravates the increase in intrabiliary pressure when the sphincter is closed. There is also evidence that sphincter dynamics are altered after cholecystectomy.<sup>2</sup> Animal studies have shown a cholecysto-sphincteric reflex with distention of the gallbladder that results in sphincter relaxation.<sup>3</sup> Interruption of this reflex could affect sphincter behavior by an altered response to cholecystokinin (CCK), or because the loss of innervation unmasks the direct contractile effects of CCK on smooth muscle. Abnormalities in both basal pressure and responsiveness to CCK have also been described in humans.<sup>4</sup>

The simple concept that the pain in these patients is wholly or partly due to increased ductal pressure is now under challenge. Another explanation stems from the concept of nociceptive

### Abstract

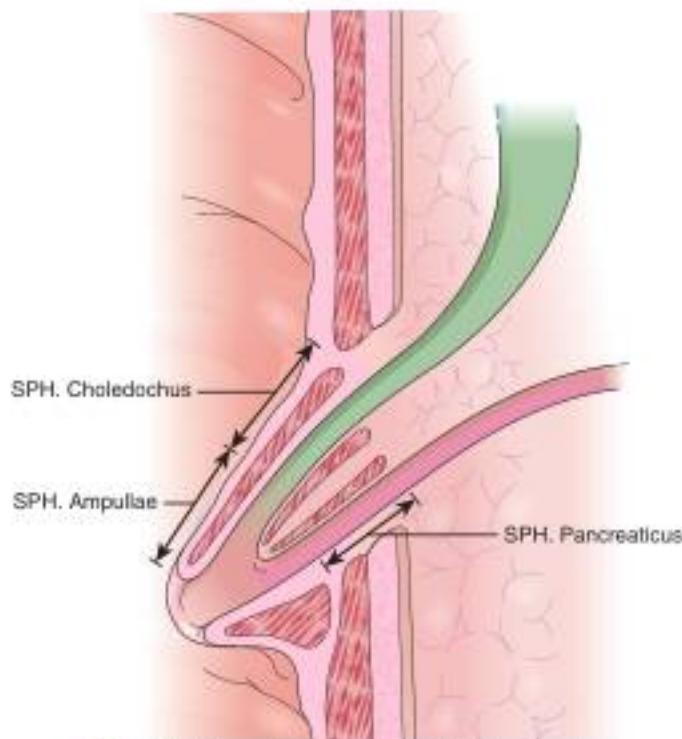

The concept that motor disorders of the sphincter of Oddi (SOD) can cause biliary pain and pancreatitis is attractive, and popular, at least in the United States, leading to the widespread use of endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy. However, the results are not uniformly good, and there are substantial risks. The role of sphincter manometry is controversial. Assessing the effects of treatment of these patients is made difficult by the fact that symptoms fluctuate, and invasive interventions have a strong placebo effect, as shown by a recent sham-controlled trial. That study showed that sphincterotomy was no better than sham treatment in patients with postcholecystectomy pain and little or no objective evidence for biliary obstruction. As a result, the old concept of "SOD type III" is discarded, and ERCP approaches are no longer appropriate in that context. The value of manometry and sphincterotomy in patients with some evidence for biliary obstruction (elevated enzymes or a dilated bile duct)—previously called *SOD type II*, now *functional biliary sphincter disorder*—need further detailed investigation, to better establish the predictors of treatment benefit and failure.

Elevated sphincter pressures are commonly found in patients with unexplained recurrent acute pancreatitis, but its etiological role, and the benefits of biliary and pancreatic sphincterotomy, are unproven.

A plea is made for clinicians to reassess their perspectives in dealing with these challenging patients, and for researchers to strengthen the evidence base for our practice.

### Keywords

sphincter of Oddi dysfunction

sensitization.<sup>7</sup> Significant tissue inflammation such as cholecystitis will activate nociceptive neurons acutely and, if it persists, also result in sensitization, and the gain in the entire pain pathway is increased. In most patients with gallbladder disease, cholecystectomy removes the ongoing stimulus and the system reverts back to its normal state. However, in a subset of patients, the "gain" stays at a high level. In such patients, even minor increases in biliary pressure within the physiological range can trigger nociceptive activity and the sensation of pain, a concept called *allodynia*.

A relevant related phenomenon is cross-sensitization. Many viscera share sensory innervation, and it is difficult to distinguish pain originating in one organ from that in another. Persistent sensitization in one organ can lead to sensitization of the nociceptive pathway from an adjacent organ. Thus, an entire region can be sensitized with innocuous stimuli (such as duodenal contraction after a meal) leading to pain that was indistinguishable from that associated with the initial insult. Evidence for this was provided by an important study in which patients with post-cholecystectomy pain were found to have duodenal, but not rectal, hyperalgesia.<sup>8</sup> A strong case can be made for nociceptive sensitization to be the principal cause of pain in these patients. Motor phenomena such as sphincter hypertension may still be relevant, but more as a marker for the syndrome rather than the cause.

There are many reasons why patients may have pains after cholecystectomy. The first task is to exclude organic causes. Possibilities include early postoperative complications (such as a bile leak or duct stricture), retained stones or partial gallbladder, other intraabdominal disorders such as pancreatitis, fatty liver disease, peptic ulceration, functional dyspepsia and irritable bowel syndrome, musculoskeletal disorders, and other rare conditions.

### BOX 56.1 Definition of Biliary Pain in Rome IV

Pain located in the epigastrium and/or right upper quadrant and all the following:

1. Builds up to a steady level and lasts 30 minutes or longer
2. Occurs at different intervals (not daily)
3. Severe enough to interrupt daily activities or lead to an emergency department visit
4. Not significantly (< 20%) related to bowel movements
5. Not significantly (< 20%) relieved by postural change **or** acid suppression

#### Supportive Criteria

The pain may be associated with the following:

1. Nausea and vomiting
2. Radiation to the back and/or right infra subscapular region
3. Waking from sleep

From Cotton PB, Elta GH, Carter CR, et al: Gallbladder and sphincter of Oddi disorders. *Gastroenterology* 150(6):1420–1429, 2016.

Nonbiliary findings are more likely when the symptoms are atypical and long-standing, similar to those suffered preoperatively and without a period of relief postoperatively, and when the removed gallbladder did not contain stones.<sup>7–8</sup> The concept and management of "functional gallbladder disorder" is equally controversial.<sup>1</sup>

Whether the pain appears to be "biliary" is a crucial clinical question because it focuses the approach to diagnosis and treatment. The Rome process has provided a consensus definition of biliary pain, which is unchanged in the IVth iteration (Box 56.1). It must be said that few, if any, of the stated criteria are sufficiently based on evidence, and more data would be helpful.

#### Initial Investigation

When the pain appears to be biliary, and is sufficiently troublesome to warrant investigation, initial testing should include liver and pancreatic enzymes (preferably taken shortly after a pain episode) and transabdominal ultrasound, supplemented with computed tomography (CT) scan or magnetic resonance cholangiopancreatography (MRCP). The goal of imaging is to rule out other pancreatic and biliary pathology and to determine the size of the bile duct. Equivocal findings are best evaluated further by endoscopic ultrasound (EUS). Upper endoscopy is usually performed to rule out mucosal diseases, especially if the pains are meal-related.

How to proceed further will depend on the findings of these initial tests. In the past, patients have been classified into 3 categories:

- Type I: dilated bile duct and elevated liver enzymes
- Type II: dilated duct or elevated liver enzymes, but not both
- Type III: no abnormalities

Rome IV concluded that this classification is now outdated and should be abandoned.<sup>1</sup> Patients with both dilated ducts and elevated liver enzymes have an organic problem (sphincter fibrosis or microlithiasis) rather than functional pathology, and they benefit from biliary sphincterotomy.<sup>7,8</sup> Thus the term *sphincter of Oddi (SOD) I* is no longer appropriate; we prefer *sphincter of Oddi stenosis*. Equally, the term *SOD III* should be abandoned.

**TABLE 56.1 Results of the EPISOD Randomized Trial, and the EPISOD 2 Observational Study, in Which Patient's Treatment Was Determined by the Results of Manometry**

Study	Sphincter Treatment	N	Pain Relief at 1 Year
EPISOD	None (sham)	73	27 (37%)
	Any sphincterotomy	141	32 (23%)
EPISOD 2	Biliary sphincterotomy	21	5 (24%)
	Dual sphincterotomy	39	12 (31%)
	None	12	2 (17%)

Modified from Cotton PB, Elta GH, Carter CR, et al: Gallbladder and sphincter of Oddi disorders. *Gastroenterology* 150(6):1420-1429, 2016.

The 2014 randomized sham-controlled effect of endoscopic sphincterotomy for suspected sphincter of Oddi dysfunction on pain-related disability following cholecystectomy (EPISOD) trial showed that those patients do not have sphincter dysfunction because the results of sphincterotomy were no better than sham (Table 56.1).<sup>11</sup> The conclusions remained valid in the 99 subjects who were followed for 3 years. Contrary to widespread clinical belief, the EPISOD patients (even those who also had irritable bowel syndrome) had psychosocial profiles no different from population norms.<sup>12</sup> We recognize that these patients are often seriously disabled with pain, but the trial strongly suggests exploring other causes, and less dangerous methods of management.

With SOD types I and III eliminated as functional sphincter disorders we are left only with patients with postcholecystectomy pain and some objective findings (the prior SOD type II, now called *suspected functional biliary sphincter disorder*).

Our main task now is to guide these patients and their advisors through the clinical minefield into optimal management. Additional methodologically rigorous studies are needed to better define the characteristics of patients who may benefit from intervention.

### Clinical Predictors of Biliary Sphincter Hypertension

Faced with a symptomatic patient with some evidence for biliary obstruction (a dilated bile duct or elevated liver enzymes) and no other determined cause, the clinician will need to assess the likelihood that the sphincter is the culprit, and that sphincterotomy may be helpful. What are those predictors? Even for bile duct size and liver enzymes, there are devils in the details. To start with, the definition of a *dilated duct* is arbitrary. It is widely believed that the bile duct enlarges normally after cholecystectomy, and radiologists often report "dilation consistent with prior cholecystectomy." However, many careful studies have shown no change, and others only a slight increase. There is a gradual increase with age.<sup>13-16</sup> Regular narcotic use can cause biliary dilation, although usually associated with normal liver enzymes. The main reason why the average size of the duct is bigger after cholecystectomy than the usual norm of 6 to 7 mm is because some of the patients had duct disease at the time of surgery. The original Milwaukee classification of SOD proposed 12 mm as the acceptable upper limit,<sup>17,18</sup> which seems high; the Rome III panel used 8 mm.<sup>7</sup> The EPISOD study used 9 mm.<sup>11</sup> It would

seem likely that a bile duct that is known to have dilated considerably since surgery would be a good sign of obstruction, but that has not been studied. In clinical practice, it is unusual to have access to perioperative imaging to make that assessment in an individual case.

Similar questions arise when considering elevated liver enzymes. Which ones, how high, how often, and when? The standard criteria state that transaminases should be more than twice normal on at least two occasions, and normalize between pain attacks. None of these are firmly evidence-based. Furthermore, as clinicians dealing with many of these patients, we know that these data elements are not always available. Patients are sometimes asked to obtain liver tests shortly after a pain episode, but the evidence that peaking transaminases predict the outcome of sphincterotomy is limited.<sup>19</sup> It is important to remember that elevation of transaminases above the usually accepted normal limits is common in the US population.

There are few data on predictors other than duct size and enzymes. Freeman et al (2007) showed that delayed gastric emptying, daily opioid use, and age less than 40 predicted a poor outcome.<sup>20</sup> They also showed no difference in outcomes between patients classified as SOD types I, II, and III. It has also been reported that patients are more likely to respond if their pain was not continuous, if it was accompanied by nausea and vomiting, and if there had been a pain free interval of at least 1 year after cholecystectomy.<sup>21</sup>

Further research is needed to establish more precisely which clinical features and investigations can best identify those who are likely to respond (or not) to sphincter ablation. Among other possible predictors that have not been investigated fully are: the reason for the cholecystectomy (stones or "gall bladder dyskinesia," another controversial diagnosis), the response to surgery, the presence of other digestive, functional or psychiatric problems, and details about the pain (classical "biliary" or not, its severity and frequency, whether it is the same as before surgery, and whether it subsided for a while). A survey of 164 members of the American Society of Gastrointestinal Endoscopy (ASGE) showed little consensus about predictors other than duct size and enzyme elevations.<sup>22</sup>

### Further Investigation for Suspected FBSD

Further investigation is warranted if there are objective pointers to biliary obstruction, if organic disease has been ruled out as far as possible, and if symptoms are severe enough to move on when simple dietary advice and medications (e.g., antispasmodics) have not been helpful.

We recommend more widespread use of EUS in patients with only a dilated duct. It is the best method to detect and exclude relevant organic causes of pain, especially small stones, tumors and pancreatitis.<sup>23</sup>

Several noninvasive techniques have been developed to assess the drainage dynamics of the bile duct. A major problem with assessing their value is the lack of a gold standard. Manometry was previously believed to be an accurate measure of sphincter function, but the gold is increasingly looking tarnished, as discussed later. One could argue that the only proof that the sphincter is (or was) the cause of the pain is if patients are satisfied by the results of sphincter ablation, albeit recognizing the strong placebo effect of ERCP intervention.<sup>24</sup> There are very few studies with such objective assessments and only small randomized trials. Thus, our comments on the value of these various tests are not based on solid evidence.

### Hepatobiliary Scintigraphy (HBS)

HBS involves intravenous injection of a radionuclide, and deriving time-activity curves for its excretion through the hepatobiliary system. This technique has been used to assess the rate of bile flow into the duodenum and to look for any evidence for obstruction. Interpretation of the literature is difficult due to the use of different test protocols, diagnostic criteria and categories of patients, and whether the results are compared with manometry (usually) or the outcome of sphincterotomy. Various parameters are used: time to peak activity, slope values, and hepatic clearance at predefined time intervals, the disappearance time from the bile duct, the duodenal appearance time, and the hepatic hilum-duodenum transit time (HHDTT).<sup>24-27</sup> One study in asymptomatic postcholecystectomy subjects showed significant false positive findings and intraobserver variability.<sup>28</sup> The reported specificity of HBS was at least 90% when manometry was used as the reference standard, but the level of sensitivity is more variable.<sup>29</sup> Although HBS with HHDTT was shown to be predictive of the results of sphincterotomy in type I and II patients,<sup>30</sup> it is not widely used currently. The ASGE survey found that very few used HBS regularly.<sup>22</sup> Further studies of dynamic biliary imaging are needed.

### Other Noninvasive Tests

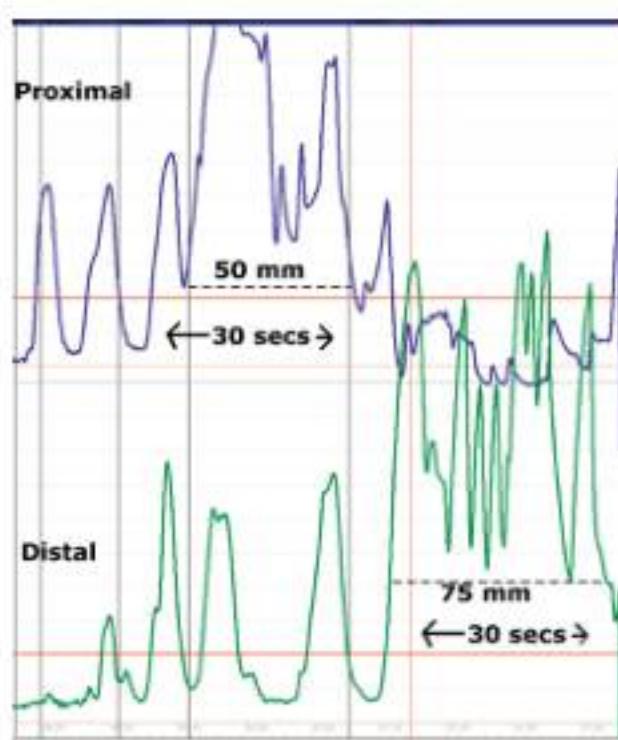

Drainage dynamics have also been tested by measuring any dilatation of the duct with standard or endoscopic ultrasound after stimulation with a fatty meal or injection of CCK. The value of these tests was questioned when the results did not correlate with sphincter manometry. These techniques deserve further evaluation, and there is potential for studying dynamic parameters with contrast agents during MRCP<sup>31</sup> and CT scanning.<sup>32</sup>

### ERCP

ERCP was widely applied to patients with postcholecystectomy pain in the past. Modern sophisticated imaging (CT, MRCP, and EUS) have eliminated its prior role in the diagnosis of structural problems, but it is still used to measure sphincter pressures. It is essential for practitioners and patients to appreciate that ERCP in this context is associated with a very high risk of pancreatitis. The rate is 10% to 15%, even in expert hands using pancreatic stent placement and/or rectal nonsteroidal antiinflammatory drugs (NSAIDs). Contrary to widespread belief, manometry does not add to the pancreatitis risk of ERCP alone in patients with suspected SOD.<sup>33</sup> ERCP should nowadays be applied only after careful reflection, and with the consent of patients who are fully informed of the potential benefits, risks, limitations and alternatives.

### Sphincter Manometry

ERCP allows measurement of both the biliary and pancreatic sphincters. It is commonly performed with a pull-back technique, using a water-perfused catheter system (Video 56.1). The assessable variables at sphincter of Oddi manometry (SOM) include the basal sphincter pressure and the phasic wave amplitude, duration, frequency, and propagation pattern. Based on a few studies in volunteers and data from patients thought not to have sphincter pathology, the normal basal biliary pressure is approximately 17 mm Hg<sup>34</sup> (Fig. 56.2). The acceptable upper limit was defined at 35 to 40 mm Hg, by taking three standard deviations. The same value is accepted for basal pancreatic pressure, with less supporting data. There is considerable overlap between biliary and pancreatic sphincter hypertension.<sup>35,36</sup>

**FIG 56.2** Abnormal sphincter of Oddi manometry tracing. Pull-through showing persistent elevation of the basal pressure in both proximal and distal leads above the accepted upper limit of normal (40 mm Hg, shown by the red line).

The belief that manometry results have clinical significance is based mainly on three small sham-controlled trials, which all showed that elevated basal biliary pressures predicted the outcome of biliary sphincterotomy in patients with SOD type II.<sup>37-39</sup> As a result, the use of manometry in SOD type II (and type III) patients was recommended by the panel of the National Institutes of Health ERCP state of the science conference in 2002.<sup>40</sup> However, confidence in the value of sphincter manometry has declined in recent years. The relevance of measurements taken when free of pain, and while under anesthetic, must be questioned. Recording periods are short and subject to movement artifact. Data showing poor reproducibility add to the concerns.<sup>40,41</sup> The ASGE survey mentioned earlier showed that most endoscopists now treat type II patients by empiric biliary sphincterotomy without manometry.<sup>22</sup> Sales of manometry catheters by the main supplier have declined progressively in recent years.<sup>22</sup>

Solid-state manometry catheters have also been used, with results identical to those of the water-perfused system.<sup>42</sup> A technique using a sleeve device also showed similar results, with the advantage of reducing movement artifacts, but is not commercially available.<sup>43</sup>

### Nonmanometric ERCP Diagnostic Approaches

Trial placement of a biliary stent to predict response to subsequent sphincterotomy has been proposed as an alternative method for diagnosing SOD, but should be avoided due to the documented very high risk of inducing pancreatitis.<sup>44</sup> Injection of Botulinum toxin (BTX) has been shown to relax the sphincter complex temporarily<sup>45</sup> and appears to be safe. Most reporters have applied

**FIG 56.3** Injecting Botox into the sphincter.

25 units in each of four quadrants into or close to the papilla (Fig. 56.3). Temporary relief of pain is claimed to predict which patients would benefit from sphincterotomy.<sup>48,49</sup> The authors' own unpublished experience with this method has been confusing. Many patients appear to respond, but for varying periods (even years in some cases), but temporary benefit has not been a consistent predictor of response to subsequent sphincterotomy. The placebo effect must be strong.

#### Treatment of FBSD

Current recommendations for management of patients with suspected FBSD are based on expert consensus, with inadequate evidence. Many patients are disabled with pain and desperate for assistance. The placebo effect of intervention is strong, with more than one-third of sham-treated patients claiming long-term benefit in blinded randomized studies.<sup>11,27–34</sup>

#### Medical Therapy

Because of the risks and uncertainties involved in invasive approaches, it is important to explore conservative management initially. Nifedipine, phosphodiesterase type-5 inhibitors, trimebutine, hyoscine butylbromide, octreotide, and nitric oxide have been shown to reduce basal sphincter pressures in patients with suspected SOD and asymptomatic volunteers.<sup>48,49</sup> H2 antagonists, gabexate mesilate, ulinastatin, and gastrokinetic agents also showed inhibitory effects on sphincter motility. Amitriptyline, as a neuromodulator, has also been used, along with simple analgesics. A small open-label trial of duloxetine had encouraging results. Only 10 of the 18 enrolled patients completed the 3-month trial, mainly due to side effects of the drug, but 9 of the 10 had a successful outcome.<sup>50</sup> A French group was able to avoid sphincterotomy in 77% of patients with suspected SOD using treatment with trimebutine and nitrates.<sup>51</sup> None of these drugs are specific to the sphincter and therefore may also have positive

effects in patients with nonbiliary dysfunctional syndromes. Transcutaneous electrical nerve stimulation<sup>52</sup> and acupuncture<sup>53</sup> also have been shown to reduce SOD pressures, but their long-term efficacy has not been evaluated.

#### Endoscopic Sphincterotomy

Consensus opinion remains that a patient with definite evidence for biliary obstruction (former biliary SOD type I) should be treated with endoscopic sphincterotomy, without manometry.<sup>17</sup> Reported results are good<sup>14–26</sup>; some patients probably had small stones undetected by prior testing methods. The evidence base for biliary sphincterotomy in patients with FBSD (prior SOD type II) is not strong; most studies have been retrospective, unblinded, and have not used objective assessments. Readers interested in the details of the many published cohort studies are referred to comprehensive reviews by Petersen<sup>52</sup> and by Squoros and Periera,<sup>54</sup> and to the SOD chapter in the 2nd edition of this book. One large study claimed success in approximately three-quarters of patients simply because the others did not return to the treatment site for further intervention.<sup>55</sup> The best data come from three small randomized studies of suspected type II patients which showed that biliary sphincterotomy was more effective than a sham procedure in patients with elevated basal biliary sphincter pressures.<sup>56–59</sup> Although convincing, these studies were small, and performed before modern imaging; some patients may have had small stones or microlithiasis. The authors did not study pancreatic pressures or their treatment. One important issue, often overlooked, is that those early studies used the original definition for bile duct dilation (i.e., > 12 mm), a very unusual finding nowadays. The Rome III panel changed that to greater than 8 mm to "make it more applicable to clinical practice and, whenever possible, to avoid the invasive ERCP procedure."<sup>5</sup> It has had the opposite result as it brings in to play many other patients with minimally dilated ducts.

No study has claimed a high percentage of success, which emphasizes the need to understand the predictors, to be able to focus invasive treatment where it is most needed.

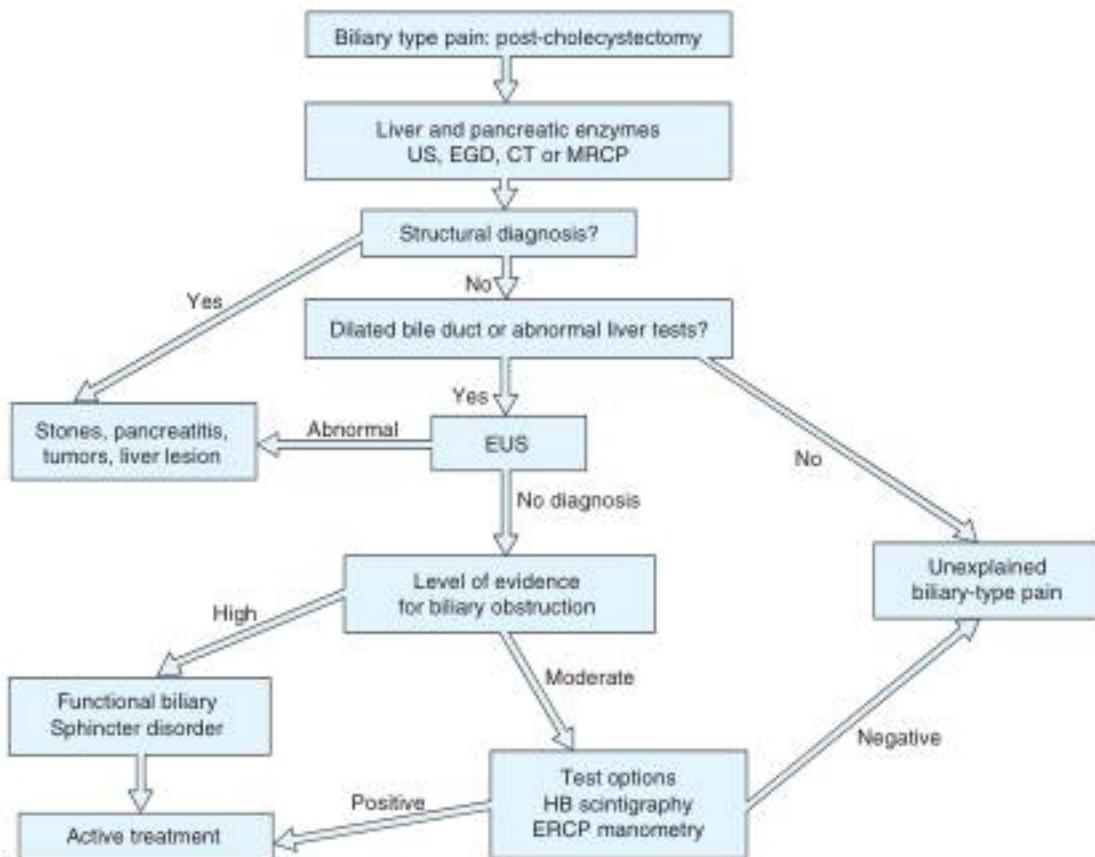

In addition to the 10% to 15% risk of postprocedure pancreatitis, sphincterotomy can cause bleeding and retro-duodenal perforation. Both occur in approximately 1% of cases, and can have devastating consequences. Late stenosis of the pancreatic orifice can occur after biliary and pancreatic sphincterotomies, and is difficult to manage.

#### Other ERCP Treatments

As mentioned previously, attempts to test or treat SOD by balloon dilation or by temporary stent placement are not recommended because of the very high risk of producing pancreatitis. Injection of BTX into the sphincter is another treatment option. It can be applied without doing an ERCP (relying on prior imaging to rule out any pathology) apparently without risk of pancreatitis.<sup>57</sup> Concern has been raised about possible scarring, especially with repeat injections. Stringent prospective studies are needed before this technique can be recommended.

#### Surgical Therapy

Surgical sphincteroplasty is more complete than endoscopic sphincterotomy and can be performed primarily, or following failed endoscopic therapy. Case series and one small, randomized study (published in abstract) suggest good outcomes in most patients<sup>60–63</sup> but less-invasive endoscopic intervention is currently preferred.

**FIG 56.4** Management algorithm for patients with postcholecystectomy biliary pain. CT, computerized tomography; EGD, upper endoscopy; ERCP, endoscopic retrograde cholangiopancreatography; EUS, endoscopic ultrasound; HB, hepatobiliary; MRCP, magnetic resonance cholangiopancreatography; US, ultrasound.

### FBSD in Patients With an Intact Gallbladder

Very few studies have addressed the role of sphincter dysfunction in patients with biliary-type pain in the presence of the gallbladder. One old small retrospective case series showed a lower chance of clinical response to biliary sphincterotomy in patients with an intact gallbladder than in those with prior cholecystectomy,<sup>52</sup> whereas a more recent one (2011) claimed more than 89% response in both groups.<sup>53</sup> Another earlier study performed biliary sphincterotomy on 35 patients with intact gallbladders and elevated biliary sphincter pressures.<sup>54</sup> Only half of them claimed improvement after a mean of 1 year. Eleven went on to cholecystectomy, and 8 improved. At this time, the data are not sufficient to recommend ERCP, manometry, or sphincterotomy in patients with intact (stone free) gallbladders. Some experts do perform sphincterotomy in this context if a patient has impressive intermittent pains with fluctuating liver enzymes, but only after complete review and discussion of the options and possible outcomes. More information is needed on how to manage these patients.

### Summary of Functional Biliary Sphincter Disorder

Postcholecystectomy pain is a common complaint, the cause of which often remains obscure after careful enquiry and standard investigations. This is a clinical minefield, which patients and

physicians should enter only with extreme caution, especially when considering the use of ERCP and sphincterotomy, with or without sphincter manometry. The EPISOD trial showed the strength of the placebo effect of intervention, which bedevils the assessment of all types of treatment.

We recommend the approach constructed in 2016 by the Rome IV consensus as shown in Fig. 56.4. Further stringent trials are needed to better inform clinical practice.

### FUNCTIONAL PANCREATIC SPHINCTER DISORDER (FPSD)

Sphincter dysfunction has been proposed as a cause of pancreatitis, and indeed also pancreatic pain without pancreatitis. Proof is lacking, and the clinical approach is currently speculative. As recommended by Rome IV, this concept is now named FPSD.

### Idiopathic Acute Recurrent Pancreatitis (IARP)

The general approach to patients with unexplained recurrent acute pancreatitis is discussed in Chapter 57. Clearly it is essential to exclude all the known possible causes by comprehensive investigations, including genetic testing, before focusing on the possible role of FPSD. Obstruction at the level of the sphincter is a well-known cause of pancreatitis in animal experiments and in several clinical situations; for example, tumors of the papilla

and intermittent obstruction of the sphincter due to passage of stones, or mucus plugs in intraductal papillary mucinous neoplasm. It is therefore reasonable to postulate that an overactive sphincter muscle could cause pancreatitis. Opiates can increase sphincter pressure and have been implicated in attacks of pancreatitis.<sup>67</sup> However, the evidence that sphincter hypertension is a common cause of pancreatitis is not strong.<sup>68–70</sup> Proof would require the demonstration of abnormal sphincter activity relative to controls, along with resolution of the attacks after sphincter ablation. Whether sphincter ablation is curative (or at least helpful) is obviously the key question. The limited data are given in the following sections.

### Assessing Sphincter Dysfunction in IRAP

Measuring the size of the pancreatic duct by MRCP (or EUS) before and after an intravenous injection of secretin is an attractive method for detecting functional obstruction at the sphincter. One report suggested that the results do not correlate with those produced by sphincter manometry, but that they may predict the outcome of sphincterotomy.<sup>71</sup> This test deserves further assessment.

Manometry of both pancreatic and biliary sphincters at ERCP has been used widely in this context. Elevated pancreatic (and biliary) sphincter pressures have been found 25% to 78% of patients with IRAP.<sup>72–73</sup> One 2012 study also showed a 3.5-fold greater likelihood of recurrent attacks (without treatment) in patients with elevated pressures, compared to those with normal pressures.<sup>73</sup> The downside of ERCP in this context is the risk (at least 15%) of inducing pancreatitis.

Injection of BTX into the sphincter as a test of the effects of temporary sphincter ablation, as described previously in the biliary section, has been applied to patients with IRAP.<sup>74</sup> Temporary pancreatic stenting has also been used as a test of sphincter dysfunction, but concerns about stent-induced duct damage have eliminated this practice.

### Treating FPPS in IRAP

Assessment of treatments in this context is difficult because any recurrences may be long delayed. Patients should be counseled to avoid factors (e.g., alcohol, tobacco, opiates) that may precipitate attacks. Certain medications, such as antispasmodics and calcium channel blockers, are known to relax the sphincter, but there have been no trials of their value in this context.

Whether to offer sphincterotomy to patients with IRAP is currently a difficult decision because the evidence base is thin and there are significant short- and long-term risks. It will be influenced by the frequency and severity of the attacks, the completeness of prior investigations, and by the patient's wishes when fully informed about the available data. The status of the gall bladder is also relevant. Empiric cholecystectomy is often advocated when gallbladder disease is still suspected despite negative investigations (e.g., in a nondrinking woman with elevated liver tests in attacks), and is probably safer than sphincterotomy.

Pancreatic sphincter ablation was initially performed by an open trans-duodenal approach. Small case series reported resolution of episodic pancreatitis in the majority of patients.<sup>75</sup> Endoscopic therapy quickly replaced surgical sphincteroplasty, with the assumption that the results would be equivalent.<sup>76–78</sup> Early small-cohort studies with short follow-up periods suggested a benefit when recurrence was reported in less than one-third of patients after pancreatic sphincterotomy.<sup>72,79–80</sup> Wehrmann (2011) reported a 51% recurrence rate after a 10-year follow-up

of 37 patients<sup>79</sup> and the recent trial by Coté et al (2012) reported a similar proportion after a mean of 6 years.<sup>75</sup>

Whether these reports indicate that sphincterotomy is beneficial is difficult to interpret in the absence of any untreated controls. A retrospective study suggested that patients who underwent dual endoscopic sphincterotomy had less recurrence than those who had either biliary or pancreatic sphincterotomy alone.<sup>79</sup> However, the Coté trial failed to show the superiority of dual sphincterotomy over biliary sphincterotomy alone.<sup>75</sup>

A confounding issue is the difficulty in performing a complete (and permanent) pancreatic sphincter ablation endoscopically. Repeat examinations in the Coté and EPISOD studies showed persistent hypertension or re-stenosis in many cases.<sup>71,75</sup> The actual incidence is uncertain as asymptomatic subjects were not studied.

Some experts perform ERCP with empiric biliary sphincterotomy initially without manometry in patients with IRAP, but the benefit is unproven.

### Conclusion

In the absence of hard data, it is currently possible to argue that sphincter ablation does not alter the natural history of IRAP and that the finding of apparent sphincter abnormality is an epiphenomenon, the result of previous attacks, or due to a different, unexplained cause.

Additional randomized trials are required to determine whether any sphincter treatment is effective and, if so, to establish the preferred approach (biliary, pancreatic, or dual sphincterotomy), and indeed whether it can be achieved adequately and safely endoscopically when compared with surgery.

At the present time, clinicians and their patients will need to make individual treatment decisions in the full knowledge of the gaps in our knowledge.

### SOD as a Cause of Pancreatic Pain Without Pancreatitis?

In the past, it was proposed that SOD can cause pancreatic pain without enzyme elevation or other evidence for pancreatitis, and a categorization of pancreatic SOD types similar to that used previously in suspected biliary SOD has been suggested.<sup>72</sup> However, there is currently no strong evidence that SOD can cause pancreatic pain in the absence of pancreatitis. Given the risks of ERCP with manometry and the short- and long-term risks of pancreatic sphincterotomy, evaluation of possible pancreatic SOD should be restricted to patients with IRAP.

### SOD and Chronic Pancreatitis?

SOD as determined by manometry has been described in 50% to 87% of patients with chronic pancreatitis of many etiologies.<sup>80</sup> This high frequency in patients with a known etiology suggests that SOD is the result of chronic inflammation rather than its cause. Endoscopic pancreatic sphincterotomy was reported to improve pain scores in short-term uncontrolled studies in 60% to 65% of chronic pancreatitis patients with pancreatic SOD.<sup>81,82</sup> Whether ERCP with SOM should be offered to chronic pancreatitis patients with unexplained recurrent episodes of acute inflammation remains to be determined.

### Summary of FPPS

At this time, there is no role for ERCP with manometry in patients with suspected pancreatic pain without evidence for pancreatitis, unless they are enrolled in a clinical trial.

Patients with a single episode of unexplained acute pancreatitis should not subject themselves to the risks of ERCP and manometry, because a second episode may never occur or be long delayed.

Patients with recurrent acute pancreatitis that remains unexplained after exhaustive investigation and appropriate medical treatments can be considered for a therapeutic intervention. Empiric cholecystectomy should be offered in some cases. It is reasonable to discuss ERCP with manometry, with a view to sphincterotomy if the pressures are elevated, while acknowledging the lack of supporting evidence. Biliary sphincterotomy alone appears as effective as dual sphincterotomy and likely lowers the procedural risk. There is currently no clear role for ERCP, manometry, or pancreatic sphincterotomy to treat postulated SOD in patients with chronic pancreatitis.

## MANAGING FAILURES OF ENDOSCOPIC TREATMENT FOR FBSD AND FPSD

Managing patients with recurrent problems after endoscopic treatment for these controversial conditions is a common and challenging problem in tertiary centers. ERCP is usually applied to look for and treat any persisting functional sphincter hypertension. Stenosis of the biliary orifice is unusual after biliary sphincterotomy, but can be managed with balloon dilation and temporary stenting. The pancreatic orifice is more often the focus of concern. Biliary sphincterotomy alone can cause functional stenosis of the pancreatic orifice.<sup>62</sup> Five of fifteen individuals with initially normal pancreatic pressures became abnormal after only biliary sphincterotomy in the EPISOD trial.<sup>41</sup> Pancreatic sphincterotomies are rarely complete in the context of SOD, when the duct is not dilated, and scarring is probably common. A 2012 review of pancreatic sphincterotomy for IRAP revealed that 48% of the patients had a re-intervention.<sup>73</sup> Three of the nine pancreatic sphincterotomies were found to be incomplete in patients undergoing repeat procedures in the EPISOD trial.<sup>41</sup> Some endoscopists rely on repeat manometry to detect problems at the pancreatic orifice; most will go directly to balloon dilation and temporary stenting. The results of these maneuvers are unpredictable. It is a slippery slope; some patients eventually proceed to surgical sphincteroplasty,<sup>63</sup> and even pancreatic resections, with uncertain results.

Managing patients who return sometime after apparently gaining substantial benefit from earlier endoscopic treatment for SOD III is especially challenging, in view of the EPISOD data showing that the results are no better than sham. They are understandably reluctant to accept a nihilistic approach, and are often dismissive of medical management with neuromodulators. Most will demand and receive another ERCP, if only to check for restenosis.

## CONCLUSION

It is clear that clinical confidence in the role of SOD, and sphincterotomy, in patients with postcholecystectomy pain and with unexplained recurrent pancreatitis has declined in recent years. The evidence is weak and there is increasing appreciation of other possible causes. The fact that ERCP carries significant hazards in the short- and long-term adds weight to our plea for clinicians to broaden their perspectives in dealing with these challenging patients, and for researchers to strengthen the evidence base to better inform our practice.

## ACKNOWLEDGEMENTS

We are indebted to Rome co-authors Elta, Carter, Pasricha and Corazziari for their input, and also to Sherman, Fogel, Watkins, McHenry and Lehman, for their comprehensive review and erudite discussion of this topic in the 2nd edition of this book, and for their permission to use some of their illustrations.

### INTRODUCTION

Acute pancreatitis (AP) has an excellent prognosis if the severity is limited, and if the underlying cause can be identified and treated. However, AP may recur if the underlying causes are not eliminated or modified. Patients with recurrent AP (RAP) endure frequent emergency room (ER) visits and hospitalizations, costly testing, potentially risky interventions, and may eventually develop chronic pancreatitis (CP) and related functional impairment. Thus, RAP has a detrimental impact on quality of life and places a tremendous cost burden on health care systems. The central clinical objective is to evaluate and treat the causes of RAP to interrupt the disease process. In this chapter, the evaluation and treatment of RAP are reviewed, with an emphasis on the appropriate role of endoscopy.

### DEFINITIONS

The diagnosis of AP can be established based on two of the following: (1) typical pancreatic pain, (2) elevation in serum lipase and/or amylase levels to greater than 3 times the upper limit of normal, and (3) confirmatory imaging findings.<sup>1</sup> The term *RAP* is found in the literature dating back seven decades.<sup>2</sup> RAP is defined as "two or more episodes of AP." Reasonable stipulations have been imposed on this basic definition, including full resolution of symptoms between attacks,<sup>3</sup> the absence of imaging changes indicating CP, and a period of at least 3 months between the initial and recurrent episode(s).<sup>4</sup> The latter criterion is used to distinguish true recurrence from a complication from the initial attack or an exacerbation related to dietary advancement. The term *idiopathic RAP* (IRAP) is used when the cause is not immediately recognized based on history, physical

examination, basic laboratory testing (e.g., serum triglyceride and calcium), and imaging tests (transabdominal ultrasound [TAUS] and/or computed tomography [CT] scan).<sup>5</sup> Patients with IRAP are at risk for further attacks and progression to CP. In efforts to find obscure causes and cure the disease, they may undergo second-line imaging tests, endoscopic retrograde cholangiopancreatography (ERCP), and genetic testing. Even after these advanced tests have been performed and thousands of dollars have been spent, the cause may remain unexplained or unmodifiable, and attacks or persistent intractable pain may persist with or without morphologic evidence of CP. The term *true idiopathic recurrent acute pancreatitis* (TIRAP) has been coined for such unfortunate patients.<sup>6</sup> An axiom of RAP and CP is that the symptom burden, especially chronic pain, correlates poorly with morphologic changes.<sup>7,8</sup> Some patients with frequent attacks or intractable pain between attacks even undergo total pancreatectomy with autologous islet cell transplantation as a last resort, despite the absence of morphologic or functional evidence of CP.<sup>9</sup>

### EPIDEMIOLOGY

The incidence of AP ranges from 13 to 45/100,000.<sup>10</sup> In 2012, AP accounted for 330,561 ER visits and 275,170 hospitalizations, with a related aggregate cost of \$2.6 billion.<sup>11</sup> Multiple observational studies have included consecutive patients followed after an index bout of AP to ascertain the rates of RAP and progression to CP. A 2015 meta-analysis showed a pooled recurrence rate of 22% (95% confidence interval [CI] 18%–26%) in 11 studies.<sup>12</sup> The pooled rate of progression from RAP to CP was 36% (CI 20%–53%) in five studies. The prevalence rates of RAP and CP were higher in alcohol-related compared to biliary pancreatitis.

**Abstract**

Recurrent acute pancreatitis (RAP) is a painful and debilitating condition for patients, and poses several challenges for clinicians. The primary management goal is to uncover the causes of RAP to prevent recurrent episodes and progression to chronic pancreatitis. Endoscopists have much to offer in the management of RAP, but endoscopic methods should be employed thoughtfully within the framework of a careful history, laboratory and genetic testing, and noninvasive imaging tests. In this chapter, the various causes of RAP will be discussed, with emphasis on the diagnostic and therapeutic role of endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic ultrasound (EUS).

**Keywords**

acute pancreatitis  
endoscopic ultrasound  
ERCP  
pancreas divisum  
microlithiasis  
sphincter of Oddi dysfunction

The results for other etiologies and idiopathic pancreatitis are not always reported. However, some studies have shown higher recurrence and progression rates in those with idiopathic compared to biliary etiology.<sup>13,14</sup>

## CAUSES

The causes of RAP and CP overlap, and have been categorized as toxic and metabolic, genetic, autoimmune, and obstructive (Table 57.1).<sup>15</sup> Several etiologies particularly relevant to endoscopists are discussed in the following sections.

### Biliary Microlithiasis

Biliary microlithiasis is a common cause of IRAP in patients who have an intact gallbladder, particularly those with risk factors such as pregnancy, rapid weight loss, critical illness, prolonged fasting, ceftriaxone use, octreotide use, bone marrow or organ transplant, and prolonged fasting.<sup>16</sup> Microlithiasis refers to small gallstones (e.g., < 3 mm)<sup>17</sup> that are not easily visible on TAUS but may easily traverse the cystic duct and impact at the ampulla of Vater. Recurrent passage of small stones may produce an inflammation and fibrosis cycle resulting in ampillary stenosis, which increases susceptibility to obstructive AP episodes. Though microlithiasis is "invisible" on TAUS, it may coincide with the presence of biliary

sludge, which is more easily seen on TAUS, repeat TAUS,<sup>18</sup> and endoscopic ultrasound (EUS). Biliary sludge is a mixture of particulate matter, mucous, and bile, and is visible as nonshadowing echogenic material that forms layers in the dependent portion of the gallbladder.<sup>16</sup> Sludge visible on EUS may not always contain stones, but may be a reasonable biomarker to guide treatment. Two studies showed high rates of sludge or biliary crystals (67%–74%) in patients with IRAP and intact gallbladders.<sup>16,19</sup> In general, we consider both findings of microlithiasis or sludge visible on TAUS/EUS or the presence of crystals in the bile to indicate biliary pancreatitis, caused by passage of particulate material that causes transient ampillary obstruction.

The diagnostic workup for microlithiasis and the threshold for an empiric cholecystectomy have been sources of some controversy. EUS may be more sensitive for detecting sludge and microlithiasis than TAUS, CT, and magnetic resonance cholangiopancreatography (MRCP)<sup>20,21</sup> (Fig. 57.1). Some use cholecystokinin stimulation with endoscopic collection of expressed bile and polarized microscopy to check for crystals.<sup>22</sup> This method is performed infrequently because of questionable specificity and reproducibility.

Cholecystectomy is the definitive and currently preferred treatment for suspected microlithiasis. A practical approach advocated by many experts is to proceed to empiric cholecystectomy in those

**TABLE 57.1 TIGAR-O<sup>®</sup> Classification of Causes of Pancreatitis**

Etiology	Clinical Clues/Risk Factors	
<b>Toxic</b>	Alcohol Cigarette smoking Cannabis	
<b>Metabolic</b>	Hypertriglyceridemia Hypercalcemia	
<b>Obstructive</b>	Cholelithiasis/choledocholithiasis Microolithiasis Sphincter of Oddi dysfunction IPMN Pancreatic cancer Chronic pancreatitis Upper GI Crohn's disease Pancreas divisum Duodenal duplication cyst Juxtapapillary diverticulum	Familial lipid disorders, poorly controlled diabetes, obesity, excess estrogen, hypothyroidism, alcohol abuse Hyperparathyroidism Rapid weight loss/gain, pregnancy, obesity, preceding biliary colic Elevated liver function tests during episode Postcholecystectomy, use of opiates Most common with main duct involvement New onset of RAP, age > 40 years, weight loss Presence of ductal stones/strictures History of Crohn's disease Dorsal duct dilation or Santonnicole on imaging
<b>Genetic</b>	CFTR SPINK1 PRSS1	Recurrent sinusitis/bronchitis, male infertility Multiple family members in consecutive generations with pancreatitis and/or pancreatic cancer
<b>Infectious</b>	Ascariasis Viral (immunos, coxsackie A)	
<b>Autoimmune/Vascular</b>	Type 1 AIP (IgG4-related sclerosing disease)  Type 2 AIP Lupus-associated pancreatitis	Typical imaging findings (pancreatic enlargement, capsular enhancement, ductal strictures) Other organ involvement (salivary glands, retroperitoneal fibrosis, renal cortical lesions, etc.) Elevated IgG4 History of IBD
<b>Medications</b>	Azathioprine, furosemide, valproic acid	Short latency from onset of medication to onset of attack, literature supportive of relationship, positive rechallenge

\*Toxic and Metabolic, Idiopathic, Genetic, Autoimmune, Recurrent and Severe Acute Pancreatitis Associated Chronic Pancreatitis, Obstructive.

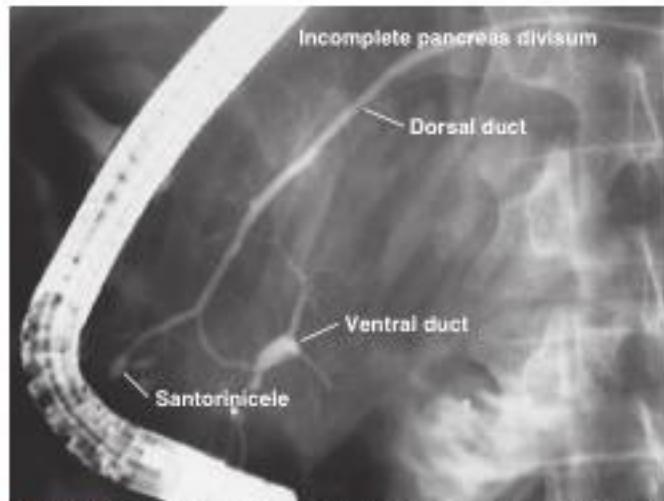

AIP, autoimmune pancreatitis; GI, gastrointestinal; IBD, inflammatory bowel disease; IPMN, intraductal papillary mucinous neoplasm; RAP, recurrent acute pancreatitis.

**FIG 57.1** Gallbladder sludge seen on endoscopic ultrasound (EUS) in a 25-year-old woman with recurrent acute pancreatitis (RAP). She had slight alanine transaminase (ALT) elevations during the most recent bout. Transabdominal ultrasound (TAUS) was read as negative for stones. The attacks ceased after cholecystectomy was performed.

with TIRAP and intact gallbladder. Some have even advocated this intervention after a first attack.<sup>23</sup> A 2015 interventional trial randomized patients experiencing their first attack of idiopathic AP to empiric cholecystectomy versus watchful waiting.<sup>24</sup> Baseline TAUS was negative for stones in all patients. The cholecystectomy group had significantly lower rates of recurrence compared to the observation group (8/39 vs. 23/46,  $p = 0.016$ ) after a mean of 36 months of follow-up. The number-needed-to-treat with cholecystectomy to prevent one patient from having a recurrence was five. The use of empiric cholecystectomy in IRAP should be considered carefully based on the patient's clinical presentation and risk factors. For example, in a young, thin patient with IRAP who has normal liver function tests and whose gallbladder appears normal on ultrasonography, it would be prudent to first obtain genetic testing for pancreatitis-causing mutations. The finding of a significant high penetrance mutation (e.g., in *PRSS1*) may obviate cholecystectomy.

Endoscopic biliary sphincterotomy (EBS) is an effective alternative for selected patients. The rationale for performing EBS is that it separates the biliary and pancreatic orifices, allowing crystals and stones to pass into the duodenum with less chance of causing pancreatic duct obstruction or biliary reflux. In observational studies, EBS has been shown to decrease the rate of recurrence of biliary pancreatitis in patients with intact gallbladders to 2% to 6%.<sup>25–27</sup> EBS can be considered for very elderly patients, those with comorbidities increasing operative risk, those refusing cholecystectomy, or as a temporizing strategy if cholecystectomy is delayed. The use of EBS has waned since the advent of laparoscopic cholecystectomy, which may be safer than ERCP in this cohort of patients.

**FIG 57.2** Endoscopic retrograde cholangiopancreatography (ERCP) performed on a patient with recurrent acute pancreatitis (RAP) shows incomplete pancreas divisum. The ventral duct and dorsal duct are connected by a small branch duct. At the most distal portion of the dorsal duct, a cystic outpouching (called a Santorinicele) is also seen. This patient responded to endoscopic minor papillotomy. (Image courtesy of Adam Slivka and Michael K. Sanders.)

### Pancreas Divisum

Pancreas divisum (PD) is a relatively common embryological anatomic variant that has been postulated to impair drainage of the pancreatic duct, contributing to obstructive pancreatitis. The pancreas begins as dorsal and ventral buds, each with separate ductal drainage into the foregut. Within the first trimester, the ventral bud rotates axially and fuses with the dorsal part. In most cases, the dorsal and ventral ducts likewise fuse, allowing redundant drainage of the entire pancreas through both minor and major papillae. In cases of PD, the ductal systems do not fuse, leading to separate drainage of the dorsal and ventral ducts, or only partially fuse (incomplete divisum), resulting in the presence of a thread-like connection between the systems (Fig. 57.2). Because the minor papilla is a smaller opening, patients with PD may suffer RAP affecting the dorsal pancreas (superior head, body, and tail of pancreas). Patients with PD are protected from biliary pancreatitis due to lack of continuity between the biliary and pancreatic ducts. As such, the diagnosis of PD may obviate empiric cholecystectomy in patients with IRAP. A rare exception is focal ventral gallstone pancreatitis, which may still occur in PD patients.<sup>28</sup>

The traditional gold standard for diagnosing PD has been ERCP. Cannulation and injection of the ventral pancreatic duct via the major papilla reveals a short, arborized ventral duct (Fig. 57.3). It is important to recognize that the finding of a short ventral duct may also indicate a benign or malignant pancreatic duct stricture.<sup>29</sup> Observance of ventral duct arborization may prompt subsequent endoscopic cannulation and injection of the minor papilla to define the dorsal duct anatomy and allow endoscopic therapy. ERCP is now rarely needed for diagnosis of PD since the advent of MRCP, secretin-enhanced MRCP, and EUS.<sup>30</sup> In most cases, endoscopists have a diagnostic MRCP available and undertake ERCP with therapeutic intent.

The decision to intervene in cases of PD must be considered carefully. PD is common, and its presence does not always indicate that it is a cause of or cofactor in IRAP. A comprehensive analysis of autopsy, ERCP, and MRCP studies suggest that the prevalence of PD in the general Western population is 8%.<sup>11</sup> PD is less

common in African Americans (1%–2%)<sup>12</sup> and Asians (1.5%).<sup>13</sup> Whether this common anomaly is a true cause of IRAP continues to be debated. Favoring causation are ERCP studies that show increased rates of PD among those with IRAP and CP compared to controls.<sup>14</sup> However, a 2011 review highlights several biases that may explain these differences.<sup>15</sup>

Multiple retrospective and prospective studies have suggested that endoscopic therapy consisting of minor papillotomy or transpapillary dilation decreases the frequency of RAP or improves pain (Table 57.2).<sup>16–21</sup> However, many of these studies are limited by significant patient heterogeneity, small sample size, limited duration of follow-up, and lack of comparison groups. Recent studies have also found that genetic mutations may confound the relationship of PD and pancreatitis. In a case-control study, patients with idiopathic pancreatitis had the same prevalence of PD as controls (7%), whereas the prevalence of PD was significantly higher in IRAP/CP patients with serine protease inhibitor Kazal type-1 (*SPINK-1*) (16%) and cystic fibrosis transmembrane conductance regulator (*CFTR*) mutations (47%). The authors concluded there was an association of PD with these genetic defects in patients with IRAP and CP,<sup>20</sup> and that PD was acting as a "partner" in the genesis of pancreatitis. This latter argument (that PD is a cofactor) has been questioned by some who believe that PD does not cause pancreatitis.<sup>21</sup> They have argued that PD may be an "innocent bystander" in what is really a genetic problem. In light of these controversies, deciding which patients are most likely to benefit from endoscopic treatment is a frequent clinical conundrum. Signs of impaired dorsal duct drainage (e.g., dorsal duct dilation, the presence of a Santorinicele, which is a saccular dilation of the terminal duodenal portion of the dorsal pancreatic duct [Fig. 57.4], focal inflammation or fibrosis of the dorsal pancreas, and decreased duodenal filling after secretin), may favor causation.

Endoscopic therapy for PD involves minor papillotomy to enhance dorsal duct drainage (Fig. 57.5). After minor papillotomy, a temporary pancreatic stent is usually placed to maintain patency

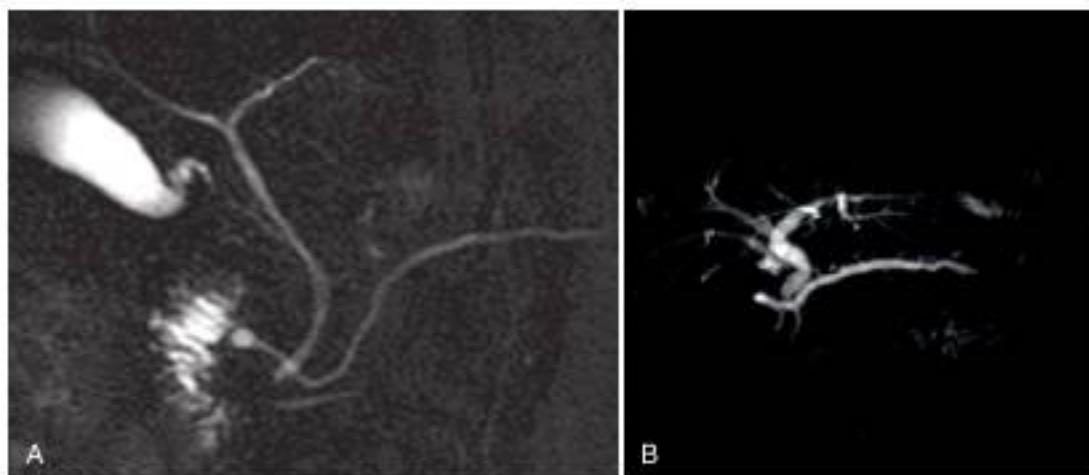

**FIG. 57.3** This 33-year-old female had presumed gallstone pancreatitis, but continued to have recurrent acute pancreatitis (RAP) following cholecystectomy. Endoscopic retrograde cholangiopancreatography (ERCP) with contrast injection of the ventral duct via the major papilla showed an arborized appearance, consistent with pancreas divisum.

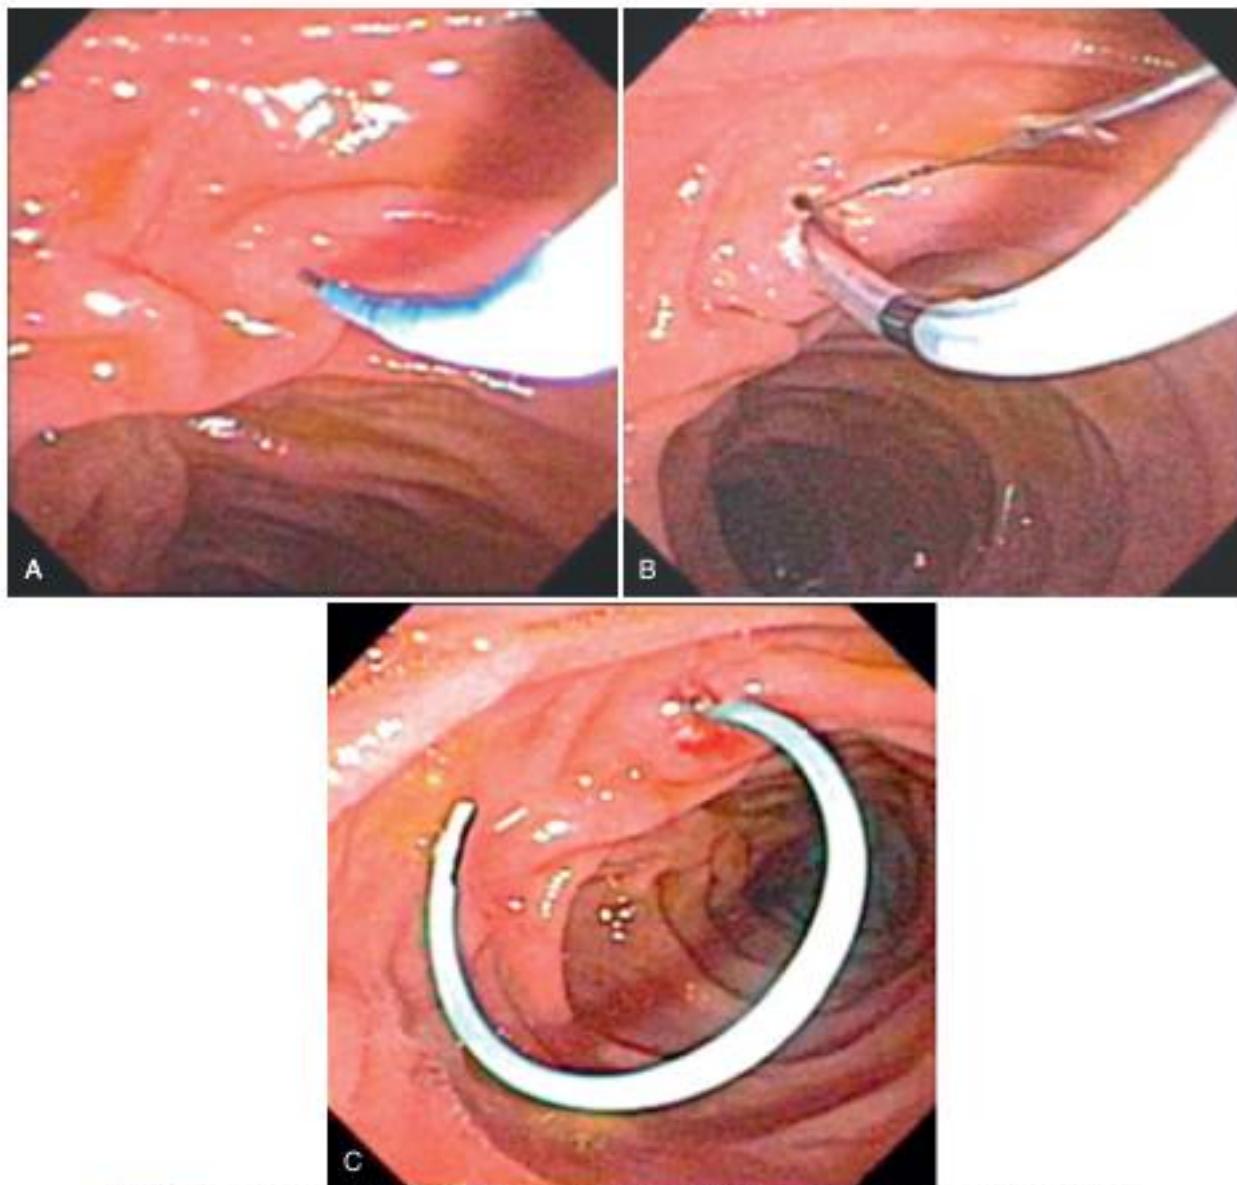

**FIG 57.4** Magnetic resonance cholangiopancreatography (MRCP) examples of pancreas divisum with Santorinicele in two patients with recurrent acute pancreatitis (RAP). **A**, A 15-year-old boy with RAP. There is a normal caliber duct with a Santorinicele. Attacks ceased after endoscopic minor papillotomy. **B**, A 45-year-old man with RAP and chronic abdominal pain. MRCP shows a Santorinicele and a dilated dorsal duct with dilated side branches, indicating outflow obstruction and possible chronic pancreatitis. This patient had no further acute pancreatitis episodes after minor papillotomy, but continued to suffer with chronic daily pain.

of the orifice during healing and as prophylaxis against post-ERCP pancreatitis. Minor papilla localization and cannulation to achieve dorsal duct access can be challenging. The minor papilla is situated proximally and to the right of the major papilla, and is often best visualized from a long scope position. The minor papilla sometimes appears as a small mound or "mini-papilla," but in other cases is quite flat with an almost invisible orifice. Localization of the orifice may be aided by intravenous secretin injection, which stimulates pancreatic juice production, causing the orifice to open.<sup>52</sup> Methylene blue sprayed over the surrounding mucosa can be a useful adjunct.<sup>53</sup> After secretin is administered, the brisk pancreatic flow washes clear the blue dye surrounding the orifice, producing a visible blush for targeted cannulation. Smaller tapered catheters loaded with hydrophilic 0.021-inch wires are best for these cases. It is best to cannulate with the wire because probing with the catheter may cause trauma and bleeding, which can impair localization. After the duct is engaged successfully with a wire and then with the catheter, great care must be taken in passing the wire to the pancreatic tail. If the wire enters a side branch and force is applied, side branch perforation can easily occur, increasing the risk of pancreatitis. As with all pancreatic duct work in the era of MRCP, limited or no contrast injection is needed for guidewire passage. Once the guidewire is positioned, a minor papillotomy can be accomplished with the traction sphincterotome. If the catheter cannot be advanced over the wire because of stenosis, a needle-knife incision can be made over the wire. When wire access fails, precut needle-knife papillotomy may be needed to achieve access. This maneuver should only be performed carefully and incrementally when there is certainty regarding the location of the papillary orifice. Another common technique for minor papillotomy is to place a stent and then perform needle-knife sphincterotomy over the stent. Limited data suggest that the pull-type (traction) and needle-knife-over-stent techniques have similar safety and restenosis rates.<sup>54</sup> Video 57.1 demonstrates several techniques relative to minor papilla access.

### Sphincter of Oddi Disorders

Elevated basal sphincter tone or spasm and ampillary stenosis may obstruct the flow of pancreatic secretions or cause bile reflux into the pancreatic duct, triggering episodes of pancreatitis. Sphincter of Oddi disorders (SODs) are sometimes considered as a possible cause of IRAP in postcholecystectomy patients. Pancreatic SOD is included in the well-known Milwaukee classification, with most IRAP patients falling into the type 2 category (pancreatic pain, recurrent elevations in amylase or lipase, and normal pancreatic duct).<sup>55</sup> There is ongoing debate over the relationship between SOD and pancreatitis, but evidence is mixed regarding a causative relationship. Multiple studies using manometry have shown elevated sphincter pressures ranging from 15% to 72% in patients with IRAP, although the significance of elevated sphincter pressures remains unclear, and hypertension may not translate to a clinical syndrome that responds to biliary or pancreatic sphincter ablation.<sup>56–64</sup>

There are no evidence-based guidelines regarding the role of ERCP in diagnosis and treatment of SOD in IRAP. Relief from recurrent attacks occurs in 52% to 89% of patients with manometrically confirmed pancreatic SOD who undergo endoscopic therapy with sphincterotomy or botulinum toxin.<sup>65–67</sup> In prospective studies, the rates of RAP after endoscopic therapy range from 14% to 48% over a mean follow-up period of 29 to 78 months.<sup>60,61,63</sup> The decision to intervene in type 1 pancreatic SOD (i.e., IRAP and a dilated pancreatic duct) is fairly clear-cut. However, most patients fall into the type 2 category, and lack ductal dilation to implicate outflow obstruction. Because of the inherent risk and uncertain effectiveness of endoscopic therapy, it is preferred that the endoscopist meet the patient prior to performing the procedure. This preprocedure consultation allows the establishment of trust and a rapport between the physician and patient, and enables the physician to communicate realistic expectations regarding the risks of the procedure and the likelihood of a response. The risk of post-ERCP pancreatitis is elevated

**FIG 57.5** Endoscopic therapy for pancreas divisum. **A**, Wire cannulation is accomplished using a tapered-tip catheter with a 0.021-inch wire. **B**, After deep wire access is achieved, a minor papillotomy is performed using a traction sphincterotome and blended current. **C**, A 5-Fr single pigtail stent is placed to prevent post-endoscopic retrograde cholangiopancreatography (ERCP) pancreatitis.

in this group compared to other indications (10% vs. 4%),<sup>68</sup> and is highest for those with pancreatic sphincter hypertension.<sup>69</sup> Many additional patients will require admission for postprocedure abdominal pain, with or without modest enzyme elevations.

Endoscopic approaches to SOD have been heterogeneous, and there are few randomized trials to define the optimal technique and the efficacy of the intervention. Furthermore, outcomes in most studies of endoscopic therapy for IRAP have been variably defined, and many studies have suboptimal follow-up.<sup>70</sup> A common practice has been to perform empiric sphincterotomy (without manometry) in RAP, citing the increased time and risk and lack of precision of sphincter of Oddi manometry (SOM) measurements. However, many experts suggest SOM as a guide for sphincterotomy, especially in cases of suspected

pancreatic sphincter hypertension, given the increased risk of pancreatic sphincterotomy. The main argument in favor of SOM is that patients with high pressures have better response rates, whereas those with normal pressures can be spared the additional risk of sphincter ablation because they are unlikely to respond. In addition, it appears that SOM does not add significantly to the risk of the procedure.<sup>71</sup> Indirect tests (e.g., secretin-stimulated EUS, nuclear scintigraphy) have not shown sufficient sensitivity to be alternatives to SOM in ruling out SOD.<sup>72,73</sup>

Another question is what type of sphincterotomy to perform. The sphincter of Oddi is comprised of three components: common, biliary, and pancreatic sphincter fibers. An EBS may suffice to treat patients with type 2 pancreatic SOD, rather than an endoscopic dual sphincterotomy (EDS), as pancreatic sphincter

hypertension is often primarily due to the common fibers rather than the pancreatic fibers. As such, cutting the common fibers may sufficiently decrease pancreatic sphincter pressure to prevent further attacks. Past observational studies have yielded mixed conclusions regarding the necessity of EDS rather than EBS in type 2 pancreatic SOD.<sup>74,75</sup> A 2012 randomized controlled trial compared EBS and EDS in patients with pancreatic sphincter hypertension. Patients with manometrically confirmed pancreatic sphincter hypertension were randomized to EBS ( $n = 33$ ) or EDS ( $n = 36$ ) and followed for a mean of 78 months (interquartile range 23–108 months).<sup>66</sup> There was no difference in the rate of RAP during follow up (48.5% vs. 47.2%,  $p = 0.20$ ). The rates of RAP following both EBS/EDS were notably high compared to retrospective studies of pancreatic SOD. This interesting finding suggests that sphincter hypertension may not always be the true pathogenic factor in pancreatic SOD, and that underlying genetic factors or other unknown variables may be at play. The investigators also randomized patients with normal SOM ( $n = 20$ ) to EBS or sham treatment. There was no difference in the rate of RAP observed during follow-up between these two groups (11% vs. 27%,  $p = \text{non-significant}$ ). The results of this study call into question the role of manometry in directing sphincterotomy, and perhaps even the value of a sphincterotomy in RAP. Although sphincter ablation may still be considered on an individualized basis, we believe a prudent strategy is to selectively cannulate the bile duct and perform EBS without preceding manometry. In patients who recur following EBS, pancreatic manometry with or without EDS can be considered as a "salvage" procedure.

### Ampullary and Pancreatic Neoplasms

A high suspicion for underlying cancer should be maintained in patients with RAP, especially in those over the age of 40 who have developed RAP in the past several months. Cancers of the duodenum, ampulla,<sup>76</sup> and pancreas may obstruct the pancreatic duct, leading to AP episodes (Fig. 57.6). In a consecutive series of 124 patients with pancreatic carcinoma, AP was the presenting symptom in 13.8%.<sup>77</sup> Though they do not arise from the pan-

creatic duct, neuroendocrine tumors may also occasionally cause AP.<sup>78</sup> Intraductal papillary mucinous neoplasm (IPMN) involving the main and branch ducts may be associated with pancreatitis in 7% to 43% of patients, though many of these reports are from surgical series that are enriched with symptomatic patients.<sup>79–82</sup> (Fig. 57.7). The pathogenesis of pancreatitis is likely related to ductal plugging by mucous secretion. Patients with IPMN presenting with AP tend to be younger, and have greater odds of harboring malignancy compared to those without AP.<sup>83</sup> AP is more commonly observed with main-duct and mixed-type variants, but may also be seen in branch-duct IPMN.<sup>82</sup> In cases of branch-duct IPMN, it may be difficult to prove that the cyst is causing pancreatitis, as incidental IPMNs are common (Fig. 57.8).

### Autoimmune Pancreatitis

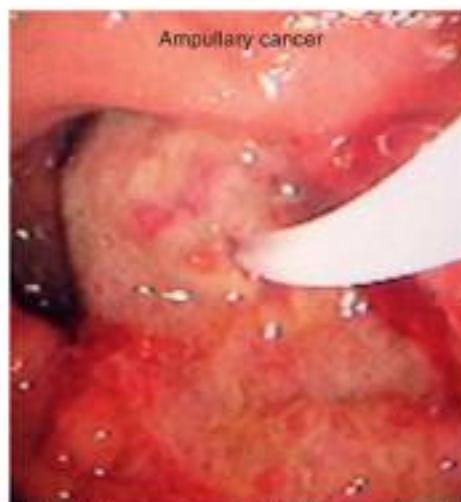

RAP is rather unusual in type 1 autoimmune pancreatitis (AIP), with obstructive jaundice, diabetes, and weight loss being more common presentations. When AP does occur, the likely explanation is pancreatic duct stricturing. A systematic review of nine studies published in 2008 (140 patients with AIP) reported the occurrence of recurrent pain or pancreatitis.<sup>84</sup> The overall rate of recurrent pain or pancreatitis was only 10.1%. RAP appears to be a more common presentation in the type 2 rather than type 1 histological variant. Type 2 AIP is more difficult to diagnose than type 1 because of the lack of a serological marker and the greater difficulty in obtaining diagnostic histology. An international survey reported RAP in 5% of type 1 AIP cases and 34% of type 2 AIP cases.<sup>85</sup> The largest US study of type 2 AIP ( $n = 43$ ) reported an even higher RAP rate of 58.1%.<sup>86</sup> In that series, type 2 AIP patients presenting with AP were younger (mean age 28 years vs. 47 years), less apt to have obstructive jaundice (16% vs. 50%), less apt to have a pancreatic mass (12% vs. 67%), and more likely to have inflammatory bowel disease (IBD) (60% vs. 22%). Though still a rare cause of AP, type 2 AIP should be considered in patients with IRAP who fit this clinical profile. Carefully selected patients (especially those with IBD) may warrant core biopsy or empiric corticosteroid trials (Fig. 57.9).

### Choledochocele

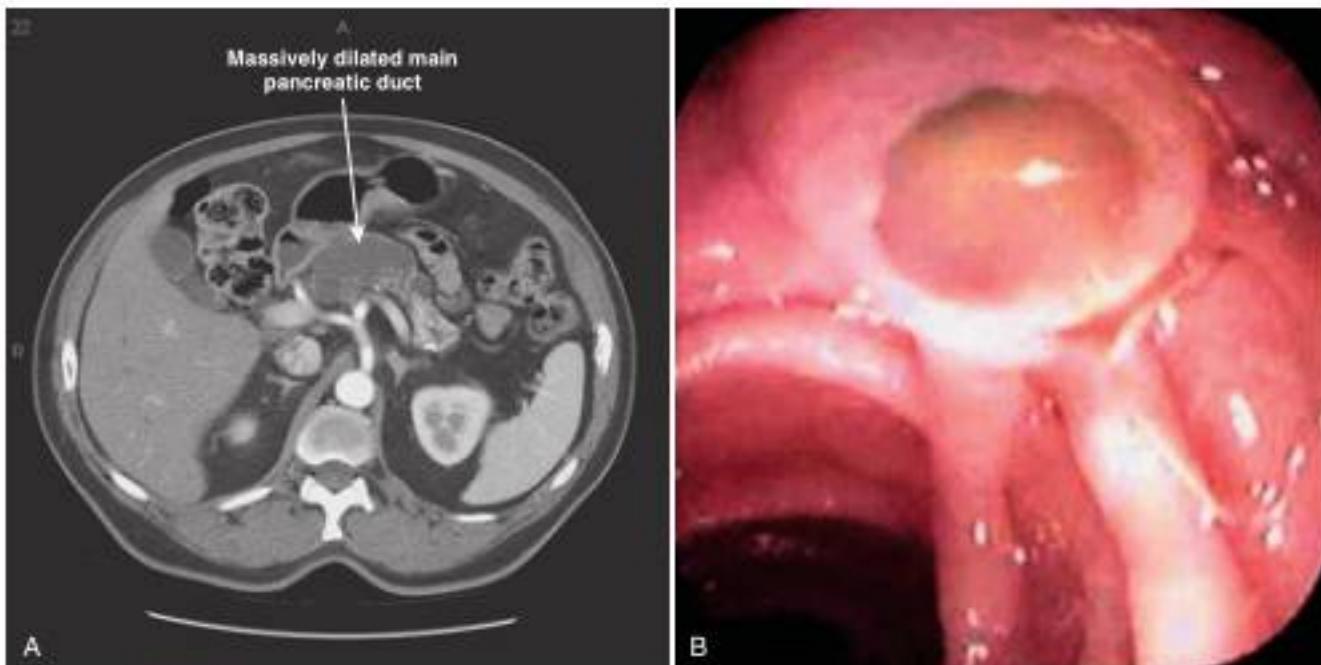

Choledochoceles are cystic dilations of the intraduodenal portion of the common bile duct (CBD). They are classified as type 3 choledochal cysts, the least common subtype.<sup>87</sup> RAP is a common clinical presentation among patients with symptomatic choledochoceles, and likely occurs as a result of biliary reflux into the pancreas.<sup>88</sup> The incidence of malignancy arising from choledochoceles is thought to be much lower than from other types of choledochal cysts, though rare cases have been reported.<sup>89</sup> EBS is the current standard of care for choledochoceles (Fig. 57.10).<sup>90</sup> EBS unroofs the cyst and separates the biliary and pancreatic duct drainage. Outcome studies are lacking; however, available evidence suggests that EBS usually resolves pancreatitis.<sup>91</sup>

## EVALUATION AND TREATMENT

The evaluation and treatment of RAP can be divided into three phases. In the primary evaluation, simple and obvious causes are sought through a careful history, laboratory testing, ultrasound with or without CT imaging, and careful review of the records from past attacks. In the secondary evaluation, advanced imaging is performed and laboratory testing is obtained to look for "occult" biliary, structural, and genetic causes. In the tertiary evaluation,

**FIG. 57.6** This 70-year-old patient presented with a single unexplained bout of acute pancreatitis. Subsequent endoscopic examination revealed ampullary cancer. (Image courtesy of Adam Slivka and Michael K. Sanders.)

**FIG 57.7** Example of a patient with recurrent acute pancreatitis (RAP) due to main duct intraductal papillary mucinous neoplasm (IPMN). **A**, CT scan shows hugely dilated pancreatic duct. **B**, Side-viewing endoscopy reveals gaping papilla with mucin extrusion. (Images courtesy of Adam Slivka and Michael K. Sanders.)

**FIG 57.8** This 55-year-old patient had three unexplained bouts of acute pancreatitis. On EUS examination, a cyst was found in the uncinate process that communicated with a side branch suggestive of a branch-type IPMN. *BOP*, bleeding on probing; *EUS*, endoscopic ultrasound; *IPMN*, intraductal papillary mucinous neoplasm; *IPMT*, intraductal papillary mucinous tumor; *PD*, pancreas divisum. (Courtesy of Dr. Kevin McGrath, University of Pittsburgh Medical Center.)

endoscopic testing and empiric endoscopic or surgical approaches may be offered to identify causes or prevent attacks. The primary evaluation is often performed during hospitalization for AP, whereas the secondary and tertiary evaluations are often performed in an outpatient setting. A number of multidisciplinary

"Pancreas Centers of Excellence" have been developed throughout the country to provide a comprehensive evaluation of patients with complex pancreatic disorders like IRAP.<sup>92</sup>

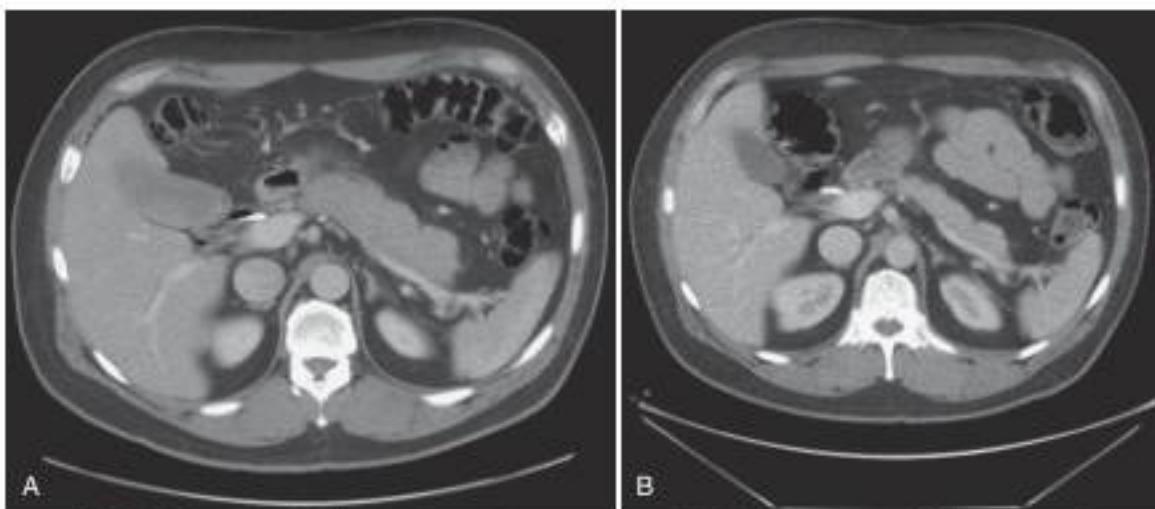

### Primary Evaluation

#### Careful History

The evaluation of RAP starts with taking a careful history to ascertain risk factors. Heavy daily or binge alcohol consumption may suggest alcohol as the cause. However, alcohol-related pancreatitis may be overdiagnosed in moderate regular drinkers.<sup>93</sup> Alcohol may not be the primary driver in these patients, and other potentially treatable causes should not be missed. Smoking has long been known to be a risk factor for CP and pancreatic cancer, but until recently has been ignored in AP. Several studies now implicate smoking as a cause or cofactor in AP as well.<sup>94</sup> Case reports from 2012 implicate cannabis as a trigger.<sup>95</sup> Preceding biliary colic may suggest gallstones. New prescription medications started within 1 to 2 months of the index episode or class I or II medications that are known to be associated with pancreatitis may suggest medication-induced pancreatitis.<sup>96</sup> The past medical history is also important to review. A personal history of high triglycerides or poorly controlled diabetes may suggest hypertriglyceridemia-mediated AP. A history of cholecystectomy suggests the possibility of SOD. A history of parathyroid issues or renal failure may suggest hypercalcemia-induced AP. A history of recurrent bronchitis or sinusitis, asthma, or male infertility may implicate a CFTR polymorphism. A family history of pancreatitis or cystic fibrosis (CF) may suggest genetic causes.

#### Basic Laboratory Evaluation

The primary laboratory evaluation of AP includes serum amylase, lipase, liver function tests, calcium, and triglyceride levels. Serum

**FIG 57.9** Example of CT findings in autoimmune pancreatitis. **A**, Pretreatment CT. The pancreatic body and tail are diffusely enlarged, with loss of normal contour. **B**, Posttreatment with corticosteroids. The previous pancreatic enlargement has resolved. (Images courtesy of Adam Slivka and Michael K. Sanders.)

alcohol levels may also be useful to detect surreptitious alcohol use. In recurrent episodes, it is helpful to obtain and review laboratory data from as many of the past attacks as possible. This serves to confirm whether significant lipase elevations are truly present to confirm the diagnosis of RAP. In addition, the presence of concomitant alkaline phosphatase and/or alanine transaminase (ALT) elevations may implicate gallstones, microlithiasis, or sphincter of Oddi dysfunction.<sup>57</sup> The admitting serum triglyceride level may help detect hypertriglyceridemia as a cause. A triglyceride level of more than 1000 mg/dL at the time of presentation strongly supports triglyceride-mediated AP; whereas a level of greater than 500 mg/dL should raise a high degree of suspicion.<sup>58</sup> If the triglyceride level was assessed later during the admission (after days of fasting), it may have decreased substantially. In these cases, repeating the serum triglyceride once the patient has returned to his or her usual diet may be warranted.

#### Imaging With TAUS and CT

The best initial imaging modality for detecting biliary causes of pancreatitis is TAUS. The results of all previous ultrasounds should be reviewed for findings that may implicate a biliary cause (e.g., sludge or stones in the gallbladder, biliary dilation) and suggest the need for cholecystectomy. CT scans have a limited role during an AP attack, and are performed primarily to detect local complications (necrosis, fluid collections, etc.). To detect necrosis, CT scans are optimally performed 3 days after symptom onset in patients who demonstrate signs of clinical severity.<sup>59</sup> If CT scans were performed during past attacks, it is useful to review them to ascertain the presence, severity, and location of inflammation. Most commonly, inflammation is diffused throughout the pancreas. However, inflammation that is focal in one area of the gland may help elucidate a structural cause. For example, inflammation confined to the tail of the pancreas may indicate a pancreatic duct tumor or stricture and indicate the need for further advanced imaging with MRCP or EUS.

#### Secondary Evaluation

In up to 90% of cases of AP, the primary evaluation reveals treatable causes (ongoing alcohol use, gallstones/sludge, liver

function tests or biliary duct abnormalities indicating SOD, high triglycerides, culprit medications, etc.).<sup>100</sup> The underlying factors can thus be eliminated or treated, and patients observed for recurrence. However, a subset of cases remains undiagnosed. These cases are properly termed IRAP, and may require "second-line" testing to look for autoimmune, genetic, and structural causes.

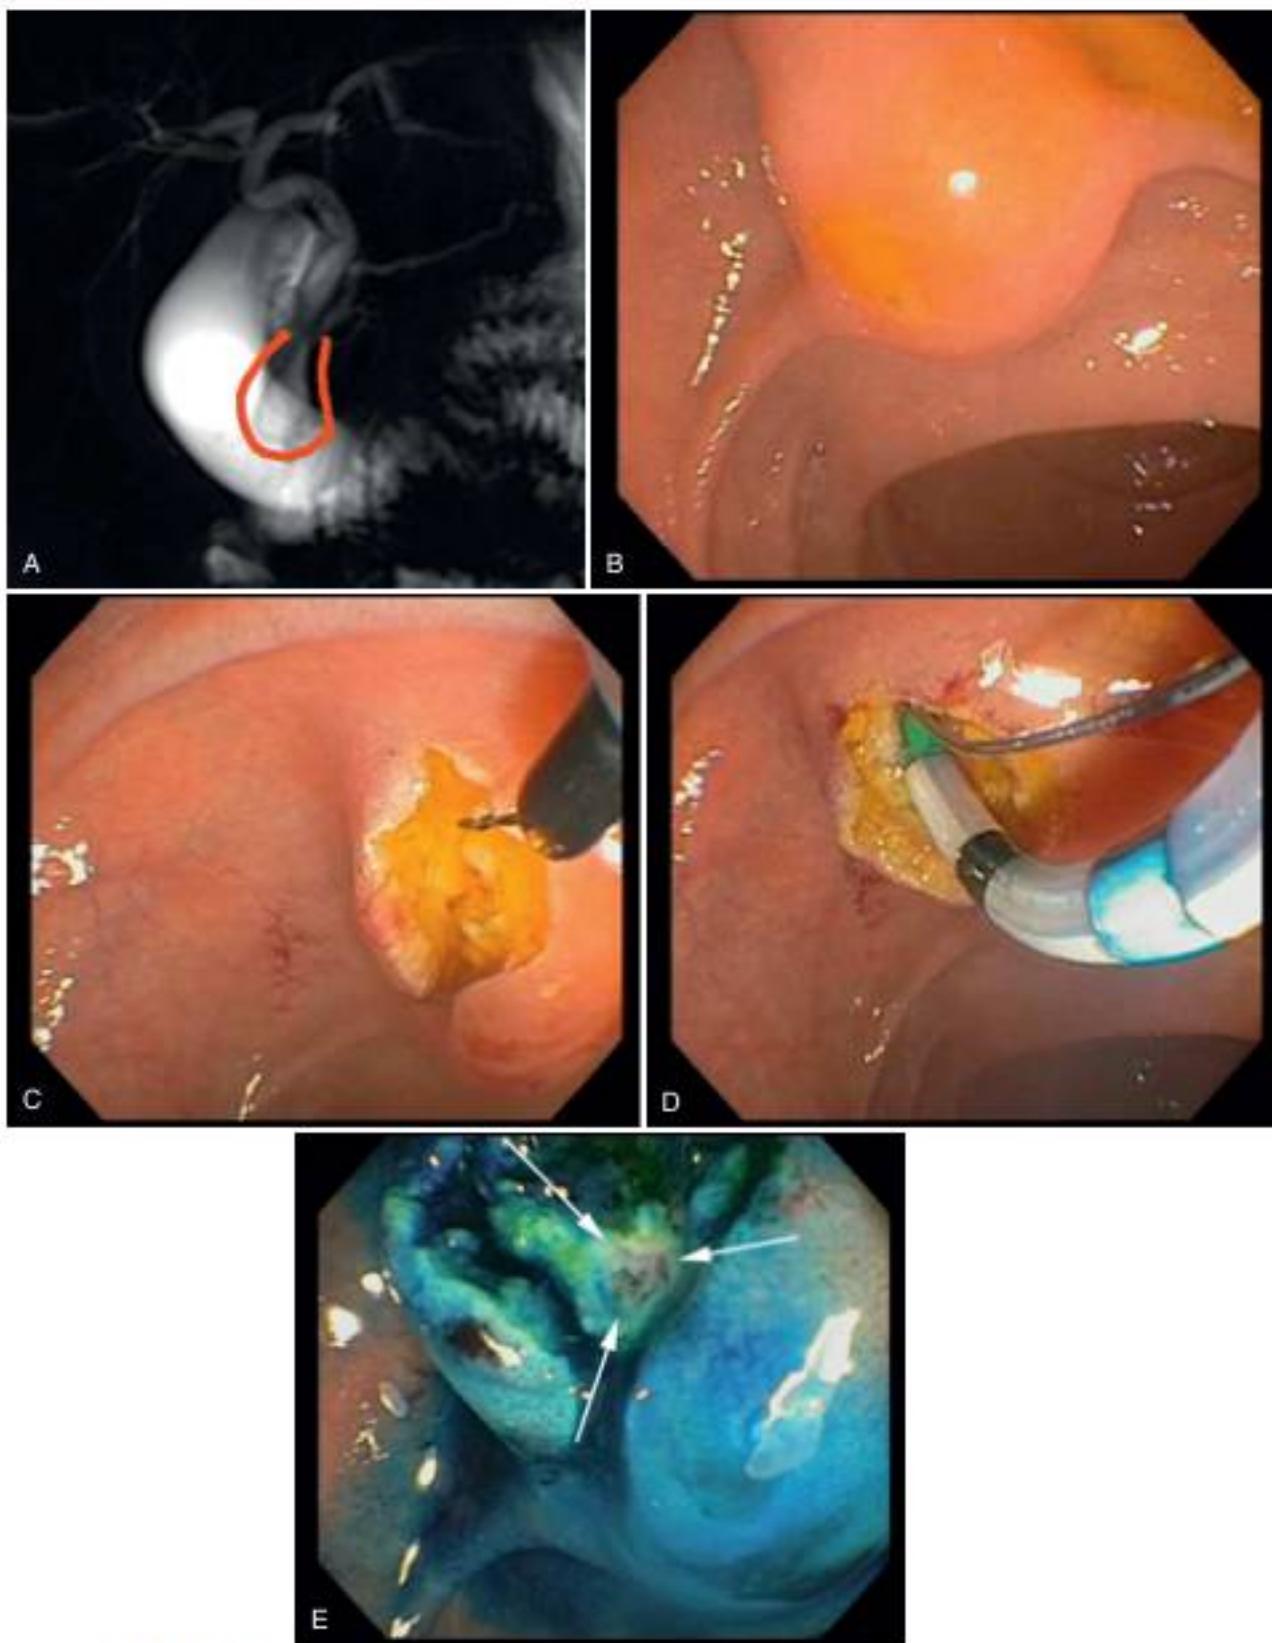

#### Autoimmune Testing

Serum total IgG and IgG4 levels may be obtained to "screen" for AIP. However, proper diagnosis of AIP is usually more complicated than simply ordering a lab test. Serum IgG4 exhibits only approximately 76% sensitivity for type 1 AIP,<sup>101</sup> and levels are normal in patients with type 2 AIP. Additionally, IgG4 may be mildly elevated in the absence of AIP. Several scoring systems have been devised to diagnose AIP, including the HISORt (histology, imaging, serology, other organ involvement and response to therapy) criteria, which include a combination of laboratory, imaging, and histological features.<sup>102</sup> It is useful to review pancreatic imaging with an abdominal radiologist to look for features of AIP, such as diffuse pancreatic enlargement, capsular enhancement, or diffuse/multiple pancreatic duct stricturing. If past imaging is not optimal or is confounded by significant acute inflammation, then obtaining a contrast-enhanced MRCP may be useful to check for ductal and parenchymal features of AIP.

#### Genetic Testing

Testing for genetic causes may be considered in IRAP. There has been an explosion in knowledge regarding the genetics of pancreatitis. Genetic testing for certain pancreatitis-associated mutations is now commercially available, and may be considered in selected patients with IRAP. Important genetic causes include mutations of the cationic trypsinogen (*PRSS1*), *CFTR*, *SPINK-1*, and chymotrypsin C (*CTRC*) genes.

Mutations in *PRSS1* cause hereditary pancreatitis (HP). HP is an autosomal dominant disease with high penetrance, so patients will often have multiple family members in consecutive generations affected with pancreatitis. These patients classically

**FIG 57.10** Example of choledochocoele diagnosis and endoscopic treatment. An 8-year-old boy presented with idiopathic acute recurrent pancreatitis (IARP). **A**, Secretin-enhanced magnetic resonance cholangiopancreatography (MRCP) shows a large saccular choledochocoele with separate entry of common bile duct and pancreatic duct (outlined in red). **B**, Endoscopic view showing prominent choledochocoele. Endoscopic therapy consisted of **C**, needle-knife unroofing of the lumen and **D**, biliary cannulation and extension of the biliary sphincterotomy. **E**, Methylene blue spray after secretin injection showing exposed pancreatic sphincter (arrows) without injury.

develop RAP in childhood and progress to CP in the teen years, and have a 40% lifetime risk of pancreatic cancer.<sup>110</sup> CF is a genetic disorder caused by impaired function of the CFTR protein that regulates chloride secretion in the pancreatic duct cells. CF is a heterogeneous disorder, likely because there are over 1200 known mutations that result in a range of problems with CFTR production, transport, and function. When the genetic defects are severe, pancreatic secretions are inspissated and plug the ductules, resulting in rapid and severe fatty replacement and atrophy of the pancreas. Children with severe mutations are often recognized promptly through newborn screening, and their pancreatic, pulmonary, and other problems are quickly and aggressively managed in CF centers. Adults may harbor milder or single allele CFTR defects that do not produce pancreatic insufficiency, but are recognized later in life with atypical manifestations including bronchitis, asthma, and RAP. Mutations in *SPINK-1* are unlikely to solely cause RAP, but may promote the development of CP, and sometimes present as a cofactor with other genetic or environmental causes.<sup>104,105</sup>

Genetic testing may be considered in patients with a family history of pancreatitis and in young patients with IRAP. This testing should be ordered with caution and should be accompanied by appropriate pretest counseling. There are several conceivable benefits of genetic testing, including obtaining insight into the cause and providing further motivation to avoid alcohol use and smoking. Although opponents counter that the results do not meaningfully affect management, this is not always the case. For example, the finding of a *PRSS1* mutation may prompt yearly imaging tests because of its associated risk of pancreatic cancer.<sup>106</sup> Finding a pancreatitis-associated mutation may also prevent empiric interventions like ERCP with sphincterotomy and cholecystectomy. Genetic mutations in patients with frequent RAP episodes may even prompt consideration of total pancreatectomy.<sup>107</sup> A major downside of testing is its high cost, and sometimes the lack of insurance coverage for testing.

### Second-Line Imaging Tests

Some structural causes of RAP may be missed on ultrasound and CT performed at the time of the attack(s), and require more advanced imaging for diagnosis. Occult pancreatic cancer is a major concern, especially in those over age 40 who developed IRAP in the past several months. Pancreatic inflammation or necrosis may mask small cancers on initial imaging. Sometimes, only slight pancreatic duct dilation indicating downstream obstruction is present. In such patients, it is wise to repeat a contrast-enhanced pancreatic protocol CT or magnetic resonance imaging (MRI), or to consider EUS. The findings of these advanced tests often help guide subsequent treatment (see Fig. 57.7). Such testing is best performed 4 to 6 weeks after discharge, once inflammation has improved.

Additional obstructive causes include PD, pancreatic duct stricture, IPMN, ampullary neoplasm, and duodenal pathology. In years past, ERCP was frequently employed as a second-line evaluation in patients with RAP. Typically, ERCP would include a cholangiogram to look for biliary stones and a diagnostic pancreatogram to check for ductal pathology. Though ERCP has significant therapeutic potential in RAP, it has since fallen out of favor as a purely diagnostic test because of the advent of MRCP and EUS. Both provide excellent detail of the pancreatic duct and parenchyma, and have been used extensively in the

workup of patients with IRAP. However, each has its own advantages and limitations.

### Magnetic Resonance Cholangiopancreatography

MRCP provides complete imaging of the pancreatic parenchyma and duct. MRCP protocols include heavily T2 (fluid)-weighted imaging to generate an "ERCP-like" image of the pancreatic duct. In young patients with IRAP, MRCP is an invaluable tool for screening for PD, and helps stratify its significance based on the presence or absence of dorsal duct dilation and Santorinicele. The addition of secretin administration improves ductal imaging resolution and has higher diagnostic accuracy for PD than standard MRCP (pooled sensitivity 86%; pooled specificity 97%).<sup>108,109</sup> The assessment of duct compliance and drainage following secretin administration has been used as a diagnostic test for outflow obstruction from SOD and PD and as a decision point for subsequent ERCP therapy.<sup>109</sup> In addition, MRCP detects pancreatic tumors, pancreatic duct strictures, and branch-type and main-duct IPMN. The main limitation of MRCP in the workup for IRAP is the lack of ampullary and luminal visualization.

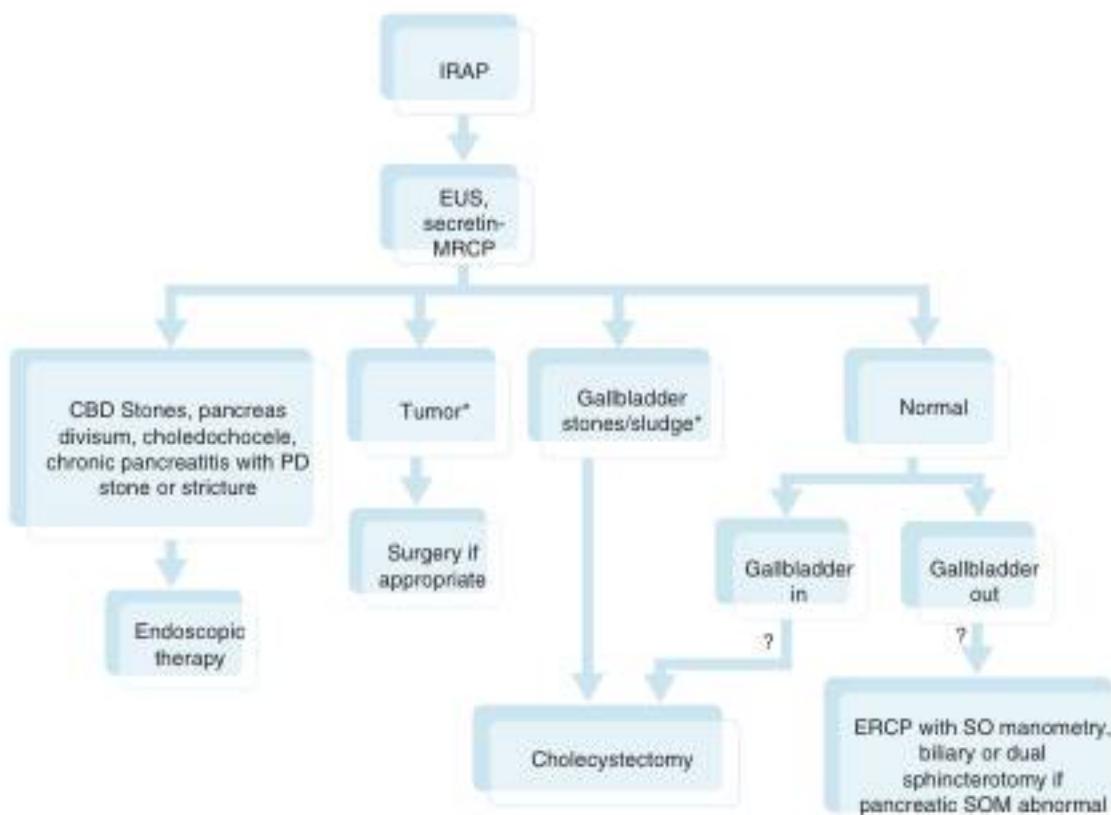

Recent evidence (2015) suggests that secretin MRCP may be quite accurate in detection of underlying CP, which may always be present in patients with RAP.<sup>110</sup> In fact, secretin MRCP may be more accurate than EUS in detecting histologically less advanced forms of CP.<sup>111</sup>

### Endoscopic Ultrasound

EUS is also frequently used in the secondary evaluation of IRAP and may help guide subsequent evaluation and therapy (Fig. 57.11). It is similar to MRCP in that it provides exquisite imaging of the pancreas. Its advantages over MRCP include luminal visualization, greater detection of biliary sludge and stones, tissue and fluid acquisition, and the ability to detect parenchymal changes indicative of CP. EUS may also be superior to CT for detecting small masses.<sup>112</sup> Some observational studies have compared the yield of EUS and MRCP in patients with IRAP.<sup>113,114</sup> One included 38 patients with IRAP who underwent both EUS and MRCP. A higher yield was observed for EUS than for MRCP (29% vs. 10.5%). MRCP was superior for detecting ductal abnormalities like PD, whereas EUS was better for biliary causes. The two tests had a combined 50% yield, suggesting that they may be complementary.

Linear EUS is most commonly used for pancreaticobiliary examinations, but radial EUS can also suffice, based on physician preference. It is usually best to delay EUS until 3 or 4 weeks after recovery from the last AP episode to maximize the diagnostic yield, as views of the pancreas can be obscured by pancreatic inflammation and peripancreatic fluid. When performing EUS to evaluate RAP, the endoscopist should have the following 7-point "checklist" in mind:

1. Is there duodenal or ampullary pathology? Generally, a screening endoscopy is advisable to look for duodenal inflammation or neoplastic pathology. The ampulla should be examined and photodocumented, with careful inspection for adenomas, masses, mucin extrusion, and diverticulae. Satisfactory ampullary views can often be obtained using the oblique view of the echoendoscope; however, a side-viewing duodenoscope should be passed if necessary.
2. Are biliary stones or sludge present? The bile duct should be carefully traced from the hilum to the ampulla, looking for layering echogenic sludge or echogenic rounded structures

**FIG 57.11** Treatment algorithm for unexplained recurrent pancreatitis. \*Indicates conditions for which EUS appears to be superior to MRCP in terms of diagnosis. CBD, common bile duct; ERCP, endoscopic retrograde pancreategraphy; EUS, endoscopic ultrasound; IRAP, idiopathic acute recurrent pancreatitis; MRCP, magnetic resonance cholangiopancreatography; PD, pancreas divisum; SO, sphincter of Oddi; SOM, sphincter of Oddi manometry.

with shadowing indicating stones. Striving to achieve complete ampullary imaging from both the duodenal bulb (long position) and the second portion (short position) decreases the chance of missing small stones. In patients with their gallbladder *in situ*, the gallbladder fundus, body, and neck should be carefully scrutinized for stones and layering sludge.

- Are there pancreatic tumors or strictures affecting the pancreatic duct? The pancreas should be viewed in its entirety, looking for masses or focal hypoechoic regions that indicate possible occult cancer. Fine-needle aspiration (FNA) should be performed of any suspicious lesions. The duct should be carefully traced into the stomach and duodenum to detect obstructing tumors, strictures, or stones, which may result in proximal duct dilation.
- Is PD present? EUS can have similar or even superior accuracy as MRCP for diagnosing PD,<sup>115</sup> but is more operator-dependent. Various EUS findings have been reported as useful in diagnosing pancreas divisum, including a crossed appearance of the bile and pancreatic duct, absence of a "stack sign" (i.e., appearance of portal vein, pancreatic duct, and bile duct in single image), and separate insertion of bile and pancreatic ducts into the duodenal wall. In our experience, the best approach is to trace the pancreatic duct from the point of its insertion with the bile duct at the ampulla into the dorsal pancreas (Video 57.2). A sensitivity of 95% and specificity

of 97% have been reported using this approach; however, this study excluded 22% of patients in whom the ductal anatomy could not be adequately assessed.<sup>116</sup> We find EUS to be most useful to rule out PD when the duct can be successfully traced. The inability to trace the duct from ampulla to dorsal pancreas may suggest pancreas divisum, but might also indicate technical limitations preventing continuous visualization of the duct. In those with pancreas divisum, the Santorini duct can sometimes be traced to the minor papilla, and inspection can be made for a Santorinicele indicating functional outflow obstruction.

- Are the pancreatic and/or bile ducts dilated? It is good practice to measure the CBD and pancreatic ducts to assess for dilation indicating ampillary outflow obstruction. Most experts agree a normal CBD diameter is 6 mm or less in patients with a gallbladder and 9 mm or less in those who are postcholecystectomy. The normal diameter of the pancreatic duct is 3 mm in the head, 2 mm in the body, and 1 mm in the tail.<sup>117</sup> Dilation of the ducts may help support a diagnosis of SO dysfunction, ampillary stenosis, or impaired drainage from PD.
- Is CP present? The EUS diagnosis of CP is discussed in detail elsewhere in the text (see Chapter 59). The presence of CP helps to stage RAP and explains abdominal pain that persists between attacks. The finding of ductal obstruction related to CP (stones and strictures) may also indicate an obstructive

cause of ongoing RAP that could benefit from endoscopic or surgical management. CP findings are often observed in RAP, with prevalence in early series ranging from 0% to 65%.<sup>23</sup> Anecdotally, we find that many patients with IRAP ultimately found to possess genetic mutations have significant CP changes on EUS.

7. Is there evidence of AIP? The EUS appearance of AIP is typically a diffusely enlarged and hypoechoic-appearing gland, sometimes with interspersed hyperechoic lines or foci (Video 57.3).<sup>118</sup> Pancreatic duct dilation is typically absent. Focal hypoechoic masses may also be observed. In such cases, FNA is indicated to help rule out malignancy.<sup>119</sup> In patients with characteristic EUS features of AIP, FNA might also be considered to make a "tissue diagnosis" of AIP, but obtaining a satisfactory tissue sample that is able to confirm histology may be challenging. Cytological specimens obtained using 22- and 19-gauge needles have shown mixed results for obtaining lymphocytes and plasma cells suitable for IgG4 staining.<sup>120,121</sup> It is unusual to detect the more confirmatory finding of obliterative phlebitis using typical EUS needles, suggesting the need for needles that would provide larger tissue specimens with preserved tissue architecture. The use of the Tru-cut biopsy needle has fallen out of favor due to technical difficulties and complications, and is no longer commercially available. However newer, more flexible and easy-to-use fine-needle biopsy (FNB) needles are emerging, which may be able to obtain tissue "cores," facilitating the endoscopic diagnosis of AIP.

### Tertiary Evaluation

After these primary and secondary evaluations, endoscopic and surgical approaches may be carefully considered to diagnose or provide targeted or empiric treatment. ERCP is the primary tool in the tertiary evaluation of RAP. As detailed previously, ERCP helps to diagnose and treat SOD, PD, ampillary pathology, and pancreatic duct strictures. Surgical approaches that are selectively employed in the tertiary evaluation of RAP include cholecystectomy; partial pancreatectomy in patients with masses, IPMNs, or strictures; major and minor sphincteroplasty; and total pancreatectomy with autologous islet cell transplant (TP/IAT) for those with genetic or "true" IRAP. In a case series of 49 patients with IRAP without evidence of CP on structural and/or function testing, improvement in narcotic utilization and quality of life was observed after TP/IAT.<sup>9</sup> In addition, 45% of patients were insulin-independent after 1 year of follow-up, with a mean hemoglobin A1C of 6.0%. Further outcome studies are needed to determine if this intervention also decreases hospitalization and health care utilization by eliminating AP attacks.

## INTRODUCTION

Pancreatic fluid collections (PFCs) and leaks develop due to main or secondary pancreatic ductal disruption caused by acute or chronic pancreatitis, trauma, or pancreatic surgery. PFCs include acute fluid collections, acute necrotic collections, pseudocysts, and walled-off necrosis.<sup>1</sup> Most nonnecrotic PFCs resolve spontaneously without need for drainage. Fluid collections that have become infected, or those that cause persistent symptoms, warrant drainage. Drainage of PFCs has historically been performed by open surgical approaches, but less invasive interventions have replaced open surgery over time. Whereas appropriate management of PFCs entails a multidisciplinary approach involving interventional endoscopy, interventional radiology, and minimally invasive surgery, endoscopic therapy of PFCs and pancreatic leaks has become a predominant initial therapeutic modality. Endoscopic transmural drainage of symptomatic pseudocysts has replaced surgical intervention as first-line therapy due to similar efficacy, less morbidity, shorter recovery, and greater cost-efficacy.<sup>2–4</sup>

## PANCREATIC FLUID COLLECTION CLASSIFICATION AND CHARACTERIZATION

Appropriate classification of PFCs helps guide management. The revised Atlanta criteria categorize PFCs as either acute or chronic based upon their presence less than or more than 4 weeks

following an episode of pancreatitis. Categorization further depends on the presence or absence of necrosis.<sup>1</sup> Acute collections without significant necrosis are termed *acute fluid collections*. These may occur in up to 40% of cases of acute pancreatitis. Most of these acute collections remain sterile, are asymptomatic, and spontaneously resolve without intervention. Approximately 30% to 50% of acute fluid collections, however, may persist.<sup>2,3</sup> Acute fluid collections that persist longer than 4 weeks may evolve into pancreatic pseudocysts, which have a well-defined wall comprised of fibrous or granulation tissue containing no to minimal necrotic material.

Acute collections arising from necrotizing pancreatitis contain necrotic tissue and are termed *acute necrotic collections (ANC)*. Mature, encapsulated collections of pancreatic necrosis may sometimes develop from acute necrotic collections, typically after 4 or more weeks following onset of necrotizing pancreatitis. These collections, called *walled-off necrosis (WON)*, are comprised of a wall of fibrous or granulation tissue separating internal necrotic material from normal pancreatic parenchyma. WON has a well-defined enhancing wall of reactive tissue present on imaging. Approximately 15% of patients with acute pancreatitis will develop pancreatic necrosis, 33% of whom will develop infected necrosis.<sup>5</sup> The rate at which ANCs develop into WON is not clear.

In general, intervention on PFCs is unnecessary because they typically remain sterile and regress spontaneously. Due to the absence of a mature, noncompliant wall, acute fluid collections

**Abstract**

Pancreatic fluid collections (PFCs) and leaks develop due to main or secondary pancreatic ductal disruption caused by acute or chronic pancreatitis, trauma, or pancreatic surgery. PFCs include acute fluid collections, acute necrotic collections, pseudocysts, and walled-off necrosis. Most nonnecrotic PFCs resolve spontaneously without need for drainage. Fluid collections that have become infected, or those that cause persistent symptoms, warrant drainage. Drainage of PFCs has historically been performed by open surgical approaches, but less invasive interventions have displaced open surgery over time. Whereas appropriate management of PFCs entails a multidisciplinary approach involving interventional endoscopy, interventional radiology, and minimally invasive surgery, endoscopic therapy of PFCs and pancreatic leaks has become a predominant initial therapeutic modality.

rarely cause mass-occupying effects such as gastric outlet or biliary obstruction.<sup>5</sup> Conservative observation is thus pursued, monitoring for symptoms or signs of infection. In the absence of infection, most ANC s are also managed conservatively with observation. If sepsis with suspicion of secondary infection of acute fluid and necrotic collections occurs, however, intervention is warranted. Whereas percutaneous drainage through small-diameter catheters may facilitate clinical improvement in some patients, persistent sepsis necessitates more aggressive débridement using either percutaneous necrosectomy or video-assisted retroperitoneal débridement (VARD).<sup>5,6,9</sup>

Once maturation of PFCs has occurred, indications for drainage include the presence of infection, gastric outlet or biliary obstruction, radiographic or clinical manifestations of vascular compression, or persistent symptoms such as anorexia, early satiety, weight loss, and refractory pain. In patients with mild symptoms or those with early pseudocysts or WON, medical supportive therapy with observation may still be appropriate to allow time for pseudocyst/WON regression. When indication for drainage is present, the maturity of the collection and differentiation of fluid versus necrotic collections helps to determine the most appropriate approach. Necrotic collections may require more intensive or multistep drainage techniques. Furthermore, the proportion of a WON that is comprised of solid debris may determine the outcome of standard endoscopic drainage, the number of therapeutic sessions required, and the need for direct endoscopic necrosectomy.<sup>10</sup> Significant complications may occur if WON is inappropriately managed as a pseudocyst.<sup>11</sup>

Differentiation of pseudocysts and WON may be performed by noninvasive cross-sectional imaging or by endoscopic ultrasonography (EUS). Although imaging for assessment of organized fluid collections is not standardized, contrast-enhanced computed tomography (CT) is most commonly performed for diagnosis and interventional planning. The sensitivity for detection of solid debris has been reported to be as low as 17% to 25%.<sup>12,13</sup> A retrospective review of CT imaging performed in patients with PFCs showed that a radiographic scoring system could improve accuracy in differentiating WON from pseudocysts up to approximately 80%.<sup>14</sup> Magnetic resonance imaging (MRI) is more accurate in prediction of solid debris within pancreatic fluid collections, with sensitivity up to 100% reported.<sup>12,15</sup> MRI has higher sensitivity for detection of pancreatic duct disruption as well, which may predict the likelihood of spontaneous PFC resolution, as the presence of pancreatic duct disruption is associated with the development of chronic, mature collections.<sup>16</sup> EUS may also be used to detect the presence of pancreatic necrosis and has been shown to be the most accurate imaging modality for characterizing pancreatic fluid collections (Fig. 58.1).<sup>17</sup> Transabdominal ultrasound may also be beneficial. In a prospective comparison of EUS, MRI, or transabdominal ultrasound, transabdominal ultrasound had a sensitivity of 92% (vs. 100% for EUS or MRI) for detection of WON, though it was less sensitive in detection of venous collaterals around the collection compared to EUS.<sup>18</sup>

## PSEUDOCYST ACCESS

### Endoscopy-Guided (Without EUS)

Endoscopic drainage without EUS guidance may be performed when a bulge into the gastrointestinal (GI) lumen is present from extrinsic compression by the pseudocyst (Fig. 58.2). In this instance, use of a duodenoscope permits good visualization of

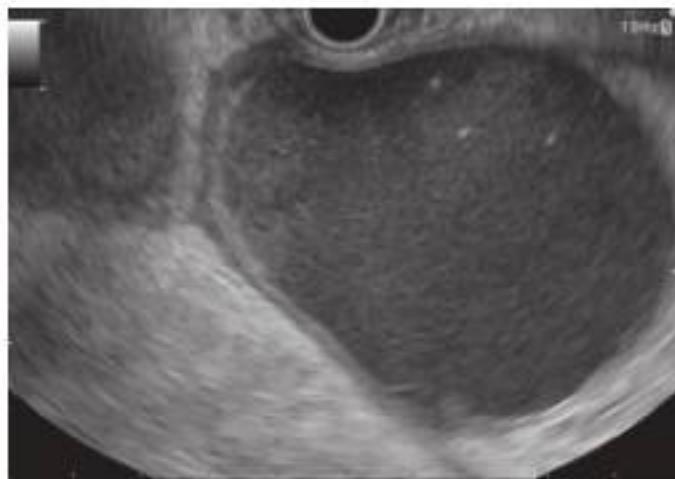

**FIG 58.1** Endosonographic image of mature walled-off necrosis. (From Siddiqui AA, Adler DG, Nieto J, et al: EUS-guided drainage of peripancreatic fluid collections and necrosis by using a novel lumen-apposing stent: a large retrospective, multicenter US experience [with videos]. *Gastrointest Endosc* 83[4]:699–707, 2016.)

**FIG 58.2** Luminal bulge from an extrinsically compressing pancreatic fluid collection (PFC).

the posterior gastric wall and the posteromedial duodenal wall. A 4.2-mm working channel will enable passage of 10-Fr stents. As described by Ballard and Coté (2012), optimal alignment ensures entrance of the pseudocyst at an area of maximal visible bulging of the gastric or duodenal wall.<sup>19</sup> The duodenoscope should be in a stable position with the ideal angle of needle puncture entry at 90 degrees to minimize the length of the GI wall that will be traversed. A cystotome or needle-knife catheter may be used to puncture across the gastric or duodenal wall and establish access into the pseudocyst. Electrocautery can be used to facilitate puncture across the wall and does not seem to affect bleeding complications.<sup>19,20</sup> Aspiration of a sample of pseudocyst contents and injection of contrast into the pseudocyst under fluoroscopy may be performed to confirm that access has been

**FIG 58.3** Endosonographic image of a mature pseudocyst.

achieved. A stiff guidewire can then be passed into the pseudocyst and coiled in the cyst under fluoroscopic visualization. The pseudocyst puncture tract is then dilated with a balloon and/or bougie catheter. Plastic or metal stents can then be deployed across the dilated cystgastrostomy or cystduodenostomy tract for drainage.

#### EUS-Guided

When EUS-guided pseudocyst drainage is performed, careful characterization of the pseudocyst is important. EUS imaging enables direct assessment of the distance separating the pseudocyst and GI tract wall, confirmation of a mature pseudocyst wall, and exclusion of interceding vessels (Fig. 58.3). As a general rule, the distance separating the pseudocyst and GI tract wall should not exceed 10 mm. Endosonographic visualization allows assessment for the presence of internal debris and/or necrosis that would warrant more aggressive drainage techniques.<sup>21</sup> Following endosonographic assessment, the next step in EUS-guided drainage involves puncture into the pseudocyst with a 19-gauge fine-needle aspiration (FNA) needle passed through a therapeutic echoendoscope. A 0.025- or 0.035-inch guidewire is passed through the needle and coiled within the pseudocyst. The needle is then exchanged over the guidewire for either a bougie catheter or dilating balloon, and dilation is performed to a size appropriate for stent delivery. Therapeutic linear echoendoscopes, which have a larger working channel (3.7 to 3.8 mm), enable pseudocyst puncture with a 10-Fr cystotome. The cystotome has an inner needle knife catheter used for initial cyst puncture and an outer 10-Fr sheath with a diathermy ring. After initial puncture, replacement of the inner needle knife catheter with a guidewire is followed by advancement of the 10-Fr outer sheath into the cyst using electrocautery, expanding the puncture site. Multiple guidewires may then be placed through the 10-Fr sheath. Plastic or metal stents may be placed across the tract for pseudocyst drainage.

#### EUS-Guided Versus Endoscopy-Guided

Though direct endoscopic pseudocyst access is possible when the fluid collection causes obvious extrinsic compression of the GI lumen, EUS-guided access has been shown to have higher success rates for pseudocyst drainage with similar adverse events.<sup>19</sup> A small, randomized, prospective trial comparing EUS-guided

versus endoscopy-guided transmural access showed higher technical success for EUS-guided access (94% vs. 72%). Furthermore, EUS-guided access was as successful as salvage crossover therapy in all cases where endoscopy-guided access failed because the pseudocysts were nonbulging. No significant difference existed in short-term clinical success rates (defined by cyst resolution) or long-term clinical outcomes.<sup>21</sup> Of note, the technical success of both approaches is similar except in cases when a luminal bulge is absent. Thus, the advantage of EUS-guided drainage seems to rest upon enhanced access specifically in cases of nonbulging pseudocysts. A meta-analysis performed by Pannomonti et al (2012) examined two randomized-controlled trials and two prospective comparisons involving 229 patients.<sup>22</sup> This review confirmed that EUS-guided drainage had significantly higher technical success rates (relative risk [RR] 12.38, 95% confidence interval [CI] 1.39–110.22) and was a successful salvage therapeutic method in all patients with failed endoscopy-guided drainage due to lack of a luminal bulge. In those with technical success, short-term and long-term clinical success rates (defined as symptomatic relief and radiologic resolution of pseudocysts) were comparable (RR 1.03, 95% CI 0.95–1.11 and RR 0.98, 95% CI 0.76–1.25, respectively). Complication rates were also similar (RR 0.98, 95% CI 0.52–1.86), with the most common complications being bleeding and infection.

## CYST DRAINAGE

#### Plastic Stents

Multiple studies have reported the use of single and multiple plastic stents ranging from 7- to 10-Fr size for drainage. No randomized controlled trial has compared the benefits of using a single stent versus multiple plastic stents. Retrospective studies have shown that insertion of even a single stent provides high rates of clinical resolution. Secondary infection does seem to be potentially more frequent in cases of single versus multiple-stent drainage, however.<sup>23</sup>

When using a plastic stent, a double pigtail design is preferentially used to reduce the risk of stent migration. Double pigtail stents also decrease delayed bleeding, as straight stents may erode into the pseudocyst wall with resultant hemorrhage.<sup>24</sup> Stents used for cyst drainage are 3 or 4 cm long. Multiple plastic stents are typically placed to enhance drainage by increasing the cumulative diameter of stent lumens, creating channel redundancy in the event one plastic stent occludes, and promoting drainage through the canals between stents. The placement of two stents is best accomplished by initially placing two guide wires. A 10-Fr catheter sheath (e.g., 10-Fr stent pusher tube, cytology brush sheath, multiport ramp catheter) is a helpful tool to accomplish this because the lumen is large enough to pass two 0.035-inch guidewires. Using a 10-Fr cystotome, two guidewires can be immediately inserted after entry into the cyst.

Of historic interest is the NAVIX device (NAVIX; Xlumena, Mountain View, CA), which enables exchange-free pseudocyst access, tract dilation, and placement of two guidewires with a single device.<sup>25</sup> This device helped streamline the otherwise laborious and time-consuming process of placing multiple plastic stents, and decreased opportunity for technical failure during multiple exchanges.

#### Fully Covered Self-Expanding Metal Stents (FCSEMS)

Compared to plastic stents, the appeal of FCSEMS is their larger lumens with resultant quicker pseudocyst drainage and decreased

risk of stent occlusion. Procedure time may also be decreased because only a single stent needs deployment. Published studies, however, have not consistently shown an advantage in using FCSEMS. A retrospective comparison has shown improved rates of complete pseudocyst resolution at 1 year follow-up after endoscopic drainage using FCSEMS versus double pigtail plastic stents (98% vs. 89%,  $p = 0.01$ ). Plastic stent usage also resulted in higher complication rates (odds ratio [OR] 2.9 after multivariate analysis).<sup>21</sup> Contrasting results, however, were obtained in a 2014 prospective randomized trial by Lee et al comparing the use of multiple plastic stents versus FCSEMS for PFC drainage. One caveat in this discussion of pseudocyst intervention is that results of this study were not necessarily stratified by fluid collection type. Drainage of WON will be discussed specifically later in this chapter.<sup>22</sup> Technical success was achieved for all cases regardless of stent type. Clinical success was achieved in 20 of 23 cases with FCSEMS and 20 of 22 cases with plastic stents ( $p = 0.97$ ). No statistical difference was present in either adverse event rates or rate of recurrence during follow-up. One point of benefit from use of FCSEMS was shown, however, with achievement of a shorter median procedure time compared to use of plastic stents.

### Lumen-Aposing Metal Stents (LAMS)

Whether plastic or metal, tubular stents have several limitations when applied to transluminal drainage. First, they do not impart lumen-to-lumen anchorage. This may result in leakage of contents if there is physical separation of the lumens. Second, stent migration may occur due to the absence of a stricture to hold it in place. Third, the length of tubular stents exceeds the anatomical requirement of a shorter transluminal anastomosis. The excess exposed stent ends may cause tissue trauma, resulting in bleeding or perforation. Placement of an internal plastic stent within a FCSEMS has been reported in an attempt to reduce migration and mitigate against erosion of the metal stent edge into the collapsed pseudocyst wall, but we have not found this method to prevent migration or tissue injury. Finally, the length of tubular stents predisposes to stent dysfunction. The longer the stent length, the more prone the stent is to clogging from food residue or cyst debris.<sup>23</sup>

A lumen-aposing metal stent (LAMS) designed for transluminal drainage was developed and first reported by Binmoeller in 2011.<sup>5</sup> The AXIOS stent (Boston Scientific, Marlborough, MA) is a nitinol braided FCSEMS with bilateral double walled flanges existing in a dumbbell configuration perpendicular to the lumen for the purpose of anastomosis creation (Fig. 58.4). Fully expanded, the flanges are either 20 mm or 24 mm in diameter, approximately twice that of the stent's mid-lumen diameter of either 10 mm or 15 mm. The bilateral flanges are designed to reduce stent migration and approximate structures in order to reduce rates of perforation and leak. Furthermore, the flanges are short in length and therefore have limited extension into the GI tract lumen and fluid collection cavity, potentially reducing the risk of stent erosion.

The AXIOS stent is deployed through a 10.8-Fr catheter delivery system. The delivery system is attached to the echoendoscope working channel port via a Luer-lock, similar to a standard FNA needle. The catheter is advanced into the fluid collection by manipulation of the distal catheter control hub and then locked into position. Retraction to a halfway point of the proximal stent deployment hub results in unsheathing of the distal stent flange within the collection cavity. The catheter

**FIG 58.4** Fully covered, biflanged, lumen-apposing metal stent (AXIOS, Boston Scientific). (Courtesy Boston Scientific, Marlborough, MA. From Siddiqui AA, Adler DG, Nieto J, et al: EUS-guided drainage of peripancreatic fluid collections and necrosis by using a novel lumen-apposing stent: a large retrospective, multicenter US experience [with videos]. *Gastrointest Endosc* 83(4):699–707, 2016.)

control hub is then unlocked and retracted until the point at which the distal stent flange starts to compress against the wall of the collection cavity. After relocking the catheter control hub, the stent deployment hub is then completely retracted and the proximal stent flange is unsheathed. To ensure that proximal flange deployment will occur within the GI lumen, catheter retraction until direct endoscopic visualization of the 2 to 3 mm of the black catheter shaft marker is advised prior to proximal flange deployment. Pulling back the echoendoscope to allow direct endoscopic visualization of this marker, however, risks excessive traction on the AXIOS stent, which may result in migration of the distal flange back into the GI lumen. To avoid excessive traction, the proximal flange may also be deployed inside the echoendoscope.<sup>24</sup> The unsheathed proximal flange may then be released from the echoendoscope by advancement of the catheter hub, again while pulling back the echoendoscope. Deployment may be performed under endoscopic, endosonographic, and fluoroscopic visualization to help ensure proper placement. With experience, however, deployment completely under endosonographic visualization is possible, and may be preferred as a way to avoid improper deployment due to excess traction on the deployment catheter (Figs. 58.5 and 58.6).

An electrocautery-enhanced delivery system ("hot AXIOS") enables placement of the AXIOS stent in a single step by obviating the need for initial 19-gauge needle puncture of the collection cavity, guidewire insertion, and puncture tract dilation. The system has an electrocautery component comprised of two radially distributed diathermic wires that converge around the guidewire lumen at the catheter tip, allowing for direct cavity penetration and transmural advancement of the stent delivery catheter without tract dilation (Fig. 58.7). Thus, delivery can be performed in an exchange-free manner, which may make PFC drainage faster and safer.

A pilot study in 2012 using the AXIOS LAMS reported drainage of 15 symptomatic pseudocysts with achievement of a 100% therapeutic success rate and 0% recurrence rate at 11-month follow-up.<sup>25</sup> A subsequent multicenter trial reported achieving technical success in 91% of patients with either pseudocysts or

WON ( $n = 33$ ) with use of the AXIOS LAMS.<sup>32</sup> Table 58.1 summarizes a published series involving LAMS placement for pseudocyst or WON management.

### Plastic Versus Metal

A systematic review by Bang et al (2015) of seventeen studies involving 881 total patients compared outcomes of plastic versus metal stent placement for transmural drainage of PFCs.<sup>33</sup> Although this review included studies examining drainage of both pseudocysts and WON, subgroup analysis of each fluid collection

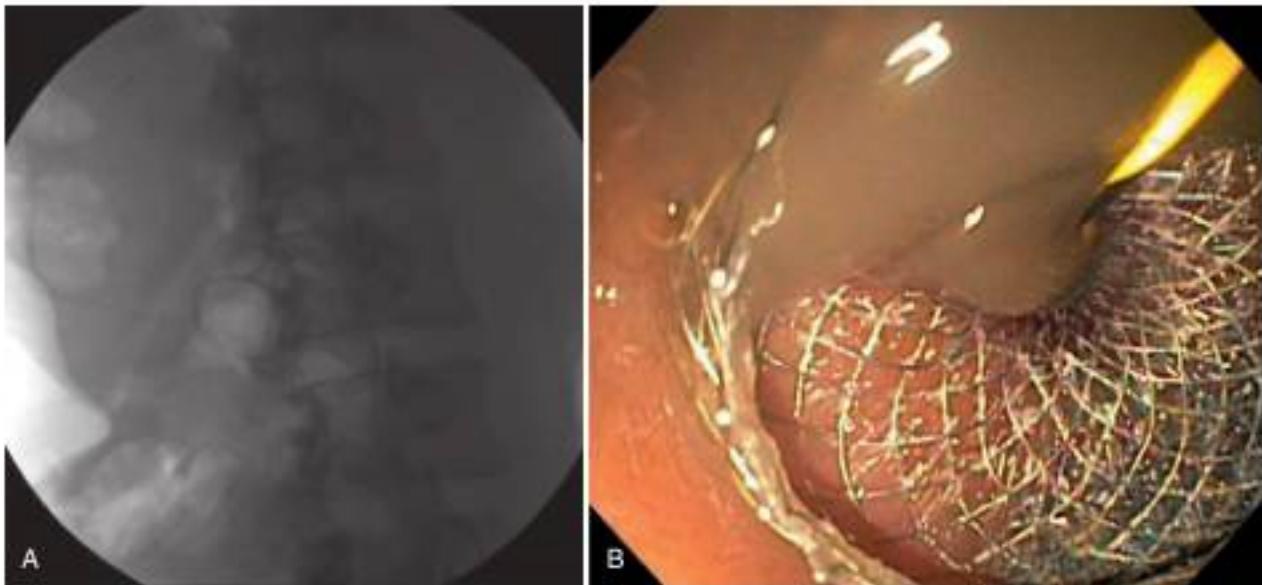

**FIG 58.5** Lumen-apposing metal stent (LAMS) deployed into a pancreatic fluid collection (PFC). (From Rinninella E, Kunda R, Dollhopf M, et al: EUS-guided drainage of pancreatic fluid collections using a novel lumen-apposing metal stent on an electrocautery-enhanced delivery system: a large retrospective study [with video]. *Gastrointest Endosc* 82[6]:1039–1046, 2015.)

type was performed. No difference was found in treatment success, adverse event rates, or recurrence rates between FCSEMS or plastic stent drainage. It was concluded that available evidence did not support the routine use of metal stents for pseudocyst drainage, particularly given their higher price. Of note, the metal stent studies included in this review consisted of only a small number of patients (maximum  $n = 22$ ).

A retrospective comparison of double pigtail plastic stents versus FCSEMS for pseudocyst drainage involved 230 patients. In this study, stent type was not associated with differences in technical success (92% vs. 98% for double pigtail plastic vs. FCSEMS,  $p = 0.06$ ).<sup>34</sup> Placement of a FCSEMS, however, was associated with a significantly higher rate of complete pseudocyst resolution, which occurred in 98% of pseudocysts drained with a FCSEMS versus 89% drained with double pigtail plastic stents at 12-month follow-up ( $p = 0.01$ ). FCSEMS placement also was

associated with a reduced rate of adverse events at 30 days (31% vs. 16%,  $p = 0.006$ ). With multivariate analysis, adverse events were 2.9 times more likely with use of double pigtail stents after adjustment for age, sex, number of endoscopy sessions, date of procedure, and original pseudocyst size. No difference occurred in long-term adverse event and recurrence rates.

### Surgery Versus Endoscopic Drainage

A 2016 Cochrane review performed on management strategies for pancreatic pseudocysts examined four randomized control trials consisting of comparisons among open surgical drainage, EUS-guided drainage, endoscopic drainage, and EUS-guided drainage with nasocystic catheter drainage. Short-term, health-related quality of life (at 4 weeks to 3 months) was worse following open surgical drainage versus EUS-guided drainage. The cost of surgery was also significantly higher. Statistically significant shorter hospital stays occurred following EUS-guided drainage with nasocystic drainage as opposed to EUS-guided drainage alone, endoscopic drainage, or open surgical drainage. Finally, EUS-guided drainage led to discharge faster than open surgical drainage, though hospital stay was the longest following endoscopic drainage alone.

A randomized trial has shown that endoscopic drainage has similar technical success and complication rates, but results in shorter stay, higher physical and mental health component scores, and lower costs compared to surgical cystgastrostomy.<sup>2</sup>

### Endoscopic Versus Percutaneous Drainage

Endoscopic drainage has been found on a retrospective review to be favorable to percutaneous drainage with less need for repeat procedures, shorter hospitalization, and decreased need for follow-up imaging while having statistically equivalent rates of technical success, clinical success and adverse events.<sup>34</sup>

## NECROSECTOMY

### Surgical

Open surgical necrosectomy has been the traditional method for management of WON. Open necrosectomy, however, may cause significant morbidity and mortality. Mortality rates are particularly high within 14 days after onset of necrotizing pancreatitis, and early surgery within this time frame is not recommended.<sup>35</sup> Besselink et al (2007)<sup>36</sup> showed that surgery on

day 30 or later following admission for necrotizing pancreatitis was associated with significantly lower mortality rates than earlier intervention (75% for days 1–14, 45% for days 15–29, 8% for day 30 or later). The mortality benefit that occurs with operative delay persists despite stratification for presence of preoperative organ failure and multiple organ failure.<sup>36</sup> A systematic review by the same authors of 11 studies with 1136 patients found a median mortality rate of 25% for open necrosectomy, with a range of 12% to 56%. This review confirmed the association between timing of intervention and mortality. Laparoscopic transperitoneal and retroperitoneal approaches are now preferred methods for surgical drainage.

### Percutaneous

Percutaneous drainage serves as an alternative option for less invasive débridement of pancreatic necrosis, obviating the need for surgery in 30% to 100% of patients specifically with infected necrosis. In a series of 18 patients, Wronski et al (2013) reported complete resolution of infected necrosis by ultrasound-guided percutaneous catheter drain placement in 33% of patients, though the remaining patients eventually required surgical necrosectomy.<sup>37</sup> An overall mortality rate of 17% occurred with this management strategy. Another series of 34 patients with infected necrosis reported use of multiple large-bore percutaneous catheters with aggressive drainage. An average of three catheter sites with four exchanges were used. Surgery was avoided in 47% of patients with an overall mortality rate of 12%.<sup>38</sup> Bello and Matthews (2013) reviewed eight studies examining percutaneous drainage, involving a total of 286 patients.<sup>39</sup> Percutaneous access was performed via ultrasound or CT guidance, and drains were used with a diameter ranging from 10 to 28 Fr. Saline flush of the drains was typically performed every 8 hours. In this review, 44% of patients had successful therapy with avoidance of surgical necrosectomy. An overall mortality rate of 20% was reported and complications occurred in 28%, including multiple organ failure, colonic perforation, intraabdominal bleeding, and GI and pancreatic fistulae. Though percutaneous drainage is frequently inadequate for definitive management of pancreatic necrosis, a step-up approach, consisting of initial percutaneous drainage of a necrotic collection followed by minimally invasive retroperitoneal necrosectomy, if necessary, is now standard. The PANTER (Minimally Invasive Step Up Approach versus Maximal Necrosectomy in Patients with Acute Necrotizing Pancreatitis)

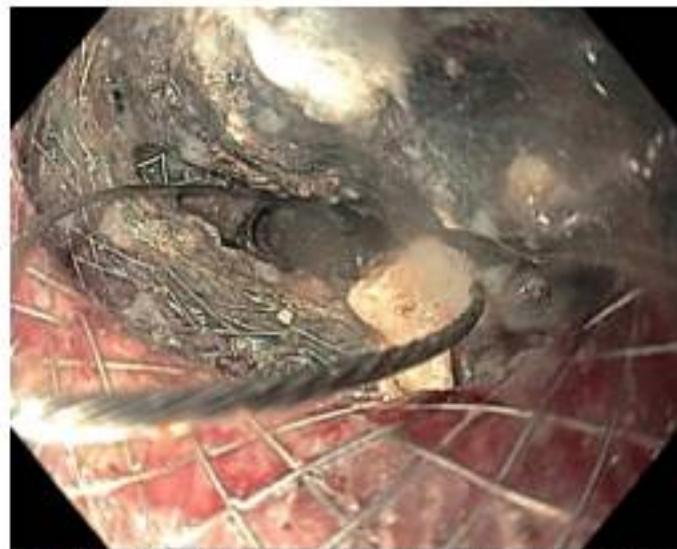

trial found a decrease in the primary endpoint of death or composite of major complications with this step-up approach as compared to open necrosectomy (40% vs. 69%,  $p = 0.0006$ ).<sup>3</sup>

Even if percutaneous drainage alone is adequate, significant morbidity may occur. Within the literature, a high rate of pancreaticocutaneous and pancreaticoenteric fistula formation occurs with pancreatic drainage approximately 20% of the time.<sup>4</sup> Furthermore, percutaneous drainage requires frequent catheter care, repeat procedures with upsizing of catheters, and frequent repeat cross-sectional imaging. WON may alternatively be managed endoscopically by direct endoscopic necrosectomy.

### Endoscopic

Direct endoscopic necrosectomy was first reported by Seifert et al (2001) in three patients who had failed endoscopic plastic stent drainage of WON.<sup>5</sup> A stoma is created between the gastroenteric lumen and the walled-off collection for direct entry into the necrotic cavity with the endoscope. Débridement and removal of necrotic tissue is performed using various endoscopic accessories (Fig. 58.8, Video 58.1). A retrospective comparison by Gardner et al (2009) showed that direct endoscopic necrosectomy was superior to transmural endoscopic drainage, with successful resolution of necrotic cavities in 88% versus 45% of patients.<sup>6</sup> Direct endoscopic necrosectomy also resulted in decreased need for subsequent percutaneous drainage, standard surgical drainage, and collection recurrence.

Several publications depict endoscopic necrosectomy as a relatively favorable WON intervention. In 2011, Haghshenass-kashani et al performed a systematic review of 260 patients in 10 series of patients with a total of 1100 endoscopic necrosectomy procedures.<sup>7</sup> Complete resolution of pancreatic necrosis was achieved 76% of the time, and the mortality rate was 5%. A median diagnosis to treatment interval of 6 weeks was present. In 2012, Bello and Matthews systemically reviewed 10 series involving endoscopic necrosectomy that reported success rates ranging from 59% to 100%.<sup>8</sup> Subsequent surgical necrosectomy was avoided in 78% of cases overall. Mortality ranged from 0% to 19% and was 5.6% overall. The mean complication rate reported was 28%.

**FIG 58.8** Direct endoscopic necrosectomy using a polypectomy snare.

A meta-analysis published in 2014 examined eight studies involving 233 patients with WON with a weighted mean necrotic cavity size of 12.9 cm.<sup>9</sup> A weighted mean of 4.1 procedures were necessary for necrotic cavity resolution. Endoscopic transmural necrosectomy had a pooled success rate of 82%. The pooled recurrence rate was 11% and complications occurred in 21%, consisting of bleeding, sepsis, and perforation. Surgery was ultimately required in 13% of patients.

Reported adverse event rates of EUS-guided treatment of WON ranges from 5% to 42%. The most significant adverse event rate associated with intervention of WON is infection, with an incidence of 15% to 26%. Additional complications include bleeding between direct endoscopic necrosectomy sessions, perforation/pneumoperitoneum, as well as stent migration, though stents are almost always retrieved successfully. Air and CO<sub>2</sub> embolisms are additional complications that may arise from blood vessel rupture with resultant direct insufflation into the bloodstream.<sup>10</sup> Air embolism has been reported to occur at a rate of 0.4%.<sup>11</sup>

### Endoscopic Versus Surgical Necrosectomy

A 2016 Cochrane review of interventions for necrotizing pancreatitis examined eight randomized controlled trials, concluding that serious adverse events and adverse events were less frequent with an endoscopic-assisted minimally invasive step-up approach versus open necrosectomy. More adverse events occurred with the video-assisted minimally invasive surgery step-up approach group versus the endoscopic-assisted minimally invasive step-up approach group. The number of interventions, however, were less with the video-assisted versus endoscopic-assisted minimally invasive step-up approach.<sup>12</sup> The TENSION (transluminal endoscopic step-up approach versus minimally invasive surgical step-up approach in patients with infected necrotizing pancreatitis) trial is currently comparing endoscopic drainage followed by endoscopic necrosectomy, if necessary, versus percutaneous drainage followed by video-assisted necrosectomy, if necessary.

Bakker et al (2012) randomized patients with confirmed or suspected infected WON to endoscopic transgastric necrosectomy or surgical necrosectomy with either VARD, when possible, or open laparotomy if necessary.<sup>13</sup> The primary endpoint examined was level of interleukin 6 following necrosectomy as a measure of the postprocedure inflammatory response, which was lower following endoscopic necrosectomy ( $p = 0.004$ ). A secondary endpoint of a composite of major complications or death was significantly lower with endoscopic necrosectomy versus surgery (20% vs. 80%,  $p = 0.02$ ). Additionally, significantly less pancreatic fistulae occurred with endoscopic necrosectomy (10% vs. 70%).

### Endoscopic Necrosectomy Versus Percutaneous Drainage

In 2014, a step-up approach with initial percutaneous drainage was compared to direct endoscopic necrosectomy in 24 patients. Resolution occurred in 92% of patients undergoing endoscopic necrosectomy versus 25% who underwent percutaneous drainage. The endoscopic necrosectomy group also had lower rates of antibiotic use, pancreatic insufficiency, and hospitalization.<sup>14</sup>

### Endoscopic Necrosectomy Technique

Endoscopic necrosectomy requires the creation of a cystogastrostomy or cystoenterostomy tract that is large enough to allow the passage of an endoscope directly into the cavity. A tract of 15 to 20 mm diameter is usually created by balloon catheter

dilation, but can also be created with a large diameter metal stent (see following section). Necrosectomy is performed using snares, forceps, baskets, and forceful irrigation. Intersession irrigation of the necrotic cavity with saline and/or hydrogen peroxide may be performed via a nasocystic catheter. Hydrogen peroxide irrigation of the collection cavity during endoscopy may decrease procedure duration, complication rates, and the total number of endoscopic necrosectomy sessions required.<sup>40</sup> Repeat necrosectomy sessions are performed until débridement of necrotic material within the cavity is complete.

### Metal Stents (FCSEMS or LAMS) for WON

FCSEMS may enhance endoscopic drainage of WON. Esophageal FCSEMS have a lumen diameter that will permit endoscope advancement through the deployed, expanded stent. In 2014, two case series were published describing use of esophageal FCSEMS for WON drainage. One study consisted of 17 patients with a complete resolution rate of 88% over an average of five necrosectomy sessions.<sup>41</sup> The other involved 10 patients with a resolution rate of 90% after an average of three necrosectomy sessions.<sup>40</sup>

LAMS have large lumens, which can be immediately dilated following placement to enable direct endoscopic exploration and débridement of the necrotic cavity. The dumbbell structure of these stents allows for more aggressive manipulation without stent dislodgement during the index endoscopic session. The lumen-apposing nature of these stents intends to reduce rates of perforation and leak, particularly in cases where the mature necrotic fluid collection is not entirely adherent to the gastrointestinal wall.

In a large, US multicenter, retrospective study of patients who underwent EUS-guided drainage of PFCs using the AXIOS stent,<sup>51</sup> 68 of 80 patients had WON with a mean PFC size of 11.8 cm. Successful LAMS placement was achieved in 97.5% of patients. Endoscopic débridement was performed through the LAMS in 54 patients requiring a mean of 2.8 ± 1.3 sessions. Stents remained patent in 98.7% of cases. Overall, endoscopic therapy with use of the LAMS was successful in 88.2% of patients with WON. One patient had PFC recurrence within the 3-month median follow-up. The procedure-related adverse event rate was 9.8%, with complications consisting of self-limiting bleeding, stent maldeployment ( $n = 2$ ), and gastric perforation following stent maldeployment in one patient requiring surgical repair.

A retrospective comparison of LAMS versus FCSEMS has shown LAMS may facilitate complete resolution of WON in fewer procedures ( $p = 0.04$ ).<sup>52</sup> Use of LAMS may cause more early adverse events, however, than either FCSEMS or plastic stents (OR 6.6,  $p = 0.02$ ).

Flared-type biflanged metal stents that are not lumen-apposing have been used for the treatment of WON. In an ex vivo study, biflanged stents were found to have a higher migration rate than LAMS.<sup>53</sup> LAMS were also found to have a higher lumen-apposing force than the biflanged stent.<sup>53</sup>

It is unclear if metal stents should be removed after cavity resolution. Removal is typically pursued, however, given uncertainty regarding long-term adverse effects. Specifically, indefinite stent indwelling could potentially result in migration of food into the collection cavity, bleeding from tissue erosion, or, occasionally, stent burial. In a 2016 ongoing trial comparing LAMS and plastic stents for WON drainage, high rates of delayed complications due to persistent indwelling LAMS have been observed.<sup>54</sup> Stent-related bleeding, stent burial, and stent-induced

biliary obstruction occurred in 50% of patients receiving LAMS, whereas 0% of plastic stent participants had stent-related adverse events. As LAMS-related events all occurred over 3 weeks after placement, these complications prompted a change in protocol to earlier imaging assessment at 3 weeks followed by LAMS removal if WON resolution was demonstrated. The authors hypothesize that the stiff, immobile nature of LAMS, in contrast to flexible, mobile plastic stents, promotes tissue and vascular erosion and impingement upon WON cavity collapse. Nonetheless, other studies have not observed adverse event rates nearly as high when employing LAMS for WON management.<sup>52,55-58</sup>

### Plastic Versus Metal Stents for WON

A two-center, retrospective comparison of EUS-guided drainage of PFCs with double pigtail plastic stents versus a flared-type biflanged FCSEMS (not lumen-apposing) showed that plastic stent use was associated with increased need for repeat drainage procedures (34.2% vs. 6.3% of patients).<sup>53</sup> This study is limited by the lack of stratified outcomes based upon the initial collection characteristics (pseudocyst or WON). Stent migration occurred in 18.4% of cases using plastic stents versus 6.3% of cases using the biflanged, but this difference was not statistically significant. Overall, this study did support a benefit to use of FCSEMS over plastic stents. Although technical success occurred in 100% of cases, inadequate drainage occurred in significantly more patients with plastic stents (26.3% vs. 0%). The initial clinical success rate was 92% in those with FCSEMS versus 65% in those with plastic stents ( $p = 0.074$ ). Furthermore, though the overall cost of plastic stent use was lower in patients with noninfected pseudocysts, the advantage was not seen for infected pseudocysts or WON due to a reduced need for interventions using FCSEMS.

A single-center, retrospective series showed no difference between plastic stents and LAMS for treatment of WON in terms of technical success, clinical success, or adverse events, even though the plastic stent group had significantly larger WON.<sup>59</sup> Mean procedure times were shorter for the LAMS group for initial EUS-guided drainage and reintervention, however, and no difference in total cost was present between plastic stent and LAMS use.

As previously mentioned, a systematic review published by Bang et al in 2015 compared the use of FCSEMS versus plastic stents for PFC drainage.<sup>55</sup> No difference was detected in the pooled rate of overall treatment success for PFCs, specifically in patients with WON (78% vs. 70%). No difference occurred in either the rate of adverse events or fluid collection recurrence. No studies in this review were direct comparative studies, however. Siddiqui et al (2017) published a retrospective comparison of 313 patients with WON who underwent endoscopic intervention using either double pigtail plastic stents or 10-mm biliary metal stents (FCSEMS or LAMS).<sup>52</sup> Though therapeutic success was comparable regardless of stent type, long-term resolution of WON was more successful using metal stents (95% vs. 81%,  $p = 0.01$ ). No prospective trials have compared the use of plastic versus metal stents in the management of WON. In some cases, initial placement of a LAMS for facilitation of direct endoscopic necrosectomy may be pursued followed by removal of the LAMS and long-term placement of multiple transmural plastic stents. This approach may be helpful in patients with a disconnected pancreatic tail that are poor surgical candidates. Exchange of the LAMS for plastic stents allows long-term management of the PFC, which may otherwise be expected to recur in the presence

of duct disruption, and avoids complications of long-term LAMS indwelling, such as tissue erosions and hemorrhage.

Several questions exist regarding the role of FCSEMS and LAMS in drainage of WON. Further study is necessary to determine if the theoretical advantages of LAMS are borne out in clinical practice. In prospective trials, does single-step deployment decrease the rate of adverse events by improving the efficiency and simplicity of the procedure? If metal stents are advantageous compared to plastic stents, are LAMS more beneficial compared to FCSEMS? Does LAMS placement decrease the need for necrosectomy entirely? Is the use of LAMS cost-effective?<sup>52</sup> Other issues to address in the future are the role and duration of antibiotics following transmural endoscopic stent placement as well as the role of nasocystic catheter drainage. No studies have examined the role of nasocystic catheter drainage as adjunct therapy to transmural FCSEMS or LAMS in the management of PFCs. The larger stent lumen of an esophageal FCSEMS or 15-mm LAMS may reduce the need for nasocystic catheter irrigation and drainage. Consideration for nasocystic catheter drain placement should be made, however, particularly when infected necrosis is present.

### TRANSPAPILLARY STENTING IN PFC MANAGEMENT

Questions have also surrounded the adjunct role of transpapillary pancreatic duct stenting in patients undergoing transmural drainage of PFCs. Pancreatic ductal leaks or disruption are the underlying mechanism of acute and mature PFCs. Spontaneous resolution of PFCs may occur in only 0% to 5% of patients with persistent ductal disruption compared to a normal pancreatic duct.<sup>53</sup> Acute pancreatic duct leaks are traditionally treated by transpapillary stent placement. In theory, treatment of persistent pancreatic ductal leaks or disruption may help promote resolution of pancreatic fluid collections, as well when applied as adjunct therapy to endoscopic transmural drainage.

Previous retrospective studies have suggested that transpapillary stenting may be an augmenting therapy for patients receiving endoscopic transmural drainage of PFCs.<sup>54</sup> Transpapillary drainage alone may be effective in the management of PFCs if the cavity communicates with the pancreatic duct, but there is concern for increased risk of PFC superinfection.<sup>55</sup> Transpapillary drainage alone could be considered in cases of small PFCs (< 4 cm) or when transmural drainage is not feasible. It is the practice at the author's institution to place two stents: one extending into the fluid collection, and the other across the area of pancreatic duct leak. As adjunct therapy, a 2016 multicenter, retrospective comparison of EUS-guided transmural drainage alone versus combined transmural and transpapillary drainage of pancreatic pseudocysts, showed no therapeutic benefit to adjunctive transpapillary drainage. Transpapillary drainage actually negatively affected the rate of long-term resolution of the pancreatic fluid collections (OR 0.11, 95% CI 0.02–0.8,  $p = 0.03$ ).<sup>56</sup> Of note, the pancreatic duct stent traversed the site of ductal disruption in only 36.2% of cases. It is possible that bridging of the defect may have resulted in better outcomes, as bridging across the disruption has been associated with improved outcomes previously.<sup>57</sup> Nonetheless, in subgroup analysis of patients in which a pancreatic duct stent did successfully bridge the site of disruption, transpapillary drainage still added no benefit to transmural drainage.<sup>56</sup> Thus, at our institution, pancreatogram is only pursued in the setting of fluid collection recurrence to document the

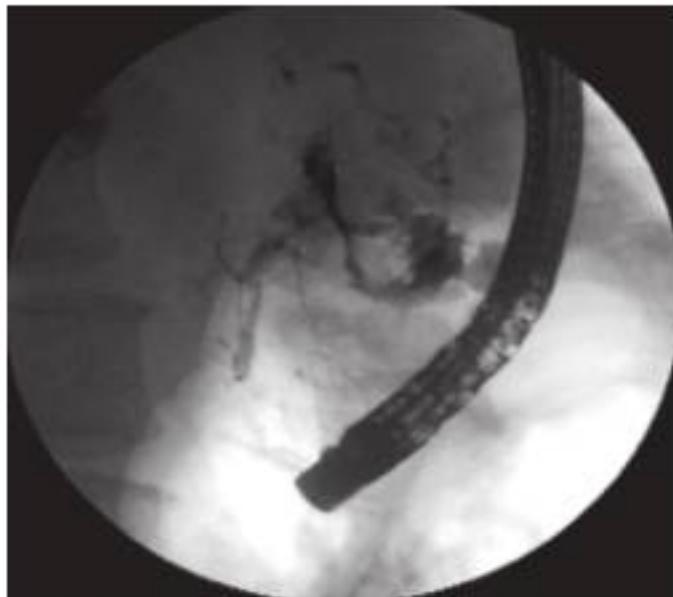

presence of a disconnected duct. These patients would then require either surgical intervention or long-term stent placement with transmural plastic stents and possible transpapillary stent placement.

### PANCREATIC DUCT LEAKS

Pancreatic leaks may result from trauma either from acute or chronic pancreatitis, direct pancreatic injury from abdominal trauma, or iatrogenic injury during endoscopy or surgery. Apart from manifesting as mature pancreatic fluid collections, pancreatic duct leaks may also result in external or internal fistulae. Magnetic resonance cholangiopancreatography (MRCP) and secretin-MRCP can delineate the ductal anatomy as a noninvasive method of diagnosing pancreatic duct leaks. Fluid aspiration of immature PFCs with amylase analysis can also be performed to diagnose pancreatic duct leaks. Endoscopic retrograde cholangiopancreatography (ERCP) with pancreatogram is the most sensitive method of detecting pancreatic duct leaks and disruption (Fig. 58.9).

Internal fistulae result from ductal disruption with the manifestation depending on the location of disruption. Anterior disruption may result in pancreatic ascites, whereas posterior disruption can lead to a mediastinal pseudocyst or pleural fistula.<sup>58</sup> Initial noninvasive management of pancreatic duct leaks may be pursued with bowel rest, deep enteral feeding, and use of octreotide. Conservative management is frequently ineffective, however, failing approximately 50% of the time. Failure occurs even more frequently in patients with advanced pancreatitis.<sup>59</sup>

Given the frequent inefficacy of noninvasive management, endoscopic therapy may be pursued as initial or second-line therapy. Transpapillary pancreatic duct stenting is effective in promoting leak healing by reducing the resistance of transpapillary flow by bypassing potential pancreatic duct strictures and stones and the sphincter of Oddi.<sup>59</sup> Tanaka et al (2013) reported on a series of six patients with internal pancreatic fistulae and associated downstream pancreatic duct stenosis.<sup>60</sup> Endoscopic therapy

**FIG 58.9** Pancreatic duct leak on pancreatogram. Completely disconnected pancreatic duct.

was performed with placement of a 5-Fr or 7-Fr plastic stent, with intention to perform stent exchange for a total duration of 1 year. Stent placement across the site of stenosis was successful in 100% of patients. Treatment was successful with resolution of leak in 66% of patients (four out of six), though one of these had recurrence refractory to further stenting. Despite endoscopic therapy, however, 50% eventually required surgery for definitive management (due to continuous pain with leak or intracystic bleeding). Bridging of the site of pancreatic duct disruption and long duration of stent therapy may enhance the efficacy of transpapillary stent therapy.<sup>70</sup> A more recent (2016) large series of 107 patients with pancreatic duct disruption showed that pancreatic duct stent placement resulted in healing of the leak in 75% of patients. Ninety-six percent had successful pancreatic duct stent placement, but bridging of the point of disruption was successful in only 44% of patients.<sup>71</sup> In cases where the disruption point was not bridged, treatment success was only 48%. In both these series, acute pancreatitis as the etiology of pancreatic duct disruption predicted poor response to pancreatic duct stenting. The presence of complete duct disruption was also predictive of failure of therapy.

In patients specifically with pleural fistulae, medical and endoscopic therapy is also typically advised prior to surgical intervention due to the latter's morbidity. Prior to intervention, pancreatic pleural fistulae can be differentiated from reactive pleural effusions that may develop in the setting of acute pancreatitis based upon the presence of a high amylase concentration within the pleural fluid. Imaging may also help diagnose a pancreatic pleural fistula. CT has a 47% sensitivity for detection of the fistulous tract, whereas MRCP and ERCP have roughly 80% sensitivity. For pleural fistulae, ERCP with transpapillary stenting is the standard endoscopic therapy. Following transpapillary stenting, diagnostic ERCP can be performed every 4 to 6 weeks for stent exchange or removal based upon assessment of fistula closure. The majority of patients with pleural fistulae that respond to endotherapeutic stenting have a stent that bridges the site of disruption. Endoscopic management fails in a significant proportion of patients, however.<sup>72</sup> Due to high failure rate, preintervention MRCP findings may be useful in guiding management strategies. Those with normal pancreatic ducts without downstream strictures may respond to conservative medical therapy. If a ductal stricture is present or disruption is noted in the head or body of the pancreas, endoscopic therapy may be the most appropriate first-line therapy. If there is complete ductal obstruction or both stricture and leakage from within the pancreatic tail, however, surgical treatment may be most appropriate due to the poor success of endoscopic stenting.<sup>73</sup>

The treatment of external pancreatic fistulae is similar to that of internal fistulae. In cases of conservative management failure, endoscopic transpapillary stenting may be pursued prior to surgical intervention. In addition, endoscopic fibrin glue injection has been reported for closure of pancreaticocutaneous fistula.<sup>74</sup>

### Disconnected Duct Syndrome

Disconnected duct syndrome denotes the presence of a pancreatic leak resulting from complete transection of the pancreatic duct (see Fig. 58.9). Excretions from the upstream proximal pancreas thus drain entirely into the abdominal cavity. Surgical treatment has been the primary management modality for disconnected duct syndrome. Due to the inability to pass a guidewire into the disconnected duct, transpapillary placement of a pancreatic duct stent is typically not effective because bridging of the ductal

defect cannot be performed.<sup>75</sup> Varadarajulu et al (2005) have reported success in only 26% of cases with attempted transpapillary stent placement.<sup>76</sup>

As an alternative to surgery or endoscopic transpapillary stenting, endoscopic transmural stenting may be performed for creation of a fistula between the fluid collection and the GI tract. Permanent transmural stenting thus produces long-term drainage of the isolated pancreatic segment. Téllez-Ávila et al (2016) reported a series of 21 patients with confirmed disconnected duct syndrome (by MRCP or ERCP) who underwent transmural stent placement with two 7 Fr by 4 cm double pigtail stents.<sup>77</sup> Technical success was achieved in 100% of patients and clinical success in 81% after a median follow-up of 28 months. In those with clinical success, 20% had recurrence for which a second endoscopic treatment was successful, consisting of tract dilation with direct endoscopic necrosectomy followed by placement of two double pigtail stents. Reported complications included stent migration (10%), infection after drainage (5%), infection after stent migration (5%), and suspected stent migration with perforation (5%), though perforation was not actually confirmed after surgical exploration.<sup>78</sup>

As noted previously, if duct disruption results in formation of a mature fluid collection (pseudocyst or WON), transmural drainage is often adequate therapy and transpapillary pancreatic duct stenting does not seem to provide adjunct benefit.<sup>79</sup> Larsen and Kozarek (2014) have reported a combined endoscopic and percutaneous approach for patients with WON and disconnected duct syndrome. At their center, frequent development of external pancreaticocutaneous fistulae with solely percutaneous drainage prompted use of combined percutaneous and transmural drainage. In this scenario, plastic transmural stents were left in place indefinitely. This approach prevented development of cutaneous fistulae and successfully avoided need for surgery in more than 95% of patients.<sup>80</sup>

### Postsurgical Acute Pancreatic Fluid Collections

Pancreatic duct leaks with resultant acute postoperative PFCs occur in approximately 30% of patients following pancreatic surgeries such as pancreaticoduodenectomy, pancreatic enucleation, and distal pancreatectomy. Spontaneous resolution typically will occur over days to weeks. Symptomatic collections may present with severe pain, gastric outlet obstruction, or intra-abdominal infection and sepsis. Classic management consists of bowel rest, TPN, antibiotics, and possible intravenous octreotide. In approximately 20% to 40% of cases, further management may be necessary, at which time percutaneous drainage is traditionally pursued. Percutaneous drainage is effective, but presence of an external drain may decrease patient quality of life, requires monitoring of fluid output, catheter flushing, and possible catheter exchange. In cases of persistent leak, pancreatic duct stenting may also be indicated. Pancreatic duct stenting is not effective, however, if disrupted duct syndrome is present where there is complete transection of the pancreatic duct. Furthermore, large or infected peripancreatic fluid collections may not resolve quickly with a transpapillary stent. The risk of post-ERCP pancreatitis also detracts from the appeal of transpapillary stenting.

EUS-guided transmural drainage has been advocated as a possible therapeutic option for acute postoperative PFCs. In 2009, Varadarajulu et al reported a prospective series of 10 patients undergoing EUS-guided plastic stent drainage of PFCs after distal pancreatectomy with 100% technical success, and 90% therapeutic success, though it is unclear if any of these postoperative

collections were acute.<sup>70</sup> A subsequent retrospective comparison of EUS-guided drainage (using one to three double pigtail stents) and percutaneous drainage of 23 patients with symptomatic PFCs following pancreatic enucleation or distal pancreatectomy showed 100% technical success with either method, but a higher rate of clinical success (defined as radiographic resolution of collection, stent, or removal, and symptomatic improvement) with EUS-guided drainage.<sup>71</sup> Necrosectomy was required in five patients with EUS-guided drainage, and two patients had concurrent ERCP with pancreatic duct stent placement. Most patients in this study were referred from an outside hospital with the possibility that varying surgical approaches, closure methods, and underlying histology may bias leak rates and subsequent clinical improvement. Furthermore, the maturity of fluid collections within this study were unknown and may not have been comparable between the two treatment groups.

In 2014, Tilara et al reported a retrospective analysis of 31 patients who underwent EUS-guided drainage of postoperative fluid collections developing following pancreatic resection.<sup>72</sup> A proportion of these patients had acute collections. The indications for PFC drainage were abdominal pain, infection, gastric outlet obstruction, and biliary obstruction. One to three double pigtail stents, 7 Fr or 10 Fr in diameter, were deployed. If symptoms persisted and PFC size did not improve on cross-sectional imaging 4 weeks postdrainage, repeated endoscopy with tract dilation, new stent insertion, and necrosectomy were performed, which was necessary in 19% of patients. Technical success was achieved in 100% of patients. PFC resolution on imaging with clinical improvement occurred in 93% of patients. Among all cases, 55% had successful early drainage within 30 days postoperatively. Forty-two percent of these patients had drainage performed within 2 weeks of surgery. Early drainage was not associated with increased complications. One complication occurred in patients undergoing early drainage: a bleed from a splenic artery stump.

Of note, the indication for drainage in patients undergoing early EUS-guided drainage was infection (fever, leukocytosis, or abscess formation) in 70% of cases. In those undergoing drainage within two weeks of surgery, the indication for drainage was infection or sepsis in all cases. Thus, most patients undergoing early EUS-guided drainage of postoperative collections had signs of sepsis necessitating drainage prior to maturation of the PFC. The authors propose that maturity of fluid collection may be less important for drainage of postoperative PFCs versus those that arise from pancreatitis adhesion formation; scarring may effectively compartmentalize the surgical bed and may limit intraperitoneal spillage. Further studies are necessary, however, to prove the safety of endoscopic transmural drainage of acute collections, particularly in the absence of preexisting infection necessitating early intervention.

## CONCLUSION

Disruption of the main or secondary pancreatic ducts can result in pancreatic leaks and development of PFCs as a complication of pancreatitis, trauma, or iatrogenesis. In general, PFCs are best observed over time to allow for their likely spontaneous regression. When PFC drainage is indicated by persistent symptoms or evidence of infection, however, endoscopic transmural drainage has become a first-line therapy in lieu of surgical intervention. Appropriate management nonetheless rests on a multidisciplinary collaboration involving interventional radiology and surgery.

Overall, endoscopic management is an efficacious treatment modality for pancreatic pseudocysts. Further prospective trials are necessary to establish the benefits of metal stents over plastic stents, particularly given their increased cost. Further study is also required to determine ideal stent length, the need for dilation of FCSEMS after placement, the benefit of same-session pseudocyst exploration through the FCSEMS, and the benefit of internal plastic stent placement for metal stent anchoring.<sup>73</sup> The use of lumen-apposing metal stents over traditional stent design has the theoretical advantages of reducing stent migration and reducing stent erosion. LAMS design may be most useful, however, in cases of walled-off necrosis, in which the large stent diameter facilitates persistent drainage and the lumen-apposing flanges establish a more secure anastomosis that enables immediate direct endoscopic exploration and necrosectomy of the necrotic cavity.

## INTRODUCTION

Chronic pancreatitis (CP) is an inflammatory condition that results in fibrosis causing destruction of pancreatic parenchyma and ducts. These permanent structural changes can lead to impairment of exocrine and endocrine function, biliary strictures, and may increase the chances of developing pancreatic cancer.<sup>1</sup>

This disorder contrasts with acute pancreatitis in that the latter is non-progressive, and the gland returns to histologic and functional normalcy once the acute event subsides. There does exist overlap between the two conditions, and recurrent episodes of acute pancreatitis may lead to more permanent chronic changes. The most common clinical presentation of CP is abdominal pain, which is multifactorial in nature, and if associated with only minimal pancreatic fibrosis, can lead to confusion over the diagnosis.

The role of endoscopy has focused on relieving abdominal pain and managing complications, but interpretation of data on this topic remains challenging due to varied presentations, clinical courses, and etiologies. Given the limitations of medical therapy and the invasiveness of surgical options, endoscopic therapy has been widely employed in the treatment of CP, but long-term randomized trials are lacking and therefore its role continues to evolve.

## ETIOLOGY

### Alcohol

Alcohol accounts for 70% to 80% of cases of CP (Table 59.1); the mechanism by which this occurs is unclear. The risk seems

to be related to the duration and amount of alcohol consumed rather than the type of alcohol or the pattern of consumption.<sup>2</sup> Only 5% to 10% of alcoholics develop CP, suggesting that other unidentified factors may be important in the pathogenesis of the disease.<sup>3</sup>

### Smoking

More recently, smoking has emerged as an independent risk factor for CP, as demonstrated in two studies by the North American Pancreas Study Group.<sup>4,5</sup> Similar to alcohol, the effects of smoking on the development of CP appear to be dose dependent, with risk increasing for people smoking more than one pack per day.<sup>6</sup> Furthermore, in those with alcohol-induced acute pancreatitis, smoking appears to be the strongest risk factor for progression to CP.<sup>7,8</sup>

### Genetic Causes

Several mutations associated with CP have been identified. Mutations in the cationic trypsin gene (*PRSS1*) that lead to premature trypsinogen activation have been suggested as the cause of hereditary pancreatitis.<sup>9-11</sup> *PRSS1* inheritance is autosomal dominant with high penetrance. Cystic fibrosis is caused by mutations in the *CFTR* gene. Most patients with cystic fibrosis develop progressive pancreatic damage as a result of defective ductular and acinar pancreatic secretion.<sup>12</sup> In some series, mutations in the *CFTR* gene have been identified in 13% to 37% of patients with idiopathic CP who have no clinical evidence of cystic fibrosis.<sup>13,14</sup> This percentage range could be an underestimation because currently available genetic screening tests identify only 18 to 23 of the most severe *CFTR* mutations that cause classic childhood cystic fibrosis.

**Abstract**

Chronic pancreatitis can be described as an inflammatory process characterized by irreversible destruction of pancreatic parenchyma and ductal structures with fibrosis formation. This term describes a wide variety of clinical findings and symptoms that require a multi-disciplinary approach to care. Making an accurate, early diagnosis can be difficult, and therefore it is important to recognize risk factors for chronic pancreatitis development (i.e., alcohol, smoking, genetic factors, etc.) and how to maximize utility from various imaging studies. Goals of treatment include pain management, correction of pancreatic insufficiency, and treating associated complications. Pain control can be the most clinically challenging aspect of care because its etiology is multi-factorial and mechanisms are poorly understood. Chronic pancreatitis management includes a combination of medical, endoscopic, and surgical approaches. This chapter will present current diagnostic and treatment modalities for chronic pancreatitis, along with an overview of the relevant published data that lend credence to their use.

**Keywords**

chronic pancreatitis  
pancreatic duct stones  
pancreatic duct strictures  
ERCP  
EUS

**TABLE 59.1 Etiology of Chronic Pancreatitis**

Alcohol	70%
Idiopathic	10%-30%
Other	10%-15%
Pancreatic duct obstruction (trauma, divisum, tumor, fibrosis)	
Heredity (CFTR gene mutation, trypsinogen gene mutation)	
Hyperlipidemia	
Tropical	

CFTR, Cystic fibrosis transmembrane conductance regulator.

*SPINK1* is expressed on pancreatic acinar cells during an inflammatory response and codes for a trypsin inhibitor. A mutation in *SPINK1* is not an independent risk factor for CP, but has been implicated in the progression of recurrent acute pancreatitis to CP.<sup>13</sup> *SPINK1* mutations are strongly associated with tropical calcific pancreatitis.<sup>14</sup> Co-inheritance of *SPINK1* with *CFTR* mutations can increase the risk of CP.<sup>15,16</sup>

### Ductal Obstruction

Obstruction of the pancreatic duct from any cause can lead to CP. The histologic abnormalities that are induced may persist after relief of the obstruction.

### Idiopathic Chronic Pancreatitis

An etiology for pancreatitis cannot be determined in 10% to 30% of patients with CP despite extensive investigations. Concealed alcohol ingestion, hypersensitivity to small amounts of alcohol, unreported pancreatic trauma, and mutations in the *CFTR* and trypsinogen genes may be contributing factors in at least a small proportion of patients with idiopathic CP.<sup>10,20</sup> Although in the past patients with idiopathic CP were considered as a single group, data from the Mayo Clinic have defined an early- and late-onset form.<sup>21</sup> Age distribution at onset of symptoms showed a bimodal distribution of patients with early- and late-onset idiopathic CP with a median age of 19.2 years for early onset and 56.2 years for late onset. No gender differences were observed among patients in either group.

### CLINICAL FEATURES

Abdominal pain and pancreatic insufficiency are the two cardinal clinical manifestations of CP.

#### Abdominal Pain

Abdominal pain in CP is typically centered in the epigastric area and frequently radiates to the back. The pain is worsened with eating and is sometimes associated with nausea and vomiting. Early in the course of CP, the pain may occur in discrete attacks; as the condition progresses, pain tends to become more continuous.

The mechanism for abdominal pain is poorly understood. Causes are likely multifactorial and include inflammation, duct obstruction, high pancreatic tissue pressure, fibrotic encasement of sensory nerves, and neuropathy characterized by both increased numbers and sizes of intrapancreatic sensory nerves, and by inflammatory injury to the nerve sheaths allowing exposure of the neural elements to toxic substances.<sup>22,23</sup> The view that chronic

pain subsides in a substantial number of patients as the disease progresses to the point of organ failure has been widely accepted, but that process may take an unpredictable number of years or may never occur.<sup>24</sup>

Furthermore, there has been increasing interest in the central nervous system's role in mediating pain in CP patients. One small study of 22 patients compared patients with CP versus healthy controls and stimulated pain electrically.<sup>25</sup> Electroencephalograms were recorded from 64 surface electrodes, and event-related brain potentials were obtained. The results demonstrated that pain in CP patients leads to changes in cortical projections of the nociceptive system. This has also been demonstrated in other conditions resulting in neuropathic pain, and should be taken into account when considering treatment approaches.

### Pancreatic Insufficiency

Patients with severe pancreatic exocrine dysfunction cannot properly digest complex foods or absorb digestive breakdown products. Nevertheless, clinically significant protein and fat deficiencies do not occur until more than 90% of pancreatic function is lost.<sup>26</sup> In a large natural history study, the median time for development of pancreatic insufficiency was 13.1 years in patients with alcoholic CP, 16.1 years in patients with late-onset idiopathic CP, and 26.3 years in patients with early-onset idiopathic CP.<sup>21</sup>

Steatorrhea usually occurs before protein deficiencies because lipolytic activity decreases more quickly than proteolysis.<sup>27,28</sup> Glucose intolerance occurs frequently in CP, but overt diabetes mellitus usually occurs late in the course of disease. Nearly 40% to 70% of patients with CP develop diabetes on prolonged follow-up. In one study, the median time to develop diabetes was 19.8 years, 11.9 years, and 26.3 years in patients with alcoholic, late-onset idiopathic, and early-onset idiopathic CP.<sup>21</sup> The nature of diabetes in this patient population is brittle, and management is more complicated than that of patients with type 1 diabetes.

### DIAGNOSIS

Advanced CP is more easily diagnosed when compared with early or mild disease, which may require interpretation of clinical symptoms, pancreatic function testing, and expert interpretation of imaging studies such as MRCP and EUS. Tests for CP can be classified into tests that evaluate its exocrine function (Table 59.2) or the structure of the gland (parenchyma, ductal anatomy, or both). Noninvasive pancreatic function tests yield sufficient diagnostic accuracy only in the advanced stages of the disease, and their sensitivity for detection of early or moderate CP is low.<sup>29</sup> Tests that evaluate pancreatic structure, although limited by sensitivity, are advantageous in that they are more widely available, and attempts have been made to develop standardized criteria for clinical use.

#### Tests of Pancreatic Function

##### Invasive or Direct Pancreatic Function Tests (Secretin Stimulation Test)

The basis for the secretin stimulation test is that secretin (with or without cholecystokinin) causes the secretion of bicarbonate-rich fluid from the pancreas. Intravenous secretin is administered, duodenal juice is collected every 10 minutes for 1 hour (either through a duodenal catheter the patient swallows or at endoscopy), and bicarbonate measured. Peak bicarbonate less than 80 mmol/L

**TABLE 59.2 Diagnostic Tests for Chronic Pancreatitis**

Structural Tests	FUNCTIONAL TESTS	
	Indirect	Direct
X-ray	Serum enzymes (trypsinogen)	Secretin stimulation test
Ultrasound	Fecal tests (fat, elastase, chymotrypsin)	
CT	Urine tests (bentiromide, pancreoluryl)	
MRCP		
ERCP		
EUS		

CT, Computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; EUS, endoscopic ultrasound; MRCP, magnetic resonance cholangiopancreatography.

is a widely accepted threshold consistent with pancreatic exocrine insufficiency. Sensitivity ranges from 74% to 97%, and specificity ranges from 80% to 90%.<sup>31–35</sup> Limitations of this test (time consuming, expensive, no standardized results) have prevented it from gaining widespread use.

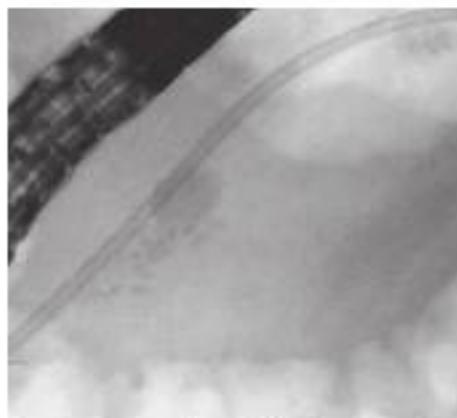

#### Noninvasive or Indirect Pancreatic Function Tests

There has been great effort and interest to develop noninvasive tests for evaluating pancreatic function. These tests are designed to measure pancreatic enzymes in blood or stool, or the effect of pancreatic enzymes on an orally administered substrate by collection of metabolites in the blood or urine.

**Serum enzymes.** Because CP is a patchy, focal disease with significant parenchymal fibrosis, pancreatic serum enzyme levels (amylase and lipase) are within normal range or only minimally elevated. Very low levels of serum trypsinogen (< 20 ng/mL) are reasonably specific for CP, but levels as low as this are seen only in very advanced stages of the disease where there is accompanying steatorrhea.<sup>36</sup>

**Fecal tests.** Steatorrhea can be diagnosed qualitatively by Sudan staining of feces or quantitatively by determination of fecal fat excretion over 72 hours while the patient is consuming a 100 g/day fat diet for at least 3 days before the test. Excretion of more than 7 g of fat per day is diagnostic of malabsorption, although patients with steatorrhea often have values greater than 20 g/day. Stool fat analysis has limited sensitivity in CP because patients with mild and moderate disease would not be detected by this technique.

The low diagnostic value of fat malabsorption in CP led to the discovery of individual pancreatic enzymes in stool specimen that have increased diagnostic sensitivity. The fecal elastase assay exclusively detects the human enzyme form, and so no interference occurs with simultaneous pancreatic enzyme supplementation and is widely used in clinical practice due to ease of testing. Using a cutoff of 200 µg, fecal elastase concentrations greater than this have a sensitivity of 63% for mild, 100% for moderate, and 100% for severe disease. The sensitivity and specificity was 93% for all patients with exocrine pancreatic insufficiency.<sup>36</sup> However, this test has lower sensitivity and specificity in early disease and may be falsely abnormal in other diseases causing steatorrhea, such as short-bowel syndrome or small-bowel bacterial overgrowth syndrome.<sup>37</sup>

**FIG 59.1** Chronic pancreatitis on digital radiography. Anteroposterior digital radiograph obtained as a scout image during endoscopic retrograde cholangiopancreatography (ERCP) shows multiple calcifications in the expected location of the pancreas with a plastic pancreatic duct stent.

**FIG 59.2** Chronic pancreatitis on computed tomography (CT). CT image shows diffusely decreased enhancement relative to the renal cortices.

#### Tests of Pancreatic Structure

##### Plain Abdominal Radiography

Calcifications within the pancreas are present on plain films in approximately one-third of patients with CP (Fig. 59.1). Calcifications occur late in the natural history of CP and may take 5 to 25 years to develop.<sup>31,38</sup> The finding of calcification is pathognomonic of CP, but the sensitivity of this test is very low.

##### Computed Tomography

The sensitivity and specificity of computed tomography (CT) for the diagnosis of CP is 75% to 90% and 85%, respectively.<sup>31</sup> The main advantage of CT is that it can be standardized and can visualize the entire pancreas. CT scan is the most sensitive test for detecting calcification, is accurate in detecting main pancreatic duct dilation, and can detect an irregular contour of the gland (Fig. 59.2).<sup>31,38,39</sup> These features are seen in advanced CP and CT is excellent in detecting these changes. However, CT is poor at detecting subtle abnormalities in pancreatic parenchyma or changes in side branches of the pancreatic duct, which are commonly seen in milder forms of the disease. CT has good specificity but lacks sensitivity for the diagnosis of CP. The newer multi-detector CT scanners may produce better sensitivity.

**FIG 59.3** Chronic pancreatitis on magnetic resonance cholangiopancreatography (MRCP). Coronal two-dimensional MRCP shows diffuse, irregular side branch dilation and dilation of the main pancreatic duct.

### Magnetic Resonance Cholangiopancreatography

Several small studies have reported on the utility of magnetic resonance cholangiopancreatography (MRCP) in assessing pancreatic duct morphology.<sup>43,44</sup> MRCP agrees with endoscopic retrograde cholangiopancreatography (ERCP) in 70% to 80% of findings, with higher rates of agreement in studies using the most advanced image analysis techniques (Fig. 59.3). In studies that compared MRCP findings with ERCP, MRCP visualized the main pancreatic duct in the head, body, and tail in 79%, 64%, and 53% of cases, respectively.<sup>41</sup> Correlation with ERCP with respect to main pancreatic duct dilation, narrowing, and filling defects was 83% to 92%, 70% to 92%, and 92% to 100%. The major disadvantage of MRCP compared with conventional cholangiography is that it has a lower spatial resolution, limiting its ability to detect subtle side branch changes, which are the earliest changes of CP.

Secretin-enhanced MRCP (SMRCP) involves administering intravenous synthetic secretin (0.2 µg/kg over 1 min) to stimulate pancreatic secretions and obtain heavily weighted T2 images of the pancreatic duct every 30 seconds over 10 minutes. This modality has recently been used to identify early changes of CP by detecting subtle abnormalities in duodenal filling, pancreatic duct compliance, and/or side branch ducts that may not be apparent on conventional MRCP.<sup>45</sup> However, due to the additional time, cost, and expertise required for the specialized protocol and interpretation of results, SMRCP is used mainly at specialized centers in select patients.

### Endoscopic Ultrasound

Endoscopic ultrasound (EUS) provides a safe, minimally invasive method of obtaining detailed structural information of the pancreatic parenchyma and ducts. There are two main advantages for EUS that make it a very sensitive test for CP. First, the pancreas lies within a few millimeters of the duodenum and stomach, allowing use of higher frequencies that provide high-resolution images (but less penetration). Second, by positioning the EUS transducer at certain stations in the stomach and duodenum, complete visualization of the pancreas can be achieved.

Numerous EUS criteria for pancreatic disease have been described (Fig. 59.4). Lees et al (1986, 1979)<sup>46,47</sup> first described EUS findings in patients with clinical and radiologic evidence of CP and characterized EUS criteria that distinguish a normal from an abnormal pancreas. Wiersema et al (1993)<sup>48</sup> refined these definitions and found that abnormal EUS changes occurred frequently in patients with abnormal endoscopic pancreatograms

**FIG 59.4** Chronic pancreatitis on endoscopic ultrasound (EUS). EUS shows the pancreatic duct (PD) becoming obstructed in the pancreatic head by a calcified intraductal stone causing upstream dilation.

**TABLE 59.3 Endoscopic Ultrasound Criteria for Chronic Pancreatitis**

Parenchymal Changes	Ductal Changes
Inhomogeneity	Ductal dilation
Hyperechoic foci	Hyperechoic main duct margins
Hyperechoic strands	Irregular main duct margins
Lobularity	Visible side branches
Pseudocysts	

and were absent in healthy volunteers. Criteria for CP that are specific to EUS can be divided into two groups (Table 59.3): parenchymal and ductal. Parenchymal criteria include inhomogeneity, hyperechoic foci, hyperechoic strands, cysts, and lobularity. Ductal criteria specific to EUS include obvious to more subtle ductal dilation ( $\geq 3$  mm in the head,  $\geq 2$  mm in the body,  $\geq 1$  mm in the tail), hyperechoic main duct margins, irregular main duct margins, and visible side branches.

A quantitative analysis with nine possible criteria (hyperechoic foci, hyperechoic strands, lobularity, ductal dilation, ductal irregularity, hyperechoic duct margins, visible side branches, calcifications, and cysts) suggested that in a population at low-to-moderate risk of CP, EUS is most reliable only when it is either clearly normal (two or fewer criteria) or clearly abnormal (five or more criteria).<sup>49</sup> When the threshold for normal is set at two or fewer criteria and the threshold for abnormal is set at five or more criteria, the predictive values are 85%.<sup>50</sup>

Some of the controversy regarding the accuracy of EUS may be due to studies that use three or four criteria (i.e., mild abnormalities) as threshold values to distinguish normal from abnormal EUS. It is unclear whether minimal EUS changes reflect early CP disease. In a prospective study that compared EUS findings of the pancreas with surgical histopathology in 42 patients, there was a significant correlation between the number of EUS criteria and fibrosis score at histology ( $r = 0.85$ ).<sup>51</sup>

As EUS provides higher resolution imaging than other imaging methods and provides information on both the ducts and the parenchyma, it is logical to assume that it can detect

earlier changes of CP. Functional testing is said to become abnormal only after greater than 60% to 70% of pancreatic functional reserve is depleted.<sup>30</sup> If this is the case, it may also be reasonable to expect that EUS could detect subtle structural changes that predate functional abnormalities. Finally, even severe CP can be asymptomatic. EUS may show pancreatic abnormalities in asymptomatic individuals. It has been shown that alcohol consumption is often associated with asymptomatic abnormalities.<sup>31,32</sup>

Elastography measures tissue resistance (strain) resulting from compression and different tissue elasticity patterns are demonstrated as different colors in a qualitative analysis (blue = hard tissue and red = soft tissue). Normal pancreatic parenchyma typically has a homogenous yellow and green pattern, whereas CP has a heterogeneous green and blue pattern.<sup>32</sup> Quantitative elastography involves calculating the strain ratio between the strain in the region of interest and a reference area in surrounding soft tissue.<sup>33</sup> Recently, quantitative elastography has been compared with standard EUS criteria for diagnosing CP. A high correlation was found between the number of EUS criteria and the strain ratio.<sup>34,35</sup> Another study has shown a strong correlation between quantitative EUS elastography strain ratio and the probability of suffering from exocrine pancreatic insufficiency.<sup>36</sup> To date, the role of contrast-enhanced EUS for the diagnosis of CP has not been well studied.

### Endoscopic Retrograde Cholangiopancreatography

In the past, ERCP with use of the "Cambridge criteria" was widely accepted as the most definitive method for interpreting pancreatography (Fig. 59.5). Studies cited a sensitivity of 70% to 90%, and specificity of 80% to 100% for diagnosing CP.<sup>30-35</sup> However, there are multiple limitations. CP can involve the pancreatic parenchyma per se and completely spare the radiographically visible portions of the pancreatic ductal system, leading to false-negative studies.<sup>37,38</sup> In addition, significant interobserver and intraobserver variability is noted in the interpretation of pancreatography.<sup>39</sup> Much of this variability is related to interpretation of mild pancreatographic changes rather than to severe abnormalities. Reliable interpretation of ERCP in the detection of early CP depends on adequate filling of side branches and this increases the risk of post-ERCP pancreatitis.

**FIG 59.5** Chronic pancreatitis on endoscopic retrograde cholangiopancreatography (ERCP). ERCP image shows irregular narrowing and dilation of the main pancreatic duct and irregular side branch dilation, most prominent in the body and tail.

Inadequate opacification of ducts, especially the secondary ducts, occurs in at least 30% of cases.<sup>31</sup>

ERCP is associated with a 3% to 7% chance of causing acute pancreatitis.<sup>40</sup> Therefore, due to the widespread use of EUS, limitations in pancreatography interpretation, and increased risk of pancreatitis, ERCP is no longer used solely for diagnostic purposes in CP.

## ENDOSCOPIC MANAGEMENT

Major goals of treatment in CP and targets for endoscopic therapy are pain relief and managing associated complications. Pain is thought to result from ductal obstruction and/or nerve damage caused by chronic inflammation and fibrosis. There are three approaches to management: decrease pancreatic exocrine secretion, decompress the pancreatic duct, and, if the first two fail, perform partial or complete resection of the gland. Successful pain management can be clinically challenging and a multidisciplinary approach is warranted. A combination of medical, surgical, and endoscopic modalities are often utilized with varying success rates due to the significant heterogeneity in the clinical presentation and natural history of CP patients. In addition to pain, other associated complications such as pseudocysts, biliary strictures, and duodenal obstruction can occur. For the purposes of this chapter, treatment will focus solely on endoscopic therapies.

### Pain Relief

#### EUS-Guided Celiac Plexus Nerve Block

Pancreatic pain is predominantly transmitted through the celiac plexus. Celiac plexus neurolysis, via a surgical or transcutaneous approach, has been used for many years to manage abdominal pain resulting from advanced malignancy.<sup>41,42</sup> These approaches have had complications such as paralysis, which might be overcome by better visualization of the region. The celiac artery is a landmark structure readily visualized on EUS (Fig. 59.6). Wiersema and Wiersema (1996) performed transgastric EUS-guided celiac plexus neurolysis and found that the success rate was similar to surgical or transcutaneous approaches.<sup>43</sup>

An injection of absolute ethanol that permanently destroys the plexus is referred to as a *celiac plexus neurolysis*, and an

**FIG 59.6** Celiac plexus block is being performed with the curvilinear array echoendoscope. The celiac artery is seen emerging from the aorta, and the needle is shown just above this point.

injection of local anesthetic and corticosteroids that temporarily blocks the plexus and reduces inflammation is referred to as a *celiac plexus block*. EUS-guided celiac plexus block and neurolysis are safe and well-tolerated procedures that can be performed in an outpatient setting with conscious sedation. Mild complications include transient diarrhea (4%–15%), transient orthostasis (1%), and transient increase in pain with neurolysis (9%). Major complications (2.5%) have included retroperitoneal bleeding and peripancreatic abscess.<sup>61</sup>

In a prospective study, Wiersema et al (1998) evaluated patients with pancreatic malignancy and CP treated by celiac plexus neurolysis, and found that the initial pain scores were similar between the two patient groups.<sup>62</sup> However, after 16 weeks of follow-up, the pain score improvement after celiac plexus neurolysis in patients with CP was not found to be significant. The malignant disease group had a mean pain score of less than baseline. Celiac plexus neurolysis is not recommended for the management of CP. Gress et al (1999)<sup>63</sup> compared EUS to CT-guided injection of triamcinolone in 22 patients with CP. At 8 weeks after the procedure, 50% of EUS patients had significant improvement in pain scores, whereas only 25% achieved this with the CT-guided approach. The corresponding results at 12 weeks were 40% and 12% for EUS and CT, respectively. In a prospective study of 51 patients with CP and pain who underwent celiac plexus block using either 1 or 2 injections, there was no significant difference in short-term pain relief between both cohorts.<sup>64</sup> Of patients, 57% who received a single injection had pain relief compared with 54% who received two injections.

Based on available data, the technique of performing celiac plexus block does not seem to affect treatment outcomes. Due to the complexity of pain associated with CP and the fact that most patients considered for celiac block have been on narcotics, it makes sense that this procedure is not a panacea for pain control in CP. It can be helpful to treat exacerbations of pain to avoid increasing narcotic dosages and sometimes it can be effective to move patients from an inpatient intravenous narcotic situation to an outpatient oral medical regimen.

### ERCP Therapy

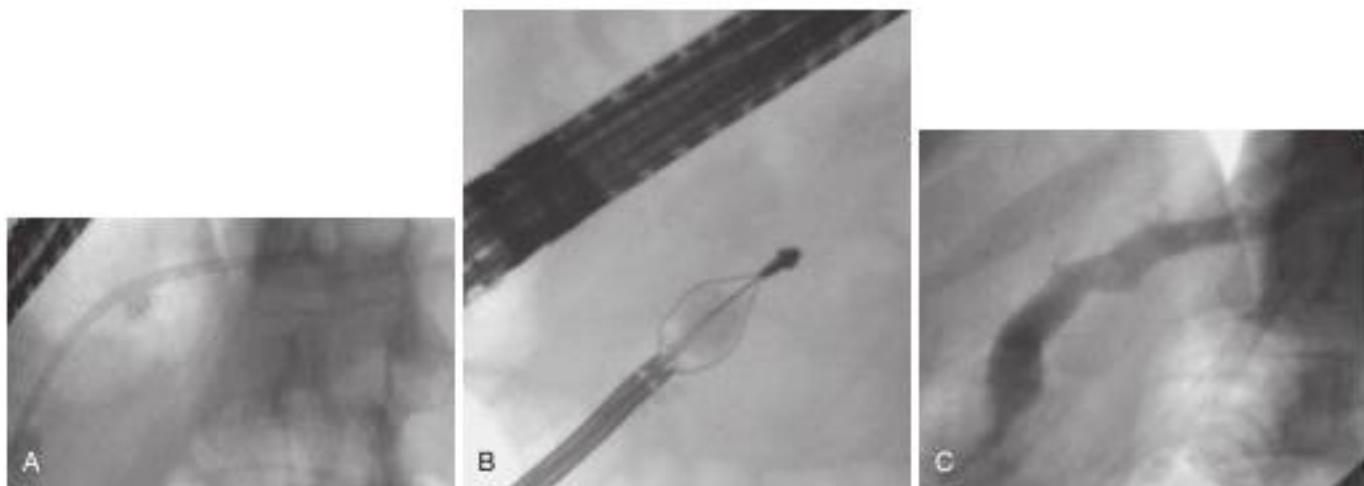

The goal of ERCP is to evaluate for an obstructive component to the pancreatopathy. Endoscopically treatable causes of obstruction can be at the level of the papilla (papillary stenosis) or along the course of the main pancreatic duct, primarily secondary to stones, strictures, or both.

**Pancreatic duct stones.** Approximately one-third of patients with CP have pancreatic stones. There is no close correlation between the presence of pancreatic duct stones and pain, and many patients with pancreatic duct stones report no pain. It is unclear if pancreatic calculi aggravate the clinical course of CP or are the consequence of ongoing glandular destruction from persistent disease processes. It is postulated that pain in CP is related to increased intrapancreatic pressure arising as a consequence of mechanical duct obstruction by stones with or without strictures.<sup>65,66</sup> This notion is supported by studies that show improvement in symptoms after ductal clearance of stones.<sup>71–76</sup>

Removal of pancreatic duct stones is recommended in patients with symptomatic CP and is most effective when applied to patients with chronic relapsing disease as opposed to those with chronic daily pain. More recently, treatment of obstructive pancreaticolithiasis in asymptomatic CP patients has been suggested to preserve pancreatic function and prevent gland atrophy. Given the limited data and risk of complications with endoscopic therapy, these authors would not currently endorse treatment in completely asymptomatic patients.

**Pancreatic sphincterotomy, stricture dilation, and stone removal with balloons and baskets.** The optimal conditions for successful endoscopic removal of pancreatic stones are a small number of mobile stones in the duct without significant strictures. Initial endoscopic management involves sphincterotomy, stricture dilation, and stone removal by baskets or balloons (Fig. 59.7 and Video 59.1). An impacted stone that impedes injection of contrast material into the pancreatic duct usually requires adjunctive therapy using extracorporeal shock wave lithotripsy (ESWL) or intraductal lithotripsy for clearance.

Removal of pancreatic stones requires an adequate opening of the pancreatic orifice. There is often thickening and fibrosis

**FIG 59.7** Pancreatic stone removal with endoscopic retrograde cholangiopancreatography (ERCP). ERCP images obtained before (**A**), during (**B**), and after (**C**) stone removal by lithotripsy. **A**, Scout ERCP image reveals a large stone within the main pancreatic duct. **B**, Second image was obtained during basket capture of the stone. **C**, Postprocedural ERCP image reveals absence of the stone within the duct and no evidence of residual obstruction.

or stenosis of the pancreatic orifice in CP. Cholangiography and pancreatography are performed initially, and the termination of both ducts is assessed. A biliary sphincterotomy may be performed first to improve access to the pancreatic orifice and to help expose the landmarks for completing a pancreatic sphincterotomy. Pancreatic sphincterotomy can be performed using either a standard pull-type sphincterotome (with or without a previous biliary sphincterotomy) or a needle-knife (usually over a previously placed pancreatic stent). In patients with pancreas divisum, a minor papilla sphincterotomy is required, which can be completed in the same way using a standard papillotome or a needle knife over a minor papilla stent. The ability to remove a stone by endoscopic methods alone depends on stone size and number, location inside the duct, presence of downstream stricture, and degree of impaction.<sup>73</sup> Downstream strictures may require dilation either with catheters or with hydrostatic balloons.

The conformation of the main pancreatic duct significantly influences the endoscopic approach to stones. If the duct makes a sigmoid turn or there is an ansa (360-degree turn within the head), it is almost impossible to get baskets or the single-operator cholangioscope around the turns. Negotiating around the genu can also be problematic if the turn is tight or there is a partial ansa. Soft-wire or wire-guided baskets may be necessary to navigate these tortuous areas of the pancreatic duct. Pancreatic stones are usually very hard because of the makeup of their crystalline structure. Careful assessment of the main pancreatic duct downstream of the stone is important prior to grasping stones to avoid basket impaction. In a grossly dilated duct, a "through-the-scope" mechanical lithotripsy device can be used, but this is often restricted to stones in the head of the pancreas with a straight line of approach to the stone. Otherwise, the rigidity of this device and its large diameter are restrictive. This device may also be used through a very dilated dorsal duct if it permits a straight approach.

Sherman et al (1991)<sup>74</sup> reported that endoscopic therapy was effective in 83% of patients presenting with chronic relapsing pancreatitis compared with 46% of patients presenting with continuous pain alone. Factors favoring successful endoscopic therapy included three or fewer stones, stones confined to the head or body of the pancreas, stone size less than 10 mm, absence of impacted stones, and absence of downstream strictures. After successful stone removal, 25% of patients had regression of ductographic changes of CP, and 42% had a decrease in the main pancreatic duct diameter. The only complication was pancreatitis encountered in 8% of patients. Studies have reported success rates with endoscopic therapy of 45% to 79% and improvement in symptoms of 60% to 90%.<sup>75–78</sup> One study reported clinical improvement in steatorrhea in 73% of patients after endoscopic management.<sup>79</sup>

### Advanced Lithotripsy Techniques

**Electrohydraulic lithotripsy.** Electrohydraulic lithotripsy (EHL) may be an effective adjunct to endoscopic treatment of pancreatic stones.<sup>76</sup> In this technique, shocks are delivered in a fluid medium under direct visualization because inadvertent firing on tissue can cause perforation or bleeding. This technique requires the use of a small-caliber pancreatoscope (either a "baby" scope or single-operator disposable catheter; SpyDigital, Boston Scientific, Natick, MA) that is passed up the pancreatic duct to the stone.

Direct pancreatoscopy is mandatory to assure the EHL probe is against the stone and not the duct, manipulation within the main pancreatic duct remains difficult, and very limited smaller

caliber baby scopes are fragile and have limited one-way tip deflection, which may hinder their utility. Additionally, the operating channel diameter is 0.75 to 1.0 mm and accepts only specialized, ultrathin accessories. The EHL probe is 1.9-Fr in diameter and can be used, but channels of 1.0 mm or less do not allow for much coaxial perfusion of saline necessary for lithotripsy. Saline is essential for transmission of the shock waves at the stone surface and for irrigation to clear debris.

Placement of a nasopancreatic tube (5-Fr) beyond the stone before pancreatoscopy is helpful for irrigation purposes, but requires that the main pancreatic duct is very dilated with no downstream strictures. Advancing the pancreatoscope requires an ample pancreatic sphincterotomy for insertion and may require a guidewire to advance through a tortuous pancreatic duct. A 450-cm wire is placed into the duct beforehand, and the proximal stiffer end is back-loaded into the baby scope. The stiff end of the wire should be slightly bent before back-loading to help negotiate the elbow junction of the accessory port and the scope body.

**Laser lithotripsy.** An alternative to EHL is laser lithotripsy. The most common laser used currently is the holmium laser (Lumenis VersaPulse Laser, Boston Scientific, Natick, MA). The holmium laser tends to pulverize stones into smaller particles when compared with EHL, which can be an advantage in the pancreas. The laser fiber is also more durable than the EHL probe. There are limited data available, but a multicenter US study of 28 patients achieved complete duct clearance in 79% (22 patients) and partial clearance in 11% (3 patients).<sup>77</sup> Even after treatment, pancreatic stones tend to recur, but this recurrence can be treated again endoscopically, whereas the rate of repeat surgery for recurrent pain is 20%, with a striking increase in morbidity and mortality after repeated surgery.<sup>78</sup>

**Extracorporeal shock wave lithotripsy.** ESWL has become almost indispensable to specialized centers treating many patients with advanced CP.<sup>79</sup> ESWL is considered a first-line therapy in Europe and Asia for the management of symptomatic chronic calcific pancreatitis. In the United States, it is not widely available, usually performed by urologists who are not experienced with the difference in treatment when compared with kidney stones, and insurance coverage is erratic. As a result, it is used more as a salvage procedure if endoscopic attempts fail. Stones are amenable to ESWL in almost all patients because the biochemical composition of the stones consists of 95% calcium carbonate on a protein matrix. The procedure is contraindicated only in patients who have coagulation disorders or who have calcified aneurysms or lung tissue in the shock wave path.

In some patients, a radiologic target is needed that can be provided by the placement of a stent. Fluoroscopic focusing of densely calcified stones can be achieved without pancreatoscopy. In other patients, MRCP with secretin or CT can show pancreatic ductal obstruction related to stones. For very small stones or radiolucent stones, visualization can be improved by instillation of contrast material via a nasopancreatic catheter. Patients require sedation, which can range from conscious sedation to general anesthesia. Routine antibiotic prophylaxis is unnecessary.

Shock waves are focused first on the distal-most stone and then on other calculi moving from the head to tail, allowing stone fragments to drain downward through the papilla. In one treatment session, 3000 to 5000 shock waves using the highest possible energy levels are delivered. Pancreatic stones are hard and usually require a higher-powered shock wave (22–24 kV). Each session lasts approximately 45 to 60 minutes.

ESWL is an effective adjunct to the nonsurgical endoscopic approach in chronic calcifying pancreatitis with complete or partial relief of symptoms in 80% of patients, which is comparable to the surgical literature.<sup>51,52</sup> In one study, stones were successfully fragmented in 99% of patients, resulting in a decrease in duct dilation in 90%.<sup>53</sup> The main pancreatic duct was cleared of all stones in 59%. However, one of the challenges in pancreatic duct therapy is evaluating treatment efficacy. Disintegration of a stone can be considered successful when a decrease is seen in the radiographic density of the stone or the stone surface area. In addition, the ability to show relief of ductal obstruction at deep cannulation of the pancreatic duct during ERCP is an indicator of treatment efficacy. Using the aforementioned criteria, the success rate of fragmentation has been approximately 76% to 100% in most series, regardless of the shock wave system used.<sup>50-53</sup>

Most patients require endoscopic extraction of stone fragments after ESWL for complete clearance from the ductal system. Some authorities recommend that pancreatic sphincterotomy be performed before ESWL to facilitate stone passage.<sup>51,54</sup> With the exception of one report<sup>55</sup> in which successful treatment was more frequent in patients with solitary stones (74% vs. 43% for multiple stones), successful fragmentation and stone clearance was not correlated with the initial size or the number of main pancreatic duct stones by others.<sup>54-56</sup>

Repeat ESWL may be required if stones have not been adequately fragmented; this can be the case in patients with large, impacted, or multiple stones. The reported mean number of treatment sessions required to complete lithotripsy has ranged from 1.3 to 4.1 per patient in most reports.<sup>51,53,56</sup> The radiographic success of ESWL has been associated with clinical improvement (Table 59.4). Complete or partial pain relief was observed in 62% to 97% of patients in the largest series during a mean follow-up ranging from 7 to 44 months.<sup>50,54,56-59</sup> However, complete stone clearance was not required for symptom relief. Many patients gained weight because of a reduction in postprandial pain attacks, improvement in pancreatic function, or both. The number and location of stones, the presence of a stricture, or continued alcohol use did not seem to be associated with recurrent pain.<sup>55,58</sup> As a result, ESWL does not have to be restricted to patients without these unfavorable clinical characteristics.

One study<sup>59</sup> identified three independent predictors of pain relapse at long-term follow-up after ESWL therapy: (1) a high frequency of pain attacks before treatment (more than or at least two pain attacks during the 2 months before treatment), (2) a long duration of disease before treatment, and (3) the presence of a nonpapillary stenosis of the main pancreatic duct. This study suggests that ESWL in association with endoscopic therapy should be performed as early as possible in the course of CP. In another study, pain relapse was noted to occur more frequently in patients who had incomplete removal of stones than in patients in whom ductal clearance was complete.<sup>56</sup>

Early ductal decompression of the main pancreatic duct may also help prevent further fibrosis, which can lead to pancreatic insufficiency. In addition, it may improve pancreatic function in patients who have already developed pancreatic insufficiency. Although some studies investigating this issue found that exocrine pancreatic function improved more often after treatment compared with endocrine pancreatic function, others have shown progressive deterioration in both exocrine and endocrine functions at long-term follow-up.<sup>50,51,56-58</sup>

In a multicenter study, the rate of recurrence of pancreatic duct stones after ESWL was reported to be 20% to 30%.<sup>59</sup> Factors predictive of stone recurrence included ongoing alcohol use and the presence of pancreatic duct strictures. Complications in series using ESWL were primarily related to the endoscopic procedure.

### Endoscopy Versus Surgery

Two prospective, randomized studies comparing surgical and endoscopic therapy in chronic calcific pancreatitis have been reported in the literature.<sup>59,60</sup> In the first study,<sup>59</sup> 140 patients with obstructive CP were treated either by endoscopic therapy or by surgical resection or drainage procedures. Although immediate relief of symptoms was identical in both groups (51.6% in the endotherapy group vs. 42.1% in the surgical group), at 5 years of follow-up complete absence of pain was more frequent after surgery (37% vs. 14%), with partial relief of pain being similar (49% vs. 51%). The increase in body weight was also greater by 20% to 25% in the surgical group, whereas new-onset diabetes mellitus developed with similar frequency in both groups (34% in the surgical group vs. 43% in the endotherapy group).

ND, Not determined.

In the second randomized trial of 39 patients with CP and pain, patients managed surgically had lower pain scores and better quality of life at 2-year follow-up.<sup>51</sup> In addition, although only 32% of patients randomly assigned to endoscopy had better or partial pain relief, 75% of patients randomly assigned to surgery had better pain relief. There was no difference in the complications, length of hospital stay, and pancreatic function between both groups; however, patients undergoing endotherapy required more interventions.

More recently, these studies have been included in two meta-analyses by the same Dutch group of Ahmed et al, published in 2012 and then updated in 2015, comparing endoscopic versus surgical intervention for painful obstructive CP.<sup>51,52</sup> The 2015 study also included an additional study examining surgery versus conservative management (no intervention) for a total of 143 patients.<sup>52</sup> This meta-analyses showed that compared with the endoscopic group, the surgical group had a higher proportion of participants with pain relief, both at long-term follow-up ( $\geq 5$  years; relative risk [RR]: 1.56; 95% confidence interval [CI]: 1.18–2.05). Morbidity and mortality were similar between the two intervention modalities, but the small study sizes may have been underpowered to detect differences. Regarding the comparison of surgical intervention versus conservative treatment, this 2015 study suggested that surgical intervention in an early stage of CP should be considered in terms of managing both pain control and pancreatic function. Obviously, these results will need further validation in larger studies, but the limited available data suggest more durable success in terms of pain management with surgery over endoscopy in patients with obstructive chronic calcific pancreatitis.

### Pancreatic Duct Strictures

Pancreatic duct strictures (Fig. 59.8) may be a complication of a previously embedded stone or a consequence of acute inflammatory changes around the pancreatic duct. Pancreatic duct strictures may contribute to pain, recurrent acute pancreatitis, and exocrine insufficiency. Strictures may also be associated with stones, pseudocysts, and pancreatic malignancy.<sup>53–56</sup> The mechanism of pain in patients with pancreatic strictures is poorly understood, but may be partly attributable to pancreatic duct hypertension. Pancreatic duct strictures may be present in association with biliary strictures, and liver function test abnormalities, jaundice, and cholangitis may be presenting symptoms.

**FIG 59.8** Endoscopic retrograde cholangiopancreatography (ERCP) shows changes of chronic pancreatitis with a stricture in the main pancreatic duct.

Endoscopic therapy for pancreatic duct strictures is primarily indicated for patients presenting with refractory abdominal pain, with or without upstream ductal dilation.

### Stenting and Dilation

The technique for placing a stent in the pancreatic duct is similar to the technique used for inserting a biliary stent. A guidewire is first maneuvered beyond the stricture several centimeters. Hydrophilic, flexible-tip wires are generally helpful. Pancreatic stents are similar to biliary stents, except for side holes along their length to allow for flow from side branches. Generally, the diameter of the stent should not exceed the size of a normal downstream duct. In small ducts, 3-, 4-, and 5-Fr stents are used commonly, whereas 7-Fr and 10-Fr stents can be used in advanced CP with dilated pancreatic ducts. Occasionally, in patients with small duct disease who have recurrent strictures, we place multiple 3-Fr stents to dilate the stricture. We believe that stent-induced trauma could be obviated by this method, but data are still forthcoming. In addition, the severity of the stricture, location, and duct size influence the choice of stent.

Generally, the best candidates for stent treatment are patients with a distal stricture and upstream dilation. Other therapy, such as pancreatic or biliary sphincterotomy, pancreatic duct stone removal, and dilation of strictures, may be required concomitantly at the time of stent placement. Dilation to widen single or multiple strictures of the main pancreatic duct in CP can be performed successfully. Dilating catheters with graded tips and balloons are generally used. In strictures where only a guidewire can be passed, use of the 7- or 8.5-Fr Soehendra stent-retrieval devices (Cook Endoscopy, Winston-Salem, NC) can be a successful salvage technique. The device is slowly rotated clockwise while pressure is applied with the same technique as advancing a stent through a tight stricture. After dilation, stents of adequate size are left in place to facilitate drainage and to prevent recurrent stricture formation. If stents larger than 7-Fr are to be used, patients often require dual sphincterotomy followed by stricture dilation. For optimal results, therapy must address both the pancreatic duct stricture and duct stones, if any are present.

The appropriate duration of pancreatic stent placement is currently unknown. Most stents in diagnostic trials or for short-term therapy are left in place for 2 to 4 weeks. In contrast, stents for long-term therapy are left in place for several months. If the patient has improvement in symptoms, the stent can be removed and the patient can be followed clinically, stent therapy can be continued for a more prolonged period, or a surgical drainage procedure can be performed. The last option suggests that the results of endoscopic stent treatment would predict the surgical outcome. Two studies support this concept, but more data are warranted.<sup>57,58</sup> Quantifying the degree of improvement in pancreatic disorders is often poorly defined. Generally, partial or complete symptom improvement indicates that intraductal hypertension was an etiologic factor. Continued improvement in symptoms after stent removal indicates adequate dilation of the narrowing. The results of stent insertion for dominant pancreatic duct strictures (Table 59.5) have been favorable, with technical success in 72% to 99%, relief of pain in 75% to 94%, and good long-term outcomes in 52% to 81%. Average stent indwelling time ranged between 3 and 12 months.<sup>50,59–61</sup>

Although long-term symptom resolution has been reported in more than 60% of patients, endoscopic resolution of strictures has been documented in only approximately one-third of patients managed by endoscopic stent placement.<sup>59–61</sup> Although these

**TABLE 59.5 Stent Therapy for Chronic Pancreatitis With Dominant Strictures**

Reference	No. Patients	Technical Success	No.	Mean Follow-Up
			Patients Improved	[Months]
Cremer et al <sup>91</sup>	76	75	41	37

Total	267	231 (94%)	154 (64%)	35

data suggest that stricture resolution is not a prerequisite for symptom improvement, other concomitant therapies at the time of pancreatic stent placement such as pancreatic sphincterotomy or pancreatic stone removal may account for successful outcomes. It is also likely that pain in CP tends to decrease over time as glandular destruction of the pancreas progresses in an uninhibited manner.<sup>26</sup>

In a study of 75 patients with pancreatic duct strictures and upstream dilation managed by placement of 10-Fr stents, Cremer et al (1991)<sup>91</sup> reported that 71 patients (94%) were improved over a follow-up of 3 years, with 40 patients (53%) symptom free. Improvement in symptoms was associated with a decrease in the pancreatic duct diameter. In addition, in a prospective study of 23 patients, Ponchon et al (1995)<sup>100</sup> reported that disappearance of stenosis at stent removal and a reduction in the pancreatic duct diameter by more than 2 mm were predictive of pain relief after pancreatic duct stent placement. Binmoeller et al (1995)<sup>102</sup> made a similar observation in their study of 93 patients with CP and dominant pancreatic duct strictures managed by pancreatic duct stent placement. Although 74% of the patients experienced complete or partial symptom relief, most patients were found to have a regression of ductal dilation after successful stent treatment.

### Multiple Stents

Based on data demonstrating that placement of multiple stents results in successful obliteration of benign biliary strictures, the role of multiple stents in pancreatic duct strictures has been evaluated. In a study of 19 patients, 11 patients with a single main pancreatic duct stricture underwent balloon dilation (6–10 mm) followed by placement of multiple stents (8.5–11.5 Fr) across the stricture site.<sup>104</sup> All stents were retrieved at a mean follow-up of 7 months. The median number of stents placed per patient was three, and the most common stent diameters used were 10-Fr and 11.5-Fr. During a mean follow-up of 38 months, 84% of patients were asymptomatic, and 10.5% developed symptom recurrence.

### Self-Expandable Metal Stents

Although all the previously described studies used conventional plastic stents, Cremer et al (1990),<sup>105</sup> in a pilot study, reported their experience with self-expandable metal stents (SEMSs) in

patients with CP. Stent placement through the major duodenal papilla was performed in 22 patients with relapsing dominant strictures of the main pancreatic duct. Successful placement, associated with an immediate decrease of pancreatic duct diameter and disappearance of pain, was noted in 100% of cases. Although no immediate complications were encountered, follow-up of these patients showed a high occlusion rate of these metal stents from mucosal hyperplasia.

Another pilot study evaluated the role of covered SEMSs (8-mm) in patients with refractory main pancreatic duct strictures.<sup>106</sup> The stents were retrieved by endoscopy 3 months after placement. Although the pain scores improved significantly, three out of six patients developed recurrent strictures warranting subsequent placement of large-caliber (10-mm) metal stents. Although this concept appears novel, more studies with a larger cohort of patients are needed to evaluate the role of covered metal stents in the management of benign pancreatic duct strictures. In addition, modification of these stents, which are designed for the biliary tree, will likely be needed before they are widely applied to the pancreatic duct. Direct comparative studies evaluating the efficacies of surgery and endoscopic therapy are required to identify a subset of patients who would benefit from either treatment modality.

### Stent-Related Adverse Events

Pancreatic stent therapy is not without consequences. Adverse events related directly to stent therapy include acute pancreatitis, pancreatic infection, pseudocyst formation, duct injury, stone formation, and migration.<sup>107,108</sup> The rate of pancreatic stent occlusion appears similar to that of biliary stents.<sup>99</sup> Most of these occlusions are without adverse clinical events, however, because pancreatic juice may siphon along the sides of the stent. Morphologic changes of the pancreatic duct directly related to stent placement occur in more than 50% of patients.<sup>107–110</sup> It is uncertain what the long-term consequences of these stent-induced ductal changes are in most patients, although permanent new strictures are seen in a few patients. EUS identified parenchymal changes in 68% of patients who underwent short-term pancreatic stent treatment.<sup>111</sup> Although such changes may have significant long-term consequences in patients with a normal pancreas, the outcomes in patients with advanced CP seem less certain.

### Associated Complications

CP may be associated with various complications. Splenic vein thrombosis, pseudoaneurysm formation, and common bile duct or duodenal strictures are occasionally encountered. Other complications such as pseudocyst formation and pancreatic ascites or pleural effusion are discussed in Chapter 58.

### Benign Biliary Strictures

Intra-pancreatic common bile duct strictures have been reported in 2.7% to 45.6% of patients with CP.<sup>102,111</sup> Common bile duct strictures can have serious sequelae of cholangitis, cholelithiasis, choledocholithiasis, intrahepatic stones, and secondary biliary cirrhosis. Deviere et al (1990)<sup>112</sup> evaluated the use of biliary stent placement in patients with biliary strictures secondary to CP. They reported that endoscopic biliary drainage is an effective therapy for resolving cholangitis or jaundice in this patient subset. However, the long-term efficacy of this therapy was unsatisfactory because stricture resolution rarely occurred.

Preliminary results using metal stents for this indication suggest they could be an effective alternative to operative biliary diversion.

More than 90% of patients had no recurrence of strictures at 3 years, but longer follow-up and controlled trials are necessary to confirm these findings.<sup>114,115</sup> In a nonrandomized retrospective study that compared surgical drainage procedures with stent insertion, Pitt et al (1989)<sup>116</sup> found a significantly higher success rate of 88% in the surgically treated group compared with 55% for patients managed by stent insertion. More recently, Cote et al (2016) published their results comparing plastic stents versus fully covered self-expandable metal stents (FCSEMS) in the treatment of benign biliary strictures, including those encountered in the post-transplant setting (65% of study patients) and with CP (31% of study patients).<sup>117</sup> Unfortunately, the study was not adequately powered to conduct subgroup analyses between these two groups and therefore all patients were analyzed together. In this randomized, open-label trial, FCSEMS were shown to be noninferior to multiple plastic stents. However, the mean number of ERCPs to achieve biliary stricture resolution was lower for FCSEMS (2.14) versus plastic (3.24; mean difference: 1.10; 95% CI: 0.74–1.46;  $p < 0.001$ ). Originally only approved for use in malignant disease, this study led to Food and Drug Administration approval of FCSEMS by Boston Scientific (Natick, MA) for use in benign biliary strictures. In our clinical practice, the FCSEMS is typically left in place for 2 to 3 months before being removed endoscopically using a snare or grasping forceps.

### Duodenal Obstruction

Duodenal stenosis is seen in approximately 5% of patients with CP, particularly patients with alcoholic pancreatitis. Coexistent obstruction of the common bile duct may be seen. The diagnosis is made at upper endoscopy or barium swallow. Attempts to dilate the stricture endoscopically are generally futile. The simplest and safest approach is operative drainage via gastrojejunostomy; this may be combined with drainage of the bile duct or pancreatic duct, or both.

Enteral stents that are currently available have been used in malignant obstruction with similarly high success rates (> 90%) compared with surgical gastrojejunostomy. However, more than 50% of enteral stents become occluded after 6 months. In addition, currently available enteral stents are uncovered and thus not removable. For these reasons, they would not be suited for use in benign disease such as CP.<sup>118–120</sup>

## FUTURE TRENDS

CP can be a difficult disease both from diagnostic and therapeutic aspects. Improvements in these areas could help prevent and manage long-term complications and perhaps reduce morbidity, mortality, and costs associated with this often debilitating disease.

### Developments in Testing

The available diagnostic armamentarium for CP focuses exclusively on pancreatic structure and function with inability to diagnose the disease in its early stages.

### CfTR Testing in Idiopathic Cases

The association between *CfTR* mutations and idiopathic CP raises the possibility of widespread use of genetic testing to evaluate idiopathic CP. The role of routine *CfTR* mutation testing is uncertain because no guidelines exist for genetic counseling or altered clinical management based on the results. As further research clarifies whether patients with idiopathic CP with *CfTR* mutations differ from other patients with idiopathic CP, this

information may lead to wider use of genetic testing during the evaluation of patients with idiopathic CP.

### Micro-RNA for Early Diagnosis

Micro-RNAs (miRNAs) have been established as modulators that control fibrogenesis and inflammation. One 2017 study demonstrated that there were significant differences of serum miRNA expression in patients with early and late CP and healthy controls.<sup>121</sup> This type of testing would enable earlier diagnoses of CP and initiation of management strategies prior to the development of late-stage complications.

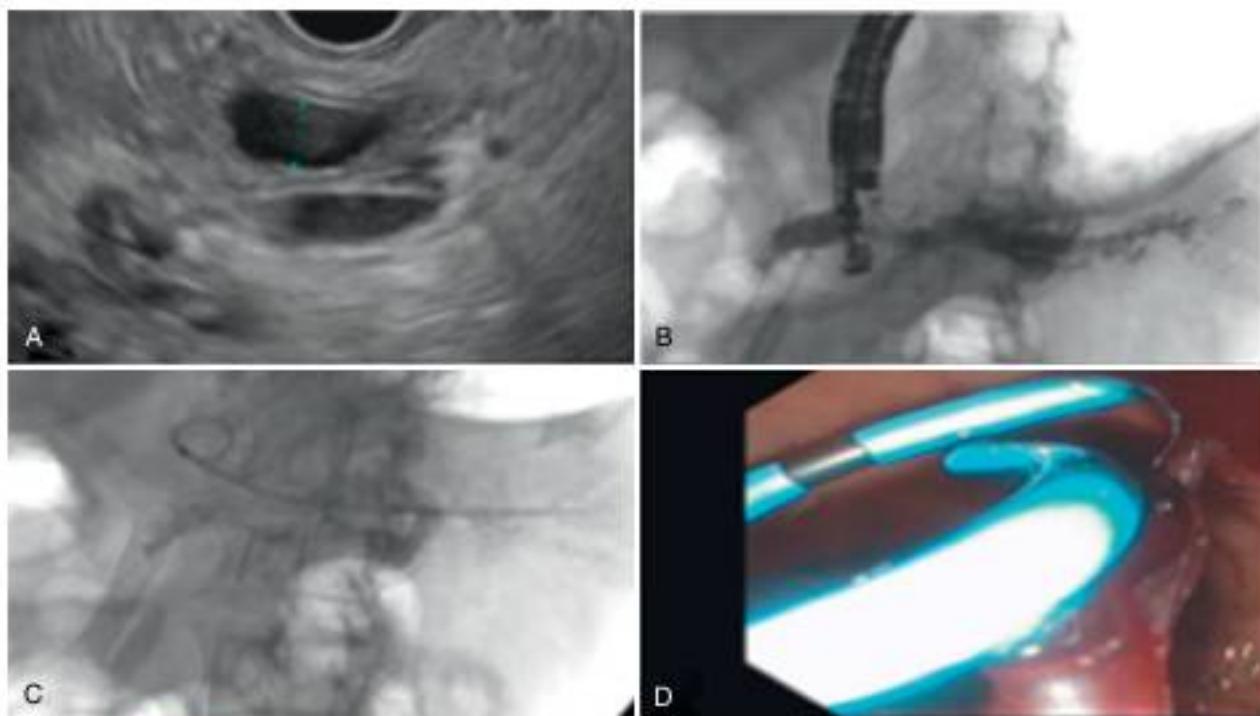

### Advances in EUS Techniques

#### EUS-Guided Pancreatic Duct Drainage

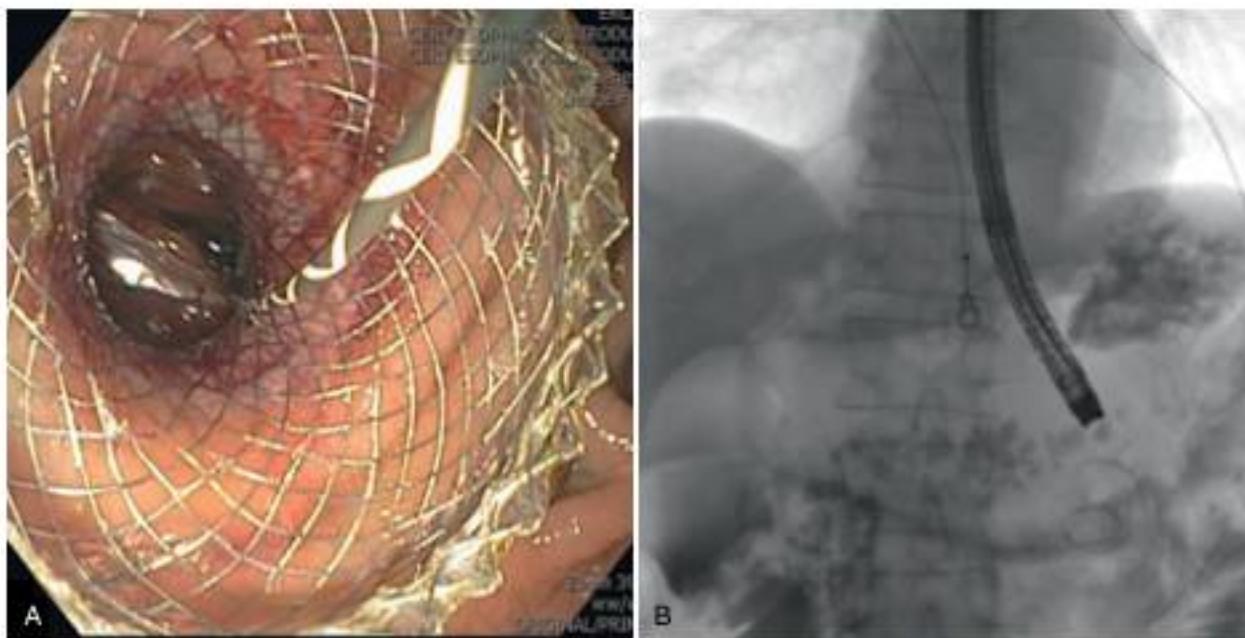

EUS has been advocated more recently as a means to establish pancreatic ductal drainage in patients after failed ERCP.<sup>122</sup> EUS-guided pancreatic duct drainage (EUS-PDD) can be accomplished either by rendezvous stent placement after passage of a guidewire into the main pancreatic duct and through the ampulla under EUS guidance, or by transmural drainage of the main pancreatic duct via the stomach or duodenum (Fig. 59.9). Itoi et al (2013) published a retrospective review of the published literature on EUS-PDD with varying technical success rates.<sup>123</sup> Technical success using the transmural technique was greater than 70% in 75 patients, whereas success rates with the rendezvous technique ranged from 25% to 100% in 52 patients. A more recent 2015 review by Fujii-Lau and Levy included 222 patients.<sup>124</sup> Technical success was achieved in 170 out of 222 patients (76.6%) and included both rendezvous and transmural EUS-PDD techniques. Reported technical difficulties include difficulty with dilation, wire passage and stripping, and inability to deploy stents or their migration.<sup>123,124</sup> Adverse event rates of nearly 20% have been reported and include pancreatitis, perforation, bleeding, and peripancreatic abscess.<sup>124–126</sup> More data are needed on long-term success rates and adverse events related to this technique.

#### EUS-Guided Gastroenterostomy

In the past few years, various EUS-guided techniques that utilize lumen-apposing metal stents (LAMS) have been described as an endoscopic treatment of gastric outlet obstruction (off-label indication). The LAMS is placed between the stomach and bypassed small bowel, with different techniques described including direct puncture with cautery-enhanced LAMS or needle puncture of a fluoroscopically placed dilation balloon and then LAMS deployment (both cautery and non-cautery) over a guidewire (Fig. 59.10). Two recent case series have been published on this technique as a treatment for both malignant and benign etiologies of gastric outlet obstruction. Khashab et al (2015) published the first American series of EUS-guided gastroenterostomy in 10 patients (7 with CP), and demonstrated high technical (90%) and clinical success rates (92%) with no adverse events.<sup>127</sup> Meanwhile, an international multicenter experience in 26 patients (9 with CP) reported similarly high technical (92%) and clinical success rates (85%), but did have significant adverse events in 11.5%.<sup>128</sup> These adverse events included peritonitis, perforation, and bleeding, with one death. EUS-guided gastroenterostomy is a promising technique that may obviate the need for invasive surgery in select patients. Currently, there are no data on optimal duration of LAMS placement. The goal would be a permanent anastomosis to allow for removal after a few months, but anecdotal reports have noted tract closure once the LAMS is removed. Therefore, some experts have advocated

**FIG 59.9** Endoscopic ultrasound (EUS)-guided transmural pancreatic ductal drainage (EUS-PDD). **A**, EUS view of dilated pancreatic duct (PD) of 7 mm. **B**, Radiographic view of pancreatogram (obtained from direct EUS puncture through the stomach) showing dilated PD with stricture in the head of the pancreas and guidewire placed into the pancreatic tail. **C**, Single pigtail plastic PD stent on radiographic view. **D**, PD stent on endoscopic view in the stomach.

**FIG 59.10** Endoscopic ultrasound (EUS)-guided gastroenterostomy using lumen-apposing metal stent (LAMS). **A**, Endoscopic view through LAMS in stomach showing small bowel. **B**, Radiographic view of LAMS with EUS scope.

leaving the LAMS in place indefinitely. Limited published data have shown that even in the hands of skilled endoscopists, this procedure can result in significant adverse events and should only be done in select patients at referral centers in collaboration with surgical colleagues. Similar to EUS-PDD, this therapeutic EUS maneuver warrants further study to establish the ideal technique and overall safety profile.

### INTRODUCTION

Indeterminate biliary stricture (IDBS) remains one of the biggest challenges that pancreaticobiliary endoscopists face. While a strict definition of IDBS is frequently not adhered to in the literature, this term refers to biliary strictures with no overt mass on noninvasive imaging such as computed tomography (CT) or magnetic resonance cholangiopancreatography, and that cannot be distinguished as malignant or benign after standard diagnostic procedures such as endoscopic retrograde cholangiopancreatography (ERCP) with tissue sampling (either brushing alone or in combination with biopsies). Surgical series demonstrate that 15% to 24% of patients who undergo resection for suspected malignant strictures based on preoperative imaging or ERCP will ultimately have a benign diagnosis on pathology.<sup>1,2</sup> This small but significant cohort of patients with benign strictures highlights the importance of accurate preoperative tissue diagnosis to avoid the morbidity and mortality of hepatobiliary surgery. For example, the two most common causes of malignant strictures are cholangiocarcinoma (CCA) and pancreatic cancer. Diagnosis of these malignancies at an early stage can allow curative surgical resection or even liver transplantation for early stage CCA. Tissue diagnosis of pancreaticobiliary malignancy via endoscopic approaches is well known to be limited due to poor cellular yield and often requires surgical exploration for definite diagnosis. This diagnostic dilemma ultimately serves as the driving force behind advances in biliary imaging, improvements in sampling techniques, and the identification of emerging molecular markers. This section will review the etiologies of biliary strictures, the initial clinical evaluation of IDBSs, the diagnostic yield of

ERCP-based sampling methods and recommended methods of improving acquisition and analysis, and the role of newer imaging tools in our approach to evaluating strictures.

### ETIOLOGIES OF BILARY STRICTURES

The leading causes of malignant biliary obstruction are pancreatic cancer and CCA.<sup>3</sup> CCA is a primary malignancy of the bile duct epithelium, and therefore can affect both intra- and extrahepatic ducts. It is the second most common primary liver malignancy after hepatocellular carcinoma.<sup>4</sup> When diagnosed in early stages, surgical resection can have an excellent prognosis.<sup>5</sup> The challenge, however, is in obtaining a histological diagnosis given the typically inadequate cellular yield from initial sampling methods such as ERCP with brush cytology and/or biopsy. Unfortunately, the differential for CCA includes a host of benign causes of biliary strictures that can radiographically mimic CCA.

Biliary strictures due to pancreatic cancer are most often found at the distal common bile duct and are due to extrinsic compression of the extrahepatic duct from a pancreatic head mass with or without biliary invasion. Diagnosis of biliary stricture in the setting of a pancreatic mass does not technically fall into the category of IDBS; however, early tumors may go undetected on cross-sectional imaging, and thorough evaluation of the pancreatic head in such strictures is a necessary part of the evaluation. This is in contrast to CCA, whose desmoplastic nature results in its growing in an infiltrative pattern along the length of the bile duct, making its early detection particularly difficult due to the lack of a visible growth or tumor on imaging. Other less common malignant causes of biliary strictures include intraductal

**Abstract**

Indeterminate biliary strictures, defined as biliary strictures with no obvious mass on imaging, that cannot be distinguished as malignant or benign despite initial endoscopic retrograde cholangiopancreatography (ERCP) and standard sampling methods, remain a challenge for pancreaticobiliary endoscopists. Advances in laboratory evaluation such as tumor markers and microRNAs may serve as complementary tools for diagnosing malignancies such as cholangiocarcinoma. Advances in imaging such as cholangioscopy, confocal endomicroscopy and optical coherence tomography may also help with optimizing identification of tissue to be targeted for biopsy. And lastly, advances in tissue sampling, such as combination sampling, molecular analysis, specimen presentation, and on-site analysis, may further improve accuracy in the evaluation of indeterminate biliary strictures.

**TABLE 60.1 Etiologies of Biliary Strictures**

Malignant	Benign
Cholangiocarcinoma	Chronic pancreatitis
Pancreatic adenocarcinoma	Primary sclerosing cholangitis
Ampullary adenocarcinoma	IgG4 (autoimmune) sclerosing cholangitis
Gallbladder cancer	Postsurgical, anastomotic stricture
Hepatocellular carcinoma	Mirizzi syndrome
Metastatic disease	Fibrostenotic benign stricture
Lymphoma	Ischemic stricture Radiation-induced stricture Infectious (HIV-associated, parasitic cholangiopathy, tuberculosis) Vasculitis

hepatocellular carcinoma, metastatic lesion, and extrinsic compression of the biliary tree from an associated visible mass or lymphadenopathy (Table 60.1).

The varying forms of malignant biliary obstruction are pathologically distinct and represent special problems when attempting tissue sampling. The first major pathologic factor influencing biopsy or cytologic yield is tumor cellularity. Pancreatic carcinoma, in particular, often stimulates an intense desmoplastic and fibrotic reaction, making the tumor very dense and of low cellularity. Sampling often produces acellular or false-negative specimens.<sup>6,7</sup> Maximizing yield requires repeated, deep, or large specimen sampling. Occasionally, an immune response or relative ischemia produces ulceration, bleeding, exudate, or debris that can obscure the rare malignant cell recovered in an endoscopic specimen. CCA of the primary type begins in the mucosa of the primary or secondary bile ducts. It is a relatively cellular cancer, and cells are more often shed in bile and can be more readily collected by sampling the superficial epithelium. However, the intrahepatic location of these tumors poses difficult access issues, making endoscopic ultrasound fine-needle aspiration (EUS FNA) yields lower, although the procedure is technically possible in select patients.<sup>18–21</sup>

Hepatocellular carcinoma can often invade and extend intraductally. Superficial sampling generally obtains diagnostic cells in this setting as well. As with pancreatic cancer, gallbladder cancer and, especially, metastatic cancer, encase or compress the biliary tree, often while preserving intact benign biliary epithelium. Establishing a tissue diagnosis often requires sampling deeper than the surface epithelium.<sup>8–10</sup> Very well-differentiated tumors represent a significant minority of malignant pancreaticobiliary tumors and prove very difficult to diagnose by cytologic criteria. Large specimens are often necessary to permit the pathologist to examine and compare these tumors to differentiate them from normal tissue. This fact likely explains why no biopsy technique, even open surgical wedge biopsy, has a 100% yield. These pathogenetic factors demand refined techniques and devices if adequate specimens are to be obtained to permit a positive cytologic or histologic diagnosis to be made in most cases.

Causes of benign biliary strictures include a variety of diseases ranging from recurrent cholangitis, postsurgical causes (most commonly after cholecystectomy or liver transplantation) to cholangiopathy from autoimmune disease, HIV, and primary sclerosing cholangitis (PSC). A long-standing yet poorly understood impersonator of a malignant stricture is autoimmune or

IgG4-associated sclerosing cholangitis (IgG4-SC). The prevalence and pathogenesis of this disease remains largely unknown, but more than 80% of patients will have elevations of serum IgG4 above the upper limit of normal, and a similar percentage of patients will have an associated autoimmune pancreatitis.<sup>11,12</sup> On cholangiogram, hilar IgG4-SC strictures can be indistinguishable from CCA. Histologic sampling, which can be diagnostic, may demonstrate diffuse infiltration of IgG4-positive plasma cells with fibroinflammatory involvement of the submucosa of the bile duct wall.<sup>13</sup>

## LABORATORY EVALUATION

The most common laboratory abnormality seen in patients with malignant biliary stricture is obstructive cholestasis. Direct hyperbilirubinemia is seen more commonly in patients with malignant obstruction than those with a benign etiology such as choledocholithiasis.<sup>14</sup> Hyperbilirubinemia also has a higher likelihood of being associated with malignancy than elevations in alkaline phosphatase.<sup>15,16</sup>

The most frequently used serologic markers for CCA are CA19-9 and possibly carcinoembryonic antigen (CEA). CEA has sensitivities and specificities that range from 33% to 84% and 50% to 87.8%, respectively.<sup>15–17</sup> Unfortunately, CA19-9 also has a wide range of sensitivity and specificity: 38% to 93% and 67% to 98%.<sup>15–18</sup> Furthermore, it can be undetectable in 7% of the general population due to absence of the Lewis antigen.<sup>20</sup> The variable diagnostic accuracies of CA19-9, therefore, limit its role in screening, and its greatest value may be in the surveillance of patients with PSC.

In response to this poor reliability of CA19-9, other serum tumor markers have been recently evaluated. For example, cytokeratin-19 fragments (CYFRA 21-1) get released into the bloodstream by malignant epithelial cells.<sup>21</sup> Several studies have demonstrated elevated CYFRA 21-1 expression in CCA, albeit with variable sensitivities depending on the cut-off value.<sup>17,20,21</sup> Specificities also vary given that elevation of CYFRA 21-1 expression has been reported in multiple other gastrointestinal (GI) and non-GI epithelial malignancies such as gastric, breast, and cervical. Similarly, high matrix metalloproteinase-7 (MMP-7) expression has been found to be associated with cancer invasion in esophageal,<sup>22</sup> colon,<sup>23</sup> and pancreatic<sup>24</sup> cancers. Given the lack of specificity for these individual markers, use of combinations of the markers may be the most useful, such as in multimarker panels. For example, a panel with the combination of these markers with CEA and CA19-9 demonstrated the highest diagnostic accuracy of 93.9%.<sup>21</sup>

Another serum marker, interleukin-6 (IL-6), which has been shown to be a biliary epithelial growth factor,<sup>25</sup> has demonstrated sensitivity as high as 100% in diagnosing CCA.<sup>26</sup> Like the other markers mentioned earlier, however, the specificities are limited due to its elevation in patients with hepatocellular carcinoma, benign biliary disease, and metastatic lesions.<sup>27</sup> Sperm-specific protein 411 (SSP411) is a protein that shows some promise in serving as a single serum-based biomarker given its elevation in the bile of CCA patients and use in distinguishing CCA from choledocholithiasis.<sup>28</sup>

Recent work has been performed evaluating the utility of measuring microRNAs (miRNAs) that are shed into the circulation in a free form when dysregulated in the setting of malignancies, compared to their stable protein-bound form.<sup>29</sup> The value of miRNAs lies in their tissue-specific patterns of expression.

MicroRNAs that are commonly upregulated in other epithelial cancers such as miR-192, 194, and 215 in colon, liver, pancreas, and stomach cancers,<sup>30</sup> are not altered in CCA. Conversely, CCA-specific miRNA expression profiles do exist, such as downregulation of miR-125a, -31,<sup>31,32</sup> or, alternatively, upregulation of some miRNAs such as miR-21.<sup>33–35</sup> The specificity is limited, however, given its upregulation in other cancers (gastric,<sup>36</sup> breast,<sup>37</sup> and colon<sup>38</sup>). As with tumor markers discussed earlier, perhaps the evaluation for miRNAs are best performed as part of a multimarker panels specific for CCA.

## ERCP

### History

While noninvasive imaging modalities such as magnetic resonance imaging/magnetic resonance cholangiopancreatography and computed tomography (CT) are an essential part of the baseline evaluation of biliary strictures, they carry low diagnostic accuracy in distinguishing benign from malignant causes of obstruction.<sup>10</sup> Furthermore, they provide no means by which to obtain tissue diagnosis and thus, when discussing IDBS, the gold standard remains ERCP.

ERCP was developed in the late 1960s as a diagnostic technique to provide detailed radiography of the biliary tree and pancreatic ducts. ERCP remained primarily a diagnostic tool until 1973, when endoscopic sphincterotomy was performed in Japan and Germany, specifically to allow for additional diagnostic and therapeutic maneuvers, such as performing forceps biopsies of proximal strictures.

### Tissue Acquisition During ERCP

The goals of ERCP for a suspected malignant biliary stricture are to first obtain definite tissue diagnosis to obviate the need for exploratory surgery, and second, to provide palliation of biliary obstruction with stent placement. In fact, the constant quest for improved methods of tissue acquisition remains the focus of innovation in biliary technology. Initial efforts were limited to simple aspiration of bile and occasionally pancreatic juice when deep cannulation was achieved. While specificity in early reports was uniformly 100%, low sensitivities of only 6% to 32% in six published studies<sup>39–44</sup> have caused this technique to fall from practice.

Aspirating bile after brush cytology has occasionally been reported to increase yield using standard cell block preparation.<sup>45</sup> Combined methods of tissue sampling will be presented later in this chapter.

Finally, advanced molecular diagnostics in bile, including proteomic, lipidomic, and volatile organic compound analysis, may reopen bile aspiration as an accepted modality to determine a malignant diagnosis with sufficient specificity.

### Brush Cytology Sampling Methods

Inadequate tissue acquisition at ERCP remains the most common reason for failing to establish an accurate pathologic diagnosis. Technical difficulty, time consideration, patient restlessness, and the need to proceed with the primary goal of biliary drainage all contribute to limit the time and thoroughness of tissue collection for many endoscopists. Because of these factors, brush cytology has been the universally adopted technique in clinical practice. Initially, standard nonwire guided endoscopic brushes were inserted, usually after sphincterotomy; however, negotiation through the stricture was often problematic. This factor and the

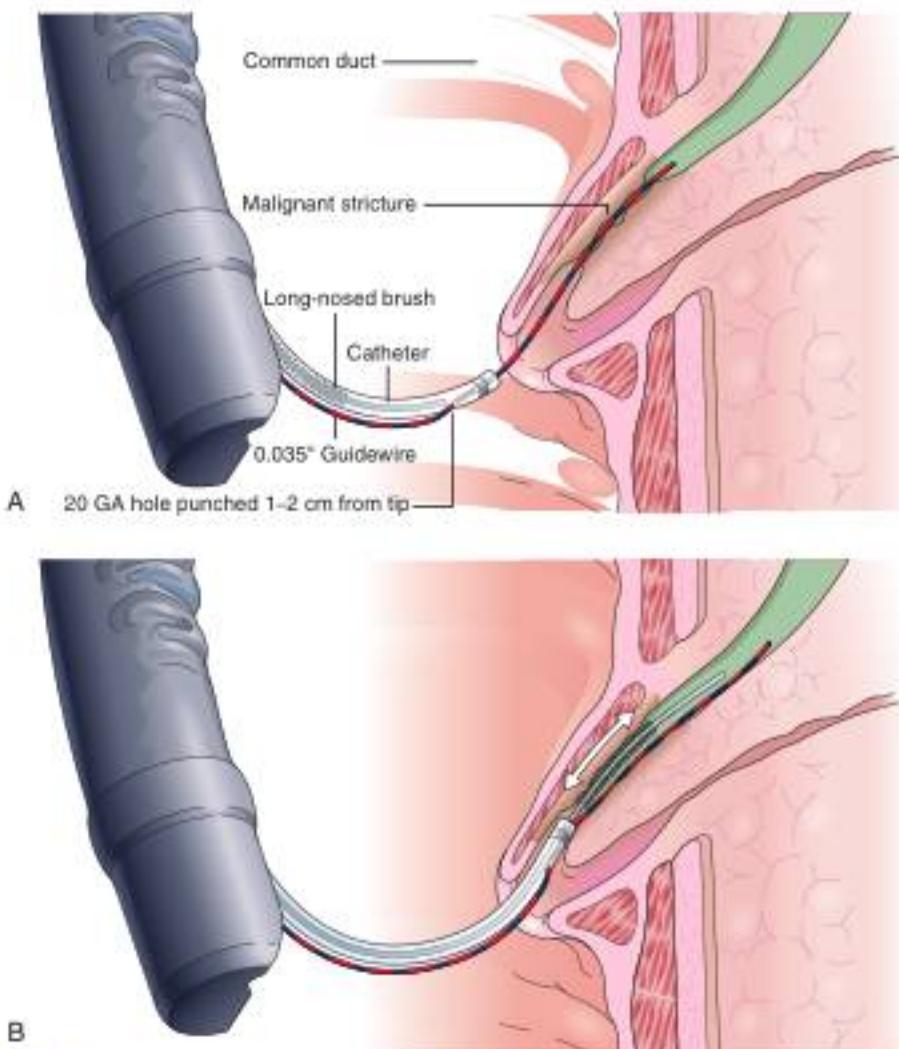

**FIG 60.1** Brushes for endoscopic retrograde cholangiopancreatography (ERCP) brush cytology. From top to bottom: **A**, Standard metal-tipped brush; **B**, Geenen spring-nosed brush in a diagnostic catheter; **C**, Cytomax 8-Fr brush catheter over a 0.035-inch guidewire; **D**, large HBIB brush for use in the Howell biliary introducer (HBI).

very superficial nature of this technique of sampling produced disappointing yields, and it never became popular. Thus, a variety of cytology brushes, some of which could be inserted over a guidewire placed through the malignant-appearing stricture before attempted sampling, were developed and are the devices we currently use today. These brushes are housed in catheters with a variety of diameters and stiffnesses, and the brushes themselves range in configuration as well as bristle length (Fig. 60.1). Techniques for performing brushing have subtle varieties but are centered around the idea of advancing the brush and catheter over the guidewire through the stricture, followed by manipulation of the exposed brush through the stricture multiple times. Protection of the acquired cells is paramount and best achieved by withdrawing the brush back into the catheter before leaving the area of the stricture (Fig. 60.2). Some also advocate for simultaneous aspiration of bile immediately after brushing, thereby collecting loose cells in the milieu of the brushing into the catheter before removing the entire device from the duct.

Published yields of ERCP brush cytology devices vary widely for reasons that can only be speculated. Generally, series that have a higher proportion of pancreatic adenocarcinomas and, perhaps, earlier smaller tumors, have a much lower yield of positive results compared with series with more cholangiocarcinomas. Published overall sensitivities using these devices range from 8% to 57%.<sup>43,46–51</sup>

A 2013 review of ERCP brush cytology covered 16 studies over 10 years from 2002 to 2012, which included a total of 1586 patients.<sup>52</sup> The combined yield of brush cytology ranged from 6% to 64% with an overall sensitivity of only 41.6%  $\pm$  3.2%, and did not appear to vary across new devices and techniques.

As discussed subsequently, many of these series are also flawed by including patients with "suspicious for malignancy" reports as positive results. A single center study of 142 patients with pancreatic or biliary cancer undergoing ERCP brushing reported in 2016 is such an example. The overall sensitivity was 58%, but actually only 50% in distal and presumably pancreatic cancer strictures. Adding "atypia" as a positive result increased yield to 65.5% but decreased specificity from 100% to 68.6%, clearly an unacceptable result.<sup>53</sup>

**FIG 60.2** **A,** Monorail brush: a long-nosed brush is preloaded into a diagnostic catheter and passed with the catheter over a guidewire in a monorail fashion through the stricture. **B,** The monorail catheter has been passed over the end of the guidewire well above the stricture. Once off the guidewire, the long-nosed brush can be advanced to brush the stricture. The long nose maintains access. The guidewire remains in place.

A probable pathologic explanation for these varied yields relates to the observation that the interiors of malignant strictures are composed of benign epithelium compressed by surrounding neoplastic tissue, with the exception of CCA of the major bile ducts. This fact explains the low yield of simple bile aspiration for cytology because few, if any, malignant cells are in contact with the bile flow as previously discussed. When the stricture is traumatized by dilation, removing the benign epithelium, the yield of aspirating bile increases.<sup>21</sup>

The yield of brushing is lower with deeper and more remote encasing tumors. One would predict the lowest yield is in metastatic malignancy, followed by pancreatic cancer, with a much higher yield with primary CCA. Generally, this prediction has been confirmed in clinical practice.

The type of brush bristles, the overall brush length, and the amount of time spent brushing all affect yield. Rabinovitz et al (1990)<sup>24</sup> used three separate brushes at each ERCP and repeated the procedure with three new brushes when suspicious strictures

were initially negative. Positive yield continued to increase until diagnoses were eventually made by brushing alone in 62% of their patients. Two additional ERCP brushing studies have been performed in an attempt to increase yield. In a large number of patients, a newer long cytology brush with stiff angulated bristles was compared with the standard-length brushes described previously. The true-positive yields were uniformly disappointing—only 27% and 30%—and no advantage was observed with the new brush.<sup>25</sup> The second study compared brushing with a more traumatic technique of inserting a grasping basket through the suspicious stricture. Of 50 malignant strictures, the basket technique had a near doubling of yield to 80% compared with a brush yield of 48% ( $p = 0.018$ ). The unexpected high yield of the brushing suggests some selection bias, and this technique requires additional study.<sup>26</sup>

Building on this concept of traumatizing the surface epithelium, a new scraping device was developed and trialed in Japan.<sup>27</sup> In 123 indeterminate stricture cases, 119 were eventually proven

**FIG 60.3** The Howell biliary aspiration needle (HBAN-22) is a 22-gauge Chiba-type needle mounted in a 7-Fr ball-tipped catheter, precurved for placement into the common bile duct (CBD) after sphincterotomy.

to be malignant. This device involves a three-leaf clover-type design of three nitinol loops, rather than bristles, that are compressed in guidewire-compatible catheters. The structure is roughly scraped and bile is aspirated using the device's side angled port. The yield was compared to a transpapillary forceps biopsy, and the device was also used in combination. The yields of forceps biopsy, the new scraping device, and both were 51%, 65%, and 75%, respectively. It is important to consider that 67% of their 119 cases had CCA and only 32% had pancreatic cancer. Furthermore, experience with this device is needed.

#### ERCP Needle Biopsy

Intraductal FNA during ERCP required the development of a specifically designed endoscopic accessory device. Howell et al (1992)<sup>40</sup> reported on such a device after developing a ball-tipped catheter with a retractable 22-gauge Chiba-type biopsy needle (HBAN-22; Wilson-Cook Medical, Bloomington, IN). The needle extends 7 mm beyond the ball tip when the catheter is placed within the duct, and permits deeper sampling than afforded by brushing (Fig. 60.3). Unlike transmural EUS-FNA, intraductal FNA cytology during ERCP traverses only tissue to be resected en bloc, and therefore there can be no contamination of the peritoneal cavity, including the lesser sac behind the stomach. The technique requires sphincterotomy, however, and proves to be technically challenging.

The initial relatively high yield of 62% (positive and suspicious samples) has not been reproduced in more recent series. The true-positive sensitivity has been reported to be 27% to 30% of cases in three series.<sup>41,42,43</sup> This technique has been used in combination with cytology and forceps biopsy, known as triple sampling, and is described later in the chapter.

#### Forceps Biopsy

Initially, there was only one method of performing intraductal forceps biopsies, known as fluoroscopically guided biopsies. Subsequently, with the development of cholangiography systems and accessories, directly visualized mini-biopsy forceps can be used as well. This method and its performance will be reviewed during the discussion of the role of cholangiography in indeterminate strictures. Initial efforts to perform fluoroscopically guided biopsies used gastroscopic forceps until special flexible-tipped duodenoscopic forceps (Olympus Medical, Center Valley, PA) were developed and proved to work better over the elevator. A large sphincterotomy was still required to pass these forceps retrograde up the duct.

The technique of forceps biopsy involves insertion of the device to the lower edge of the stricture. Using fluoroscopy, an accurate biopsy specimen can be obtained from the lower edge of the apparent tumor. Several passes of the forceps are required to produce an optimal yield. Reporting on their experience, Ponchon et al (1995)<sup>4</sup> suggested a minimum of three forceps bites.

For the technique to be practical, specialized forceps were developed. Several devices have been marketed to permit easier

**FIG 60.4** Howell biliary introducer (HBI; Wilson-Cook) with three tissue sampling devices advanced to biopsy or cytology position. Each device is placed sequentially to attempt to maximize yield at a single endoscopic retrograde cholangiopancreatography (ERCP) procedure. The HBI is placed over a prepositioned 0.035-inch guidewire.

insertion, including two devices that are purported not to need sphincterotomy. Easier to insert but still unguided, pediatric forceps of 5-Fr to 6-Fr work reasonably well but provide small specimens. Disposable 6-Fr pediatric forceps are now available, although they are relatively expensive. A device has been marketed to enable forceps placement over a guidewire. As previously discussed, the guidewire is generally placed early in therapeutic ERCP to ensure that the major goal of biliary stent placement is successful. It is logical to use the in-place guidewire for subsequent tissue sampling.

The guidewire-based device currently in use, developed by the author, is the Howell biliary introducer (HBI; Cook Medical). The 10-Fr device goes over a 0.035-inch or smaller guidewire while permitting the passage of a specially designed reusable 5-Fr long forceps (Fig. 60.4). Multiple passes of the forceps and other sampling devices can be quickly accomplished once the introducer is in position.

In a review published in two consecutive issues of *Gastrointestinal Endoscopy*, the journal of the American Society of Gastrointestinal Endoscopy (ASGE), de Bellis et al (2002)<sup>44</sup> tabulated all reports in the literature for the three major techniques, including forceps biopsy and ERCP tissue sampling, since 1989 (see Table 60.1). Complications of forceps biopsy have been reported but seem to be rare. Among the 502 patients tabulated in Table 60.1, major bleeding requiring transfusion in one cancer patient was reported,<sup>45</sup> and a significant perforation of a benign stricture required surgery in one additional patient.<sup>46</sup> The perforation may have been caused by the use of a large cup forceps and repeated biopsy sampling of the same location. Pediatric forceps produce a smaller specimen, but no complications were encountered in more than 200 cases. A review of the devices for endoscopic tissue sampling has been published by the ASGE Technology Assessment Committee.<sup>47</sup>

#### Combining Multiple Sampling Techniques

With the disappointing yields of single technique sampling as presented previously, endoscopists began to report their experience of combining techniques during the same ERCP procedure. Although this approach takes more time than a single technique, improved yields have made the combined approach the preferred

sequence in many, particularly academic, centers. Using standard brushes and nonguidewire forceps, Ponchon et al (1995)<sup>67</sup> reported improved combined yields for diagnosing cancer at ERCP. Although brushing had a sensitivity of 43% and forceps biopsy had a sensitivity of 30%, their combined yield was increased to 63% (a 20% overall gain). A more comprehensive approach was studied by the Indiana University group. Researchers attempted to perform all three techniques of brush, FNA, and forceps sampling and submitted withdrawn indwelling stents for cytology when present. This demanding approach resulted in a positive diagnosis in 82% of patients at a single ERCP.<sup>68</sup> When the investigators analyzed their results, each technique contributed to making the diagnosis in at least some patients. In other words, many patients had only one of the techniques positive, and the other two or three techniques were negative or equivocal.

Despite this report and the logic of this approach, the technique of triple sampling has not become a standard practice during ERCP. Several explanations can be advanced. The first and probably most important reason was previously discussed: triple sampling is technically difficult, time-consuming, and ancillary to the main goal of the therapeutic procedure.

The second may be the delay in tissue diagnosis when specimens are submitted for processing. Most important has been the wider availability of EUS-guided FNA cytology with its high sensitivity and safety.<sup>69</sup> EUS procedures are often done before ERCP, or during the same setting, especially when anesthesia is being used. This approach can shorten the ERCP, have a higher yield with multiple needle passes, and permit immediate cytologic diagnosis when a cytologist is in-suit. However, in many patients, a role remains for ERCP tissue sampling, especially when advanced disease makes EUS less valuable for staging and a cytologist is not available. Finally, newer techniques for intraprocedural tissue diagnosis during initial ERCP have been developed and will be discussed later in this chapter.

As introduced earlier, the HBI 10-Fr device introducer was developed to enhance the ability of the average endoscopist to perform triple sampling with a minimum of time, expense, and risk. The goal was to permit maximum sampling at various depths to increase the chance of detecting all three types of malignancy and to do so without requiring a sphincterotomy if so desired. The details of the device and our initial procedural sequence, techniques, and yields were reported in 1996.<sup>64</sup> An overall sensitivity of 69%, despite a large proportion of small early pancreatic cancers, suggested the potential of the device. The HBI introducer is a double-lumen 10-Fr tapered dilator that contains a 0.035-inch channel for a standard ERCP guidewire and a 6-Fr large channel for the introduction of endoscopic accessories.

The device includes a biliary introducer needle, which is a 5-Fr ball-tip catheter with a 22-gauge needle (HBIN, Cook Medical), 5-Fr reusable forceps (HBI forceps, Cook Medical), and a spring-tipped, through-the-channel brush (HBIB, Cook Medical). This brush has extra-long, extra-stiff bristles and is mounted on a stiff braided-wire shaft resulting in an aggressive device (see Fig. 60.1D). Its use is illustrated in Fig. 60.5.

A comparative trial of the HBI device against standard brushing was reported.<sup>65</sup> For the purpose of their study, the authors considered any "positive," "suspicious," or "atypical or suggestive of malignancy" to be true-positive samples. The authors used only the HBIN 22-gauge needle and HBI brush and reported an 85% yield compared with a sensitivity of 57% for brushing alone. Presumably, if the HBI forceps had also been used, yield would have been greater.

### Other Methods of Endoscopic Retrograde Cholangiopancreatography Tissue Sampling

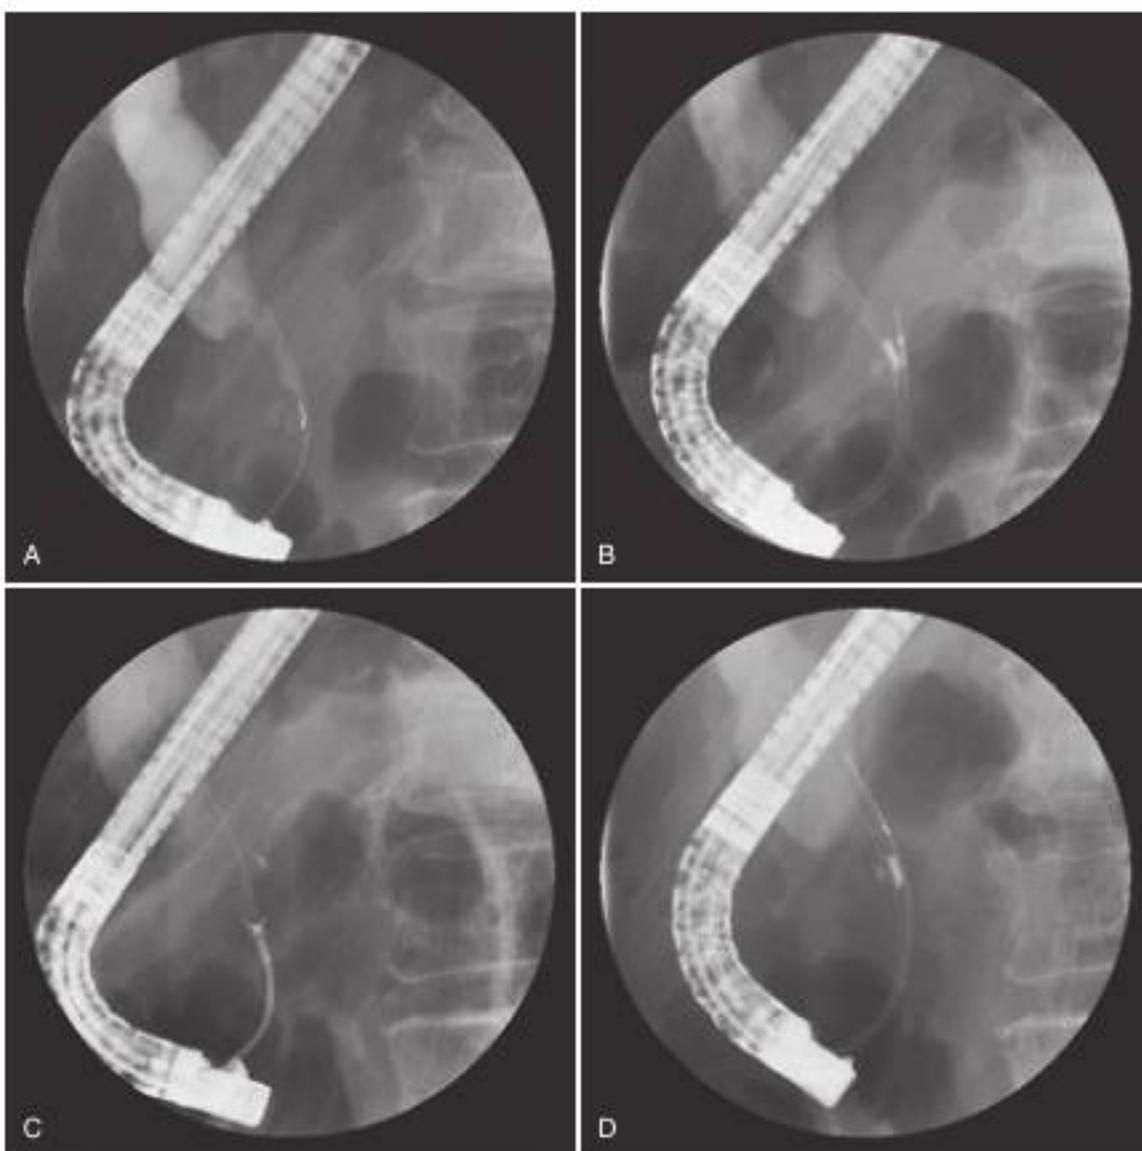

Numerous, less productive or controversial techniques of tissue acquisition have been reported and warrant review. Leung et al (1989)<sup>70</sup> originally reported that examining indwelling plastic biliary stents on their removal may produce a positive cytologic specimen when the diagnosis had not been established at the initial ERCP placement. Since 1989, only one series<sup>60</sup> has approached the initial 70% yield of Leung and coworkers. Most centers report only 11% to 44% positive specimens.<sup>63,68,69</sup> The most recent report (1997) of stent cytology included withdrawn pancreatic stents and stents from biliary strictures.<sup>71</sup> The true-positive yield from pancreatic stents was 25% compared with only 11% from biliary stents. In addition, the investigators agreed with other authors that the technique had limited clinical value because of the long delay in diagnosis when positive results were obtained.

Another approach to tissue acquisition at ERCP has been to attempt to collect specimens from the adjacent stricture of the pancreatic duct. Collection of pancreatic juice has been advocated by a few authors.<sup>71,72</sup> The technique involves deep insertion of a standard ERCP catheter and aspiration of juice below a malignant-appearing stricture. Yields may increase to greater than 50% with the infusion of secretin. This approach has not become popular, perhaps because of its complexity and concern for inducing pancreatitis. Pugliese et al (1995)<sup>73</sup> concluded that pancreatic juice collection did not add to positive diagnosis when pancreatic duct strictures were directly sampled by brushing.

Brushing in the pancreatic duct has been reported since 1979.<sup>74</sup> More recent reports (1994–96) emphasize that yields increase very little when a biliary stricture is also present and can be sampled.<sup>74–76</sup> Most concerning has been the report of postprocedural pancreatitis after pancreatic ductal stricture brushing. Vandervoort et al (1999)<sup>77</sup> noted a 21.5% pancreatitis rate after such procedures in both benign and malignant cases, but noted a marked decrease in risk if pancreatic temporary plastic stents were placed. Other authors have also advocated stent placement after pancreatic brushing, but all studies do not outline the eventual management and outcome of these temporary stents. The utility of stents is likely outweighed by subsequent procedures for pancreatic stent removal and delayed stent obstruction with resulting pancreatitis or sepsis, and other approaches to tissue sampling are favored. At the present time, we sample from the pancreatic duct only when a pancreatic stent is clinically warranted to manage obstructing pancreatitis, fistula, or upstream pseudocyst. We prefer to use the over-the-guidewire technique for brushing as outlined previously, so that the guidewire, which was placed before tissue sampling, can remain in position.

### Specimen Handling and Analysis

When intraprocedural diagnosis is not a goal or not available, specimens need optimal care. Improper handling of collected specimens remains a problem in many endoscopy units. A major cause of uninterpretable smears is an air-drying artifact that can occur rapidly after creation of appropriate thin smear.<sup>78</sup> Thick smears and specimens with excessive blood are other significant problems.<sup>79</sup> Slide preparation requires the time and attention of ERCP team members during a busy and often complex procedure. Preference should be given to depositing all collected specimens into transport media rather than preparing any smears or slides in the ERCP suite, unless an in-suit cytologist is present. Available transport media include 95% ethanol or commercially prepared

**FIG 60.5** Howell biliary introducer (HBI) triple device tissue sampling. **A**, The guidewire is first negotiated through a malignant-appearing stricture. Sphincterotomy is optional. **B**, HBI preloaded with the 5-Fr, 22-gauge needle for fine-needle aspiration (FNA) is placed over the guidewire and positioned just beneath the lower edge of the stricture. The needle has been thrust into the tumor at 30 degrees from the axis of the guidewire. **C**, The 5-Fr reusable HBIN forceps is passed for repeat biopsies of the lower edge of the stricture. **D**, To perform brush cytology with the HBI, the introducer is advanced so that the metal port lies above the stricture. The special brush (HBIBI) is advanced into the proximal duct. The introducer is pulled down into the stricture to permit vigorous brushing with adequate side pressure to maximize cellular collection.

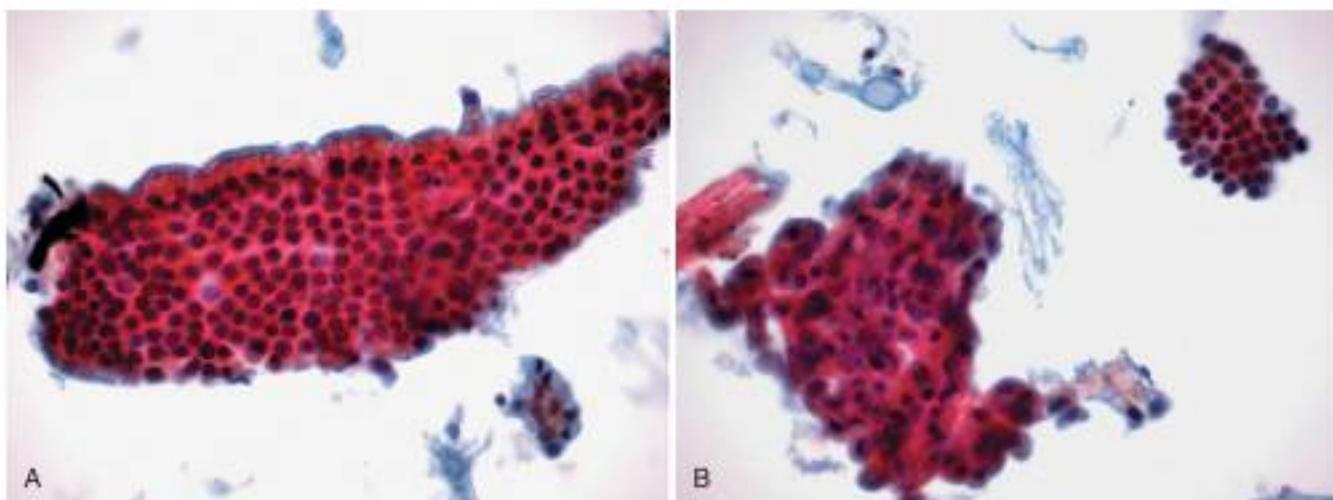

solutions such as CytoLyt (Cytac Corporation, Marlborough, MA) or CytoRich (UtoCyte, Burlington, NC). Papanicolaou-stained spun smears and, when applicable, hematoxylin and eosin-stained cell block sections are prepared for cytologic evaluation. In our institution, we prefer CytoLyt solution, which lyses red blood cells and minimizes obscuring debris, with smears prepared via the Thin Prep method (Cytac Corporation).

Interpretation of specimens should follow accepted cytologic criteria to be clinically useful. Several such schemes exist with each accepting frankly positive (Fig. 60.6A) and negative (see Fig. 60.6B) features. Intermediate cytologic abnormalities present

on the slides may lead to interpretations such as "atypical," in which mild cellular abnormalities are usually associated with inflammation and reparative changes, and "suspicious," in which there are rare cells exhibiting cytologic features of malignancy, but they are present in insufficient numbers to render a definitive diagnosis of malignancy.

In patients with PSC or postbiliary irradiation, be aware that cytologic changes can result in occasional false-positive samples. A larger series noted only 80% specificity in this setting.<sup>79</sup>

The findings of "cellular atypia" should include criteria that make the diagnosis of malignancy unlikely and demand further

**FIG 60.6** **A**, Benign biliary sample collected at endoscopic retrograde cholangiopancreatography (ERCP) by fine-needle aspiration (FNA). The specimen shows normal monolayer architecture with cells of high cytoplasm-to-nuclear ratio. The nuclei are smooth with fine chromatin and without obvious nucleoli. **B**, ERCP-collected specimen reveals malignant features diagnostic of adenocarcinomas. Note the clusters of cells with nuclear crowding. The nuclei have irregular membranes, coarse chromatin, and prominent nucleoli. Finally, the nuclei are large, producing high nuclei-to-cytoplasmic ratio.

attempts at confirmation. We interpret all atypia findings as negative, understanding that many will turn out to be falsely negative. Finally, because of the inherent difficulties in ERCP tissue sampling, negative results can never be accepted as definitive.<sup>7,11</sup>

Sampling problems are often due to the relative hardness of pancreaticobiliary adenocarcinomas that may greatly resist needle puncture and forceps sampling. These desmoplastic tumors can be relatively hypocellular, resulting in inadequate numbers of cells for interpretation. A small fraction of adenocarcinomas are so well differentiated they can be diagnosed histologically only in the setting of an excisional biopsy to permit the recognition of invasion; this is also true of lymphoma, which does occasionally produce biliary obstruction. As previously discussed, metastatic lesions obstructing the biliary tree are relatively deep and cannot be readily accessed at ERCP from within the ductal stricture, except occasionally by intraductal FNA. These lesions are best approached with EUS FNA or the new core-type needles. All these factors result in a low negative predictive value in all series reporting techniques of tissue sampling. This low negative predictive value should not discourage endoscopists from developing a preferred sequence of tissue sampling at ERCP because specificity in most reports is generally 100% for true-positive samples except as noted previously. A false-negative result leads to additional invasive tests, procedures, or surgery,<sup>10</sup> the same result as when no effort is made. Using the outlined techniques of endobiliary sampling during ERCP, patients receive benefit at a minimum of expense and risk.

### Intraprocedural Techniques at ERCP

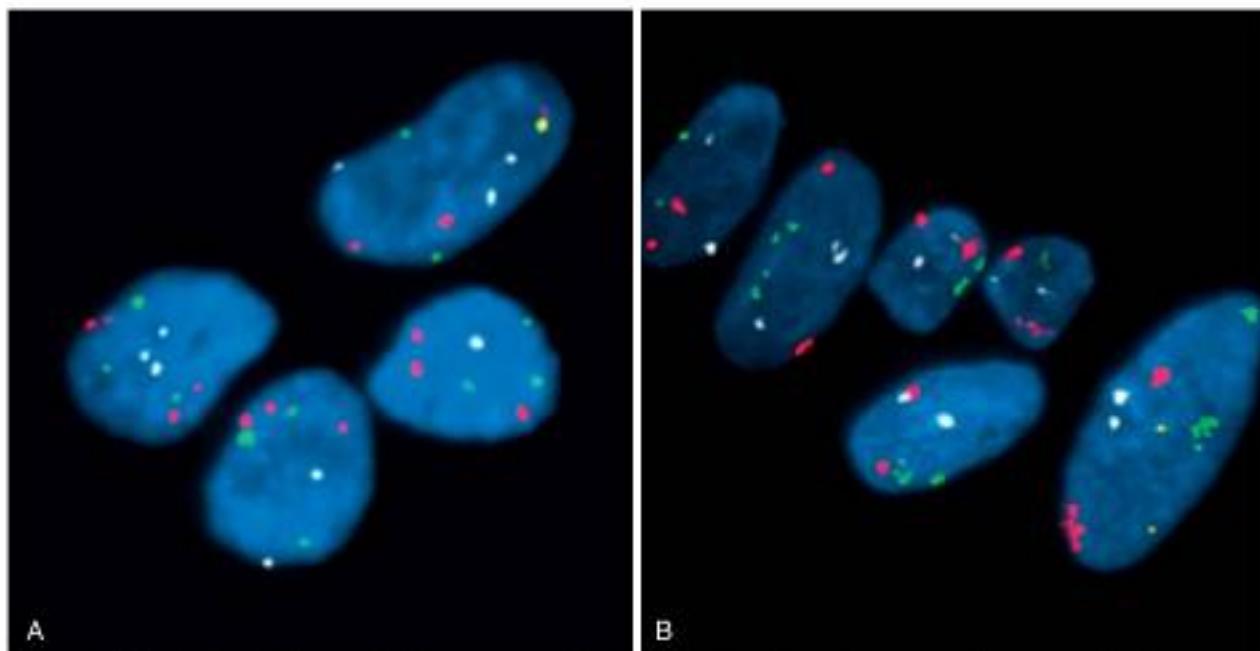

A major development in indeterminate biliary stricture sampling has been the development of intraprocedural analysis of specimens obtained by EUS FNA, and ERCP specimens as well.

We have experimented with triple sampling as previously outlined and on occasion had ERCP FNA or brushings slides made and sent for immediate Papanicolaou staining and interpretation. With additional experience, we noted increasing yield

with increased numbers of forceps biopsy without an increase in complications, but needed techniques for immediate processing and interpretation. ERCP-guided FNA has the disadvantages of technical difficulty, more shallow depth of puncture, and limited number of passes before needing to employ a new needle.

A new technique developed in our unit using a new cytologic preparation of forceps specimens at ERCP can permit direct intraprocedural diagnosis similar to the sequence used at EUS.<sup>11</sup> In neurosurgery, intraoperative samples of margins during brain tumor resection have been sampled by preparing quick fixed smears of brain tissue on dry slides. Termed *squash prep*, this technique evolved because frozen sections cannot be done on fat-rich brain tissue. Paralleling this established technique, our group prepared small 5-Fr or 6-Fr forceps biopsy specimens by vigorously smashing them between two dry glass slides to attempt to create a monolayer. These specimens are immediately stained by rapid Papanicolaou and read in suite. This new technique is termed *SMASH protocol* (Video 60.1).<sup>11</sup> At our center, experience with this approach added only an additional 10 to 20 minutes to the ERCP procedure and produced a definitive positive diagnosis in 49/66 (74%) of pancreaticobiliary cancers.<sup>11</sup> This high yield is in part produced by the cytopathologist who can request additional specimens similar to EUS. We generally halt at 10 specimens, in favor of collecting additional biopsy specimens for histology and a final one or two ERCP-guided FNA passes. This new approach at tissue sampling adds little time and little cost and avoids delay in tissue diagnosis in most patients. Immediate tissue diagnosis avoids additional efforts at biopsy, such as EUS-guided FNA or CT-guided FNA, and often shortens hospital stay.<sup>11</sup>

When in-suit cytopathology is not available and time permits, we have reported a further method of intraprocedural diagnosis. Forceps biopsies can be sent to most hospital pathology labs for frozen section analysis, often on short notice and at odd hours. Our initial technique was to send five rapidly obtained specimens from the lower edge of an indeterminate stricture using only

**FIG 60.7** **A**, Trisomy of chromosomes 3,7,17 (3 copies of red, green, and aqua probes). **B**, Homozygous deletion of 9p21 (absence of gold probes in all but one normal cell). (Images courtesy of Dr. Tamas Gonda.)

fluoroscopic guidewire during ERCP. If negative, an additional five specimens could be sent. Noting no complications in greater than 50 cases using only 5-Fr or 6-Fr pediatric forceps, we now send 10 specimens and complete our sampling with two forceps specimens for H&E staining and do a single ERCP FNA sample.

Our experience suggests that the yield of the frozen section protocol is somewhat lower than SMASH protocol, likely due to the absence of the cytopathologist, but provides prompt, simple, and widely available interpretation with a true positive yield of 80+%.<sup>33</sup>

In the specific setting of CCA of the common bile duct, common hepatic duct, or bifurcation, these techniques of forceps tissue sampling by SMASH, frozen, or standard triple sampling established an overall true positive diagnosis in 87% of consecutive cases at our institution.<sup>34</sup> The intraprocedural diagnosis by SMASH or frozen was 79% and the addition of H&E and ERCP FNA added 8% to achieve the final total.

#### Advanced Specimen Analysis

Despite these advances in tissue sampling of indeterminate biliary strictures, false negative specimens still plague the goal of 100% diagnostic accuracy. After collection, specimens can undergo additional techniques of analysis in an attempt at increasing positive results, only their current status demands an update.

#### FISH

While improved methods of acquisition of tissue remains a challenge, developments in the methods of analysis of available tissue has made significant advancement. One promising tissue-based diagnostic tool that gained a prominent role in the diagnostic armamentarium for IDBS is the use of fluorescent in-situ hybridization (FISH) to detect chromosomal aneuploidy or polysomy. Positive findings are found in an estimated 80% of pancreaticobiliary malignancies.<sup>35</sup> FISH uses fluorescently

labeled chromosome-specific DNA probes to identify cells with an abnormal number of chromosomes or mutations. The four commercially available FISH probes target chromosomes 3 (CEP3), 7 (CEP7), 17 (CEP17), and the 9p21 locus of chromosome 9 (Fig. 60.7). While this method of molecular analysis is markedly different from the cytological methods used conventionally, its use adds no additional burden of sampling as these tests can be performed on cells obtained from routine brush cytology samples during ERCP. In fact, the same brush can even be used to provide both FISH results and cytology results with the use of a multipart brush, such as a brush with 3 separate clusters of bristles (Infinity Brush, US Endoscopy, Mentor, OH). The relative disadvantage is that centers that analyze FISH samples are limited and may require samples to be sent out. Another disadvantage is that FISH analysis typically can take up to 3 weeks to return, depending on the practices of the individual center, as many samples are run in batches and the evaluation for aneuploidy or polysomy is not an automated process.

Data regarding diagnostic yield has been variable and is dependent on the specific panel of probes included in individual studies. Early prospective data on the diagnostic yield of FISH in indeterminate strictures by Levy et al (2008), using CEP3, CEP7, and CEP 17 probes found that, in previously cytology-negative strictures, the sensitivity of FISH was 62%, with specificity of 79% for malignancy.<sup>36</sup> When a fourth probe to the 9p21 loci of chromosome 9 (associated with mutation of the p16 tumor suppressor gene) is added to the repertoire, the sensitivity of FISH can be improved significantly from 47% to 84%, with preserved specificity of 97%.<sup>37</sup> As discussed earlier with respect to combined sampling, Nanda et al (2007) demonstrated that triple modality sampling with brush cytology, fluoroscopically guided biopsies, and FISH resulted in significantly higher sensitivity of 82% versus 42% for brush cytology alone.<sup>37</sup> Individual modality results for cytology, biopsies, and FISH were 27%, 50%,

and 59% respectively. Cost analysis in a study population, in which the respective sensitivity of cytology and FISH was 42% and 70% respectively, suggested that FISH testing be used as a second-line evaluation if cytology samples were negative given the significant additional cost for FISH analysis.<sup>65</sup> The main limitation of FISH is its reduced specificity in the setting of chronic inflammatory conditions such as PSC where polysomy can occur in the absence of CCA.<sup>66</sup> By adding trisomy-7 as a marker of malignancy in the combined cohort of both PSC and non-PSC patients, the overall sensitivity for diagnosing malignancy was 64%, specificity 82%, and diagnostic accuracy 72%. However, trisomy 7 in particular can be found in benign strictures of PSC patients and decreases the specificity of FISH for malignancy in that challenging cohort. This elevated rate of false positive results in the setting of PSC has resulted in recommendations suggesting FISH results be followed in surveillance sampling of PSC patients and that a positive FISH result alone not be considered positive.

Other molecular-based techniques that have been examined to improve the diagnostic yield include bile aspirate analysis for p53 and KRAS mutations, but these are not currently considered part of the routine workup and are still in the early phases of investigation.<sup>67</sup> One study has evaluated the value of combination testing of FISH and genetic analysis (KRAS mutation, LOH, tumor suppressor genes at 10 loci)<sup>68</sup> and found that adding both FISH and molecular profiling to cytology can increase sensitivity from 32% to 73% ( $p < 0.001$ ). This supports that sampling methods and analysis should be performed in tandem to optimize diagnostic accuracies. Nevertheless, the proven performance of FISH in the evaluation of biliary strictures has earned the recommendation by cytologic societies that it be considered the only ancillary technique to biliary brushing with sufficient efficacy.<sup>62</sup>

#### Endoscopic Ultrasound-FNA

EUS FNA is another modality that has entered the algorithm of evaluation of IDBS as a complementary tool to ERCP. A discussion regarding its role and results in tissue sampling is discussed elsewhere. It is worthy to note, however, that the exact role of FNA in the setting of suspected proximal CCA remains controversial. This is mostly due to the theoretical potential for malignant peritoneal seeding via the needle access pathway. Data from a small number of case series of patients who underwent percutaneous biliary biopsies for CCA who developed carcinomatosis with rates as high as 83%<sup>69,70</sup> have driven most transplant centers to adopt protocols in which tissue sampling with EUS FNA of the primary lesion is a contraindication to liver transplantation of hilar CCA.<sup>71</sup> For those patients who are not going to be considered for transplant or who have extrahepatic disease and are being considered for resection only, the reported overall sensitivity of EUS FNA is 43% to 86% for the diagnosis of all malignant strictures.<sup>69–70</sup> EUS FNA is generally less reliable in the evaluation of proximal CCA, as its sensitivity decreases to 59% compared to 81% in distal CCA.<sup>69</sup> The presence of a previously placed biliary stent can also decrease its sensitivity for malignancy detection due to a combination of stent-related acoustic shadowing, image degradation, and difficult needle access.

#### Intraductal Ultrasound

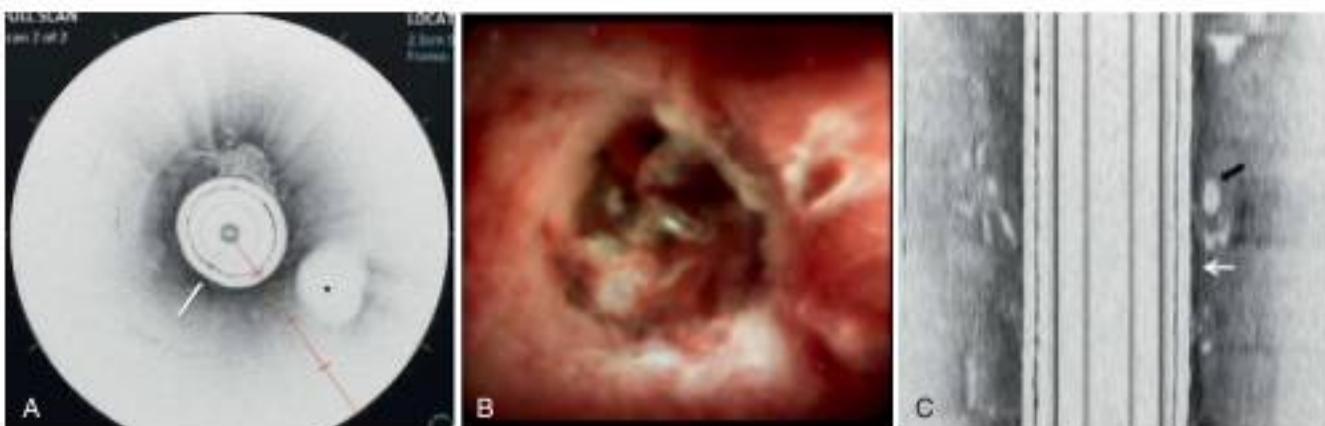

If the infiltrative nature of CCA and other biliary strictures serves as an obstacle to adequate tissue acquisition, then having a method of investigating wall layers to identify and characterize

that invasion might be helpful in providing a predictive diagnosis, as well as targeting tissue. One such intraductal imaging modality is intraductal ultrasound (IDUS), which enhances endobiliary imaging by the wire-guided placement of a high-frequency probe directly into the bile ducts. Technically, this is a simple maneuver to perform as the probe is a small-caliber catheter that is passed over a wire during ERCP, does not require a sphincterotomy, and is radiopaque, and thus the probe's exact location can be determined. The probe provides high-quality imaging of the periductal tissue along with limited tumor staging, such as mass size and periportal vascular invasion (full lymph node staging still requires EUS).<sup>72</sup> IDUS criteria for differentiating benign from malignant strictures have been established and include disruption of the normal triple layer wall architecture, eccentric wall thickening, presence of a hypoechoic mass with irregular margins or invasion of adjacent structures, papillary surface, and malignant-appearing periductal lymph nodes.<sup>73</sup> These criteria have been validated in multiple studies demonstrating diagnostic sensitivities of IDUS to be 80% to 90%, specificity 83%, and improvement in the accuracy of ERCP from 58% to 83%.<sup>70,72</sup> The disadvantage to IDUS is that it is solely an adjunctive imaging tool that helps direct evaluation of IDBSs but does not provide histopathology. This may explain the relatively rare use of this modality in the algorithm of evaluation. Furthermore, the probe itself is relatively fragile, and not disposable, and requires a separate processor, and therefore, it falls into the capital inventory of most endoscopy suites and limitations this incurs.

#### Optical Coherence Tomography

Another technology that allows for greater evaluation of the bile duct wall layers is optical coherence tomography (OCT), which was introduced over 20 years ago<sup>74</sup> and allows for high-resolution, cross-sectional, tomographic imaging of tissue. An earlier catheter version worked by measuring the interference of low-power infrared light (750–1300 nm) reflected from the tissue and light reflected from reference mirrors. In-vitro and in-vivo studies have demonstrated the feasibility of using this catheter to visualize multiple wall layers of the gut and pancreaticobiliary ducts, as well as visualizing microscopic structures, such as blood vessels, lymphoid aggregates, crypts, and glands.<sup>74–78</sup> Early animal and human studies of the pancreaticobiliary epithelium and sphincter of Oddi helped to demonstrate OCT findings that correlated to the three ductal wall layers, single layer epithelium, deeper fibromuscular layer, and an outer smooth muscle layer. The corresponding OCT images were an inner hyporeflective layer, a homogenous hyperreflective layer, and a less defined hyporeflective layer, respectively.<sup>79</sup> In addition, neoplastic and nonneoplastic tissue could be differentiated.<sup>78–81</sup>

Using two OCT criteria to diagnose malignancy, including unrecognizable layer architecture, and the presence of large, nonreflective areas compatible with tumor vessels, Arvanitakis et al (2009)<sup>82</sup> evaluated the feasibility of OCT in detecting malignant biliary strictures in 35 patients. Using the mid-focus OCT probe (PENTAX Corporation Tokyo, Japan/Lightlab Imaging Ltd, Boston, MA; outer diameter 0.75 mm, depth of penetration 1 mm, resolution 10  $\mu$ m) malignant strictures were diagnosed in 19/25 (54%) of patients compared to tissue as gold standard. The sensitivity of at least one or both OCT was 79% and 53%, respectively, and accuracy was 70% for both categories. When combining brushings and biopsies to at least one criteria, sensitivity increased to 84%.<sup>82</sup>

**FIG 60.8** **A**, VLE cross-sectional image of biliary stricture with hyperreflective surface (white arrow), and periductal vessel (asterisk). **B**, Spy image of corresponding biliary stricture to (A). **C**, Longitudinal image of biliary stricture with features of subepithelial glands (black arrow) and hyperreflective surface (white arrow). (Images courtesy of Dr. Doug Pleskow.)

A newer probe has just become commercially available in the United States that uses volumetric laser electromicrography to provide very similar images to the prior OCT catheter (NinePoint Medical, Cambridge, MA). Similar to its predecessor, the probe fits through the working channel of the ERCP scope, is not currently wire-guided, and requires a dedicated processor for imaging. Circumferential radial and 6-cm longitudinal images are provided with depth of 3 mm, lateral resolution of 40 microns, and axial resolution of 7 microns. Similar to prior OCT work, the principles of image interpretation come from data using the technology in setting of Barrett's epithelium, where features such as loss of wall definition, increased reflectivity, and glandular structures are indicative of dysplastic areas (Fig. 60.8). Data regarding the use of this low-profile catheter is currently being collected from select centers. Similar to its predecessor, it holds promise as an additional tool to increase the predictive value of imaging and targeting for further sampling of pancreaticobiliary strictures.

### Cholangioscopy

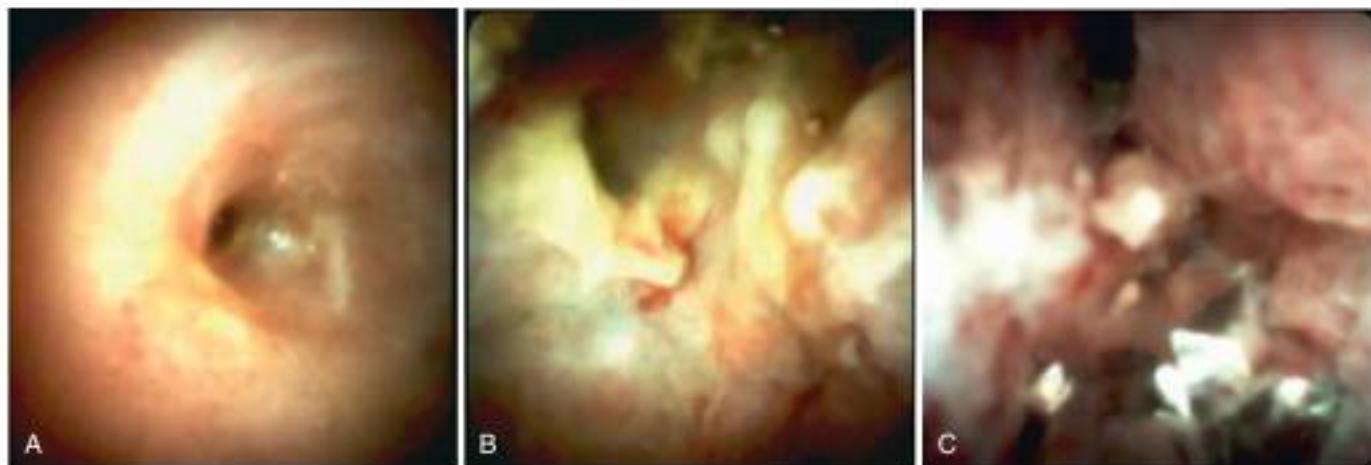

Logically, the most direct way to diagnose a malignancy in the practice of any endoscopy is to directly visualize the epithelium to allow for a diagnostic impression and for precise targeted sampling. This technique, cholangioscopy, was first made possible in the 1970s with the use of the first generation "mother-baby" cholangioscopes. While newer versions of the video cholangioscopy systems provided outstanding imaging, widespread adoption was limited due to the need for two operators, scope fragility, limited tip maneuverability, and prolonged procedures.<sup>123</sup> The development of single-operator cholangioscopy (SOC), and the release of the Spyglass Direct Visualization System (Boston Scientific, Marlborough, MA) in 2005 have measurably changed the practice of cholangioscopy worldwide.

The Spyglass system (Boston Scientific, Marlborough, MA) consists of a 10-Fr access catheter (SpyScope) that can be inserted through the standard 4.2-mm working channel of a therapeutic duodenoscope; a reusable optical probe (SpyGlass) that fits through the SpyScope catheter, and disposable 3-Fr biliary biopsy forceps to allow visually-directed biopsies (SpyBite). The optical catheter provides 6000 pixel images and has tip maneuverability to allow 30-degree views in four directions.<sup>124</sup> A second-generation

**FIG 60.9** Spy DS scope and spybite forceps (insert). (Courtesy of Boston Scientific, Marlborough, MA.)

Spyglass system, known as Spyglass DS, has a digital chip embedded at the end of the SpyScope and thus eliminates the need for the optic fiber and the necessary preprocedural calibration required, while providing a wider field of view (Fig. 60.9). The accessory channel size is also slightly larger and thus facilitates passage of accessories such as forceps and lithotripsy probes. Last, there are dedicated individual irrigation and aspiration

**FIG 60.10** **A**, Spy image of benign biliary stricture. **B**, Spy image of malignant biliary stricture. **C**, Spy image of directly visualized biopsy. (Images courtesy of Dr. Amrita Sethi.)

channels that improve duct clearance of debris and visualization significantly.

At this stage, data regarding outcomes of the use of SOC in the evaluation of IDBSs reflect use of the first-generation system.

The largest prospective, multicentered, observational study of the operating characteristics of the SOC system by Chen et al (2011)<sup>115</sup> included 226 patients with biliary strictures (not all were cytology negative) with a sensitivity, specificity, positive predictive value, and negative predictive value for malignancy of 78%, 82%, 80%, and 80%, respectively, based on the visual impression criteria.<sup>113,116</sup> Visual impression had a higher sensitivity compared to visually targeted biopsies, which was only 47%, although biopsy specificity was much higher at 98%, with a positive predictive value of 100%. A smaller prospective series from Ramchandani et al (2011)<sup>117</sup> involving 36 patients with indeterminate strictures also found the sensitivity of the SOC visual impression to be 95%, and specificity of 79%, while sensitivity and specificity for SpyBite biopsies were lower at 82%. A comparison study of directly visualized (DV) biopsies versus both brush cytology and fluoroscopically guided biopsies in 26 patients demonstrated that despite adequate tissue quantity with all three modalities, the accuracy of the DV biopsies was 84.6%, which was significantly higher than brush cytology (38.5%) and standard forceps (53.8%).<sup>118</sup> By analysis in a systematic review, the sensitivity and specificity of cholangioscopy-directed biopsies' ability to detect malignancy in IDBS with prior negative findings in a total of four studies was 74.7% (95% confidence interval [CI], 63.3%–84.0%) and 93.3% (95% CI, 85.1%–97.8%).<sup>119</sup> Another systematic review found that the sensitivity and specificity of visual impression were 90% (95%CI, 73%–97%), and 87% (95% CI, 76%–94%), respectively.<sup>120</sup> In a more recent study evaluating the role of performing rapid on-site evaluation of touch imprints of DV biopsy specimens (ROSE-TIC), Varadarajulu et al (2016) studied 31 patients and with a mean of 3.3 biopsies, were able to achieve a sensitivity of 100% and accuracy of 93.5% in diagnosing malignancy in IDBS.<sup>121</sup>

The issue of visual impression remains an unanswered topic given the lack of validated criteria by which to diagnose malignancy. Early imaging with video cholangioscopy led to considerations for imaging criteria that have been proposed for the diagnosis of malignancy including dilated, tortuous blood vessels (also termed tumor vessels), intraductal nodules or masses,

#### BOX 60.1 Malignant Stricture Criteria for SOC Cholangioscopy

- Dilated, tortuous blood vessels
- Intraductal nodules or mass
- Infiltrative or ulcerated stricture
- Papillary or villous mucosal projections

SOC, single-operator digital cholangioscopy.

Data from Seo DW, Lee SK, Yoo KS, et al: Cholangioscopic findings in bile duct tumors. *Gastrointest Endosc* 52(5):630–634, 2000.

infiltrative or ulcerated strictures, and papillary or villous mucosal projections<sup>122</sup> (Fig. 60.10; Video 60.2). The strongest feature suggestive of malignancy has been the presence of dilated and tortuous vessels with a reported specificity and positive predictive value of 100%<sup>113–123</sup> (Box 60.1), as this was felt to represent underlying neovascularization of the malignant tumor. However, when viewed by first fiber optic and now digital cholangioscopy, and when removed from clinical context, it is not clear that these findings are validated. In two consecutive studies, interobserver agreement of SOC visual findings, using the fiber optic system, and final diagnosis, were only slight to fair and the accuracy was less than 50% on diagnosing malignancy.<sup>124,125</sup> Further attempts are being made by multiple groups to create a new classification system using the digital cholangioscopy system, with the hopes that clearer imaging and new tissue-correlated definitions may lead to a validated system. Ultimately, however, in this tissue-based era, it is unclear what role visual impression alone will play and whether the true benefit will be in the ability to target sampling and additional diagnostic methods.

A few considerations need to be made when performing cholangioscopy, namely, the need for biliary sphincterotomy to advance the system into the biliary tree and higher rates of complications due to sphincterotomy and cholangitis. Chen et al (2011)<sup>115</sup> reported serious procedural complication rates of 7.5%; a later study by Sethi et al (2011)<sup>126</sup> confirmed a complication rate of 7.0% versus the routine ERCP rate of 2.9%, with the difference attributed to higher incidence of cholangitis in the cholangioscopy group. Such findings have led to routine use of antibiotics when performing cholangioscopy in otherwise low-risk patients during ERCP.

### Confocal Laser Endomicroscopy

Another method of direct evaluation of the biliary epithelium is probe-based confocal laser endomicroscopy (pCLE), which uses an optical probe during ERCP to allow real-time, microscopic level examination of the bile ducts.<sup>129</sup> The CholangioFlex probe (Maunakea Tech, Paris, France) fits into multiple ERCP accessory devices or the 1.2 mm-diameter working channel of the SpyGlass (Boston Scientific) cholangioscope. This probe provides images to a depth 40 to 70  $\mu\text{m}$  below the tissue surface. An intravenous contrast agent, usually fluorescein, is used to delineate cellular features that have been determined to represent criteria of malignancy versus benign disease and inflammation. Identification of these criteria have been performed in a series of steps, the first iteration known as the "Miami Classification," which helped to distinguish malignant from benign features. This was prospectively studied in a multicentered, larger cohort of 89 patients with indeterminate pancreaticobiliary strictures by eight investigators (Table 60.2).<sup>129,131</sup> The sensitivity, specificity, positive predictive value, and negative predictive value of pCLE using the Miami criteria were 98%, 67%, 71%, and 97%; the accuracy of combination ERCP with pCLE was significantly higher than ERCP with tissue sampling alone (90% vs. 73%).<sup>131</sup>

In attempts to improve the specificity of these criteria, refinement with the Paris classification was conducted that allowed for identification of features that would predict inflammation from benign and malignant disease (Fig. 60.11). Addition of these

criteria did in fact improve specificity from 61% to 81.2% in lesions previously scored by the Miami classification system.<sup>132</sup> Prospective validation of the Paris criteria was performed by Slivka et al (2015)<sup>133</sup> in the FOCUS trial in which confocal diagnosis was added to ERCP imaging and sampling, as well as clinical history, and scored by two physicians. The results of this prospective study demonstrated that the additive value of all three diagnosis (pCLE, ERCP, and sampling) could provide an accuracy of 88% in the diagnosis of malignancy in indeterminate strictures.<sup>133</sup>

Practically, the low specificity of pCLE and the dedicated operator training needed (as has been demonstrated in interobserver agreement studies)<sup>134</sup> for accurate interpretation of confocal images remain the major limiting factors of its widespread use as a routine tool in the evaluation of indeterminate strictures. However, in expert centers with pCLE experience, it has become a valuable tool in the multimodality approach to the management of difficult cases of biliary stricture.

### EVALUATION OF STRICTURES IN PSC

The caveat to the preceding discussion regarding IDBSs is the ever-elusive diagnosis of CCA in PSC. PSC is a chronic, progressive inflammatory condition of the intrahepatic and extrahepatic bile ducts, characterized by diffuse stricturing that can lead to biliary cirrhosis and increases patients' risk for CCA three-fold.<sup>135,136</sup> Liver transplantation is the only curative treatment for both end-stage biliary cirrhosis and early-stage hilar CCA, with a posttransplant, 5-year survival of 65% to 88% when performed in expert centers under rigorous protocols.<sup>137,138</sup> However, due to the chronic stricturing nature of the disease, differentiating between benign and malignant strictures in this population is particularly difficult. Per guidelines, the presence of a dominant stricture prompts an endoscopic evaluation that often includes many of the modalities discussed earlier in this chapter. However, the diagnostic performance of these modalities from molecular analysis to advanced imaging appear to be even more challenged in PSC patients. A recent meta-analysis showed that FISH sensitivity for CCA in PSC is only 51%, although specificity is preserved at 93%.<sup>139</sup> Similarly, confocal endomicroscopy's reduced reliability in distinguishing chronic inflammatory benign changes from malignant transformation suggests that further refinement is needed for evaluation of PSC strictures by this modality. Cholangioscopy may be the most promising method, with some prospective studies suggesting sensitivity for CCA in PSC patients of 92%, specificity 93%, and overall accuracy

**TABLE 60.2 Miami and Paris Classification of pCLE for Predicting Malignant Biliary Stricture**

Criteria Suggestive of Malignancy	Criteria Suggestive of Inflammation	Criteria Suggestive of Benign Disease
Thick, dark bands (> 40 $\mu\text{m}$ )	Thick reticular network	Thin, dark bands
Thick, white bands (> 20 $\mu\text{m}$ )	Increased intraglandular space	Thin, white bands
Dark clumps	Vascular congestion	
Villous glands		
Fluorescein leakage		

pCLE, probe-based confocal laser endomicroscopy.

of 93%, but in half of the patients a second cholangioscopy was needed for tissue diagnosis.<sup>113</sup> Furthermore, there is the theoretical increased risk of cholangitis when performing these advanced imaging modalities in patients with PSC. Thus, the literature suggests a multimodality approach in any PSC patient in whom there is a high clinical suspicion for malignancy, such as a persistently, markedly elevated CA19-9 despite biliary decompression, or new or symptomatic dominant stricture, is likely to offer the greatest diagnostic value.

## CONCLUSION

IDBSs remain a challenge despite developments in imaging, tissue acquisition, development of additional tissue analysis methods, and even serum markers. There is no question, however, that a multimodality approach must be employed to optimize diagnostic results. The components of this combined approach will depend on local expertise and resources. First-line approach should include routine ERCP with brushings and FISH, and if nondiagnostic despite high clinical concern, consider an adjunct endobiliary imaging study, to either confirm clinical suspicions or to use for continued close surveillance. Proximal biliary strictures may be best imaged by IDUS, whereas EUS can evaluate for suspicious periductal lymph nodes. Practices in the use of cholangioscopy and confocal endomicroscopy will vary more widely depending on its availability, operator experience, and further definition and validation of diagnostic criteria. Ultimately, the future for endoscopic evaluation of biliary strictures will need to move toward developing a diagnostic algorithm that reconciles the cost-effectiveness of extensive and repeated evaluations for stable-appearing strictures with the potential for a missed malignancy and/or unnecessary surgical exploration. Ultimately, the inherent problem may not lie within the methods used, but rather the nature of the disease. And in this era of tissue-specific diagnoses, future efforts will likely focus on identifying the highest yield area for sampling and maximizing acquisition from this area. Indeed, the evaluation of IDBS remains a rich area for research and eventual change in practice as new tools are developed and their respective roles established.

## Pancreatic Cystic Lesions

Anne Marie Lennon, Omer Basar, and William R. Brugge

### CHAPTER OUTLINE

<b>Nonneoplastic Cysts, 713</b>	<b>Intraductal Papillary Mucinous Neoplasm, 715</b>	<b>Pancreatic Neuroendocrine Tumors, 719</b>
Pancreatic Pseudocysts, 713	Serous Cystic Neoplasm, 717	<b>Approach for a Patient With a Pancreatic Cyst, 720</b>
<b>Neoplastic Cysts, 713</b>	Solid-Pseudopapillary Neoplasm, 718	
Mucinous Cystic Neoplasm, 714		

Pancreatic cysts are relatively rare lesions, and their diagnosis has increased with the widespread availability and use of cross-sectional imaging. In many cases pancreatic cysts are detected on imaging performed for another indication; however, they can also be seen in patients with symptoms such as abdominal pain or jaundice. Pancreatic cysts are reported to be found in 3% of computed tomography (CT) scans and 20% of magnetic resonance imaging (MRI) scans, and an increased prevalence is reported with advancing age. Patients with intraductal papillary mucinous neoplasms (IPMNs) and mucinous cystic neoplasms (MCNs) are at higher risk of pancreatic malignancy compared to the general population. The majority of pancreatic cystic lesions are nonneoplastic cysts, which are predominantly pancreatic pseudocysts (PPs) and are mostly seen as a local complication of pancreatitis.<sup>1</sup> Neoplastic cysts of the pancreas are broadly categorized as mucinous and nonmucinous lesions, and the type of epithelial lining determines the risk of malignancy. Once a PP has been eliminated as a possibility, the next step is to determine the type of cyst based on cross-sectional imaging, aspiration cytology, and cyst fluid analysis (Box 61.1).

### NONNEOPLASTIC CYSTS

#### Pancreatic Pseudocysts

PPs may occur secondary to acute or chronic pancreatitis or pancreatic trauma. They are inflammatory fluid collections and 10% to 20% of patients with acute pancreatitis develop a PP.<sup>2</sup> A pseudocyst is often diagnosed when cross-sectional imaging demonstrates an enhancing capsule surrounding a peripancreatic fluid collection 4 weeks from the onset of acute nonnecrotizing pancreatitis. The capsule does not contain an "epithelial lining,"<sup>3</sup> and a PP usually contains an opaque, dark, low-viscosity fluid free of epithelial cells. PP are usually sterile collections, but may become infected or hemorrhagic. The majority of PP are solitary, unilocular cysts ranging from 2 to 20 cm in diameter.<sup>1,3,4</sup> Abdominal pain, early satiety, and weight loss are common symptoms, and a PP is suspected when abdominal pain continues and serum amylase is consistently elevated after clinical resolution

of pancreatitis.<sup>5</sup> PP may be complicated by intracystic hemorrhage, infection or rupture, which leads to pancreatic ascites. Symptoms of abdominal pain, fever, and chills suggest an infection in a patient with known PP.

Large PP are well-circumscribed, oval or round, thick-walled fluid collections on abdominal ultrasound (US) and CT<sup>1</sup> (Fig. 61.1). CT imaging may also reveal signs of inflammation of the pancreatic tissue in the course of acute or chronic pancreatitis. MRI, magnetic resonance cholangiopancreatography (MRCP), and endoscopic retrograde cholangiopancreatography (ERCP) do not contribute much to the diagnosis. Currently, endoscopic ultrasound (EUS) is the most used modality for the differential diagnosis, and they appear as hypoechoic fluid collections surrounded by a thick rim (Fig. 61.2). Cysts can be aspirated by EUS-guided fine-needle aspiration (FNA) (EUS-FNA), and the cyst fluid is high in amylase and low in carcinoembryonic antigen (CEA); cytologic analysis shows histiocytes and inflammatory cells.

The majority of PP resolve spontaneously.<sup>7-9</sup> Symptomatic and large PP can be drained endoscopically or via a percutaneous route. With a high degree of success and low recurrence rate, EUS-guided transgastric or transduodenal endoscopic drainage is the current choice of treatment.<sup>10</sup> Furthermore, cystogastrostomy or cystoduodenostomy allows removal of debris and necrotic material in some patients. Surgical drainage is not preferred currently, except in the face of endoscopic drainage failure.<sup>11</sup>

### NEOPLASTIC CYSTS

Neoplastic cysts of the pancreas can be broadly categorized as mucinous cystic lesions and nonmucinous cystic lesions. MCNs and IPMNs both produce mucus and are often combined and called either *mucin-producing neoplasms* or *mucinous neoplasms*. MCNs and IPMNs share similar cyst fluid features, and have the potential for transformation into pancreatic adenocarcinoma.<sup>11,12</sup> Nonmucinous neoplastic cystic lesions include serous cystic neoplasms, solid pseudopapillary neoplasms (SPNs), and cystic pancreatic neuroendocrine tumors (PNETs). The common

### Abstract

Pancreatic cysts are relatively rare lesions, and their diagnosis has increased with the widespread availability and use of cross-sectional imaging. In many cases pancreatic cysts are detected on imaging performed for another indication; however, they can also be seen in patients with symptoms such as abdominal pain or jaundice. The majority of pancreatic cystic lesions are nonneoplastic cysts, which are predominantly pancreatic pseudocysts (PPs) and are mostly seen as a local complication of pancreatitis. Neoplastic cysts of the pancreas are broadly categorized as mucinous and nonmucinous lesions, and the type of epithelial lining determines the risk of malignancy. Once a PP has been eliminated as a possibility, the next step is to determine the type of cyst based on cross-sectional imaging, aspiration cytology, and cyst fluid analysis.

### Keywords

pancreatic cystic lesions  
pancreatic pseudocysts  
intraductal papillary mucinous neoplasms  
mucinous cystic neoplasms  
solid pseudopapillary neoplasms  
cystic pancreatic neuroendocrine tumors

features of pancreatic cystic neoplasms (PCNs) are summarized in Table 61.1.

### Mucinous Cystic Neoplasm

MCNs are relatively rare, and account for 16% of surgically resected pancreatic cysts.<sup>13</sup> They occur almost exclusively in women, with men accounting for less than 5% of MCNs in large

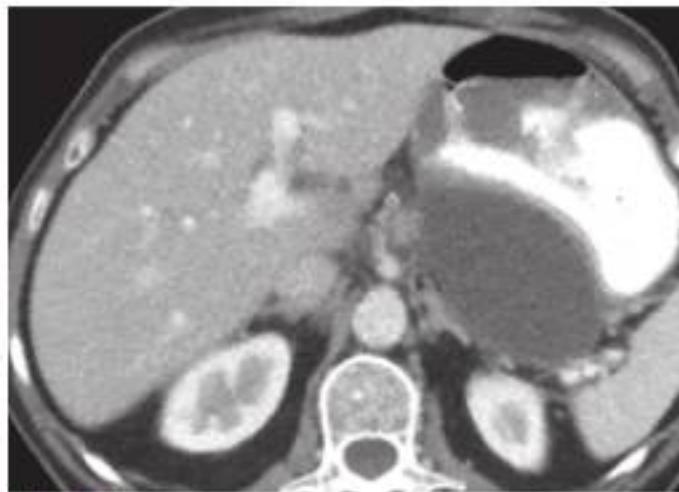

### BOX 61.1 Common Types of Pancreatic Cysts

#### Neoplastic Pancreatic Cysts

- Mucinous cystic lesions
- Intraductal papillary mucinous neoplasm
- Mucinous cystic neoplasm
- Nonmucinous cystic lesions
- Serous cystic neoplasm
- Solid-pseudopapillary neoplasm
- Pancreatic neuroendocrine tumors

#### Nonneoplastic Pancreatic Cysts

- Pancreatic pseudocysts
- Retention cysts
- Squamoid cysts of the pancreatic duct
- Lymphoepithelial cysts

**FIG 61.1** CT showing a pseudocyst measuring 6.7 × 7.6 × 5.0 cm.

series.<sup>14,15</sup> Although over 70% of patients are symptomatic, most of the symptoms are nonspecific abdominal pain and unrelated to the cyst, with only 13% of patients who undergo surgical resection for MCNs presenting with symptoms related to their cyst. The most common of these is acute pancreatitis, which occurs in approximately 9%.<sup>14,15</sup> MCNs have some features that are very helpful in differentiating them from other types of pancreatic cysts; they are single, occur almost exclusively in women, and are located in the body and tail of the pancreas in over 97% of cases.<sup>14,15</sup> They can be uni- or multilocular and are classically well defined with a thin wall. Approximately 15% of MCNs have calcification, which is located at the edge of the cyst, in contrast to serous cystadenomas (SCAs) in which the calcification occurs in the center of the cyst (Fig. 61.3). The key-imaging feature used to differentiate IPMNs from MCNs, is that in MCNs, the main pancreatic duct is of normal diameter with no communication between it and the MCN.

Both MCNs and IPMNs are mucin-producing cysts and have very similar cyst fluid analysis features, namely, a high cyst fluid CEA and the presence of mucin on cytology. There is debate about the optimum CEA level to differentiate mucin from nonmucin-producing cysts, with all major studies defining

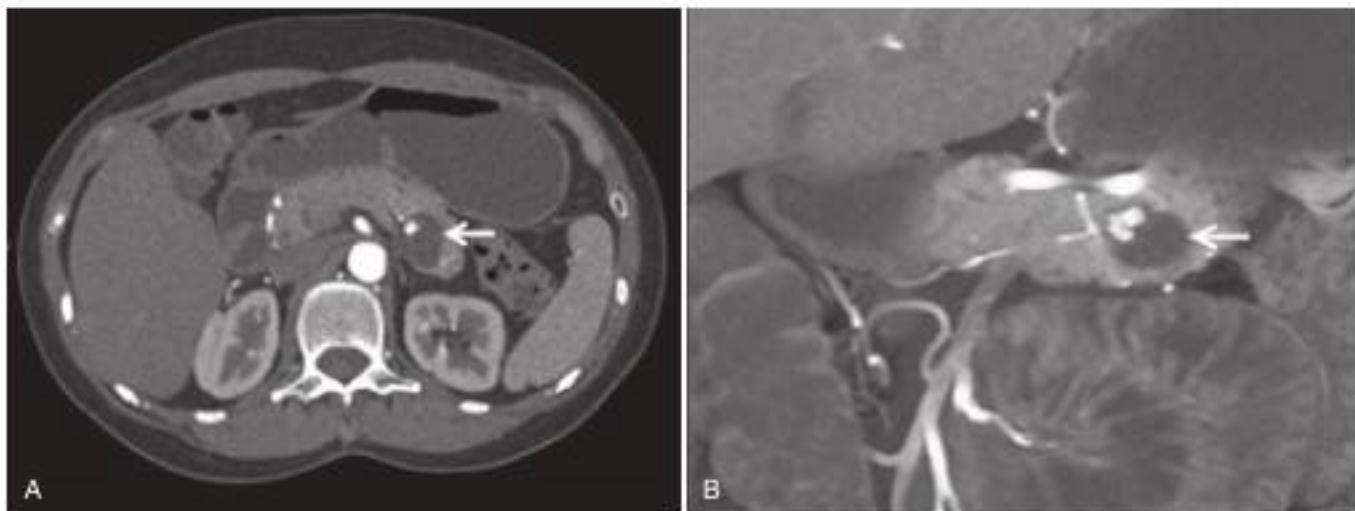

**FIG 61.2** Endoscopic ultrasound (EUS) showing a 4.8 cm unilocular pseudocyst in the pancreatic body. The cyst is adjacent to the gastric wall and contains some debris.

**TABLE 61.1 General Features of Pancreatic Cystic Neoplasms**

Cysts Type	Sex	Median Age	Pancreatic Localization	Morphology	Communication with PD	Epithelium Type	Malignancy Risk
IPMN	d/f	65	Head	Unilocular, septated; associated dilated main pancreatic duct	Yes	Papillary mucinous	High
MCN	f	40	Body & tail	Unilocular	No	Mucinous	High
SCN	f	60	Entire pancreas	Microcystic	No	Serous IPAS-positive for glycogen	Low
SPN	f	30	Body & tail	Mixed solid and cystic	No	Endocrine-like	Low
PNET	d/f	50	Entire pancreas	Associated mass	No	Endocrine	Low

IPMN, Intraductal papillary neoplasm; MCN, mucinous cystic neoplasm; SCN, serous cystic neoplasm; SPN, solid-pseudopapillary neoplasm; PD, pancreatic duct; PNET, pancreatic neuroendocrine tumor.

**FIG 61.3 A and B,** Cross-sectional CT scan demonstrating a mucinous cystic neoplasm (MCN) (arrows) in the body with a calcification in the wall.

mucin-producing cysts as those with a CEA greater than 192 ng/mL, which was derived from the 2004 prospective, multicenter cooperative cyst study by Brugge et al.<sup>12</sup> However, cyst fluid CEA alone is imperfect; a recent meta-analysis of 18 studies with 1438 patients found that cyst fluid CEA had 63% sensitivity and 88% specificity for identifying mucin-producing cysts.<sup>13</sup> Cyst fluid amylase levels are high in both MCNs and IPMNs, and cannot be used to differentiate MCNs from IPMNs.<sup>17</sup>

In both IPMNs and MCNs, columnar or cuboidal epithelial cells, as well as mucin, can be found. In addition, cytology can detect marked atypia (the cytological equivalent of high-grade dysplasia) or invasive adenocarcinoma. Although cytology has a high specificity of over 90%, it suffers from a low sensitivity of only 50% in the diagnosis of a mucinous cyst. In addition, over 60% of cases are found to have inadequate cellularity. On the other hand, the cyst fluid cytology rarely provides a definitive diagnosis. A needle-guided tissue micro forceps was approved recently for epithelial tissue acquisition in pancreatic cysts. In a study, the micro forceps provided a tissue sample that was sufficient for histological evaluation in 90% of patients. It also provided better information about the subgroup of PCN and the grade of dysplasia.<sup>18</sup> In surgically resected cysts, MCNs are differentiated from IPMNs by the presence of ovarian-like stroma.

There are no long-term studies examining the natural history of MCNs; thus the estimate of the risk of malignant transformation into pancreatic adenocarcinoma is based on retrospective surgical series in which the risk of invasive adenocarcinoma in modern series is between 4% to 13% at the time of resection.<sup>14,15</sup>

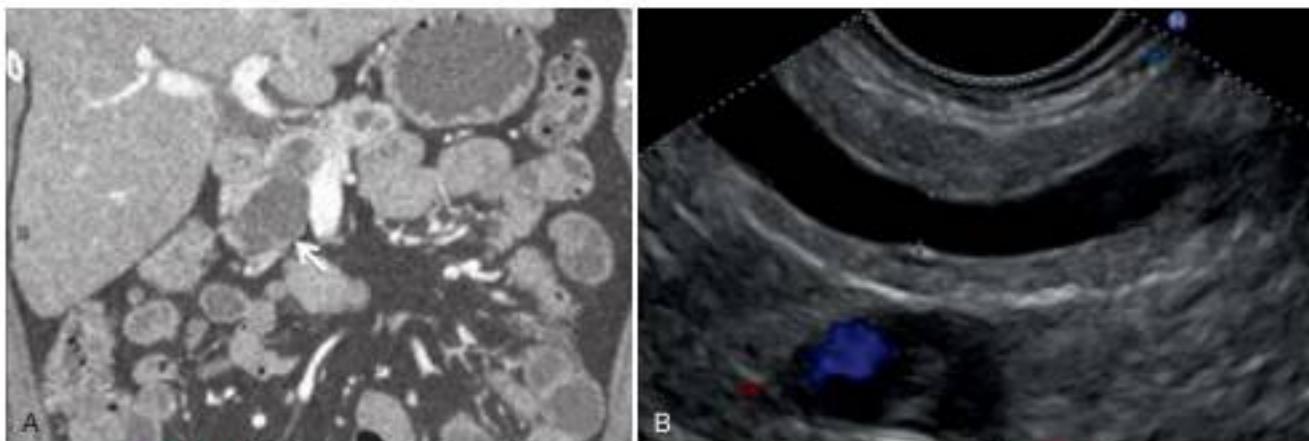

There is debate about whether MCNs can be watched or if all should undergo surgical resection.<sup>16–21</sup> There is an agreement that MCNs that are clearly causing symptoms, such as acute pancreatitis, have imaging features concerning for malignant transformation, such as a solid component or cytology showing marked atypia (the cytological equivalent of high-grade dysplasia), or invasive adenocarcinoma should undergo surgical resection. However authors, guidelines, and surgeons differ as to the management of presumed MCNs that measure less than 3 cm and have no concerning features. Some authors argue that all MCNs should be resected.<sup>19</sup> This is because (1) they occur in young women, who would otherwise require 30 to 40 years of

surveillance, (2) they are single cysts which, in contrast to IPMNs, do not recur, and (3) they are located in the body or tail of the pancreas, which is technically easier to surgically resect than performing a Whipple. However, others argue that it is not always possible to differentiate MCNs from IPMNs preoperatively, that more recent data suggest that the risk of malignant transformation of MCNs is less than that of branch-duct IPMNs, and that although associated with a low mortality, a distal pancreatectomy has an approximate 25% morbidity rate, which includes a 15% to 20% risk of diabetes.<sup>21,22</sup> When caring for a patient with a presumed MCN, it is important to discuss these two differing views, the pros and cons of each approach, and ensure that the patient is reviewed by a multidisciplinary pancreatic cyst group.<sup>24</sup> Once patients undergo surgical resection for an MCN, in the absence of invasive adenocarcinoma, no further follow-up is required.

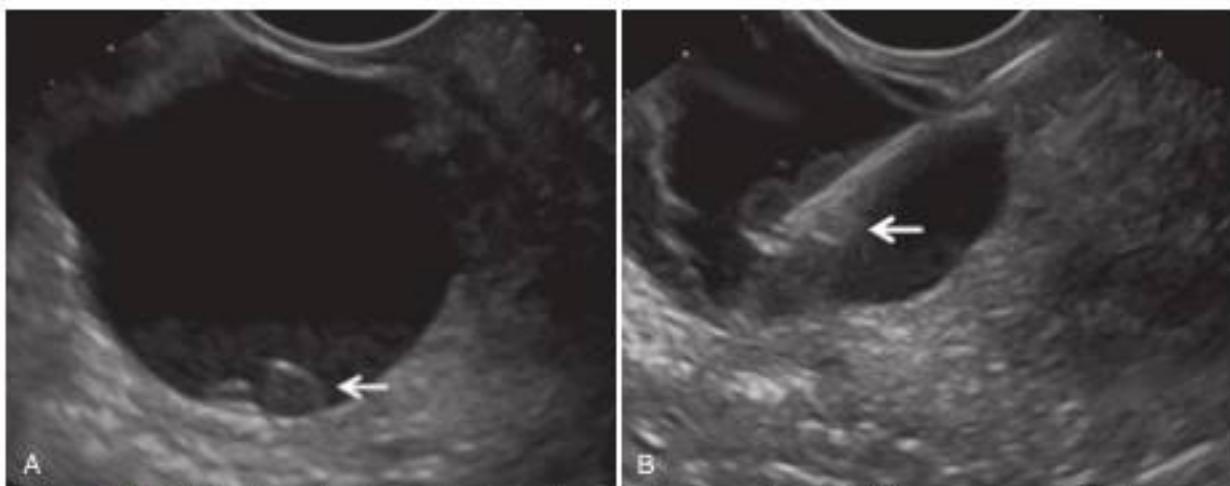

### Intraductal Papillary Mucinous Neoplasm

IPMNs are the most common type of neoplastic pancreatic cyst encountered, and account for over 50% of surgically resected pancreatic cysts in modern series.<sup>12</sup> They can occur at any age, but usually present in patients in their late 60s or early 70s, with an equal distribution between men and women. IPMNs can cause symptoms including jaundice and acute pancreatitis; however, the vast majority of patients with IPMNs do not have pancreatic symptoms.

IPMNs can present with dilation of the main pancreatic duct alone ( $\geq 5$  mm) which is called *main-duct IPMN* (Fig. 61.4A).<sup>20</sup> IPMNs can also present with a pancreatic cyst(s) termed *branch-duct* or *side-branch IPMNs* (see Fig. 61.4B). Finally, a small number of patients present with both a dilated main pancreatic duct and pancreatic cysts, which is referred to as a *mixed IPMN*. Up to 40% of IPMNs have multiple pancreatic cysts. This finding is useful; with the exception of pseudocysts, the majority of other types of cysts are single. Although they have a slight preponderance for the head and uncinate process, they can also occur in the body and tail. Thus, unlike MCNs, the location of IPMNs is not helpful. Branch-duct IPMNs can be uni- or multilocular, are typically well defined with thin walls, and have no calcification. The classic feature of a branch-duct IPMN is the presence of

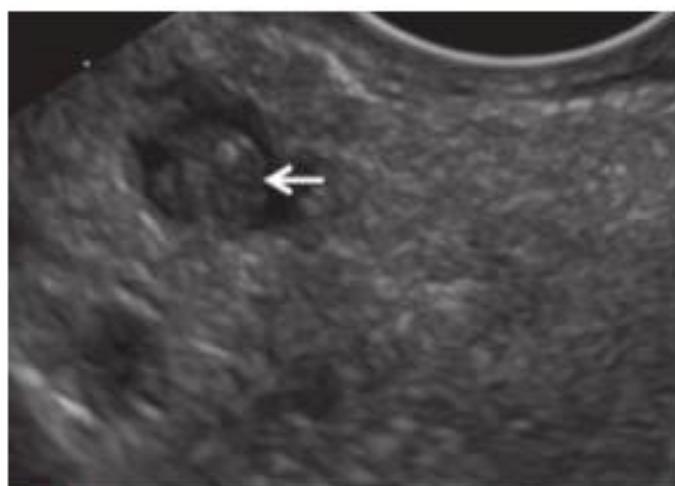

**FIG 61.4** **A**, CT image of main-duct intraductal papillary mucinous neoplasm (IPMN) (arrow highlights a dilated main pancreatic duct in the head of the pancreas). **B**, Endoscopic ultrasound (EUS) image of main-duct IPMN.

**FIG 61.5** **A**, A branch-duct intraductal papillary mucinous neoplasm (IPMN) showing a mucin ball (arrow). **B**, Endoscopic ultrasound fine-needle aspiration (EUS-FNA) of the lesion in Fig. 5A showing that the lesion (arrow) is not attached to the wall and is indeed mucin and not a mural nodule.

communication, or a connection, between the main pancreatic duct and the cyst. This feature of communication between the cyst and the main pancreatic duct is used to differentiate IPMNs from MCNs. This is best assessed with EUS or MRI/MRCP, which have a reported sensitivity of between 89% to 100%.<sup>25</sup>

IPMNs are neoplastic cysts and have the potential for progression to invasive adenocarcinoma. Imaging features that raise concern that an IPMN may have high-grade dysplasia or an associated invasive adenocarcinoma are the presence of a mural nodule (particularly if it is shown to enhance on CT or MRI), a dilated main pancreatic duct (especially if it is over 9 mm in diameter), and thick or enhancing cyst walls or an abrupt change in the diameter of the main pancreatic duct, particularly if there is evidence of upstream ductal obstruction. On EUS it can sometimes be difficult to differentiate a mural nodule from a mucin ball within the cyst (Figs. 61.5 and 61.6). Three features can be used to separate these two entities: (1) mucin will have a smooth edge whereas a mural nodule has an irregular edge, (2) mucin is hypoechoic compared with adjacent tissue, whereas a mural nodule is iso- or hyperechoic compared with surrounding

**FIG 61.6** Mural nodule (arrow) within a branch-duct intraductal papillary mucinous neoplasm (IPMN). The patient underwent surgery, and high-grade dysplasia was detected.

tissue, (3) mucin has a hyperechoic (bright) rim whereas a mural nodule has none. The presence of all three of these features can differentiate mucin from a mural nodule with 90% accuracy.<sup>20</sup> The second issue that endoscopists encounter is whether a slight protuberance of the wall of a cyst is significant or not. The first question is whether this area is enhancing on CT or MRI. The presence of an enhancing mural nodule is highly concerning for the presence of high-grade dysplasia or an associated invasive adenocarcinoma.

It is important to remember that the main pancreatic duct can be dilated for a number of reasons, such as a small pancreatic adenocarcinoma, ampullary adenoma, papillary stenosis, chronic pancreatitis, or main-duct IPMN, and can also increase with age. When referring a patient with a dilated main pancreatic duct, it is important to try to exclude these other entities. The presence of a "fish mouth" in which mucin is seen extruding from the ampulla, is highly suggestive of main-duct IPMN. On EUS the presence of mucin within the main pancreatic duct, or a thickened or irregular wall, are suggestive of main-duct IPMN. In cases where the diagnosis remains unclear, pancreatoscopy has been used to identify papillary projections and to determine the extent of involvement of the main pancreatic duct.

The cyst fluid analysis for IPMNs is identical to that of MCNs described previously. The presence of an elevated cyst fluid CEA or mucin is used to make the diagnosis of a mucin-producing cyst. The presence of marked atypia or invasive adenocarcinoma on cytology raises the concern for the presence of high-grade dysplasia or an associated invasive adenocarcinoma. Patients with these cytology findings should be seen by a multidisciplinary group and considered for surgical resection.

Several studies have focused on the underlying genetic mutations in pancreatic cysts, and have found that cysts have a unique molecular profile (Table 61.2).<sup>21</sup> MCNs and IPMNs share mutations in KRAS, RNF43, and TP53, whereas IPMNs have a unique mutation in GNAS, which is present in 58% of IPMNs and can be used to differentiate IPMNs from other types of cysts.<sup>21</sup> Preliminary studies examining the use of a combination of molecular markers in cyst fluid to identify different types of pancreatic cysts appears very promising, identifying SCAs with 100% sensitivity and 91% specificity, MCNs with 100% sensitivity and 75% specificity, and IPMNs with 76% sensitivity and 97% specificity.<sup>15</sup> The presence of a mutation in GNAS or KRAS is particularly helpful in identifying mucin-producing cysts, and is found in over 90% of IPMNs.<sup>21,22</sup> Recent studies (2016) have shown that the use of molecular markers is cost effective and alters patient management.<sup>20,21</sup> The final results of large, multi-center studies are expected to be published in 2017. If these studies confirm the findings of the smaller studies, it is likely that the use of molecular markers will be incorporated into clinical practice in cases in which the diagnosis is unclear. It is

important to note that not all techniques for identifying molecular markers are the same, with significant variations in the sensitivity for identifying a mutation. The results reported previously were performed using SafeSeq sequencing, which can detect a mutation that is present in 0.01% of alleles.

IPMNs are neoplastic pancreatic cysts with the potential to progress from low-, to intermediate-, to high-grade dysplasia, and ultimately invasive pancreatic adenocarcinoma.<sup>11</sup> It is currently impossible to know the exact grade of dysplasia present in an IPMN without sending the patient for surgical resection; however, certain imaging features are associated with a higher prevalence of high-grade dysplasia or invasive adenocarcinoma. The presence of a mural nodule or solid component within the cyst is associated with an odds ratio (OR) of 7.73, the presence of a dilated main pancreatic has an OR of 2.38, and cyst size greater than 3 cm is associated with an OR of 2.97 for high-grade dysplasia or invasive cancer. In contrast, there is accumulating evidence that the risk for developing invasive malignancy from suspected branch duct (BD)-IPMN without concerning features is low, about 0.72% per year, or 2% to 4% (average 2.8%, 95% confidence interval 1.8%–4%) over a period of 10 years.<sup>12</sup> Several different groups have developed guidelines for the management of IPMNs.<sup>21–23</sup> The most commonly used guidelines are the International Consensus Criteria (ICC), which will be reviewed here.<sup>21</sup> These guidelines recommend consideration of surgical resection in the presence of "high risk features," which are jaundice caused by an IPMN, an enhancing mural nodule, or main-duct IPMN measuring greater than 9 mm. "Worrisome features" are the presence of dilation of the main pancreatic duct between 5 to 9 mm, abrupt change in caliber in the main pancreatic duct, a nonenhancing mural nodule, thickened or enhancing wall, cyst size of 3 cm or more, or a recent history of acute pancreatitis. In the case of worrisome features, EUS should be performed; where there is clear evidence of main-duct IPMN, a definite mural nodule on EUS, or cytology showing marked atypia or invasive adenocarcinoma, surgical resection should be considered. In all other cases surveillance can be undertaken with the interval determined by the size of the cyst. The positive predictive value of worrisome, high-risk, or worrisome or high-risk features is 29%, 66%, and 36%, respectively, for the presence of high-grade dysplasia or invasive cancer.<sup>21</sup> The absence of any of these features has a negative predictive value of 90%.<sup>21</sup>

IPMNs affect the entire pancreas and can develop in the residual pancreas following resection. In addition, patients with IPMNs are also at risk of developing pancreatic adenocarcinoma in an area unrelated to a pancreatic cyst.<sup>14</sup> The remnant pancreas should therefore undergo surveillance following a Whipple or distal pancreatectomy.<sup>21,22</sup>

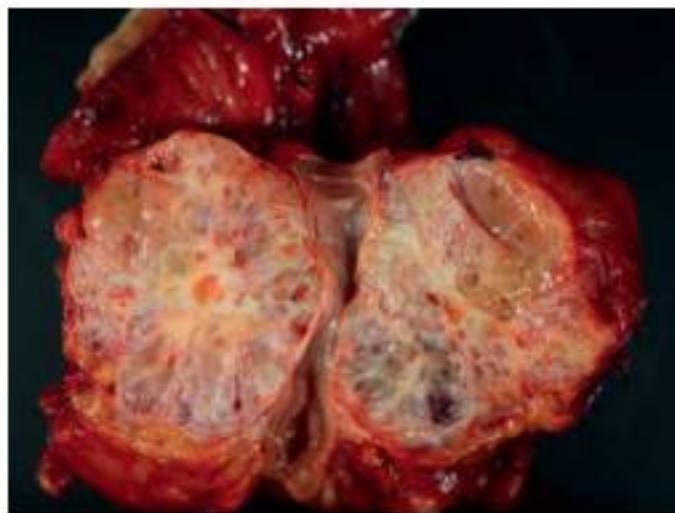

In cases that cannot tolerate or refuse surgery, or in asymptomatic BD-IPMN patients without risk factors, EUS-guided cyst ablation has emerged as a promising approach. The first well-demonstrated study showed a 33% rate of complete cyst ablation following EUS-guided cyst lavage with ethanol.<sup>24</sup> Infusing and leaving paclitaxel in the cyst after ethanol lavage raised the complete ablation rates to 60% to 79% in further studies.<sup>25–27</sup> EUS-guided radiofrequency ablation is another alternative treatment. In a preliminary study, the response ranged from complete resolution to a 50% reduction in size.<sup>28</sup>

### Serous Cystic Neoplasm

SCNs are predominantly benign neoplasms that can arise anywhere in the pancreas, and malignant SCNs are extremely

**TABLE 61.2 Genetic Profile of Pancreatic Cysts**

Mutation	SCA	SPN	MCN	IPMN

**FIG 61.7** Macroscopic view of a serous cystic neoplasm. Note the stellate-shaped central scar and numerous small cysts.

rare<sup>39</sup> (Fig. 61.7). The degree of dysplasia categorizes these cysts into serous cystadenomas and serous cystadenocarcinomas. The typical clinical presentation of a SCN occurs mostly in women over the age of 60 years. SCNs are slow-growing tumors<sup>40</sup> and are usually incidentally detected on abdominal imaging for other unrelated conditions.<sup>41,42</sup> The *VHL* gene mutation plays an important role in the pathogenesis of SCNs<sup>43,44</sup> and, in contrast with mucinous cysts, *KRAS* mutations are not seen in SCN.<sup>45</sup>

Glycogen-rich cells that are stained periodic acid-Schiff (PAS)-positive arise from centroacinar cells of the pancreas and line SCNs. The SCN wall is thin and surrounds a thin nonviscous and bloody cyst fluid. SCNs contain a prominent fibrous stroma, glycogen-rich epithelial cells, and endothelial, as well as smooth, muscle cells.<sup>46</sup> Ultrastructurally, the fibrocollagenous stroma is composed of myofibroblasts and endothelial cells embedded in thick collagen bundles. Estrogen and progesterone receptors are not present.<sup>47</sup>

Histologic variants include macrocystic serous cystadenomas, solid serous adenomas, VHL-associated SCNs, and mixed serous neuroendocrine neoplasms.<sup>39</sup> The majority of SCNs are microcystic, and the classical appearance of a microcystic SCN is a cluster of numerous tiny cysts separated by a delicate fibrous septa, which resembles a "honeycomb-like appearance" on cross-sectional abdominal imaging or EUS. Microcystic lesions grow slowly; however, they may reach large diameters. Frequently the large lesions have a stellate-shaped central scar. Macrocystic (oligocystic) serous cystadenomas are composed of fewer and larger cysts<sup>48–49</sup> and can be difficult to distinguish from an MCN, BD-IPMN, and a pseudocyst. VHL-associated SCN consists of multiple SCNs that affect patients with the *VHL* syndrome. The mixed serous neuroendocrine neoplasms are rare and highly suggestive of *VHL* syndrome.<sup>39</sup>

Although most SCN patients present with abdominal pain and discomfort historically, many patients may present with a palpable mass when the cyst attains a large size. Currently, SCNs are mostly detected in asymptomatic patients during evaluation for another indication.

On CT and MRI, the diagnostic classical appearance is a solitary lesion composed of a central scar surrounded by multiple tiny cysts. Alternatively, the macrocystic serous cystadenomas

on cross-sectional imaging are usually indistinguishable from BD-IPMNs and MCNs.<sup>40,50</sup> As discussed previously, MCNs are solitary, thinly septated cysts and may have "eggshell" peripheral calcification, which is in contrast with central scar and calcification in SCNs. Pseudocysts are unilocular lesions with pancreatic parenchymal changes (calcification and atrophy). The presence of multiple, small, thin-walled cysts is suggestive of *VHL* syndrome.<sup>51</sup> Additionally, SCNs generally do not communicate with the pancreatic duct, which is best seen on MRCP. The typical appearance of SCNs on EUS is numerous anechoic small cysts with thin septations. EUS with Doppler may demonstrate the characteristic hypervascular central region. The cyst fluid is nonviscous and may be bloody (because of this hypervascular nature) during EUS-FNA. The cytology is negative for malignancy, but PAS-positive small cuboidal cells are diagnostic for SCNs.<sup>52</sup> However, diagnostic cytology for SCN is rare. A CEA level of less than 5 ng/mL is also highly suggestive of an SCN,<sup>53</sup> and SCNs are negative for both *KRAS* and *GNAS* mutations but positive for *VHL* mutations.<sup>54–56</sup>

Currently, with the available diagnostic studies, the differentiation of pancreatic cysts is sometimes challenging. Needle-based confocal endomicroscopy is a novel endoscopic technique that enables real-time optical biopsies and provides in vivo histopathological assessment during EUS-FNA. On confocal endomicroscopy, SCNs demonstrate a typical superficial vascular network, whereas IPMNs show papillary projections with an epithelial border and vascular core.<sup>57,58</sup>

The prognosis for SCNs is excellent.<sup>59</sup> Generally, SCNs should be followed by surveillance imaging. Previously large SCA size or rapid growth had been considered indications for surgical resection; however, a large, multicenter study in over 2500 patients with SCA found that the risk of serous cystadenocarcinoma was 0.1%.<sup>60</sup> Surgery should only be considered for symptomatic SCAs or when there is an uncertainty about the diagnosis and a concern for malignancy.<sup>61</sup>

### Solid-Pseudopapillary Neoplasm

SPNs are rare neoplasms of the pancreas that typically affect women in their 30s. Microscopically, a mixture of solid (solid pseudopapillary) and cystic (hemorrhagic-necrotic pseudocystic) components is observed. SPNs are usually well-circumsized, single, round, and fluctuant masses and are most commonly found in the body and tail of pancreas.<sup>62,63</sup> The majority of SPNs were symptomatic in the past; however, currently incidental detection on cross-sectional imaging is becoming more common. The most common symptoms are abdominal pain, vomiting, nausea, and patients may have a palpable mass.<sup>64</sup>

Although the majority of SPNs demonstrate a benign behavior, they are generally considered as low-grade malignant neoplasms. Criteria for solid pseudopapillary carcinoma are defined as vascular invasion, perineural invasion, invasion of adjacent tissues, or metastases.<sup>65</sup> The most common site of metastases is the liver.

On CT and MRI, SPNs may appear as well-demarcated encapsulated pancreatic masses mixed with solid components without septa (Fig. 61.8). MRI reveals lower signal intensity on T1-weighted images and higher signal intensity on T2-weighted images. The capsule is usually thick, and sometimes internal calcifications may be observed.<sup>66</sup>

The typical appearance of SPN on EUS is a well-demarcated, hypoechoic, solid-appearing mass, which can also sometimes appear as a mixed cystic and solid lesion or purely cystic lesion.<sup>67</sup> The aspirated fluid is typically bloody, highly cellular, and CEA level is low, consistent with nonmucinous epithelium.<sup>67</sup>

SPNs are slow-growing neoplasms, and complete resection is the treatment of choice. Surgery is curative in most cases, and recurrence rates after resection are very low.<sup>61,62</sup> Prolonged survival is reported even in patients with recurrence and metastases.<sup>64,65,70</sup>

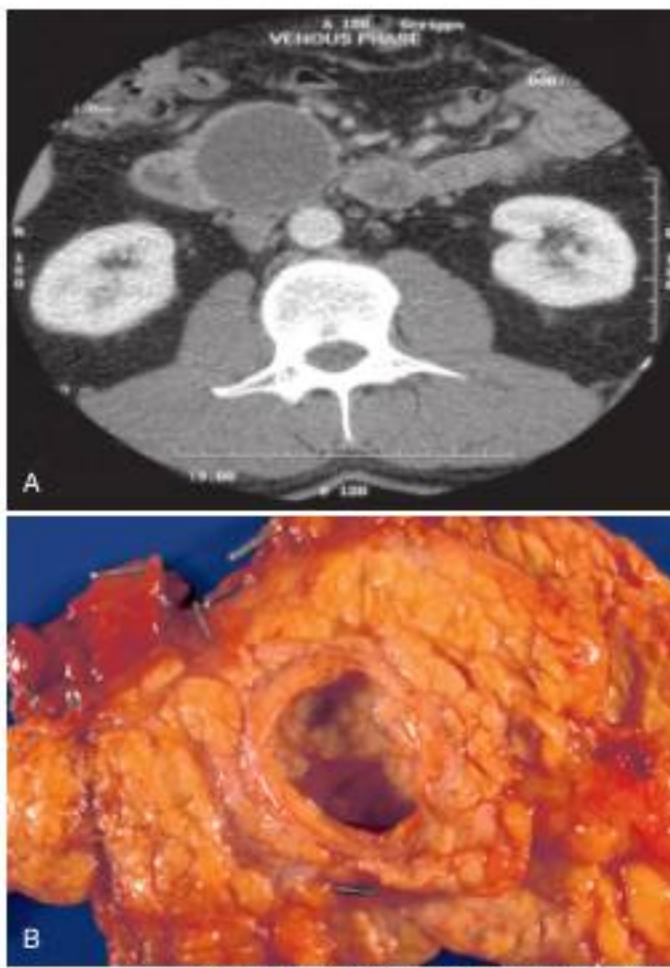

**FIG 61.8** CT showing a solid-pseudopapillary neoplasm. Note the mixture of solid and cystic components.

### Pancreatic Neuroendocrine Tumors

PNETs are rare neoplasms that account for less than 10% of all pancreatic neoplasms.<sup>66,71</sup> They are indolent tumors, which arise from both endocrine and nervous system cells with a variable malignant potential. 1% to 2% of pancreatic neoplasms are PNETs,<sup>72</sup> both sexes are equally affected, and the incidence of PNETs increases with age. The majority of PNETs are hormonally nonfunctional and are frequently sporadic; however, an association with von Hippel-Lindau syndrome (vHL), multiple endocrine neoplasia type 1, and neurofibromatosis type 1 may be seen.<sup>73-76</sup>

PNETs are well-circumscribed lesions, surrounded by a thick, fibrous capsule and may be unilocular or multilocular. Generally, they do not communicate with the pancreatic duct, and their size varies from small to large. The aspirated fluid is usually hemorrhagic, and the lesion appears like a hypoechoic mass after aspiration. A large hypervascular pancreatic mass on CT/MRI in a patient without producing hormonal symptoms is highly suspicious for nonfunctional PNETs.<sup>77,78</sup> To differentiate from malignant tumors of pancreas, EUS-FNA and scintigraphy are the most valuable tools (Fig. 61.9).

Surgery with complete resection is the only curative therapy for PNETs. Somatostatin analogs for functional tumors are recommended. Locoregional treatment is suggested for liver metastasis and chemotherapy is suggested for residual disease.<sup>79</sup> The prognosis is better than for pancreatic adenocarcinoma.<sup>80</sup>

**FIG 61.9** **A**, CT showing a thick-walled cystic lesion consistent with a cystic pancreatic neuroendocrine neoplasm. **B**, Macroscopic view of the same lesion. **C**, Histologic view of the same lesion.

## APPROACH FOR A PATIENT WITH A PANCREATIC CYST

When a patient with a pancreatic cyst is seen, we review their cross-sectional imaging to determine the type of cyst, and to evaluate whether there are any features concerning for the presence of high-grade dysplasia or invasive carcinoma. In cases in which the diagnosis is unclear, or there are concerning features, then EUS +/- FNA is performed with cyst fluid sent for CEA, amylase (if there is concern for a pseudocyst), KRAS, GNAS, and cytology.

For patients with BD-IPMNs, there are several different guidelines available, including those developed by the American College of Gastroenterology<sup>20</sup> (ACG), the ICC,<sup>21</sup> the European Consensus Criteria (ECC),<sup>21</sup> and the American Gastroenterology Association (AGA).<sup>22</sup> Updated guidelines are expected from the ACG and ECC in 2017, as concerns have been raised about several aspects of the AGA guidelines.<sup>21–23</sup> We therefore currently follow the revised ICC with presumed BD-IPMNs measuring under 1 cm followed every 2 years, 1 to 2 cm BD-IPMNs followed yearly, and BD-IPMNs over 2 cm, or IPMNs with main duct involvement, followed every 6 months. Surveillance intervals can be increased if the cysts are stable in size and have no concerning features.

### EUS FOR THE EVALUATION AND STAGING OF PANCREATIC TUMORS

#### Introduction

Examination of the pancreas and biliary structures by endoscopic ultrasound (EUS) can be technically challenging to master due to the need to recognize patterns of normal, benign, and pathologic anatomy. However, once these skills are learned, EUS permits the most detailed nonoperative view of the pancreas and the bile ducts. This chapter summarizes the role of EUS for the evaluation of solid malignant pancreatic and biliary neoplasms.

#### EUS Detection of Pancreatic Tumors

EUS is the most sensitive imaging test for the detection of all pancreatic and periampullary lesions (Table 62.1).<sup>1–4</sup> In studies that compared EUS and computed tomography (CT), the sensitivity of EUS for mass detection was superior to CT.<sup>1–4</sup> EUS is clearly superior to conventional CT<sup>1–4</sup> and transabdominal ultrasound (US).<sup>1–3</sup> A few comparative studies between EUS and multidetector-row CT (MDCT) for pancreatic tumors have demonstrated the superiority of EUS for tumor detection. There are relatively sparse comparative data between EUS and magnetic resonance imaging (MRI) for tumor detection, with at least one study showing the superiority of EUS.<sup>4</sup> EUS is particularly useful for identification of small tumors that can go undetected by other imaging modalities.<sup>1,4,7,8</sup> For tumors of 30 mm or less in diameter (Fig. 62.1), EUS was found in early literature to have a sensitivity of 93% compared to 53% for CT and 67% for MRI.<sup>4</sup> Nowadays, with thinner slice imaging and precisely timed contrast administration coupled with multiplanar reconstruction, CT (often referred to as *pancreas protocol*) may now be able to identify

small pancreatic masses that previously may have been undetected by conventional or even single-detector dual-phase imaging.<sup>9</sup> EUS remains the test of choice in all patients with obstructive jaundice or dual pancreatic and bile duct dilations in whom CT or MRI do not identify a lesion.

EUS has a few limitations including the potential failure to identify true pancreatic masses in patients with chronic pancreatitis, a diffusely infiltrating carcinoma, a prominent ventral/dorsal split, or after a recent episode (< 4 weeks) of acute pancreatitis. Therefore, a normal pancreas by EUS examination essentially rules out pancreatic cancer, although follow-up EUS or other studies should be undertaken in the setting of chronic pancreatitis due to impaired visualization. It is also important to remember that acoustic shadowing caused by an indwelling biliary or pancreatic stent may also impede visualization of a small pancreatic mass.

Due to the ability of EUS to provide high-resolution images, there has been increasing interest in using this technique to screen asymptomatic high-risk cohorts for early cancer detection. A consensus statement by the International Cancer of the Pancreas Screening Consortium recommended screening with EUS and/or MRI for the following groups: first-degree relatives (FDRs) of patients with pancreatic cancer from a familial pancreatic cancer kindred with at least two affected FDRs; Peutz-Jeghers syndrome; *p16* or *BRCA2* mutations; and hereditary nonpolyposis colorectal cancer mutation carriers with 1 or more affected FDRs.<sup>9</sup> A 2016 comparative analysis highlighted the complementary roles EUS and MRI play in screening these high-risk individuals.<sup>10</sup> MRI was found to be more sensitive for the detection of cystic lesions of any size; EUS, however, detected more solid lesions than MRI. The optimal screening modality, interval, need for

**Abstract**

Endoscopic ultrasound (EUS) permits the most detailed non-operative view of the pancreas and extrahepatic biliary system that is available. This facilitates the detection of malignant pancreaticobiliary lesions at an early stage before such lesions become detectable by conventional cross-sectional imaging like computed tomography (CT) or magnetic resonance (MR). The tissue acquisition (TA) capabilities of EUS add a substantial depth to its clinical applications, providing a safe and accurate method to confirm various types of pancreaticobiliary pathologies prior to initiation of therapy. EUS continues to play an important role in the care of pancreaticobiliary malignancies by triaging patients to operative or non-operative care largely due to its ability to detect early metastasis and vascular invasion. Recently, EUS provided a solid platform for a variety of novel tissue and imaging-based technologies that can help render better-quality care to this group of patients. This chapter summarizes the role of EUS for the evaluation of solid malignant pancreatic and biliary neoplasms.

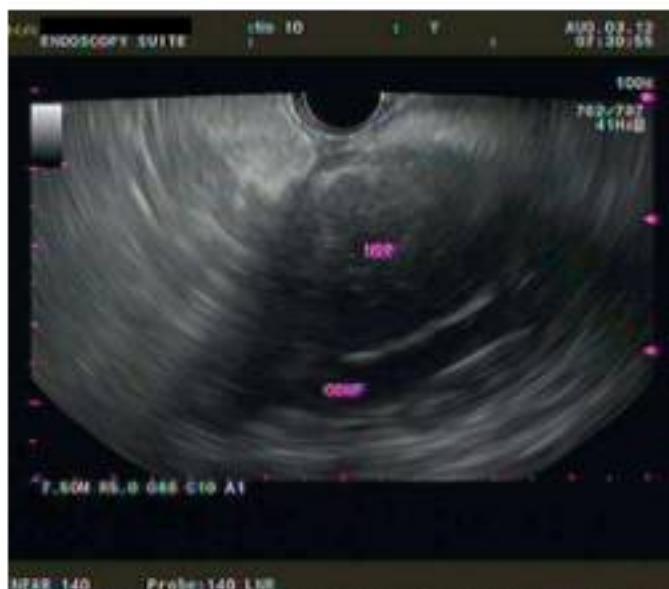

**FIG 62.1** Endoscopic ultrasound images of a 2.9-cm hypoechoic, irregular pancreatic body mass encasing the splenic vessels. SA, Splenic artery; TU, tumor.

fine-needle aspiration (FNA), and screening abnormalities of sufficient concern for surgery remain unknown, and further studies are required to answer these questions.

Autoimmune pancreatitis (AIP) may mimic pancreatic adenocarcinoma, and accurate preoperative detection may avoid unnecessary surgery. The EUS morphology of AIP may include diffuse pancreatic enlargement, a focal mass, focal hypoechoic areas, bile duct wall thickening, or peripancreatic lymphadenopathy (Fig. 62.2).<sup>11</sup> EUS-guided fine-needle aspiration (EUS-FNA) may demonstrate a nonspecific plasmacytic predominant chronic inflammatory infiltrate, but this finding has variable sensitivity and poor specificity. Diagnosis may be confirmed by EUS-guided core biopsies with staining for IgG4 plasma cells.<sup>12,13</sup>

Imaging-based technologies such as contrast-enhanced ultrasonography (CE-EUS) may be able to differentiate pancreatic adenocarcinoma from pancreatic neuroendocrine tumors (PNETs) and inflammatory pseudotumors, which can all present as a hypoechoic mass. Whereas ductal adenocarcinomas typically demonstrate hypoenhancement, PNET and inflammatory pseudotumors are hyperenhancing or isoenhancing. A recent

**FIG 62.2** Endoscopic ultrasound images of autoimmune pancreatitis presenting as a hypoechoic mass in the head of the pancreas with dilation of the common bile duct. CONF, Portovenous confluence; HOP, head of pancreas.

meta-analysis of 12 studies involving 1139 patients reported a pooled sensitivity, specificity, and receiver operating characteristic (ROC) of 94%, 89%, and 0.9732, respectively.<sup>14</sup> EUS elastography is another emerging technique based on the different stiffness of benign and malignant tissue. In a meta-analysis of 13 studies involving 1044 patients, the pooled sensitivity, specificity, and ROC was 95%, 67%, and 0.90.<sup>15</sup> However, several limitations to their routine use exist and include costs and the lack of both agent availability and expertise with the technique.

#### Staging of Pancreatic Adenocarcinoma

Staging of pancreatic malignancy is done according to the American Joint Committee for Cancer (AJCC) Staging TNM classification, which describes the tumor extension (T), lymph node (N), and distant metastases (M) of tumors, respectively. Reported accuracies of T-staging by EUS range from 62% to 94% (Table 62.2).<sup>2-4,6,8,10-21</sup> This wide variation may be due to improved detection of distant metastasis or vascular invasion by MDCT, resulting in less operative management for suspected locally advanced or metastatic disease. The exclusion of such patients may have resulted in the decreased T-staging accuracy of some recent studies compared to earlier ones. For the last decade, some tertiary referral centers will attempt to achieve negative surgical margins by surgical resection with or without reconstruction of the portal and/or superior mesenteric vein in patients with venous invasion without thrombosis or occlusion. Currently, only vascular invasion of the celiac or superior mesenteric arteries is classified as T4 cancer (Box 62.1).

Nodal (N) metastases have uniformly been classified as absent (N0) or present (N1) across all AJCC editions. The accuracy of EUS for N-staging of pancreatic tumors ranges from 50% to 86%.<sup>2-4,6,8,10-21</sup> Various criteria have been proposed for endosonographic features of metastatic lymph nodes including: size greater than 1 cm, hypoechoic echogenicity, distinct margins, and round shape. When all four features are present within a lymph node, there is an 80% to 100% chance of malignant invasion.<sup>22</sup> However,

**BOX 62.1 American Joint Committee on Cancer (AJCC) 2010 TNM Staging Classification for Pancreatic Cancer**

**Primary tumor (T)**

TX: Primary tumor cannot be assessed

T0: No evidence of primary tumor

Tis: Carcinoma in situ

T1: Tumor limited to the pancreas, 2 cm or less in greatest dimension

T2: Tumor limited to the pancreas, more than 2 cm in greatest dimension

T3: Tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery

T4: Tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor)

**Regional lymph nodes (N)**

NX: Regional lymph nodes cannot be assessed

NO: No regional lymph node metastasis

N1: Regional lymph node metastasis

**Distant metastasis (M)**

MX: Distant metastasis cannot be assessed

MO: No distant metastasis

M1: Distant metastasis

**AJCC Stage Groupings**

Stage 0: Tis, NO, MO

Stage IA: T1, NO, MO

Stage IB: T2, NO, MO

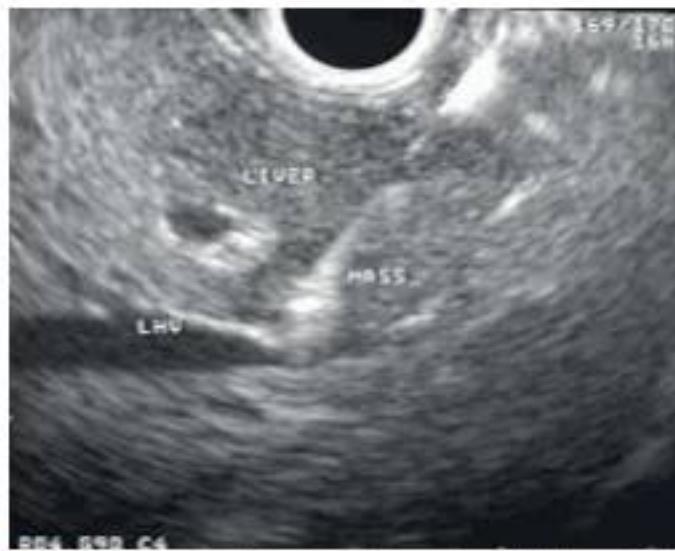

Stage IIA: T3, NO, MO

Stage IIB: T1, N1, MO or T2, N1, MO or T3, N1, MO

Stage III: T4, any N, MO

Stage IV: Any T, any N, M1

sensitivity of EUS for malignant lymphadenopathy is often lower, presumably for two reasons. First, most metastatic lymph nodes do not have all four endosonographic features described previously. Second, peritumoral inflammation and large tumor size may obscure visualization of adenopathy. The specificity of EUS alone for the diagnosis of metastatic adenopathy in pancreatic cancer is 26% to 100%,<sup>2,6,17,19</sup> with most reported specificities being above 70%. It is presumed that the addition of EUS-FNA of suspicious lymph nodes may increase specificity, although little data support this. For tumors involving the head of the pancreas, malignant lymph nodes are removed en bloc, with the surgical specimen and accurate detection of these lymph nodes not essential. However, as preoperative identification and EUS-FNA of celiac nodes may preclude surgery, meticulous survey of this region is critical during staging of all pancreatic tumors. Mediastinal lymph node metastases occur in a minority of patients and thus, a brief survey of this region may be helpful during staging of pancreatic lesions.

Although early studies found EUS to be superior to conventional CT for tumor<sup>1,6</sup> and nodal<sup>2–4</sup> staging of pancreatic cancer, more recent studies have found that the two are equivalent for both tumor<sup>17,18</sup> and nodal staging.<sup>8,17,19</sup> Similarly, early experience reporting on the superiority of EUS over MRI<sup>3,4</sup> have been replaced by more recent data that have found little to no difference.<sup>18,21,23</sup> Clearly, the initial advantage demonstrated by EUS over other imaging modalities for the staging of pancreatic tumors has narrowed considerably due to the rapid advancement in imaging technologies.

For detection of non-nodal metastatic cancer, CT and MRI are superior to EUS due to both the anatomic limitations of normal upper gastrointestinal anatomy and the limited range of EUS imaging. However, EUS still has an important role in the evaluation of hepatic metastasis in the left or caudate lobe and malignant ascites, both of which may be accessible by EUS-FNA (Fig. 62.3). Identification of liver metastases or malignant ascites by EUS-FNA may preclude surgical resection and is associated with poor survival following diagnosis.<sup>24</sup>

### Assessment of Vascular Invasion

Interpretation of data regarding the accuracy of EUS for vascular invasion is difficult for several reasons. First, there is little histologic correlation with intraoperative findings regarding vascular invasion in most studies. Second, there is no established consensus among endosonographers for the optimal criteria to utilize for determination of vascular invasion. Consequently, multiple criteria have been proposed by various authors for this indication.

For overall vascular invasion, the accuracy of EUS ranges from 68% to 93%.<sup>6,10,23,25</sup> Sensitivity and specificity of EUS for malignant vascular invasion range from 42% to 91% and 89% to 100%, respectively.<sup>6,10,23,25</sup> Although some have reported EUS as more accurate<sup>6</sup> than CT for vascular invasion, others report the opposite.<sup>14,25</sup> Overall accuracy of MRI is reportedly equivalent<sup>19</sup> or superior<sup>25</sup> to EUS.

The sensitivity of EUS for tumor invasion of the portal vein (PV) or PV confluence is 60% to 100%<sup>3,17,18,26</sup> with most studies demonstrating sensitivities over 80% (Fig. 62.4). The sensitivity of EUS for PV invasion is consistently superior to that of CT.<sup>23,27,18</sup> For the superior mesenteric vein, superior mesenteric artery (SMA), and celiac artery, the sensitivity of EUS is only 17% to 83%,<sup>25</sup> 17%,<sup>27</sup> and approximately 50%,<sup>2,18</sup> respectively. The sensitivity of CT for staging of the SMA<sup>17,27</sup> and celiac artery<sup>2,18</sup> appear to be better than EUS. EUS staging of the superior mesenteric vessels may be difficult due to either the inability to visualize the entire course of the vessel or the obscuring of these vessels by a large tumor in the uncinate or inferior portion of the pancreatic head.<sup>20</sup> This is in contrast to the splenic artery and vein, which are generally easily seen and staged well by EUS.<sup>18,28</sup> Until further conclusive data become available, assessment of tumor resectability should be done by both EUS and CT (or MRI) rather than by EUS alone.

Several studies have attempted to describe the accuracy of various endosonographic features to assess vascular invasion by malignant pancreatic tumors. Using the criteria of abnormal contour, loss of hyperechoic interface, and close contact, Rosch et al (1992)<sup>2</sup> found a sensitivity, specificity, and accuracy of 91%, 96%, and 94%, respectively, for invasion of the PV. The same

authors later found that no single criterion was able to predict venous invasion with a sensitivity and specificity exceeding 80%.<sup>26</sup> However, they found that both complete vascular obstruction and the presence of collaterals demonstrated a specificity of 94% for vascular invasion. There exists a tradeoff between various criteria for sensitivity and specificity for vascular invasion. However, criteria with the highest specificity are needed to optimize selection of those most likely to benefit from surgical exploration. Therefore, the findings of an irregular vascular wall, venous collaterals and visible tumor within the vessel are the preferred criteria for assessment of vascular invasion.

### Resectability of Pancreatic Tumors

Complete surgical resection of pancreatic cancer with negative histopathologic margins (R0 resection) is the only potentially curative treatment and is an independent predictor of postoperative survival.<sup>28,29</sup> Therefore, the main role of preoperative evaluation is to accurately identify patients with resectable disease who may benefit from surgery while avoiding surgery in patients with suspected unresectable disease (Fig. 62.5).

In a pooled analysis of 9 studies involving 377 patients, the sensitivity and specificity of EUS for resectability of pancreatic cancer was 69% and 82%, respectively.<sup>6,8,16,19,23,25,30–32</sup> Ranges of reported sensitivities and specificities were 23% to 91% and 63% to 100%, respectively. Overall EUS accuracy for tumor resectability was 77%.

Because most studies have reported that EUS is similar to both CT and MRI for assessment of resectability, some authors have proposed that optimal preoperative imaging of pancreatic cancer requires the use of multiple modalities. Using a decision analysis, Soriano et al (2004)<sup>33</sup> found that accuracy for tumor resectability was maximized and costs were minimized when CT or EUS was performed initially, followed by the other test in those with potentially resectable neoplasms. Ahmad et al (2000)<sup>34</sup> proposed that although EUS and MRI individually are not sensitive for tumor resectability, their use together may increase positive predictive value of resectability compared to either test alone. When surgery is performed only when MDCT and EUS agree on tumor resectability, DeWitt et al (2004)<sup>35</sup> reported a nonsignificant trend toward improved accuracy of resectability compared to either study alone. However, a study by Bao et al (2008)<sup>36</sup> found that MDCT was a better predictor of resectability than EUS, although the performance of EUS improved in patients without biliary stents. From a practical standpoint, the actual role of EUS in staging of pancreatic cancer will depend on its availability, referral patterns, and local expertise.

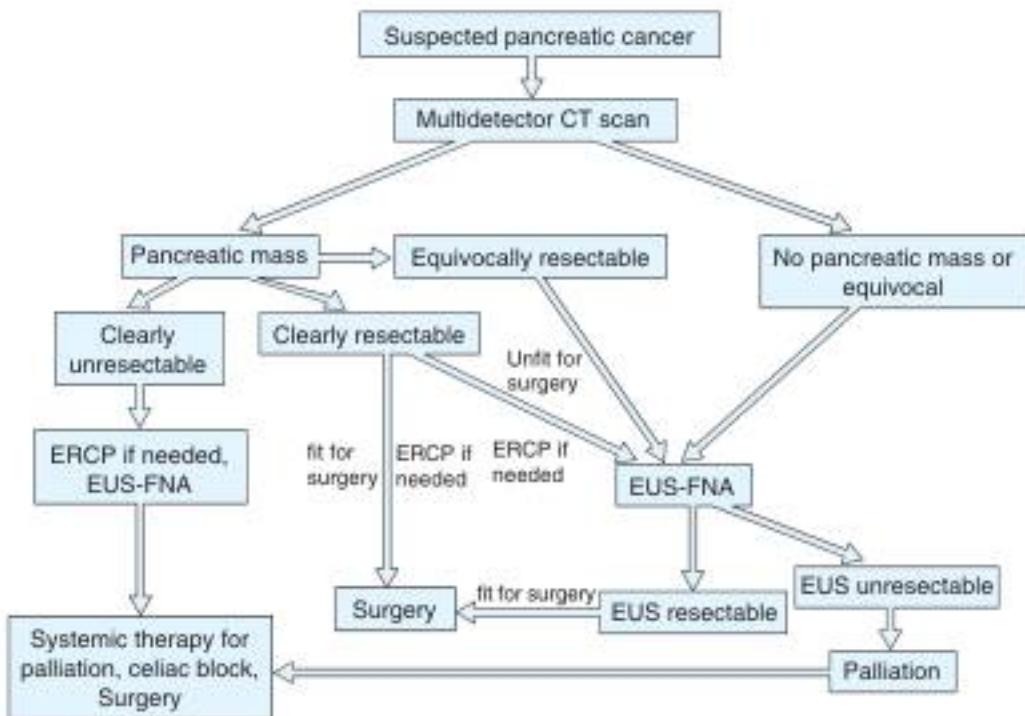

### EUS-FNA of Pancreatic Cancer

EUS-FNA remains the preferred method to sample pancreatic mass lesions due to its high accuracy, well demonstrated by two meta-analyses that reported sensitivity and specificity in the range of 85% to 89% and 96% to 98%, respectively.<sup>34,35</sup> However, the diagnostic accuracy of EUS-FNA may be impaired in the setting of chronic pancreatitis. Fritscher-Ravens et al (2002)<sup>36</sup> found that in a series of 207 consecutive patients with focal pancreatic lesions, the sensitivity of EUS-FNA for the diagnosis of malignancy in patients with normal parenchyma (89%) was superior to those with parenchymal evidence of chronic pancreatitis (54%).

On-site cytopathology review is available currently at most referral centers to provide immediate feedback to the endosonographer about the quality of EUS-FNA specimens obtained. On-site

**FIG. 62.4** A pancreatic head mass with direct invasion into the portal vein (PV) and superior mesenteric artery (SMA). CON, Portovenous confluence.

review was found to correlate highly with the final diagnosis and can improve diagnostic certainty.<sup>35</sup> Occasionally, on-site cytology review of a suspected pancreatic cancer demonstrates insufficient tissue to confirm malignancy. This may be due to tumor necrosis, fibrosis, or hypervascularity. Yield may be increased by "fanning the lesion" using different angles of scope deflection in order to sample the peripheral parts of the lesion with a more viable tumor.<sup>36</sup> Increasing the number of passes may also overcome this problem, but the additional yield typically plateaus at 7 passes, and the amount of blood in the aspirate may increase with additional passes.<sup>37</sup> In this situation, avoiding suction and switching to a smaller-gauge needle could help limit the amount of blood in the specimen. Improving the yield of EUS-FNA by modifying the current sampling techniques has been the focus of several recent studies. Among the factors found to not increase the diagnostic yield include replacing the stylet after every pass.<sup>38</sup> Use of suction during FNA is generally recommended for pancreatic solid lesions but not for associated adenopathy due to increase in bloodiness of the sample.<sup>39</sup> Other novel techniques involving wet suction instead of vacuum, and the capillary stylet withdrawal technique showed superior diagnostic yield and cellularity and is discussed elsewhere in this book.<sup>41,42</sup>

The most commonly used commercially available EUS-FNA needles are 19-, 22- and 25-gauge needles. The impact of needle size on the diagnostic accuracy of EUS-FNA has been an area of uncertainty until recently. In a meta-analysis of 8 studies involving 1292 patients who underwent EUS-FNA with either a 22- or 25-gauge needle and had surgical histology or at least 6 months follow-up as the reference standard, Madhoun et al (2013)<sup>40</sup> reported that the sensitivity of the 25-gauge needle was superior to the 22-gauge (93% vs. 85%,  $p = 0.0003$ ), although they have comparable specificity (97% and 100%, respectively).

Major complications following EUS-FNA of solid pancreatic masses occur in 0.5% to 2.5% of patients, including a 1.2% risk of pancreatitis and a 1% risk of severe bleeding.<sup>44–46</sup> In another prospective study, no delayed complications following EUS-FNA were reported in 127 patients with solid pancreatic masses followed for 30 days.<sup>47</sup> The risk of peritoneal seeding of tumor cells following EUS-FNA (2.2%) appears to be less than CT-guided FNA (16.3%) but requires further study.<sup>48</sup>

Despite excellent accuracy and a low incidence of major complications, EUS-FNA of pancreatic masses has several limitations. First, an on-site cytopathologist during EUS-FNA is recommended for assessment of specimen adequacy but is not available at some centers. Second, primary pancreatic lymphomas and well-differentiated ductal adenocarcinomas are often difficult to diagnose by use of cytology alone. Finally, the low negative predictive value of EUS-FNA does not permit exclusion of malignancy in negative specimens. To address these limitations, core biopsy devices have been developed to obtain histological tissue samples using a standard linear array echoendoscope. Two such devices include the Quick-Core and ProCore biopsy needles (Cook Medical, Bloomington, IN). In a multi-center cohort study of 109 patients with intestinal and extra-intestinal lesions (including 47 pancreatic tumors), the ProCore needle provided adequate histology and a correct diagnosis in 96% and 89% of cases, respectively.<sup>49</sup> However, a recent meta-analysis comparing the performance of the ProCore needle with standard FNA needles, including nine studies of 576 patients, demonstrated no difference in diagnostic adequacy (75% vs. 89%), diagnostic accuracy (86% vs. 86%) or rate of histological core specimen acquisition (78% vs. 77%) between the ProCore and standard FNA needles, respectively. The mean number of passes required for diagnosis, however, was significantly lower when using the ProCore needle

(standardized mean difference 1.2,  $p < 0.001$ ).<sup>30</sup> Nevertheless, ProCore biopsy needles will continue to have niche applications including autoimmune pancreatitis<sup>12</sup> and lymphoma,<sup>31</sup> where its superiority has been demonstrated. In addition, core biopsy needles could be used as a rescue technique when on-site FNA results are inconclusive or if this service is not available.

Some investigators have evaluated whether analysis of abnormal genes may increase the diagnostic yield of EUS-FNA of pancreatic masses. A meta-analysis of 8 prospective studies, involving 931 patients who had k-ras mutation, reported a pooled sensitivity and specificity of 77% and 93%, respectively.<sup>31</sup> When combined with EUS-FNA alone, the addition of k-ras mutation testing increased sensitivity from 81% to 89% but reduced specificity from 97% to 92%. Fluorescence in situ hybridization is another assay that was found to augment the sensitivity of cytology alone by 11%, according to Levy et al (2012).<sup>32</sup> Due to the high diagnostic accuracy of standard EUS-FNA, as well as the cost and limited availability of these genetic tests, it appears that use of genetic testing of EUS-FNA samples should be limited to inconclusive specimens and research protocols. Additional assays (like microRNAs and proteomics) are being evaluated on an experimental basis,<sup>33</sup> but clinical studies are needed to define its role in the diagnostic work-up of pancreatic tumors.

### Pancreatic Neuroendocrine Tumors

PNETs are rare solid, cystic or mixed neoplasms that represent less than 10% of pancreatic tumors (Fig. 62.6). Approximately one-third of these tumors are classified as functional PNETs (FPNETs) in which excessive hormone secretion produces a distinct clinical syndrome. The two most clinically important FPNETs are gastrinomas and insulinomas. When PNETs do not produce a clinical syndrome, they are classified as nonfunctional (NFPNETs). Due to a lack of characteristic symptoms related to hormone excess, NFPNETs are usually recognized later, with larger tumors and nonspecific symptoms such as jaundice, weight loss, abdominal pain, or pancreatitis. Similar to primary ductal adenocarcinoma, surgical resection is the only cure for these tumors. Therefore, a high index of suspicion coupled with a stepwise preoperative evaluation for localization may optimize patient selection for potentially curative surgery.

**FIG 62.6** Thick-walled cystic tumor in the head of the pancreas diagnosed on fine-needle aspiration (FNA) as a neuroendocrine tumor.

In a series of studies that compared EUS to other imaging modalities, the sensitivity of EUS for detection of PNETs was 77% to 94%.<sup>34–38</sup> EUS appears especially useful for detection of small PNETs (< 2.5 cm) missed by other imaging studies. The sensitivity of transabdominal ultrasound for detection of PNETs is poor and only between 7% and 29%.<sup>34,35,37</sup> Similarly, early studies with CT demonstrated poor sensitivity that was generally less than 30%.<sup>34,36,37</sup> However, with ongoing improvements in CT scanners and the development of MDCT, the sensitivity of CT for PNETs has improved. In their study of 217 patients with 231 PNETs, Khashab et al (2011)<sup>39</sup> reported an overall sensitivity for MDCT of 84%. Factors associated with reduced sensitivity include small lesions less than 2 cm in diameter and insulinomas, which had a sensitivity of 54%. Among the 56 patients who had both CT and EUS, the sensitivity of EUS was far greater than CT (91.7% vs. 63.3%,  $p = 0.0002$ ). Whereas MDCT is a suitable initial imaging modality for PNET, EUS provides cytologic confirmation and the detection of suspected CT negative PNET. In addition, EUS is the preferred initial imaging modality for insulinomas due to the low sensitivity of MDCT. In addition to their known role in assessing cystic lesions, MRI is an excellent imaging modality for PNET with sensitivity of 85% to 100%.<sup>40,41</sup>

The use of EUS-FNA permits tissue confirmation of a suspected PNET. In a retrospective study of 30 patients, Ardenghi et al (2004)<sup>42</sup> reported a sensitivity, specificity, positive and negative predictive values, and accuracy of EUS-guided FNA of 82.6%, 85.7%, 95%, 60%, and 83.3%, respectively for tumor diagnosis. In a larger 2012 study of 81 patients, EUS-FNA correctly diagnosed a PNET in 73 out of 81 patients, with a diagnostic accuracy of 90.1%.<sup>43</sup> For cystic PNETs, the use of FNA was studied by Riditid et al (2015) in a case-controlled study comprising 50 patients with cystic PNETs compared to a cohort of 50 patients with solid PNETs over a 14-year period.<sup>44</sup> EUS-FNA accuracies for malignancy of cystic and solid PNETs were 89% and 90%, respectively; cystic PNETs were less associated with metastatic adenopathy (22% vs. 42%,  $p = 0.03$ ) and liver metastasis (0% vs. 26%,  $p < 0.001$ ). Cyst fluid analysis showed that benign cystic PNETs had low carcinoembryonic antigen, Ki-67 (< 2%). Immunocytochemistry staining for synaptophysin was seen in all 100 cases included in the study, whereas chromogranin A was positive in 90% and 88% of the cystic and solid PNETs, respectively.

Preoperative EUS-guided tattooing has been demonstrated to aid in intraoperative localization of an insulinoma,<sup>45</sup> and more recently demonstrated to be of utility for all small pancreatic lesions.<sup>46</sup> This information may confirm clinically suspected tumors and aid in appropriate planning of medical or surgical management.

### Other Pancreatic Tumors

Primary pancreatic lymphoma (PPL) is rare and accounts for less than 0.5% of pancreatic tumors.<sup>47</sup> They are localized to the pancreas and peripancreatic lymph nodes and, by definition, do not involve other lymphoid tissue. PPL may present as a hypoechoic mass with poorly defined borders indistinguishable from pancreatic adenocarcinoma (Fig. 62.7). Whereas EUS and radiographic imaging alone may not confirm the diagnosis, EUS-FNA with flow cytometry is very accurate for PPL. In a case series of 16 patients with PPL, Khashab et al (2010)<sup>48</sup> reported a sensitivity and specificity of EUS-FNA with cytology and flow cytometry of 85% and 100%, respectively. This is in contrast to EUS-FNA with cytology alone, which had a sensitivity and

**FIG 62.7** A well-delineated hypoechoic mass in the pancreatic tail adjacent to a cyst, diagnosed on FNA as a primary pancreatic lymphoma.

specificity of less than 30%. This diagnosis should be suspected based on clinical appearance, lack of definite malignancy, and abundance of abnormal lymphocytes on rapid cytological review.

Isolated pancreatic masses are usually due to focal chronic pancreatitis, benign neoplasms, or primary pancreatic malignancies. Rarely, metastasis to the pancreas from another primary malignancy occurs and has been reported in 2% to 3% of pancreatic resections.<sup>53</sup> Accurate identification of isolated pancreatic metastases is clinically important because aggressive surgical resection in selected patients may permit long-term survival. In other patients, however, proper diagnosis may avoid unnecessary surgery and permit triage to more appropriate nonoperative therapy.

EUS features of pancreatic metastases appear to be different from those observed in cases of primary pancreatic cancer. In 7 patients with metastatic pancreatic lesions, Palazzo et al (1996)<sup>54</sup> described homogeneous, round, well-circumscribed lesions in 15 out of 16 masses observed. Compared to patients with primary cancer ( $n = 80$ ), DeWitt et al (2005)<sup>55</sup> found that pancreatic metastases ( $n = 24$ ) were more likely to have well-defined borders compared to irregular margins. In another report of 11 patients with metastatic renal cell carcinoma (RCC),<sup>56</sup> ten had well-defined borders (Video 62.1). Therefore, it appears that EUS visualization of a well-defined pancreatic mass in a patient with a history of malignancy should raise suspicion for a metastatic lesion.

EUS-FNA permits an accurate cytologic diagnosis of metastatic lesions to the pancreas. In the largest series to date of 72 masses in 49 patients, El Hajj et al (2013)<sup>57</sup> reported metastatic lesions from the kidney ( $n = 21$ ), lung ( $n = 8$ ), skin ( $n = 6$ ), colon ( $n = 4$ ), breast ( $n = 3$ ), small bowel ( $n = 2$ ), stomach ( $n = 2$ ), liver ( $n = 1$ ), ovary ( $n = 1$ ), and bladder ( $n = 1$ ). Metastasis to the pancreas may occur many years (especially for RCC) after diagnosis of the primary tumor. In patients with a remote history of malignancy, obtaining additional cytological material for cell block and the use of immunocytochemistry may be helpful to confirm the diagnosis of pancreatic metastases and recurrent malignancy.

## Conclusion

We can confidently state that EUS has passed the test of time as the modality of choice for the detection of pancreatic tumors, mainly small solid lesions. Although the competitive edge of EUS in the staging of pancreatic tumors appears to be eroding due to the rapid improvement in imaging technologies, the role that EUS plays in predicting their resectability remains obvious due to its ability to detect occult metastasis missed by other preoperative imaging studies. EUS-guided tissue acquisition is essential in the management of pancreatic tumors, mainly due to its high accuracy and low overall morbidity and mortality. Tissue confirmation is of particular importance in pancreatic cancer where the majority of patients are unresectable and tissue is needed prior to initiation of any systemic palliative therapies or neoadjuvant therapy in some potentially resectable patients. Finally, EUS-guided tissue helps triage the patients to the appropriate care in some conditions presenting as pancreatic cancer, such as pancreatic lymphoma and autoimmune pancreatitis.

## EVALUATION AND STAGING OF CHOLANGIOCARCINOMA

### Introduction

Cholangiocarcinoma (CCA) is rare tumor that is occurring with increasing frequency and develops from bile duct epithelium found within the intrahepatic and extrahepatic biliary tree, excluding the ampulla or gallbladder.<sup>58</sup> CCA is associated with a poor prognosis largely due to the tumor biology, late presentation, and difficulty in diagnosis. For hilar CCA, the 5-year survival after resection is 20% to 40%, largely dependent on tumor stage.<sup>59–61</sup> Liver transplantation of unresectable hilar CCA has a 5-year survival that approaches 75%.<sup>59–61</sup> Diagnostic and staging procedures must be improved to help identify patients most apt to benefit from these aggressive medical and surgical therapies, especially in regard to liver transplantation. This information helps direct resource utilization and allocation of scarcely available organs.

The limitations of diagnostic and staging modalities largely encouraged the new technology development. One such technology, EUS has seen a growing use for CCA due to its unprecedented imaging and tissue acquisition capabilities. However, there is some controversy regarding the role of EUS in CCA, especially as it pertains to the use of primary tumor FNA. Although FNA enhances diagnosis, it does so at the risk of tumor seeding. Whereas EUS findings help guide patient care and improve outcomes, misdirected use may result in iatrogenic upstaging and compromise patient care.

An aim of this section is to suggest a role for EUS in patients with suspected or known extrahepatic CCA based on published data. These data must be carefully considered because some investigators preselected patients with a suspected or confirmed CCA, versus others who evaluated a broader cohort having a "biliary stricture," "jaundice," or "pancreatic head mass."<sup>62–65</sup> (Table 62.3). Enrollment from a diverse patient cohort does help determine the role of EUS among patients with a given symptom or presentation. However, such studies often lack the ideal target enrollment population and often provide insufficient detail to establish the role of EUS in this setting (see Tables 62.3 and 62.4).<sup>62–67</sup> Another potential limitation when drawing any conclusion from existing studies of patients with CCA is the lack of clarity regarding the tumor location within the biliary tree. The

<sup>i</sup>Patients with cholangiocarcinoma cannot be reliably distinguished because the studies combine data from patients with other pathologies (e.g., pancreatic carcinoma, metastatic biliary lesions). Therefore, some of the following analyses are based on grouped data.

<sup>j</sup>The cited study included preselected patients whose enrollment necessitated endoscopic ultrasound (EUS) visualization and fine-needle aspiration (FNA). Therefore, the findings do not apply in terms of stricture/tumor detection.

<sup>k</sup>Tumor detection varied by site: Proximal 25/30 (83%) versus distal 51/51 (100%).

CCA, cholangiocarcinoma.

clinical presentation, diagnostic approach, and management vary for tumors within the proximal versus distal extrahepatic duct. Therefore, uncertainty regarding the tumor location leaves uncertainty as to how best to interpret and apply the data. Likewise, there are no published data to guide the use of EUS for intrahepatic CCA. To facilitate our discussion, we use the term *perihilar* to indicate tumors that are designated as hilar,

common hepatic duct, or proximal,<sup>17</sup> and use the term *distal* to represent tumors designated as distal or common bile duct (Video 62.2).

### EUS Stricture/Tumor Detection

Studies indicate that EUS imaging (not necessarily with FNA confirmation), identified 156 of 162 (96%) biliary strictures or

tumors.<sup>62,64–66</sup> In the two studies that clearly and specifically reported their data for CCA patients, EUS imaging detected 87 of 93 (94%) primary tumors.<sup>64,67</sup> One study provided separate data for proximal versus distal tumors and noted that proximal CCA was identified less often than distal CCA; 25 of 30 (83%) versus 51 of 51 (100%), respectively.<sup>67</sup>

### EUS-FNA Diagnostic Accuracy

One of the most beneficial yet potentially harmful applications of EUS in CCA patients is the use of FNA for primary tumor diagnosis (Fig. 62.8). The desmoplasia and tendency for longitudinal rather than radial growth associated with CCA can compromise efforts at a tissue diagnosis and result in a delayed or failed diagnosis. Endoscopic retrograde cholangiography and brush cytology with intraductal biopsy are the standard diagnostic approaches yielding a high specificity, but low diagnostic sensitivity of 20% to 60%.<sup>68–70</sup> The poor performance characteristics have led to the use of molecular markers, such as fluorescence in situ hybridization which increases diagnostic sensitivity by

<sup>a</sup>Indicates that data were not provided.<sup>b</sup>The diagnostic sensitivity was significantly greater when sampling distal versus proximal CCA; 38 of 47 (81%) versus 16 of 27 (59%),  $p = 0.04$ . EUS, endoscopic ultrasound; FNA, fine-needle aspiration.

10% to 30%, but in combination with standard cytology and biopsy still offer a composite sensitivity of only 60% to 70% in most series.<sup>62–64</sup>

Published reports show a diagnostic sensitivity for primary tumor EUS FNA between 29% and 89%, depending on the means by which cytological specimens were analyzed<sup>62–67</sup> (Tables 62.5 and 62.6). For studies that deemed a "positive" or "suspicious" cytological interpretation as indicative of malignancy, the diagnostic sensitivity was 124 of 169 (73%).<sup>62–67,67</sup> However, studies requiring a "positive" cytological interpretation reported a diagnostic sensitivity of only 63/106 (59%).<sup>62–66</sup> The diagnostic sensitivity of EUS FNA may be greater for distal versus proximal CCA; 38 of 47 (81%) versus 16 of 27 (59%),  $p = 0.04$ .<sup>67</sup> In contrast, one study reported a sensitivity of 32/36 (89%) for hilar strictures or tumors.<sup>62</sup> The diagnostic capabilities of EUS FNA are further demonstrated in studies employing FNA after either a negative or unsuccessful endoscopic retrograde cholangiography (ERC) sampling, yielding sensitivities of 77% and 89% for EUS FNA in these respective settings.<sup>62,67</sup>

### Tumor Seeding

The perceived risk and implications of tumor seeding following EUS FNA for CCA is debated. There are insufficient data to meaningfully guide this discussion, but our views are largely based on those of transplant centers, for which the impact of any perceived risk of tumor seeding most substantially impacts patient management. Tumor seeding is often referred to as needle track seeding or implantation metastasis and has been reported following EUS-,<sup>105–107</sup> percutaneous ultrasound- or CT-guided FNA of various sites including the brain, eye, thyroid, breast, lung, tongue, liver, gallbladder, pancreas, colon, kidney, ureter, bladder, stromal tumor, bone and bone marrow, and bile duct among others.<sup>98–103</sup> Tumor seeding has also been associated with preoperative percutaneous drainage and ERC with stent placement.<sup>104,105</sup>

Limited data suggest that the risk of clinically apparent tumor seeding following FNA is 1/10,000–40,000.<sup>106,107</sup> However, there are a number of limitations in determining the incidence of tumor seeding and the cited rates likely significantly underestimate the occurrence. The high mortality, short survival, and obviated need for subsequent abdominal imaging in patients with unresectable cancer prohibit accurate determination of the tumor seeding rate. Even for patients who undergo potentially curative resection, tumor seeding may result in minute foci of occult cells undetected in the surgical specimen or result in deposition outside the field of resection. These occult reservoirs of tumor cells may ultimately result in apparent clinical disease that is falsely considered to represent tumor recurrence rather than disease progression of occult tumor cells deposited during needle track seeding. There is also controversy as to the implications of tumor seeding, with some finding a correlation with clinical outcomes including tumor stage, prognosis, resectability, surgical margin status, recurrence, and survival.<sup>108–110</sup> Other investigators have failed to discover a correlation with clinical outcomes.<sup>110–112</sup>

The potential of tumor cells to be displaced during FNA was been demonstrated.<sup>113</sup> In 140 prospectively enrolled patients who underwent EUS, luminal fluid that is typically aspirated via the accessory channel was instead submitted for cytological analysis. The cytology specimens from the aspirated luminal fluid were positive for malignancy in 48% of patients, who had a luminal cancer, which may be accounted for by cells shed from the luminal cancer. More concerning was the post-FNA luminal fluid cytology that was positive for malignancy in 3/26 patients with pancreatic adenocarcinoma. Among patients with extraluminal cancers one would not anticipate recovering malignant cells from the gastrointestinal luminal fluid. These findings may indicate that the process of FNA displaces some malignant cells from the original primary site to the needle track and even more distant locations, and may help explain the process of needle track seeding. This hypothesis is supported in a study that evaluated the rates of peritoneal carcinomatosis in matched pancreatic adenocarcinoma cohorts diagnosed by either EUS versus percutaneously guided FNA.<sup>114</sup> Peritoneal carcinomatosis developed in 1 in 7 patients (2.2% vs. 16.3%;  $p < 0.025$ ) in the EUS FNA versus percutaneous FNA group, respectively. The findings indicate a potential difference in tumor seeding risk between biopsy approaches and potentially greater frequency of tumor seeding than historically appreciated. Similarly, a meta-analysis of 8 studies identified tumor seeding in 2.7% of patients following hepatocellular carcinoma biopsy.<sup>115</sup>

Another study evaluated the tumor seeding risk among 191 patients with hilar CCA who underwent primary tumor transperitoneal FNA as part of liver transplant evaluation for locally unresectable disease.<sup>120</sup> Among all 16 patients who underwent transperitoneal FNA (13 percutaneous, 3 EUS), the initial cytological specimens were interpreted as positive for malignancy ( $n = 6$ ), negative for nine ( $n = 9$ ), and one equivocal test result ( $n = 1$ ). During intraoperative staging, peritoneal metastases were identified in 5/6 (83%) versus 0/9 (0%) patients who had an FNA interpretation of positive versus negative, respectively. In addition, peritoneal metastases were discovered in only 14/175 (8%) patients who did not undergo FNA versus 5/6 (83%),  $p = 0.0097$ , with a positive preoperative FNA. However, the study findings must be carefully considered. For instance, based on their data it is not possible to determine whether clinical or tumor-related features indicated more advanced disease, which might have removed concern for tumor seeding, thereby leading to FNA. In addition, whereas both study groups had similar CA 19-9 levels, frequency of mass detection, tumor size, and histology, precise staging information was not provided. A discrepancy in staging may itself explain the greater occurrence of peritoneal metastasis rather than performing FNA.

Based on our communications, most liver transplant centers consider primary tumor FNA of suspected CCA an absolute contraindication, which must not only be considered by colleagues within such centers, but also by referring clinicians given the medical implications. This philosophy places additional burden and exhaustive efforts to firmly establish a CCA. Caution is needed if proceeding to surgery without a tissue diagnosis because 10% to 20% of patients resected for presumed CCA are ultimately diagnosed with benign disease or alternate tumor type.<sup>127–130</sup> The challenges of CCA diagnosis leads some to advocate less stringent surrogate markers (e.g., CA 19-9 levels and imaging criteria alone) as means of a presumptive diagnosis setting. Whereas this practice may be questioned even for highly experienced clinicians, there is particular concern for false diagnosis that may result in inappropriate and often risky surgery. Proper patient counseling is required to convey the potential for extensive operative intervention (even transplantation) for benign disease. Patients often accept this approach once understanding the diagnostic challenges and the importance of avoiding delayed oncologic care, as well as the risks and implications of tumor seeding.

### Staging and Resectability

Accurate tumor staging is needed to optimize clinical decision making. Several staging systems are utilized for CCA,<sup>77,131,132</sup> which differ in intended application and accuracy for determining prognosis and resectability, and when guiding the extent of resection. Common features employed by each staging system including the longitudinal tumor margins (proximal and distal), presence of nodal disease, vascular infiltration, parenchymal lobar atrophy, and distant metastasis. Improved preoperative staging reduces the need for isolated staging laparoscopy and rate of tumor upstaging at laparoscopy (Fig. 62.9).

Published data are limited and prohibit any meaningful effort to establish the utility of EUS for CCA staging. Existing studies provide few EUS staging details and the underlying aims and methodologies were insufficient to determine of EUS staging accuracy. One study did provide some useful staging data for the cohort of 81 patients, 75 of whom underwent evaluation for surgical candidacy.<sup>17</sup> Among the 15 patients ultimately designated as unresectable, EUS discovered the evidence of unresectable

**FIG 62.9** A cholangiocarcinoma infiltrating the portal vein on linear endoscopic ultrasound (EUS) exam. The X's delineate the interface between the bile duct and the portal vein.

disease in a greater number than CT; 8/15 (53%) versus 5/15 (33%), respectively. EUS identified six disease sites that were not discovered by CT/MRI including tumor infiltration of the PV ( $n = 2$ ), hepatic artery, celiac lymph node, liver metastasis, and peritoneum. In contrast, the sites discovered by CT/MRI that were not identified by EUS included PV invasion ( $n = 2$ ) and celiac lymphadenopathy ( $n = 1$ ). Finally, 4 disease sites were confirmed only at surgery and failed prior EUS or CT/MRI detection including malignant infiltration of the hepatic artery, PV, celiac node, and longitudinal bile duct extension. Other key data were excluded from this report, thereby limiting firm calculation of EUS staging and resectability accuracy.

#### EUS Nodal Staging and Features of Malignant and Benign Lymph Nodes

Most published data do not thoroughly indicate the accuracy of EUS nodal staging.<sup>87,133</sup> Other studies only indicated if any nodes had been identified<sup>82,24</sup> or often ignored this issue.<sup>83,200,201</sup> For CCA, lymph node metastasis is a poor prognostic indicator,<sup>134,135</sup> and distant malignant nodal involvement precludes curative resection. However, the significance of locoregional lymph node metastasis is debated. Transplant centers uniformly view any nodal involvement as an absolute contraindication to liver transplant and for many centers even precludes attempted curative resection.

The accuracy of EUS FNA nodal staging was studied among 47 patients with locally unresectable hilar CCA undergoing liver transplantation evaluation.<sup>133</sup> Lymph nodes were seen at EUS in each patient, resulting in FNA of 70 lymph nodes with metastatic adenopathy diagnosed in 8 patients. Only 2/8 patients' malignant nodes were detected by CT and/or MRI. For the 22 patients who had benign lymph nodes at FNA cytology, 20 (91%) were confirmed benign at exploratory laparotomy. However, EUS failed to detect malignant lymph nodes in 2 patients. Data were also obtained to help determine EUS features to distinguish benign from malignant nodes in patients with CCA. Conventional EUS features that include long-axis length, roundness, echogenicity, and homogeneity both individually and collectively provided poor predictive value (Table 62.7; Figs. 62.10 and 62.11). Therefore, in our practice, in patients with CCA we biopsy all

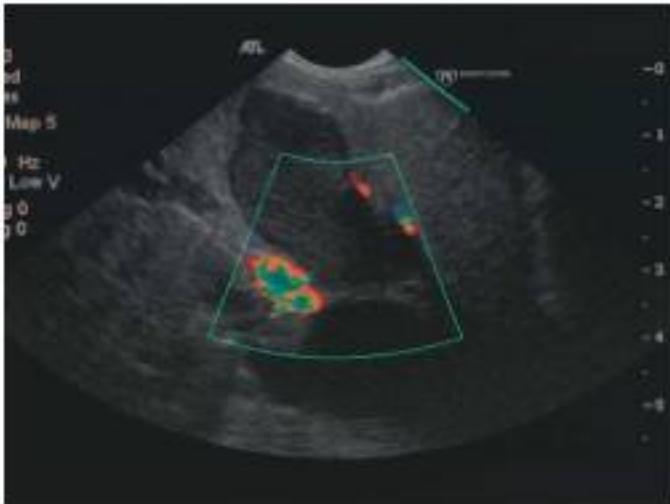

**TABLE 62.7 EUS Features for Malignant and Benign Lymph Nodes**

Mean	Malignant LN	Benign LN	P Value
Long Axis (mm)	1.61 +/- 0.61	1.47 +/- 0.78	0.68
Roundness Score	2.5 +/- 1.55	2.9 +/- 0.81	0.32
Echogenicity Score	4.0 +/- 0.63	3.78 +/- 0.71	0.48
Homogeneity Score	3.0 +/- 1.1	3.32 +/- 0.84	0.41

EUS, endoscopic ultrasound.

**FIG 62.11** Endoscopic ultrasound image of an established benign lymph node.

locoregional visualized lymph nodes regardless of the EUS appearance.

A separate study compared EUS and surgical nodal staging in 45 patients and reported an EUS diagnostic sensitivity of only 2/23 (9%). In this study, locoregional lymph nodes were not routinely sampled, which may have contributed to the low sensitivity.<sup>87</sup>

**TABLE 62.8 Potentially Confounding Variables and Complications**

Study	PSC Present	Stent Present at time of EUS	Complications Related to EUS

Summary	10/228 (4%)	131/146 (90%)	

<sup>a</sup> Indicates that data were not provided.

<sup>b</sup> Primary sclerosing cholangitis.

<sup>c</sup> There was no evidence of PSC at the time of EUS. Cholangiographic features of PSC subsequently developed in 3 patients.

<sup>d</sup> EUS FNA was falsely negative in the 4 patients with PSC.

<sup>e</sup> The diagnostic sensitivity of EUS FNA was 45 of 64 (70%) versus 9 of 10 (90%) for patients with and without a stent, respectively.

<sup>f</sup> Stent data were given for the initial 42 patients evaluated, but not specifically for the 40 patients ultimately included in the overall analyses.

EUS, endoscopic ultrasound; FNA, fine-needle aspiration.

### Potentially Confounding Variables and Complications

Primary sclerosing cholangitis (PSC) is a prime risk factor for developing CCA. Although details pertaining to PSC were typically limited or omitted among the 5 studies documenting this information, only 10/228 (4%) patients had PSC (Table 62.8).<sup>32–37</sup> This is important, as PSC is routinely associated with multiple and diffuse bile duct strictures, increased desmoplasia, and benign lymphadenopathy. Each of these features can negatively impact EUS imaging and FNA performance. Therefore, the low rate of PSC in the study cohort is likely to have artificially improved EUS imaging and FNA results from most practice settings.

Among the cited studies, a biliary stent was in place at the time of EUS in 131/146 (90%) patients (see Table 62.8). The presence of an indwelling biliary stent can impair EUS imaging due to stent-induced artifacts and stent-induced sludge. However, any impaired imaging is seldom of consequence except for diminutive biliary or pancreatic lesions. Imaging can be optimized by examination various locations, by limiting the amount of air insufflated that may pass through the stent into the duct, or by removing the stent prior to EUS. The presence of a stent can facilitate detection of a biliary mass, as the stent often courses through the lesion, aiding detection.

### Conclusion

The proper management of patients with suspected CCA requires a definitive tissue diagnosis. EUS is increasingly being used to both diagnose and stage CCA largely due to the limitations of endoscopic bile duct sampling. Whereas studies indicate the utility of EUS in patients with CCA, there remains debate as to the accuracy and role in this setting. Although some perform bile duct EUS FNA for primary tumor diagnosis, we strongly discourage doing so because of the potential for tumor seeding and impact on transplant candidacy or standard resection.

One should also consider the high false-negative of primary tumor FNA.

We consider CCA data to most strongly support EUS FNA to evaluate lymphadenopathy when considering liver transplantation. Confirmation of malignant lymphadenopathy avoids unnecessary neoadjuvant therapy and staging laparotomy, and resulting quality of life and cost. We believe EUS is indicated irrespective of the CT and/or MRI findings due to their insufficient sensitivity for lymph node detection and poor discrimination of benign from malignant nodes. Likewise, extensive sampling is indicated regardless of the nodal appearance due to the poor predictive value of EUS imaging features. Patients with negative FNA cytology subsequently undergo staging laparotomy to verify N0 status. Additional data are needed to clarify the role of EUS regarding other staging criteria in patients being considered for liver transplantation. More research is also needed to determine the impact of EUS staging among patients considered for non-transplant forms of operative intervention. Finally, existing reports provide no information pertaining to the use of EUS for intrahepatic CCA.

## INTRODUCTION

Pancreaticobiliary malignancies comprise a mixed bag of cancers including pancreatic cancer, carcinoma of the ampulla of Vater, duodenal carcinoma, gallbladder carcinoma, and cholangiocarcinomas. When they are located at the level of the liver hilum, cholangiocarcinomas are referred to as *Klatskin's tumors*. Although there are marked differences in biologic behavior and clinical outcome, the overall prognosis of these tumors is dismal. At the time of presentation, more than 80% to 90% of patients have locally unresectable disease or distant metastases, leaving only a few patients suitable for curative resection. Other treatment modalities such as chemotherapy and radiotherapy have little to no effect on survival, although various multimodality schemes in a (neo)adjuvant setting to surgery are currently being explored. Hence many patients, sooner or later in their disease course, are in need of optimal palliative treatment directed toward relief of jaundice, pain, and gastric outlet obstruction.

More than 85% of patients with pancreaticobiliary malignancies develop obstructive jaundice, and often it is a presenting symptom. Endoscopic retrograde cholangiopancreatography (ERCP) with placement of plastic or metallic self-expandable biliary stents has become the standard of care to relieve jaundice and has largely replaced surgical treatment. In case of failure of ERCP, percutaneous transhepatic cholangiographic drainage (PTCD) or endosonographic guided (EUS) biliary drainage are alternative treatment options.

## EPIDEMIOLOGY

Of all pancreaticobiliary malignancies, pancreatic adenocarcinoma has the highest incidence. It is the fourth leading cause of cancer death in the United States, and it is estimated that in 2016 approximately 53,070 people will be diagnosed with pancreatic cancer, and 41,780 will die as a result of the disease.<sup>1</sup> It is predicted to become the second leading cause of cancer death in the United

States by 2030.<sup>2</sup> Only a minority of patients (10% to 20%) are suitable candidates for curative resection, although this number is increasing with the advent of (neo)adjuvant chemo(radiation) therapy. The overall 5-year survival rate is still less than 4%. For patients having undergone a surgical resection it is less than 20%. Tobacco smoking doubles the risk of pancreatic cancer.<sup>3</sup> Patients with chronic pancreatitis have an increased risk for developing pancreatic cancer that is estimated at 4% per 20 years.<sup>4</sup> The risk of developing pancreatic cancer in patients with hereditary pancreatitis is 20% to 40%, with smoking as an important risk modifier.<sup>5</sup>

The incidence of gallbladder carcinomas averages 1 per 100,000 person-years, but is considerably higher among Native Americans. Patients most likely to survive are those in whom early cancer is detected in a postcholecystectomy specimen, with a 5-year survival of 80% to 100% for early T1-T2 cancers.<sup>6</sup> For locally advanced T3/4 tumors, survival drops to 10% to 30%. Gallstone disease is the most important risk factor for gallbladder cancer.<sup>7</sup>

Hilar cholangiocarcinoma originates from the biliary epithelium at the hepatic confluence. Radical surgical resection of the tumor offers the only chance for long-term survival, with 5-year survival rates reported between 25% and 40%.<sup>8,9</sup> The median survival of patients with unresectable disease is only 12 to 15 months.<sup>10</sup> Neoadjuvant chemoradiation followed by orthotopic liver transplantation has been employed for the treatment of patients with unresectable, nonmetastatic, perihilar cholangiocarcinoma with encouraging results.<sup>11</sup> Established risk factors for cholangiocarcinoma include parasitic infection of the biliary tract, primary sclerosing cholangitis (PSC), bile duct cysts, hepatolithiasis, and toxins (e.g., Thorotrast).<sup>12</sup>

Duodenal cancer is a rare condition that may occur sporadically, but patients with multiple duodenal adenomas, such as those that occur in familial adenomatous polyposis (FAP) and Gardner syndrome, are at particularly high risk.<sup>13,14</sup>

Ampullary carcinoma is a rare condition with an incidence of 0.49 per 100,000 persons.<sup>15</sup> Biliary obstruction usually develops

**Abstract**

Pancreaticobiliary malignancies include, but are not limited to, pancreatic cancer, carcinoma of the ampulla of Vater, duodenal carcinoma, gallbladder carcinoma, and cholangiocarcinomas. The overall prognosis of these tumors is dismal. At the time of presentation, more than 80% of patients have local unresectable disease or distant metastases. Chemotherapy and radiotherapy have limited effect on survival, although various multimodality schemes in a (neo)adjuvant setting to surgery are currently being explored. It is recognized that more than 85% of patients with pancreaticobiliary malignancies develop obstructive jaundice, and often it is a presenting symptom. Many of them will need optimal palliative treatment directed toward relief of jaundice, pain, and gastric outlet obstruction. Endoscopic retrograde cholangiopancreatography (ERCP) with placement of plastic or metal biliary stents has become the standard of care to relieve jaundice. Plastic stents insertion is usually reserved for patients with expected survival time limited to 3–4 months. Another indication for the use of plastic stents is the uncertainty of the malignant diagnosis, although the use of fully covered metal stents has been increasingly advocated for this situation. There is robust evidence on the superiority of metal stents over plastic ones with regard to long-term patency rate. There is a trend to give preference to fully and partially covered metal stents over uncovered ones, even considering a possible discrete increase in some adverse event rates such as migration and acute cholecystitis. Endoscopic biliary drainage of malignant hilar obstruction should aim for draining greater than 50% of liver parenchyma and every manipulated liver segment. Finally, in case of ERCP failure, endoscopic ultrasound (EUS)-guided biliary drainage has emerged as a valid option to percutaneous drainage. Local expertise, logistics, and cost issues should be taken into consideration in the planning of the therapeutic algorithm in case of ERCP failure.

jaundice

early in the course of the disease. As a result, tumors are often relatively small, and radical resection is possible in a large proportion of cases with an overall 5-year survival rate of 50%.<sup>18</sup>

## CLINICAL FEATURES

The most common presenting symptoms of pancreaticobiliary malignancies are painless jaundice, anorexia, and weight loss. If pain occurs, it is most often located in the epigastric region or right upper quadrant and may radiate to the back. Back pain usually indicates retroperitoneal tumor infiltration and unresectability. Other symptoms related to obstructive jaundice include dark urine, pale stools, and pruritus. At the time of presentation, approximately 80% of patients with pancreatic cancer have impaired glucose tolerance or diabetes mellitus. Carcinoma of the body and tail of the pancreas manifests with similar features, although jaundice is usually absent or develops very late in the course of the disease.

## PATHOLOGY

Approximately 90% of pancreaticobiliary malignancies are ductal adenocarcinomas (Fig. 63.1). Most tumors arise from the pancreatic head. Other exocrine malignancies are mucinous cystic adenocarcinoma and acinar cell carcinomas. Endocrine tumors include gastrinoma and insulinoma. Metastases of a primary tumor (mammary, lung, and melanoma) and lymphoma are rare but must be considered because of important treatment implications (e.g., chemotherapy) that influence prognosis. Mesenchymal tumors are extremely rare.

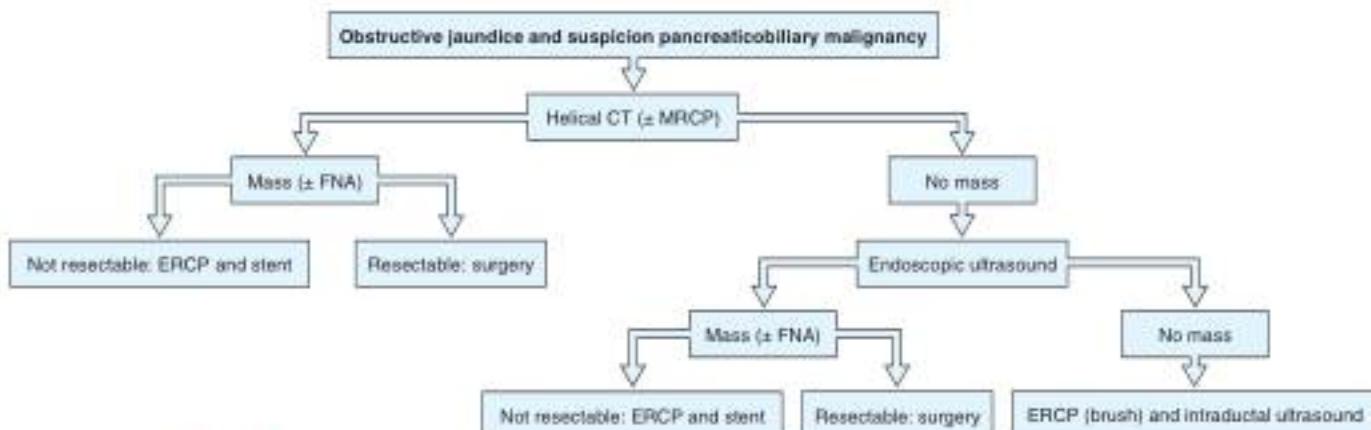

The definitive diagnosis of malignancy is dependent on acquiring a tissue diagnosis. Currently, with various means of tissue acquisition that all have proven to be safe procedures, it is advisable to always attempt to obtain a tissue diagnosis for diagnostic confirmation regardless of management consequences. Evidently it is a prerequisite when (neo)adjuvant or palliative chemo(radio)therapy is considered. If an ERCP is indicated for biliary drainage, one can attempt to obtain a tissue diagnosis by means of brush cytology, intraductal biopsies, or fluid collection from the bile duct or pancreas or both. Cytologic brushings are easy to obtain. Specificity approaches 100%, but sensitivity is relatively low, ranging from 30% to 45%.<sup>19</sup> The yield of intraductal

forceps biopsies is higher compared to brush cytology and approaches 50% to 60%.<sup>17,18</sup> Sampling of ductal fluid is a simple method that is not widely used, but may offer an additional way of obtaining a tissue diagnosis.<sup>20</sup> Several studies have shown that sensitivity can be increased by combining various techniques of tissue sampling. Endoscopic ultrasound (EUS)-guided fine-needle aspiration (FNA) or biopsy (FNB) has an excellent sensitivity of 85% to 90% and specificity that approaches 100%.<sup>21</sup> Although FNB provides the opportunity to obtain tissue cores with preservation of cellular architecture, thereby potentially increasing sensitivity and accuracy (including a better opportunity for advanced tissue processing, such as immunohistochemical analyses), that verdict is still out. Percutaneous computed tomography (CT)-guided FNA biopsy is another method for confirmation of malignancy, with a reported sensitivity of 60% to 90%. Some have argued that, because of the risk of needle tract seeding, this technique should only be used in cases of unresectable disease.

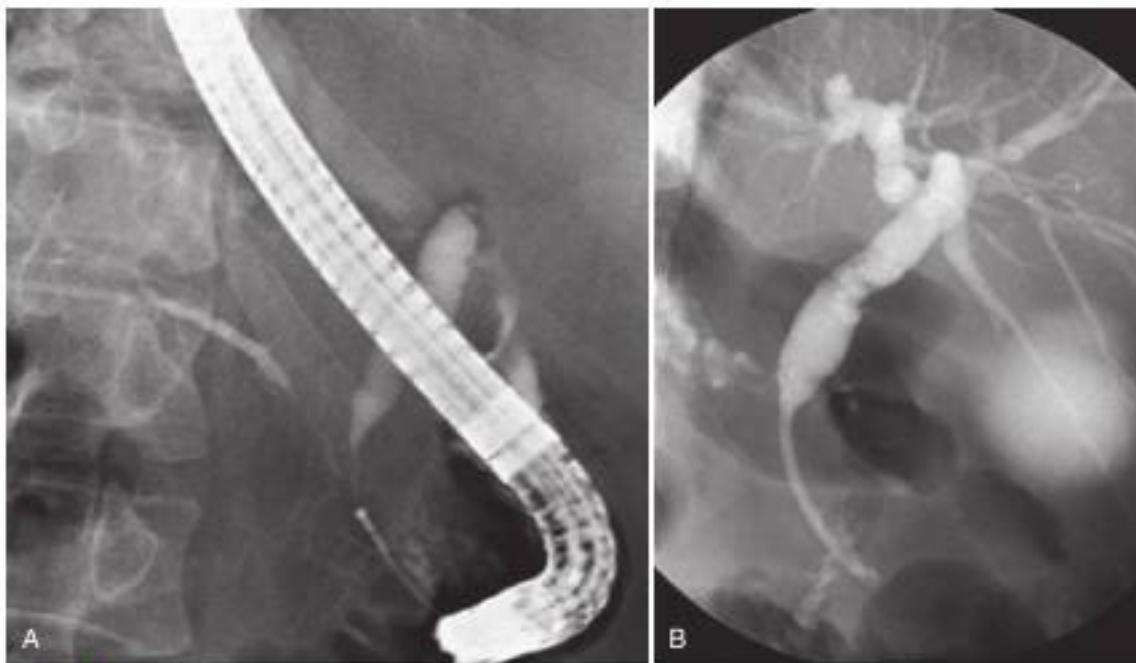

Single-operator digital cholangioscopy (SOC) and probe-based confocal laser endomicroscopy (pCLE) are recent additions for determining the nature of indeterminate biliary strictures. In a multicenter, observational study, SOC was performed in 44 patients with indeterminate biliary strictures.<sup>22</sup> The sensitivity and specificity of SOC visual impression for diagnosis of malignancy was 90% and 95.8%, respectively. All 44 patients underwent SOC-guided biopsies of which specimens were adequate for histologic evaluation in 43 patients (97.7%). The sensitivity and specificity of SOC-guided biopsies for diagnosis of malignancy was 85% and 100%. In a prospective, international, multicenter study, pCLE was investigated in 112 patients with indeterminate biliary strictures, of which 71 finally proved to be malignant. ERCP and pCLE had an 89% sensitivity, 71% specificity, and 82% accuracy rate for the correct diagnosis of the nature of the biliary stricture.<sup>23</sup>

## DIFFERENTIAL DIAGNOSIS

Adequate discrimination between a benign or malignant nature of a pancreatic head lesion is pivotal, as management differs substantially. In the case of the former, surgery may not be indicated and even harmful to the patient. In the latter case, surgery is the treatment of choice, if a lesion proves to be resectable. An enlarged pancreatic head may be caused either by

**FIG 63.1** Algorithm for diagnosis of pancreaticobiliary cancer. *CT*, computed tomography; *ERCP*, endoscopic retrograde cholangiopancreatography; *FNA*, fine-needle aspiration; *MRCP*, magnetic resonance cholangiopancreatography.

**FIG 63.2** **A**, Stenosis of both the common bile duct and the pancreatic duct, also called a double-duct sign, caused by pancreatic adenocarcinoma. **B**, A 10-Fr, 9-cm plastic endoprosthesis inserted through a distal bile duct stricture.

pancreatitis or by carcinoma. Autoimmune pancreatitis is a condition that is increasingly recognized and may mimic a malignant tumor. Differential diagnosis is based on a distinct clinical picture with a diffusely enlarged pancreas with a nondilated pancreatic duct, elevated IgG4 levels, and a prompt response to corticosteroid therapy with improvement of clinical symptoms, including jaundice, and resolution of morphologic abnormalities on cross-sectional imaging.<sup>23</sup>

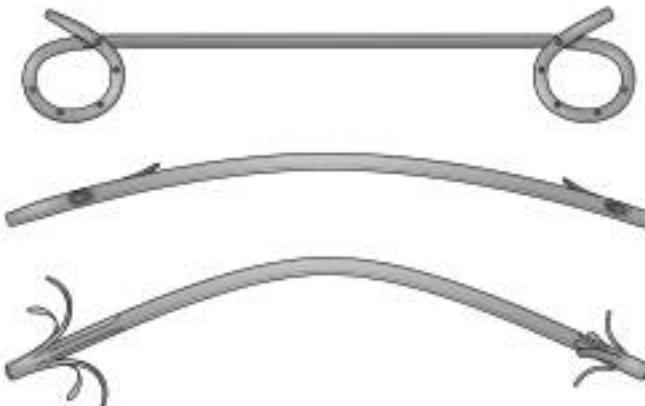

Paraduodenal pancreatitis, also known as groove pancreatitis, may also mimic pancreatic adenocarcinoma.<sup>24</sup> This condition is associated with chronic pancreatitis, male gender, and alcohol abuse.<sup>25</sup> Cross-sectional imaging typically demonstrates an enhancing mass in the paraduodenal space, with medial duodenal wall thickening and multiple cysts.<sup>26</sup>

Cystic lesions of the pancreas may be benign (pancreatic pseudocyst or serous cystadenoma), premalignant (intrapancreatic mucinous neoplasm [IPMN] mucinous cystadenoma), or malignant (cystadenocarcinoma, malignant degenerated IPMN). Radiologic imaging is used to characterize these lesions, although differential diagnosis, as well as assessing the degree of neoplastic progression, is notoriously difficult and challenging. EUS in combination with FNA, fluid analysis, intracystic biopsy, and probe-assisted CLE may increase diagnostic accuracy.<sup>27</sup>

Whenever there is a suspicious stricture in the mid-bile duct or proximal bile duct, a gallbladder carcinoma should be considered. It is also important to exclude benign causes of strictures, such as Mirizzi's syndrome, primary and secondary sclerosing cholangitis, and postoperative conditions. An algorithm for the diagnosis of pancreaticobiliary cancer is presented in Fig. 63.2.

### ENDOSCOPIC STENTING OF MALIGNANT BILIARY OBSTRUCTION

Since the introduction of endoscopic biliary stent therapy in 1980, the management of biliary obstruction due to pancreatic-

**FIG 63.3** Different types of plastic endoprostheses (from top downward): double-pigtail stent, Amsterdam-type stent (one side hole and one side flap at each end), and Tannenbaum-type stent (without side holes and multiple side flaps at each end).

cillary malignancies has changed considerably. Nowadays, endoscopic stent placement is the preferred treatment to relieve jaundice (Fig. 63.3). Compared with percutaneous and surgical drainage, endoscopic biliary stent therapy is associated with lower morbidity and mortality rates.<sup>28,29</sup> A potential complication of endoscopic biliary drainage is late stent occlusion causing recurrent jaundice, or cholangitis, which necessitates stent exchange. The technical success rate of endoscopic biliary drainage is between 70% to 90% and is higher for distal tumors compared with proximal malignancies involving the bifurcation. The complication rate of therapeutic ERCP is 5% to 10%.<sup>30</sup>

### Indications and Contraindications

Nowadays ERCP is almost exclusively a therapeutic procedure. Magnetic resonance imaging (MRI) and EUS have largely replaced

it for diagnostic purposes. Clinical symptoms that prompt biliary drainage via ERCP include jaundice, fever, and pruritus. Biliary stent placement has been shown to improve symptoms of anorexia and quality of life.<sup>31,32</sup> It has also been suggested that preoperative biliary drainage may improve surgical outcome after pancreaticoduodenectomy, but this has not been substantiated in clinical trials.<sup>33–35</sup> In a randomized study comprising 202 patients with pancreatic head carcinoma comparing direct surgery with delayed surgery after biliary drainage, surgical outcome and complication rates were not affected by preoperative stent placement.<sup>36</sup> The overall complication rate in the delayed surgery group with preoperative stent placement was significantly increased, mainly owing to stent-related complications. The outcome of this study strongly argues against standard preoperative drainage in patients with pancreatic head cancer in whom immediate surgery is planned. Preoperative drainage is indicated, however, when operative resection is not imminent; for example, because serum bilirubin exceeds 14 mg/dL, or when patients need to undergo neoadjuvant chemotherapy. In such cases, biliary drainage should be accomplished by inserting a metal biliary stent, as stent-related complications (occlusion and exchange) are significantly lower (6% versus 31%) compared to plastic stenting.<sup>37</sup>

There are few absolute contraindications to perform ERCP. Coagulation disorders are a relative contraindication and should be corrected before ERCP.

### Plastic Stents

The median patency of a conventional 10-Fr plastic stent is 3 to 6 months. The incidence of stent occlusion is 20% to 50%.<sup>38–40</sup> The initial event in stent blockage is adherence of proteins and bacteria to the inner wall of the stent and subsequent formation of a biofilm. Bacteria are introduced into the biliary system during transpapillary placement of the stent. Sludge forms from the accumulation of bacteria, which produce  $\beta$ -glucuronidase and

form calcium bilirubinate and calcium palmitate.<sup>41</sup> Many efforts have been made to prolong stent patency, some of which are discussed in the following paragraphs.

### Stent Diameter

The first biliary stents that were placed were only 7-Fr or 8-Fr in diameter because of limitations of the diameter of the working channel of the endoscope (2.8 mm). When side-viewing endoscopes with large-diameter working channels (4.2 mm) were introduced in 1980, it became possible to insert large-bore plastic stents. Larger stents (10-Fr) perform better than smaller stents (7- or 8-Fr) because of the higher flow rate, as predicted by Poiseuille's law, and because there is less stasis with larger diameter stents.<sup>42</sup> Theoretically, bile flow rate is proportional to the internal diameter raised to the fourth power; even a small increase in diameter results in a substantial increase in flow capacity. Contrary to this hypothesis, the use of even larger diameter plastic stents of 11.5-Fr or 12-Fr did not result in further improvements in stent patency.<sup>42–44</sup>

### Stent Design

The first biliary stents had a pigtail configuration at the proximal end to provide better anchorage. Straight stents were developed because of their improved bile flow characteristics compared with pigtail stents (Fig. 63.4).<sup>45–47</sup> Huibregtse and Tytgat developed the Amsterdam-type stent—a straight design with two side holes to facilitate biliary drainage and two side flaps to prevent dislocation—which has been the standard type of stent since 1980.<sup>48</sup> Sludge in plastic stents mainly accumulates around side holes.<sup>39,49</sup> This accumulation seems to be the result of higher intraluminal flow turbulence and decreased flow rates.<sup>41</sup> Soehendra and others postulated that elimination of side holes might improve patency rates and designed the so-called Teflon Tannenbaum stent (a straight stent without side holes and with multiple

**FIG 63.4** **A**, Mid-common bile duct stricture caused by gallbladder carcinoma. **B**, An 11-cm, 10-Fr plastic endoprosthesis has been inserted.

proximal and distal side flaps to prevent dislocation).<sup>51,52</sup> At first, uncontrolled results were encouraging, with patency rates comparable to metal stents, but randomized trials could not confirm these initial results.<sup>53-56</sup> Omitting side holes in a standard-design polyethylene stent also did not improve stent patency.<sup>53</sup>

#### Stent Material and Coating

Different materials have been used for stent construction, including polyethylene, polyurethane, and polytef (Teflon). In vitro studies have shown a direct relationship between the coefficient of friction and the amount of encrusted material. Teflon has the lowest friction coefficient and the best potential for preventing stent clogging. Initially, Teflon Tannenbaum stents showed a favorable patency rate.<sup>51,52</sup> A randomized study comparing Amsterdam-type stents made from polyethylene versus Teflon did not show a difference in stent patency.<sup>56</sup> Other controlled clinical trials also could not confirm the superiority of Teflon material in a Tannenbaum-design stent.<sup>52-54</sup> Scanning electron microscopy of out-of-package biliary stents has shown that the inner surface smoothness of plastic stents is highly variable. This variability is possibly a result of the manufacturing process of plastic stents by extrusion. Only the polyurethane stent was found to have an extremely smooth surface.<sup>57</sup> Two new polymers were introduced with an ultra-smooth surface, Vivathane and Hydromer. Both materials have been shown to reduce bacterial adherence in vitro. In addition, the Hydromer stent not only has a smooth texture but also a coating that absorbs water and provides a hydrophilic sheath. Because bacteria initially attach by hydrophobic interactions, this coating could potentially lower bacterial adhesion and increase stent patency. However, the encouraging results of in vitro studies could not be confirmed in prospective clinical trials.<sup>58,59</sup>

Priming the inner surface of a stent with a coating that comprises some form of antiadhesive property may reduce biofilm formation and stent clogging. Antibiotics, antithrombotics, silver, and hydrophilic coating all were effective in reducing bacterial colonization in vitro.<sup>60-62</sup> However, clinical studies using antibiotic-coated or hydrophilic-coated stents did not show any benefit.

#### Supra- Versus Transpapillary Plastic Stent Placement

Placing a plastic stent entirely within the common bile duct has the theoretical advantage of preserving the barrier function of the sphincter of Oddi; this prevents duodenal reflux of food and bacteria into the stent and biliary tree. This so-called inside stent approach can be performed only when a free margin of 1 to 2 cm is maintained between the distal end of the stricture and the papilla. With this parameter in mind, approximately one-third of patients with malignant obstructive jaundice are potential candidates for such treatment.<sup>63</sup> However, for plastic stents no difference was found in stent performance in a randomized trial. In the inside stent group, stent migration occurred significantly more often.<sup>64</sup>

#### Oral Antibiotics

Bacteria can enter the bile duct through the portal circulation, but more easily directly from the duodenum. When an endoprosthesis is placed, the barrier function of the sphincter of Oddi is lost, and bacteria enter the biliary tract freely. Sludge may form because these bacteria produce  $\beta$ -glucuronidase and form calcium bilirubinate and calcium palmitate. To prolong stent patency, prophylactic treatment with antibiotics seemed a logical step. In vitro studies showed that antibiotic treatment reduced

bacterial adherence to plastic stents.<sup>65</sup> In a prospective randomized study with ciprofloxacin, no difference in stent patency was found.<sup>66</sup> In another study, rotating antibiotics (cycles of 2 weeks of ampicillin, metronidazole, and ciprofloxacin) were combined with ursodeoxycholic acid, and no difference in stent patency was shown.<sup>67</sup> Only one small pilot study showed a reduced rate of stent blockage with norfloxacin plus ursodeoxycholic acid.<sup>68</sup> Other studies combining antibiotics and bile salts (ofloxacin and ursodeoxycholic acid, ciprofloxacin, and rowachol) did not show a longer duration of stent patency.<sup>69,70</sup> There is no compelling evidence that stent patency benefits from antibiotic prophylaxis.

#### Bile Salts

Bile salts have a potent antibacterial effect and may stimulate bile flow. Because bacteria attach by hydrophobic interactions, hydrophobic bile salts (deoxycholate, taurodeoxycholate) inhibit initial bacterial attachment, as was shown in experimental studies.<sup>71</sup> However, hydrophobic bile salts are not well tolerated. Hydrophilic bile salts such as ursodeoxycholate, which are better tolerated, have a minimal effect on bacterial adhesion. Except for one small pilot study, different prospective clinical studies using ursodeoxycholic acid alone or combining ursodeoxycholic acid with antibiotics could not show an improvement in stent patency.<sup>65-70</sup>

#### Aspirin

Animal studies in prairie dogs showed that aspirin inhibits mucous glycoprotein secretion by blocking prostaglandin synthesis.<sup>72</sup> In a clinical study, the use of aspirin reduced the content of all sludge components, although no effect was shown on stent patency.<sup>73</sup> No further studies using aspirin to prevent early stent clogging have been performed.

#### Elective Stent Exchange

Some endoscopists prefer to schedule patients for elective stent exchanges, usually every 3 to 4 months. The optimal time interval however, is unknown.<sup>74,75</sup> Prophylactic stent exchanges require multiple elective endoscopies over time. The risk and burden of such policy must be weighed against a policy of watchful waiting with a risk of (severe) cholangitis developing. Because many patients do not experience stent occlusion before dying of the underlying disease, some endoscopists favor an expectant management strategy.

#### Self-Expanding Metal Stents

The diameter of biliary stents was restricted by the size of the instrumentation channel of the endoscope until the development of self-expanding metal stents (SEMSs). All currently available expandable stents are made of metal. They differ in the way they are braided, the size of the mesh, the metal used, and their rigidity. One of the first available metal stents was the self-expanding Wallstent (Boston Scientific, Marlborough, MA). This stent is delivered in a collapsed configuration on an 8-Fr delivery system. When deployed, it expands to a final diameter of 30 Fr (approximately 10 mm) and foreshortens approximately 30% in length. The final diameter is achieved after 2 days to 1 week, when equilibrium is achieved between the dilating force of the stent and the resistance of the bile duct wall and tumor. These large-caliber SEMSs of 30 Fr remain patent for longer than plastic stents but do not prevent blockage indefinitely. Metal stents with a 6-mm diameter occlude significantly more frequently than 10-mm (30-Fr) metal stents, again showing that size is the most

\*Mean.

PE, polyethylene stent; SEMS, self-expanding metal stent.

important determining factor for stent patency.<sup>70</sup> Because of their design, SEMSs have much less surface to which bacteria can adhere. The mechanism of stent blockage differs from that seen in plastic stents and includes tumor ingrowth through the interstices of the stent or overgrowth of the end of the stent and intima hyperplasia. Several studies have shown a median stent patency of approximately 6 to 9 months of uncovered metal stents (Table 63.1).<sup>70,72-74</sup>

Various types of SEMSs are available to date. The wire construction is made of Nitinol or platinum-coated Nitinol Platinfold (Boston Sci, Natick, MA). Stents are available in uncovered, partially covered, and fully covered versions. The covering is intended to resist tumor ingrowth. Partially covered stents have noncovered parts at both stent ends. It was thought that the covering would reduce stent obstruction while fixation of the proximal stent end due to intimal hyperplasia would prevent stent migration. This, however, was not substantiated in a 2015 trial.<sup>75</sup> Nowadays, depending on the manufacturer, metallic expandable stents are available in 3 diameters (6, 8, and 10 mm) and various stent lengths ranging from 40 up to 120 mm. Most expandable metal stents foreshorten, and this should be taken into account when they are deployed. Stents with a slotted tube design like the Zilver biliary self-expandable stent (Wilson-Cook Medical, Winston-Salem, NC) have a particular advantage in that they do not foreshorten on expansion. Specially designed metal uncovered stents with a Y-type and T-type design are available for the treatment of hilar obstruction (see later section on Intrahepatic Biliary Obstruction).

#### Covered Metal Stents

Tissue ingrowth through the mesh of the stent is responsible for stent occlusion in approximately 22% to 33% of patients.<sup>75,76</sup> To overcome this problem, SEMSs have been covered with a polyurethane or silicone membrane. At first, many prospective cohort studies could not confirm a lower rate of tumor ingrowth while using covered metal stents.<sup>71,72</sup> However, in a prospective comparative study, stent obstruction owing to tumor ingrowth occurred significantly less frequently with covered stents compared with uncovered stents.<sup>73</sup> Data with regard to the risk of complications are limited, but stent migration, cholecystitis, and pancreatitis seem to occur at a slightly higher rate.<sup>72-74</sup> There seems to be no benefit from endoscopic papillotomy before deployment of covered metal stents with regard to the prevention of pancreatitis, whereas migration rates may increase.<sup>75</sup> Covered stents should not be used intrahepatically because of occlusion of hepatic side branches by the covering membrane. Taking into consideration the previously mentioned points, many endoscopists have more often used fully covered SEMS as the first-line stent to palliate malignant obstruction.

#### Supra- Versus Transpapillary Metal Stent Placement

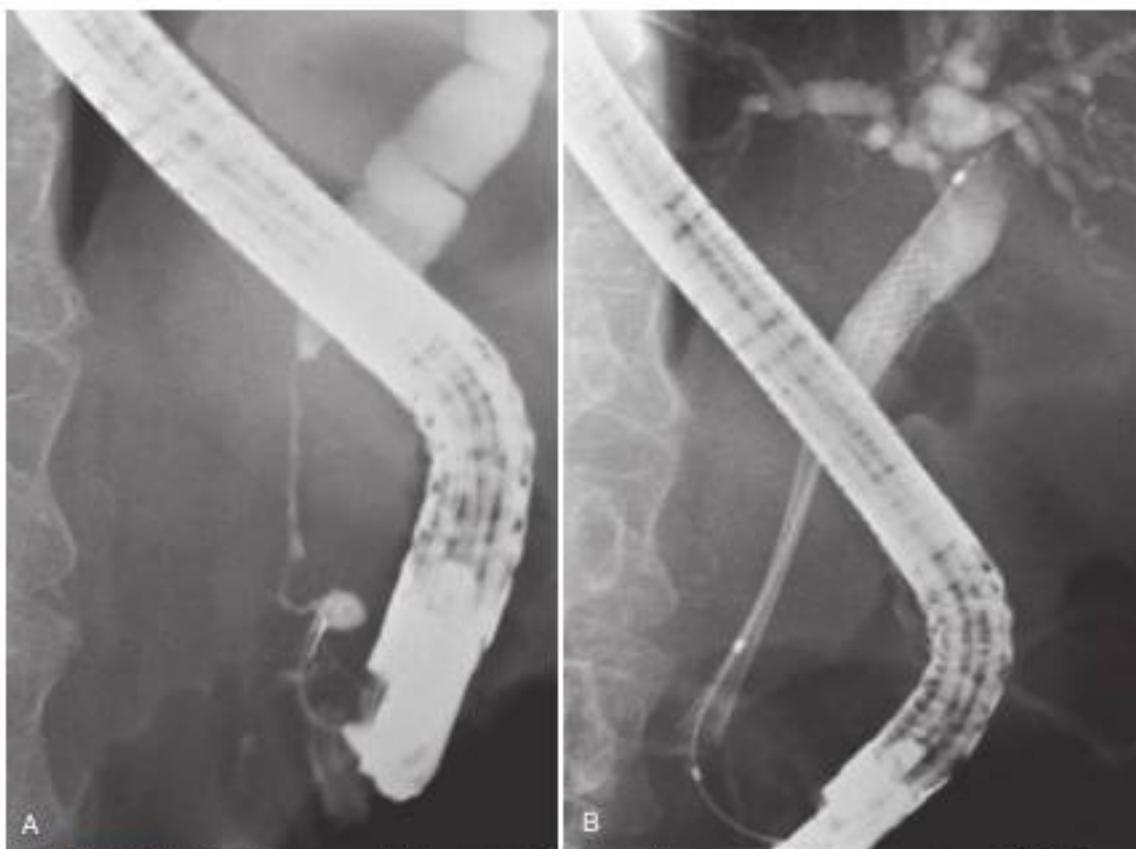

No studies have compared endoscopic supra- versus transpapillary metal stent placement without a preceding sphincterotomy to reduce metal stent clogging. After percutaneous transhepatic SEMS placement, however, stent occlusions by tumor growth was more frequently observed after suprapapillary stent placement ( $p = 0.007$ ), whereas stent occlusion by sludge incrustation was more frequently found after transpapillary stent placement.<sup>76</sup> Overall there was no significant difference in cumulative stent patency ( $p = 0.401$ ). For more proximal strictures, our routine practice is to place metal stents not crossing the papilla (after sphincterotomy), ensuring that the distal stent ends align horizontally with the duct for easy recannulation in case of obstruction. However there is no evidence to preferentially support either approach (having stent(s) cross the papilla after sphincterotomy or not).

#### Plastic Versus Metal Stent

SEMSs have a longer duration of patency than plastic stents and ideally should be placed in all patients. The high initial costs have limited their use in different health care settings worldwide. In a cost-effective approach, the choice between a plastic and metal stent depends mainly on an estimate of patient survival. Tumor size seems to be a reliable predictor of survival. Prat et al (1998) claimed that in the case of a tumor greater than 30 mm, a polyethylene stent should be placed because of shorter expected survival.<sup>77</sup> The presence and number of liver metastases have also been shown to be independently related to prognosis.<sup>78,79</sup> Comparative studies did not show any benefit of SEMSs compared with polyethylene stents in the first 3 months after insertion.<sup>75,77</sup> Therefore, it seems reasonable to insert a polyethylene stent in patients with a life expectancy of less than 3 months (Fig. 63.5). If expected survival is 3 to 6 months, a SEMS should be considered (Fig. 63.6), as various authors have shown this strategy to be cost-effective.<sup>77,78-80</sup> Patients scheduled to undergo neoadjuvant chemo(radio) therapy in preparation of a surgical resection are immunocompromised and at particular risk of severe cholangitis and cholangiosepsis due to stent clogging. In these patients, a metal expandable stent should be inserted to minimize this risk.<sup>77</sup>

#### Technique of Biliary Stent Placement

A large-channel (4.2-mm) side-viewing therapeutic endoscope is introduced into the second portion of the duodenum. Standard cannulation of the papilla of Vater is performed by a ball-tip, cone-tip catheter or sphincterotome with or without a guidewire. Use of the latter device may aid in achieving an optimal angle for bile duct cannulation. If a sphincterotome is unsuccessful, a precut sphincterotomy is performed to obtain biliary access.

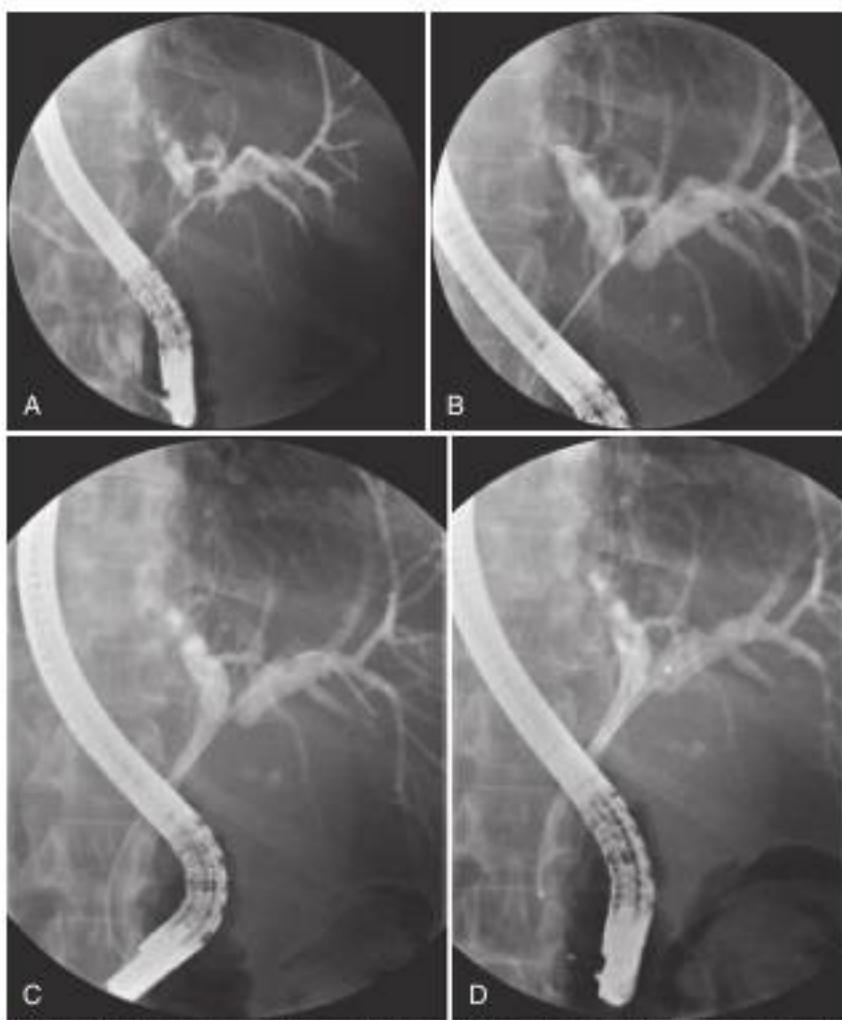

**FIG 63.5** **A**, Distal common bile duct stricture caused by pancreatic adenocarcinoma. **B**, Self-expanding metal stent has been inserted.

With the use of all these different techniques, deep cannulation is achieved in up to 95% of patients. After the bile duct is selectively cannulated, a contrast agent is injected. It is important to define the exact anatomy, location, and nature of the stenosis. To avoid postprocedural cholangitis in patients with complex hilar strictures, contrast filling of segments that are not to be drained should be avoided as much as possible. A guidewire is used to pass strictures and to facilitate introduction of devices. Various guidewires are available with different flexibility, diameter, and tip shape. On the one hand, rigid guidewires facilitate the introduction of devices (e.g., an intraductal ultrasound probe) and small-diameter stents. On the other hand, very slippery guidewires with a hydropolymer coating are used to pass asymmetric strictures. After the guidewire is passed through the stricture, a catheter can be advanced, and selective contrast filling can be achieved. If only one biliary stent is inserted, a sphincterotomy is not routinely required.

#### Plastic Stents

Preferably, a guiding catheter is introduced over the guidewire through the stricture to ensure a more rigid introductory system to facilitate stent placement. This can be achieved by the conventional method using a long wire and a standard guiding catheter, as well as with the so-called short wire exchange technique in which the guidewire follows the devices only at its distal tip, making it possible to use a short guidewire which, during device manipulation, can be safely locked at the scope handle using a locking device. The endoprosthesis is positioned over the guiding catheter and inserted into the instrumentation

channel. With a pusher tube, the stent is advanced farther toward the tip of the endoscope with the elevator bridge closed. When the prosthesis has reached the distal end of the instrumentation channel, the elevator bridge is opened, and the stent is pushed out of the endoscope under endoscopic and fluoroscopic control. During advancement of the stent, it is important to keep the endoscope tip close to the papilla. The stent should be pushed out the scope and into the common bile duct one step at a time to avoid looping and dislocation into the duodenal lumen. After the stent has been pushed out a little, the elevator bridge is closed, which raises and fixes the stent. The tip of the endoscope is moved closer to the papilla using the up-and-down knob, thus pushing the stent into the common bile duct. These steps are repeated until the distal side flap has reached the papilla. Finally, the assistant pulls out the guiding catheter and guidewire while the endoscopist keeps the endoprosthesis in position with the pusher tube. In most distal common bile duct and mid-common bile duct strictures, it is usually possible to insert a 10-Fr endoprosthesis without prior dilation. In proximal strictures, however, the stricture may need to be dilated to allow stent passage; this can be achieved with the use of dilating catheters that are introduced over a rigid guidewire or, more easily, with a dilation balloon. If it is still impossible to insert a 10-Fr stent, a smaller-caliber prosthesis (7-Fr) should be inserted that can be exchanged for a 10-Fr prosthesis at a later stage. When both right and left liver lobes have to be drained, it is usually more convenient to drain the left side first, followed by the right side, which is typically straighter and thus presents less challenge to stent insertion.

**FIG 63.6** **A**, Klatskin type II tumor (unresectable because of vascular involvement). **B**, Guidewires inserted to both the left and the right biliary system. **C**, Self-expanding metal stent has been inserted into the left system and deployed. **D**, Bilateral self-expanding metal stent drainage.

The required length of the endoprosthesis can be determined by checking the predefined markers on the guidewire or by using the guidewire as a ruler. For this, the proximal tip of the guidewire is positioned under fluoroscopic control at the level at which the proximal tip of the endoprosthesis is intended. The guidewire is then fixed between index finger and thumb at the level where it exits the working channel. Subsequently, under fluoroscopic control, the guidewire is withdrawn from the catheter until the proximal tip reaches the duodenum. When using a short wire system, the distance between finger and thumb and the exit hole of the working channel is the required length of the endoprosthesis. When using a long wire system, the technician can obtain the same measurement at the end of the catheter. Biliary plastic stents are available in various diameters (range 5-Fr to 12-Fr) and lengths (range 5 to 20 cm).

**Management of plastic stent occlusion.** A clogged plastic stent can be removed with the use of a snare or basket. When a snare is used, the stent is caught in the snare and removed either by pulling out the scope or by pulling the stent through the instrumentation channel of the endoscope. When a basket is used, the stent is pulled close to the endoscope and, while the catheter of the basket is kept fixed at the scope handle, both the endoscope

and the stent are withdrawn. When massive tumor invasion is present in the duodenum, and difficult stent exchange is anticipated because of a nonoptimal scope position, it can be helpful to leave the occluded stent in place and use it as a guide for common bile duct cannulation and introduction of a second stent. Soehendra et al (1990) described a technique that enables the removal of a clogged stent while maintaining the original pathway into the bile duct.<sup>34</sup> A ball-tip catheter is positioned at the distal end of the stent, after which the stent is cannulated with the guidewire. A Soehendra retriever is introduced over the guidewire, and its tip is screwed into the distal end of the stent. The retriever is pulled out the scope along with the stent, leaving the guidewire in place to facilitate the placement of a new stent.

#### Self-Expanding Metal Stents (Video 63.1)

For introduction of a SEMS, a stiff guidewire is positioned through the stricture using standard techniques. The insertion device containing the constrained metal stent is inserted through the instrumentation channel over the guidewire. When the insertion device has been properly positioned across the stricture with the help of the radiopaque markers, the prosthesis can be released

by removing the outer catheter while keeping the inner catheter in place. Deployment occurs gradually as the outer catheter is withdrawn and can be followed fluoroscopically. If deployment is not proceeding according to plan and repositioning is required, the stent may be constrained again by pushing the outer catheter inward, provided that the point of no return has not yet been passed. This point may vary with stent type but may extend up to 83% of total stent deployment and is indicated by a fluoroscopic marker and a marker on the handle of the insertion device. Deployment reduces the length of certain SEMSs up to approximately 30%. It is therefore important to constantly adjust the position of the expanding stent under fluoroscopic or endoscopic control, meaning that the endoscopist has to pull on the insertion device while deploying the stent. When the expanding metal stent needs to bridge the ampulla, for example in the case of a distal common bile duct stricture, the endoscopic image is used to keep a fixed distance of approximately 1 cm between the papillary orifice and the distal margin of the stent. The distal end of the stent can be checked either fluoroscopically (represented by the most distal radiopaque distal marker) or endoscopically (represented by a color indicator on the insertion catheter). Stent diameter ranges from 6 to 10 mm, and stent lengths are available from 40 mm to 120 mm.

There are two techniques for inserting dual metal stents in the intrahepatic biliary tree. The conventional technique consists of inserting stents side-by-side (SBS technique; Fig. 63.7).<sup>65</sup> The potential limitation of the SBS technique is failure to advance the second metal stent alongside the first metal stent that is already expanded. A 6-Fr delivery system made possible simultaneous introduction and positioning of two insertion devices with subsequent simultaneous deployment of metal stents in 85% to 100% of patients. Another technique is referred to as the "stent-in-stent" (SIS) technique. This technique makes use of a specially designed "Y" stent consisting of two uncovered Nitinol Y-type biliary stents (TaeWoong Medical Co. Ltd., Goyang, South Korea). The first SEMS has a radiologically marked segment with wider mesh holes in its middle part, through which the second stent is advanced into the contralateral liver lobe.<sup>66</sup> A more challenging approach for introducing a second stent through the wire mesh of a conventional metal stent using balloon dilation has also been described.<sup>67</sup> The slim 6-Fr delivery system seems particularly suited to pass the dilated metal mesh.<sup>68,69</sup> There are only retrospective reports comparing SBS and SIS techniques for the management of intrahepatic malignant obstruction. In one study, no

differences in stent patency or adverse event rates were observed.<sup>70</sup> In another study a higher adverse event rate (44% vs. 13%) but longer stent patency were reported in the SBS group (469 vs. 181 days, respectively).<sup>71</sup>

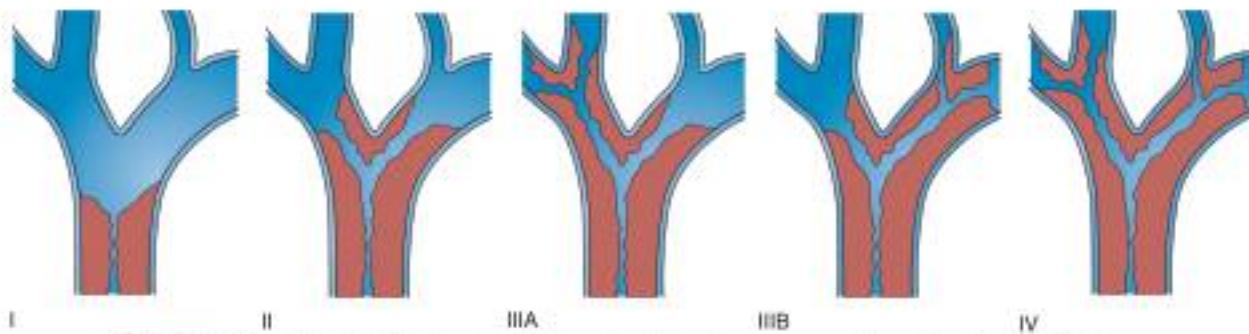

To facilitate reintervention in case of stent obstruction, it is important to either ensure that the ends of both metal stents cross the ampulla or to confirm that when located within the common bile duct, both distal metal stent ends are positioned at the same level.

#### **Management of self-expanding metal stent occlusion.**

Covered metal stents can be removed by grasping the distal stent end with a snare or with a forceps in case a retrieval loop is present. An uncovered SEMS can only be removed early after its deployment. These stents quickly become embedded due to tumor ingrowth and formation of hyperplastic tissue through the stent mesh after which stent extraction becomes extremely difficult or impossible. Mechanical cleaning using a balloon and water flushing is effective only in cases of sludge formation. Placement of a polyethylene stent or a second SEMS through the occluded SEMS may resolve the obstruction but may not provide optimal drainage because the new stent may not expand to its intended size, leaving the patient at higher risk for reobstruction. A novel technique for removal of metal stents entails the so-called SIS technique.<sup>72,73</sup> With this technique, a fully covered stent is deployed through the obstructed stent (either an uncovered or a partially covered stent), making sure that both stent ends are covered. Tissue that has grown through the interstices or over the stent ends is entrapped by the newly placed fully covered stent and becomes necrotic. Two to four weeks after placement of the fully covered stent in the obstructed stent, it is pulled out, after which the original stent can usually be removed without much difficulty. This strategy proves particularly useful when an uncovered metal stent is inadvertently placed into an apparently malignant biliary stricture that ultimately proves to be benign.

#### **Intrahepatic Biliary Obstruction**

Strictures at the level of the hepatic confluence account for approximately 20% of malignant bile duct obstructions and mainly involve primary cholangiocarcinoma, gallbladder neoplasms, and metastatic spread to hilar nodes. Cholangiocarcinomas arising at the hilar level are also referred to as Klatskin tumors and are classified according to the degree of involvement of the intrahepatic bile ducts (Fig. 63.8).<sup>74</sup> Stent placement in case of a proximal stricture in the biliary tree is more challenging and

**FIG 63.7** Bismuth classification. *I*: Stricture involving the common hepatic duct. *II*: Stricture involving both the right and the left hepatic duct. *IIIA*: Stricture extending proximally to the right secondary intrahepatic ducts. *IIIB*: Stricture extending proximally to the left secondary intrahepatic ducts. *IV*: Stricture involving secondary intrahepatic ducts bilaterally.

**FIG 63.8** Pancreatic adenocarcinoma growing into the duodenum with a self-expanding metal stent (not yet fully deployed) in the biliary tract and a self-expanding metal stent in the duodenum.

associated with lower success rates than stent placement for distal common bile duct stenosis. Drainage can be achieved either endoscopically (retrograde) or percutaneously (antegrade). Procedure-induced cholangitis caused by contrast agent injection into undrained biliary branches is the main complication and occurs in 30% of cases.<sup>105–107</sup> The current management strategy (depending on local services available) is first to attempt endoscopic drainage. When this is unsuccessful, percutaneous drainage is attempted.<sup>108–110</sup> When internal drainage fails, an external drain can be left in situ, thus minimizing the risk of cholangitis. Based on consensus statements, some societies have suggested that the percutaneous route is the preferred option to drain patients with a Bismuth III and IV hilar strictures. As long as scientific data are not available, local expertise should guide individual patient management.<sup>111</sup>

**Unilateral versus bilateral drainage.** There is controversy regarding whether to drain one or both liver lobes in patients with a proximal cholangiocarcinoma (Klatskin tumor) with a Bismuth type II, III, and IV stricture. In Bismuth type I, one stent suffices because the left and right ducts communicate. An early study suggested that at least 25% of the liver volume should be drained to achieve biochemical improvement and relief of symptoms.<sup>112</sup> More recently, it has been suggested that drainage of more than 50% of liver volume of patients with malignant hilar strictures is predictive for lower cholangitis and higher survival rates.<sup>108,113</sup> Drainage of a dilated duct of an atrophic hepatic segment does not contribute to relief of jaundice and therefore should only be attempted in case of segmental cholangitis.

For patients with Bismuth III and IV strictures, this concept has important implications, as drainage of either the right or left lobe is usually not enough to achieve this goal. What seems undisputed based on the literature is that the worst treatment results are achieved in patients with cholangiographic opacification of both lobes, but drainage of only one.<sup>114</sup> Obviously, such practice promotes bacterial contamination with ensuing cholangitis in the undrained lobe. Indeed, in a prospective randomized trial comparing unilateral with bilateral hepatic duct drainage,

the latter procedure was associated with a significantly higher rate of complications because of early cholangitis.<sup>115</sup> Magnetic resonance cholangiopancreatography (MRCP)-guided endoscopic stent placement in Bismuth III and IV malignancies has been shown to be associated with lower morbidity and mortality rates in an uncontrolled study.<sup>116</sup> The intention was to place a unilateral stent in one lobe guided by MRCP findings, and to avoid guidewire entry and contrast agent injection in the contralateral lobe. In patients in whom, by accident, guidewire entry (50%) or contrast agent injection (20%) occurred in the contralateral liver lobe, stents were placed bilaterally. This treatment strategy resulted in a very low cholangitis rate of only 6%. In a 2003 study in which selective unilateral MRCP-targeted or CT-targeted drainage was evaluated, no episodes of cholangitis were observed.<sup>117</sup>

The message seems to emerge that unilateral drainage is appropriate when unilateral cannulation and opacification has been achieved. If the contralateral lobe is (unintentionally) opacified or probed, it should also be drained to avoid cholangitis. On the other hand, a 2015 meta-analysis suggests that bilateral stenting for malignant hilar strictures is not recommended because it does not reduce obstruction or 30-day mortality rates. A point of criticism is that most studies pooled in this meta-analysis included patients with Bismuth I hilar strictures for whom bilateral stents are not useful.<sup>118</sup>

It seems that clinical decision-making and future studies should focus on the following three factors: (1) Complete versus incomplete drainage based on MRCP findings with the aim to drain at least 50% of liver parenchyma; (2) Drainage of all endoscopically manipulated liver segments during ERCP (unintentional contrast injection, guidewire entry or cannulation); and (3) Avoiding drainage of massively dilated but atrophic intrahepatic segments.

**Plastic versus self-expanding metal stents in hilar malignant strictures.** By design, expandable stents may be more suitable than plastic stents for draining hilar tumors. The stent lumen is much wider, and, more importantly, intrahepatic side branches can drain through the metal mesh. SEMSs that were inserted via the percutaneous route showed a higher rate of treatment efficacy than plastic stents.<sup>119,120</sup> No randomized studies comparing endoscopic and percutaneous insertion of SEMSs in hilar strictures are available. Additional proof of the superiority of SEMSs over plastic stents is suggested by a retrospective series of patients with unresectable hilar cholangiocarcinoma in whom plastic stents were replaced by metal expandable stents during stent treatment.<sup>121</sup> Successful palliation without the need for further biliary reintervention was achieved in most patients (69%). In a prospective multicenter observational cohort study in patients with a malignant hilar biliary obstruction, metal stents were superior to plastic stent in terms of short-term outcomes (30 days), independent of disease severity, Bismuth class, or drainage quality.<sup>121</sup> A 2015 meta-analysis on the use of plastic versus metal stents for hilar strictures showed that for the latter, 30-day and long-term occlusion rates were lower with no impact on survival.<sup>118</sup>

**Antibiotics before stent placement to avoid postprocedure cholangitis.** The mainstay of therapy for patients presenting with a biliary obstruction caused by a malignancy with or without cholangitis is endoscopic drainage. There is controversy about the routine use of preprocedure antibiotic prophylaxis.<sup>122–124</sup> Preoperative administration of antibiotics should definitely be started in a patient with fever. Because failure to drain the entire biliary tree is the most important risk factor associated with

occurrence of cholangitis after ERCP, in particular when contrast has been injected into segments that cannot be drained, antibiotic prophylaxis should also be administered in patients in whom incomplete drainage is anticipated, such as patients with a hilar malignancy or patients with PSC.<sup>125,126</sup> Prophylaxis can be commenced by a single intravenous dose shortly before the procedure and is usually continued orally for 3 to 5 days.

Gram-negative bacteria are consistently the most common organisms in bile (*Escherichia coli* and to a lesser extent *Klebsiella* species and gram-positive *Enterococcus* species). Antibiotics in these cases should be bactericidal and aimed at gram-negative bacteria with good penetration in liver tissue and bile. Ciprofloxacin is currently the first choice of antibiotic in our unit, with the caveat that it does not cover *enterococci*. In cases of fever despite ciprofloxacin, the addition of amoxicillin or a switch to piperacillin/tazobactam is advisable.

### Duodenal Stenosis

Duodenal stenosis resulting from pancreaticobiliary malignancies occurs in 10% to 20% of patients.<sup>127</sup> Symptoms include nausea and vomiting resulting from gastric outlet obstruction. Duodenal stenosis is usually a late event in patients in poor general condition who have already undergone biliary drainage. Surgical bypass has a significant procedure-related mortality of 10% and related morbidity and prolonged hospital stay.<sup>28,128,129</sup> Placement of a duodenal stent has a high technical success rate without major procedure-related complications.<sup>130-132</sup> In a systematic review comprising 1281 patients from 19 studies early (< 30 days) and late (> 30 days), perforations occur in 0.7% and in 0.5% of patients, respectively.<sup>133</sup> Massive bleeding requiring urgent intervention was observed in 0.8% of cases.

Duodenal stent placement is performed under simultaneous endoscopic and fluoroscopic control. Immediately after stent placement patients are usually able to tolerate a liquid diet. Full stent expansion may take a few days, during which time soft foods are allowed. Uncovered duodenal stents seem to be associated with a higher occlusion rate, whereas partially covered duodenal stents seem to have a higher migration rate.<sup>133</sup> A retrospective study in 95 patients suggested that duodenal stent placement is associated with better short-term outcomes, whereas surgical gastrojejunostomy is associated with better long-term outcomes.<sup>134</sup> The choice of treatment modality may depend on the life expectancy of the patient. On the other hand, in patients with longer survival, duodenal stenting may still be considered a valid treatment modality, as endoscopic reintervention for stent dysfunction, albeit common (30%-40% of the cases), is clinically successful in most cases. Some recent small case series (2015-16) have reported promising results of EUS-guided gastrojejunostomy thanks to the advent of lumen apposing metal stents.<sup>135-137</sup>

Similar success rates have been reported for simultaneous endoscopic decompression of biliary and duodenal obstruction compared with duodenal stent placement alone.<sup>138</sup> In the former case, because of the difficulty accessing the biliary tree after duodenal stent placement, an expandable metal biliary stent should be placed first (Fig. 63.9). In case a plastic biliary stent is already in situ, it should be exchanged for a metal expandable stent. In expert hands, it may be feasible to drain the biliary tree endoscopically through the mesh of a metal duodenal stent, but this is a technically challenging procedure.<sup>139</sup> More recently, EUS-guided biliary drainage has been employed in the setting of a failed biliary drainage by means of ERCP in patients with

a duodenal stent in situ. In a small case series, this approach was successful in most of the patients using various strategies, including transmural hepaticogastrostomy or choledochoduodenostomy or even antegrade or "rendez-vous" transpapillary drainage.<sup>140</sup>

If endoscopic treatment of biliary obstruction after duodenal stent placement fails, remaining treatment options include percutaneous stent placement, combined percutaneous and endoscopic management, and surgical bypass.

### Postprocedural Care

General measures after conscious sedation include observation in a day care unit for several hours monitoring blood pressure and oxygen saturation. When a patient develops fever after ERCP, blood samples should be obtained for culture, and antibiotics should be administered. If fever does not subside, the accuracy of biliary drainage should be reassessed, and migration and early stent occlusion should be excluded. In the case of a complex malignant hilar stricture, it is important to check for undrained dilated intrahepatic segments and to rule out abscesses by transabdominal ultrasound or CT. Depending on the findings, ERCP should be reattempted or percutaneous drainage performed.

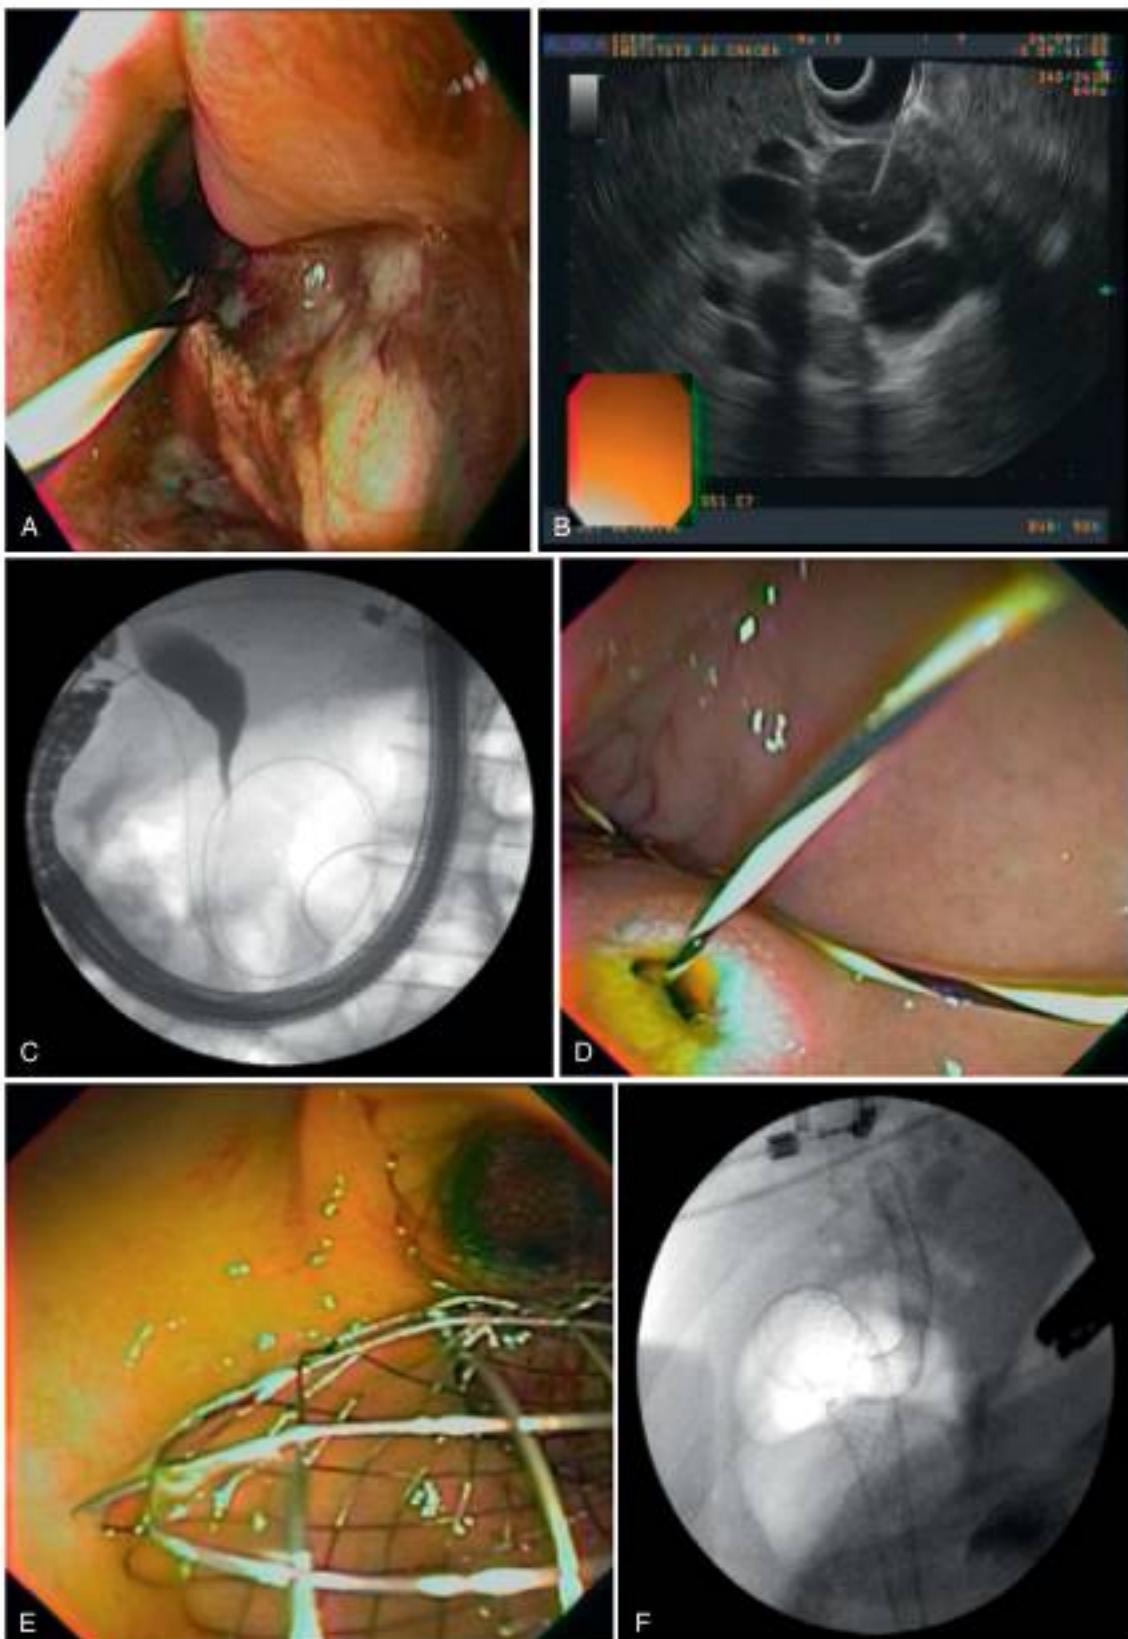

### Complications

#### Early Complications

Early complications are defined as complications that occur less than 1 week after the conclusion of the procedure. The rate of complications is 5% to 10% for therapeutic ERCP with a mortality rate of up to 1%.<sup>20,141,142</sup> Cotton et al (1991) introduced a classification system in which complications are graded as mild, moderate, and severe, and these guidelines are still widely used.<sup>141</sup> The most frequent early complication is cholangitis, probably resulting from introduction of bacteria into the biliary tract during the procedure. Cholangitis is reported in approximately 10% to 15% of patients in most series. It occurs more often after endoscopic procedures for complex hilar strictures when incomplete drainage is achieved. The same holds true for patients with PSC. In these high-risk procedures, antibiotics should be administered prophylactically and continued for a few days after the procedure.

Pancreatitis develops after ERCP in approximately 5% to 7% of patients. It is defined as new-onset or increased abdominal pain lasting at least 24 hours after ERCP, with associated elevation in serum amylase or lipase to at least three times normal, and a minimum of 2 days of hospital admission.<sup>20,141</sup> Most cases are mild and self-limiting, requiring only intravenous fluids and gut rest. Selected cases may evolve into (infected) necrotizing pancreatitis with multi-organ failure.

The rate of postsphincterotomy bleeding is approximately 0.2% to 5%, with an associated mortality rate less than 1%.<sup>143</sup> Bleeding usually occurs immediately after sphincterotomy but can be delayed for hours or several days. In our experience, most episodes of delayed bleeding are managed successfully by conservative measures and blood transfusions. Postsphincterotomy bleeding usually occurs at the apex of the sphincterotomy site and can be managed endoscopically with injection of epinephrine. When clipping or thermal coagulation are used to stop the bleeding, one should be cautious to avoid the pancreatic orifice for obvious reasons. When in doubt, or the site of hemostatic therapy is close to the pancreatic orifice, a protective pancreatic stent should be placed first. In some situations, the apex of the sphincterotomy can be clipped away from the pancreatic orifice with minimal risk of pancreatitis. In such cases, the risk of further

**FIG 63.9** EUS-guided choledochoduodenal anastomosis with concomitant duodenal stenting in a patient with a malignant biliary and duodenal stricture due to advanced adenocarcinoma of the pancreas. **A**, Duodenal stenosis caused by advanced pancreatic adenocarcinoma. **B**, EUS-guided puncture of the dilated common bile duct with a 19-gauge needle. **C**, EUS-guided cholangiography revealing a long and tortuous malignant stricture of the distal common bile duct stricture. **D**, bulbo-choledochal fistula created with a cystotome with a guidewire positioned well into the biliary tree. **E**, Endoscopic image of the expanded biliary and duodenal stent. **F**, Radiologic image of the expanded biliary and duodenal stent.

manipulation of the pancreatic duct for prophylactic pancreatic stent insertion may not be justified.

Retroperitoneal perforation occurs in less than 1% of cases.<sup>144</sup> It may be caused by standard sphincterotomy, precut sphincterotomy, or guidewire manipulation. Most cases are diagnosed or suspected during ERCP. These retroperitoneal perforations mostly heal with conservative measures consisting of nil per mouth, intravenous antibiotics, and nasogastric suction. In cases of peritoneal perforation caused by the duodenoscope, prompt exploratory laparotomy, with repair or oversewing of the defect in the duodenal wall, has traditionally been deemed mandatory.<sup>145</sup> Recently, the use of large over-the-scope clips has been reported to successfully close duodenal perforations caused by side viewing endoscopes.<sup>146</sup>

### Late Complications

The most common late complication of stent placement is occlusion of the endoprosthesis, which occurs in approximately 50% of cases.<sup>77,78</sup> These patients clinically present with recurrent jaundice, a flulike syndrome with cholestasis or frank cholangitis. Treatment consists of exchange of the occluded stent or, in the case of an occluded uncovered SEMS, of insertion of a polyethylene stent or second SEMS through the obstructed expanding stent. See also the earlier sections on Management of Plastic Stent Occlusion and Management of Self-Expanding Metal Stent Occlusion.

### Future Trends

#### Photodynamic Therapy

Photodynamic therapy (PDT) involves the intravenous administration of a photosensitizer that is activated with a laser light, causing necrosis of the exposed tissue. Preliminary results suggest prolonged survival and stent patency for PDT in cholangiocarcinoma at the hilum.<sup>147-149</sup> There are, however, no prospective randomized controlled studies available. Previously, it was thought that metal stents and PDT were incompatible.<sup>150</sup> However, this does not seem to be a major issue as long as the light dose is adjusted to counteract the reduction of light transmittance caused by the metal.<sup>151</sup> PDT has also been used successfully to recanalize metal stents that were blocked by tumor ingrowth.<sup>152</sup>

#### Radiofrequency Ablation

Radiofrequency ablation (RFA) is a relatively simple low-cost procedure that is increasingly being studied for local treatment of biliary obstructive malignancies.<sup>153</sup> RFA can be performed via an antegrade route by means of PTC or a retrograde route using ERCP. With the use of a bipolar probe that is mounted on a catheter, coagulative necrosis of the intraductal tumor mass is achieved after which biliary stents are placed; generally plastic when multiple RFA sessions are planned. A retrospective study comparing 16 patients treated with RFA and 32 patients treated with PDT did not show a difference in median survival (9.6 vs. 7.5 months).<sup>154</sup> Some studies have successfully explored the use of RFA to de-obstruct metal expandable stents after they had become clogged with tumorous or hyperplastic tissue ingrowth.<sup>155,156</sup>

#### Drug-Coated Biliary Stents

Covering biliary stents with a chemotherapeutic agent, thereby delivering the drug directly into the tumor, may provide protection against tumor ingrowth and overgrowth. For an optimal therapeutic effect, these drugs should be released over a longer period with good penetration into the tumorous tissue and without

causing systemic toxicity. Carboplatin and paclitaxel have been shown to inhibit cell proliferation in vitro.<sup>157,158</sup> Carboplatin-coated plastic stents have been used with promising preliminary results in a few patients.<sup>159</sup> In a small pilot study, placement of a metal stent covered with a paclitaxel-incorporated membrane in patients with malignant biliary obstruction proved feasible, safe, and effective.<sup>159</sup> Median patency was 270 days (range 68 to 810 days), and cumulative patency rates at 3 months, 6 months, and 12 months were 100%, 71%, and 36%. However, whether drug-eluting stents represent an advancement in the treatment of patients with malignant biliary strictures remains to be proven in prospective comparative trials.

#### Endoscopic Ultrasound-Guided Biliary Drainage

EUS-guided biliary drainage is being explored as an alternative to ERCP. The successful outcome of EUS-guided drainage of pancreatic pseudocysts and infected pancreatic necrosis, and the development of specially designed fully covered metal lumen apposing stents has accelerated its introduction for this novel indication. EUS-guided biliary drainage encompasses EUS-guided antegrade rendezvous drainage, EUS-guided choledochoduodenostomy, and EUS-guided hepaticogastrostomy.

In a retrospective study including 208 patients from multiple tertiary referral centers, a single session of EUS-guided biliary drainage (EUS-BD) after 1 or more failed ERCP attempts, either EUS-guided choledochoduodenostomy or EUS-guided antegrade rendezvous drainage, was compared to ERCP in patients with a distal common bile duct obstruction requiring placement of a SEMS.<sup>160</sup> SEMS was equally successful after both procedures (93.26% vs. 94.23%,  $p = 1.00$ ). The frequency of adverse events in the ERCP and EUS-BD groups was comparable (8.65%), but postprocedure pancreatitis rates were higher in the ERCP group (4.8% vs 0%,  $p = 0.059$ ).

EUS-guided hepaticogastrostomy has been reported by several groups as an alternative treatment to percutaneous biliary drainage or surgical bypass in the case of failed ERCP, in particular in the case of a bulboduodenal obstruction or a proximal stricture at the level of the hepatic hilum when EUS-guided choledochoduodenostomy is not possible.<sup>161,162</sup> For this, a dilated biliary branch in the left lobe is punctured by a 19-gauge needle under EUS guidance. Next, a guidewire is advanced, and the needle is removed. A cystotome is introduced over the wire to create a fistulous tract by the use of electrocautery. Successful long-term drainage has been reported with plastic stents and covered metal stents.

In conclusion, in case of ERCP failure, EUS-guided biliary drainage has emerged as a viable alternative to percutaneous tranhepatic drainage. Local expertise, logistics, and cost should be taken into consideration in the planning of the therapeutic algorithm in cases of ERCP failure.
