Medial ureter Injuries to the abdominal ureter between the UPJ and the pelvic brim are repaired by means of uretero-ureterostomy [see Figure 10]. After debridement, the ends are spatulated on opposite sides, and an interrupted approximation is completed over a double J stent. In cases of overlying colonic, duodenal, or pancreatic injury, the anastomosis should be covered with omentum or retroperitoneal fat. Large defects in the abdominal ureter may necessitate transuretero-ureterostomy, in which the injured ureter is passed behind the mesocolon to the contralateral side. Anastomosis of the injured ureter to a 1 to 2 cm opening in the medial side of the normal ureter can be achieved without tension. With transuretero-ureterostomy, a stent (usually a 5 French pediatric feeding tube) should cross the anastomosis and be brought out through the normal lower ureter or bladder.

Distal ureter Ureteral injuries in the pelvis should be managed with reimplantation into the bladder. The distal stump is ligated, and after the anterior bladder wall is opened, the proximal end of the ureter is brought through a new hiatus on the back wall of the bladder. The ureter is then spatulated and approximated to the bladder mucosa with interrupted chromic sutures. One 3-0 anchoring stitch brings the distal apex of the ureter to the muscle and mucosa; the rest of the sutures approximate the mucosa. A refluxing reimplantation is acceptable in adults. Larger defects can be bridged by performing a vesicopsoas hitch, in which the bladder is sewn to the central tendon of the psoas muscle. The dome is mobilized by dividing the obliterated umbilical arteries bilaterally and, if necessary, the contralateral superior vesical artery. Three interrupted nonabsorbable sutures that enter the detrusor muscle

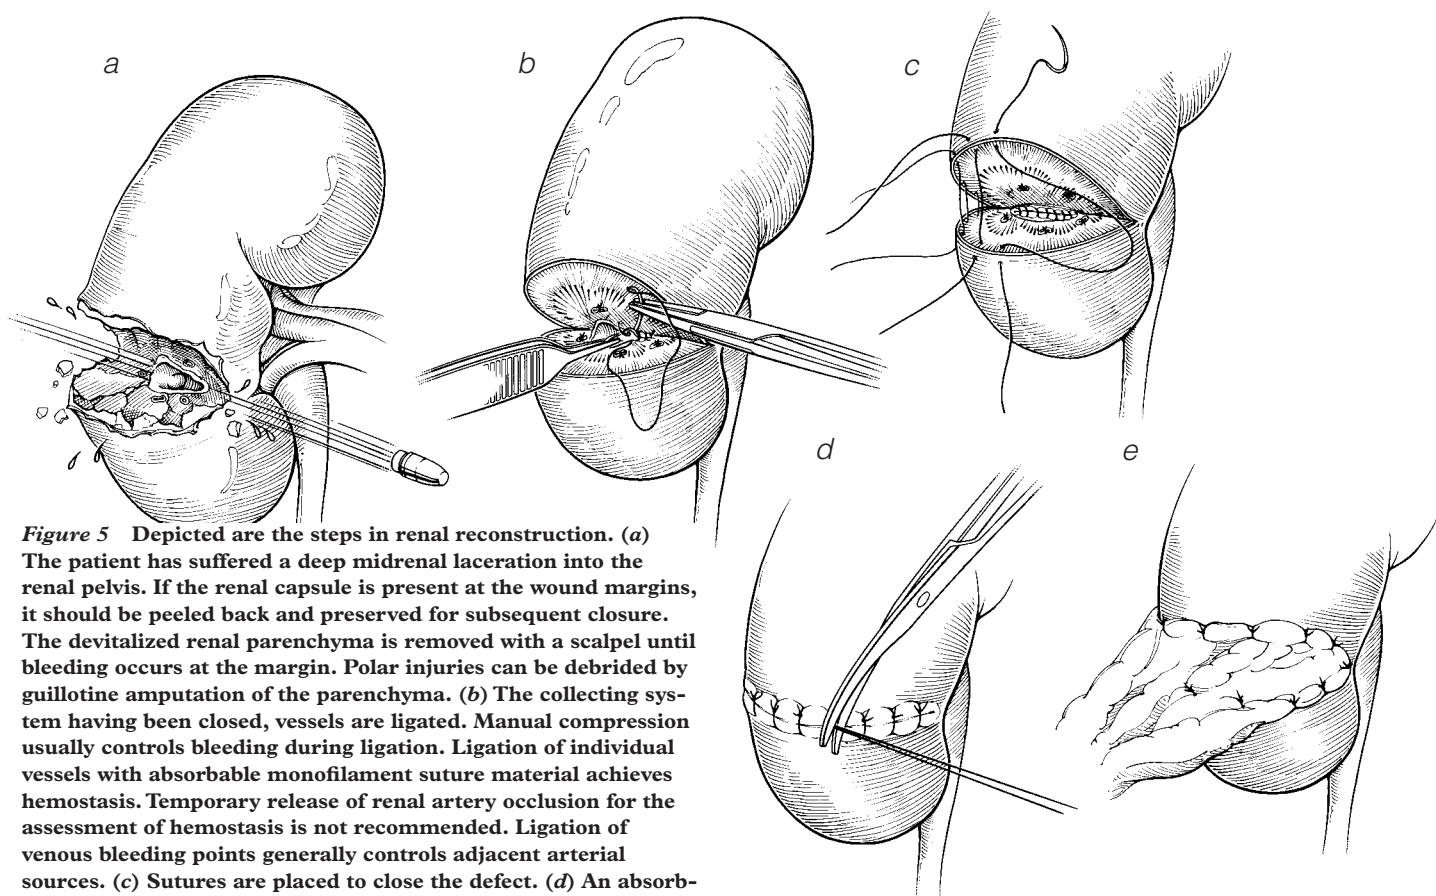

Figure 5 Depicted are the steps in renal reconstruction. (a) The patient has suffered a deep midrenal laceration into the renal pelvis. If the renal capsule is present at the wound margins, it should be peeled back and preserved for subsequent closure. The devitalized renal parenchyma is removed with a scalpel until bleeding occurs at the margin. Polar injuries can be debrided by guillotine amputation of the parenchyma. (b) The collecting system having been closed, vessels are ligated. Manual compression usually controls bleeding during ligation. Ligation of individual vessels with absorbable monofilament suture material achieves hemostasis. Temporary release of renal artery occlusion for the assessment of hemostasis is not recommended. Ligation of venous bleeding points generally controls adjacent arterial sources. (c) Sutures are placed to close the defect. (d) An absorbable gelatin sponge is placed. (e) Alternatively, the defect may be closed with an omental pedicle flap.

(but not the bladder lumen) anchor the dome above the iliac vessels. Complex bladder or vascular injuries in the pelvis make transureteroureterostomy a more attractive option for avoiding further dissection in the injured area. A ureteral stent should be used in all ureteral reimplantations. The bladder is closed in two layers with a continuous 2-0 absorbable suture. Closed-suction retroperitoneal drainage and Foley catheter decompression of the bladder are essential.

Postintervention Care

Postoperative care of ureteral trauma relates mainly to the manipulation of drains and the management of complications. Retroperitoneal drains may have significant output for several days but are removed after 2 to 3 days unless output is consistent with a urine leak as determined by creatinine measurement (see above). Bladder catheterization is necessary for 7 days after ureteral reimplantation. In combined bladder and ureteral reconstructions, contrast cystography is indicated before catheter removal. Cystoscopic removal of the double J stent is usually performed with local anesthesia 4 to 6 weeks after operation. CT, IVP, or renal scintigraphy 3 months after removal of the stent rules out the possibility of asymptomatic obstruction.

Fistula formation, usually the result of distal obstruction or necrosis of the ureter, should be managed by means of antegrade or retrograde drainage of the collecting system with percutaneous or endoscopic techniques. Drainage of periureteral fluid collections may also be necessary. If recognition of an injury or a complication is delayed, reconstruction should be deferred for at least 3 to 6 months until all inflammation has subsided.

Injuries to the Bladder

INITIAL EVALUATION

Bladder injury [see Table 2] is most often caused by blunt injuries, with penetrating trauma accounting for 14% to 33% of civilian cases. About 9% of patients with a pelvic fracture have an

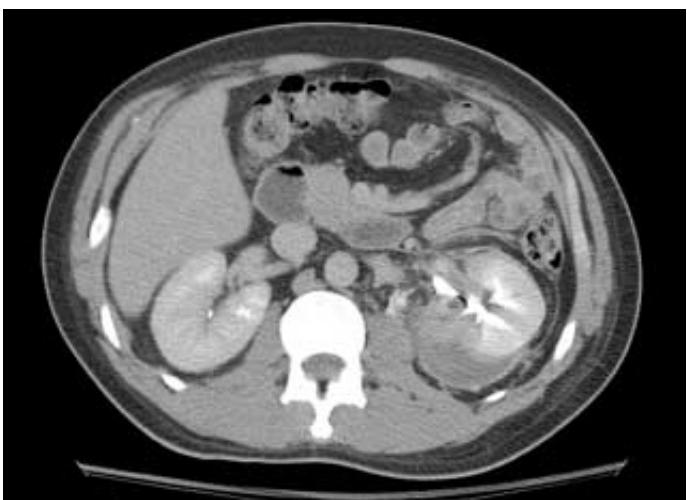

Figure 6 CT scan shows an infected urinoma in a patient with left grade IV injury who presented 7 days after injury with fever and sepsis and subsequently underwent ureteral stenting. The urinoma was drained percutaneously.

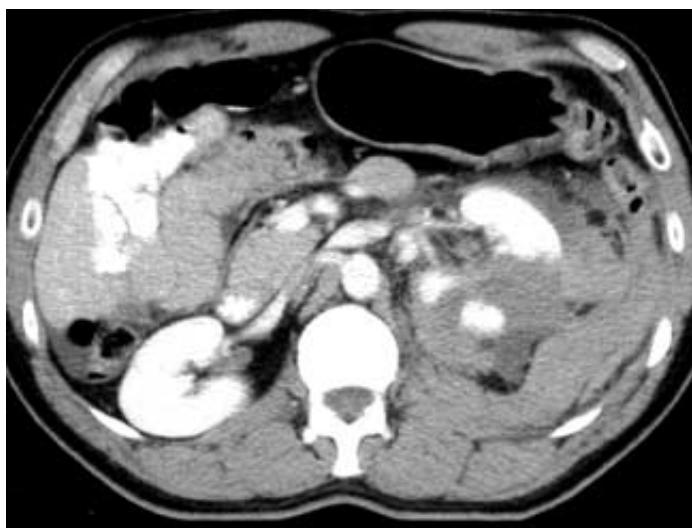

Figure 7 Shown is a pseudoaneurysm of the left kidney after blunt injury.

associated injury to the bladder, though there is only a weak association between the type of fracture sustained and the likelihood of bladder injury.⁴² Because the fracture type has poor predictive value for the type of associated genitourinary trauma, all patients with pelvic fractures and any degree of hematuria should be suspected of having a bladder injury. Approximately two thirds of bladder injuries are extraperitoneal and one third intraperitoneal, a distinction that has important management ramifications.

The signs and symptoms of bladder injury are generally non-specific [see Figure 11], though 95% of patients with bladder rupture present with gross hematuria. Patients may complain of suprapubic pain, dysuria, or an inability to void. Physical examination may reveal tenderness in the suprapubic region, ileus, or an acute abdomen. The percentage of patients without any hematuria ranges from 0% to 3%.^{43,44} Laboratory studies are usually inconclusive unless significant reabsorption of urine causes elevated serum creatinine levels, hyperkalemia, or hyponatremia.⁴⁵

Bladder rupture can be accurately diagnosed with either retrograde CT cystography or plain-film retrograde cystography. The indications for cystography include blunt trauma with gross hematuria in the presence of free abdominal fluid on CT; blunt trauma with a pelvic fracture and any degree of hematuria (> 3 red blood cells [RBCs] per high-power field [hpfl]); stable penetrating trauma with any degree of hematuria; and an injury to the pelvis. The appearance of intraperitoneal and extraperitoneal rupture with each modality is characteristic [see Figure 12]. Insufficient instillation of the contrast agent can yield false negative results. At one large center, the sensitivity and specificity of CT cystography for bladder rupture caused by blunt trauma were 95% and 100%, respectively.⁴⁴ With current patterns of CT usage for trauma evaluation, including imaging of pelvic bony fractures, CT cystography appears to be more efficient than plain-film studies. Furthermore, CT cystography clearly identifies the location of many bladder injuries and may be able to identify bladder neck injuries [see Figure 12a]. With penetrating trauma, there must be a higher level of suspicion for bladder injury because the sensitivity and specificity of cystography (CT or conventional) in this setting has not been determined. If bladder injury is associated with a pelvic fracture in a male patient, the possibility of a urethral injury is 10% to 29% and must be excluded.⁴⁶ A successfully placed Foley catheter rules out a complete urethral disruption.

MANAGEMENT

Nonoperative

Extraperitoneal bladder injuries caused by blunt trauma are generally managed nonoperatively with 10 days of catheter drainage.⁴⁷ Contraindications to nonoperative management include urinary infection; pelvic fractures requiring internal fixation; the presence of bony fragments in the bladder; bladder neck injury, which may compromise continence; rectal injury; and female genital lacerations associated with pelvic fracture. After 10 days, plain-film or CT cystography is performed to document healing. Once the extravasation has resolved, catheter removal can be based on the patient's overall status and mobility. If extravasation persists, cystography is repeated at appropriate intervals until healing occurs.

Operative

All penetrating injuries and all intraperitoneal ruptures of the bladder are managed by means of bladder exploration and repair.

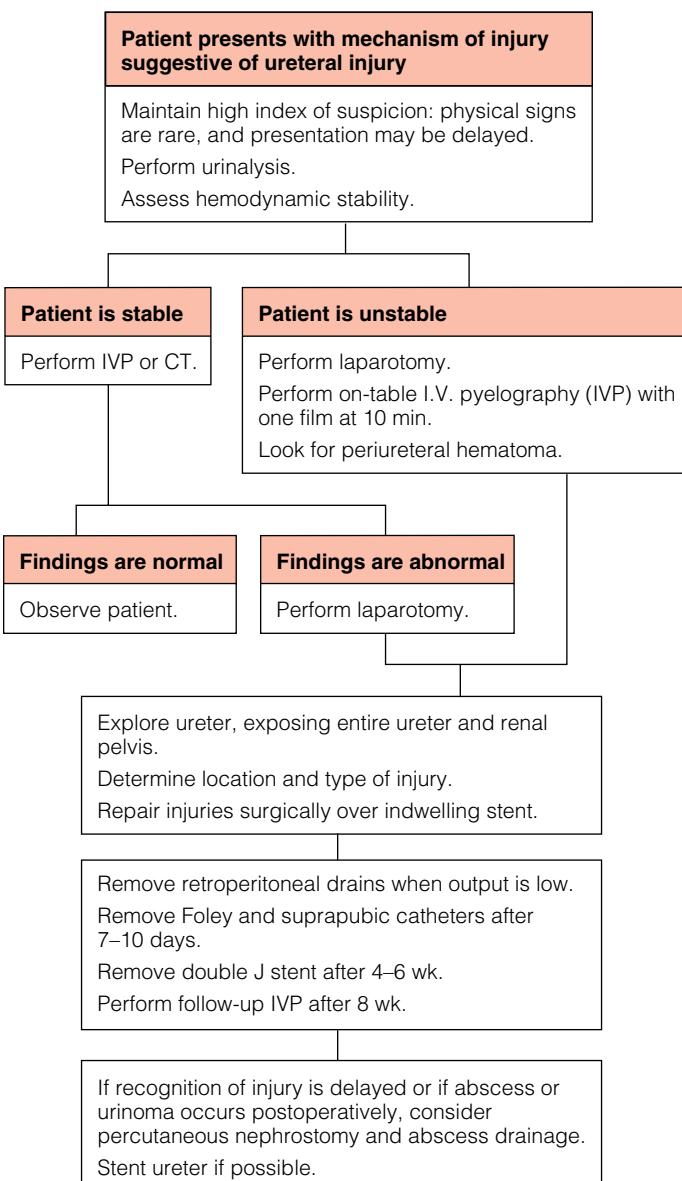

Figure 8 Algorithm outlines management of ureteral injuries.

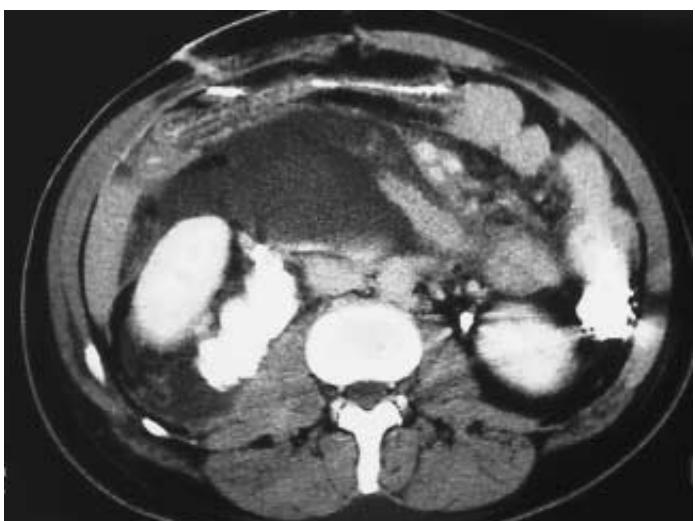

Figure 9 CT scan shows extravasation and urinoma caused by unrecognized right upper ureteral injury.

If the patient requires laparotomy for associated injuries and can tolerate the extra operating time, repair of extraperitoneal bladder injuries is also recommended. Conversely, in severely unstable patients, catheter drainage can be used as a temporizing measure until the patient is able to undergo exploration.

Bladder exploration can be performed via an intraperitoneal approach or by entering the extraperitoneal space of Retzius in the anterior pelvis. Intraperitoneal injuries present as a stellate rupture of the dome of the bladder. By enlarging this opening, one can inspect the interior of the bladder to exclude concomitant extraperitoneal injuries, which occur in 8% of cases.⁴⁸ In cases involving orthopedic reconstruction of the pelvis, the bladder may be approached extraperitoneally through the incision used to expose the pubic symphysis. Although extensive hemorrhage has been described in this scenario, it is a rare occurrence. Most extraperitoneal bladder injuries associated with pelvic fractures are anteriorly located, small in size, and easily closed without a more extensive bladder exploration.

Penetrating injuries and unrecognized blunt injuries discovered at laparotomy without previous CT cystography call for systematic evaluation. By opening the bladder vertically at the dome or along the anterior surface, one can identify sites of injury intravesically and inspect the ureteral orifices and the bladder neck. Lacerations are closed with 3-0 absorbable sutures, which approximate detrusor muscle and mucosa in one layer and provide hemostasis. In patients with penetrating injuries, entrance and exit sites must be identified. The cystotomy is then closed with two layers of continuous 2-0 slowly absorbable sutures.

Postintervention Care

Adequate urinary drainage is essential to successful healing of the repaired bladder. There is no evidence that suprapubic catheters are superior to urethral catheters in this context.^{49,50} However, the catheters placed during trauma resuscitation are not of sufficient caliber to allow easy bladder decompression; therefore, a 20 French urethral catheter should be substituted at the end of the operation. A closed-suction drain near the bladder closure (but not overlying the suture line) is recommended. Cases of severe hematuria resulting from extensive injuries or coagulopathy warrant additional drainage with a suprapubic cystostomy tube to allow irrigation of clots and proper decompression of the bladder.

The perivesical drain can be removed after 48 hours unless the creatinine level in the drained fluid indicates ongoing urinary leakage. In the majority of patients with a bladder repair, 7 days of catheter drainage is sufficient to allow healing. Because bladder repair is reliable, any complications of bladder injury are usually related to a delay in diagnosis rather than to postoperative morbidity. Azotemia, ascites, and sepsis can result from an unrecognized intraperitoneal injury. Bladder neck injury, if overlooked, leads to scarring and incompetence of the proximal sphincter mechanism, with resultant incontinence, especially in females.

Injuries to the Urethra

INITIAL EVALUATION

Almost all injuries to the male urethra [see Table 2] are caused by blunt trauma. Prostatomembranous urethral distraction

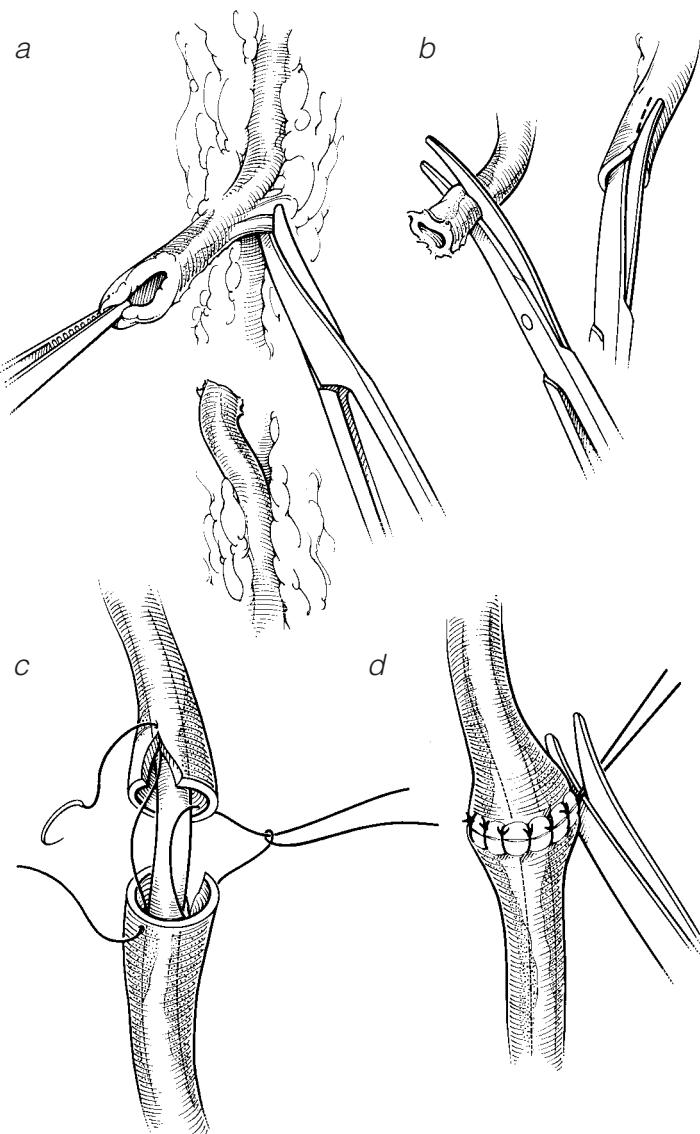

Figure 10 Depicted are the steps in a ureteroureterostomy. (a) The injured ureter is dissected free. (b) The ends are debrided and spatulated. (c) A stent is placed, and the anastomosis is begun. (d) The anastomosis is completed.

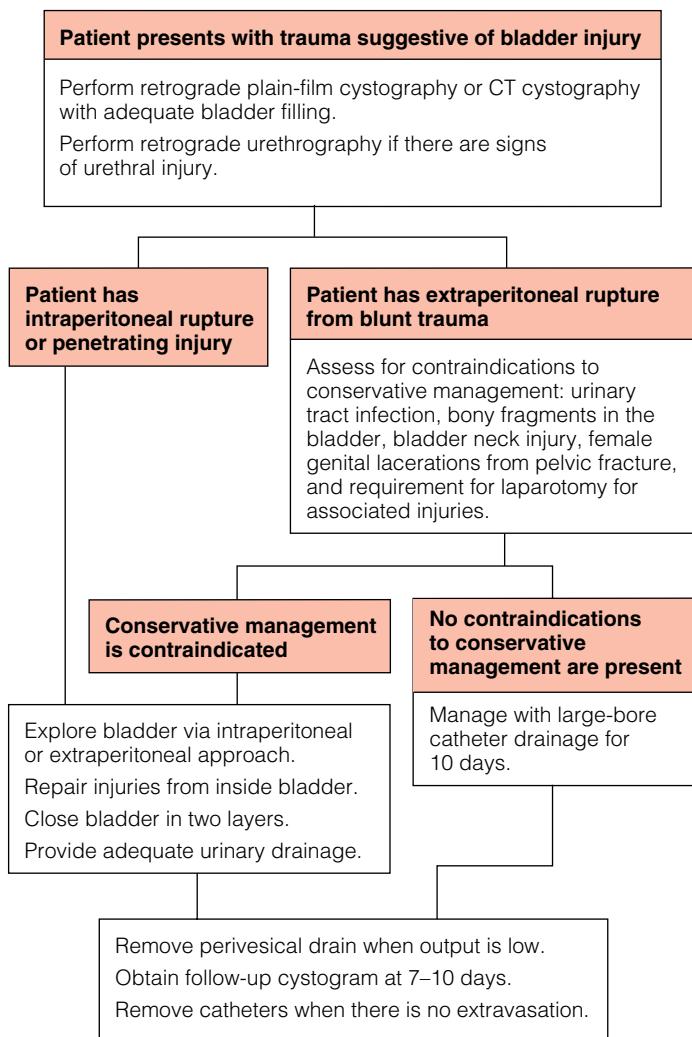

Figure 11 Algorithm outlines the management of bladder injury.

injuries in males occur in 5% of pelvic fractures, which are the most common cause of posterior urethral injury. Anterior urethral (penile and bulbar urethral) injuries are commonly caused by straddle injury but may be the result of penile fracture or penetrating injuries to the genitalia. The female urethra is rarely injured, but when such injury occurs, it is usually associated with bladder injury and pelvic fracture.⁵¹

Blood at the urethral meatus—the classic sign of injury to the male urethra—is an indication for immediate urethrography. Attempts at catheter placement risk converting an incomplete injury to a complete disruption and are to be discouraged if urethral injury is suspected.

Because signs of urethral injury are variable, retrograde urethrography is the essential diagnostic test used for documenting the location, nature, and extent of injury. Extravasation of the contrast agent is evidence of urethral injury [see Figure 13]. In the absence of extravasation, a Foley catheter should be passed. If a catheter has been placed but its position is unclear, contrast injection will confirm its placement in the bladder. In such cases, the catheter should be left in place until a pericatheter contrast study can fully evaluate the urethra. In cases of pelvic fracture and complete posterior urethral injury, bladder injury must be excluded by open bladder exploration or via cystography through a percutaneously placed suprapubic tube.

MANAGEMENT

Traumatic urethral injuries have traditionally been managed by means of suprapubic cystostomy, with reconstruction delayed for 3 to 6 months; however, most urethral trauma patients can undergo immediate realignment, with or without sutured repair. The exception is the patient with a straddle-type crush injury to the bulbar urethra, which should always be treated with urinary diversion and delayed repair. The recommended treatment is based on the location and mechanism of injury [see Figure 14 and Table 3].

Posterior Urethra

Posterior urethral (prostatic and membranous urethral) injuries can be managed with suprapubic cystostomy or early primary urethral realignment. Realignment without sutured repair renders definitive reconstruction unnecessary in a significant percentage of patients.⁵² Bladder neck injury and wide separation of the bladder from the urethra warrant immediate surgical intervention.⁵³ Simultaneous rectal injury often occurs in this setting and necessitates evacuation of the pelvic hematoma, irrigation, placement of drains, and primary realignment of the urethra. Primary realignment is also preferred in cases of open reduction and internal fixation of pelvic fractures because the risk of hardware contamination is considered to be lower with a urethral catheter than with suprapubic cystostomy.⁵⁴

Primary realignment is usually performed through a lower midline abdominal incision, which allows antegrade passage of instruments through the bladder at the same time as retrograde passage of instruments from the urethral meatus. Flexible cystoscopes or magnetic-tipped catheters advanced under fluoroscopic guidance are used to place a wire into the bladder beyond the injury, and a Council-tip Foley catheter is then advanced over the wire. Neither mucosal approximation nor direct anastomosis is the goal. Suprapubic catheter drainage is not required, but a perivesical drain should be left in place for 48 hours.

Anterior Urethra

Immediate surgical reconstruction is preferred for penetrating injuries of the bulbar and penile urethra and for urethral injuries associated with penile fracture. For these grade III and IV injuries, primary repair is associated with a lower stricture rate than simple realignment.^{55,56} Wounds accompanied by major tissue loss and defects larger than 2 cm (e.g., grade V injuries) or major associated injuries are best treated with suprapubic tube urinary diversion (see below) and subsequent reconstruction at a tertiary referral center.

Suprapubic Cystostomy

Many centers continue to use suprapubic cystostomy as the primary management of prostatomembranous urethral disruption and straddle injuries to the bulbar urethra. Suprapubic cystostomy, with the tube percutaneously placed under fluoroscopic guidance, allows temporary urinary diversion for initial stabilization and evaluation of the patient. Cystography can then be performed via the suprapubic tube to rule out associated bladder injury. Straddle injuries must be treated with suprapubic diversion unless the urethral disruption is only partial and allows passage of a guide wire or catheter under fluoroscopic guidance. Finally, suprapubic cystostomy is also recommended for penetrating injuries to the anterior urethra if the injuries were caused by high-velocity weapons and are characterized by extensive tissue loss; if serious associated injuries are present; or if bony fractures prevent proper placement of the patient in the lithotomy position.

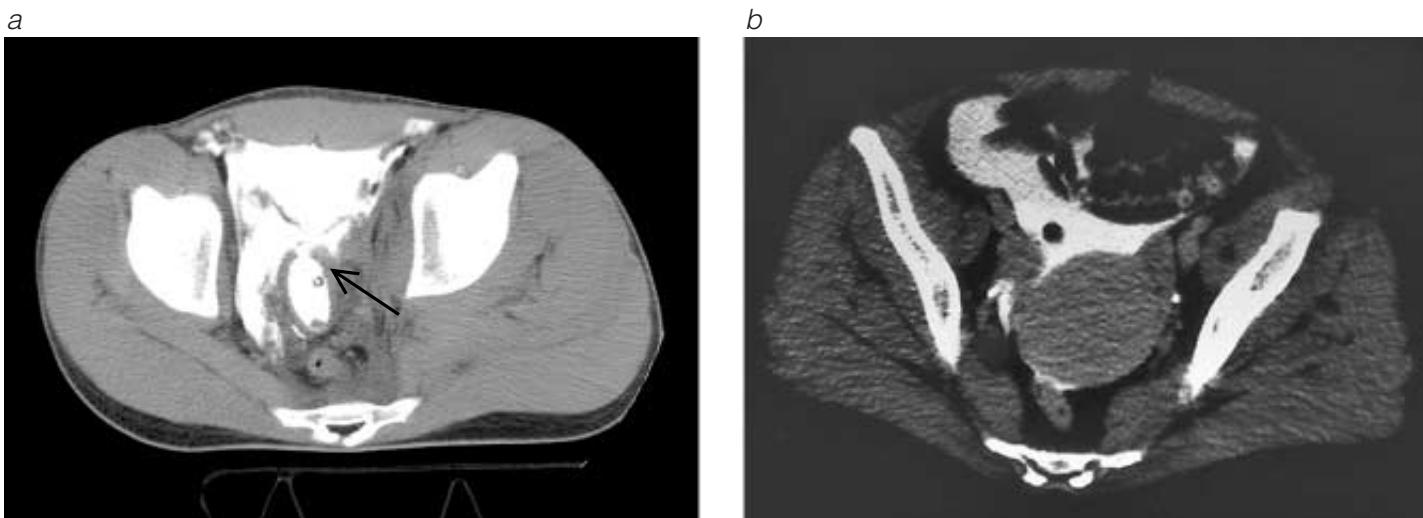

Figure 12 (a) CT cystogram shows extraperitoneal bladder rupture. A definitive discontinuity in the bladder wall is visible (arrow). (b) CT cystogram shows intraperitoneal bladder rupture.

Postintervention Care

Catheter care is of great importance after urethral reconstruction or suprapubic cystostomy. Urethral catheters should be secured to the abdominal wall in the early postoperative period. After immediate reconstruction of the anterior urethra, the Foley catheter should remain in place for 3 weeks, at which time a contrast voiding cystourethrogram should be obtained. If extravasation is present, the catheter should be replaced for 1 week and the study repeated. After primary realignment of urethral injuries, the urethral catheter is left in place for 6 weeks, at which time a pericatheter retrograde urethrogram is obtained, with the expectation that any extravasation will have resolved.

If the patients initially underwent diversion with a suprapubic tube alone, the tube should be changed after a tract has formed (usually about 4 weeks after the procedure) and then monthly until

reconstruction can be performed. Stricture formation or complete obliteration of the urethra may be the final result of this nonoperative approach. Subsequent radiographic studies will indicate whether secondary endoscopic or open procedures are needed.

Injuries to the Vagina, Uterus, and Ovaries

Injuries to the female genitalia [see Table 4 and Figure 15] must be regarded as especially morbid because of their association with sexual assault and interpersonal violence, as well as because of the potential medical complications (infection and bleeding). Genital trauma is reported in 20% to 53% of sexual assault victims.^{57,58} Blunt unintentional trauma, including pelvic fracture and straddle injuries, often results in perineal and vaginal injuries and, less commonly, cervical and uterine trauma.⁵⁹⁻⁶¹ Enlargement of a reproductive organ predisposes that organ to injury.⁶² Penetrating

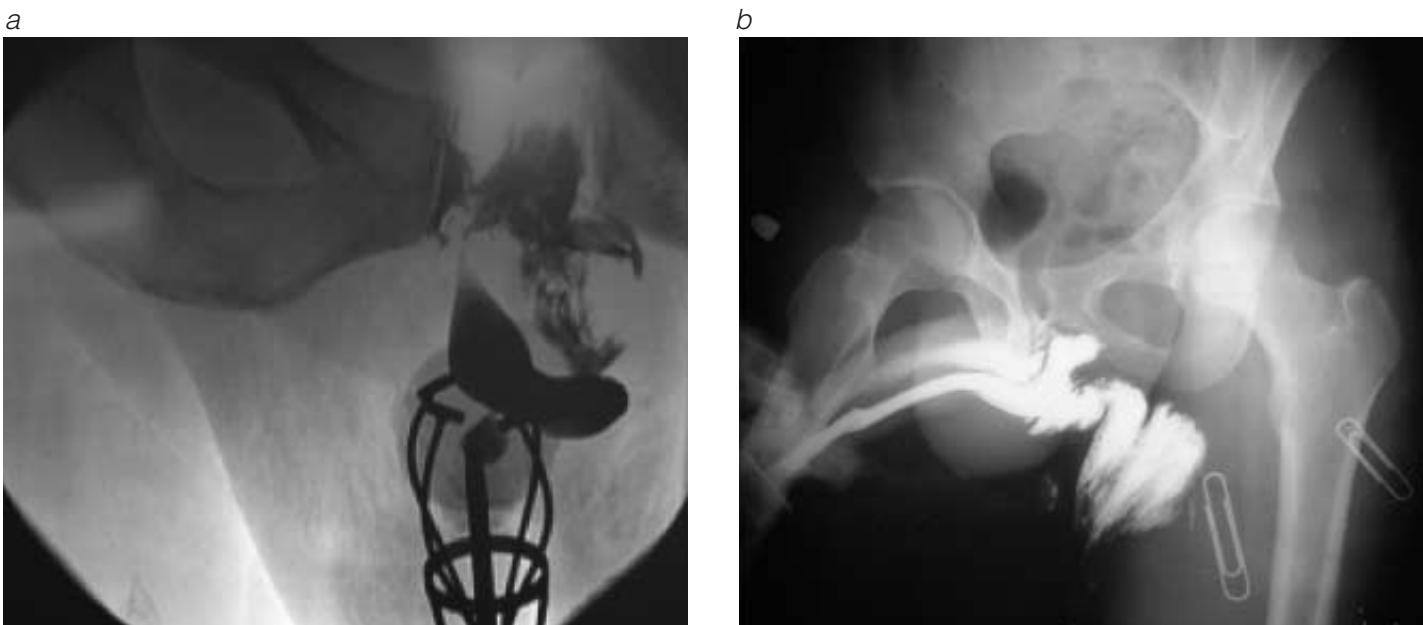

Figure 13 (a) Retrograde urethrogram of a posterior urethral injury after pelvic fracture shows extravasation at the level of the urogenital diaphragm. (b) Retrograde urethrogram of an anterior urethral injury caused by a gunshot wound shows extravasation at the level of the bulbous urethra.

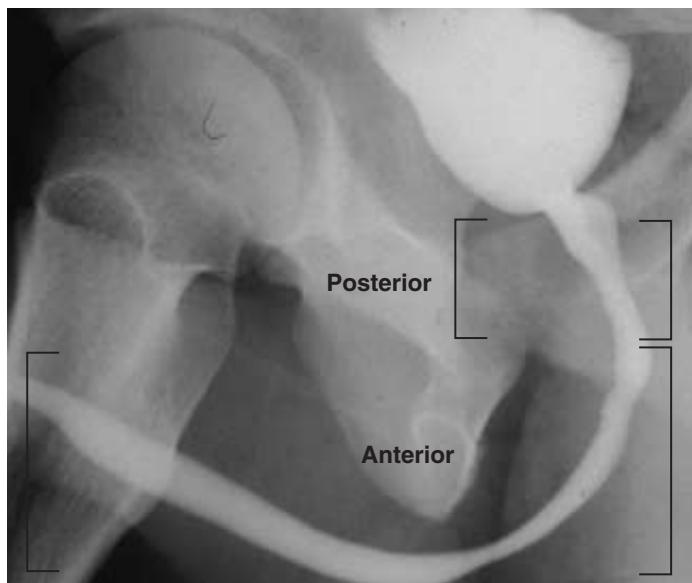

Figure 14 Shown are the posterior and anterior portions of the urethra. The posterior portion comprises the prostatic urethra and the membranous urethra; the anterior portion comprises the bulbar urethra and the penile urethra. Treatment of urethral injury depends on the location and mechanism of injury.

injuries account for almost all injuries to the fallopian tubes, the ovaries, and the nongravid uterus.⁶³

INITIAL EVALUATION

A history of sexual trauma must be sought; if such a history is elicited, appropriate police and support services must be notified.⁶⁴ In addition, if sexual assault has occurred, informed consent for the rest of the patient assessment must be obtained. This assessment includes a history, physical examination, collection of evidence and laboratory specimens, and treatment, as outlined by the American College of Obstetricians and Gynecologists.⁶⁵ The percentage of assault victims with identifiable spermatozoa in the vaginal specimens is lower than 50%.⁶⁶

All female patients with evidence of lower urinary tract and urethral injury should undergo examination of the external genitalia, as well as speculum examination of internal organs. The finding of blood implies vaginal laceration. In the presence of pelvic fracture or impalement injury, vaginal laceration warrants complete evaluation (with cystourethrography, proctoscopy, and laparotomy, as indicated) to rule out associated urinary tract and GI tract injuries. Failure to identify vaginal injury associated with pelvic fracture may lead to abscess formation, sepsis, and death.

MANAGEMENT

Perineal lacerations in the absence of associated urinary tract and rectal injury can be managed in the emergency department.

Only large hematomas must be incised and drained, with ligation of vessels. Lacerations of the vulva may be closed primarily after irrigation and debridement. Interrupted absorbable sutures allow any accumulated fluid to drain and eliminate the need for suture removal. Drains are used if there is a large cavity; if hemostasis is suboptimal, the wound may be packed.⁶¹

Vaginal and cervical lacerations from either blunt or penetrating injury will bleed extensively if the pudendal vessels are injured.⁶¹ If bleeding is not severe, examination and repair with local anesthesia is possible in the ED. If large lacerations are associated with bleeding and hematoma, speculum examination under anesthesia permits more complete assessment and repair of injuries. Vaginal lacerations should be closed with continuous or interrupted absorbable sutures that include mucosal and muscular layers. Antibiotic-soaked vaginal packing should be left in place for 24 hours. Perioperative administration of broad-spectrum antibiotics is sufficient, unless injuries are more complex.

Complex vaginal and perineal lacerations associated with pelvic fracture must be managed much more aggressively to prevent the morbidity and mortality characteristic of open fractures.⁶⁷ Evaluation of vaginal injuries with the patient under anesthesia, cystography, and rigid proctoscopy are mandatory. The vaginal laceration should be closed with absorbable sutures. Even in the absence of injury to the bladder or the rectum, diversion of the urinary and fecal streams should be considered to facilitate care of the perineal wound⁶⁷; however, I rarely divert the fecal stream unless the perineal injury extensively involves the rectum or the sphincter.⁶⁸ Extraperitoneal bladder rupture associated with vaginal lacerations must be repaired operatively to prevent infection of a pelvic hematoma or formation of a vesicovaginal fistula. Urologic, gynecologic, and orthopedic consultations are necessary for care of associated injuries.

Injury to the pelvic genital organs is rare in a nongravid patient. Penetrating trauma is the most common cause, and the majority of patients have associated injuries necessitating laparotomy.⁶² Blunt injury of the nongravid uterus and the pelvic organs occurs in the face of preexisting abnormalities; DPL demonstrates hemoperitoneum in these instances.⁶³ The uterus, the organ most commonly injured, is repaired with figure-eight sutures or a two-layer closure using slowly absorbable sutures.⁶² Avulsion of the uterine artery or extensive blast destruction of the uterus may necessitate hysterectomy.⁶¹ When hysterectomy is necessary for trauma, the vaginal cuff should be left open to allow drainage of the operative bed.⁶⁹ Lacerations to the ovary or the fallopian tube are managed by primary closure or salpingo-oophorectomy if contralateral structures are normal.

After hysterectomy or repair of vaginal lacerations, a vaginal pack should remain in place for 24 hours. Hemorrhage caused by uterine injury has been treated with oxytocin, which increases uterine tone and controls bleeding. Fertility after injury to the female reproductive organs is not well documented, but patients must be counseled about the possible adverse consequences of uterine and adnexal trauma.

Injuries to the Penis

Injury to the flaccid penis is rare, occurring mainly as a result of penetrating trauma and machinery accidents.^{56,70,71} The increased use of protective armor on the torso has caused a shift in battlefield urologic injuries from renal structures to pelvic and genital organs.⁷² Penile fracture is an uncommon injury of the tunica albuginea that occurs only with full penile rigidity.^{73–75} Prompt operative treatment allows recovery of erectile function after most penile injuries [see Table 5]. Remarkably, in many cases,

penile replantation successfully restores erectile capability.

INITIAL EVALUATION

Missed intromission, acute bending of the penis, and a snapping or popping sound followed by acute pain and immediate detumescence are characteristic of penile fracture. Delayed presentation, attributable to embarrassment, is common. Penetrating injuries to the penis may result from deliberate attempts at mutilation, as well as from accidental firearm injury (typically occurring when a

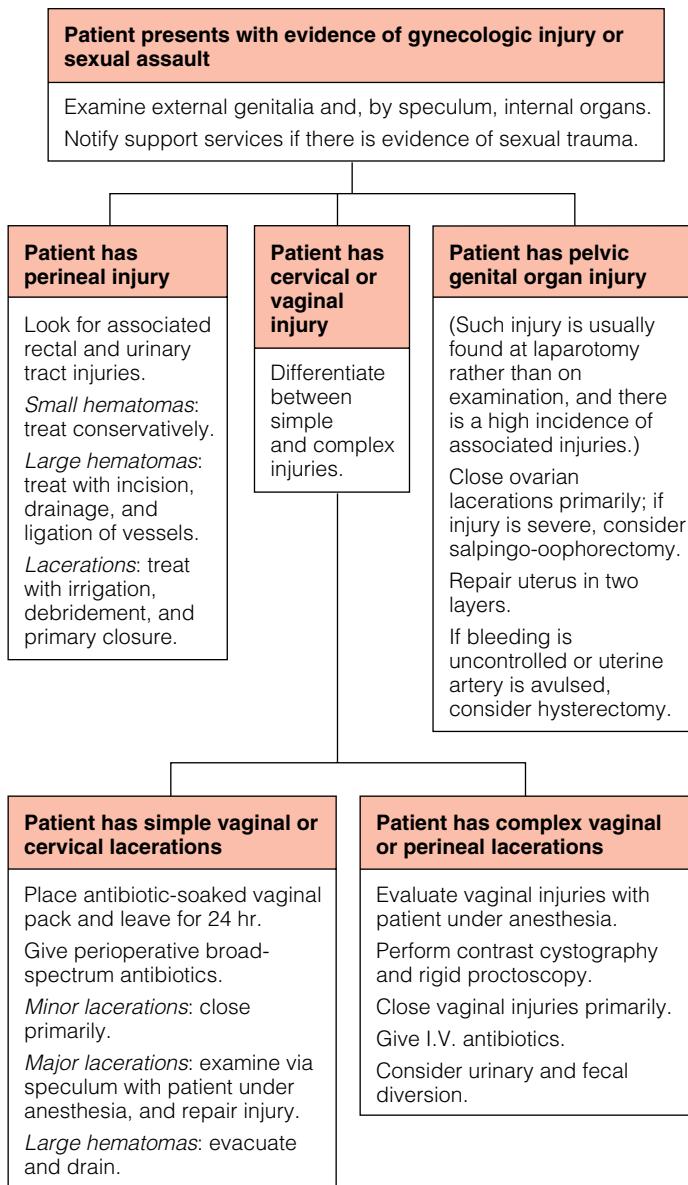

Figure 15 Algorithm outlines management of injuries to the female genitalia.

handgun goes off while in a man's pants pocket). Because of the pliability of the flaccid penis, entry and exit wounds may be complex. Penile swelling is usually limited to the shaft of the penis by Buck's fascia; scrotal and perineal ecchymosis develop if the deep investing fascia of the penis is disrupted. Imaging of the corpora cavernosa with contrast cavernosography has limited sensitivity and specificity and thus is not recommended.⁷⁶ Associated urethral, scrotal, bladder, and rectal injuries must be excluded.

Inability to void, gross hematuria, and blood at the meatus all imply urethral injury and warrant further investigation. A uniform policy of exploration for all penile fractures and penetrating injuries will ensure that urethral injuries are identified. Passage of a catheter in the operative field with inspection of the involved urethra allows identification and primary repair of a lacerated or transected urethra.

Penile Amputation

Whether caused by a jealous lover or by self-mutilation, penile amputation is a catastrophic event.⁷⁷ Proper preservation of the

amputated organ is critical for successful restoration of function. The amputated part should be placed on saline-soaked gauze inside a clean bag, which should then be sealed and placed inside a second bag containing ice slush.⁷⁷ Cold ischemia times longer than 24 hours are acceptable and allow transport of the patient to tertiary centers, where replantation can be performed. Even at normal temperatures, replantation 16 hours after injury has been successful.⁷⁸ Microsurgical repair techniques have certain advantages, including better preservation of the penile shaft skin and the possibility of a sensate glans and normal orgasmic function. However, astonishing results have also been reported with the conventional technique of corporal reattachment without microvascular reanastomosis of the dorsal neurovascular structures.

MANAGEMENT

A circumferential subcoronal incision provides exposure after penile fracture and most penetrating injuries of the shaft and permits corporal and urethral repair. The superficial layers and skin are bluntly degloved back to the base of the penis. For deeper injuries, proximal to the suspensory ligament or in the crura, a penoscrotal or perineal incision is required to provide access to the corpus cavernosum. Rupture of the corpus cavernosum as a result of a fracture, a stab wound, or a bullet wound is signaled by the presence of active bleeding and a defect in the fibrous tunica albuginea. Careful exploration and inspection of the corpus spongiosum are mandatory, even if urethrography shows no extravasation. Tunical ruptures caused by fracture are transversely oriented [see Figure 16] and sometimes extend behind the spongiosum; this structure may have to be mobilized and retracted for adequate visualization of the injury.

The tunica albuginea is closed with interrupted 3-0 slowly absorbable sutures. Debridement and curettage have occasionally been used in this setting but generally are reserved for late presentations. Skin closure is possible with most penetrating injuries to the penis. The extensive vascular supply to the skin is rarely compromised. Interrupted chromic sutures provide a cosmetic closure and allow drainage of residual blood between the sutures. A lightly compressive dressing is sufficient; tight wraps are to be avoided because they may lead to necrosis of swollen shaft skin. Catheter drainage is mandatory if urethral injury is present. Sexual intercourse is contraindicated for 1 month after penile injury.

Penile Amputation

Microsurgical replantation differs from simple corporal reattachment in that the neurovascular structures are reanastomosed in addition to the urethra and the tunica albuginea. With corporal reattachment, a spatulated end-to-end urethral anastomosis is performed with interrupted absorbable sutures over a urethral catheter. The adventitia of the corpus spongiosum is reapproximated in a second layer, and the tunica albuginea and its septum are then connected. The restored cavernosal blood flow preserves the distal corpora, the glans, and the urethra. Ischemic skin loss is expected without reanastomosis of the dorsal artery and vein. When microsurgical techniques are available, the dorsal nerves, the dorsal arteries, and the deep dorsal vein are each reanastomosed with fine nonabsorbable sutures. Meticulous closure of the superficial tunica dartos and the skin completes the repair.

Temporary ectopic replantation of the penis has been described in cases where the perineum is heavily contaminated or too extensively damaged for immediate replantation.⁷⁹ Postoperative care includes urinary diversion, bed rest, anticoagulation (in selected

cases), hydration, and monitoring of arterial flow in the distal penis.

Injuries to the Scrotum and Testes

INITIAL EVALUATION

Scrotal trauma may result in testicular injury or genital skin loss [see Table 5]. Because blunt injuries to the testicle are difficult to recognize, high-resolution ultrasonography has become a key element in the evaluation of scrotal trauma [see Figure 17]. When a straddle injury or penetrating mechanism suggests the possibility of urethral injury, retrograde urethrography is indicated.

Penetrating scrotal injuries commonly involve not only the testis but also the corpora cavernosa, the urethra, and the spermatic cord. Ultrasonography is useful to ascertain the integrity of the arterial inflow to the testis.⁸⁰ The excellent blood supply of the scrotal skin allows most penetrating injuries to be debrided and closed. Even simple bite injuries can be irrigated and closed with appropriate antibiotic coverage. Exceptions to this general rule include complex contaminated human and animal bites, which are left open and are treated with intravenous antibiotics and local wound care (or debridement in cases of severe soft tissue infection).⁸¹

Rupture of the testicle is often immediately painful, with rapid onset of swelling. Falls, straddle injuries, and direct blows are common mechanisms of injury.⁸² However, seemingly minor degrees of trauma may be associated with delayed onset of pain; in this scenario, testicular torsion must be included in the differential diagnosis. Physical signs of rupture include scrotal swelling, tenderness, and ecchymosis. Injury to the scrotal wall or the tunica vaginalis may cause significant swelling without rupture of the tunica albuginea of the testis; pelvic hematoma caused by fracture can result in massive scrotal swelling. For these reasons, blunt injury to the scrotum should be evaluated by ultrasonography unless the findings from the physical examination are normal.

The ultrasonographic characteristics of testicular rupture [see Figure 18] include loss of normal homogeneity of the testicular

Figure 16 Shown is a case of penile fracture. A linear tear in the tunica albuginea can be seen (arrow).

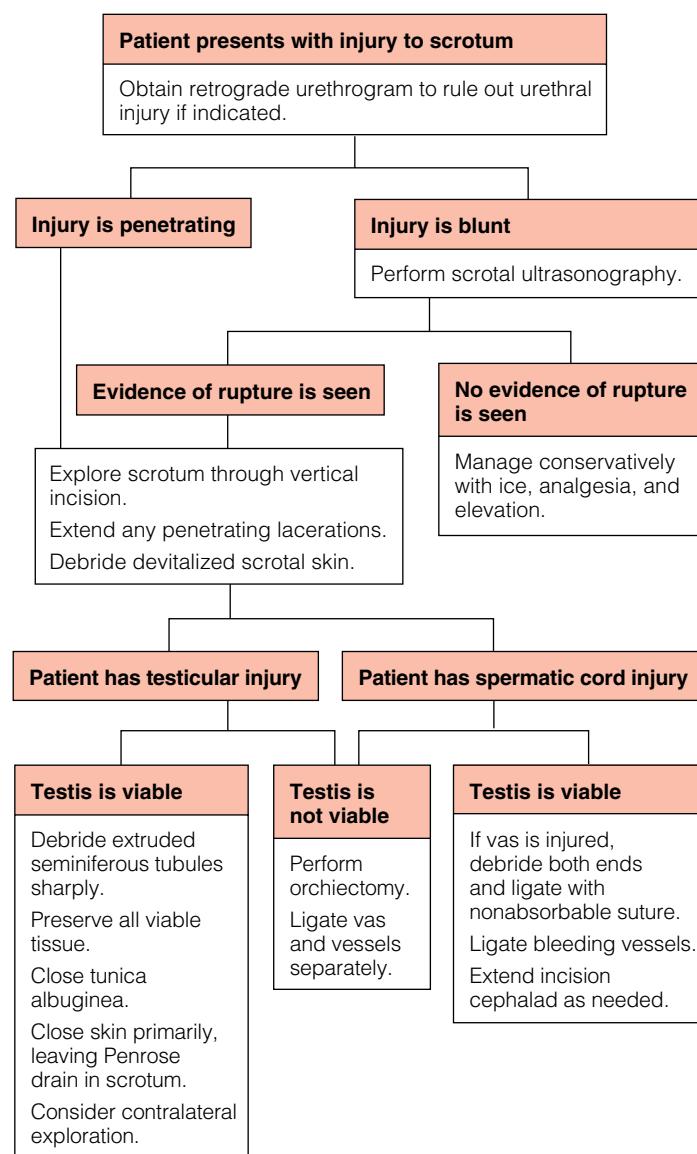

Figure 17 Algorithm outlines management of injury to the scrotum or testes.

parenchyma, loss of continuity of the tunica albuginea, and intraparenchymal hematoma.⁸³ A discrete break in the tunica is relatively rare. In cases of pelvic fracture with massive scrotal edema, ultrasonography can document the integrity of the testis and allow conservative management of the swelling. If rupture is not documented, treatment with ice packs, analgesics, and elevation allows resolution of swelling.

MANAGEMENT

Exploration of the scrotum through a vertical incision allows inspection of the scrotal contents; when spermatic cord injury is discovered, the incision can be extended cephalad to the groin. The goal is preservation of testicular parenchyma for endocrine and cosmetic purposes; normal sperm production and transport are not expected after repair of rupture. Clots and extruded seminiferous tubules are debrided with scissors to allow closure of the tunica albuginea over the edematous parenchyma. A continuous 3-0 slowly absorbable suture is sufficient.

When spermatic cord injury is detected, the first priority is determination of the viability of the testis. A small incision into the tunica albuginea should cause some bleeding; if the testis is cyanotic and does not bleed when cut, orchiectomy should be performed. If only the vas deferens or spermatic vessels are injured, the testis will remain viable. Ligation of the spermatic vessels is performed in the standard fashion; if vasa ligation is necessary, use of nonabsorbable suture with long tails enables later identification for reconstruction if infertility ensues.

Scrotal skin lacerations can be closed primarily in most instances. Exceptions arise if there is a prolonged delay between injury and definitive care or if grossly contaminated wounds are associated with rectal injuries. Hemostasis should be meticulous. Interrupted suture closure of the tunica dartos and skin in separate layers, with a Penrose drain brought out through a separate dependent stab wound, limits postoperative hematoma formation. Fluffed gauze should be used for dressing, and a scrotal supporter should be used to keep the scrotum elevated. The Penrose drain is removed on postoperative day 1. There are no major restrictions to activity after scrotal surgery, and patients can be discharged once they have recovered from associated injuries.

Scrotal avulsion can be devastating and must be differentiated from complex lacerations. Skin avulsed by shear forces in MVCs may be suitable for cleansing and preparation for full- or split-thickness grafts; however, when high-speed rotating machinery is

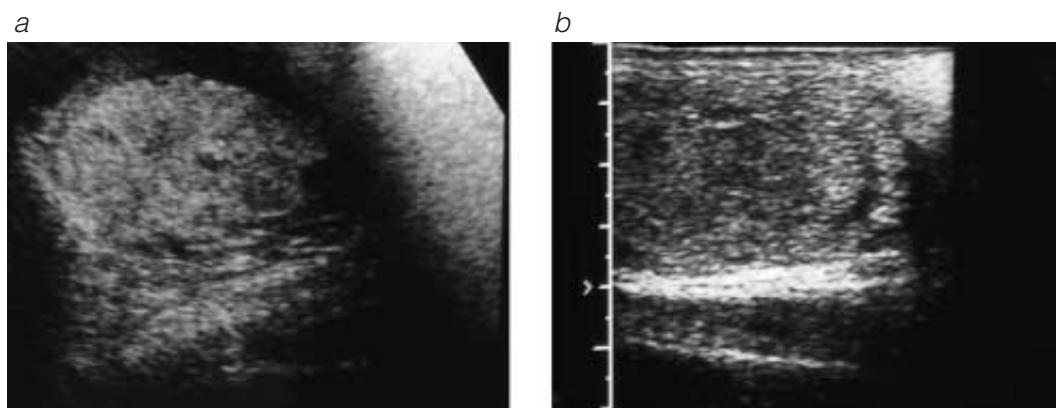

Figure 18 (a) Ultrasonogram of ruptured testes shows intraparenchymal hematoma and heterogeneous echotexture. (b) Ultrasonogram of ruptured testes shows indistinct testicular contour and abnormal echotexture.

the mechanism, as when clothing and skin are caught in a power takeoff, this approach is not recommended. The intrinsic microvasculature of the skin is probably damaged. Scrotal skin loss caused by burns or electrical or mechanical injury usually spares the testis, which has a separate blood supply. Conservative debridement is possible if there is no infection, but

the demarcation between viable and nonviable tissue should be identified before extensive debridement.⁸⁴ Management depends on the amount of skin remaining. Options include primary closure, immediate coverage with meshed split-thickness skin grafts, and placement of the testes in subcutaneous pouches in the thigh.

12 INJURIES TO THE PELVIS AND EXTREMITIES

J. C. Goslings, M.D., Ph.D., K. J. Ponsen, M.D., and O. M. van Delden, M.D., Ph.D.

Injuries to the pelvis and extremities are common, occurring in approximately 85% of patients who sustain blunt trauma. Improper management can have devastating consequences. Major long bone fractures are a sign that substantial force has been applied to the body, and they are frequently associated with torso injuries. Trauma to the pelvis or the extremities can result in injuries that are potentially life-threatening (e.g., pelvic disruption with hemorrhage, major arterial bleeding, and crush syndrome) or limb-threatening (e.g., open fractures and joint injuries, vascular injuries and traumatic amputation, compartment syndrome, and nerve injury secondary to fracture dislocation). In this chapter, we outline the basic knowledge the general or trauma surgeon requires for initial management of injuries to the pelvis, the extremities, or both.

Evaluation and Assessment

INITIAL PRIORITIES

In the surgical management of musculoskeletal injury, the priorities are (1) to save the patient's life, (2) to save the endangered limb, (3) to save the affected joints, and (4) to restore function; these priorities are pursued in accordance with advanced trauma life support (ATLS) guidelines.¹ The musculoskeletal injury that it is most important to identify during the primary survey is an unstable pelvic injury, which can lead to massive and life-threatening internal bleeding. If manual compression-distraction of the iliac crests elicits abnormal movement or pain, a pelvic fracture is probably present. In this case, a prefabricated splint or sheet wrap is applied around the pelvis to reduce the intrapelvic volume, and the legs are wrapped together to induce internal rotation of the lower limbs. Grossly deformed extremities are reduced by means of manual traction to reduce motion and to enhance the tamponade effect of the muscles. In the initial phase, control of hemorrhage from deep soft tissue lesions and vessel injury is best achieved with direct compression.

During the secondary survey, the rest of the musculoskeletal system is assessed to identify fractures, dislocations, and soft tissue injuries. It is advisable to perform a tertiary survey 24 to 48 hours after admission to detect any missed injuries, especially in multiply injured patients whose condition at admission precluded the completion of a full secondary survey.²

IMAGING

Diagnostic imaging usually begins with conventional x-rays. The pelvis is imaged during the primary survey, but x-rays of the extremities typically are obtained only after life-threatening injuries have been corrected and the patient's general condition is such that the surgeon can afford to spend the time necessary to complete extremity and spine imaging (which is often as long as several hours). Conventional x-rays of the affected limb are guided by the injury mechanism, the history, and the physical examination and

are always done in two planes (anteroposterior [AP] and lateral). Long bones should be visualized over their entire length, including the adjacent joints. After reduction of fractures and dislocations, x-rays should be repeated, unless no time is available (e.g., because of the presence of limb-threatening vascular injury).

Computed tomographic scanning is frequently used as an adjunct to conventional x-rays, especially in patients with periartricular fractures and dislocations or pelvic fractures. Axial, sagittal, coronal, and three-dimensional reconstructions allow exact determination of the extent of the fracture and the position of fracture fragments. CT scanning also helps in the process of deciding between operative and nonoperative treatment, and it facilitates preoperative planning when a surgical therapy is adopted. In addition, CT scanning may play a role in detecting bleeding sources in the pelvis, though hemodynamic instability or ongoing blood loss in the presence of a pelvic fracture usually is best managed with immediate angiography rather than CT.

Magnetic resonance imaging can be helpful with complex malunions, soft tissue injuries, and certain fracture types (e.g., scaphoid fracture).³ Bone scintigraphy and ultrasonography are less frequently employed in the setting of pelvic and extremity trauma. Triphasic bone scanning is primarily used to detect osteomyelitis, avascular necrosis, and malignant lesions, whereas ultrasonography is mostly used to assess soft tissue injuries.

CLASSIFICATION OF INJURIES

Fracture

Of the many existing fracture classification systems, the one that is most frequently used is the system developed by two Swiss organizations, the Association for Osteosynthesis (AO) and the Association for the Study of Internal Fixation (ASIF) [see Figure 1].⁴ The AO-ASIF fracture classification system serves both as a means of documenting fractures (e.g., for research purposes) and as an aid to the surgeon in assessing the severity of the fracture and determining the appropriate treatment.

In the AO-ASIF system, any given extremity fracture can be described in terms of a five-place alphanumeric designation [see Figure 1a]. The first place represents the bone injured. The second represents the segment affected by the injury (proximal, middle or diaphyseal, or distal, with malleolar a fourth category that is sometimes employed). The third represents the fracture type (A, B, or C). In middle-segment long bone fractures, type A refers to simple fractures with two fragments, type B refers to wedge fractures with contact between the main proximal and distal fragments after reduction, and type C refers to complex fractures without contact between the main fragments after reduction [see Figure 1b]. In proximal and distal long bone fractures, type A refers to extra-articular fractures with the articular surface intact, type B refers to partial articular fractures in which there is some articular involvement but part of the articular surface remains attached to the diaphysis, and type C refers to complete articular fractures in which

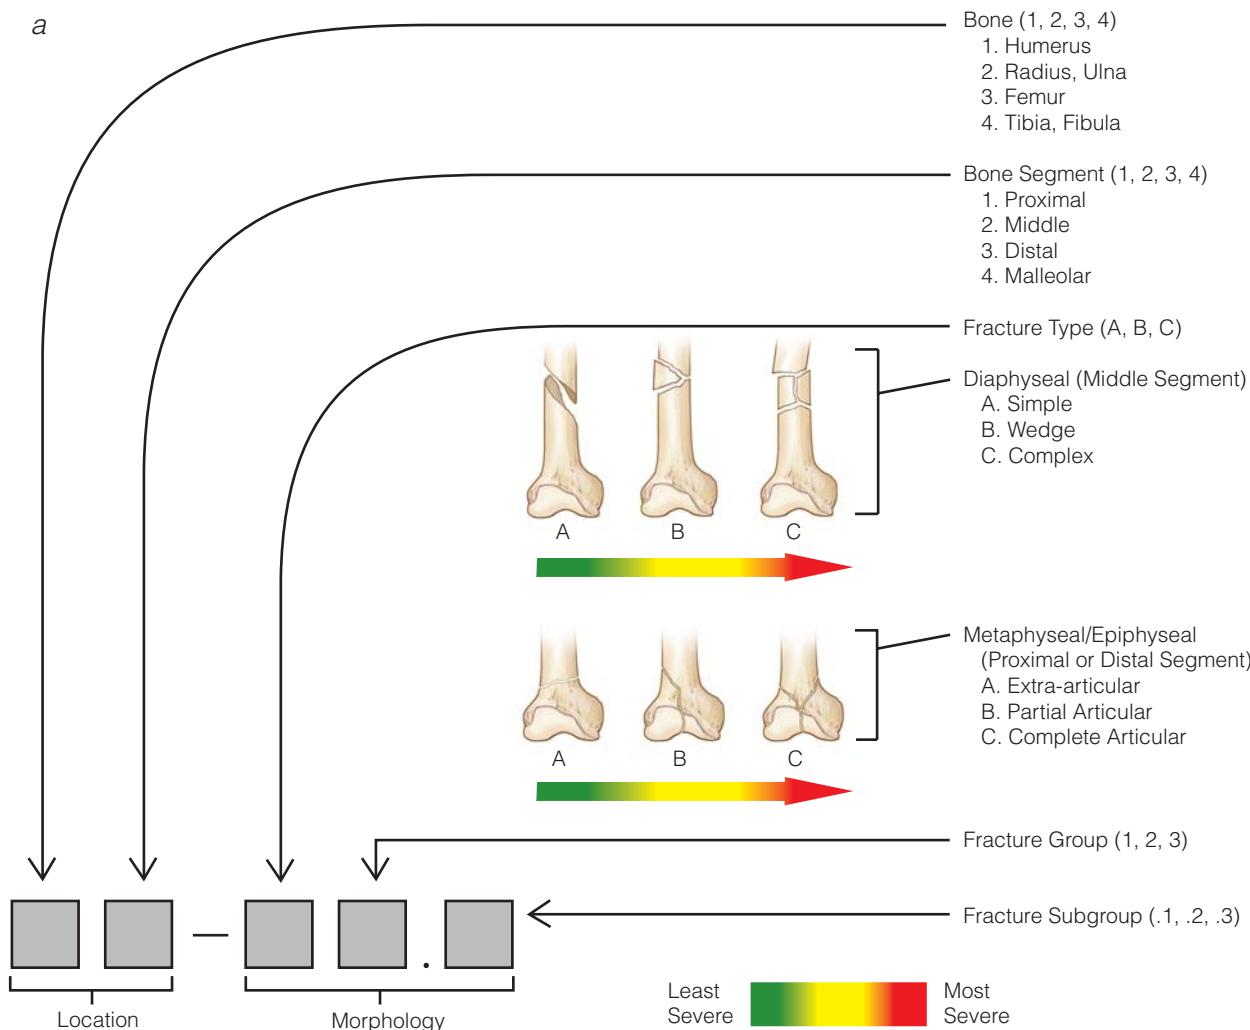

Figure 1 (a) Shown is the AO-ASIF classification system for fractures, as expressed in a five-place alphanumeric designation. (b) Illustrated are the three types of diaphyseal long bone fractures, along with the three groups into which each type is divided. (c) Depicted are the three types of metaphyseal or epiphyseal long bone fractures.

the articular surface is disrupted and completely separated from the diaphysis [see Figure 1c]. The fracture types are then further subdivided into three groups (1, 2, or 3), represented by the fourth place, and (mainly for scientific purposes) three subgroups (.1, .2, or .3), represented by the fifth place.

For the fracture types, groups, and subgroups, increasing letter and number values represent increasing severity, as determined by the complexity of the fracture, the difficulty of treatment, and the prognosis. Thus, an A1 fracture is the simplest injury with the best prognosis, and a C3 fracture is the most complex injury with the worst prognosis. For practical purposes, the first four places of the AO-ASIF alphanumeric designation are usually sufficient for treatment planning; the fifth (the subgroup) adds little to the process.

Pelvic ring and acetabular fractures are classified in essentially the same fashion [see Management of Pelvic and Acetabular Injuries, below].

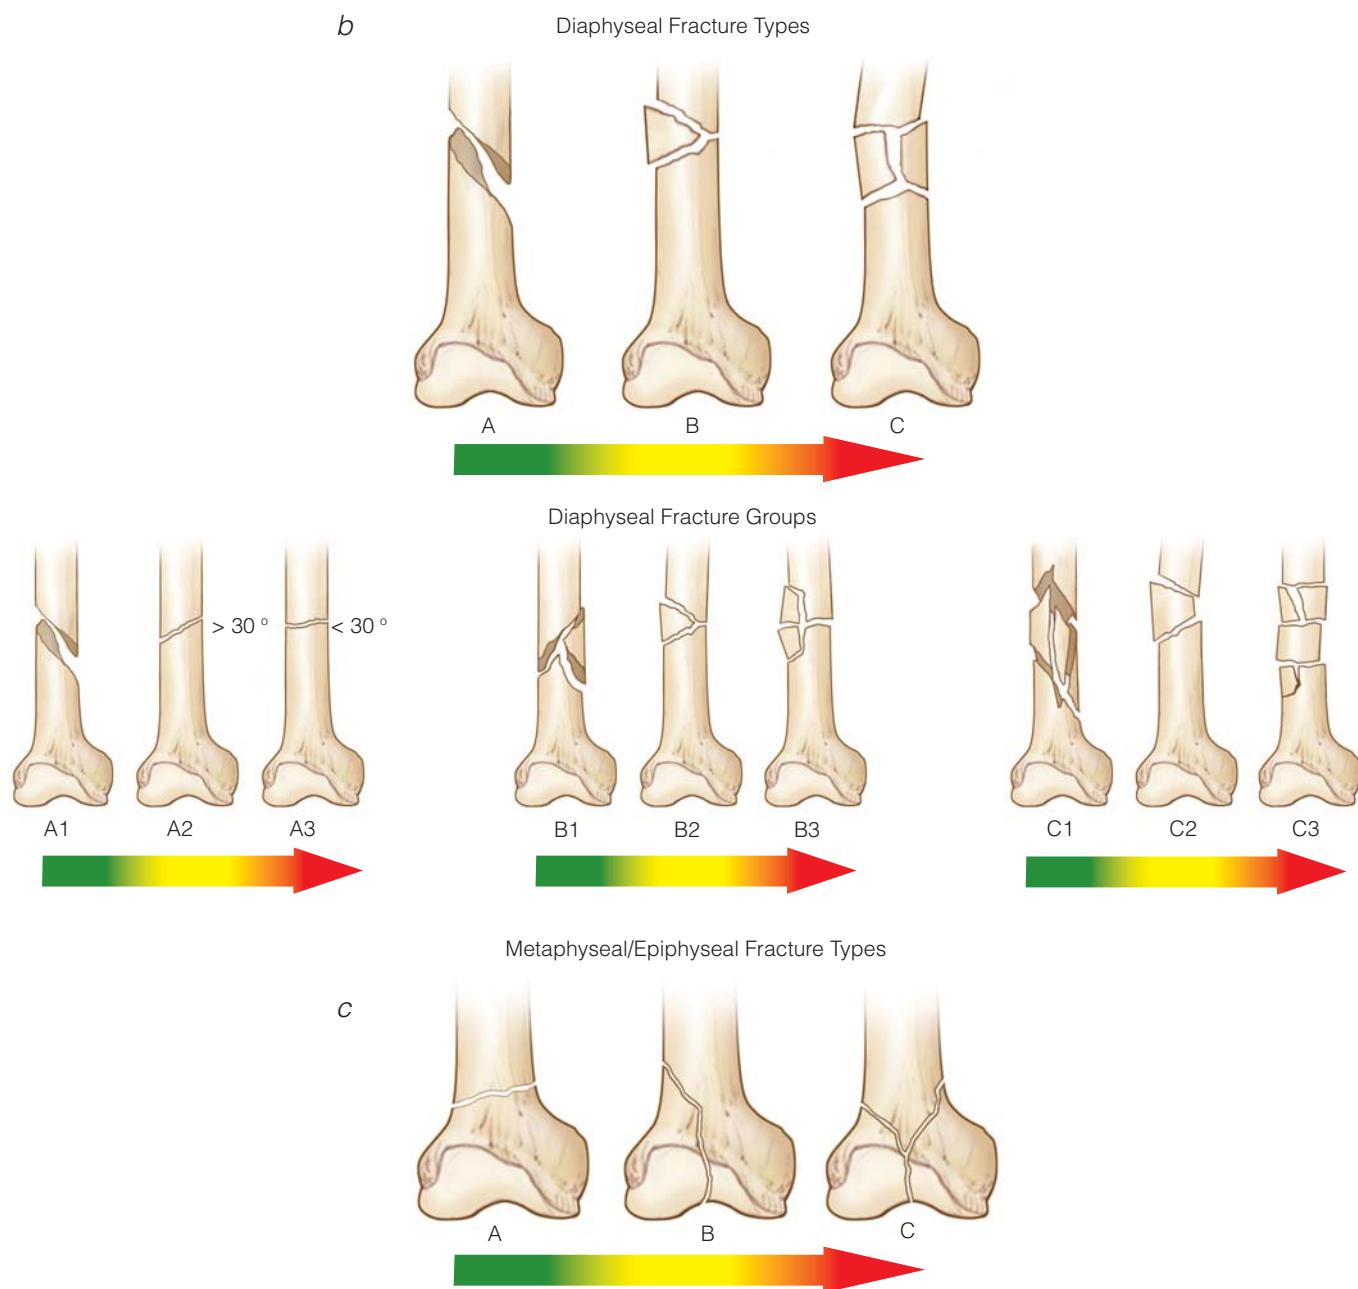

Soft Tissue Injury

The type of soft tissue injury present and its extent are determined by the type of insult sustained (e.g., blunt, sharp, or crush), the degree and direction of the force applied, the area affected, and

the extent of contamination (if any). With closed injuries, the intact skin prevents direct assessment of the subcutaneous tissues, and as a result, soft tissue injuries are frequently underestimated. In the emergency department, a single inspection is made, and the wound is covered by a sterile dressing; at this point, it may be helpful to take pictures with a digital camera. Exact grading of the soft tissue injury is best done in the operating room by an experienced surgeon who can also decide on a treatment plan.

The system most commonly used for classification of open fractures is the one developed by Gustilo and Anderson, which divides these fractures into three types as follows [see Figure 2]^{4,5}:

1. Type I: the wound is smaller than 1 cm and results from an inside-out perforation, with little or no contamination; the fracture type is simple (type A or B).
2. Type II: the skin laceration is larger than 1 cm but is associated with little or no contusion of the surrounding tissues; there is no dead musculature, and the fracture type is moderate to severe (B or C).
3. Type III: extensive soft tissue damage has occurred, with or without severe contamination, frequently in association with compromised vascular status; the fracture is highly unstable (type C) as a result of comminution or segmental defects. Type

III fractures are further divided into the following three sub-categories:

- III A: adequate soft tissue coverage of the bone is still possible.
- III B: extensive soft tissue loss occurs with periosteal stripping and exposed bone; contamination is usually massive.
- III C: an arterial injury is present that requires repair; any open fracture accompanied by such an injury falls into this category, regardless of fracture type.

Closed fractures are less frequently classified according to the type and extent of soft tissue injury, though this does not mean that such injury is not an important consideration with closed fractures. The classification system most commonly used for closed fractures is that of Tscherne, which recognizes the following four grades:

- Grade 0: soft tissue injury is absent or minor; the fracture type is simple.
- Grade I: superficial abrasion or contusion is present as a result

of pressure applied by the fragment from the inside; the fracture type is simple or moderate.

- Grade II: deep contaminated abrasions and localized skin or muscle contusion are present as a consequence of direct trauma, possibly leading to compartment syndrome; the fracture type is moderate to severe.
- Grade III: extensive skin contusions, destruction of musculature, and subcutaneous tissue avulsion have occurred; the fracture is severe and mostly comminuted.

Timing and Planning of Intervention

In multiply injured patients, the timing of operative treatment of injuries to the pelvis and extremities depends both on the condition of the patient and on the particular combination of skeletal and soft tissue injuries sustained [see Table 1]. In such cases, the threshold for adoption of a damage-control strategy [see Damage-Control Surgery, below] to minimize operating time and tissue

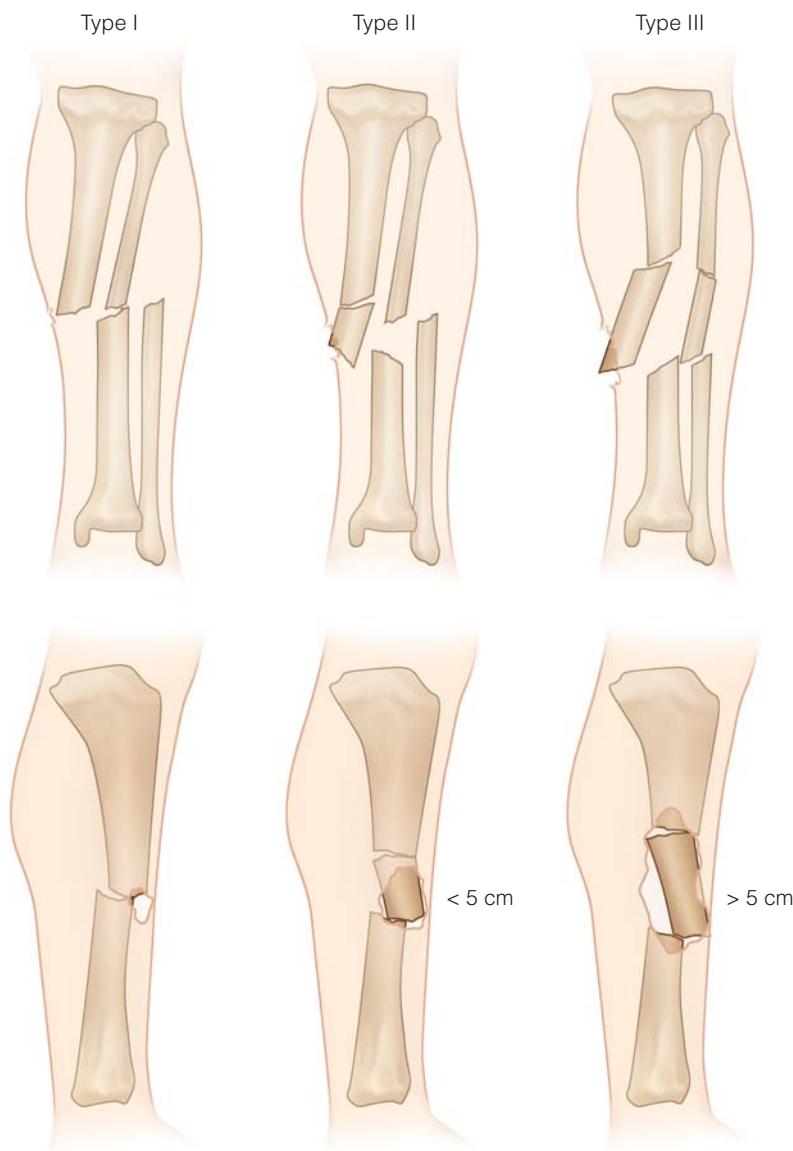

Figure 2 Illustrated is the Gustilo-Anderson classification system for open fractures.

insult should be low.^{6,7} The performance of multiple definitive osteosyntheses is an option only in patients who have been successfully resuscitated (as indicated by stable hemodynamic status without a need for inotropes; absence of hypoxia, hypercapnia, and acidosis; normothermia; normal coagulation parameters; and normal diuresis).

In other cases, the timing and extent of operative treatment of musculoskeletal injuries may be more complex. Generally, if open reduction and internal fixation are indicated, the sooner the operation is performed, the better. With early operation, fracture surfaces are more easily cleaned of blood clots and other material, and reduction is facilitated by the absence of prolonged dislocation and shortening. After 6 to 8 hours, swelling develops, making both the operation and the subsequent closure more difficult and thereby increasing the risk of infection and other wound complications. There are some cases, however, in which it might be preferable to postpone a complex articular reconstruction in order to ensure that the surgical team is optimally prepared. If, for any reason, significant swelling precludes a definitive operation, it is usually safer to stabilize the fracture temporarily (e.g., with splinting or external fixation), then wait 5 to 10 days for the swelling to subside. Temporary stabilization usually allows the surgeon to achieve a

reasonable provisional reduction; however, complete joint dislocations are not acceptable. Clinically, sufficient reduction of swelling has occurred when the skin has regained its creases and is wrinkled over the operative site. Early definitive surgery may also be contraindicated when abrasion or degloving injury is present at the fracture site on admission.

Swelling is less of a problem with shaft fractures that will be treated with intramedullary nailing. If, however, it is not possible to perform nailing within 24 to 48 hours after the injury, it is better to postpone the operation for 7 to 10 days; patients operated on between days 3 and 7 are at higher risk for the acute respiratory distress syndrome (ARDS).^{8,9} If the procedure must be delayed for more than 2 to 3 weeks (e.g., because of sepsis and organ failure), reconstruction of bones and joints will be substantially more difficult. If such delay leads to suboptimal axial alignment and nonanatomic reconstruction of the articular surface, the long-term prognosis will be worse.

Thorough preoperative planning is necessary for any operation done on the musculoskeletal system. Depending on the procedure to be performed, logistical considerations may include availability of the appropriate operating team, availability of the correct operating table, availability of the specific instruments needed, avail-

ability of the appropriate implants, and availability of intraoperative imaging. Technical considerations include the operative approach to be followed and the fixation method to be used, which are determined on the basis of an understanding of the extent of the injuries and a detailed knowledge of the anatomy in the area to be exposed. For example, awkward placement of fixator pins could seriously obstruct soft tissue reconstruction if the pins are in the area that should be used for a soft tissue flap. Before operation, the correct operative site is verified (with the patient awake) and marked with a permanent marker pen. A drawing of the planned reduction maneuvers and fixation techniques may be helpful for the surgeon while also serving as an educational tool for the assisting team members. Correct documentation is important for both medical and legal reasons.

DAMAGE-CONTROL SURGERY

Immediate and complete care of all fractures, dislocations, and soft tissue injuries may seem the ideal treatment strategy for patients with musculoskeletal injuries. However, this is not always the case. Major trauma leads to a systemic inflammatory response syndrome (SIRS) characterized by increased capillary leakage, high energy consumption, and a hyperdynamic hemodynamic state. Especially in the setting of severe single-organ injury or multiple injuries, the physiologic and immunologic impact of extend-

Table 2 Goals of and Indications for Damage-Control Surgery in Management of Pelvic and Extremity Trauma

Goals	Control of hemorrhage Control of contamination Removal of dead tissue and prevention of ischemia-reperfusion injury Facilitation of ICU treatment Pain relief
Indications	Clinical parameters Multiple trauma (ISS > 15) and additional chest trauma Pelvic ring injuries with exsanguinating hemorrhage Multiple trauma with abdominal or pelvic injuries and hemorrhagic shock (BP < 90 mm Hg) Radiographic findings indicating (bilateral) lung contusion Femoral fractures in polytrauma patient Polytrauma in geriatric patient Resuscitation, operation, or both expected to last > 90 min Physiologic parameters Severe metabolic acidosis (pH < 7.20) Base deficit (< -6 mEq/L) Hypothermia (T° < 35° C) Coagulopathy (PT > 50% of normal) Multiple transfusions

ISS—Injury Severity Score PT—prothrombin time

Table 1 Time Frames for Operative Treatment of Pelvic and Extremity Trauma*

Category I: immediate	(Imminent) hemodynamic instability (e.g., pelvic fracture) Neurovascular injury with compromised vitality of extremity (Imminent) compartment syndrome
Category II: urgent (within 6–12 hr)	Open fractures (increased risk of infection) Joint dislocations that cannot be reduced in ED Primary stabilization (e.g., external fixation) in multiply injured patients who are hemodynamically stable Femoral neck fractures in patients < 65 yr (to prevent femoral head necrosis) Long bone fractures (to prevent complications and immobilization) Severe soft tissue injury (e.g., degloving caused by rollover accident) Closed fractures with compromised skin Dislocated talar neck fractures
Category III: semiurgent (within 12–24 hr)	Femoral neck, intertrochanteric, and subtrochanteric fractures Closed reduction of fractures in children Treatment of soft tissue injuries (e.g., to tendons of wrist and hand) Closed fractures that benefit from early treatment (e.g., to prevent swelling with ankle fractures) Spine fractures that are unstable or associated with neurologic deterioration Wound debridement and irrigation or washout
Category IV: semiselective (within 24–72 hr or delayed)	Achilles tendon ruptures Stable spine fractures Other fractures Revision procedures other than those done for infection

*These time frames are general guidelines and may be modified in accordance with individual patient parameters (e.g., physiologic condition, soft tissue injury, and fracture type) and local preferences.

ed surgical procedures on the patient's general condition can increase the risk of the multiple organ failure syndrome (MODS), ARDS, and other complications. Balanced against this risk is the understanding that early fracture fixation in polytrauma patients is beneficial in terms of mortality and morbidity. Improved understanding of the physiologic response to major trauma over the past decade has led to the approach known as damage-control surgery (DCS) or staged surgery, the purpose of which is to keep the patient from having to deal with the "second hit" imposed by the operation right after experiencing the "first hit" imposed by the initial trauma.

Currently, DCS is widely promoted for management of intraabdominal, vascular, and musculoskeletal injuries. It can be divided into three main phases: (1) a resuscitative phase, (2) an intensive care phase, and (3) a reconstructive phase.¹⁰ The initial focus is on control of bleeding, contamination, and temporary stabilization of fractures; time-consuming reconstructions and osteosyntheses are avoided at this point. At a later stage, when vital functions have been restored, definitive reconstructions are performed during one or more planned reoperations.

The decision whether to employ DCS should be made before the operation to avoid a scenario in which the patient's general condition of the patient deteriorates seriously during a difficult operation (e.g., a complex femoral nailing procedure) [see Table 2]. An experienced and judicious surgeon will make an appropriate decision about DCS more often than not. If, as sometimes happens despite the surgeon's best efforts, the patient's condition does show serious deterioration unexpectedly during operation, the surgeon should immediately choose a bailout option, usually involving external fixation.

As applied to musculoskeletal trauma, DCS begins with debridement of open wounds and irrigation with pulsed lavage (so-called washout). Amputation of the injured limb or limbs is considered if it appears potentially lifesaving [see Management of Life-Threatening or Limb-Threatening Injuries, Mangled Extremity, below]. During the initial debridement, osteochondral

fragments in open joint fractures are retained—provided that they are not severely contaminated—to allow later reconstruction of the joint surface. Dislocations and diaphyseal fractures are reduced and stabilized with simple external fixator frames (if necessary, placed so as to span the adjacent joint or joints), and wounds are provisionally closed. Fixator pins are placed through stab incisions in safe zones. Fractures need not be reduced anatomically under image intensifier control; the only goals at this point are to restore length and align long bone fractures and joints, to reduce contamination, and to enable postoperative wound management in the intensive care unit while definitive treatment is pending. The more complex the fixator frame, the more time-consuming its application usually is. Muscle compartments believed to be at risk for compartment syndrome are widely decompressed.

At all times, the operating surgeon must keep the goals of DCS clearly in mind. The main aim of this strategy is not necessarily a nice-looking postoperative x-ray showing parallel fixator pins and a perfectly reduced tibia; rather, it is the survival of the patient in stable physiologic condition. Depending on the severity of the injuries, the reconstructive procedures likely to be performed, and the availability of specialists or subspecialists, consultation with a plastic surgeon during the initial operation may be advisable to optimize operative and logistical planning.^{6,7}

Careful attention must be paid to the logistical aspects of DCS. As soon as the decision for DCS is made, OR personnel should be notified of the type of procedures to be performed and the implants required. It may be helpful to have a dedicated DCS equipment trolley with all the materials and equipment necessary for the first hour.¹¹ Once the patient and the operating team are in the OR, the injuries sustained, the operative plan, and the injuries (known or suspected) that need special attention (e.g., a small pneumothorax) are written down or sketched on a whiteboard so that all persons present in the OR know what is to be done.

During the operation, the surgeon should stay in close contact with the anesthesiologist regarding the condition of the patient and the procedure currently under way. If operative procedures are required in more than one organ system (e.g., laparotomy and external fixation of the femora), they should, whenever possible, be performed simultaneously by multiple teams working together. The end of the procedure should be announced well ahead of time so that the anesthesiologist can take the precautions necessary for transport of a potentially unstable patient and so that the ICU can be notified of the patient's arrival. In this way, unnecessary waiting times in the OR can be kept to a minimum.

The second phase of DCS is restoration of vital functions in the ICU. This phase is crucial for ensuring that the patient is fit to undergo a second procedure.¹⁰ Close cooperation between surgeon and critical care physician is required to outline an aggressive strategy for ventilation, circulatory support, and reversal of hypothermia, coagulopathy, acidosis, and other abnormalities. Administration of large volumes of fluid will be necessary as a consequence of massive tissue swelling and bowel edema. Cardiac monitoring with central venous access should usually be employed. Application of external fixators allows the nursing staff to place the patient in the position that is most suitable for intensive care of head, chest, and abdominal injuries, while still allowing wound inspection and dressing changes as required. During this phase, imaging studies may be performed (or, if already performed, repeated) to allow planning for repeated washouts and definitive reconstructive procedures.

The third phase in the DCS sequence is the performance of one or more planned reoperations. This usually takes place at least 24

to 48 hours after the initial procedure, when the patient is stable and normothermic and has normal or near-normal coagulation parameters.¹⁰ Subsequent visits to the OR are used to continue wound debridement and coverage and to exchange external fixators for definitive fixation (e.g., with intramedullary nails).^{12,13} During these operations, multiple teams can work simultaneously on the repair of abdominal, musculoskeletal, and other injuries. The period from postinjury day 5 to day 10 is often referred to as the window of opportunity for reconstruction of intra-articular or periarticular fractures and of upper-limb fractures.

Management of Life-Threatening or Limb-Threatening Injuries

LIFE-THREATENING PELVIC TRAUMA

Pelvic fractures are frequently associated with significant hemorrhage, not only because of the fracture itself but also because pelvic trauma is often accompanied by serious injuries to other parts of the body (e.g., the chest or the abdomen). Significant arterial hemorrhage is present in approximately 25% of patients with unstable pelvic fractures.^{4,5,10,14,15} Bleeding from pelvic trauma can be quite severe: as much as 4 L of blood may accumulate in the retroperitoneal space. Whether hemorrhagic shock is associated with certain fracture types remains a matter of debate, but there is certainly a link between the severity of the pelvic injury and the incidence of hemorrhagic shock. Hemorrhagic shock in patients with pelvic fracture strongly influences outcome and necessitates immediate evaluation and treatment.

Hemorrhage may originate either from within the fractured pelvic bones themselves or from torn arteries and veins in the pelvis, which are in close proximity to the bony structures of the pelvis. In particular, the presacral venous plexus and the internal iliac arteries and side branches may be lacerated. The most commonly injured anterior branches of the internal iliac artery are the internal pudendal artery and the obturator artery, whereas the most commonly injured posterior branches are the superior gluteal artery and the lateral sacral artery.^{16,17}

Given that bleeding in pelvic fracture patients can occur in other body compartments besides the pelvis and can be arterial as well as venous, it is of the utmost importance to identify its source and, ideally, determine its nature as soon as possible. This information is crucial in determining what the next steps in management should be [see Figure 3].

The first step after diagnosing a pelvic fracture should be the immediate application of some type of external stabilization device (e.g., a sheet wrap or a device such as the Pelvic Binder [Pelvic Binder Inc., Dallas, Texas]) [see Figure 4].¹⁸ The rationale behind this step is that approximating the fractured bones and thereby decreasing the volume of the pelvis may reduce blood loss, particularly from the fractured bones and the lacerated venous plexus. In addition, stabilization may minimize further damage to blood vessels and prevent dislodgment of recent clots. It is doubtful, however, whether this procedure actually reduces arterial hemorrhage to a significant degree.

In hemodynamically unstable patients with clinical signs of a pelvic fracture, the next step (immediately after—or, preferably, while—x-rays of the chest, the pelvis, and the cervical spine are obtained according to ATLS protocols) should be the FAST (focused assessment for sonographic evaluation of the trauma patient) to rule out a significant intra-abdominal bleeding source. If the FAST is negative and no other obvious sources of hemorrhage (e.g., chest or extremities) are found, the pelvis is the most

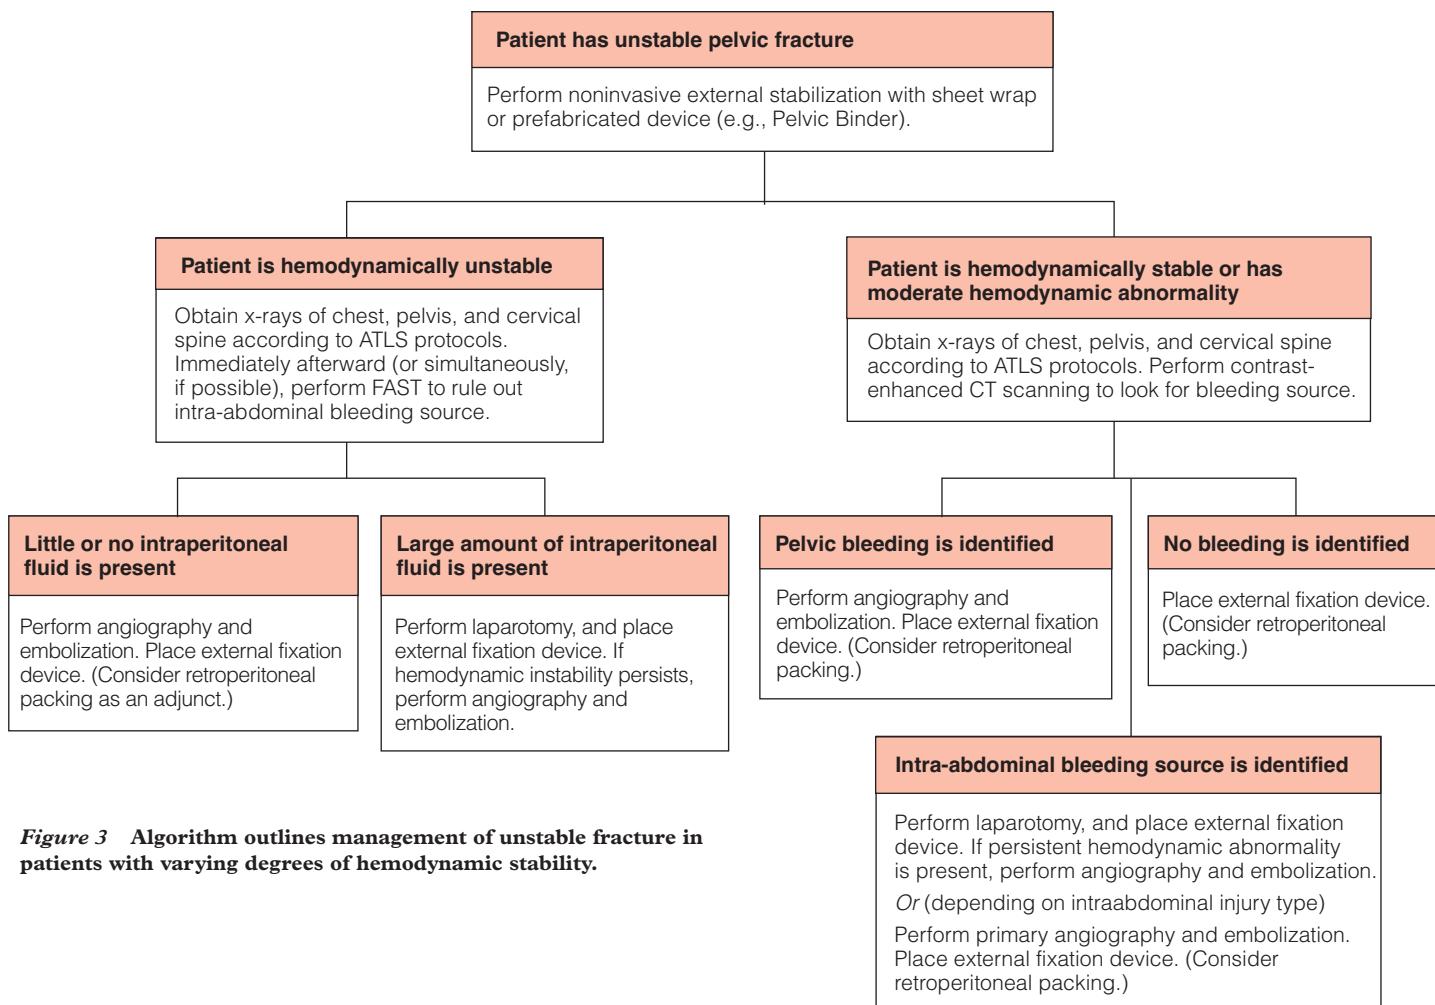

Figure 3 Algorithm outlines management of unstable fracture in patients with varying degrees of hemodynamic stability.

likely source of the bleeding. The question then arises whether the pelvic hemorrhage is predominantly arterial or venous. An arterial bleeding source in the pelvis is found in 73% of hypotensive patients who do not respond to initial fluid resuscitation.¹⁹

Contrast-enhanced CT scanning is extremely helpful in determining the presence of arterial hemorrhage in cases of pelvic fracture, but it can be performed only if the patient is stable enough to undergo the time-consuming transfer to the imaging suite. If a CT scanner is available in the shock room, it may be possible to extend the use of this modality to unstable patients. Extravasation of contrast medium, a large retroperitoneal hematoma, or abrupt cutoff of an artery on CT indicates that angiographic embolization is necessary. Contrast extravasation (so-called contrast blush) is a particularly good predictor of arterial hemorrhage necessitating embolization, having a sensitivity and specificity of well over 80%.²⁰ Thus, CT is an ideal means of identifying patients who should be treated with angiographic embolization and ideally should be performed in all pelvic fracture patients who are stable enough to undergo this procedure.

Arterial hemorrhage should preferably be treated by angiographic embolization, which has shown excellent results in current studies [see Table 3].^{21,22} Several authors have argued that in unstable patients, angiographic embolization should be done immediately, before operative placement of an external fixation device, because the chance of finding an arterial bleeding source is high and because the duration of the interval between arrival in the ED

and the performance of embolization strongly influences outcome. Angiographic embolization with gel foam or coils can almost always be performed via the common femoral artery approach, even with a sheet wrap or an external fixation device in place. Success rates exceed 90%, and major complication rates are below 5%. This technique does, however, require a skilled, experienced, and permanently available interventional radiology service.

In patients with unstable fractures, venous hemorrhage is treated with operative placement of an external fixation device. This measure requires specific expertise on the part of the trauma surgeon; in experienced hands, it should take no longer than 20 minutes to perform. Patients with more severe pelvic fractures (e.g., AO-Tile type B and C fractures and higher grades of lateral compression and anteroposterior compression fractures [see Management of Pelvic and Acetabular Injuries, Pelvic Ring, below]) probably benefit most from this procedure. Retroperitoneal packing may be employed as an adjunct to external fixator placement.²³ It is unlikely that external fixation has a significant impact on arterial hemorrhage; consequently, it is vital to decide whether angiographic embolization should precede placement of an external fixation device in the OR.

The optimal strategy for controlling bleeding in patients with life-threatening pelvic injuries remains subject to debate.^{24,25} We favor a prominent role for CT scanning and angiographic embolization, whereas others favor more liberal use of surgical retroperitoneal packing of the pelvis.

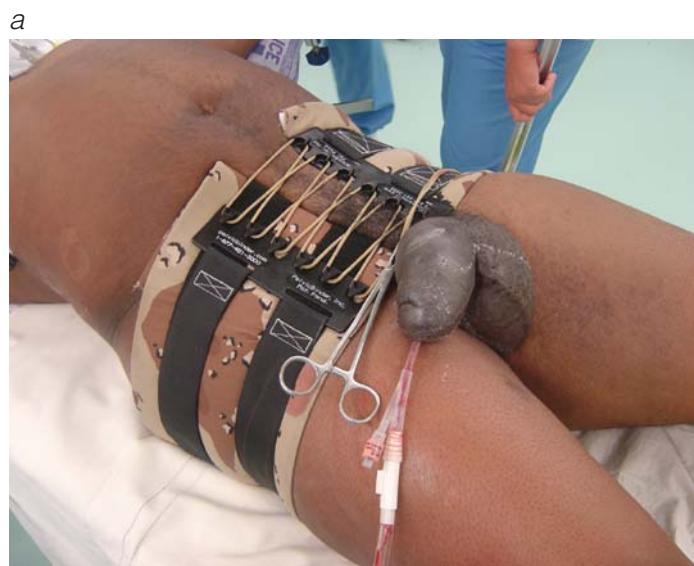

Figure 4 (a) Shown is initial stabilization of pelvic fracture in a patient with severe head injury, life-threatening unstable pelvic fracture, distal femoral fracture, and proximal tibial fracture. (b) Shown is the same patient after DCS.

OPEN FRACTURES AND SOFT TISSUE RECONSTRUCTION

Approximately 3% to 5% of all fractures and 10% to 15% of all long bone fractures are open. The prognosis after an open fracture is very different from that after a closed fracture; treatment of open fractures is much more complex than treatment of simple fractures or traumatic wounds. The existence of an open fracture means that a great deal of energy has been delivered to the bone to produce soft tissue disruption. Accordingly, it can be inferred that there has been considerable stripping of muscle, periosteum, and ligament from the bone, resulting in relative devascularization, and that varying degrees of contusion, crushing, and devascularization of the associated soft tissues have occurred. All of these events greatly influence the rate of healing, the incidence of nonunion, and the risk of infection (most commonly by *Staphylococcus aureus*, *Enterococcus*, or *Pseudomonas*). As noted [see Evaluation and Assessment, Classification of Injuries, Fracture, above], open fractures are typically classified according to the system formulated by Gustilo and Anderson.^{4,5,26}

Management of open fractures in the ED starts with a detailed history that includes the patient's medical condition before the injury, the mechanism of injury, and the time elapsed since the injury. A careful physical examination is then performed, with particular attention paid to neurovascular status, muscle function, and the presence or absence of associated injuries. Compartment syndrome [see Management of Life-Threatening or Limb-Threatening Injuries, Mangled Extremity, below, and 7:17 Injuries to the Peripheral Blood Vessels] should be ruled out in patients at risk; as many as 10% of open tibial fractures are associated with compartment syndrome as a result of severe soft tissue injury. If the limb is malaligned, gentle gross reduction should be performed to relieve any vascular compromise. The wound is then inspected, and a sterile dressing is applied. Once this is done, the dressing should not be removed until the patient is in the OR and preparation for operation has begun. The need for repeated inspections by various specialists can be eliminated by taking pictures of the fractured limb with a digital camera. A temporary splint is applied to the limb to relieve pain and prevent further soft tissue injury. X-rays are obtained in two planes, with the adjacent joints included. Antibiotic treatment is started in the ED, and antitetanus measures

are instituted according to local protocols.

The goals of treatment are to prevent infection, achieve adequate soft tissue coverage, allow bone healing, and promote early and full functional recovery. The basic principles of management consist of aggressive debridement, open wound treatment, soft tissue and bone stabilization, and systemic administration of antibiotics.^{4,5} These principles have reduced the formerly high mortality associated with open fractures to acceptable levels.

High-velocity gunshot wounds and open fractures must be approached differently from closed fractures because of the force imparted to the soft tissues. Open fractures call for emergency surgical treatment. Ideally, such treatment should begin within 6 hours of injury; the incidence of infection is directly related to the time elapsed before initiation of treatment. Typically, a second-generation cephalosporin is administered for 48 to 72 hours; prolonged administration is not necessary. For grade III open fractures, gentamicin should be added to cover gram-negative bacteria; for farmyard injuries, which are at risk for contamination with *Clostridium*, penicillin should be added.^{27,28}

The first stage of operative treatment consists of thorough irrigation of the wound with 6 L of normal saline; pulsed or jet lavage

Table 3 Indications for Angiographic Embolization in Patients with Pelvic Fracture

Hemodynamic instability; FAST negative for intra-abdominal bleeding source; inadequate response to fluid resuscitation
Contrast blush on contrast-enhanced pelvic CT scan
Large retroperitoneal hematoma on CT scan; expanding retroperitoneal hematoma on sequential CT scans
Persistent hemodynamic instability after operative placement of external fixator, laparotomy, or both
Hemodynamic stability with prolonged transfusion requirement (> 3 units of RBCs/24 hr) or other clinical signs of ongoing hemorrhage

FAST—focused assessment for sonographic evaluation of the trauma patient
RBCs—red blood cells

can be helpful for this purpose. Cultures are ordered at this time. To determine the true extent of the soft tissue damage, it is frequently necessary to enlarge the skin wound. Foreign contaminants, as well as dead bone and other devitalized tissues, predispose to infection and should therefore be removed. It is good practice to perform a routine second-look operation 48 to 72 hours after the initial debridement; debridement should be repeated until the soft tissues appear healthy and clean.

Although grade I open fractures may sometimes be treated in much the same way as similar closed fractures, grade II and grade III open fractures must be surgically stabilized during the second stage of the initial operation. Restoring of the normal anatomy through reduction and stabilization improves circulation; promotes healing of bone and soft tissue; reduces inflammation, bleeding, and dead space; and increases revascularization of devitalized tissue. It also results in earlier mobilization of multiply injured trauma patients and improves their overall status.

Internal fixation is preferred for most open fractures, with plates and screws mostly used for articular and metaphyseal fractures and intramedullary nailing for femoral and tibial shaft fractures. It is not always necessary, however, to achieve definitive fixation in the first operation. In the case of complex fractures for which additional imaging or a specialized operative team is required, a correctly placed external fixator is a safe and sensible option. External fixation as a temporary bridge to definitive fixation is also frequently used for severely contaminated grade III open fractures. Surgically created wound extensions may be closed; however, the traumatic wound itself should be left wide open. If the wound is small, a portion of the surgical extension should be left open to allow adequate drainage and to prevent the traumatic wound from sealing off prematurely. Every attempt should be made to cover bone, joint surfaces, implants, and sensitive structures (e.g., tendons, nerves, and blood vessels) with available local soft tissue, but such coverage must be achieved without tension. As an alternative to soft tissue coverage, a temporary method of wound coverage may be chosen (e.g., traditional wet dressings, synthetic membranes, allografts, or other skin substitutes).^{4,5,29,30}

Because leaving a wound open for prolonged periods increases the risk of infection, skin coverage and soft tissue reconstruction should ideally be achieved within 1 week after the injury. In the case of a grade I or II open fracture for which the initial culture is negative, the wound may be allowed to close by granulation and secondary intention, or the patient may be returned to the OR in 5 to 7 days for delayed primary closure. For larger wounds, split-thickness skin grafts are often required. For grade III open fractures, some type of flap is often required for soft tissue coverage [see 3:3 *Surface Reconstruction Procedures*]. Local fasciocutaneous flaps are suitable for smaller defects with intact surrounding skin. Muscle flaps have the advantage of adding vitality to exposed bone and can cover substantial defects; they are frequently covered with a split skin graft. Large wounds and those for which a local flap is not suitable require a free flap that is anastomosed to the local vessels. The flap procedure should preferably be done early, 5 to 10 days after the injury; some authors have even reported good results with definitive soft tissue reconstruction completed during the initial operation (so-called fix and flap).^{4,5,31}

A comparatively new method of wound coverage is negative-pressure wound therapy (NPWT) with a vacuum-assisted closure device (VAC Abdominal Dressing System; Kinetic Concepts, Inc., San Antonio, Texas).^{32,33} The perceived advantages of this approach include provision of a moist wound healing environment, reduction of the wound volume, minimization of bacterial colonization, removal of excess fluid, and (most important) pro-

motion of granulation tissue. Sponges are available in different sizes and can be further trimmed to fit the size of the wound, filling all dead space. An airtight seal is created with an adhesive drape covering the wound and the sponge. Dressings are changed every 2 to 4 days until the desired goals are reached. NPWT has proved to be a viable adjunct for treatment of various soft tissue injuries, including open tibial fractures and pelvic injuries). It is also a useful means of securing skin grafts and is reported to lead to improved graft survival. Although NPWT has yielded promising results in several case series, it should still be regarded primarily as a method of providing temporary coverage of soft tissue defects, not as a replacement for surgical debridement. Surgeons using NPWT should take care not to delay definitive closure, even if such closure involves a complex free muscle transfer.

Rehabilitation should be started soon after the operation. It is facilitated by following an aggressive treatment algorithm consisting of adequate fracture stabilization and early soft tissue coverage to prevent prolonged immobilization of joints and soft tissues. Infection is the most common complication after an open fracture and can be the result of inadequate surgical technique, incomplete debridement, or delayed soft tissue coverage. Open fractures are also associated with a higher incidence of delayed union and nonunion, which often necessitate placement of a cancellous bone graft or, in the case of a large defect, a free fibular graft.

MANGLED EXTREMITY

One of the more difficult decisions for a trauma surgeon is whether to amputate a severely injured or mangled extremity [see 7:17 *Injuries to the Peripheral Blood Vessels*]. The Mangled Extremity Severity Score (MESS) is frequently used as an aid in making this decision,^{4,5} with a score of 7 or higher generally considered an indication for amputation. The final decision whether to amputate or to attempt salvage, however, is based on the individual patient's overall condition, level of neurovascular function, and expected functional result.^{34,35}

The decision between amputation and salvage does not necessarily have to be made immediately; often, it can wait until the involved specialists have discussed the matter in the hours or days following the initial operation. If a mangled extremity does not pose an acute threat to the patient during the initial resuscitation, it may be best treated with irrigation and debridement (as with open fractures), some form of external stabilization, and temporary soft tissue coverage. Amputation in the acute phase should be performed at a safe level by means of a guillotine technique, combined with open wound management.

The functional prognosis after limb salvage is based on the presence or absence of nerve injury and the surgeons' judgment of whether adequate vascularization, soft tissue coverage and long-term bony stabilization are likely to be achievable. Often, multiple operations must be performed over several months, and even then, the outcome may be uncertain. In patients with limbs at high risk for amputation, the 2-year outcomes after reconstruction typically are about the same as those after amputation.³⁶ Accordingly, some patients may be better served by early amputation as definitive treatment.

COMPARTMENT SYNDROME

Compartment syndrome is defined as high-pressure swelling within a fascial compartment [see 7:17 *Injuries to the Peripheral Blood Vessels*]. Many physicians still believe, incorrectly, that compartment syndrome cannot develop in conjunction with an open fracture, because the break in the skin provides decompression. This is a dangerous assumption: compartment syndrome occurs in

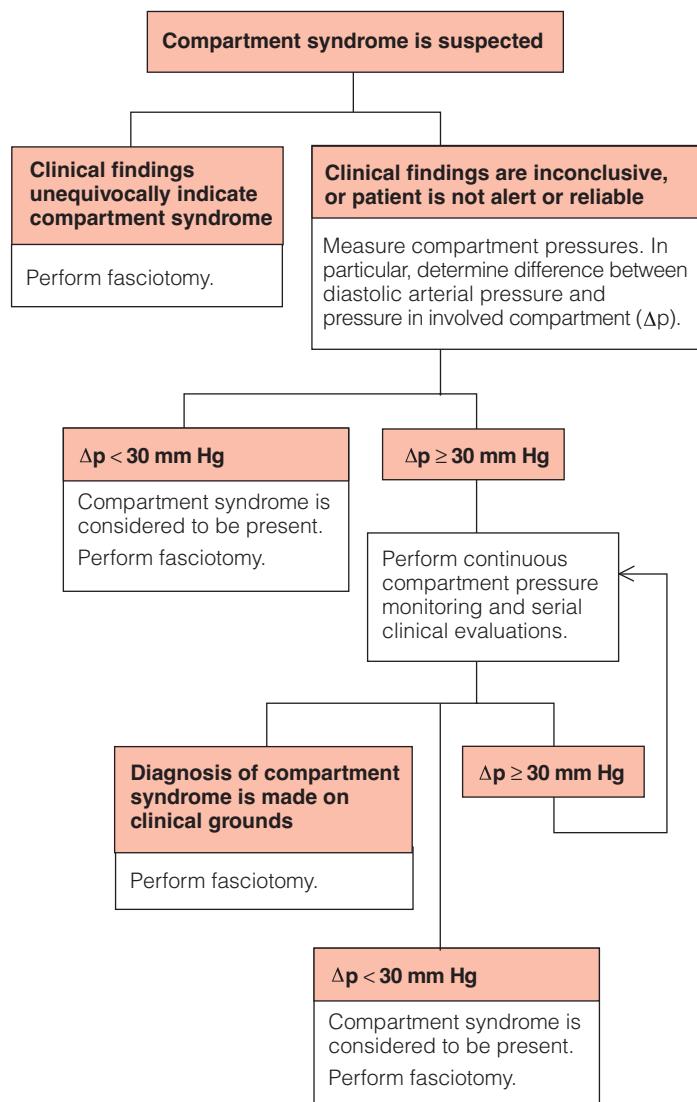

Figure 5 Algorithm outlines diagnosis of suspected compartment syndrome.

a significant number of patients with open fractures—for example, as many as 10% of patients with open tibial fractures. The most common cause of compartment syndrome is hemorrhage and edema in the damaged soft tissues seen with fractures. Other causes include a too-tight dressing or cast, disruption of the limb's venous drainage, advanced ischemia, and eschar from a circumferential burn. Multiply injured patients with hypovolemia and hypoxia are predisposed to compartment syndrome.^{4,5,10}

The key to diagnosis of compartment syndrome [see *Figure 5*] is to maintain a high level of suspicion in any situation involving an extremity injury where there is a significant chance that this syndrome might develop (e.g., tibial fractures, forearm fractures, and all comminuted fractures associated with severe soft tissue injury). The diagnosis is primarily a clinical one, with the five Ps—*pain, pallor, paresthesia, paralysis, and pulselessness*—constituting the classic signs. The surgeon should not wait until all these signs are present; the prognosis is much better if they are not. Severe ischemic muscle pain occurs that is unrelieved by the expected amounts of analgesia. On palpation, the compartment is tense and swollen, and passive stretching of the digits of the extremity

increases the pain. Paresthesia occurs early and should be actively watched for; paralysis develops when ischemia has caused permanent damage. Pulselessness occurs late and is a relatively rare sign; it has been shown that irreversible damage can occur in a patient who still has palpable pulses.^{4,5,10,37}

Measurement of compartment pressures is also employed in the diagnosis of compartment syndrome. Monitoring can be particularly helpful in patients who are not alert or are difficult to examine.³⁸ There is no agreement on what constitutes the critical pressure threshold for a definitive diagnosis. An absolute value of 30 to 35 mm Hg has frequently been adopted as a diagnostic indicator; however, the evidence suggests that the difference between the diastolic arterial pressure and the pressure in the involved compartment (delta pressure, or Δp) is more important than any particular absolute value. Currently, a diagnosis of compartment syndrome is usually made if Δp is less than 30 mm Hg, depending on the clinical signs and the level of suspicion.

If compartment syndrome is suspected, the first step is to remove all circumferential bandages to relieve any pressure. If a plaster cast is present, it should be split, spread, or removed; if necessary, maintenance of reduction should be sacrificed. If the clinical picture does not improve after these measures are taken, then a decompressive fasciotomy is indicated. Fasciotomy is described in greater detail elsewhere [*see 7:17 Injuries to the Peripheral Blood Vessels*].

PERIPHERAL VASCULAR INJURY

Vascular injuries can result from either blunt or penetrating trauma to the extremities, though the vascular injuries seen in urban trauma centers tend to be caused more often by penetrating trauma. Early diagnosis and prompt multidisciplinary treatment are crucial for successful management. The severity of the vascular injury and the length of the interval between injury and restoration of perfusion are the major determinants of outcome.^{37,39-42} Diagnosis and management of such injuries are outlined in greater detail elsewhere [*see 7:17 Injuries to the Peripheral Blood Vessels*].

There has been considerable discussion regarding the optimal order of repair in cases of combined musculoskeletal and vascular trauma—that is, whether fracture stabilization should precede vascular repair or follow it.⁴³ Fracture stabilization facilitates the exposure needed for vascular repair and reduces the risk of subsequent disruption of a fresh arterial repair, but it inevitably takes time to perform. Rapid application of an external fixator is a good alternative for extensive fracture repairs. Insertion of a temporary intraluminal shunt can be valuable and limb-saving when DCS is performed in a patient with severe vascular extremity injury or when a patient has a grossly unstable fracture that must be stabilized before arterial repair is possible.⁴⁴ Endovascular repair plays a limited, albeit growing, role in the treatment of arterial injuries associated with extremity trauma.⁴⁵

PERIPHERAL NERVE INJURY

Injury to a peripheral nerve can result in loss of motor function, sensory function, or both; it is the principal factor accounting for limb loss and permanent disability. Because the upper extremities have less muscle and bone mass and more neurologic structures than the lower extremities do, upper-extremity injuries are twice as likely to result in nerve damage as lower-extremity injuries are. Penetrating injuries from cuts or stab wounds that result in a clean laceration of a nerve are amenable to early intervention and repair; penetrating injuries from gunshot wounds are more difficult to assess and manage. Blunt

injuries result primarily from compression or stretching.^{4,5,46-48}

Nerve injuries are generally categorized according to the Seddon classification system, which divides them into three types: (1) neurapraxia, (2) axonotmesis, and (3) neurotmesis. Complete recovery from neurapraxia and axonotmesis can usually be achieved, but neurotmesis usually necessitates surgical intervention. How quickly and successfully nerves regenerate depends on several factors, including age, type of nerve (sensory or motor), level of injury, and duration of innervation.

Careful assessment of motor and sensory function is essential for diagnosis. Additional diagnostic information can be obtained by means of electromyography (EMG), MRI, and nerve conduction studies.

In the setting of blunt trauma, surgical treatment is recommended for closed injuries when the injured nerve shows no evidence of recovery either clinically or on electrodiagnostic studies done 3 months after the injury. It is also recommended for gunshot wounds without vascular or bony problems; such wounds have relatively good potential for neurologic recovery. For most open injuries (e.g., laceration with neurotmesis), surgical exploration at the earliest opportunity is recommended. If possible, the nerve is reapproximated primarily and the epineurium is sutured, or (sural) nerve grafts are employed.^{4,5,46}

Physical therapy should be started soon after nerve injury to maintain passive range of motion in the affected joints and preserve muscle strength in the unaffected muscles. Splinting of affected joints may be necessary to prevent contractures and minimize deformities.

CRUSH SYNDROME

Crush syndrome (also referred to as traumatic rhabdomyolysis) is a clinical syndrome consisting of rhabdomyolysis, myoglobinuria, and subsequent renal failure. It is caused by prolonged compression of muscle tissue (frequently in the thigh or the calf) and is usually seen in victims of motor vehicle accidents who required a long extrication procedure or in earthquake victims who are rescued from beneath rubble after being trapped for several hours or days. Once released from entrapment, crush syndrome patients are likely to exhibit agitation, severe pain, muscle malfunction, swelling, and other systemic symptoms.^{4,5,10,49,50}

The pathophysiologic process underlying this syndrome begins with muscle breakdown from direct pressure, impaired muscle perfusion leading to ischemia and necrosis, and the release of myoglobin. As long as the patient is entrapped, the ischemic muscle is isolated from the circulation, and this isolation affords some protection against the systemic effects of the released myoglobin and other toxic materials. Extrication and the resulting reperfusion of necrotic and ischemic muscle lead to the second insult, the reperfusion injury. This injury is caused by the formation of toxic reactive oxygen metabolites, which leads to failure of ion pumps and increasing permeability of cell membranes and microvasculature. When large amounts of muscle are involved, the resulting fluid changes can rapidly induce shock. The large quantities of potassium, lactic acid, and myoglobin that are released into the circulation can lead to renal failure, disseminated intravascular coagulation, and circulatory arrest.^{49,50}

Treatment should begin at the time of extrication so as to anticipate the onset of the syndrome. The first step is initiation of I.V. fluid therapy, starting with a 2 L crystalloid bolus and continuing with crystalloid infusion at a level of 500 ml/hr (the dosage must be adjusted in pediatric and cardiac patients). Cardiac monitoring is essential (T waves indicate hyperkalemia). Intravascular fluid expansion and osmotic diuresis, by maintaining high tubular vol-

ume and urine flow, may prevent renal failure. Forced diuresis can be achieved by giving mannitol or other diuretics. Alkalization of the urine with sodium bicarbonate (1 mEq/kg I.V. to a total of 100 mEq) is a controversial measure but is recommended by some on the grounds that it should, in theory, reduce intratubular precipitation of myoglobin. If compartment syndrome is suspected, compartment pressures should be measured [see Compartment Syndrome, above].^{49,50}

General Management of Fractures

FIXATION METHODS AND IMPLANT TYPES

Fracture fixation can be accomplished either nonoperatively (by means of external splinting) or surgically. Surgical fixation can be achieved with many different techniques, which yield varying degrees of stability. Screws, metal wires (e.g., Kirschner or cerclage wires), plates, nails, and external fixators have all been used for this purpose. Surgical fixation methods may be broadly divided into techniques of absolute stability and techniques of relative stability.⁴

Treatment of fractures with techniques of absolute stability was widely promoted by the ASIF. Anatomic reduction and achievement of absolute stability by means of interfragmentary compression plating were advised for treatment of articular, metaphyseal, and diaphyseal fractures. This method reduces strain at the fracture site and allows bone healing without visible callus formation (so-called direct bone healing). However, obtaining interfragmentary compression usually necessitates a fairly extensive surgical approach, which disturbs the local blood supply.

Unlike techniques of absolute stability, techniques of relative stability (e.g., intramedullary nailing, use of bridging plates across a comminuted fracture, and external fixation) allow small interfragmentary movements to occur when a load is applied across the fracture site. Such movements can stimulate callus formation and lead to union of the bone in four stages: (1) inflammation, (2) soft callus, (3) hard callus, and (4) remodeling. The various techniques of relative stability (also referred to as splinting or bridging techniques) yield varying degrees of stiffness.

Both biologic factors (fracture healing) and biomechanical factors (strength and stiffness) are important for recovery after a fracture. Over the past two decades, clinical experience and data from basic studies have led to a shift in focus away from the mechanical aspects of fracture treatment and toward the biological aspects. Today, a common practice is so-called biologic osteosynthesis, which means careful handling of the soft tissues to take advantage of the remaining biologic support, coupled with the use of techniques of relative stability to stimulate callus formation. Anatomic reduction is no longer considered a goal in itself, except in the case of intra-articular fractures.⁴

Conventional dynamic compression plates are applied tightly against the bone. Their application can compromise the blood supply and thereby induce partial necrosis of the underlying bone. The presence of avascular tissues may reduce the healing potential and lower the local resistance to infection. To overcome some of these disadvantages, plates with smaller contact areas were developed. This process has culminated in the introduction of locking compression plates (e.g., LCP; Synthes, West Chester, Pennsylvania), which can be regarded as noncontact plates. The LCP is a plate-and-screw system in which the screws are also locked in the plate by means of an extra thread in the head of the screw; thus, the plate is no longer tightly fixed to the bone and the periosteum. Locking compression plates (also referred to as locked internal fixators) are designed in such a way that both conventional dynamic compres-

sion techniques and bridging techniques can be used, depending on the fracture type. They may be applied via a less invasive approach using closed reduction techniques.^{4,5}

Intramedullary nails are placed within the medullary canal and therefore have the same biomechanical properties in both the frontal and the sagittal plane. They differ from plates in that the latter are attached eccentrically to the bone. Intramedullary nails may be inserted in either an unreamed or a reamed fashion; both techniques have advantages and disadvantages. With unreamed nailing, the nails are inserted without widening the medullary canal. This approach causes somewhat less operative trauma than reamed nailing, but it places some limitations on the diameter and strength of the nail and the locking bolts. If larger-diameter nails (> 9 mm) are needed, the medullary canal must be reamed to accommodate them. Reaming takes time, leads to increased intramedullary pressure, and produces debris that may be embolized in the pulmonary circulation. The clinical consequences of reamed intramedullary nailing have not yet been fully clarified. Current evidence suggests, however, that reamed nailing is associated with significantly lower rates of nonunion and implant failure than unreamed nailing is.^{4,5,51}

External fixators consist of metal pins (Schanz screws) that are placed in the bone proximal and distal to the fracture and connected outside the skin by one or more rods. Most external fixators are used only on one side of the limb, but in specific instances, multiplanar or circular devices may be used. The stability of the frame depends primarily on the stiffness of the rods, the distance between the rod or rods and the bone (the smaller the distance, the greater the rigidity), and the number, placement, and diameter of the fixator pins. As a general rule, two pins proximal and distal to the fracture are sufficient for fixation of long bone fractures. The main advantage of external fixators is that their use minimizes additional surgical trauma. The main disadvantages are the occurrence of pin-tract infections and the frequent lack of stability for definitive fracture treatment. Appropriate placement of fixator pins requires a detailed knowledge of the cross-sectional anatomy of the injured limb.^{4,5}

BASIC PRINCIPLES OF TREATMENT

Although most fractures heal readily with casting, long periods of immobilization with restriction of muscle activity, joint motion, and weight bearing are known to lead to so-called fracture disease, characterized by muscle atrophy, joint stiffness, disuse osteoporosis, and persistent edema. Accordingly, the goals of fracture treatment should include not only the achievement of bony union but also the early restoration of muscle function, joint mobility, and weight bearing.^{4,5}

Currently, there are seven main indications for operative treatment of fractures:

1. Preservation of life (e.g., decreasing morbidity and mortality through fixation of femoral shaft fractures);
2. Preservation of a limb (as with open fractures, fractures associated with vascular injury, and fractures complicated by compartment syndrome);
3. Articular incongruity;
4. Facilitation of early mobilization and rehabilitation;
5. Inability to maintain reduction with conservative treatment;
6. The presence of more than one fracture in the same limb (so-called floating joint); and
7. The presence of additional fractures in other limbs (e.g., bilateral humeral or tibial fractures).

Improved understanding of the biology of fracture repair and

the importance of the soft tissues has led to substantial changes in the treatment of diaphyseal fractures. It is now widely recognized that anatomic reduction of each fracture fragment is not always a prerequisite for restoration of normal limb function (see above). For most long bone fractures, radial and ulnar fractures excepted, the most important goal is restoration of the mechanical axis of the limb without significant shortening, angulation, or rotational deformity. Good functional results may be expected even if fracture fragments lying between the proximal and distal main fragments are not anatomically reduced.^{4,5}

In the upper extremity, both plates and intramedullary implants are frequently used for operative fixation of fractures. In the lower extremity, intramedullary nails are generally preferred because they allow early weight bearing, in contrast to plates and screws, which are more susceptible to failure. However, intramedullary nailing may not be suitable for shaft fractures that extend into the metaphysis or the adjacent joint. The treatment plan may also be influenced by the local condition of the soft tissues (e.g., the presence or absence of contusions or wounds), the quality of the bone (e.g., the presence or absence of osteoporosis), and the origin of the fracture (pathologic or nonpathologic).^{4,5}

For intra-articular fractures, alignment alone is insufficient. Anatomic reduction of the articular surface is required to restore joint congruity, and rigid fixation is necessary to allow early motion and thereby prevent the joint stiffness resulting from prolonged immobilization. Impacted osteochondral fragments are elevated, and the resulting metaphyseal defect underneath is filled with cancellous bone or a bone substitute. Fracture fragments may be reduced either via direct exposure or via more limited approaches, with the assistance of an image intensifier or arthroscope, or both. Regardless of which approach is followed, care must be taken not to devascularize bone fragments. Fixation may be achieved with metal wires, screws, and plates. The reconstructed articular surface is connected to the diaphysis with plates or, alternatively, external fixators.^{4,5}

Nonoperative treatment usually consists of application of plasters or (less frequently) traction and may be employed as either temporary or definitive therapy. It reduces the risk of infection and eliminates operative risk, but it also frequently results in a longer time to union, a higher risk of malunion, and a greater likelihood of stiffness of the involved joints. Accordingly, nonoperative management is mostly reserved for extra-articular and minimally displaced fractures.^{4,5}

Autologous bone grafting remains the gold standard for improving and accelerating fracture healing. In recent years, however, various other methods have been developed and evaluated for this purpose. There is some evidence from randomized trials indicating that low-intensity pulsed ultrasonography may shorten the healing time for fractures treated nonoperatively.^{52,53} Ultrasound treatment does not, however, appear to confer any additional benefit after intramedullary nailing with prior reaming. The discovery of specific bone growth factors (bone morphogenetic proteins [BMPs]) was an important step forward in the understanding of bone physiology and raised the possibility that these factors could be locally applied to enhance fracture healing. However, clinical trials have not yet determined the most appropriate indications for the use of BMPs in managing specific fractures or nonunions.⁵⁴

The indications for implant removal are not well established. There are few definitive data to guide the decision as to whether an implant should be removed or left in place. In general, implants in most adult patients may be left in place; the same is true of implants in the upper extremity. When implants are removed for relief of pain and mitigation of presumed functional impairment

alone, the results are unpredictable and depend on both the implant type and its anatomic location. Implant removal is often technically challenging and may lead to complications such as infection, neurovascular injury, or refracture. Current data do not support routine removal of implants to protect against allergy, carcinogenesis, or metal detection. The decision for or against implant removal is therefore based on individual patient and surgeon preferences, as well as on the clinical circumstances.^{55,56}

Management of Upper-Extremity Injuries

SHOULDER

Fractures of the clavicle are common and are usually caused by falling on the shoulder. Approximately 80% of clavicular fractures occur in the middle third of the bone, 15% in the lateral third, and 5% in the medial third. Dislocation results from traction of the pectoral and sternocleidomastoid muscles. Neurovascular injury is uncommon, but the patient should always be evaluated for such injury nonetheless. Treatment is primarily conservative, employing a collar and cuff or a sling; union rates approach 95%. Operative fixation is indicated only when there is impending perforation of the overlying skin, an associated injury to the subclavian artery and brachial plexus, an ipsilateral scapular neck fracture (so-called floating shoulder), a dislocation greater than 2 cm (a relative rather than absolute indication), or painful nonunion. Fixation methods include plate osteosynthesis and intramedullary osteosynthesis.⁵⁷

Scapular fractures result from high-energy trauma and are frequently accompanied by life-threatening injuries to the head, the chest, or the abdomen. CT scanning is usually required to determine the fracture pattern. Most scapular fractures can be treated conservatively. Severely ($> 40^\circ$) dislocated scapular neck fractures and dislocated intra-articular glenoid fractures are treated with open reduction and internal screw or plate fixation.

HUMERUS

Proximal

Fractures of the proximal humerus are common, especially in elderly women. Correct positioning of the four main bony structures of the proximal humerus (the head, the greater tuberosity, the lesser tuberosity, and the shaft) and their muscle attachments is important for a good shoulder function. Consequently, fractures of this segment of the humerus may have significant functional consequences. Damage to the blood supply of the head may lead to avascular necrosis of this part of the bone. Conservative treatment with a sling is preferred for elderly patients with minimally displaced fractures, and early range-of-motion exercises are encouraged. Operative treatment is indicated for patients with dislocated two-, three-, or four-part fractures and fracture-dislocations. The optimal fixation method has not been established, but plate osteosynthesis is frequently employed; alternatives include intramedullary techniques and prosthetic replacement.^{58,59} Rehabilitation usually takes several months, and continuing impairment of shoulder function is a common complaint.

Shoulder (glenohumeral joint) dislocations mostly occur in young persons participating in sports. The size difference between the large articular surface of the humeral head and the small surface of the glenoid renders the shoulder particularly vulnerable to dislocation. The majority (95%) of patients have anterior dislocations, resulting from abduction and exorotation. The relatively few posterior dislocations that occur tend to be difficult to diagnose and are frequently missed initially. A particularly rare and severe

type of shoulder dislocation is luxatio erecta, characterized by inferior dislocation of the abducted arm. Injuries associated with shoulder dislocation include injury to the axillary nerve, injury to the labrum (Bankart lesion), and a depression in the humeral head (Hill-Sachs lesion); the last two predispose to recurrence. Radiographs should be obtained in AP, axillary, and Y-scapular views to determine the position of the humeral head and detect any fractures. Treatment consists of gentle and closed reduction. This can usually be done in the ED; if necessary, it can be done in the OR with the patient under general anesthesia. Reduction is followed by immobilization in a sling.⁵

Dislocations of the sternoclavicular joint are rare, but they are potentially life-threatening when they occur posteriorly (anterior dislocations are far less dangerous). Diagnosis of these injuries is difficult with conventional x-rays; accordingly, CT is recommended when sternoclavicular joint dislocation is suspected. Compression of the mediastinal vessels and trachea can sometimes lead to respiratory and circulatory failure. In such cases, urgent operative reduction, performed with an eye to potential vascular emergencies, is warranted.^{5,10}

Dislocations of the acromioclavicular joint result from falling on the shoulder and are frequently classified according to the system formulated by Tossy. Tossy 1 dislocations (sprains) and Tossy 2 dislocations (subluxations) are treated conservatively with a collar and a cuff. For Tossy 3 dislocations (complete separations), operative treatment may be considered, though the optimal technique remains to be determined and the results of operative fixation are still uncertain.⁵

Shaft

Fractures of the humeral shaft typically result from direct trauma. Depending on the level of the fracture, dislocation mainly results from traction placed on the deltoid or pectoral muscles. Fractures of the middle and distal thirds of the humeral shaft can result in injury to the radial nerve, which is the most severe functional complication. Most closed AO-ASIF type A1 and A2 fractures can initially be treated conservatively with functional bracing techniques (rather than hanging casts); this approach yields good or excellent results in the majority of cases. Moderate angulation, rotation, and shortening are well tolerated. Generally accepted indications for operative treatment include open fractures, AO-ASIF type B and C fractures, associated vascular injury, multiple trauma, bilateral fractures, combined humeral shaft and forearm fractures (so-called floating elbow), pathologic fractures, secondary radial nerve palsy, and nonunion.⁶⁰ The standard technique is open reduction and plate fixation; the main alternative is locked intramedullary nailing, either antegrade (entering in the proximal humerus) or retrograde (entering in the distal humerus).^{61,62} External fixation is employed in the presence of severe soft tissue injuries and in polytrauma patients as part of DCS.

Distal

Fractures of the distal humerus result from falling on the elbow with the forearm flexed. In elderly persons, many of whom are osteoporotic, a fall from a standing position is often sufficient to cause such a fracture, whereas in young patients, high-energy trauma is required. Extra-articular injuries usually have a good prognosis. Intra-articular fractures are more difficult to manage: limitation of flexion and extension and pain often occur, even after optimal treatment. In addition to AP and lateral x-rays, it may be advisable to obtain CT scans to help clarify the fracture pattern. For minimally displaced AO-ASIF type A fractures, conservative treat-

ment is appropriate, but for all other fractures, open reduction and plate osteosynthesis are required, frequently in conjunction with an olecranon osteotomy to provide adequate exposure. In comminuted fractures, the articular surface can be difficult to reduce. In osteoporotic bone, finding good bone stock can be a serious problem.^{4,5,63,64}

ELBOW

Olecranon fractures are the most common fractures in the area of the elbow and usually are caused by falling directly on the elbow. They frequently lead to impaired extension as a consequence of the discontinuity between the triceps and the proximal ulna. All dislocated olecranon fractures are treated operatively, with Kirschner wires and a tension band employed for simple fractures and plate osteosynthesis for comminuted fractures. Both methods allow early functional therapy postoperatively.

Fractures of the radial head are caused by falling on the outstretched arm and may occur either in isolation or in combination with an elbow dislocation, an ulnar shaft fracture (Monteggia fracture), a coronoid process fracture, or a medial collateral ligament rupture. In addition, the interosseous membrane between the ulna and the radius may be disrupted over its entire length, thereby disturbing the distal radioulnar joint at the wrist (Essex-Lopresti injury). Fractures with dislocations smaller than 2 mm can be treated conservatively with early range-of-motion exercises; external support is usually unnecessary. Dislocated fractures and fractures causing mechanical blockage (e.g., of pronation or supination) are mostly treated operatively, with plate or screw fixation. When the fracture is comminuted, adequate reduction and fixation may be impossible. If the elbow is otherwise stable, radial head excision may be performed; if not, a radial head prosthesis may be inserted to stabilize the joint. Active and passive range-of-motion exercises should be started soon after the operation.

Elbow dislocations are typically caused by falling on the outstretched hand. Posterior dislocations, characterized by dorsal displacement of the radius and the ulna, are more common than anterior dislocations. Associated injuries may include coronoid process fractures and collateral ligament injuries, as well as neurovascular injuries. Most elbow dislocations can be treated with closed reduction by applying traction with the forearm flexed 30°. After reduction, the stability of the elbow should be carefully evaluated. Plaster immobilization should not be continued beyond 3 weeks. Operative reduction is necessary only when the dislocation is associated with an open fracture, when interposing fragments preclude adequate closed reduction, or when neurovascular injury is present.^{4,5}

FOREARM

The bones in the forearm have a complex relation with each other and with the elbow and the wrist, and this complex relation allows numerous different combinations of flexion, extension, pronation, and supination. The mechanism of a forearm injury is a frequently a vehicular accident or a fall; isolated fractures of the radius or the ulna are rare and usually result from a direct blow. The goal of treatment is to achieve anatomic restoration of length, axial alignment, and rotation with stable fixation in a manner that permits free movement (especially pronation and supination) of the elbow and the wrist postoperatively [see *Figure 6*]. Only nondisplaced fractures may be treated nonoperatively; all other forearm fractures must be treated operatively. The standard technique is open reduction with plate fixation; intramedullary fixation is an alternative. The radial nerve is at risk during plate fixation of the proximal radius.⁶⁵⁻⁶⁷

Approximately 10% of ulnar fractures are accompanied by a

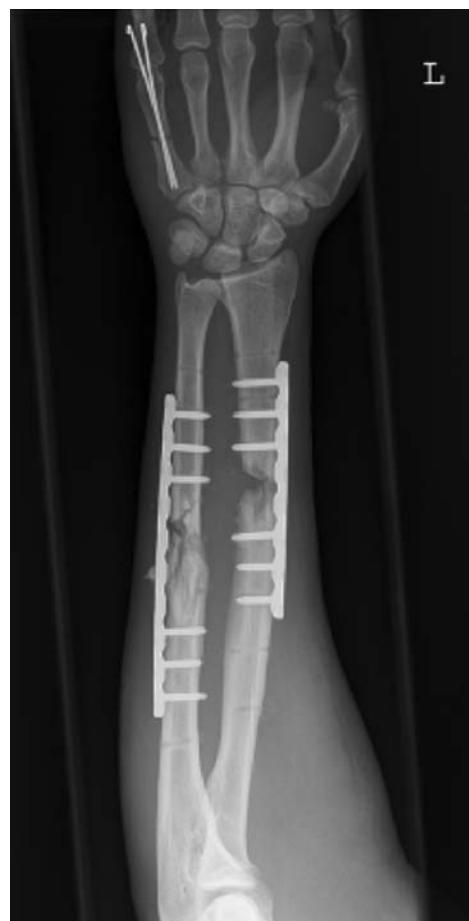

Figure 6 Shown is grade II open forearm fracture with segmental bone loss in the radius, initially stabilized with debridement and external fixation. Injury is treated with secondary plate osteosynthesis and Kirschner wire fixation of metacarpal fracture.

radial head dislocation (Monteggia fracture). Appropriate x-rays must be obtained to ensure that this injury is not missed. The radial head is reduced by closed or open methods during plate fixation of the ulna. Radial shaft fractures are sometimes associated with a dislocation of the ulna in the distal radioulnar joint (Galeazzi fracture). If the distal radioulnar joint remains unstable after plate fixation of the radius, temporary transfixation is necessary.^{4,5}

WRIST

Distal radial fractures are among the most commonly encountered fractures. Like elbow dislocations, they are usually caused by falling on the outstretched hand. The incidence rises sharply with increasing age, especially in osteoporotic women. Associated injuries include ulnar styloid process fractures and ligamentous carpal injuries. Dislocations are classified as dorsal (Colles type) or volar (Smith type); the former are more common. Partial articular fractures (AO-ASIF type B) are also referred to as dorsal or volar Barton fractures. Diagnostic imaging plays an important role in assessment; the critical radiographic parameters are radial angle, radial length, and dorsal angulation. Radiologic signs of instability include initial dorsal angulation greater than 20°, greater than 5 mm reduction in radial length, intra-articular involvement, and metaphyseal comminution. An articular stepoff greater than 2 mm is associated with a poor prognosis.

Minimally displaced AO-ASIF type A distal radial fractures and stable impacted fractures may be treated conservatively in plaster for 4 to 6 weeks. If necessary, this can be done after closed reduction, though loss of reduction may occur after an initial satisfactory position has been achieved. For all other fractures, operative treatment is advised, depending on fracture type and patient status [see Figure 7]. AO-ASIF type B fractures are best treated with open reduction and screw or plate fixation; however, optimal treatment of AO-ASIF type C fractures remains to be determined. External fixation combined with Kirschner wires and plate osteosynthesis is frequently employed. In some cases, it may be necessary to fill a subchondral or metaphyseal defect with a cancellous bone graft or a bone substitute. Reflex sympathetic dystrophy develops in some patients [see Special Considerations, Complications, Reflex Sympathetic Dystrophy, below]. Treatment of this syndrome can be difficult, and complete functional loss is occasionally the final result.^{4,5,68}

Fracture of the scaphoid typically is caused by falling on the outstretched or dorsally flexed hand. It tends to be difficult to diagnose and is easily missed. Signs such as pain, functional impairment, and tenderness at the anatomic snuff box are often absent initially, and standard AP and lateral x-rays of the wrist may be insufficient to identify the injury. If special scaphoid views do not confirm the presence of a fracture, the wrist is immobilized and x-rays are repeated after 7 to 10 days. Alternatively, CT, MRI, or bone scintigraphy may be performed to confirm the diagnosis.³ Undisplaced fractures may be treated conservatively in plaster. Immobilization should be continued for 6 to 12 weeks to minimize the risk that disturbance of the delicate blood supply of the scaphoid might result in avascular necrosis or pseudarthrosis. Dislocated fractures (with dislocation greater than 2 mm or angulation greater than 25°) are treated with screw osteosynthesis.^{4,5,69}

Perilunate dislocations result from high-energy trauma and include a spectrum of severe ligamentous wrist injuries, fractures, and dislocations characterized by dorsal dislocation of the distal carpal row, the scaphoid, and the triquetrum with respect to the lunate. Perilunate dislocations may be missed initially in multiply injured patients if the physical examination is incomplete or the x-rays of the wrist are inadequate or not carefully examined. Treatment consists of closed or open reduction; additional fixation may be performed as needed, depending on the degree of stability achieved after reduction. Associated fractures of the radius or the scaphoid are treated operatively.⁵

HAND

Fractures of the hand can result from direct blows, twisting injuries, crush injuries, and gunshot wounds. Neurovascular status, wounds (e.g., bites), and tendon function should all be carefully evaluated. Most fractures can be detected on posteroanterior, lateral, and oblique views.

Metacarpal neck fractures, most frequently of the fourth or fifth metacarpal (so-called boxer's fracture), can usually be treated conservatively with 3 to 4 weeks of immobilization and early range-of-motion exercises.⁷⁰ Fracture healing may result in cosmetic deformity but good function. Severely dislocated fractures are typically treated with Kirschner wires or plate fixation. Most fractures of the metacarpal shafts can be treated nonoperatively with immobilization in a cast or splint for 4 weeks. If the wrist is immobilized in plaster, it should be positioned in 20° of extension, with the metacarpophalangeal joints in 70° to 90° of flexion and the interphalangeal joints in complete extension to prevent shortening of ligaments. Rotation (as indicated by nail position) should be checked frequently. Indications for operative treatment include angulation greater than 10° to 30°, shortening, malrotation (more

Figure 7 Illustrated is treatment of distal radial fracture with (a) volar plate osteosynthesis and (b) external fixation.

frequent in the second and fifth metacarpals), and multiple fractures. Bennet's fracture (an intra-articular fracture of the base of the first metacarpal with a small ulnar fragment that remains attached to the second metacarpal) should be treated with reduction or, if unstable, fixation with percutaneously placed Kirschner wires or screws. Other metacarpal base fractures are less frequent but may also be associated with carpometacarpal dislocations. Treatment focuses on reduction of the joint and restoration of alignment and the articular surface, if necessary by means of open reduction.^{5,71,72}

Phalangeal fractures are common. In the distal phalanx, fractures often result from crush injury and may be associated with subungual hematoma (which should be drained) and soft tissue injury. The vitality of the fingertip may be compromised. Nondisplaced fractures may be treated with immobilization in plaster or a splint for 3 weeks, followed by active range-of-motion exercises. Dislocated fractures may be treated with closed or open reduction and fixation with Kirschner wires or small screws or plates.^{71,72}

Dislocations of the interphalangeal joints usually are easily recognized by the obvious deformity they cause, but x-rays must still be obtained to exclude fractures. Dorsal dislocations are associated with injuries to the volar plate or collateral ligaments, which tend to increase instability. Treatment consists of closed or open reduction, followed by testing through the range of motion to check stability and x-rays to ensure adequate reduction. If reduction is unstable, transarticular Kirschner wire fixation may be necessary.⁵

So-called gamekeeper's thumb is an injury to the ulnar collateral ligament of thumb metacarpophalangeal joint that causes instability at that joint; the ulnar collateral ligament frequently becomes dislodged between the adductor pollicis aponeurosis and its normal position (Stener lesion). Partially unstable lesions (< 20° to 30° opening at stress examination in comparison with the uninjured side) may be treated in a plaster splint for 3 to 4 weeks. Completely unstable lesions are treated with surgical repair to prevent chronic instability.⁵

TENDONS

Injuries to the rotator cuff reduce the shoulder's strength and impair its function. Most ruptures occur in cuff muscles or tendons that are already affected by degenerative changes. Operative treatment is advised for young patients and for patients who have experienced substantial ruptures as a result of recent trauma.

Rupture of the distal biceps tendon occurs mainly in middle-aged men. The tendon is torn off the radial tuberosity during flexion against resistance. The muscle belly is visibly retracted proximally, and flexion and supination are reduced by 30% to 40%. In cases where the diagnosis is not clear, MRI or ultrasonography may be helpful. Treatment consists of reattaching the tendon to the radius with suture anchors or drill holes.

In the case of tendon injuries around the wrist and the hand, appropriate clinical testing and diagnosis depend on a solid knowledge of the exact anatomy and function of the various tendons. The extensor tendons are located just under the skin, directly on the bone, on the back of the hands and the fingers; their superficial location makes them easily injured even by a minor cut. The flexor tendons pass through fibrous rings called pulleys, which guide the tendons and keep them close to the bones; because of the more complex anatomy, flexor tendon injuries are usually more challenging than extensor tendon injuries. Partial injuries with intact function may be treated conservatively, but most injuries, especially sharp lacerations, are treated with surgical repair followed by

protected motion. Postoperative treatment and rehabilitation of tendon injuries are very important and require the services of a special hand therapist.

A commonly encountered extensor tendon injury is so-called mallet finger, which results from forcible flexion of the extended distal interphalangeal joint. The extensor tendon is torn off the distal phalanx, with or without an intra-articular fragment of its base. Clinically, the distal interphalangeal joint is in flexion, and active extension of the distal phalanx is impossible. Most lesions can be treated with a special splint that keeps the distal interphalangeal joint in extension for 4 to 6 weeks.⁵

Management of Pelvic and Acetabular Injuries

PELVIC RING

Pelvic fractures occur in about 3% of trauma patients. These injuries can have a devastating influence on the outcome of trauma care and therefore must be identified as early as possible. Internal retroperitoneal bleeding is the main concern in the early management of these patients because over 40% of the mortality from pelvic trauma is attributable to persistent bleeding. Accordingly, the initial physical examination and the AP pelvic x-ray (which is diagnostic in 90% of cases) during the primary survey are essential for placing the focus on the potential risk of internal bleeding. Additional inlet and outlet views (taken at a 45° angle from cephalad and caudal) may be useful for accurate classification and determination of dislocation.^{4,5} CT scanning is performed in nearly all cases but not necessarily as an emergency evaluation. The CT scan facilitates fracture classification and provides additional information on active bleeding and associated injuries. Administration of I.V. contrast material during CT scanning helps in detecting active arterial bleeding, which suggests the need for early angiographic embolization. Angiographic embolization may be lifesaving in patients with pelvic arterial bleeding.

Pelvic injuries are frequently associated with other serious injuries. Fractures of the anterior pelvic ring, especially when seen in combination with blood from the urethral meatus, are an indication for retrograde urethrography before placement of a transurethral catheter to detect or exclude urethral and bladder injuries. Vaginal and rectal examinations are components of the standard workup for detecting or excluding fracture perforations and abnormalities of prostate position (indicative of urethral injury).

Posterior pelvic ring injuries may be accompanied by sacral plexus nerve injuries. Perineal and groin wounds often are in continuity with fracture components and pose a serious threat of further complications. With open pelvic injuries, early surgical debridement and fecal deviaiton must be considered.

The AO-Tile classification of pelvic ring and acetabular fractures is based on the degree of pelvic stability or instability. The pelvis is divided into an anterior section (comprising the symphysis pubis and the pubic rami) and a posterior section (comprising the ilium, the sacroiliac joint complex, and the sacrum).⁴ Determination of whether and to what extent the posterior section is displaced is crucial for estimating the stability of the injury. Depending on the degree of posterior bony or ligamentous instability, pelvic ring injuries may be classified into three types as follows:

1. Type A: injuries where the mechanical stability of the pelvic ring is intact—the most common type, seen in 50% to 70% of pelvic fracture patients.
2. Type B: injuries characterized by partial posterior stability (i.e., injuries that are rotationally unstable but vertically stable)—seen in 20% to 30% of pelvic fracture patients.

3. Type C: injuries characterized by combined anterior and posterior instability (i.e., injuries that are both rotationally and vertically unstable)—seen in 10% to 20% of pelvic fracture patients.

Another system used to categorize pelvic fractures is the Young-Burgess classification, which is based on the force vectors causing the fracture. In this system, pelvic ring fractures are divided into the following four major groups: (1) lateral compression, (2) anteroposterior compression, (3) vertical shear, and (4) combined mechanical injury. The stability or instability of the fracture can be determined on the basis of knowledge of the ligamentous anatomy of the pelvis coupled with assessment of the fracture pattern and the direction of the injuring force.^{4,5}

Provisional stabilization is advised after manual reduction of pelvic ring disruption, especially in open-book fractures with significant dislocation. External fixation is one means of achieving provisional stabilization; however, it is more time consuming than applying a sheet wrap or a similar device for temporary stabilization. For this reason, many institutions prefer the latter approach during initial management in the ED. The Pelvic C-Clamp (Synthes, West Chester, Pennsylvania) is also employed for external stabilization, primarily in hemodynamically unstable patients with unstable (i.e., type B or C) pelvic ring injuries. This device acts by exerting direct compression on the posterior part of the pelvic ring, thereby reducing the intrapelvic volume, compressing fracture parts, and providing stability. Application of this device should also be considered if operative retroperitoneal pelvic packing is necessary.

Definitive treatment of pelvic injuries depends on the type of injury, the classification (stability), the local soft tissue situation, and the general condition of the patient [see Figure 8]. Type A fractures are stable and usually need not be treated operatively. Functional treatment, with early ambulation and weight bearing as tolerated, usually suffices.

Type B1 (open-book) injuries with minimal dislocation of the

symphysis may be treated conservatively. If symphyseal dislocation is less than 2.5 cm, anterior plate fixation of the symphysis is usually sufficient. If the patient cannot undergo formal internal fixation, an external fixator (which may have been applied initially for bleeding control) is a reasonable alternative for definitive treatment. However, the discomfort and the complications (e.g., infection) caused by external fixator pins motivate many surgeons to convert to internal plate fixation after the initial stabilization phase. In the setting of an emergency laparotomy, early anterior plate fixation may be considered during the same laparotomy, provided that patient is or has been rendered physiologically stable. Type B2 (lateral compression) injuries with minimal anterior dislocation often have good intrinsic stability and can frequently be treated conservatively.

For type C injuries, both anterior and posterior stabilization is required. Of the many techniques currently in use, plate fixation of the anterior pelvic ring combined with either percutaneous sacroiliac screws or plate fixation of the posterior pelvis provides the best mechanical stability. The main goals are to restore the anatomy and prevent any leg-length discrepancy while encouraging allowing early mobilization of the patient to prevent the complications of prolonged bed rest.^{4,5,73-75}

Percutaneous placement of iliosacral screws under fluoroscopic guidance is already the preferred technique for stabilization of the majority of unstable sacroiliac injuries. The continuing development and growing availability of modern surgical tools (e.g., computer-assisted intraoperative navigation) are providing ever more opportunities for minimally invasive approaches to pelvic fracture fixation. Nevertheless, stabilization of the pelvis through open surgical reduction and internal fixation using standard plate and screw techniques are still proper alternatives and are the treatment of choice for many pelvic ring fractures.

ACETABULUM

Traumatic acetabular fractures may occur either in isolation or as part of a pelvic ring injury [see Figure 8a]. On occasion, they occur in combination with hip dislocation; in such cases, urgent

Figure 8 Shown are (a) plate osteosynthesis for combined pelvic ring injury and left-side acetabular fracture in a multiply injured patient and (b) treatment of type C unstable pelvic ring injury with initial angiembolization (coils visible) and external fixation, followed by secondary percutaneous placement of sacroiliac and pubic screws.

reduction of the dislocated hip is essential for restoring blood flow to the femoral head. For adequate fracture classification, x-rays must be obtained in Judet views (oblique views taken with the beam stationary and with the patient rolled 45° to both sides along the vertical axis). CT scanning with axial and three-dimensional reconstructions can greatly clarify the extent of the injury and help identify the number and size of fracture fragments. An accurate neurologic examination that includes assessment of the integrity of the sciatic nerve should also be part of the initial workup.

Until the 1960s, the vast majority of patients with acetabular fractures were treated conservatively. Thanks to the impressive efforts of Letournel and Judet (who also introduced the most frequently used classification system), operative treatment has become standard for dislocated acetabular fractures.^{76,77} The most important goal of operative treatment is to restore the articular surface so that a congruent hip joint can be obtained. Achievement of this goal nearly always requires open reduction and internal fixation with plates or screws through anterior or posterior approaches. Extensive experience on the part of the operating team is necessary to ensure optimal long-term results. After the operation, the patient should be able to take part in non-weight-bearing exercises.

The majority of acetabular fractures can be treated in a delayed fashion between 3 and 14 days after the injury. Acute operative fracture treatment may be indicated if a dislocated hip cannot be reduced, if redislocation of the hip cannot be prevented, or if interposition of intra-articular fracture fragments occurs. In many instances, however, initial skeletal traction (if indicated after hip reduction) will be applied.

Adequate prophylaxis of deep vein thrombosis (DVT) is essential for both patients with pelvic fractures and those with acetabular fractures. Functional outcome after acetabular fracture surgery is determined by many factors, the most important of which are anatomic fracture reduction, the development of osteoarthritis, avascular necrosis, and heterotopic ossification.^{4,5,77-79}

Management of Lower-Extremity Injuries

FEMUR

Proximal (Hip Fracture)

Fracture of the proximal femur (hip fracture) is one of the most common conditions seen by orthopedic and trauma surgeons. It is particularly common in the elderly. Substantial force is required to fracture a hip in a young person, whereas a minor trauma or fall may be sufficient to do so in an elderly osteoporotic woman. Almost 90% of patients with proximal femoral fractures are older than 65 years. Between 5% and 10% of these elderly patients die during hospital admission; 25% die within the first year after the accident.

Hip fractures are typically classified into four broad categories according to their anatomic site: (1) femoral head fractures, (2) intracapsular (femoral neck) fractures, (3) intertrochanteric fractures, and (4) subtrochanteric fractures. Within these broad categories, they may be further divided into subcategories according to various classification systems (see below). Such classifications can be helpful in guiding decision making with respect to treatment, which necessarily differs from one type of hip fracture to another.^{4,5} In general, the choice of treatment is influenced by a range of patient-related factors that includes age, the presence and severity of comorbid medical conditions, previous mobility, cognitive status, fracture classification, and the status (i.e., preserved or disrupted) of the all-important blood supply to the femoral head. Failure of treatment frequently results from inappropriate choice of a

fixation method or misinterpretation of the fracture configuration.

Fractures of the femoral head are the most devastating of hip injuries and must be handled as surgical emergencies. They are generally classified according to Pipkin's system. Because substantial force is required to produce femoral head fractures, they are often seen in association with hip joint dislocations and acetabular fractures, most commonly in multiply injured patients who were involved in motor vehicle accidents. The diagnosis is made on the basis of pelvic and acetabular x-rays, supplemented by CT scans. Concomitant hip dislocations (most often posterior) should ideally be reduced with the patient under general anesthesia and with muscle relaxation achieved by upward traction with the hip in 90° of flexion.⁸⁰ If possible, this should be done in the ED to minimize delay in restoring blood flow to the femoral head. After reduction, the stability of the joint is tested clinically, and CT scanning is performed to assess impaction fractures, loose fragments in the hip joint, and the integrity of the acetabulum.

Most femoral head fractures are treated operatively if the patient's condition permits. For optimal results, this should be done within 24 to 48 hours after the injury, if possible. Closed treatment of dislocated fractures yields uniformly poor results. Internal fixation of these injuries is technically demanding and should allow early passive and active motion exercises postoperatively. Indomethacin is administered to prevent heterotopic ossification around the hip. Weight bearing is allowed after 10 to 12 weeks. In some patients, particularly physiologically older patients with major fractures, it may be best to insert a hip prosthesis primarily. Although operative treatment is usually necessary to provide the best chance of recovery, the magnitude of the initial trauma is generally such that good results can be obtained in only 50% to 70% of cases.^{4,5,81}

A typical patient with an intracapsular (femoral neck) fracture presents with a shortened, externally rotated, and abducted lower extremity. These fractures are often classified according to Garden's system. Treatment is determined by the fracture type and associated patient factors. Especially in young patients, because of the risk of nonunion and avascular necrosis, dislocated femoral neck fractures should preferably be treated on an emergency basis within 12 hours after the injury.⁸² In otherwise healthy and ambulatory patients, incomplete and impacted fractures (intact trabeculae of the inferior neck; Garden 1) may be managed with conservative treatment, consisting of early mobilization with crutches or a walker (to the extent permitted by the pain experienced) and supervised by a physical therapist. Secondary dislocation occurs in 10% to 50% of cases, leading to secondary operative treatment. Complete but undislocated fractures (Garden 2) are mostly treated operatively with cannulated screws or a sliding hip screw (e.g., Dynamic Hip Screw [DHS]; Synthes, West Chester, Pennsylvania). Sliding hip screws allow controlled compression of the fracture to be obtained during weight bearing as the lag screw slides into the plate. Complete fractures with partial (Garden 3) or complete displacement (Garden 4) are treated by means of early anatomic reduction with fixation to eliminate the risk of displacement and permit rapid mobilization. When the patient is physiologically older than 70 years, placement of a primary hip prosthesis is often indicated instead of internal fixation; however, this procedure is associated with higher perioperative morbidity and mortality.^{4,5,81,83}

Trochanteric fractures are the most common fractures of the proximal femur. They do not threaten the blood supply to the femoral head, because they occur below the extracapsular ring of vessels. Trochanteric fractures are classified according to the AO-ASIF system. Almost all patients with such fractures are candidates for internal fixation. The main exceptions are elderly patients who

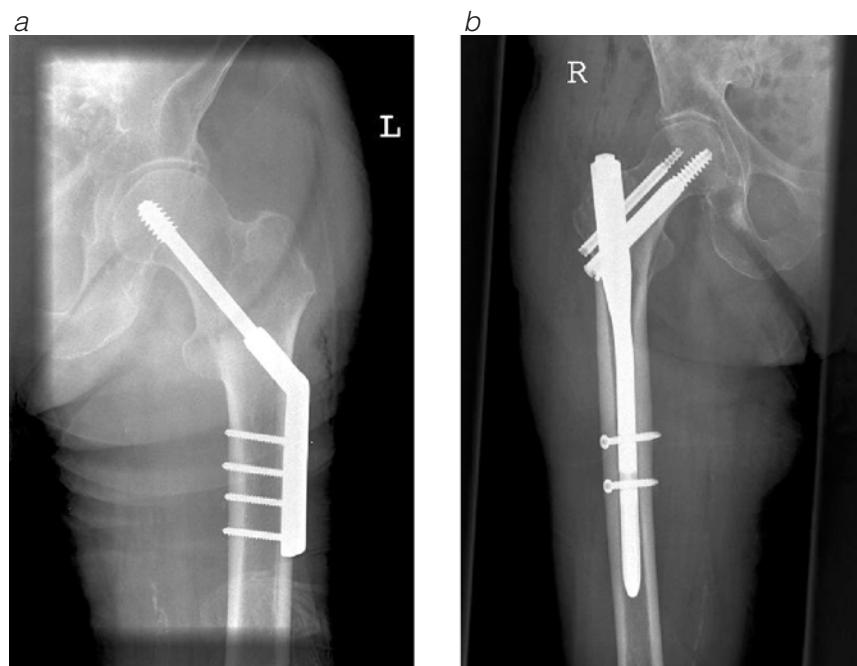

Figure 9 Shown are (a) fixation of AO-ASIF type A1 fracture with the Dynamic Hip Screw and (b) fixation of AO-ASIF type A2 fracture with the Proximal Femoral Nail.

had significant arthritis of the hip before sustaining the fracture; for these patients, placement of a hip prosthesis is an alternative.

The lesser trochanter provides crucial support for the medial femoral cortex; thus, assessment of its integrity is important for determining the stability of the fracture, which, in turn, helps determine treatment. The main treatment options are extramedullary and intramedullary implants. Extramedullary implants include sliding hip screws (see above), which are relatively easy to insert and also allow open reduction of the fracture if necessary. These implants are most suitable for stable (AO-ASIF type A1) fractures [see Figure 9a]. For unstable (AO-ASIF type A2 and A3) intertrochanteric fractures, intramedullary fixation is the treatment of choice because of the favorable position of the implants in the biomechanical loading axis of the femur. Examples include the Proximal Femoral Nail (PFN; Synthes, West Chester, Pennsylvania) [see Figure 9b], the Intramedullary Hip Screw (IMHS; Smith & Nephew, London, England), and the Gamma Nail (Stryker, Kalamazoo, Michigan). The operative technique for intramedullary fixation is more complex and unforgiving than that for extramedullary fixation, and various complications may arise, including malpositioning and femoral shaft fractures during insertion. Intramedullary implants are usually inserted percutaneously on a traction table with one or more screws in the femoral head and one or more distal locking screws. Internal fixation of trochanteric fractures should allow mobilization from postoperative day 1, preferably with full weight bearing or the use of a walker.^{4,5,84}

Subtrochanteric (AO-ASIF type A3) fractures are inherently unstable. Operative treatment may be difficult because high bending forces in the region (resulting from the angular shape of the proximal femur) often lead to implant failure before union. The preferred management approach is intramedullary nailing; the use of angled blade plates is an alternative, especially in young patients who require anatomic reduction.^{4,5}

Shaft

In most adults, considerable force is necessary to fracture the

femoral shaft; a simple fall seldom results in this type of fracture unless the bone has been weakened by osteoporosis or other disease. A patient with a femoral shaft fracture should therefore be considered a victim of high-energy trauma and evaluated accordingly.

Most fractures of the femoral shaft are easily recognized clinically on the basis of pain and abnormal position or movement. Because of the shape of the thigh, more than 1 L of blood may be lost into this space with little or no external indication. Neurovascular injuries are relatively uncommon in this setting; however, when the fracture is in the distal third of the femoral shaft, injury to either the superficial femoral artery or the popliteal artery may ensue as a consequence of the tethering of these vessels against the shaft at the level of the adductor canal. Femoral shaft fractures are often associated with injuries to knee ligaments, which are difficult to assess in the presence of the femoral fracture. Thus, when the patient is under anesthesia for treatment of the fracture, the stability of the knee should be assessed as well. Imaging consists of AP and lateral x-rays, with the hip and knee joints included.

In the ED, a fractured femur is immobilized with a vacuum splint or a Thomas splint. This measure reduces blood loss and lessens patient discomfort, and the splints need not be removed for x-rays to be taken. Ideally, femoral shaft fractures should be treated within 12 to 24 hours after the injury; preoperative skeletal traction is therefore superfluous. The main goal is stable fixation that yields correct length, rotation, and alignment, with full weight bearing possible within a few days of the operation.

Femoral shaft fractures of AO-ASIF types A to C are best treated with locked intramedullary nailing [see Figure 10]. In isolated instances, a plate or an external fixator may be indicated. Nailing lowers the incidence of respiratory distress syndrome, blood loss, and tissue trauma and reduces the patient's need for narcotics. In the setting of DCS, femoral fractures are initially stabilized by means of external fixation. The external fixator can then be exchanged for an intramedullary nail 2 to 10 days later without a significant increase in complications.^{12,13,85} Nailing can be performed with the patient supine on a fracture table or in a lateral

Figure 10 Illustrated (a through e) is treatment of comminuted AO-ASIF type C femoral fracture with intramedullary nailing. No attempt was made to reduce fracture fragments in order to preserve their vascularization. Healing was uneventful, with complete restoration of function.

decubitus position with closed reduction (or, if necessary, open reduction) of the fracture. Most nails are inserted in an antegrade manner through the greater trochanter or piriform fossa, though retrograde nailing through the intercondylar notch is becoming increasingly popular for distal shaft fractures. Reaming is generally advised because it reduces the rate of nonunion.⁵¹

Most complications with femoral shaft fractures are secondary to technical problems at the time of nailing and can therefore be prevented by paying close attention to technical details (in particular, the entry point of the nail and correct rotation). In rare instances, embolization of debris from reaming may lead to fat embolism syndrome (FES) [see Special Considerations, Complications, Fat Embolism Syndrome, below]. Infections occur mostly in open fractures and fractures where there is substantial soft tissue involvement. Compartment syndrome of the thigh may occur after femoral shaft fracture, albeit infrequently; it should be suspected if severe swelling is present.^{4,5}

Distal

Supracondylar (AO-ASIF type A) and intercondylar (AO-ASIF type B and C) fractures of the distal femur typically occur in young patients who have sustained high-energy trauma or in elderly patients with osteoporotic bone. Careful assessment of neurovascular status is important. X-rays focused on the knee should be supplemented with x-rays of the femoral and tibial shafts. CT can provide additional information on the fracture pattern and help in preoperative planning. Standard treatment consists of operative reduction and internal fixation, followed by partial-weight-bearing or non-weight-bearing active or passive exercises.

Supracondylar fractures can be treated with retrograde

intramedullary nailing or plating, depending on the surgeon's preference. Open reduction with extensive techniques for applying angled blade plates, condylar plates, sliding hip screws, and similar devices is currently being replaced by less invasive plating techniques using screws that are locked into the plate. An example of the latter is the Less Invasive Stabilization System (LISS; Synthes, West Chester, Pennsylvania), which allows submuscular fixation and percutaneous placement of self-drilling unicortical fixed-angle screws. The focus with this system is more on correction of length and alignment and less on anatomic reduction.

Intercondylar fractures are treated with anatomic reduction and screw fixation of the articular surface to allow early motion and thereby facilitate cartilage healing. Either open methods or image intensifier-assisted closed methods may be employed. The reconstructed articular surface is then connected en bloc to the femoral shaft with one of the previously described techniques (usually plating).^{4,5,86}

KNEE

Patellar Fracture

Knee injuries are common in multiply injured patients, in large part because of the vulnerability of this joint to dashboard injuries in automobile accidents and to direct trauma in motorcycle accidents. Patellar fractures usually result from a fall on the knee, a sudden forceful contraction of the quadriceps muscle with knee flexion, or a combination of the two. Other injuries (e.g., cruciate ligament failure and femoral fracture) may be present as well. The most important task in the examination is to confirm that the extensor mechanism is intact by asking the patient to raise the leg with the knee fully extended. X-rays should include AP, lateral, and

(optionally) tangential views.

Transverse and stellate fractures with minimal (< 1 to 2 mm) displacement and an intact extensor mechanism may be treated conservatively by keeping the joint in a cast for 6 weeks, with weight bearing allowed. All other fractures are treated by open reduction with internal fixation, typically with Kirschner wires and tension bands or cerclage wires. Postoperatively, early active motion and partial weight bearing are allowed. Severely comminuted patellar fractures may be irreparable; in such instances, a partial or total patellectomy with reconstruction of the extensor apparatus may be required. Ligamentous patellar injuries (e.g., to the quadriceps tendon or the patellar tendon) are treated by means of operative repair and reinsertion to the patella.^{4,5}

Dislocation

Knee dislocations, though potentially severe injuries, are generally rare, with only a few small series having been reported. They result primarily from motor vehicle and pedestrian accidents, falls, and sports activities, though they also occur spontaneously in morbidly obese persons. Their severity is determined by the complexity of the ligamentous injury and any associated trauma, including popliteal artery and vein injury (20% to 30% of cases) and peroneal nerve injury (25% to 35%). Failure to recognize vascular injury can lead to muscle necrosis and amputation. It is therefore essential that reduction of knee dislocations be carried out immediately, either before arrival at the hospital or in the ED, followed by vascular examination and x-rays. Anterior dislocation (30% to 40% of cases) is often caused by severe knee hyperextension, whereas posterior dislocation (25% to 30%) occurs with the application of force to the proximal tibia in an anterior-to-posterior direction, as in a dashboard-type injury or a high-energy fall on a flexed knee.

Physical examination reveals gross deformity around the knee with swelling and immobility. Occasionally, the knee will have relocated spontaneously before the patient arrives at the ED. Attention should be focused on the presence or absence of hard signs of vascular injury [see 7:17 *Injuries to the Peripheral Blood Vessels*]; if preferred, the ankle-brachial index (ABI), duplex scanning, or both may be employed in addition.^{5,37} Although many authors recommend mandatory arteriography or operative exploration for all knee dislocations, this recommendation is increasingly being questioned.⁸⁷⁻⁸⁹ The current literature indicates that the absence of hard signs reliably excludes a significant arterial injury that necessitates operative repair. The presence of hard signs of vascular injury, however, is an indication for arteriography; because about 25% of patients with hard signs actually have no vascular injury, arteriography serves to prevent many unnecessary vascular explorations. Another potentially valid (and timesaving) approach may be to take those with hard signs directly to the OR and obtain an on-table angiogram. In some instances, noninvasive tests may be able to distinguish patients who have vascular injuries requiring repair from those who do not.

Asymptomatic intimal injuries visualized by angiography do not call for surgical exploration, and the clinical value of interventional radiology techniques (e.g., stent placement) in this context is questionable. If there is a vascular injury that requires surgical repair, an external fixator that spans the knee joint should be quickly placed. Restoration of circulation has absolute priority in this situation; the amputation rate exceeds 80% when vascular repairs are done more than 8 hours after injury. Operative repair of nerve injuries is controversial. Optimal treatment of multiple ligament ruptures is also subject to debate. Many authors recommend early operative ligamentous repair followed by functional bracing and mobilization for

optimal results, whereas others recommend primary immobilization followed, if necessary, by late reconstructions.^{4,5,90}

Ligamentous Injury and Meniscal Tearing

Distortions of the knee are common injuries; most involve varus, valgus, or rotational deformities. The history should focus on the mechanism of injury, the type and location of pain, any associated symptoms, the amount of immediate dysfunction, the presence and onset of joint edema, and any history of past knee problems. The physical examination should include inspection, active motion, and stress testing to detect instability. Hemarthrosis is a sign of possible cruciate ligament injury. If pain and swelling preclude reliable examination, the examination should be repeated in 5 to 7 days. Collateral ligament injuries are graded on a scale of I to III. A grade I injury is a sprain (with stretching but no tearing of the ligament, local tenderness, minimal edema, and no gross instability on stress testing), a grade II injury is a partial ligament tear (with moderate local tenderness and mild instability on stress testing), and a grade III injury is a complete tear (with discomfort on manipulation, a variable amount of edema, and clear instability on stress testing).

X-rays of the knee are obtained to detect any fractures of the tibial plateau or the intercondylar eminence. The number of unnecessary x-rays may be substantially and safely reduced by applying the so-called Ottawa knee rule. This rule specifies the following indications for x-rays: age 55 years or older, tenderness at the head of the fibula, isolated tenderness of the patella, inability to flex the knee 90°, and inability to walk four weight-bearing steps immediately after the injury and in the ED. MRI is useful for detecting ligamentous, meniscal, and cartilage injuries but is rarely indicated on an emergency basis.

Treatment depends on the patient's age and activity level and should always include appropriate reeducation and strengthening of the relevant muscles (hamstrings and quadriceps). Grade I and II collateral ligament injuries (which are usually medial) may be treated conservatively with early active motion, with or without a knee brace. Grade III medial collateral ligament injuries may be treated in a knee brace for 6 weeks, but grade III lateral collateral ligament injuries must be treated surgically because conservative treatment frequently leads to chronic instability. Anterior cruciate ligament ruptures are increasingly being treated by operative means in serious athletes and other physically active persons. The ligament is arthroscopically reconstructed with a section of the patellar tendon or the semitendinosus tendon. Isolated posterior cruciate ligament ruptures, which are considerably less common, are primarily treated nonoperatively.^{4,5,91}

Meniscal tears occur mainly in physically active persons, though they may also result from simple distortions experienced during activities of daily living, especially if the meniscus has previously undergone some degeneration. Complaints include mild pain, swelling, grinding, locking, and "giving way." Clinical diagnosis is aided by provocative tests (e.g., the McMurray and Appley tests), but when symptoms persist, MRI is often performed. Mild meniscal tears may be treated conservatively, whereas symptomatic lesions usually call for surgical treatment. In general, meniscal repair is indicated when the tear is in the vascular outer one third of the meniscus, and partial excision is indicated when the injury is in the avascular inner two thirds.⁵

TIBIA

Proximal

Tibial plateau fractures are intra-articular fractures that mostly

result from indirect varus or valgus trauma. The amount of displacement and comminution is determined by the magnitude and direction of the forces applied. High-energy fractures may be associated with severe soft tissue injuries, as well as ligamentous and meniscal tears. It is important to recognize that severe proximal tibial fractures can represent a reduced fracture dislocation of the knee, and thus, the neurologic and vascular concerns that accompany knee dislocations can apply to these fractures as well [see *Knee, Dislocation, above*].

Tibial plateau fractures are characterized by local pain, swelling from hemarthrosis, and, in some cases, instability of the knee joint. Aspiration of a tense hemarthrosis is sometimes required to decompress the joint and relieve pain. Only 6% of patients with knee trauma have a fracture. The need for x-rays is generally determined according to the Ottawa knee rule [see *Knee, Ligamentous Injury and Meniscal Tearing, above*].⁹² If a fracture is confirmed, CT scanning with axial, coronal, and sagittal reconstructions is done to delineate the severity and orientation of the fracture lines. This measure also helps the physician decide whether operative or nonoperative treatment is indicated and, if the former, which operative approach should be taken. If the condition of the soft tissues precludes early definitive operative treatment, a plaster splint or temporary external fixation may be employed to allow the soft tissues time to heal or to give the surgeon time to plan an operative procedure for soft tissue coverage.

Proximal tibial fractures are classified according to the AO-ASIF system or the Schatzker system. Extra-articular AO-ASIF type A1 and A2 fractures and minimally (< 2 mm) displaced intra-articular fractures (AO-ASIF type B and C) may be treated conservatively; all others should be treated operatively. Operative treatment consists of anatomic reduction of the articular surface, either under direct vision (arthrotomy) or via a less invasive approach (with arthroscopic or fluoroscopic assistance). Reduction is held with screws, plates, or both, and often, the use of iliac bone grafts or bone substitutes (e.g., calcium phosphates) is required to maintain the elevation of the articular surface. The articular “block” is connected to the tibial shaft by means of plates and screws; if soft tissue injuries preclude plating, special external fixation devices (i.e., ring fixators with tensioned wires) may be employed instead. Fixed-angle plating systems that allow less invasive insertion methods are also gaining popularity for use in the proximal tibia. Early motion is appropriate after operation, with weight bearing allowed after 8 to 12 weeks. Disabling complications include infection, posttraumatic arthritis, and instability of the knee.^{4,5}

Shaft

Fractures of the tibial shaft are among the most common serious fractures. The subcutaneous location of the tibia affords little protection from direct violence, and high-energy fractures are associated with longer healing times. Tibial fractures can be fraught with complications (e.g., compartment syndrome, nonunion, delayed union, malunion, and infection), and in their most severe manifestations, they can end in amputation. Tibial shaft fractures are easily diagnosed clinically in the ED. Examination includes palpation for signs of possible compartment syndrome and assessment of the neurovascular status. If the fracture is grossly angulated or malaligned, gentle restoration of axial alignment helps relieve vascular kinking and compromise. The extremity should be splinted, and appropriate x-rays should then be obtained to allow full assessment of the fracture.

Selected closed fractures without dislocation and minimally displaced AO-ASIF type A fractures may be treated conservatively

with an above-the-knee cast for 2 to 4 weeks, followed by functional bracing for 10 to 16 weeks. Bracing relies on the intact soft tissues, primarily the interosseous membrane, to prevent shortening and dislocation.⁹³ Displaced and unstable AO-ASIF type A, B, and C fractures, as well as all open fractures, are treated operatively. The severity of any associated soft tissue injury is a crucial factor in deciding how to manage of tibial shaft fractures. The standard treatment for such fractures—closed reduction with reamed, interlocking intramedullary nailing—has a high success rate and a low complication rate [see *Figure 11*]. In those unusual circumstances in which the fracture pattern does not permit insertion of an intramedullary rod (e.g., certain fractures in the proximal or distal third of the shaft), plate fixation may be employed instead; unfortunately, this procedure is associated with a high rate of nonunion.^{4,5,51}

For open fractures associated with complex wounds, the standard treatment has been external fixation, which permits stabilization of the fracture, affords ready access to large open wounds, and facilitates nursing care. Currently, however, nailing appears be superior to external fixation for grade 1 and 2 open fractures: the infection rate is no higher, the complication rate is lower, and the functional end results are better. Grade 3 open fractures are highly complex injuries, and an expert team that includes a plastic surgeon is required for optimal management. Aggressive irrigation and debridement are followed by either external fixation or intramedullary nailing, depending on the state of the surrounding soft tissue factors, the fracture pattern, time-related factors, and the surgeon’s preference. If secondary soft tissue procedures involving a pedicle or a free flap are warranted, they should be planned at an early stage in treatment. In multiply injured patients who require DCS, tibial shaft fractures are initially stabilized with external fixation, with care taken to place the fixator pins strategically, in anticipation of subsequent soft tissue coverage procedures. Once the patient is physiologically stable, the fixator may be removed and intramedullary nailing performed. In these patients, a combination of retrograde femoral nailing and antegrade tibial nailing done through a single knee incision offers an elegant and less invasive means of stabilizing a floating knee.

One of the most severe complications that may develop after a tibial fracture is compartment syndrome [see *7:17 Injuries to the Peripheral Blood Vessels*]. When the fracture is in the distal third of the shaft, delayed union or nonunion is a particular risk as a consequence of the limited vascularization provided by the predominantly posterior soft tissue envelope.^{4,5}

Distal

Fractures of the distal tibia mostly result either from vertical loading that drives the talus into the tibia (as in a fall from a height or a motor vehicle accident) or from low-energy trauma with torsion (as in skiing). Intra-articular fractures in this region are called tibial plafond (ceiling) or pilon fractures. Pilon fractures are frequently accompanied by severe soft tissue swelling and comminution of the articular surface and the metaphysis; the fibula may or may not be fractured. Standard AP and lateral x-rays are obtained in conjunction with CT scans to define the fracture pattern and aid in preoperative planning. The goals of treatment are to restore ankle joint integrity, congruency, and stability; to achieve bony union; and to allow functional painless motion. In cases where there is substantial soft tissue involvement, staged surgery may be advisable. A safe option is to apply a bridging external fixator from the midtibia to the foot, leaving enough distance between the fixator pins to allow future incisions in the distal tibia; this may be done with or without primary percutaneous screw fixation of the joint

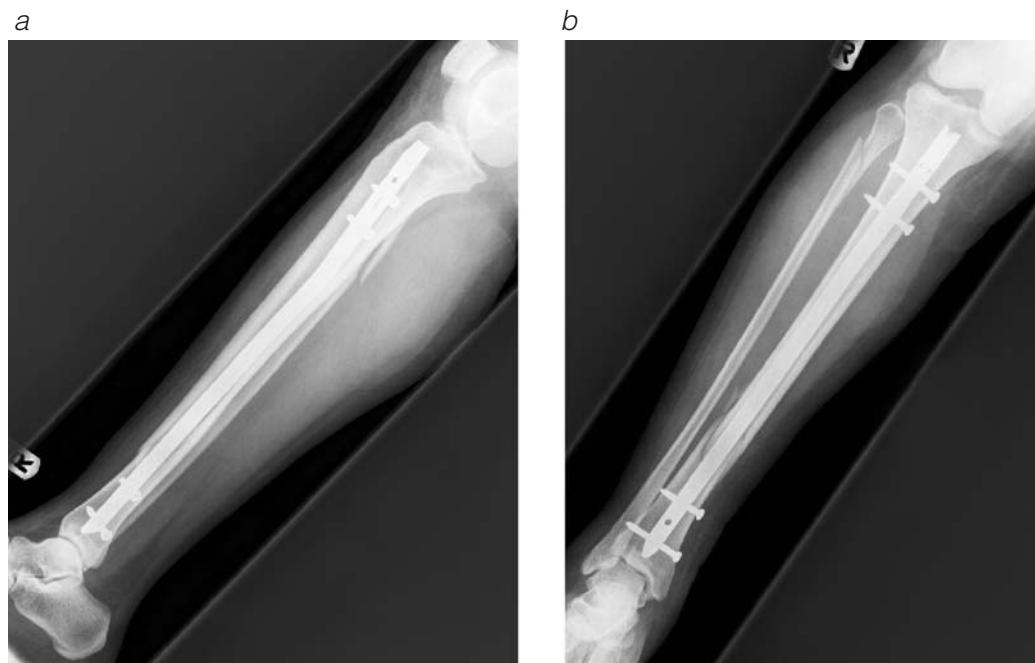

Figure 11 Shown (a, b) is treatment of closed AO-ASIF type A1 tibial fracture with reamed intramedullary nailing.

surface and with or without primary fixation of the fibula to restore the length of the ankle.

Fractures that are not accompanied by dislocation (mostly AO-ASIF type A1) may be treated conservatively in a cast for 8 weeks. All other distal tibial fractures generally require operative treatment, the basic principles of which resemble those appropriate for proximal tibial fractures. Because of the typical swelling and the frequent presence of fracture blisters, optimal timing of the procedure is critical. For extra-articular (AO-ASIF type A) fractures, a minimally invasive approach involving percutaneous insertion of a plate with locking screws (e.g., the LCP) may be feasible. For intra-articular (AO-ASIF type B and C) fractures, anatomic reduction of the articular surface and internal fixation are required, preferably performed by an experienced surgeon. As a rule, the fibula is fixed first through a lateral incision, and the tibia is then fixed via an anterior or medial approach. Dissection should be minimized to prevent further soft tissue injury. Any debris present in the joint is removed. After reconstruction of the articular surface, a connection with the tibial shaft is made, most frequently with a plate and screws or with a hybrid ring fixator. With most AO-ASIF type C distal tibial fractures, the use of a bone graft or bone substitute is required to support the articular surface. After the procedure, the patient is allowed to engage in active movement without weight bearing for 8 to 12 weeks. The outcome of treatment of pilon fractures depends primarily on the quality of the articular reduction and the recovery of the soft tissues. Such fractures frequently give rise to severe posttraumatic arthritic pain, and delayed ankle fusion may be required.^{4,5}

FIBULA

Shaft

Generally, fibular shaft fractures may be ignored. Such fractures heal readily, sometimes so readily that they interfere with the union of associated tibial fractures. Isolated midshaft fibular fractures that do not involve the ankle joint may be treated symptomatically, often without a cast. In some instances, plating the fibular fracture

provides additional stabilization for an unstable distal tibial shaft fracture; however, rendering the fibula stable may diminish the cyclic compression that occurs with weight bearing at the site of the tibial fracture and thus may delay healing. For this reason, in most cases of combined tibial and fibular fracture, the fibula is not stabilized.⁵

ACHILLES TENDON

Achilles tendon ruptures are mainly caused either by sudden forceful dorsiflexion of the foot with the knee extended (placing the soleus and gastrocnemius muscles on maximal stretch) or by sudden takeoff during athletics. They are frequently seen in weekend athletes, as well as in more regular participants in active sports (e.g., football, volleyball, tennis, and squash). A common scenario is one in which the patient wrongly believes that someone has hit him or her on the heel; sometimes, the patient hears a snap as well. On physical examination, a visible or palpable dent is apparent in the tendon 2 to 6 cm above the calcaneus. The Thompson test is useful for confirming or ruling out an Achilles tendon rupture. For this test, the patient is placed in the prone position with both feet extending past the end of the examining table. If squeezing of the calf muscles on the affected side does not result in plantar flexion of the foot, the tendon is ruptured; if this maneuver does result in plantar flexion, the tendon is intact. If the patient does not present until several days after the injury, diagnosis may be more difficult. In such cases, ultrasonography or MRI may be helpful.

Treatment may be nonoperative (i.e., immobilization in plantar flexion) in certain patients, but it is operative in most. Operative treatment consists of surgical repair of the tendon either via full exposure of the tendon or via a minimally invasive approach (e.g., suture anchors); the latter may be preferable for minimizing wound healing problems. After the procedure, the injured area is kept in a soft cast for 6 weeks, during which period the patient is allowed active movement with weight bearing. Surgical treatment substantially reduces the incidence of recurrent ruptures; however, it is also associated with an increased risk of wound healing problems and surgical site infection.^{5,94}

ANKLE

Fracture and Dislocation

Ankle fractures are usually caused by indirect trauma. They are generally categorized according to the AO-ASIF classification system, which also guides treatment decisions. The factors that determine the type of fracture present include age, bone density, the position of the foot at the time of injury (pronation or supination), and the direction of the forces that acted on the joint to produce the injury (adduction, abduction, exorotation, or axial loading). The history and physical examination reveal pain, swelling, functional impairment, and inability to bear weight. Conventional x-rays usually suffice for diagnosis. A true AP (mortise) view requires 20° of internal rotation for adequate assessment of the joint. If the fracture is particularly complex, CT scanning should be performed to obtain additional information. The two main factors to consider in the management of ankle fractures are the congruency of the ankle joint medially, laterally, and superiorly (i.e., with respect to the tibia, the fibula, and the talus) and the presence of soft tissue injury (because there is little muscle coverage in this area). Even small disturbances of ankle congruity (e.g., widening of the mortise) can lead to overloading of the cartilage and predispose to posttraumatic arthritis.

Type A fractures are transverse lateral malleolar fractures that occur distal to the syndesmosis, at or just below the level of the ankle joint. They may be treated either conservatively in a plaster cast or functionally in a soft cast for 4 to 6 weeks with full weight bearing allowed.

Type B fractures are oblique or spiral fractures of the lateral malleolus that occur at the level of the syndesmosis, with or without a fracture of the medial malleolus. Whereas nondislocated type B fractures may be treated conservatively, all other type B fractures are treated by means of open reduction and internal fixation with a plate or screws, followed by protected weight bearing. The best time for operative treatment is within the 8 hours following admission. After 24 hours, edema increases, and surgery is best postponed until 5 to 7 days later, when the condition of the soft tissue has improved. In the meantime, the fracture or dislocation is reduced, and a splint is applied.

Type C fractures occur above the syndesmosis. Sometimes, a fracture is located near the fibular head proximally. In such cases, the interosseous membrane and the syndesmosis are ruptured between the fibular fracture and the ankle joint (Maisonneuve fracture). This type of injury is easily missed if a careful examination is not performed and the appropriate proximal x-ray obtained. Type C fractures are generally treated surgically with plating or with one or two fibulotibial syndesmotic positioning screws, which allow the syndesmosis to heal with a correct length and position relative to the talus of the fibula.

Malleolar fractures are frequently associated with fractures of the posterior lip of the tibial plafond (trimalleolar fractures). Large fragments (> 20% of articular surface) should be reduced and fixed to prevent posterior dislocation of the talus. Early complications include inadequate reduction and fixation, wound problems, and infection. Long-term results are primarily determined by the presence and extent of cartilage damage and by the congruency of the ankle joint. Approximately 30% of patients experience persistent symptoms around the ankle.^{4,5,95}

Isolated ankle dislocations without fractures are rare; 30% of these injuries are associated with an open wound extending into the joint. A dislocated ankle should immediately be reduced—before x-rays are taken if possible—to minimize further neurovascular compromise. After closed or open reduction, wound care is

provided and immobilization instituted.⁵

Ligamentous Injury

Ankle ligament injuries are among the most common injuries seen in the ED. They often occur during sports activities as a result of inversion during plantar flexion of the ankle. Approximately 85% of ligamentous ankle injuries involve one or another of the three lateral ligaments: the anterior talofibular ligament, the calcaneofibular ligament, and the posterior talofibular ligament. Approximately 65% of ankle sprains resulting from inversion occur in the anterior talofibular ligament alone. Ankle sprains are commonly classified into three grades: grade I is a sprain with stretching of the ligament, grade II is a partial ligament tear, and grade III is a complete tear. This classification does not, however, guide treatment. Diagnosis is based on the history and the physical examination (including the anterior drawer test). X-rays are obtained if a fracture is suspected. The number of unnecessary x-rays can be markedly and safely reduced by applying the so-called Ottawa ankle rule [see Figure 12], which is analogous to the Ottawa knee rule described earlier [see Knee, Ligamentous Injury and Meniscal Tearing, above].⁹⁶

The main treatment options for ankle ligament injuries are immobilization in plaster, functional treatment (early mobilization with the joint in tape or a soft cast), and surgical repair. Current evidence indicates that functional treatment is the recommended strategy for most patients.^{97,98} Approximately 20% of patients experience varying levels of recurrent or chronic symptoms.

FOOT

The foot is a complex system consisting of numerous bones, ligaments, and tendons. Accordingly, many different types of foot injury are seen. The history plays an important role in identifying the mechanism of injury. Foot injuries do occur as isolated events, but they also frequently occur in conjunction with distant injuries and thus may easily be missed initially in cases of polytrauma. Physical examination includes assessment of the soft tissues of the foot and ankle, the degree of pain felt on compression, the stability of the injured area, and the neurovascular status of the foot. Conventional x-rays are often supplemented with CT scans; MRI and bone scintigraphy are also sometimes employed, though less frequently.^{4,5} The pain, swelling, functional impairment, and deformity associated with foot injuries can markedly limit the patient's mobility. In recent years, it has become clear that function can be improved by restoring the normal anatomy and avoiding prolonged immobilization in plaster.

Talus

The talus plays an important role in the transmission of force to the rest of the foot, with 60% of its surface covered by cartilage. This cartilaginous covering, in combination with a delicate blood supply, makes talus fractures complex injuries. Fractures and dislocations of the talus typically result from high-energy trauma (as in motor vehicle accidents or falls). Most talus fractures are intra-articular; sometimes, the only damage consists of an osteochondral flake (e.g., from an ankle sprain).

Most talus fractures are treated operatively. Ideally, surgical treatment should be carried out as early as possible, especially if the fracture involves the talar neck. Screw fixation may be accomplished either via open reduction or percutaneously (if displacement is minimal). After the operation, active motion is allowed, and weight bearing is started after 8 to 12 weeks. The outcome of treatment is determined primarily by the presence or absence of open wounds, the fracture type, and the status of the remaining

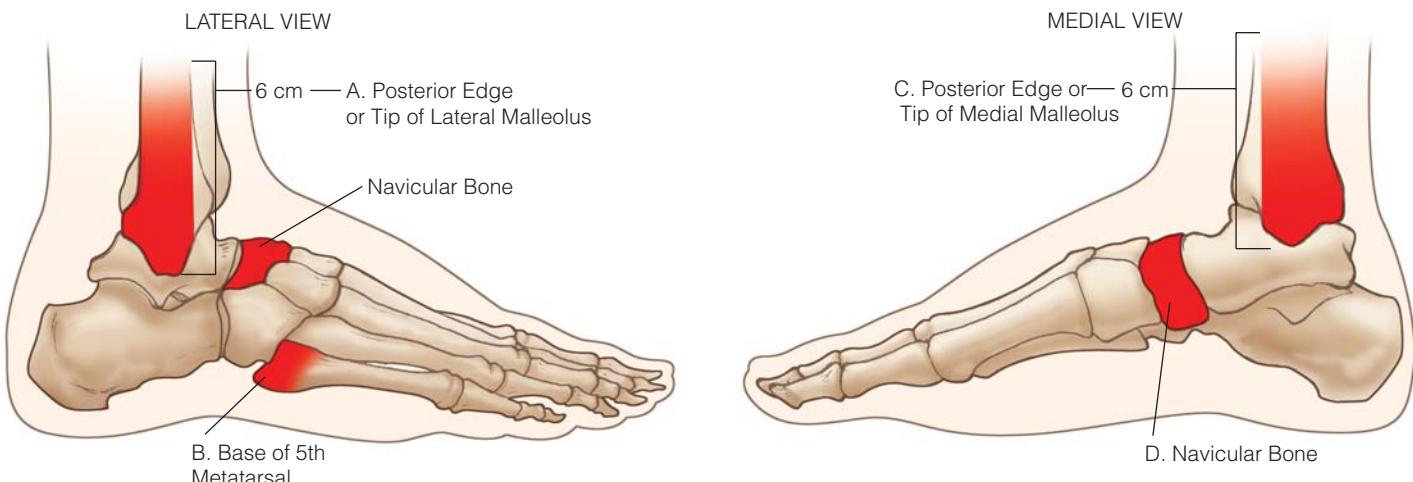

Figure 12 Illustrated is the Ottawa ankle rule. According to this rule, an ankle or foot x-ray series is required only if (1) palpation of the marked areas is painful or (2) the patient is completely unable to bear his or her own weight both immediately after the injury and for four steps in the ED.

blood supply. Avascular necrosis, infection, and posttraumatic arthritis can lead to severe disability.^{4,5,99}

Calcaneus

The calcaneus is the most frequently fractured bone in the foot. Fractures of the calcaneus are primarily caused by falling or jumping from a height and thus are commonly seen in combination with other injuries (e.g., spine fractures). Examination typically reveals marked swelling of the foot, with or without deformity. Lateral x-rays of the foot show a reduction in Böhler's angle (the posterior angle formed by the intersection of a line from the posterior to the middle facet with a line from the anterior to the middle facet) from the normal range of 20° to 40°. Conventional x-rays are always supplemented with CT scans to delineate the extent of the fracture.

Most extra-articular and nondislocated intra-articular fractures can be treated conservatively with non-weight-bearing mobilization of the ankle and the foot over a period of 6 to 12 weeks; there is no need for a splint or a cast. Optimal treatment of intra-articular fractures—in particular, the role of surgery—remains subject to debate, however. Depending on the fracture configuration, reduction and internal fixation of the joint surfaces may be accomplished either via an open approach or percutaneously. The same measures recommended as conservative treatment are then carried out as postoperative treatment. Whether this strategy yields better functional results than conservative treatment is not clear. However, there is currently a trend toward operative treatment in situations where anatomic reconstruction of the subtalar and calcaneocuboidal joints can be achieved. Smoking, advanced age, diabetes, and noncompliance are relative contraindications to surgical management. A substantial percentage of patients heal with malunion or experience posttraumatic arthritis. These patients are candidates for arthrodesis of the subtalar joint.^{4,5,100,101}

Midfoot

The midfoot contains the navicular bone, the cuboid bone, and the three cuneiform bones (medial, intermediate, and lateral). Proximally, the navicular and the cuboid articulate with the talus and the calcaneus (Chopart's joint); distally, the cuboid and the cuneiforms articulate with the metatarsals (Lisfranc's joint). Fractures and ligamentous injuries in these joints are easily missed

and can lead to prolonged deformity, pain, and functional impairment. Restoration of the anatomy both medially and laterally is important for a good outcome.

The majority of nondislocated fractures, extra-articular fractures, and ligament avulsion fractures of the midfoot can be treated nonoperatively in plaster or with functional therapy and early motion. Dislocated fractures are generally treated operatively with screw or plate fixation unless such treatment is precluded by severe comminution. Fractures in Lisfranc's joint mainly result from high-energy trauma and are often associated with dislocation of one or more metatarsal bones. Such fractures are treated by means of operative reduction and fixation with Kirschner wires or screws.^{4,5,102,103}

Metatarsals and Toes

Most metatarsal fractures result from direct trauma (e.g., from a heavy object falling on the foot); however, they can also occur with chronic repetitive loading in the absence of obvious trauma (so-called stress or march fracture).

For the most part, fractures of the second through fourth metatarsals and nondislocated fractures of the first and fifth metatarsals can be treated nonoperatively by using a plaster cast or a heavy supportive shoe for 4 to 6 weeks. With the majority of displaced fractures, closed reduction can be achieved, but maintenance of the reduction requires internal fixation; malunion can disturb ambulation. Many fractures of the lesser metatarsals and subcapital fractures can be treated with percutaneous pinning. Fractures with joint involvement and multiple fragments frequently necessitate treatment with open reduction and plate fixation. Fractures of the base of the fifth metatarsal form a special group. The mechanism of injury is identical to that seen in ankle sprains. These fractures are generally divided into two types: avulsion fractures (involving the insertion of the peroneus brevis tendon) and transverse fractures of the base of the fifth metatarsal (Jones fracture). Both types may be treated nonoperatively if displacement is minimal, but delayed healing is common with Jones fractures. Operative treatment consists of tension-band wiring or screw or plate fixation.^{4,5,104}

Fractures and dislocations of the toes result from direct trauma. Virtually all toe fractures can be treated conservatively by taping the injured toe to an adjacent, uninjured toe (so-called buddy tape). On

rare occasions, reduction and Kirschner wire fixation of a dislocated toe fracture are indicated. Toe dislocations are reduced with traction and are treated in much the same way as toe fractures.⁵

Special Considerations

GERIATRIC TRAUMA

Musculoskeletal injuries in the elderly are a rapidly growing health problem and cause considerable morbidity and mortality. Advanced age, increased risk of falling, and reduced bone mineral density are the most important risk factors for the occurrence of osteoporotic fractures. Although many standard principles of extremity trauma management apply to the elderly, there are also certain concerns that are specific to this population. Hence, in evaluating an elderly person who has sustained an extremity injury, it is essential to assess the entire patient, not just the affected bone or joint.

One issue is that injured elderly persons often have one or more comorbid conditions, the presence of which increases perioperative risk. Advances in medical and anesthetic techniques have made it safe for many patients to undergo surgical procedures that previously would have been contraindicated; however, the timing of surgery can still pose problems. Ideally, sufficient time should be taken to ensure that patients receive optimal preoperative preparation, but such preparation should be provided with the understanding that delaying surgery unnecessarily will increase mortality. Inadequate nutrition is common in the elderly and should receive appropriate attention. The presence of osteoporosis can be confirmed by measuring bone mineral density (e.g., with dual-energy x-ray absorptiometry). Treatment of osteoporosis consists of a combination of physical exercise, dietary supplementation (with calcium and vitamin D), and administration of bisphosphonates (e.g., alendronate). Elderly patients have special needs with regard to rehabilitation, in that dependence or immobility may necessitate institutional care.¹⁰⁵⁻¹⁰⁷

REHABILITATION

The care of a patient with musculoskeletal injuries does not stop when the last operation is performed. Adequate rehabilitation is critical for ensuring the best possible functional outcome. Physical therapists, occupational therapists, speech trainers, dietitians, social workers, and psychologists may all play roles in this process. To ensure optimal continuity of treatment from the hospital to the rehabilitation center, rehabilitation experts should be involved early after the admission of a patient who has sustained severe pelvic or extremity trauma.^{4,5}

COMPLICATIONS

Systemic complications of pelvic and extremity trauma include FES, ARDS, hemorrhagic complications, crush syndrome, and thromboembolism. Severe local complications include compartment syndrome, acute and chronic infection, infected nonunion, malunion, and posttraumatic reflex sympathetic dystrophy.

Fat Embolism Syndrome

FES is most commonly associated with fractures of long bones of the lower extremity. The classic clinical triad consists of respiratory distress, cerebral dysfunction, and petechial rash. The pathophysiology is not clear, but there is some evidence to suggest that extravasation of fat particles from long bone fractures may play an important part. Furthermore, early stabilization of long bone fractures has been shown to decrease the incidence of FES. Signs and

symptoms of clinical FES usually begin within 24 to 48 hours after trauma. Treatment is primarily prophylactic and supportive, consisting of early fracture fixation, careful volume replacement, analgesia, and respiratory support. The role of corticosteroids in this setting is controversial.^{4,5,108,109}

Thromboembolism

Both symptomatic and asymptomatic DVT can pose serious problems in trauma patients. DVT is an important cause of pulmonary embolism (PE) and often results in major morbidity or death. The incidence of DVT ranges from 4% in patients with conservatively treated lower-extremity injuries to between 20% and 35% in patients with pelvic and acetabular injuries and patients with hip fractures. All trauma patients should therefore receive DVT prophylaxis. Once a thromboembolic event has occurred, the patient should be immediately be treated with I.V. anticoagulants according to local protocols. Prevention and treatment of DVT and PE are discussed in greater detail elsewhere [see 6:6 *Venous Thromboembolism*.]^{4,5,10,110-113}

Infection

Infections that develop after osteosynthesis are nearly always caused by exogenous bacteria. Contamination may occur in the course of the injury (as with an open fracture), during surgical treatment, or postoperatively (as a result of disturbed wound healing). Most infections manifest themselves within the first 7 days after the operation. Some become apparent only after a longer period has elapsed; these are often preceded by an unnoticed low-grade infection. The infection types most frequently associated with osteosynthesis are implant-related infections (involving colonization of fixation materials), osteomyelitis (a bone infection), and infectious arthritis. Diagnosis is based primarily on clinical signs (e.g., redness, fever, and pain), laboratory studies (e.g., C-reactive protein level and leukocyte count), and bacteriologic tests. In patients with late-developing infections, x-rays, CT, and MRI can provide additional useful information. Treatment consists of surgical debridement, open or closed wound management, and supplemental local or systemic antibiotic coverage. For cases of chronic osteomyelitis, advanced soft-tissue coverage procedures are frequently required. Implant removal is generally unnecessary as long as the implant provides stable fixation.

Gas gangrene is the most serious infection seen in traumatic wounds; *Clostridium perfringens* is the classic causative pathogen. Other gas-forming organisms common seen include coliforms, anaerobic streptococci, and *Bacteroides*. Pain is the initial symptom of gas gangrene, followed by edema and exudation of a thin, dark fluid. The wound acquires a bronze discoloration and a musty smell, and crepitations develop in the muscles. Symptoms progress rapidly, and profound shock and MODS usually ensue. The diagnosis is made on clinical grounds, supported by Gram's staining. Successful treatment depends on early diagnosis, radical surgical debridement, fasciotomy, and I.V. antibiotic therapy.^{4,5,114}

Delayed Union, Nonunion, and Malunion

At present, there is no consensus among surgeons on how best to assess fracture healing—and, therefore, no consensus on precisely what constitutes delayed union, nonunion, or malunion. In general, delayed union refers to a fracture that heals more slowly than the average. “Average” depends on the fracture’s location and type, but 3 months is a frequently accepted time limit for delayed union.

Nonunion refers to a failure of bone healing that results from an arrested growth process; 6 months is the usual time limit. Nonunion has numerous potential causes, but the most important

factors leading to nonunion are disturbance of the blood supply and insufficient fracture stability. The blood supply is disturbed both by the injury itself and by the surgical procedure performed to treat the injury. Instability results from inadequate fixation technique, a suboptimal implant choice, or implant failure. In some nonunions, a false joint with a fibrocartilaginous cavity lined with synovium is formed (a condition also referred to as pseudarthrosis). Treatment of hypertrophic nonunions focuses primarily on achieving adequate stability, whereas treatment of atrophic nonunions requires not only achieving stability but also reversing the atrophy to the extent possible. The gold standard for treatment of atrophic nonunions is placement of a cancellous autologous bone graft, which has the advantage of being osteogenic, osteoinductive, and osteoconductive. Unfortunately, the morbidity from cancellous bone harvesting can be considerable.

Malunion is a deformity characterized by abnormal length,

rotation, or angulation. The degree of malunion that is acceptable with respect to function and cosmesis varies with the age of the patient and the location of the fracture.^{4,5}

Reflex Sympathetic Dystrophy

Posttraumatic reflex sympathetic dystrophy (also referred to as complex regional pain syndrome) is a poorly understood complication that may develop in any of the extremities after an operation or even minor trauma. It is capable of causing severe disability^{4,5,115,116}. Symptoms include unexplained diffuse pain, skin changes, edema, temperature changes, and functional impairment. The optimal treatment regimen has not been established; common therapeutic measures include free radical scavenger treatment (e.g., with systemic acetylcysteine and local dimethyl sulfoxide cream), administration of vitamin C, analgesia, vasodilatation, and careful physical therapy.

13 MANAGEMENT OF THE PATIENT WITH THERMAL INJURIES

Nicole S. Gibran, M.D., F.A.C.S., and David M. Heimbach, M.D., F.A.C.S.

Optimal care of the burn patient requires not only specialized equipment but also, more important, a team of dedicated surgeons, nurses, therapists, nutritionists, pharmacists, social workers, psychologists, and operating room staff. Burn care was one of the first specialties to adopt a multidisciplinary approach, and over the past 30 years, burn centers have decreased burn mortality by coordinating prehospital patient management, resuscitation methods, and surgical and critical care of patients with major burns. Detailed practice guidelines for burn patients, as well as lists of the resources needed in a burn center, have been developed.^{1,2}

Where to Treat Burn Patients

Patients with critical burns, as defined by the American Burn Association [see *Table 1*], should be transferred to a specialized burn center as soon as possible after their initial assessment and resuscitation. A community general or plastic surgeon with an interest in burns could manage moderate burns that do not involve functionally significant body sites. However, even patients with small burns benefit from the expertise of a specialized burn care team. Furthermore, the burn center's focused approach facilitates patient and family education, reentry into society, long-term rehabilitation needs, and reconstructive surgical needs.

OUTPATIENT VERSUS INPATIENT MANAGEMENT

Outpatient management may be appropriate for small burns (1% to 5% of total body surface area [TBSA]) that do not involve joints or vital structures. However, successful outcomes in such cases require a well-organized plan and clear communication with the patient and family. Many outpatient management plans fail because insufficient teaching during a short visit to an emergency department leads to inadequate pain control, wound infection, and limited movement.

Three important reasons for hospitalizing a patient with a burn injury are wound care, physical therapy, and pain management. A short hospital stay immediately after the injury gives the burn team the opportunity to teach the patient how to properly clean and dress the burn; this is especially important for burns to the extremities. A therapist should assess patient movement and educate the patient about expected activity levels and exercise programs. Background pain (pain experienced with ordinary daily activities) and procedural pain (pain experienced during wound care) should be carefully assessed, and analgesic medications should be titrated to the individual patient's pain levels.

Complex burn wound management is discussed in detail elsewhere [see *7:14 Management of the Burn Wound*]. For outpatient management, however, simplicity is the key to success. Patients and their families are unlikely to manage complicated dressing plans. For outpatient burn care, once-daily dressing changes are adequate. A common misconception is that these wounds must be

cleaned with sterile saline. In fact, burns can be effectively washed during a daily shower or bath with regular tap water and nonperfumed soap. A second misconception is that the patient must scrub the wound to debride all the superficial exudates. Simply wiping the wound with a soapy washcloth to remove the topical ointment and wipe away the bacteria that have accumulated over the past day provides adequate care. Intact blisters can be left as a protective wound cover if they do not prevent movement of a joint. Dressings must allow full range of motion.

Physical therapy is an essential component of burn management. A common misconception is that burns over joints should be immobilized to promote healing. Actually, immobilization of extremities leads to swelling, which worsens burn wound pain and increases the risk of wound infection. Patients with hand burns must be taught exercises to maintain range of motion. Likewise, patients with foot burns must ambulate without assistive devices, so that normal muscle contraction can facilitate lymphatic drainage of the lower extremity. Patients must be taught to elevate burned extremities when they are not actively exercising.

Inadequate pain management is a frequent reason for return visits to the emergency department or readmission to the hospital. Often, inadequate pain control results from poor patient understanding of how to care for the burn (e.g., excessive scrubbing during wound care or inactivity and subsequent swelling). Although a healing partial-thickness burn may become more painful as the epithelial buds begin to emerge and healing progresses [see *7:14 Management of the Burn Wound*], an acute increase in stinging pain may be the first sign of a superficial wound infection. This is an indication that the burn should be evaluated for signs of infection, including erythema and breakdown of a previously epithelialized wound; cellulitis may or may not surround an infected burn. Systemic antibiotics and a change in the topical antimicrobial agent are indicated in this situation.

Socioeconomic issues can be important contraindications to

Table 1 American Burn Association Criteria for Burn Injuries That Warrant Referral to a Burn Unit

- Partial-thickness burns of greater than 10% of total body surface area
- Third-degree burns
- Electrical burns, including lightning injury
- Chemical burns
- Inhalation injury
- Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or increase mortality
- Burns with concomitant trauma

Table 2 Criteria for Outpatient Management of Burn Patients

Outpatient Management Appropriate	Outpatient Management Inappropriate
Patients with small burns* who have demonstrated understanding of wound care, pain control, and therapy	Abused patients Demented patients Intoxicated patients Homeless patients Patients with comorbid conditions Patients with a language barrier

*1%–5% of total body surface area.

outpatient management of a burn wound [see *Table 2*]. Any suggestion of abuse—of a child or an adult—mandates admission for full evaluation of the home situation by the burn team; if the history and the burn distribution are consistent with a nonaccidental injury or potential neglect, the patient must be referred to protective services. Likewise, suggestion of a self-induced burn injury should trigger admission for psychological evaluation. For example, the presence of multiple small cigarette burns in various phases of healing is an absolute indication for admission to the hospital for psychological evaluation, even though the burns themselves may be easily cared for at home with small adhesive bandages. Although language barriers are not an absolute indication for hospital admission, there must be assurance that patients fully understand the treatment plan before they leave the emergency department. Underinsured and homeless patients may not have the resources to care for a wound outside the hospital and should be admitted for initial wound care and planning for transfer to a facility where they have access to a daily shower. Finally, the success of outpatient burn wound management depends on the ability to arrange a follow-up visit with an outpatient health care provider who can assess the outcome.

For patients with large burns, transition from inpatient to outpatient status is based on the same principles listed above. When burn pain can be controlled with oral medication and the patient and family can provide wound care, perform range-of-motion exercises, and manage splints and other assistive devices, outpatient management is appropriate. In some cases, daily or weekly outpatient therapy sessions to maintain range of motion may be included. If there are concerns about nonhealing wounds, weekly follow-up visits with the burn surgeon may be indicated initially. Because of possible long-term sequelae—scarring, contractures, and rehabilitation difficulties [see *7:16 Rehabilitation of the Burn Patient*]—the burn team should follow burn patients for 1 to 2 years after injury; longer follow-up may be necessary for patients with persistent contractures and scar formation. Prolonged follow-up is especially important with young children, who may encounter difficulties as they grow and may therefore require periodic monitoring until adulthood.

Fluid Management

In the late 1960s, Charles Baxter developed objective criteria for resuscitation of the thermally injured patient.^{3,4} The Baxter formula (also known as the Parkland formula) calls for the infusion, over 24 hours, of 3 to 4 ml of crystalloid per percentage of TBSA burned. Half of this volume is delivered during the first 8 hours after injury, and the other half is delivered over the subsequent 16 hours. It is important to remember that this is an esti-

mate of need; individual patients may have higher or lower fluid requirements, depending on their overall condition and comorbidity. Continuous monitoring and reliance on objective clinical outcomes must dictate patient management.

The reliability of the Parkland formula directly depends on accurate assessment of burn depth and percentage of TBSA affected.⁵ There are two formulas for quick estimation of burn size. One is the commonly used Rule of Nines: each arm is considered to be 9% of TBSA, each leg 18%, the anterior trunk 18%, the posterior trunk 18%, and the head 9% [see *Figure 1*]. Another easy method involves using the patient's full palm, including digits, to represent 1% of TBSA. First-degree burns [see *7:14 Management of the Burn Wound*] should not be included in the calculation of burned areas.

Despite improvements in invasive monitoring techniques, the most reliable measures of adequate tissue perfusion for burn resuscitation continue to be mean arterial pressure (MAP) and adequate urine output (UOP). MAP should be maintained above 60 mm Hg to ensure adequate cerebral perfusion. For an otherwise healthy adult, a UOP of 30 ml/hr should be adequate; for a child, 1.0 to 1.5 ml/kg/hr should suffice. No evidence supports the use of pulmonary arterial (PA) catheter measurements for routine resuscitation; in fact, reliance on PA catheters may lead to overresuscitation and contribute to the development of fluid-related complications (see below). Use of diuretics and inotropes should be restricted to patients with underlying comorbidity, especially preexisting cardiac disease. Use of inotropes will not stop the leak of plasma into the extravascular space but may lead to ischemia in the wound, resulting in conversion of a partial-thickness wound into a full-thickness wound. Use of mannitol may be appropriate for patients with myoglobinuria who require an osmotic diuretic to maintain a UOP of 100 ml/hr [see *7:15 Miscellaneous Burns and Cold Injuries*].

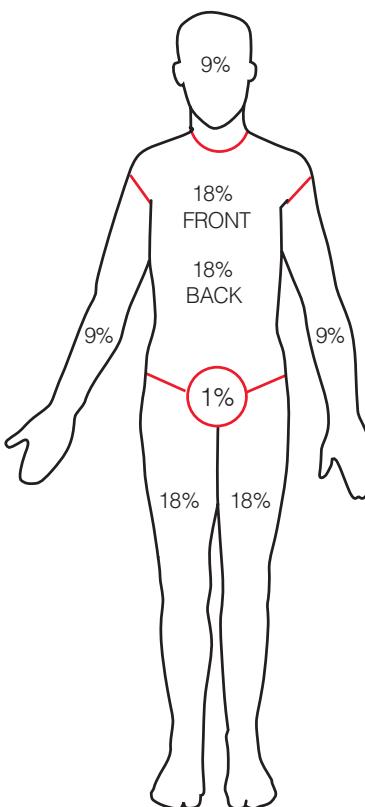

Figure 1 The size of a burn can be estimated by means of the Rule of Nines, which assigns percentages of total body surface to the head, the extremities, and the front and back of the torso.

Table 3 Acute Physiologic Changes during Burn Resuscitation

Measurement	Comment	Goal	Signs of Underresuscitation	Signs of Overresuscitation
Fluid volume	Fluid input generally exceeds output during the early post-burn period as edema develops	Urine output: adults, 30 ml/hr; children < 20 kg, 1.0–1.5 ml/kg/hr	Low urine output	Urine output > 30 ml/hr; hyperosmolar diuresis from hyperglycemia must be excluded
Body weight	An accurate dry weight is necessary for estimation of resuscitation fluid requirements	Weight will increase because of intravascular leak and resuscitation volume	Weight approaches dry weight	Massive weight gain from anasarca
Body temperature	Hyperthermia may indicate a hyperdynamic state	Normothermia	—	—
Electrocardiographic status	Dysrhythmias are uncommon in young patients but may complicate management of older patients	Normal sinus rhythm	Tachycardia may reflect intravascular contraction	Dysrhythmias may reflect poor oxygenation, electrolyte imbalance, or pH abnormality

Although the first 24 hours after a burn is usually considered the resuscitative phase of a burn injury, stabilization of the flux of mediators and closure of capillary leaks in fact take place on a continuum, occurring gradually from 12 to 48 hours after the burn injury. As capillary leakage resolves, the amount of fluids needed to maintain a MAP of 60 mm Hg and a UOP of 30 ml/hr should progressively decrease. A patient with both a large, deep burn and a profound inhalation injury or a patient in whom resuscitation has been delayed may require significantly more fluid than predicted by the Parkland formula to maintain blood pressure and UOP.

Colloid administration (albumin or fresh frozen plasma) after the capillary leak has closed (12 to 72 hours) may facilitate resuscitation in the patient with persistent low urine output and hypotension despite adequate crystalloid delivery. In such cases, the formula used is 5% albumin, 0.3 to 0.5 ml/kg/% TBSA burned over 24 hours. Alternatively, plasmapheresis may reduce intravenous fluid requirements in patients who are not responding to resuscitation.⁶ Indications for plasmapheresis include a sustained MAP of less than 60 mm Hg and a UOP less than 30 ml/hr in a patient with ongoing fluid needs that exceed twice the estimated volume requirements. Early plasmapheresis (12 to 24 hours after injury) may decrease the incidence of complications from administration of excessive fluid (see below). Why plasmapheresis works is unknown, but theoretically, the process should remove inflammatory mediators that cause vasodilatation and capillary leak.

Once resuscitation is complete (24 to 48 hours after injury), insensible losses and hyperthermia associated with a hyperdynamic state may indicate the need for ongoing fluid administration. The route of administration can be intravenous or, preferably, enteral. Reliable daily weights can be extremely valuable for detection and measurement of insensible fluid loss or fluid retention.

Along with MAP and UOP, several laboratory variables can be used to ensure that patients are receiving appropriate amounts of resuscitation fluid [see Tables 3 and 4].

COMPLICATIONS OF FLUID ADMINISTRATION

Before the development of current resuscitation formulas, inadequate resuscitation was a common cause of death in burn patients, as a result of decreased tissue perfusion and subsequent multiorgan failure.⁷ In addition, this ischemia caused conversion of the burn to a deeper injury, thereby increasing surgical requirements. However, there are also complications associated with overresuscitation, or so-called fluid creep.^{8,9} Whereas Baxter sug-

gested that 12% of patients would require more than 4.3 ml/kg/%TBSA resuscitation fluid, subsequent reports suggest that more than 55% of patients receive this amount of fluid.⁸ Excessive fluid resuscitation increases the risk of complications, including poor tissue perfusion, compartment syndrome involving the abdomen or extremities, pulmonary edema, and pleural effusion.

Abdominal compartment syndrome (ACS) is an increasingly well-recognized posttraumatic complication that occurs in patients who require extensive fluid resuscitation. Increased abdominal pressure decreases lung compliance and impedes lung expansion, resulting in elevated airway pressures and hypoventilation. The classic presentation includes high peak airway pressures, decreased venous return, oliguria, and intra-abdominal pressures exceeding 25 mm Hg.¹⁰ Sustained intra-abdominal hypertension is often fatal. Bedside decompressive laparotomy can alleviate ACS and can be performed safely through burn wounds,¹¹ and its use should be considered in patients with hemodynamic instability, hypoventilation, and elevated abdominal pressures. Whether the patient survives, however, depends on the comorbid conditions that led to the requirement for large resuscitative volumes.

Airway Management

Abnormal pulmonary function commonly complicates the management of thermally injured patients. It may result from inhalation injury or from the systemic response to the burn. Understanding the management of pulmonary dysfunction in the thermally injured patient requires a working knowledge of pulmonary function measurements and of pulmonary pathophysiology [see Tables 5 and 6].

INHALATION INJURY

Inhalation injuries occur in approximately one third of all major burns, and mortality is more than double that of cutaneous burns.^{12–14} Curiously, isolated inhalation injuries do not result in high mortality.¹⁵ Presumably, the combination of inhalation injury and cutaneous thermal injury creates a double insult in which recurrent or persistent bacteremia aggravates the pulmonary injury.

Three distinct components of inhalation injury exist: carbon monoxide (CO) poisoning, upper airway thermal burns, and inhalation of products of combustion. Diagnosis of an inhalation injury requires a thorough history of the circumstances surrounding the injury and is often suggested by fire in a closed

Table 4 Acute Biochemical and Hematologic Changes during Burn Resuscitation

Measurement	Comment	Goal	Signs of Underresuscitation	Signs of Overresuscitation
Serum creatinine and blood urea nitrogen	Normal baseline values rule out preexisting renal disease, which reduces urine output reliability as an index of tissue perfusion	Normal values	Rising values may reflect underresuscitation or acute tubular necrosis	May be normal
Hematocrit and hemoglobin	Significant blood loss from incorrectly performed surgical interventions such as escharotomies or central venous line placement may lower values	Should approach normal	May be elevated with severe intravascular depletion; this is typical with delayed resuscitation	May be low in patients with excessive intravascular volumes
White blood cell count (WBC)	The initial WBC may vary, depending on the stress response and cell margination; the absolute value is not particularly useful during the early postburn period; once leukopoiesis increases, neutropenia resolves without treatment with stimulatory factors	Normal values	May increase	May decrease, but this generally represents margination of circulating neutrophils into the wound
Blood glucose	Increased release of catecholamines in burn patients may lead to hyperglycemia; diabetic patients may require insulin	Levels maintained at ≤ 120 mg/dl	Hyperglycemia, which may misleadingly increase urine output	Hypoglycemia, especially in infants (< 20 kg), who have decreased glycogen stores
Electrolytes	Electrolyte status depends on the type of crystalloid used for resuscitation; hypernatremia and hyponatremia can be avoided by resuscitation with lactated Ringer solution; use of normal saline should be avoided because it can lead to hyperchloremic acidosis	Normal electrolyte levels	—	—
Plasma protein and myoglobin levels	Patients with very deep burns or electrical burns may have elevated plasma myoglobin levels	Decreased albumin level within the first 8 hr after burn injury may be normal	Myoglobinemia may result from prolonged underresuscitation and tissue ischemia	Myoglobinemia may result if excessive resuscitation leads to compartment syndrome; escharotomy should be performed to minimize rhabdomyolysis
Prothrombin time, partial thromboplastin time, and platelet count	Initial values are useful to determine whether the patient has preexisting hepatic or hematologic disease	Normal	Prolonged shock and underresuscitation may lead to disseminated intravascular coagulation; coagulation factors and platelets may be needed in such cases	Unrecognized compartment syndrome and delayed escharotomy may cause tissue ischemia and disseminated intravascular coagulation; a dropping platelet count may indicate heparin-induced thrombocytopenia

space, carbonaceous sputum, and an elevated carboxyhemoglobin level ($> 15\%$).

Carbon Monoxide Poisoning

CO injury is the most commonly recognized form of inhalation injury and the most common cause of death in inhalation injury. Clinical signs and symptoms of CO toxicity correlate with arterial carboxyhemoglobin levels, which can be used to quickly and precisely determine the degree of CO intoxication [see Table 7]. CO intoxication can be easily treated with 100% inhaled oxygen, which rapidly accelerates the dissociation of CO from hemoglobin [see Table 8]. Hyperbaric oxygen therapy has been touted as a superior treatment for quickly reducing carboxyhemoglobin levels,¹⁶ but the data are controversial and the studies are generally poorly controlled.¹⁷ Hyperbaric oxygen therapy may be appropriate in a patient with impaired neurologic status and a markedly elevated carboxyhemoglobin level ($\geq 25\%$). However, the risks (including barotrauma) associated with isolation in a hyperbaric chamber may be too significant for a burn patient ($\geq 10\%$ TBSA) undergoing resuscitation. In one study of 10 patients with combined inhalation injury and burns treated acutely with hyperbaric oxygen, seven patients survived but the complications included aspiration (two cases), cardiac arrest (two cases), hypovolemia with metabolic acidosis (three cases), respiratory acidosis (four cases),

cardiac dysrhythmia (three cases), and eustachian tube occlusion (two cases).¹⁸ Consensus is growing that when cardiac arrest complicates inhalation injury, the result is uniformly fatal regardless of aggressive therapy, including hyperbaric oxygen therapy.¹⁹

Upper Airway Thermal Injury

Direct thermal damage tends to occur in the upper airway rather than in the lower airway because the oropharyngeal cavity has a substantial capacity to absorb heat. Upper airway thermal injury constitutes an important indication for intubation, because it is mandatory to control the airway before airway edema develops during resuscitation.

The diagnosis of upper airway thermal injury is achieved with direct laryngoscopic visualization of the oropharyngeal cavity. The decision whether to intubate should be based on visual evidence of pharyngeal burns or swelling or carbonaceous sputum coming from below the level of the vocal cords. If a patient is phonating without stridor, intubation can often be delayed. Singed facial and nasal hair does not constitute an adequate independent indication for intubation.

Treatment of upper airway injuries includes hospital admission for observation and provision of humidified oxygen, pulmonary toilet, bronchodilators as needed, and prophylactic endotracheal intubation as indicated. Upper airway thermal burns usually man-

ifest within 48 hours after injury, and airway swelling can be expected to peak at 12 to 24 hours after injury. A patient with a true upper airway burn will likely require airway protection for 72 hours. A short course of steroids may facilitate earlier resolution of airway edema in a patient with small cutaneous burns, but a patient with a burn larger than 20% TBSA should not be treated with steroids because of the risk of infection and failure to heal. The decision whether to extubate can be based on pulmonary weaning criteria but also on the presence of an air leak around the endotracheal tube.

Lower Airway Burn Injury

Burn injury to the tracheobronchial tree and the lung parenchyma results from combustion products in smoke [see Table 9] and, under unique conditions, inhaled steam. Numerous irritants in smoke or the vaporized chemical reagents in steam can cause direct mucosal injury, leading to mucosal slough and bronchial edema, bronchoconstriction, and bronchial obstruction. Tracheo-bronchial mucosal damage also leads to neutrophil chemotaxis and release of inflammatory mediators into the lung parenchyma, accentuating the injury with exudate formation and microvascular permeability. Together, these may progress to pulmonary edema, pneumonia, and acute respiratory distress syndrome (ARDS). Reduced myocardial contractility secondary to smoke-toxin inhalation may also contribute to resus-

Table 5 Measures of Pulmonary Function

Measurement	Normal Values	Abnormal Values Indicating Need for Mechanical Ventilation
Tidal volume (V_T), ml/kg	5–8	< 5
Vital capacity (V_C), ml/kg	65–75	< 10; < 15*
Forced expiratory volume in 1 sec (FEV_1), ml/kg	50–60	< 10
Functional residual capacity (FRC), % of predicted value	80–100	< 50
Respiratory rate (f), breaths/min	12–20	> 35
Maximum inspiratory force (MIF), cm H ₂ O	80–100	< 20; < 25; < 30*
Minute ventilation (V_E), L/min	5–6	> 10
Maximum voluntary ventilation (MVV), L/min	120–180	< 20; < (2 × V_E)*
Dead space fraction (V_D/V_T), %	0.25–0.40	> 0.60
P_{aCO_2} , mm Hg	36–44	> 50; > 55*
P_{aO_2} , mm Hg	75–100 (breathing room air); < 70 (mask O ₂)*	< 50 (room air); < 70 (mask O ₂)*
Alveolar-to-arterial Po ₂ gradient [$P(A-a)O_2$], mm Hg	25–65 (breathing 100% O ₂)	> 350; > 450*
Arterial-alveolar Po ₂ ratio (P_{aO_2}/P_{AO_2})	0.75	< 0.15
Arterial Po ₂ -inspired O ₂ (P_{aO_2}/F_iO_2), mm Hg	350–450	< 200
Intrapulmonary right-to-left shunt fraction (Qs/Qt), %	≤ 5%	> 20%; > 25%; > 30%*

*More than one value indicates lack of uniform agreement in the literature.

Table 6 Mechanisms of Pulmonary Dysfunction and Indications for Mechanical Ventilation

Mechanism	Best Indicator
Inadequate alveolar ventilation	P_{aCO_2} and pH
Inadequate lung expansion	Tidal volume, respiratory rate, VC
Inadequate respiratory muscle strength	MIF; MVV; VC
Excessive work of breathing	V_E required to keep Pco_2 normal; V_D/V_T ; respiratory rate
Unstable ventilatory drive	Breathing pattern, clinical setting
Severe hypoxemia	$P(A-a)O_2$; P_{aO_2}/P_{AO_2} ; P_{aO_2}/F_iO_2 ; Qs/Qt

MIF—maximum inspiratory force MVV—maximum voluntary ventilation
 $P(A-a)O_2$ —alveolar-to-arterial Po₂ gradient P_{aO_2}/F_iO_2 —ratio of arterial Po₂ to inspired O₂
 Qs/Qt—intrapulmonary right-to-left shunt fraction VC—vital capacity V_D/V_T —dead space fraction V_E —minute ventilation

citation failures in burn victims with concomitant inhalation injury.

Inhalation injury can often be a clinical diagnosis.¹⁴ Lower airway injury can be confirmed by bronchoscopy or xenon-133 ventilation-perfusion scan,²⁰ but these modalities do not change therapeutic choices or clinical outcome.²¹

ACUTE LUNG INJURY AND ACUTE RESPIRATORY DISTRESS SYNDROME

Understanding of the pathophysiology of ARDS has improved since its initial description in the late 1960s,²² and ARDS-related deaths were lower in the period 1995 through 1998 than in the period 1990 through 1994; however, 40% to 70% of patients with ARDS still die of the disease.²³ ARDS is an independent risk factor for death in burn patients.²⁴ Mortality in burn patients with ARDS is attributable to overwhelming sepsis and

Table 7 Clinical Manifestations of Carbon Monoxide Poisoning

Carboxyhemoglobin Level (%)	Clinical Manifestations
< 10	None
15–25	Nausea, headache
30–40	Confusion, stupor, weakness
40–60	Coma
> 60	Death

Table 8 Half-life of Carbon Monoxide–Hemoglobin Bonds with Inhalation Therapy

Carboxyhemoglobin Half-life	Treatment Modality
4 hr	Room air
45–60 min	100% oxygen
20 min	100% oxygen at 2 atm (hyperbaric oxygen)

Table 9 Clinical Findings Associated with Specific Inhaled Products of Combustion

Source	Product of Combustion	Clinical Effect
Organic matter	Carbon monoxide Carbon dioxide	Poor tissue oxygen delivery Narcosis
Wood, paper, anhydrous ammonia	Nitrogen oxides (NO, NO ₂)	Airway mucosal irritation, pulmonary edema, dizziness
Polyvinyl chloride (plastics)	Hydrogen chlorine	Airway mucosal irritation
Wool, silk, polyurethane (nylon)	Hydrogen cyanide	Respiratory failure, headache, coma
Petroleum products (gasoline, kerosene, propane, plastics)	Carbon monoxide, nitrogen oxide, benzene	Airway mucosal irritation, coma
Wood, cotton, paper	Aldehydes	Airway mucosal irritation, lung parenchyma damage
Polyurethane (nylon)	Ammonia	Airway mucosal irritation

multiple organ failure rather than to respiratory failure alone.²⁵

Clinically, ARDS is characterized by pulmonary edema, refractory hypoxemia, diffuse pulmonary infiltrates, and altered lung compliance. Pathologically, it is distinguished by diffuse alveolar epithelial damage with microvascular permeability and subsequent inflammatory cell infiltration into the lung parenchyma, interstitial and alveolar edema, hyaline membrane formation, and, ultimately, fibrosis.

The development of ARDS is presaged by high fluid resuscitation requirements, reflecting increased microvascular permeability and leading to increased pulmonary edema. ARDS commonly develops within 7 days after injury. The likelihood of death is significantly increased in patients with a multiple organ dysfunction score of 8 or higher and a lung injury score of 2.76 or higher. In one review, burn patients with inhalation injury had a 73% incidence of respiratory failure (with hypoxemia, multiple pulmonary infections, or prolonged ventilator support) and a 20% incidence of ARDS, whereas patients without inhalation injury had a 5% incidence of respiratory failure and a 2% incidence of ARDS.²⁴ Advanced age is also an important risk factor for the development of ARDS—indeed, one small retrospective study has suggested that age is the only independent major predisposing factor for ARDS.²⁶ Curiously, acute lung injury rarely develops in patients with inhalation injury but without cutaneous burns.^{27,28}

Inflammatory Mediators in ARDS with Burn Injuries

Local and systemic inflammatory mediators released in response to burn injury include platelet-activating factor, interleukins (IL-1, IL-2, IL-6, and IL-8), prostaglandin, thromboxane, leukotrienes, hematopoietic growth factors (granulocyte-macrophage colony-stimulating factor, macrophage colony-stimulating factor, and granulocyte colony-stimulating factor), cell adhesion molecules (intercellular cell adhesion molecule-1, endothelial-leukocyte adhesion molecule-1, and vascular cell adhesion molecule-1), and nitric oxide (NO).^{29,30} Systemic levels of circulating tumor necrosis factor- α (TNF- α) and IL-1 correlate with ARDS severity. IL-2 promotes multisystem organ edema,

lung neutrophil sequestration, and platelet activation through alterations in microvascular permeability. Clinical studies have correlated infection—but not isolated inhalation injury—with increased IL-2 levels, which reemphasizes the potential significance of the double insult inflicted by the combination of a burn and an inhalation injury.³¹ Some data suggest that relative imbalances in levels of inflammatory mediators may be more important than absolute values.

An important cell in the inflammatory cycle is the pulmonary alveolar macrophage, a phagocytic cell that produces reactive oxygen intermediates (ROIs) as a means of killing microorganisms. In animal models, addition of a burn injury to a smoke insult exaggerates lipid peroxidation and hypoproteinemia, implicating reactive oxygen species in the pathophysiology of ARDS. With systemic inflammation, unchecked ROI production may lead to local tissue injury. ROIs damage cells by direct oxidative injury to cellular proteins and nucleic acids, as well as by inducing lipid peroxidation, which leads to the destruction of the cell membrane. ROIs are generated under conditions of ischemia-reperfusion (as with failed resuscitations), which occurs when the flow of oxygenated blood is restored to ischemic tissue such as unexcised eschar. During ischemia, there is increased activity of xanthine oxidase and increased hypoxanthine production; when reperfusion reintroduces oxygen, the xanthine oxidase and hypoxanthine generate ROIs, which cause more tissue injury.

Management of ARDS

In spite of 30 years of advances in ARDS treatment, patients with ARDS still must depend on mechanical respiratory support—not treatment—as the primary therapeutic intervention while the alveolar epithelium repairs itself, the capillary permeability resolves, and the lung heals. Restricting fluids to prevent further edema formation has increased survival. The most encouraging strategy to prevent lung injury and increase survival has been low tidal volume mechanical ventilation, commonly called lung protective ventilation, with or without high levels of positive end-expiratory pressure.³² Pharmacologic approaches to treating ARDS in burn patients parallel those used in other critically ill surgical patients and are addressed elsewhere [see **8.4 Pulmonary Insufficiency**].

For most patients with pulmonary complications from thermal injury, conventional ventilatory approaches will be adequate. However, the population at risk for development of ARDS may need more sophisticated management to reduce barotrauma and pulmonary infection in the minimally compliant lung with increased airway pressures. In the past, conventional ventilator management of inhalation injury and ARDS, which emphasizes normalization of blood gases, promoted high rates of barotrauma—that is, ventilator-induced lung injury that is physiologically and histopathologically indistinguishable from ARDS itself. Overdistention and cyclic inflation of injured lung exacerbates underlying lung injury and perpetuates systemic inflammation. These effects can be minimized by maintaining low tidal volumes and peak pressures and by applying positive end-expiratory pressure. Hence, the use of alternative modes of ventilation (e.g., volume-limited ventilation with or without inverse-ratio ventilation, prone positioning, and tracheal gas insufflation) has increased in patients at risk for ARDS. No single approach is likely to benefit all patients, and adjustment of ventilatory controls must be based on individual clinical responses.

Lung-protective ventilation Lung-protective ventilation utilizes low inspiratory volumes (4 to 6 mL/kg) to keep peak inspi-

ratory pressures below 40 cm H₂O. This strategy is limited by the accumulation of carbon dioxide (so-called permissive hypercapnia), although respiratory acidosis with a pH as low as 7.20 is tolerated.

The ARDS Network Study found that ARDS patients ventilated with low tidal volumes had a 22% lower mortality than patients ventilated with conventional means.^{32,33} The volume-preset, assist-control mode is recommended for tidal volume control, and the respiratory rate should be slowly increased as tidal volume is reduced to maintain minute ventilation and prevent acute hypercapnia. Tidal volume can be increased for severe acidosis (pH ≤ 7.15). Ventilator inspiratory flow should be optimized to minimize dyspnea. If dyspnea results in asynchronous breaths, sedation may be necessary or the tidal volume can be titrated to 7 to 8 ml/kg, provided that peak inspiratory pressures are below 40 cm H₂O. Pressure support levels between 5 and 20 cm H₂O can be titrated to keep the respiratory rate below 35 breaths/min and may be useful for weaning.

One study of children with burns found that low tidal volume ventilation was associated with low incidences of ventilator-induced lung injury and respiratory-related deaths,³⁴ which supports the use of this modality in thermally injured patients. In fact, in patients with large burns and inhalation injury, it may be warranted to use low tidal volume ventilation before ARDS develops. The early resuscitative phase may be the optimal time to initiate this approach.

Prone positioning Changing a patient's position from supine to prone is emerging as a simple and inexpensive strategy to improve gas exchange in acutely injured lungs. Studies report that despite concerns about airway protection, this is a safe intervention that may improve the ratio of arterial oxygen pressure to fraction of inspired oxygen (P_aO_2/F_iO_2) early in the course of ARDS.³⁵ Some data suggest that prone positioning in conjunction with NO administration may improve arterial oxygenation.³⁶ However, no clinical trials have examined the use of prone positioning in burn patients. If prone positioning has a significant effect, this positive result presumably would be evident during operative procedures when a patient with an acute lung injury is placed in this position (e.g., for excision of a posterior torso burn). Furthermore, prone positioning may be relatively contraindicated in a patient with a burned head who is at extreme risk for loss of control of the airway because of facial swelling and difficulty securing an endotracheal tube.

Extracorporeal membrane oxygenation Few centers have experience with extracorporeal membrane oxygenation (ECMO), and published information on its use for the treatment of ARDS in patients with inhalation injury and burns is mostly confined to anecdotal case reports.³⁷ Given its experimental nature and its high cost, ECMO is reserved for patients in whom other ventilatory modalities fail. Although ECMO has been shown to increase survival in some children with large burns and severe acute lung injury, patients with higher ventilator requirements before undergoing ECMO generally do not survive, suggesting that if ECMO is to be successful, it must be instituted early to prevent barotrauma and irreversible lung injury.³⁸ Early implementation of permissive hypercapnia may be equally effective.

High-frequency percussive ventilation High-frequency percussive ventilation (HFPV) is another strategy for maintaining low peak pulmonary pressure and preventing alveolar overdistension. HFPV has the added advantage of facilitating mucosal clear-

ance of tracheobronchial casts that occlude the airway and predispose to pulmonary infection. Although HFPV is usually described as rescue therapy for patients in whom conventional therapy has failed, there is some evidence that it can reduce mortality and the incidence of pneumonia in patients with inhalation injury.^{39,40} Improved oxygenation and pulmonary toilet has been reported in patients treated early with HFPV,⁴¹ which suggests that a larger-scale prospective trial is warranted to determine whether the benefits of HFPV justify the added cost and effort of maintaining multiple types of ventilators and credentialing for respiratory therapists.

A similar method, high-frequency oscillatory ventilation, may have no impact on burn mortality. However, it may have a role in the supportive management of burn patients with severe oxygenation failure that is unresponsive to conventional ventilation.⁴²

Nitric oxide inhalation Endogenously produced NO plays an important role in the changes in systemic and pulmonary microvascular permeability seen in an animal model of combined smoke inhalation and third-degree burn.³⁰ Clinically, inhaled NO may be useful in burn patients with severe acute lung injury in whom conventional ventilatory support is failing.⁴³ The safety of inhaled NO in these patients is indicated by low methemoglobin levels and absence of hypotension attributable to the NO. Strong, immediate, and sustained improvement in the P_aO_2/F_iO_2 and reduction in pulmonary arterial mean pressure in response to NO seem to correlate with survival. However, the use of inhaled NO has been reported in only small numbers of burn patients, and a prospective study is warranted.

Corticosteroids The use of corticosteroids in the treatment of burns is problematic because of the negative effect these agents have on wound healing. Nevertheless, there is some evidence that rescue treatment with corticosteroids in the late chronic fibroproliferative phase of ARDS may decrease mortality and lower the P_aO_2/F_iO_2 .⁴⁴ Ongoing multicenter studies in patients with small burns and inhalation injury are under way.

TRACHEOSTOMY VERSUS ENDOTRACHEAL INTUBATION

Transmural airway inflammation from inhaled gases and heat necessitates endotracheal airway protection, yet the use of endotracheal tubes in such cases may be complicated by tracheal pressure necrosis. Hence, survivors of inhalation injury may develop laryngotracheal strictures. One report suggests that there is a 5.5% incidence of tracheal stenosis in patients with burns and inhalation injury.⁴⁵ The relative risks and benefits of tracheostomies and endotracheal intubation have been debated since the early 1970s. Each modality has its own advantages and complications. Nasotracheal intubation is the least advantageous form of airway protection because of its association with paranasal sinusitis,⁴⁶ as well as pressure necrosis of the alar rim of the burned nose, which is nearly impossible to reconstruct. Therefore, nasotracheal intubation should be avoided unless absolutely necessary.

Tracheostomies are also associated with complications, including tracheal malacia, tracheal stenosis, trachea-innominate artery fistulas, tracheoesophageal fistulas, and posttracheostomy dysphagia.⁴⁷ However, complications associated with tracheostomy may relate to previous long-term endotracheal intubation and to the underlying pathophysiology, suggesting that if tracheostomy is to be done, it should be done early on; furthermore, the tracheostomy tube should be removed at the earliest possible time. In a 1985 study of airway management, tracheal stenosis and tracheal scar granuloma formation were reported to be more frequent and

more severe after tracheostomy than after translaryngeal intubation.⁴⁸ As expected, the duration of tube placement significantly affected the development of permanent damage, leading to the conclusion that initial respiratory support with translaryngeal tubes is preferable for up to 3 weeks. Burn patients who undergo tracheostomy before postburn day 10 may have a lower incidence of subglottic stenosis with no difference in pneumonia incidence, when compared with orally intubated patients.⁴⁹ Nevertheless, tracheostomy has been reported to provide no benefit for early extubation or overall outcome for burn patients.⁵⁰ One major consideration in deciding whether to perform a tracheostomy has been the presence of eschar at the insertion site, which complicates tracheostomy-site care and increases the risk of airway infection. Percutaneous dilatational tracheostomy may provide a reasonable, less invasive approach for patients who are likely to need prolonged ventilatory support.⁵¹ This procedure can be safely performed at the bedside, at one quarter the cost of a conventional tracheostomy. Given ongoing controversies over the relative risks and benefits of endotracheal intubation and tracheostomy in burn patients and the rarity of complications from intubation in our own practice, we perform tracheostomies only when multiple attempts at extubation have failed; these failures usually occur because the patients cannot protect their airway.

Temperature Regulation

Because the burn patient has lost the barrier function of the skin, temperature regulation is an important goal of successful management. Keeping a patient warm and dry is a major goal during resuscitation, especially during the pre–burn center transport of patients. This includes maintaining a warm ambient temperature. Large evaporative losses⁵² combined with administration of large volumes of intravenous fluids that are at room temperature or colder may accentuate the hypovolemia, which will complicate the patient's overall course and may lead to disseminated intravascular coagulopathy. Mild hyperthermia may occur in the first 24 hours as a result of pyrogen release or increased metabolic rate⁵³ and may cause tachycardia that misleadingly suggests hypovolemia. Because infection is unlikely early on, especially within the first 72 hours after injury, elevated temperatures should be treated with antipyrogens to control the energy expenditure associated with increased catabolism.⁵⁴ About 72 hours after injury, patients with thermal injuries commonly develop a hyperdynamic state, the systemic inflammatory response syndrome (SIRS), which is characterized by tachycardia, hypotension, and hyperthermia—classic signs of sepsis that in this case do not have an infectious source.

Although patients with burns are likely to have elevated temperatures and may even have elevated white blood cell counts, fevers in burn patients are not reliable indicators of infections.⁵⁵ At least one study has demonstrated that in pediatric burn patients, physical examination is the most reliable tool for evaluating the source of fever.⁵⁵

Infection Control

Infection is a major potential problem for patients with large thermal injuries. In one review, up to 100% of such patients developed an infection from one or more sources during the hospital stay. It is important to apply sound epidemiologic practice to treating infections, both to limit development of opportunistic infections in individual patients and to achieve good infection control in the burn unit itself.

Tetanus prophylaxis has been standard for patients admitted for

Table 10 Formulas for Estimating Caloric Needs in Burn Patients

HARRIS-BENEDICT FORMULA

$$\text{Basal energy expenditure (BEE)}^* \times \text{activity factor}^\dagger = \text{calories needed daily}$$

CURRERI FORMULA

$$25 \text{ kcal / kg} + 40 \text{ kcal / \%TBSA burned} = \text{calories needed daily}$$

*Women: BEE = $65.5 + 9.6(\text{weight in kg}) + 1.8(\text{height in cm}) - 4.7(\text{age in years})$.

Men: BEE = $66.5 + 13.8(\text{weight in kg}) + 5.0(\text{height in cm}) - 6.8(\text{age in years})$.

†For burns, the activity factor is 2, which may overestimate caloric needs for patients with smaller burns.

TBSA—total body surface area

any type of trauma, primarily because the disease is so devastating and its prevention so simple. There are a few cases in modern medical literature of tetanus in patients who had received immunization during childhood.⁵⁶

For many years, all patients admitted with burn injuries received antibiotic prophylaxis against gram-positive organisms. This practice often led to the development of gram-negative bacterial infections or, even worse, fungal infections. Studies have now verified that prophylactic antibiotics not only are unnecessary but may well be contraindicated in patients with burns.⁵⁷ Therefore, treatment of infections in patients with burns should be based on clinical judgment and supportive laboratory and radiologic findings.

The wound is a primary source of infection for patients with burns [see 7:14 *Management of the Burn Wound*]. The mainstay of both prevention and treatment is daily washing with soap and water and application of a topical broad-spectrum antimicrobial agent. As soon as it becomes evident that a burn wound will not heal, excision and grafting should be performed. Preferably, the decision to proceed with surgery should be made before postburn day 21. For patients who undergo surgery, perioperative antibiotics may reduce postoperative wound infection.⁵⁷

Nutrition

In the early 1970s, Curreri and others recognized that patients with major thermal injury experience hypermetabolism, with an increased basal metabolic rate, increased oxygen consumption, negative nitrogen balance, and weight loss; hence, these patients have exaggerated caloric requirements.⁵⁸ Furthermore, inadequate caloric intake can be associated with delayed wound healing, decreased immune competence, and cellular dysfunction.

A patient with a large burn may lose as much as 30 g of nitrogen a day because of protein catabolism. Not only is urinary excretion of urea nitrogen increased, but large amounts of nitrogen are lost from the wound itself. Therefore, total urea nitrogen levels do not accurately reflect all nitrogen losses in burn patients.⁵⁹ A patient with a small burn ($\leq 10\%$ TBSA) may lose nitrogen at a rate of 0.02 g/kg/day. A moderate burn (11% to 29% TBSA) may be associated with nitrogen losses equaling 0.05 g/kg/day. A large burn ($\geq 30\%$ TBSA) may result in the loss of as much as 0.12 g/kg/day, which may be equivalent to daily losses of 190 g of protein or about 300 g of muscle.

Catabolism generally continues until wounds have healed. However, once a patient becomes anabolic, preburn muscle takes three times as long to regain as it took to lose.^{60,61} Therefore, a

patient in whom it takes 1 month for burn wounds and donor sites to heal may need 3 or more months to regain preburn weight and muscle mass. These statistics underscore the importance of accurately estimating each patient's caloric needs during hospitalization. Over the years, a number of equations have been developed to estimate calorie needs [see Table 10]. Probably the most widely used formula is the Harris-Benedict equation, which estimates basal energy expenditure according to gender, age, height, and weight. The basal energy expenditure is then multiplied by an activity factor that reflects the severity of injury or the degree of illness; for burns, this multiplier is 2, the maximal factor for this formula. The limitation of the Harris-Benedict equation is that it may overestimate caloric needs for patients with burns smaller than 40% TBSA. A formula specific for patients with burns is the Curreri formula,⁶² which is based on patient weight and burn size; this formula may overestimate caloric needs for patients with large burns and therefore is best used for patients with burns less than 40% TBSA.^{63,64}

Ongoing evaluation of metabolic status of the burn patient is necessary to take into account changes in wound size and clinical condition. Metabolic demands decrease with burn healing or grafting; on the other hand, donor sites create new wounds, which may increase catabolic rates. Development of infection or ARDS greatly increases catabolism and may alter caloric needs.⁶⁵ Simple assessment of nitrogen requirements can be determined by measuring 24-hour total urea nitrogen levels in the urine. However, this does not account for nitrogen lost from the wound itself. Serum albumin levels are notoriously unreliable markers of adequate nutrition because they lag behind clinical progress; they are especially known to be low in patients with burns larger than 20% TBSA.⁶⁶ Transthyretin (also known as prealbumin, although it is not related to albumin in structure or function) levels correlate more closely with catabolic status,⁶⁷ and a trend over several weeks may indicate whether the patient's caloric needs are being met.⁶⁸ C-reactive protein levels also provide an indication of the patient's general inflammatory state; high levels may correlate with increased catabolism.⁶⁷ For intubated patients, indirect calorimetry may be helpful in measuring caloric needs but may not be more exact than the Curreri formula.⁶⁹ The so-called metabolic cart is a portable gas analyzer that quantifies volumes of inspired O₂ and expired CO₂ and calculates nutritional requirements according to the following formula:

$$\text{kcal/day} = ([3.9 \times \text{VO}_2] + [1.1 \times \text{VCO}_2]) \times 1.44$$

This result can also be indirectly measured in patients with pulmonary artery catheters in place by using the Fick equation:

$$\text{kcal/day} = \text{cardiac output} \times (\text{arterial PO}_2 - \text{venous PO}_2) \times 10 \times 6.96$$

ENTERAL NUTRITION

As early as 1976, the benefits of enteral nutrition over parenteral nutrition had already been identified for patients with functional gastrointestinal systems.⁷⁰ The problems of prolonged ileus and Curling stress ulcers in burn patients have been largely eliminated by early feeding.⁷¹ Multiple studies have shown that patients with major thermal injury can receive adequate calories within 72 hours after injury.⁷² At the University of Washington burn center, tube feeding is started a median of 5 hours after admission.

There is ongoing debate about the benefits of gastric feeding versus duodenal feeding. Although feeding distal to the pylorus should pose less aspiration risk, one study found evidence of enteral formula in pulmonary secretions of 7% of patients receiving gastric feeds compared with 13% of patients receiving transpyloric

feeding.⁷³ Hence, for burn patients with high caloric needs, the benefit of decreased aspiration with transpyloric feeds may only be theoretical and may be offset by the delay in feeding for confirmation of tube placement; such confirmation is necessary because these tubes can easily flip back into the stomach.

Continuation of tube feedings during surgery in intubated patients who require multiple operations is a safe way to maximize caloric intake and decrease wound infection. There is no need to stop feedings for anesthesia induction and endotracheal intubation⁷⁴; however, intraoperative positioning, especially if the patient will be prone during surgery, may necessitate stopping feedings preoperatively. Mayes and colleagues have presented data that support continuation of tube feedings in critically ill burn patients undergoing decompressive laparotomy.⁷⁵

GLUCOSE LEVELS

The adverse effects of hyperglycemia on wound healing and morbidity highlight the importance of maintaining blood glucose levels at 80 to 110 mg/dl.⁷⁶ In pediatric burn patients, poor glucose control has been associated with bacteremia, reduced skin-graft take, and higher mortality.⁷⁷

ALBUMIN LEVELS

Burn patients characteristically have hypoalbuminemia that persists until wounds are healed and the rehabilitation phase of recovery has begun. In fact, patients with large burns have serum albumin levels that average 1.7 g/dl and never exceed 2.5 g/dl.⁶⁶ Management of hypoalbuminemia is controversial, but there is general agreement that once burn resuscitation is complete, infusion of exogenous albumin to serum levels above 1.5 g/dl does not affect burn patient length of stay, complication rate, or mortality.⁷⁸

NUTRITIONAL SUPPLEMENTS

Specialized nutritional formulas with purported effects on metabolic rate and immunologic status have garnered a great deal of interest as adjuncts in the management of critically ill and injured patients.⁷⁹ Much of the information on nutritional requirements for critically ill patients was derived from an animal burn model,⁸⁰ however, and studies on the efficacy of specialized nutritional supplements in humans have generated contradictory data. A randomized trial of nutritional formulas that were intended to enhance immune status and that included essential amino acids and omega-3 fatty acids showed no clinical advantage in burn patients.⁸¹ However, another study demonstrated that glutamine supplementation in adult burn patients resulted in significantly lower mortality and infection rates.⁸² Other nutritional or metabolically active supplements that have demonstrated promise in promoting anabolism in burn patients include insulin, recombinant human growth factor, the anabolic steroid oxandrolone, and propranolol.⁸³ Oxandrolone in particular has produced marked improvements in weight gain, return to function, and length of hospital stay.⁸⁴ Early administration of antioxidant supplementation with α-tocopherol and ascorbic acid has been shown to reduce the incidence of organ failure and shorten ICU length of stay in critically ill surgical patients.⁸⁵ Whether this is true for burn patients remains to be demonstrated, but the relative low cost and the low risk of complications make this an attractive intervention for burn patients at risk for ARDS.

Anemia

Because acute blood loss is uncommon in a patient with an isolated burn injury, a rapidly decreasing hematocrit during resuscita-

tation should prompt an evaluation for associated injuries. Procedures during resuscitation, such as central venous line placement or escharotomies, should not be associated with significant blood loss.

Anemia was a major problem in burn management before early excision and grafting became commonplace. As excision techniques have become more sophisticated [see 7:14 Management of the Burn Wound], operative blood loss has decreased, as has the need for transfusion.^{86,87} Nevertheless, excision and grafting may be associated with large blood loss, and the operating team must be prepared for intraoperative blood transfusion.

Decisions about transfusion must be based on the patient's age, overall condition, and comorbidity. The risks of viral transmission and transfusion reactions, as well as the cost, must also be carefully considered. For an otherwise healthy patient who does not need surgery, a hematocrit as low as 20% may be tolerated. However, patients with inhalation injury or ARDS may benefit from the greater oxygen-carrying capacity afforded by a higher hematocrit. Patients with large burns and anticipated blood loss during hospitalization should probably receive iron supplements.

Given that the literature contains some indication that erythropoietin levels may be elevated in patients with large burns, the benefit of exogenous erythropoietin is debatable.⁸⁸ At least one prospective study suggests that administration of recombinant erythropoietin in acutely burned patients does not prevent anemia or decrease transfusion requirements.⁸⁹

Pain Management

Pain management for patients with burn injuries can be challenging. The simplest approaches work best; polypharmacy is likely to confuse both patient and health care providers and should therefore be avoided. Burn patients experience several different classes of pain: background, breakthrough, and procedural. Each responds to a different approach.

Background pain is the discomfort that burn patients experience throughout the day and night. It is best treated with long-acting pain relievers. For a hospitalized patient with large burns, methadone or controlled-release morphine sulfate may be the most appropriate choice for background pain. In an outpatient with a small burn, a nonsteroidal anti-inflammatory drug (NSAID) may be optimal; if excision and grafting are planned, the NSAID should be stopped at least 7 days before surgery to permit recovery of platelet function.

Breakthrough pain results when activities of daily living exacerbate burn-wound discomfort. Short-acting narcotics or acetaminophen are used to alleviate breakthrough pain. Persistent breakthrough pain indicates that the dose of the long-acting medication should be increased.

Procedural pain is the discomfort that patients experience during wound care and dressing changes. This usually requires treatment with a short-acting narcotic. For inpatients with larger burns,

oral narcotics or transmucosal fentanyl citrate⁹⁰ work well for wound care; I.V. morphine or fentanyl is used for uncontrolled pain. For outpatients, oxycodone (5 to 15 mg) works well for daily wound care.

Anxiety related to wound care is an underdiagnosed and under-treated source of discomfort that is often construed as pain, especially in children. Therefore, patients with large burns requiring wound care once or twice a day should be evaluated to determine whether they would benefit from a short-acting anxiolytic agent for procedures.

Learning to accurately assess pain in burn patients can help prevent complications related to excessive narcotic use, such as prolonged sedation, delirium, and, more urgently, loss of airway control. This is especially true in young children and elderly patients, who may have decreased ability to tolerate narcotics.^{91,92}

Nonpharmacologic approaches are also an important component of pain management in burn patients. Hypnosis—administered either by trained health care providers or, more efficiently, by patients themselves—has proved to be a useful tool for reducing narcotic use in patients with burns.⁹³ Another distraction modality that has shown promise and garnered significant publicity has been virtual reality. Although it is not a standard of care for all patients admitted with burn injuries, preliminary observations suggest that use of virtual reality can enhance patient comfort during wound care and intense therapy.

Discomfort in the healed wound may persist for months after injury. In general, narcotics do not control such symptoms; exercise and deep massage are more effective. Itching can be a pervasive long-term symptom for which there is no reliable topical or systemic therapy. Diphenhydramine, cyproheptadine, or cetirizine may relieve itching. There are also promising data on the use of doxepin ointment as a topical treatment for itching of healed wounds.⁹⁴ Keeping the wound moist with a topical salve may be as effective as other pharmacologic approaches.

Deep Vein Thrombosis Prophylaxis

The incidence of deep vein thrombosis (DVT) and, thus, the need for DVT prophylaxis in patients with thermal injury have never been clearly defined. Whereas some studies report DVT in as many as 25% of all hospitalized burn patients and advocate DVT prophylaxis,⁹⁵ others report that thromboembolism is responsible for only 0.14% of deaths in burn patients and does not warrant the potential complications of anticoagulation therapy.⁹⁶ At the University of Washington burn center, a quality-assurance review found that in patients with burns larger than 20% TBSA, clinically evident thromboembolic disease occurred in 9% of those who received prophylaxis with unfractionated heparin and in 18% of those who received low-molecular-weight heparin. On the basis of these data, patients with burns larger than 20% TBSA receive prophylaxis with subcutaneous unfractionated heparin, 5,000 U twice a day.

14 MANAGEMENT OF THE BURN WOUND

Matthew B. Klein, M.D., David Heimbach, M.D., F.A.C.S., and Nicole Gibran, M.D., F.A.C.S.

Advances in resuscitation and critical care have significantly improved survival after thermal injury. Ultimately, survival remains contingent on effective wound management and complete wound closure. Current approaches to burn management are based on an understanding of the biology and physiology of human skin and the pathophysiology of the burn wound.

Anatomic and Physiologic Considerations

BIOLOGY OF SKIN

Skin consists of two distinct layers, the epidermis and the dermis; these layers are integrated by a structure known as the basement membrane zone (BMZ) [see Figure 1]. The epidermis is the outer layer and acts as the barrier between body tissues and the environment. This layer protects against infection, ultraviolet light, and evaporation of fluids and provides thermal regulation. The epidermis is derived from fetal ectoderm and thus, like other ectodermal derivatives, is capable of regeneration. Repair of epidermal wounds is achieved through regeneration of epidermal cells both from the perimeter of the wound and from the adnexal structures of the epidermis (i.e., hair follicles, sweat glands, and sebaceous glands). Accordingly, pure epidermal injuries heal without scarring.¹

The principal cell of the epidermis is the keratinocyte. These cells are arranged into five progressively differentiated layers, or strata: the stratum basale, the stratum spinosum, the stratum granulosum, the stratum lucidum, and the stratum corneum. The outermost of these layers—the relatively impermeable stratum corneum—provides the barrier mechanism that protects the underlying tissues. Besides keratinocytes, the epidermis contains cells from other embryologic layers that carry out specific functions. Melanocytes, derived from fetal neuroectoderm, produce melanosomes, which become pigmented as a result of the formation of melanin through the action of the enzyme tyrosinase. Melanin provides the skin with its pigment and absorbs harmful ultraviolet radiation. Langerhans cells, derived from bone marrow cells, play a critical role in the immune function of the skin. These cells recognize, phagocytize, process, and present foreign antigens and, through their expression of class II antigens, initiate the rejection process in skin transplantation.¹

In contrast to the epidermis, the dermis is a complex network comprising cellular and acellular components. This layer provides skin with its durability and elasticity. Structurally, the dermis consists of two sublayers, a superficial one (the papillary dermis) and a deeper one (the reticular dermis). Collagen is the major structural matrix molecule, constituting approximately 70% of the skin's dry weight. Elastic fibers account for approximately 2% of the skin's dry weight and play an important role in maintaining the integrity of the skin after mechanical perturbation.¹ Glycosaminoglycans (GAGs), the third major extracellular component of the dermis, regulate intracellular and intercellular events by binding to, releasing, and neutralizing cytokines and growth factors.^{2,3}

The fibroblast is the principal cell of the dermis and is responsible for synthesis and degradation of fibrous and elastic dermal proteins. The dermis also contains various inflammatory cells (derived from bone marrow stem cells), mast cells, and cells associated with vascular, lymphatic, and nervous tissue.

The BMZ is a complex region of extracellular matrix connecting the basal cells of the epidermis with the papillary dermis. At the light-microscopic level, the dermal-epidermal junction consists of protrusions of dermal connective tissue known as dermal papillae, which interdigitate with epidermal projections known as rete ridges. The structure of the BMZ is best appreciated on electron microscopy, where it appears as a trilaminar zone consisting of a central electron-dense region (the lamina densa) flanked on both sides by regions of lower electron density [see Figure 2]. Within the basal cells of the epidermis are multiple sites of attachment to the basal lamina, which are known as hemidesmosomes. On the dermal side of the basal lamina are numerous anchoring fibrils, which reach from the lamina into the connective tissue of the dermis.¹ The BMZ plays a significant role in burn wound healing: epithelialized wounds undergo blis-

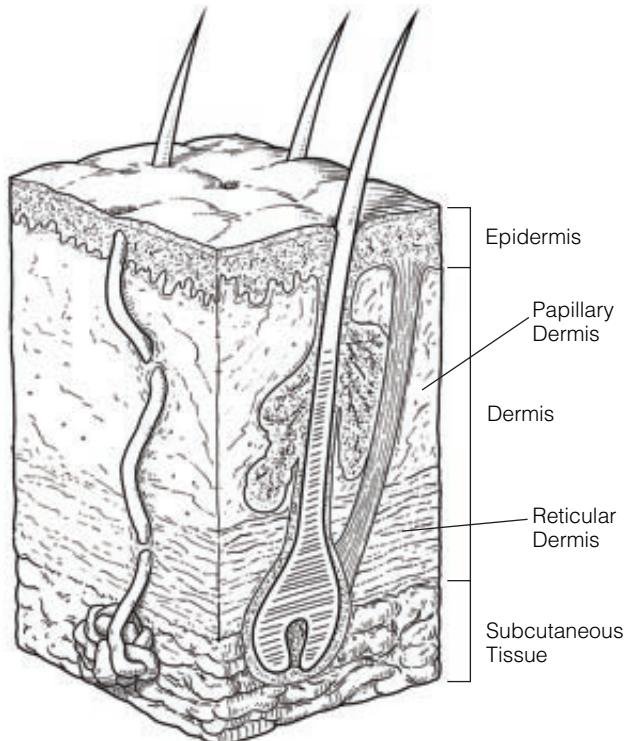

Figure 1 Cross-sectional diagram shows the two distinct layers of the skin—the epidermis and the dermis (papillary and reticular)—and the underlying subcutaneous fat.

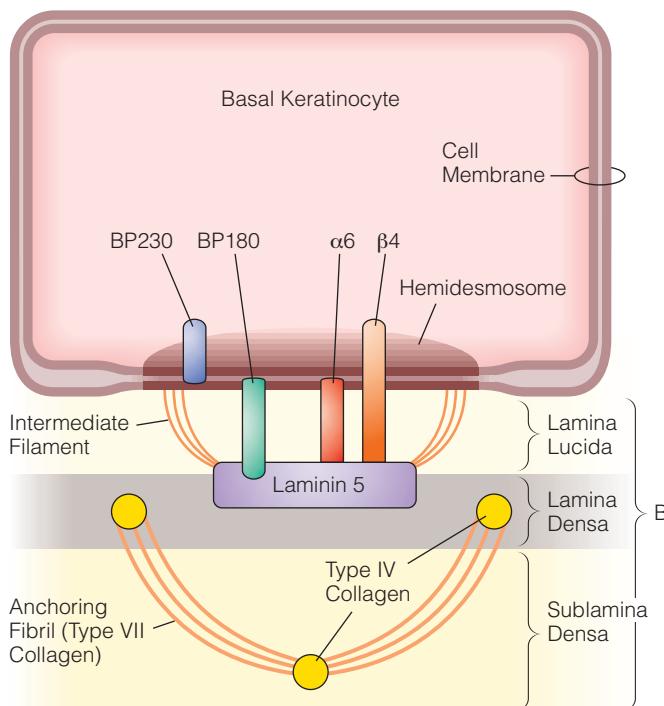

Figure 2 The basement membrane zone (BMZ) integrates the epidermis with the underlying dermis. On electron microscopy, the BMZ has three layers: a central electron-dense region known as the lamina densa and two regions of lower electron density to either side of this central region.

tering until the anchoring structures of the BMZ mature and provide protection from shearing.

PATOPHYSIOLOGY OF THERMAL INJURY

Jackson's classification of burn wounds remains the foundation of our understanding of the pathophysiology of thermal injury to the skin.⁴ In this classification, there are three zones of tissue injury resulting from a burn [see Figure 3]. The central, most severely damaged area is called the zone of coagulation because the cells in this area are coagulated or necrotic. Tissue in this zone must be debrided

Table 1 Overview of Burn Wound Management

Burn Wound Type	Clinical Features	Management
Superficial	Erythematous, painful	Soothing, moisturizing lotions (i.e., aloe)
Partial-thickness	Blistered, pink, moist, painful	Silver sulfadiazine; greasy gauze once epithelial buds are present
Deep partial-thickness	Dry, mottled pink-and-white, less painful	Silver sulfadiazine dressings daily; surgical excision and grafting if not going to heal within 3 wk
Full-thickness	Dry, leathery, black or white, painless	Silver sulfadiazine; early excision and skin grafting

ed. The zone of coagulation is surrounded by the zone of stasis, an area characterized by vasoconstriction and ischemia. Tissue in this zone is initially viable; however, it may convert to coagulation as a consequence of the development of edema, infection, and decreased perfusion.⁴ With good wound perfusion, tissue in the zone of stasis generally remains viable. Surrounding the zone of stasis is the zone of hyperemia, an area characterized by vasodilation resulting from the release of inflammatory mediators from resident cutaneous cells. Tissue in this zone typically remains viable.

Clinical Evaluation and Initial Care of Burn Wound

After admission to the burn center, the burn wound is cleaned with soap and water, blisters and debris are removed, and the extent and depth of the wound are assessed. Management of tar burns warrants special mention. When tar that has been heated to maintain a liquid form comes into contact with skin, it can transfer sufficient energy to cause a significant burn injury. As the tar cools on the skin, it solidifies, thereby becoming difficult to remove. Solvents such as petrolatum, petrolatum-based ointments, lanolin, and Medi-Sol (Orange-Sol, Inc., Gilbert, Arizona) are useful for tar removal. For optimal effect, 10 to 15 minutes should be allowed after solvent application before removal of the tar is attempted. Repeat applications may be necessary for complete removal.

ASSESSMENT OF BURN DEPTH

Thermal injury can damage the epidermis alone, the epidermis along with a portion of the dermis, or the entire skin and can even extend into the underlying subcutaneous tissue. The depth of the injury affects the subsequent healing of the wound; thus, assessment of burn wound depth is important for selection of wound dressings and, ultimately, for determination of the need for surgery [see Table 1].

Superficial burns involve only the epidermis. They typically are erythematous and painful, much as a sunburn would be. Most such burns heal within 3 to 4 days, without scarring. The usual treatment is a soothing moisturizing lotion (e.g., one containing aloe vera), which both optimizes the rate of reepithelialization and provides comfort to the patient.

Partial-thickness burns extend through the epidermis and into the papillary dermis. Blistering is their hallmark [see Figure 4]. These burns can be further categorized as superficial or deep. Superficial partial-thickness burns are typically pink, moist, and

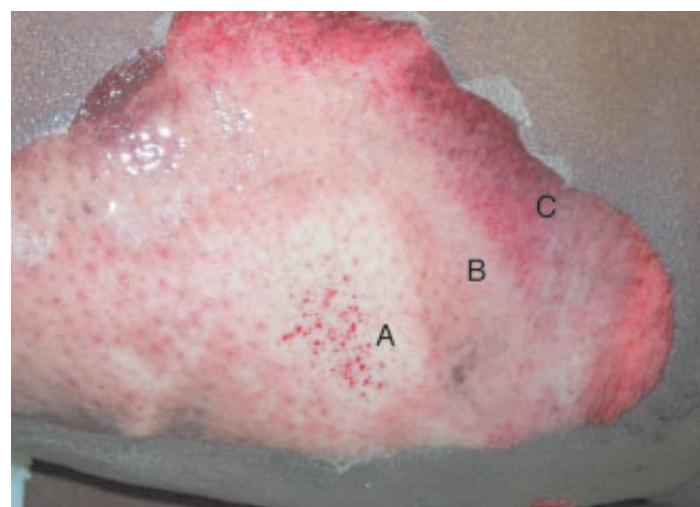

Figure 3 A burn wound is characterized by three zones of injury: A represents the zone of coagulation, B the zone of stasis, and C the zone of hyperemia.

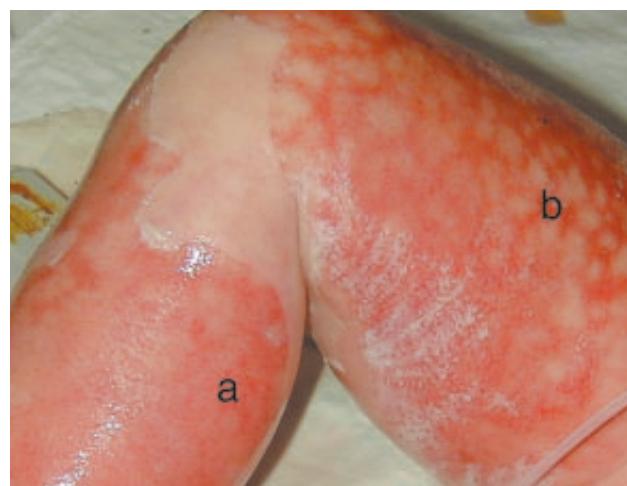

Figure 4 Shown at left is a shallow scald burn with the pink, moist appearance typical of a superficial partial-thickness burn wound. Such injuries typically heal without the need for excision and grafting. A superficial partial-thickness burn (right, *a*), which involves only the papillary dermis, is visually distinct from a deep partial-thickness burn (right, *b*), which is mottled in appearance, extends into the reticular dermis, and is more likely to require excision and grafting.

painful. They usually heal within 2 to 3 weeks, without scarring or functional impairment. Deep partial-thickness wounds extend into the reticular layer of the dermis. They are typically a mottled pink-and-white, dry, and variably painful. In some cases, they may be difficult to distinguish from full-thickness burns. Deep partial-thickness burn wounds, if they do not become infected, typically heal in 3 to 8 weeks, with severe scarring, contraction, and loss of function. Therefore, if a partial-thickness burn has not healed by 3 weeks, surgical excision and skin grafting may be required.

Full-thickness burn wounds extend through the entire dermis and into the subcutaneous tissue. These burns are typically white or black, dry, and painless [see *Figure 5*]. Some full-thickness burns appear red, but they can be distinguished from superficial burns because they are not moist and do not blanch with pressure. Because all skin appendages are burned away, full-thickness burns can heal only by contraction or migration of keratinocytes from the periphery of the wound. Accordingly, all full-thickness burns, unless they are quite small (e.g., the size of a quarter or smaller), must be treated with excision and grafting.

As a rule, both superficial and full-thickness burns are easily recognized, and treatment decisions are relatively straightforward. It is frequently difficult, however, to determine the ultimate fate of intermediate partial-thickness burns soon after injury. For this reason, these wounds are often referred to as indeterminate-thickness wounds. Over the course of the first several postburn days, it usually becomes easier to determine which indeterminate-thickness wounds are likely to heal in a timely manner, without the need for grafting.

Various techniques for accurately and readily assessing burn depth have been described, including the use of vital dyes, laser flowmetry, thermography, and magnetic resonance imaging, but none of these has ever been shown to yield a more precise determination of burn depth than clinical evaluation by an experienced burn care provider.⁵

DETERMINATION OF NEED FOR ESCHAROTOMY

Burn wound eschar consists of dead skin, has the consistency of leather, and may restrict limb perfusion by creating a nonelastic exoskeleton. A key issue in assessing burn wounds is whether

escharotomies are necessary. In general, escharotomies are required only for circumferential full-thickness extremity burns in which distal perfusion has been compromised or for chest burns in which eschar poses an external mechanical barrier to respiration. Escharotomies can be performed at the bedside with either a scalpel or an electrocautery. They should extend through the eschar only, not through the muscle fascia. Adequate release is signaled by separation of the eschar, improved distal perfusion, and, sometimes, a popping sound. Because an escharotomy is a superficial incision through dead tissue, only minimal doses of analgesics and anxiolytics are required.

DAILY BURN WOUND CARE

The use of hydrotherapy tanks, previously a standard component of burn unit wound care, has fallen from favor somewhat because of the risks of cross-contamination between one burn wound area and another. It is preferable to place the patient on a

Figure 5 Shown is a full-thickness flame burn with a characteristic brown, leathery appearance. Such wounds require excision and subsequent skin grafting.

Figure 6 Shower tables are generally preferred to Hubbard tanks for burn wound care. A clean plastic drape can be used to cover the shower table during patient care.

shower table, which is inclined so that water runs off the wounds and into a drain [see Figure 6]. Smaller wounds can often be managed with bedside wound care after a shower. Washing with tap water and regular soap suffices for daily burn wound cleansing. It is important to be cognizant of the need to provide adequate sedation and analgesia while performing daily wound care—a particularly challenging task with infants and elderly patients.

Topical Burn Wound Treatment

GENERAL PRINCIPLES

Because thermal injury disrupts the protective barrier function of the skin, dressings are needed to protect the body against environmental flora. Burn dressings also protect against evaporative heat loss. The ideal burn dressing would be inexpensive and comfortable and would not require frequent changing. Daily dressing changes allow the burn care provider not only to apply clean dressings but also to clean the wounds and debride fragments of separated eschar and devitalized tissue.

Numerous topical agents and dressings are available for use in burn patients; we limit our discussion to the ones that are most commonly employed and have proved most effective. Selection of an appropriate dressing for a given wound is governed by the specific goals of management. With purely superficial wounds, the goal is to create a moist environment that will optimize reepithelialization. Typically, this is achieved by applying ointments or lotions. With partial-thickness and full-thickness wounds, however, it is necessary to include agents that protect against microbial colonization (see below). Once a partial-thickness burn demonstrates evidence of epithelialization, dressings should be changed to a regimen that facilitates healing (e.g., greasy gauze with ointment).

ANTIMICROBIAL AGENTS

It must be emphasized that systemic antibiotic prophylaxis plays no role in the management of acute burn wounds and provides no protection against microbial colonization of burn eschar⁴; in fact, use of prophylactic antibiotics in burn patients increases the risk that opportunistic infections will develop. Because eschar has no microcirculation, it is impossible for systemically administered antibiotics to reach the eschar surface, where colonization occurs. Therefore, topical preparations, which are capable of supplying high concentrations of antimicrobial agents at the wound surface, must be used. In the early postburn period, the dominant colonizing organisms are staphylococci and streptococci—typical skin flora. Over time, however, the burn wound becomes colonized with gram-negative organisms.⁵ Thus, topical antimicrobial agents used in early burn care should have broad-spectrum coverage to minimize colonization of the wound, but they need not be able to penetrate the burn eschar deeply.

Of the antimicrobial agents used in this setting [see Table 2], sil-

Table 2 Topical Antimicrobial Agents Used in Burn Care

Agent	Antimicrobial Coverage	Advantages	Disadvantages/Precautions
Bacitracin	Gram-positive bacterial	Soothes and moisturizes; good for facial care and epithelializing wounds	Not appropriate for deeper wounds
Mafenide	Broad-spectrum antibacterial; anticlostridial	Penetrates eschar well; available as solution or cream	Painful on application; causes metabolic acidosis (via carbonic anhydrase inhibition)
Mupirocin	Anti-MRSA	Effective against MRSA	Narrow (poor gram-negative) antimicrobial coverage
Nystatin	Antifungal (<i>Candida</i>)	Provides fungal prophylaxis with swish-and-swallow solution	May interfere with activity of mafenide
Silver nitrate	Broad-spectrum antibacterial	Effective for both prophylaxis and treatment of wound infection	Penetrates eschar poorly; causes hyponatremia; stains linen and dressings; induces methemoglobinemia
Silver sulfadiazine	Broad-spectrum antibacterial; antipseudomonal	Soothes on application and causes no pain	Penetrates eschar poorly; causes leukopenia

ver sulfadiazine is the one most commonly employed for partial-thickness and full-thickness burns. Silver sulfadiazine is soothing on application and is active against a broad spectrum of microorganisms. Because it does not penetrate eschar, very little is systematically absorbed; therefore, it is ineffective against already established burn wound infections. Wounds treated with silver sulfadiazine may form a tenacious yellow-gray pseudoeschar, which can be mistaken for true eschar. This pseudoeschar develops when silver sulfadiazine combines with the wound exudates; it can be gently debrided during daily wound care. It has been suggested that silver sulfadiazine may be responsible for the leukopenia that sometimes develops during the first week after a major burn. This attribution may not be entirely accurate, however, given that this leukopenia may also develop in patients treated with silver nitrate. It is possible that the leukopenia results not from either agent but from the margination of neutrophils secondary to the pathophysiology of the burn injury itself. In any case, the leukopenia is typically self-limited and necessitates no change in therapy. Patients with a history of sulfa allergy typically do not have adverse reactions to silver sulfadiazine; however, if there is concern about a possible reaction, a test patch can be applied to a small area of the wound. If the patient is allergic, silver sulfadiazine will cause pain on application or, in some cases, a rash.

Mafenide acetate is also commonly used in the management of burn wounds. It provides excellent coverage against gram-negative organisms, but it is not as active against staphylococci and has no antifungal activity. Unlike silver sulfadiazine, mafenide penetrates eschar very well, and this ability makes it effective in treating as well as preventing burn wound infections. Mafenide does, however, have some drawbacks. Because it is a potent carbonic anhydrase inhibitor, regular use and the consequent ongoing systemic absorption can lead to metabolic acidosis. In addition, because it is so well absorbed, twice-daily administration is necessary. Finally, topical application of mafenide, particularly to partial-thickness burns, is painful, which limits its utility in the routine management of burn wounds. Mafenide is frequently used on the ears and the nose because of its ability to penetrate eschar and protect against suppurative chondritis; however, silver sulfadiazine appears to be equally effective in this setting.⁷ Mafenide is available both as a cream and as a solution. The solution is useful as a topical agent for skin grafts when the wound bed is considered likely to benefit from postoperative antimicrobial treatment.

Silver nitrate provides broad-spectrum antimicrobial coverage, including good activity against staphylococci and gram-negative organisms (e.g., *Pseudomonas*). It is relatively painless on administration and must be reapplied every 4 hours to keep the dressings moist. It does not readily penetrate eschar. Silver nitrate is used in the form of a 0.5% solution, which is bacteriostatic but is not toxic to epithelial cells. The hypotonic formulation (it is reconstituted in water) can cause osmolar dilution, resulting in hyponatremia and hypochloremia. Therefore, careful electrolyte monitoring and diligent replacement are necessary. In rare cases, use of silver nitrate solution can also lead to methemoglobinemia; if this condition is detected, administration of silver nitrate should be discontinued. A principal disadvantage of silver nitrate solution is that it stains everything it touches black.

Acticoat (Smith & Nephew, London, England), a relatively new antimicrobial dressing, consists of a polyethylene mesh impregnated with elemental silver. Silver has unique antimicrobial properties and works by disrupting bacterial cellular respiration. Acticoat has been successfully used for coverage of partial-thickness burns, as well as for coverage of donor sites and meshed skin

grafts. With burn wounds, the Acticoat dressing is typically changed every 3 days. The reduced frequency of dressing changes simplifies burn care somewhat but can hinder evaluation of evolving partial-thickness burns. With donor sites, Acticoat can be left in place until the underlying partial-thickness wound heals. Typically, an adhesive tape such as Hypafix (Smith & Nephew) is used to secure the dressing to the donor site for 7 days. Once the tape has been removed, the Acticoat usually is sufficiently adherent to allow patients to shower daily and towel-dry the dressing until it eventually peels off the healed wound. The development of Acticoat has led to the introduction of several other silver-based dressings.

Bacitracin, neomycin, and polymyxin B have all been used for coverage of superficial wounds in conjunction with Xeroform or petrolatum gauze to accelerate epithelialization and minimize colonization. These ointments also are commonly administered several times daily in the care of superficial face burns. Mupirocin has proved effective in treating methicillin-resistant *Staphylococcus aureus* (MRSA) colonization; however, because of the potential for the development of bacterial resistance, it should be employed only in MRSA-positive wounds.

Surgical Burn Wound Management

As noted [see Clinical Evaluation and Initial Care of Burn Wound, Assessment of Burn Depth, above], superficial burns and superficial partial-thickness burns typically heal without any need for surgical excision and grafting. Dressing changes and daily wound care can remove necrotic debris and provide an environment conducive to healing in a timely fashion (2 to 3 weeks), with minimal scarring. For deep partial-thickness and full-thickness burns, however, operative debridement with subsequent skin graft coverage is necessary. Timely removal of eschar is critical for successful management. Surgical excision removes necrotic tissue that serves as a nidus for microbial proliferation and the development of burn wound sepsis.⁸

EARLY EXCISION AND GRAFTING

Surgical excision of burn wounds is a concept whose importance was not fully appreciated until the 1970s. Previously, the usual practice was to leave eschar intact over the wound surface, the idea being that proteolytic enzymes produced by migrating neutrophils and bacteria within the contaminated eschar would cause a natural separation of the eschar from the wound bed (sloughing) and that the resulting granulating wound would serve as the bed for grafting.⁹ The rationale for delaying surgical management was it would presumably allow the burn care provider time to determine which wounds would heal spontaneously and which would have to be covered with skin grafts. It has since become clear, however, that in cases of extensive burn injury, delayed management results in more extensive bacterial colonization, as well as an increased likelihood of burn wound sepsis, multiple organ failure, and, ultimately, death.⁹

Early excision and skin grafting of small burn wounds were first described by Lusgarten in 1891. After the Cocoanut Grove fire in 1942, Cope suggested that patients treated with early excision and grafting had better overall outcomes.¹⁰ In 1960, Jackson and associates reported discouraging results with early burn wound excision,¹¹ and it was not until 10 years later, when Janzekovic reported good results with surgical burn wound excision,¹² that enthusiasm for early excision was rekindled. As clinical experience with early excision was accumulated, the benefits became clear.

Since Janzekovic's report, studies have repeatedly shown that early wound excision and closure improve survival, reduce the infection rate, and shorten hospital stay.¹³⁻²⁴ Other studies have demonstrated that early removal of dead and severely damaged tissue interrupts and attenuates the systemic inflammatory response syndrome (SIRS).^{8,25} Early excision of deep burn wounds also appears to decrease hypertrophic scarring. Similarly, early excision and grafting have been shown to be beneficial for burns of indeterminate depth as well. In one study of patients with burns covering less than 20% of their total body surface area (TBSA), early excision and grafting reduced length of stay, cost of care, and time away from work in comparison with nonoperative treatment.¹⁷

Wound Excision

Early staged excision, beginning as early as postburn day 3 if feasible, is now conventional treatment for major burns. Operations are spaced 2 to 3 days apart until all eschar is removed and full wound coverage is achieved. Debrided wounds can be temporarily covered with biologic dressings or cadaveric allograft until autogenous donor sites are available.

Generally, the decision whether to perform operative wound excision is guided by whether spontaneous wound healing is likely to occur in a timely fashion (i.e., within 2 to 3 weeks after the burn). Burn wounds over joint surfaces, however, should undergo excision and grafting sooner so as to minimize healing by wound contraction, which can ultimately lead to disabling contractures. In patients with extensive burns, hemodynamic and pulmonary status must be considered in deciding on the timing of operation. Any critically ill burn patient will have some degree of respiratory dysfunction, but the patient should at least be capable of being safely transported from the ICU to the operating room and back. The risk of hypothermia and the need for blood transfusion must be anticipated before operation and clearly communicated to the anesthesiologist.

There are two main technical approaches to surgical excision of the burn wound: fascial excision and tangential excision. Fascial excision, as the name suggests, involves excising the burned tissue and the underlying subcutaneous tissue down to the muscle fascia [see Figure 7]. A major advantage of fascial excision is that it yields an easily defined plane that is well vascularized and therefore can readily accept a graft. In addition, bleeding is generally easier to control at the fascial level of dissection because the vessels are easier to identify and coagulate. Furthermore, the entire excision can be performed with the electrocautery, and blood loss is thereby minimized. The principal drawback of this approach is that the excision inevitably includes some healthy, viable subcutaneous tissue. Another disadvantage is that the removal of subcutaneous tissue may create an unaesthetic contour deformity.

Tangential excision, as the name suggests, involves sequentially excising the layers of eschar in a tangential fashion until a layer of viable bleeding tissue capable of supporting a skin graft is encountered [see Figure 8].^{26,27} The goal is to remove only the nonviable tissue, particularly in the case of deep dermal wounds. Typically, tangential excision is performed with a handheld knife (a Watson knife or a Weck/Goulian blade). A back-and-forth carving motion is used, and very little force is applied. The guard on the knife can be used to control the depth of excision. The appearance of diffuse punctate bleeding signals that viable tissue has been reached. The main disadvantages of tangential excision are that (1) it may be difficult to control the diffuse bleeding from the wound bed, and (2) it may be difficult to assess the suitability of the underlying fat for accepting a graft.

Figure 7 Fascial excision involves excision of the burned skin and the underlying subcutaneous tissue down to the level of the muscle fascia. It is typically performed with the electrocautery. As shown (arrows), the edges should be tacked down to minimize the ledge at the edge where normal tissue adjoins the exposed fascia.

Figure 8 Tangential excision of the burn wound is carried out with a Watson knife (as shown here) or a Weck/Goulian blade. Eschar is tangentially excised until healthy, bleeding tissue that is suitable for skin grafting is reached.

Regardless of which excision technique is used, tourniquets can be placed on extremities to minimize blood loss, and the extremities can be suspended from OR ceiling hooks [see Figure 9] to provide access to their entire circumference.

A water jet-powered instrument (VersaJet Hydrosurgery System; HydroCision, Andover, Massachusetts) is available that can be used for tangential burn wound excision. This device offers an easy and relatively precise way of excising eschar and is particularly useful for excising nonviable tissue from the concave surfaces of the hands and feet, as well as the eyelids and ears.

To minimize hematoma formation and graft loss, it is critical that adequate hemostasis be achieved before the placement of skin grafts, cadaveric grafts, or skin substitutes. Telfa pads (Kendall, Mansfield, Massachusetts) soaked in an epinephrine solution (1:10,000) are a mainstay of hemostasis, combined with topical

Figure 9 Extremities can be suspended from OR ceiling hooks to facilitate exposure for burn excision and grafting.

pressure and cauterization when necessary. A fibrinogen thrombin delivery system (*Tisseel Fibrin Sealant*; Baxter, Deerfield, Illinois) is commercially available that improves the ability to control bleeding after excision.

Skin Grafting

The best replacement for lost skin is clearly skin itself. The first known report of skin grafting comes from the *Sushruta Samhita*, an ancient Indian surgical treatise that may date back as far as the seventh century B.C. This text describes the use of both skin flaps and grafts for the repair of mutilations of the nose, the ears, and the lips. The Indian method of grafting was first introduced to Western medicine by English surgeons, who observed it during the late 18th century.²⁸

It was not until 1804 that successful transplantation of free skin grafts was reported by Baronio of Milan, who successfully grafted large pieces of autogenous skin onto different sites on sheep.²⁸ In 1869, F. J. C. Guyon and Jacques Reverdin, in a report to the Societe Imperiale de Chirurgie, described the use of a small epidermal graft, which became known as the pinch graft. This technique did not, however, gain wide recognition until 1870, when successful experiments in skin grafting for the treatment of burn patients were performed by George David Pollock.²⁹ In 1872, Ollier described the use of both full-thickness and split-thickness skin grafts and realized the possibility of covering large areas with such grafts if a satisfactory method of cutting them could be devised.²⁸

Currently, a 95% success rate is the standard of care for skin grafting. To achieve this level of success requires adequate wound bed preparation (see above), careful selection of suitable donor sites, and appropriate postoperative care.

Skin grafts are broadly classified as either full-thickness or split-thickness grafts, depending on whether they contain the full thickness of the dermis or a partial thickness [see 3:7 *Surface Reconstruction Procedures*]. Split-thickness grafts are further categorized as thin, intermediate, or thick, depending on the amount of

dermis harvested with the graft. The thinner the skin graft, the greater the degree of contraction that occurs at the recipient site after engraftment. Although thicker grafts have the advantage of contracting less, they leave a greater dermal deficit at the donor site, which can lengthen the time needed for healing and increase the risk of hypertrophic scarring at that site.

Full-thickness skin grafts can be harvested either through use of a dermatome or through direct excision of skin from the flank, the groin crease, the hypothenar eminence, or the forearm and can be used for coverage of small defects of the hand or the face. Standard (intermediate) split-thickness grafts are typically harvested at a thickness of 0.010 to 0.012 in. Thin (0.006 in.) split-thickness skin grafts are generally used in conjunction with skin substitutes, whereas thick (0.018–0.025 in.) split-thickness grafts are typically used in grafting of the hand and the face. The thickness of the graft depends both on the dermatome setting and on the pressure the harvester applies to the dermatome during harvesting.³⁰

Donor site selection for split-thickness skin grafts is based on the distribution of the burn. The anterolateral thigh, when available, is the donor site of choice for most adult patients: it can be harvested in the supine position, it can easily be left open to the air so the donor-site dressing can dry, and it can be covered by shorts if desired. When larger grafts are needed or the thighs are burned, the back, the buttocks, and the abdomen can serve as donor sites. Subcutaneous infiltration of a physiologic salt solution yields a smooth, firm surface that facilitates the harvesting of these areas. If this is done, the anesthesiologist should be informed that additional fluid is being administered. In children, the buttocks and the scalp are commonly employed as donor sites. Once healed, these sites are usually inconspicuous: the buttock donor site can be harvested in such a way that it can be covered by a bikini, and the scalp donor site is typically covered by regrown hair. It is important to reassure the patient's parents that if the graft is harvested appropriately, the donor site will not exhibit alopecia and the recipient site will not grow hair. Generally, however, these sites are sufficient only for the grafting of small wounds.

Skin grafts can be applied as sheet (or unmeshed) grafts, or they can be meshed at ratios ranging from 1:1 to 4:1 [see 3:7 *Surface Reconstruction Procedures*]. Meshing allows the egress of serum and blood from wounds, thereby minimizing the risk that hematomas or seromas will form that could compromise graft survival. In addition, meshed grafts can be expanded or stretched to cover larger surface areas. When grafts are meshed at ratios of 3:1 or higher, allograft skin or another biologic dressing can be applied over them to prevent the interstices from becoming desiccated before they close.²⁰ Because of the lack of dermis in the interstices, widely expanded mesh always scars, takes a long time to close, and results in permanent unattractive mesh marks. In our center, widely spread mesh is never used unless it is grafted onto a dermal template to minimize scarring (see below).

Sheet grafts should be used on the face, the neck, the hands [see Figure 10], and, whenever possible, on the forearms and the legs. In these exposed areas, the superior cosmetic and functional results obtainable with sheet grafts make such grafts preferable. Because sheet grafts have no interstices, they must be closely monitored and periodically rolled with a cotton-tipped applicator to drain any fluid collection. Any serous or bloody blebs that form beneath the graft should be incised with a No. 11 scalpel and drained expeditiously. A common practice known as pie-crusting, which involves making incisions in a sheet graft at the time of surgery, actually does not yield much improvement in graft survival, because blebs often form in areas without incisions. Use of fibrin sealant at the time of grafting may lower the incidence of blebs.

Figure 10 Sheet grafts are the gold standard for skin grafting of the face, the neck, and, whenever possible, the forearms and the legs. This 1-month follow-up demonstrates the aesthetic superiority of sheet grafts.

Graft and Donor Site Dressings

Once the graft is secured in place, a dressing may be applied to protect it from shearing, as well as to accelerate closure of meshed graft interstices. Numerous options for graft dressings exist, including wet dressings and greasy gauze. The use of a nonadherent dressing such as Conformant 2 (Smith & Nephew) along with an outer antimicrobial wet dressing allows the overlying dressings to be periodically removed without dislodging the graft from the wound bed. Bolsters consisting of cotton and greasy gauze are employed to help grafts conform to concave wound surfaces, and splinting of extremities may be necessary for safe graft immobilization, especially over joints. The Vacuum Assisted Closure system (Kinetic Concepts Inc., San Antonio, Texas) is another option for promoting graft healing. Alternatively, an Unna boot can be placed on both the upper and the lower extremity to immobilize the graft and provide vascular support, allowing mobilization of the extremity in the immediate postoperative period.³¹

Sheet grafts can be either left open to the air to allow continuous monitoring and rolling (depending on the patient) or wrapped with dry dressings, which can be removed if necessary to allow interval inspection and debriding.

There are also various options for donor-site dressings. The ideal donor-site dressing would not only minimize pain and infection but also be cost-effective. Greasy gauze and Acticoat are often employed for this purpose. Typically, these dressings are left in place until the donor site reepithelializes, at which time the dressing is easily separated from the healed wound. Op-Site, a transparent polyvinyl adherent film, is also commonly used. With Op-Site, the underlying wound is easily examined without removal of the dressing; however, intermittent drainage of the wound fluid that accumulates is necessary. Op-Site does not work well over joint surfaces and concave or convex areas (e.g., the back). Silver sulfadiazine in a diaper is an excellent covering for buttock donor sites in children; dressing changes can be done with each diaper change.

Postoperative Wound Care

Even with complete graft take and timely donor-site reepithelialization, several wound management issues may still arise in the early postoperative period. Physical therapy and scar management are discussed in more detail elsewhere [see 7:16 *Rehabilitation of the Burn Patient*]. Blisters are common on newly healed donor sites and ungrafted wounds. The new epithelial layer of these wounds lacks the connections to the underlying wound bed normally provided by the BMZ, which protect the epidermis from shearing. During the months it takes for these structures to reconstitute, their absence frequently leads to blistering. These blisters are usu-

ally best managed by draining them with a clean pin, reapplying the epithelial layer to the wound surface, and covering the site with adhesive bandages. The bandages can be soaked off in the shower to ensure that the adhesives causes no additional injury.

Inclusion cysts may develop in healed grafts that were placed over excised wound beds that still contained a thin layer of dermis with adnexal structures. The secretions from the adnexal structures collect beneath the skin graft to form the cysts. Inclusion cysts are treated by unroofing the affected area with a needle.

A condition known as sponge deformity (so called because the skin looks like a bridge of coral sponge [see Figure 11]) may occur if a skin graft is placed over a wound that heals underneath the graft in multiple small areas, with or without sloughing of the overlying graft.³² Where the graft does not slough, a bridge forms. This unsightly deformity can be treated by incising the bridges over the healed tissue with sharp scissors.

Healed donor sites, skin grafts, and ungrafted burns can also break down as a result of infection—a process referred to as melting. Such melting can occur quite rapidly: a graft or healed wound that demonstrates complete take one day may exhibit significant breakdown the next day. Wound cultures should be obtained from these areas, and the open sites should be treated with topical antibiotic ointment and, if the problem worsens, systemic antibiotics.

Malignant degeneration can occur in healed burn wounds decades after the initial injury. These tumors—known as Marjolin ulcers—are usually squamous cell carcinomas and are more aggressive than typical skin cancers.³³ Marjolin ulcers have a high metastatic potential and are associated with a high mortality. New or chronic ulcers in burn wounds should raise the suspicion of malignancy and be considered an indication for biopsy.

BIOLOGIC DRESSINGS AND SKIN SUBSTITUTES

As noted [see Early Excision and Grafting, above], conventional burn wound management dictates early, aggressive excision of burn wound eschar to minimize the chances of sepsis or progression of burn wound depth.^{15,17,34-36} In some cases, the body surface area to be excised is larger than can be covered by autografts from the available donor sites. The solution is to strategically select areas for autograft coverage and then temporarily cover the remaining open areas with biologic dressings. Donor sites typically reepithelialize within about 2 weeks, after which time they can be reharvested, allowing temporary dressings to be serially removed and covered with new autografts.³⁷

Biologic dressings perform several important functions. By adhering to the wound bed, they provide a physical covering that controls water vapor transmission, thus minimizing loss of water, electrolytes, and proteins and preventing desiccation and macera-

tion of wounded tissue (which can lead to extension of the depth of injury). In addition, biologic dressings help prevent microbial invasion from the environment.³⁸

Allograft and Xenograft Skin

Although the technique of skin grafting is thousands of years old, skin grafting between individuals was not reported until the late 19th century. In 1869, Reverdin published a report on the transplantation of small epidermal grafts from his own arm onto a patient's burn wound.²⁸ In 1881, Girdner described transplantation of skin grafts from a cadaver to a burn patient and reported a 75% immediate take rate. It was widely noted that these grafts initially performed well but survived for only 6 to 8 weeks.²⁸ The mechanisms underlying the rejection of these grafts were eventually elucidated by the efforts of Sir Peter Medawar, who received the Nobel Prize in 1960 for his seminal work on defining the basis of allograft rejection and tolerance induction.

The use of allograft was popularized by James Barrett Brown in the 1940s and 1950s,³⁹ and with the subsequent development of skin banking, allograft became the standard temporary graft for excised burn wounds when sufficient autograft is unavailable or autografting is not indicated.⁴⁰

Ultimately, allograft skin is always rejected unless the donor and the recipient are immunologically identical. The rejection process usually begins within 10 days in an immunologically competent host, but allografts can be tolerated for up to 1 month in a host who is severely immunocompromised (e.g., as a result of extensive burn injury).^{9,41} The use of immunosuppressive agents such as cyclosporine has led to the achievement of prolonged allograft tolerance,^{14,42-44} but it also exposes the burn patient to the risks inherent in prolonged systemic immunosuppression.

In addition to providing temporary wound closure, allograft has been used as an overlay for meshed autograft with the aim of accelerating epithelialization of the interstices. Allograft has also been used to cover donor sites after autograft harvesting and to cover wounds after excision as a means of assessing the suitability of a bed for autograft placement.¹⁵

Recognition of the weaker immunogenicity of the dermal layer of cadaver allograft stimulated various attempts to employ allograft for permanent dermal replacement. Jackson was the first to report the use of alternating strips of autograft and allograft for

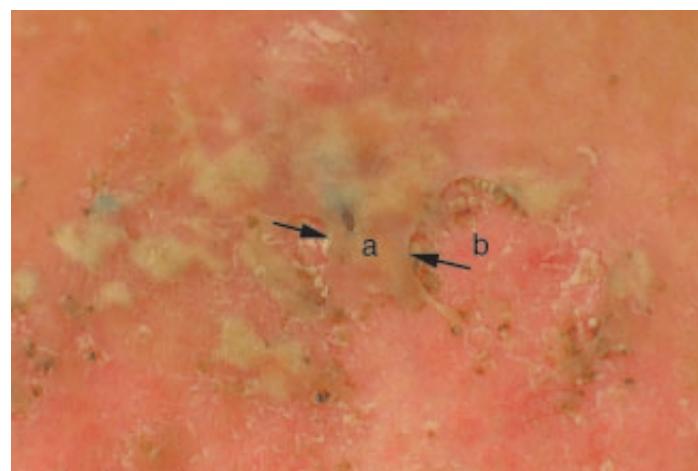

Figure 11 Sponge deformity can occur if a skin graft is placed over a wound that heals beneath without sloughing of the overlying graft. Arrows depict the bridge of skin graft (a) that forms over healed skin (b).

definitive closure of large burn wounds.¹¹ In 1985, Heck and associates constructed the first deliberate combination of allogeneic dermis with autologous epidermis.³⁶ This basic idea was subsequently expanded on by Cuono and colleagues, who used cryopreserved allogeneic dermis as a bed for autologous keratinocyte cultures.^{45,46} These investigators demonstrated long-term survival and documented the reconstitution of a normal-appearing BMZ with anchoring fibrils.

Use of allograft skin as a temporary cover or as the permanent dermal replacement in the composite technique does have several drawbacks, including the limited availability of suitable skin, the variable quality of the skin obtained, the substantial cost of allograft procurement and preservation, and the significant potential for disease transmission.⁴⁷ In addition, the cryopreservation process significantly compromises the viability, and therefore the efficacy, of the allograft.³⁸

Xenografts from a number of species have also been used as biologic dressings. Porcine xenograft has been used in the management of exfoliative skin disorders (e.g., toxic epidermal necrolysis) as well as for temporary wound coverage after excision and before definitive autografting.⁴⁸

Since the 1980s, research efforts have focused on the development of skin replacements that could serve as either a temporary or a permanent substitute for human skin. Conceptually, any skin replacement must recapitulate the native skin biology—that is, it must include an epidermal component, a dermal component, and a BMZ equivalent linking the two.

Cultured Epidermal Autografts

Replacement of the epidermis alone was successfully accomplished in the 1970s with the development of cultured epidermal autografts (CEAs). In 1975, Rheinwald and Green reported the successful isolation and culture of epidermal keratinocytes,⁴⁹ and several years later, O'Connor and coworkers reported the first clinical use of CEAs to cover burn wounds.⁹ In 1984, Gallico and associates described the use of CEAs to resurface the burn wounds of two children who had sustained injuries over 95% of their TBSA.²⁹ CEAs are grown in the laboratory from a biopsy of the patient's own skin. A current example is Epicel (Genzyme Biosurgery, Cambridge, Massachusetts), which is approved by the Food and Drug Administration for use in the United States.

CEAs are most commonly applied to the granulation tissue of chronic wound beds. As more clinical experience with CEAs was amassed, the drawbacks of using epidermal components alone to replace full-thickness skin loss became evident.⁵⁰⁻⁵⁴ The lack of a dermal component made the CEAs extremely fragile and led to high rates of sloughing and infection. Even when CEA engraftment occurred, the BMZ structures critical to graft durability were poorly reconstructed.⁵⁴ Compton and coworkers compared the outcome of wounds covered with CEAs alone with the outcome of wounds covered first with allograft dermis and then with CEAs. They found that in wounds containing the allograft dermal component, there was greater initial take, better long-term durability, and accelerated formation of important BMZ structures.⁵⁵ It is now well recognized that CEAs are capable of replacing the epidermis but are not effective when used alone to resurface deep partial-thickness and full-thickness wounds.

In vitro development of an epidermal replacement was made possible by the simpler biology of the epidermis. Development of a dermal replacement has proved a more formidable challenge. Dermis consists mainly of extracellular matrix, and its complex structure is not amenable to growth in culture.

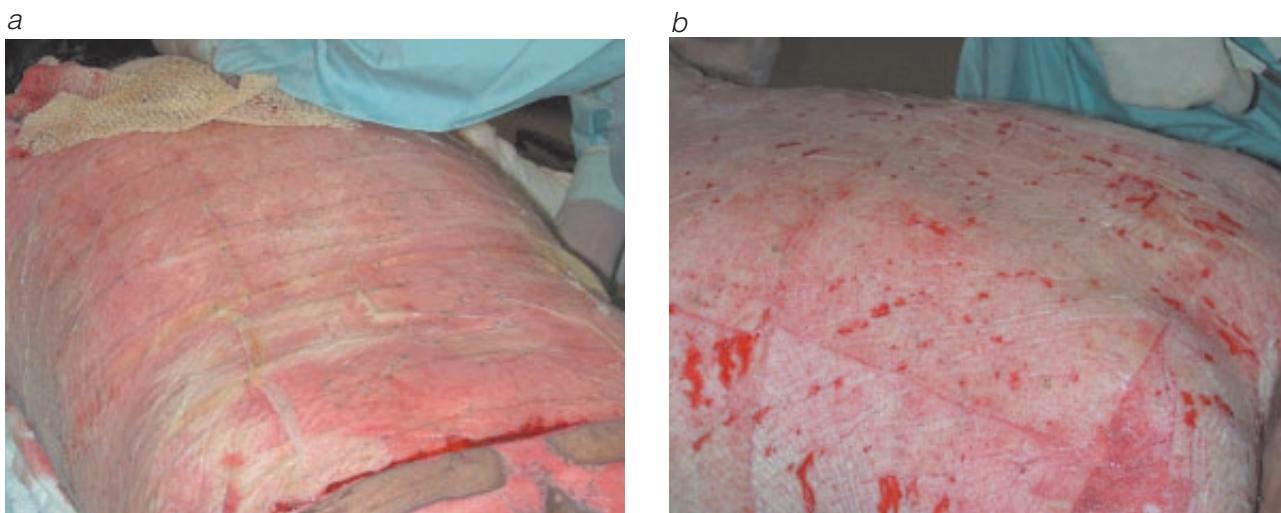

Figure 12 A bilaminar skin substitute is placed on the excised burn wound (*a*) and secured with staples. The skin substitute typically vascularizes in 2 weeks, at which point the Silastic outer layer is removed (*b*) and the neodermis can be autografted.

Skin Substitutes

The drawbacks of allograft and xenograft skin have further underscored the need for an off-the-shelf dermal replacement. A pioneering approach to the development of a skin replacement containing both an epidermal and a dermal component was described by Yannis and Burke in the early 1980s.⁵⁶⁻⁵⁹ Recognizing the importance of the dermis in skin replacement, they developed a bilayer construct that is now commercially available under the name Integra (Integra LifeSciences Corporation, Plainsboro, New Jersey). The epidermal component of this construct consists of a layer of Silastic film, which acts as a protective barrier against infection and evaporation from the wound bed; the dermal layer consists of a porous matrix of fibers composed of cross-linked bovine collagen and a single type of GAG (chondroitin-6-sulfate). Integra can be placed on a completely excised, noninfected wound bed. Initial studies indicated that a neodermis forms, created by the ingrowth of fibroblasts and endothelial cells into the dermal matrix template provided by the Integra. Once this neodermis forms and the dermal scaffold is well incorporated into the wound (typically, after 14 days), the Silastic component is removed. A thin (0.006 in.) split-thickness autograft is then placed on the neodermis [see *Figure 12*.]^{56,60} Integra not only is a useful adjunct in the management of large burn wounds but also can play an important role in the management of hand and facial burns requiring excision and grafting.⁶¹ It must be emphasized, however, that for Integra to vascularize completely, it must be applied to a viable, noninfected wound bed. In addition, meticulous surgical technique and appropriate postoperative care are critical for a successful outcome.⁶²

Another product marketed for dermal replacement is AlloDerm (LifeCell, Branchburg, New Jersey), which is an acellular dermal matrix produced from human cadaveric skin. The cadaveric skin is first stored in normal saline for 15 hours to remove the epidermal component. The cadaveric dermis is then incubated in sodium dodecyl sulfate to extract any remaining cellular components. The decellularized substrate is freeze-dried and reconstituted by soaking it in crystalloid solution before use.⁴⁴ AlloDerm can be used for immediate wound coverage in combination with a thin split-thickness autograft. Data from multicenter trials indicate that AlloDerm works best with thin (0.006–0.008 in.) autografts: the

thicker the autograft, the lower the take rates.^{44,63} AlloDerm has also been used for abdominal wall reconstruction and for soft tissue augmentation in the face.⁶⁴

A product known as TransCyte (Smith & Nephew)—formerly Dermagraft-TC—is approved by the FDA as a temporary (as opposed to permanent) cover for full-thickness wounds after excision. TransCyte is produced by seeding neonatal fibroblasts isolated from foreskin onto Biobrane, a synthetic dressing consisting of Silastic attached to a nylon mesh, which is coated with porcine peptides prepared from type I collagen. The Silastic layer of Biobrane serves as a temporary impermeable barrier, whereas the fibroblast-impregnated nylon mesh serves as a dermal component.⁶⁵ TransCyte is placed on an excised wound bed; when clinically indicated, it is removed and replaced with split-thickness autograft. TransCyte has been found to be statistically equivalent to cryopreserved human allograft skin with respect to adherence to the wound bed, fluid accumulation, and ease of removal.⁶⁶ It has also been used as a dressing for partial-thickness wounds, including donor sites.^{67,68}

Dermagraft (Smith & Nephew), in contrast, is employed as a permanent dermal replacement. Dermagraft consists of human neonatal fibroblasts seeded onto an absorbable polyglactin mesh scaffold, which is intended to mimic the native dermal architecture.^{35,69} It is approved by the FDA for treatment of venous stasis ulcers, but it was developed for coverage of excised burn wounds in conjunction with a split-thickness autograft.

Although a permanent off-the-shelf skin replacement has yet to be developed, the available products have already significantly influenced the management of burn wounds. In addition, the shortcomings of each product and strategy have improved our understanding of skin biology and physiology and confirmed the importance of both the epidermis and the dermis in the structure and function of skin. One group has combined keratinocytes genetically modified to overproduce vascular endothelial growth factor with a fibroblast-collagen-GAG biopolymer matrix to accelerate the vascularization of these constructs and improve the overall healing of wounds covered with them.⁷⁰ This approach addresses the shortcomings of using CEAs alone and the absence of an epidermal component in the currently available dermal substitutes.

15 MISCELLANEOUS BURNS AND COLD INJURIES

David M. Heimbach, M.D., F.A.C.S., and Nicole S. Gibran, M.D., F.A.C.S.

Electrical Injury

Three main forms of electrical injury exist: low-voltage burns (i.e., burns resulting from contact with circuits of less than 440 volts [V]), high-voltage burns (i.e., burns resulting from circuits of greater than 1,000 V), and super-high-voltage burns (caused by lightning). There is also a poorly defined “intermediate-voltage” category, which includes burns caused by contact with industrial circuits of 440 to 800 V; these burns have characteristics of both high-voltage and low-voltage burns, depending on the circumstances.

A common “electrical,” though noncontact, injury is an intense flash burn resulting from the short-circuiting of an industrial circuit by an electrician with a metal tool. Such a short-circuiting causes the metal part of the tool to vaporize, as if it were an uncontrolled arc welder; this vaporization results in a very high temperature flash that causes deep burns to the hand holding the tool and less deep burns to the upper body and face. Clothing can catch fire, compounding the problem. These burns are not, however, associated with the problems of contact electrical burns, and they should be treated in much the same way as other thermal burns.

An electrical burn is managed in essentially the same way as any other burn except that a higher urinary output is necessary in the presence of myoglobinuria. In addition to the potentially devastating tissue destruction seen with high-voltage injury, electrical injuries can lead to chronic and debilitating nonsurgical conditions that must be addressed.

LOW-VOLTAGE INJURIES

The human body is three to four times as sensitive to alternating current as it is to direct current. Alternating current has generally replaced direct current for all commercial power applications because it is cheaper to transmit and can be more easily transformed to any required voltage. The amount of 60-cycle alternating current that can just be perceived in the hand is about 1.1 milliamperes (mA), which produces a tingling sensation. Skin resistance, however, varies according to the thickness of the epidermal keratin layer, as well as the cleanliness and dryness of the skin. The calloused hand may provide resistance of as much as 1,000,000 ohms/in² while dry; normal skin provides resistance of 5,000 ohms/in²; and wet skin provides resistance of only 1,000 ohms/in². With currents higher than 2 to 4 mA, the tingling gives way to muscle contractions, which get stronger as the current increases. The “let go” current is reached at approximately 15 mA, above which the victim cannot release his or her grasp of the conductor. Above 20 mA, there is sustained spasm of the respiratory muscles. If the passage of current lasts less than 4 minutes, respiration will resume; however, if it lasts longer than 4 minutes, asphyxiation may occur, and mouth-to-mouth resuscitation may be required. At levels above 30 to 40 mA, ventricular fibrillation (VF) may be induced. As the current is increased, the heart’s susceptibility to fibrillation first increases and then decreases. At 1 to 5 A, the heart goes into sustained contraction, and the likelihood of VF becomes

negligible. When the high current is terminated, the heart usually reverts back to sinus rhythm, just as happens in cardiac defibrillation, when such high currents are deliberately applied to the chest to depolarize the entire heart.

In the event that the victim of electric shock is unconscious, the initial responder should remove the source of the current (taking care not to become a victim of shock himself or herself) and then provide cardiopulmonary resuscitation (CPR); paramedics may then begin defibrillation. If a sinus rhythm has not been established on arrival at the emergency department (ED), the physician should treat the patient as he or she would any other dysrhythmia patient. If sinus rhythm has been established, the patient should be treated as a sudden death victim, with evaluation for anoxic damage and cardiac monitoring.

Many patients come to the ED after receiving an electric shock from household current. If the electrocardiogram and rhythm strip are normal, the patient should be reassured and discharged without hospital admission. Muscle soreness will resolve spontaneously in 24 to 48 hours and may be treated with analgesics, such as nonsteroidal anti-inflammatory drugs (NSAIDs).

Cutaneous burns with significant tissue necrosis rarely result from contact with low-voltage current. Usually, the area of contact is large enough to dissipate the heat of the current, and underlying tissue destruction is minimal.

Mouth Burns in Children

The exception to this rule is a child who may chew on the end of a live electric extension cord. The child’s saliva completes the circuit between the positive and neutral leads; the resulting electrical short may cause significant tissue destruction of the lips, tongue, or both [see Figure 1]. These burns should be evaluated and treated by a plastic surgeon or a burn surgeon. The patient is often admitted to ensure he or she receives proper nourishment and that the parent is comfortable with pain management and wound cleansing. The parent should be forewarned that the eschar might separate in a few days, resulting in bleeding from the labial branch of the facial artery. In an emergency setting, this bleeding can be easily treated by pinching the lip between thumb and forefinger while the child is brought to the ED for suture ligation.

There are two plans for definitive care.¹⁻³ Long-term results appear to be about equal for nonoperative and operative acute management. If nonoperative management is chosen, splinting is usually recommended to keep the mouth stretched to prevent contracture, but patients and parents do not always comply fully with splint use. Immediate coverage with flaps hastens the healing but leaves a permanent scar and may result in the sacrifice of some normal tissue.

HIGH-VOLTAGE INJURIES

Current in wires containing 1,000 V or more may cause massive tissue destruction. The tissue destruction results from electrical energy being converted to heat as it meets resistance in the tissues.

Figure 1 Shown is an electrical burn caused by a 110-volt household current. The injury resulted from the patient's sucking on an extension plug. The burn was treated conservatively with a mouth splint, which resulted in a nearly normal-appearing mouth with good function.

The smaller the size of the body part through which the electricity passes, the more intense the heat and the less the heat is dissipated. Fingers, hands, forearms, feet, and lower legs frequently are totally destroyed; areas of larger volume (e.g., the trunk) usually dissipate enough current to prevent extensive damage to viscera unless the contact wound is on the abdomen or the chest. As current passes through the body, arc burns, as well as the usual contact wounds, are common. These deep wounds, which may be as destructive as contact wounds, occur when current takes a direct path, often between joints in close apposition to one another at the time of injury. Burns of the volar aspect of the wrist, the antecubital fossa when the elbow is flexed at the time of injury, and the axilla are most common. Such injuries should always be seen immediately by a surgeon with a special interest in burns. The immediate evaluation of the patient with a major electrical burn is similar to that of any severely injured patient and includes evaluation of the ABCs (*Airway, Breathing, and Circulation*).

In addition to burns, which may be obvious, the patient may have other associated injuries resulting from falls or may have broken bones resulting from the tetanic spasms of major muscle groups. Common potential fractures include those of the lumbar spine and hip.

RESUSCITATION

Flash and flame burns without electrical contact injuries are treated in the same manner as all thermal burns are. For patients with electrical contact injuries, fluid requirements are considerably greater than are predicted by the various formulae used for thermal burn victims; the reason is that the cutaneous injury is usually only the “tip of the iceberg,” and underlying deep tissue damage may be extensive. A good general starting point is to administer lactated Ringer solution at two to three times the quantity specified by the Baxter (Parkland) burn formula. This would initially require providing 8 to 10 ml/kg/% of total body surface area (TBSA) that is burned. Fluid administration should be adjusted, with the aims of correcting metabolic acidosis, normalizing vital signs, and attaining a urinary output of approximately 100 ml/hr

in adults, especially in the presence of myoglobinuria. With significant myonecrosis, rhabdomyolysis results in increased levels of circulating myoglobin and hemoglobin, as well as cell fragments, which can plug the renal tubules and cause acute tubular necrosis. Myoglobin precipitation is accentuated by acidic urine and decreased by alkaline urine. There has never been a report of a correlation between exact myoglobin levels in the urine or the blood and development of renal failure.^{4,5} Because urinary myoglobin levels can be significantly elevated even when the urine is clear, the clinical relevance of quantifying such levels is unclear. However, gross myoglobin in the urine should be treated with aggressive fluid hydration. If the urine is red or reddish black, urinary flow of at least 1 ml/kg/hr is indicated until the pigment clears, and acidosis should be corrected. An osmotic diuretic such as mannitol (25 g bolus, followed by 12.5 g every 2 to 4 hours) may be necessary to maintain adequate urinary output. Use of sodium bicarbonate to maintain urinary pH above 7 without raising blood pH above 7.5 theoretically may minimize protein precipitation in the urine.

SURGICAL CONSIDERATIONS

There are two indications for early operation in a patient with a high-voltage electrical burn. If the burn is making the patient sick (e.g., myoglobin will not clear or acidosis will not resolve), the wound should be explored and all grossly necrotic tissue removed. If the burn is making an extremity sick (e.g., there are signs of a compartment syndrome), early escharotomy, fasciotomy, or both should be performed. Otherwise, delaying surgical exploration by a few days can often allow definitive debridement and wound closure through a single operation.^{6,7}

Escharotomy and Fasciotomy

In general, an escharotomy is indicated for a circumferential deep burn when there is evidence of impaired distal perfusion. Fasciotomy is indicated for concomitant electrical injury to underlying muscle when there is evidence of increased compartment pressure, myoglobinuria, tense muscle compartments, or nerve or vessel compression. Careful monitoring, including measurement of compartment pressures, is mandatory, and escharotomies and fasciotomies should be performed at the slightest suggestion of progression. Routine compartment pressure measurements may be helpful, but any of the signs of impending compartment syndrome (i.e., increased pain, pallor, absence of pulse, decreased sensation, and tense swelling) mandate prompt compartment release in the operating theater.

One unique injury that must be considered in patients with electrical injuries to the hand is a carpal tunnel injury.⁷ With the associated swelling, relatively small electrical injuries can lead to swelling in the carpal tunnel that manifests as increasing paresthesias and numbness in the distribution of the median nerve. If the injury is sufficiently devastating to create a mummified hand, carpal tunnel release probably has no role in the treatment plan.

CONTACT SITES

Because most electrical injuries result from alternating current, entrance and exit sites are better referred to as contact points. These are thermal burns resulting from heat generation, but unlike flame burns, they are often associated with significant injury to the deep tissues. The amount of heat generated depends on the resistance to current flow. A dry hand or foot in contact with high voltage may generate heat in excess of 1,000° C, leading to mummification at the contact site [see Figure 2].

With the passage of a large current, multiple contact sites may be seen along the route of the current, resulting in injuries that

suggest the effects of an explosion. Sites of current arcing (see above) should be treated in the same manner as primary contact sites because the underlying damage can be just as severe.

WOUND MANAGEMENT

In general, if there are large amounts of necrotic muscle as a result of high-voltage electrical contact, aggressive surgical debridement to decrease myoglobinemia is indicated. This intervention may minimize subsequent organ dysfunction. If gross myoglobinuria does not resolve after several hours of aggressive hydration, diuresis, and compartment release, the presence of a large amount of dead muscle is a virtual certainty. Muscle of indeterminate viability should be spared, but if a limb is obviously unsalvageable, guillotine amputation may be appropriate and life-saving. The goal of subsequent surgical procedures is to conserve viable tissue while removing neighboring dead tissue. The uneven nature of the injuries makes this approach difficult and time-consuming. If they are not exposed, small, scattered areas of injured muscle will be replaced by fibrous tissue. A high fever and tachycardia, however, may be physiologic evidence that remaining non-viable muscle has become infected. Because bone resists current and becomes very hot, there may be a substantial amount of non-viable necrotic muscle tissue along the bone that must be debrided. It is not uncommon for superficial forearm muscles to appear viable while necrotic muscle surrounds the radius and ulna. Use of vascular grafts to replace clotted arteries is sometimes an option. However, such grafts may actually increase morbidity and prolong recovery; amputation followed by use of one of the newer prostheses may result in better function than would be available in a hand or foot that has poor sensation and motor function.

In accordance with the principles used for thermal burns, devitalized tissue below the skin at the contact sites should be debrided within 7 days after injury [see Figure 3]. Sequential debridement of residual necrotic tissue may be necessary over the ensuing 3 to

Figure 2 Shown is a contact-point injury caused by a 15,000-volt current, seen on day 1. Although the injury looks relatively simple, a similar injury to this patient's right foot led to a below-the-knee amputation. Careful monitoring for compartment syndrome in the leg is mandatory in such injuries.

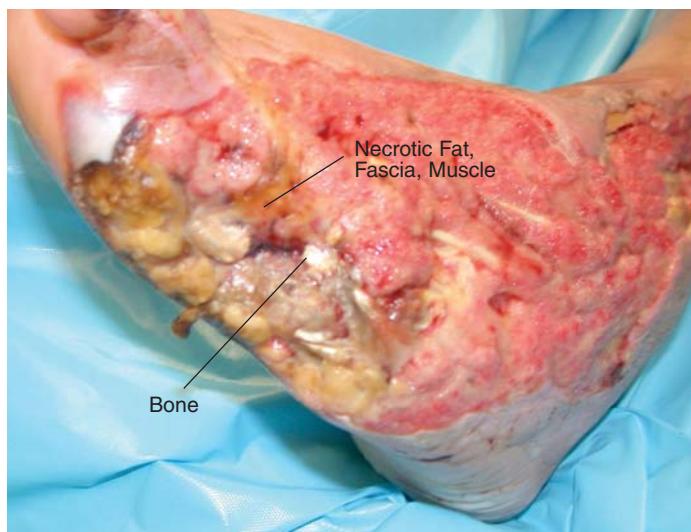

Figure 3 Shown is the same injury seen in Figure 2 just before a second debridement on day 7. Because this patient's right leg was amputated, every attempt was made to salvage as much of the left foot as possible. At initial debridement, it is difficult to tell precisely how much of the foot is possibly viable; note that there is still considerable nonviable soft tissue under the metatarsals and that the metatarsals are considerably exposed. After the second debridement, the foot was treated in a Wound Vac to stimulate vascularization.

Figure 4 Shown is the same foot as in Figures 2 and 3 at the time of discharge (day 21 after injury). Two toes and the fifth metatarsal were removed, leaving a stable, sensate foot with satisfactory cover.

5 days. Early aggressive debridement, followed immediately by reconstructive surgery with tissue transfer by rotation or free flaps to cover remaining viable tissue, nerves, vessels, and bone, may facilitate early recovery [see Figure 4].

To help determine the optimal timing and results of operation, one group reviewed the charts of 62 patients who underwent treatment for high-voltage electrical burns of the upper extremities.⁶ A total of 100 upper extremities were treated. Of these, 22% underwent decompression within 24 hours because of progressive nerve dysfunction, clinical compartment syndrome, or failure of resuscita-

tation. This subset required a mean of 4.2 operations; the amputation rate was 45%, which was similar to that reported in other series. For another 35% of the burned extremities, the first operative procedure was delayed until resuscitation was complete. This subset required a mean of 2.1 operations and no amputations. For the remaining 43% of the extremities, no operations were required to achieve healing. Overall results showed a 10% amputation rate and a mean hospital stay of 27 days; these results were better than the results reported by others.

NONSURGICAL PROBLEMS RELATED TO ELECTRICAL INJURY

Cardiac Injuries

Immediate cardiac arrest is the most common cause of death from electrical injury. Low-voltage exposure is likely to induce ventricular fibrillation, whereas high-voltage exposure is more likely to produce cardiac standstill. Cardiac standstill and respiratory arrest may revert spontaneously if CPR prevents anoxia; VF is more likely to necessitate defibrillation. Conventional wisdom states that patients who have sustained high-voltage injuries should be admitted for 24-hour telemetry monitoring and that cardiac isoenzyme levels should be followed. Studies have shown that if the ECG is normal on admission, subsequent cardiac dysrhythmias are rare and intensive monitoring is probably not necessary.^{8,9} The transient interest in isoenzyme and troponin levels has now waned, and assessment of these variables has not proved useful in predicting cardiac damage.^{8,10-13}

Myocardial infarction is uncommon, but it has been reported in a small percentage of cases in each series. In one patient at the University of Washington (UW) Burn Center, a papillary muscle ruptured within 24 hours; this led to immediate, fatal congestive heart failure.

Neurologic Complications

Neurologic complications are common sequelae of high-voltage electrical injuries and can affect the brain, spinal cord, and peripheral nerves. Immediate but frequently transient symptoms include varying levels of unconsciousness, respiratory paralysis, and motor paralysis. Permanent changes include cortical encephalopathy, caused by the electrical injury itself or resulting from hypoxia at the time of the accident. Spinal cord injuries are rare but may present as progressive muscular atrophy, amyotrophic lateral sclerosis, or transverse myelitis. These conditions may occur days to months after the injury and progress slowly.¹⁴⁻¹⁶

A study of 90 patients (82 male and 8 female) with electrical burns was conducted at the UW Burn Center to identify and evaluate neurologic consequences.¹⁷ There were four deaths. Of the 86 remaining patients, 22 sustained low-voltage injury. Of these 22, 11 had immediate neurologic symptoms; these symptoms resolved in nine of the 11 patients. A total of 64 patients sustained high-voltage injury; of these, two thirds had immediate central or peripheral neurologic symptoms (or both). Loss of consciousness accounted for the largest percentage of central nervous system sequelae in the high-voltage group (45%). Of the 29 patients who lost consciousness, 23 (79%) regained consciousness before arrival at the hospital. Six patients remained comatose, three died, and three awoke but had neurologic sequelae. One third of the patients in the high-voltage group had one or more acute peripheral neuropathies; of these neuropathies, 64% resolved or improved. Five patients had transient initial paralysis, but there were no delayed spinal cord symptoms. Eleven patients experienced one or more delayed peripheral neuropathies; half of these delayed neuropathies resolved or improved.

Peripheral neuropathies are relatively common in burned extremities, resulting either from direct nerve injury or from fibrosis occurring around the nerves. Reflex sympathetic dystrophy is not uncommon. Many patients suffer aches, headaches, chronic pain, and various nonanatomic neurologic complaints for some months after injury.¹⁸⁻²⁰

Cataracts

The incidence of premature cataract development may be as high as 5% to 10% after electrical injury.²¹⁻²³ Surprisingly, cataracts occur equally in patients who have obvious contact points on the face or head and in those who do not. The latent period may range from weeks to years, with the average being 6 months.²³ Therefore, complete ophthalmologic examination for cataracts at the time of hospitalization and, subsequently, with any subjective decrease in visual acuity is warranted. For workers' compensation claims, an eye examination shortly after the injury is indicated to document normal lens transparency in case cataracts occur as an injury-related disease and not from preexisting problems.

Psychological Effects

Posttraumatic stress syndrome is more common after electrical burns than after thermal burns.²⁴ However, general rehabilitation and self-assessed quality of life are comparable after thermal burns and after electrical burns.²⁵

LIGHTNING INJURY

A lightning strike is an extraordinarily high-voltage discharge of brief duration. The current generated may reach 300,000 A and 100 million V. Fortunately, the current often flows around the surface of, rather than through, the body; this "flashover" permits an overall survival rate of 65% or higher.²⁶⁻²⁸ The most common immediate potentially fatal complications are paralysis of the respiratory center and cardiac standstill. Cardiac activity will usually resume spontaneously, but apnea may be present for 15 minutes or longer—long enough to cause anoxic brain injury in the absence of pulmonary resuscitation. A rare but fascinating complication is keraunoparalysis, which is a transient paralysis associated with extreme vasoconstriction and sensory disturbances of one or more extremities. It usually lasts only an hour (in rare instances, as long as 24 hours); a lifeless appearance should not result in the patient's being treated as a victim of sudden death.²⁹ Cardiac and neurologic complications are frequent and are generally similar to those resulting from man-made high-voltage injuries.³⁰ Dendritic superficial skin burns, known as Lichtenberg's flowers or fractals,³¹ are sometimes seen. These superficial burns heal rapidly without sequelae. Ruptured tympanic membranes and vertigo are common accompaniments.^{32,33} Treatment of systemic effects is generally supportive; tissue injuries are treated in the same manner as other high-voltage injuries.

Chemical Burns

GENERAL EMERGENCY CARE

Immediate treatment of chemical burns involves the immediate removal of affected clothing; the burns should then be thoroughly flushed with copious amounts of water at the scene of the accident. The only exception to this is for chemical burns involving dry powder; for such burns, the powder should be brushed from clothing and skin. Chemicals will continue to burn until removed; washing for at least 15 minutes under a stream of running water may limit the overall severity of the burn. No thought should be given to

searching for a specific neutralizing agent. Delay results in deepening of the burn, and neutralizing agents may cause burns themselves; they frequently generate heat while neutralizing the offending agent, adding a thermal burn to the already potentially serious chemical burn.

Chemical burns, usually caused by strong acids or alkalis, are most often the result of industrial accidents, assaults, or the improper use of harsh solvents and drain cleaners. In contrast to a thermal burn, chemical burns cause progressive damage until the chemicals are inactivated by reaction with the tissue or are diluted by being flushed with water. Individual circumstances vary, but acid burns may be more self-limiting than alkali burns. Acid tends to tan the skin, creating an impermeable barrier that limits further penetration of the acid. Alkalies combine with cutaneous lipids to create soap and thereby continue dissolving the skin until they are neutralized. A full-thickness chemical burn may appear deceptively superficial, seeming to cause only a mild brownish discoloration of the skin. The skin may appear to remain intact during the first few days after the burn and only then begin to slough spontaneously. Chemical burns should be considered deep dermal or full-thickness burns until proved otherwise. In general, definitive treatment of these burns is the same as for thermal injuries—shallow burns heal with infection prevention; deep burns are excised and grafted as soon as their depth is determined.

Some chemicals, such as phenol, cause severe systemic effects; others, such as hydrofluoric acid, may cause death from hypocalcemia even after moderate exposure. Unless the characteristics of the chemical are well known, the treating physician is advised to call the local poison control bureau for specifics on treatment.

ALKALIS

Lime (calcium oxide/hydroxide) and sodium or potassium hydroxide are examples of common alkalies used in industry and around the home.

Sodium or potassium hydroxide (drain cleaner) is ingested by children accidentally and by adults attempting suicide. Mouth burns are the tip of the iceberg. Emergency treatment should be directed to the oropharynx and the upper GI tract; description of such treatment is beyond the scope of this chapter. Sodium or potassium hydroxide is also used in assaults, especially in areas where people cannot afford handguns.³⁴ Teen hoodlums sometimes fill water pistols with sodium hydroxide and squirt sleeping homeless people. Contact of concentrated sodium hydroxide with the cornea results in prompt and permanent corneal destruction and blindness. Drain and oven cleaners are also favorite substances of patients who deliberately and repeatedly inflict injury on themselves (Munchausen syndrome).³⁵⁻³⁷

The unwitting homeowner or novice construction worker who does not protect the skin when working with concrete cement (calcium hydroxide) is often surprised at day's end with painful red contact areas on the hands, feet, knees, and forearms. By bedtime, these injuries have become excruciating and require emergency treatment and, frequently, excision and grafting.^{38,39}

Strong alkali burns are invariably deep, though they may seem deceptively shallow at their onset.

ANHYDROUS AMMONIA

Anhydrous ammonia is a colorless, pungent gas that is stored and transported under pressure in liquid form. Ammonia injury is uncommon, but it is associated with high morbidity and mortality. Particularly devastating is severe acute respiratory distress syndrome (ARDS) and long-term restrictive disease with bronchiectasis. Most of the literature consists of case reports, but all emphasize

size the severity and long-term sequelae of the respiratory and ocular problems.⁴⁰⁻⁴⁴

ACIDS

As noted (see above), acid burns tend to denature (tan) the skin. Although they may be full-thickness burns, destruction of deeper tissues is often limited as a result of the formation of an impervious carapace of the dermis.

Hydrochloric and Nitric Acids

Hydrochloric and nitric acids are strong acids that denature proteins but usually do not result in systemic poisoning unless inhaled or ingested.

Chromic Acid

Some acids, such as chromic acid and dichromate, cause both systemic and cutaneous problems. Chromium poisoning is characterized by complete anuria, hepatic damage, and progressive anemia. It can occur from the cutaneous absorption of chromium from chromic acid burns that are as small as 1% of TBSA. Aggressive surgical excision and prompt hemodialysis may be lifesaving.⁴⁵⁻⁴⁸

Formic Acid

Similarly, formic acid causes metabolic acidosis, intravascular hemolysis, and hemoglobinuria when ingested or when concentrated solutions contact the skin.^{49,50}

Carbolic Acid

Phenol (carbolic acid) is used as a hospital, industrial, and home disinfectant. Exposure may lead to rapid CNS depression, vomiting, coughing, stridor, and, in rare instances, seizures.⁵¹ The cutaneous burns are usually first degree.

Hydrofluoric Acid

Hydrofluoric acid burns are unique in terms of their presentation and current treatment. Hydrofluoric acid is used in industrial cleaners and rust removers. It is used in concentrated form in the etching of circuit boards and in dilute form as a cleaner for glass and milk cans. Hydrofluoric acid is a very strong acid that coagulates skin and allows entry of fluoride ions, which then chelate calcium and magnesium in tissue and plasma. Local cell death results; with severe exposure, severe systemic hypocalcemia and hypomagnesemia can result in fatal cardiac dysrhythmias.⁵²⁻⁵⁴ Fluoride, as the most electronegative element, tightly binds many cations essential to hemostasis, inhibiting normal blood coagulation. As a metabolic poison, it stimulates some enzymes (e.g., adenylate cyclase) and severely inhibits others (e.g., Na^+,K^+ -ATPase and the enzymes of carbohydrate metabolism).⁵⁵ Treatment of severe poisoning requires careful monitoring in an ICU, replacement of magnesium and calcium, and consideration of dialysis.

More commonly, industrial exposure is limited to the hand.⁵⁶ Exposure to concentrated solution will cause immediate symptoms, but the more common dilute solutions may not cause symptoms for hours. Often, the worker will go home and experience increasingly severe pain, which will prevent sleep and lead to a nighttime visit to the ED. The worker will likely be unaware of the cause of the pain; the emergency physician should question the patient about solvents used that day.

Conventional treatment of burns to the hand and digits has consisted of local application of calcium liquids and gels. Direct injection of calcium gluconate into the injury site is somewhat

effective but may cause pressure necrosis of fingers that are already swollen. A much better treatment that can yield almost magical results is direct intra-arterial infusion of a dilute calcium gluconate solution through the radial or brachial artery. The sooner the infusion is started after the onset of pain, the better the result. Pain is immediately mitigated if not cured, and tissue destruction is often minimal.^{57,58} This measure has become the treatment of choice in the UW Burn Center and has yielded good results with no complications to date. However, therapy must be started within the first 24 hours; after this point, tissue damage is permanent. An alternative is intravenous infusion of calcium gluconate with the Bier block technique (i.e., a venous tourniquet applied proximal to the infusion site),⁵⁹⁻⁶¹ but this measure can increase swelling in the extremity.

War and Chemicals of Mass Destruction

NAPALM

Napalm is jellied gasoline that is generally ignited and sprayed on material and combatants in wartime. It causes devastating burns because the gasoline sticks to clothing and skin while it is burning. Injuries are usually fourth-degree thermal burns, which are treated in the same manner as other very deep thermal burns.

WHITE PHOSPHORUS

White phosphorus is used in many types of military munitions, as well as in fireworks and in industrial and agricultural products. In the presence of oxygen, it ignites spontaneously; when in contact with skin, it causes deep thermal injuries. It may also give rise to multiple organ dysfunction syndrome (MODS) because of its toxic effects on erythrocytes, the liver, the kidneys, and the heart. Treatment of the injured patient is difficult. The particles must be debrided to prevent continued burning and systemic poisoning. Conventional wisdom was to use a solution of copper sulfate to convert the elemental phosphorus into copper phosphate. However, this approach has fallen into disfavor because copper poisoning may result, the effects of which are often as bad as those of phosphorus poisoning.^{62,63} During debridement in the operating theater, exposure of the particles to air can reignite the phosphorus and thereby endanger the patient and the operating team.

MUSTARD GAS, LEWISITE, AND PHOSGENE

Sulfur mustard is a vesicant that alkylates DNA. In liquid or gas form, its main targets are the skin, the eyes, and the lungs.⁶⁴⁻⁶⁸ Its clinical effects are similar to those of burns, with loss of immunity, respiratory failure, and ophthalmic, gastrointestinal, and hematologic signs. In the Iraq-Iran war (1981-1989), extensive use of chemical weapons such as mustard gas caused injuries with high mortality and morbidity, as well as chronic side effects in vital organs, especially the respiratory tract. In a study that examined long-term effects of mustard gas exposure in 220 survivors, nearly all the victims complained of cough, dyspnea, and suffocation. Hemoptysis was found in six victims. Respiratory distress with use of accessory muscles was observed in four. Two thirds of the subjects had wheezing and coarse rales. Most had obstructive patterns on pulmonary function testing.⁶⁹ Cutaneous exposure is manifested by a delayed erythema of skin occurring after about 4 hours, followed by blistering in 12 to 48 hours. The blisters rupture, leaving shallow, painful ulcers. Other vesicants are more corrosive: lewisite (arsine) and phosgene are both more potent than mustard gas, and symptoms appear sooner with these agents.⁷⁰

Rescuers should be protected with suitable clothing, respirators,

gloves, and boots. The victim's clothing is removed, and extensive water lavage is provided, along with copious isotonic eye irrigation. Once decontamination has been completed, there is no danger to attendants; blister fluid does not contain chemicals.⁷¹ Burns are usually of partial thickness and can be treated in the same manner as other partial-thickness burns.

Cold Injury

Cold injuries limited to digits, extremities, or exposed surfaces are the result of either direct tissue freezing (frostbite) or more chronic exposure to an environment just above freezing (chilblain or pernio; trench foot). Cold injury has been a major cause of morbidity during war, and it is described as being the single major injury sustained by British soldiers in the Falklands expedition. Cold injury resulted in over 7 million soldier fighting days lost by Allied forces in World War II.⁷²

CHILBLAIN, PERNIO, AND TRENCH FOOT

Chilblain and pernio are descriptive terms for a form of local cold injury characterized by red-purple, pruritic skin lesions (papules, macules, plaques, or nodules) that are often associated with edema or blistering. These lesions are caused by a chronic vasculitis of the dermis, and their development appears to be provoked by repeated exposure to cold, though not freezing, temperatures. The injury typically occurs on the face, the anterior tibial surface, or the dorsum of the hands and feet—areas that are poorly protected or are subject to long-term exposure to the environment. With continued exposure, ulcerative or hemorrhagic lesions may appear and progress to scarring, fibrosis, and atrophy. Treatment consists of sheltering the patient, elevating the affected part on sheepskin, and allowing gradual rewarming at room temperature. Rubbing or massage is contraindicated, because further damage and secondary infection may result.⁷³⁻⁷⁵

Trench foot or cold immersion foot (or hand) describes a non-freezing injury of the hands or feet, typically sustained by sailors, fishermen, or soldiers as a consequence of long-term exposure to wet conditions (e.g., water or mud) and temperatures just above freezing.⁷⁶⁻⁸⁰ Alternating arterial vasospasm and vasodilatation appear to occur, with the affected tissue first cold and anesthetic and then becoming hyperemic after 24 to 48 hours of exposure. With the hyperemia comes an intense, painful burning and dysesthesia, as well as tissue damage characterized by edema, blistering, redness, ecchymosis, and ulceration. Complications consisting of local infection and cellulitis, lymphangitis, and gangrene may occur. After 2 to 6 weeks, a posthyperemic phase ensues, resulting in tissue cyanosis with increased sensitivity to cold. Treatment is best started during or before the reactive hyperemia state; it consists of immediate removal of the extremity from the cold, wet environment and exposure of the extremity to warm, dry air. The limb is elevated to minimize edema, pressure spots are protected, and local and systemic measures to combat infection are undertaken. Massage, soaking of the feet, and rapid rewarming are not indicated.

FROSTBITE

Frostbite is a common, severe form of cold injury that involves local freezing of tissues. Frostbite is classified into four grades of severity^{81,82}:

1. First-degree injury involves the freezing of tissue with hyperemia and edema but without blistering.
2. Second-degree frostbite involves the freezing of tissue with hyperemia, edema, and characteristic large, clear blisters.

3. Third-degree frostbite involves the freezing of tissue with the death of subcutaneous tissues and skin, resulting in hemorrhagic vesicles that are generally smaller than those seen in second-degree frostbite.
4. Fourth-degree frostbite is notable for tissue necrosis, gangrene, and, eventually, full-thickness tissue loss.

The degree of severity of frostbite is often not apparent for several days. For all forms of frostbite, the initial presentation is pain or discomfort, as well as pruritus if the injury is mild. With more severe injury, there is a progressive decrease in range of motion, and edema becomes prominent. The injury progresses to numbness and eventual loss of all sensation in the affected tissue. The involved area appears white or blue-white and is firm or even hard (frozen) to the touch. The tissue is cold and insensate. Although the initial symptoms may be mild and may be overlooked by the patient, severe pain, burning, edema, and even necrosis and gangrene may appear with rewarming.

Weather conditions, altitude, degree of protective clothing, duration of exposure, and degree of tissue wetness are all contributing external factors to the development of frostbite. Acclimation to cold may be protective, whereas a previous history of frostbite probably does predispose an individual to another cold tissue injury. Smoking and a history of arterial disease also are contributing factors. In urban environments, more than 50% of frostbite injuries are alcohol related, and a significant percentage (16%) of patients have an underlying psychiatric illness.^{83,84}

Current evidence suggests that frostbite injury may in fact have two components: (1) the initial freeze injury and (2) a reperfusion injury that occurs during rewarming.⁸⁵⁻⁸⁷ The initial response to tissue cooling is vasoconstriction and arteriovenous shunting, relieved intermittently (every 5 to 7 minutes) by vasodilatation. With prolonged exposure, this response fails, and the temperature of the freezing tissue will approximate ambient temperature until a temperature of -2° C is reached. At this point, extracellular ice crystals form; as these crystals enlarge, the osmotic pressure of the interstitium increases, resulting in the movement of intracellular water into the interstitium. Cells begin to shrink and become hyperosmolar, disrupting cellular enzyme function. If freezing is rapid (i.e., if the temperature falls by more than 10° C/min), intracellular ice crystal formation will occur, resulting in immediate cell death. Intravascularly, endothelial cell disruption and red cell sludging result in cessation of circulation.⁸⁸⁻⁹¹

During rewarming, red cell, platelet, and leukocyte aggregation is known to occur; this results in patchy thrombosis of the microcirculation.⁹² These accumulated blood elements are thought to release, among other products, the toxic oxygen free radicals and the arachidonic acid metabolites prostaglandin F₂ and thromboxane A₂, which further aggravate vasoconstriction and platelet and leukocyte aggregation. However, the exact mechanism of tissue destruction and death after freeze injury remains poorly defined. Animal studies suggest that vascular injury, in the form of endothelial cell damage and subsequent interstitial edema (but not vessel thrombosis) is the primary initial event in rewarming injury. It has been demonstrated that a marked amelioration of the frostbite injury can be achieved in a rabbit ear model by treating the animals (after cold injury and before rewarming) with a monoclonal antibody to the neutrophil CD18 glycoprotein complex.⁹³ The implication of this observation is that neutrophil adherence to the endothelium of frostbitten tissue during rewarming (reperfusion) is at least partially responsible for the subsequent tissue injury. Clinical application of these experimental observations remains untested.

TREATMENT

Prehospital or field care of a victim of cold injury should focus on removing the patient from the hostile environment and protecting the injured body part from further damage. Rubbing or exercising the affected tissue does not augment blood flow and risks further cold injury or mechanical trauma. Because repeated bouts of freezing and thawing worsen the injury, it is preferable for the patient with frostbite of the hands or feet to seek definitive shelter and care immediately rather than to rewarm the tissue in the field and risk refreezing. Once rewarming has begun, weight bearing should be avoided.

The ED treatment of a frostbite victim should first focus on the basic ABCs of trauma resuscitation [see 7:1 *Initial Management of Life-Threatening Trauma*] and on identifying and correcting systemic hypothermia. Frostbitten tissue should be immersed in a large water bath of 40° to 42° C (104° to 108° F). The bath should be large enough to prevent rapid loss of heat, and the water temperature should be maintained. This method of rapid rewarming may significantly decrease tissue necrosis caused by full-thickness frostbite.^{88,90,91} Dry heat is not advocated, because it is difficult to regulate and places the patient at risk for a burn injury. The rewarming process should take about 30 to 45 minutes for digits. The affected area appears flushed when rewarming is complete and good circulation has been reestablished. Narcotics are required, because the rewarming process may be quite painful.

The skin should be gently but meticulously cleansed and air-dried, and the affected area should be elevated to minimize edema. A tetanus toxoid booster should be administered as indicated by the immunization history. Sterile cotton should be placed between toes or fingers to prevent skin maceration, and extreme care should be taken to prevent infection and to avoid even the slightest abrasion. Prophylactic antibiotics and dermal blister debridement are both controversial; most clinicians debride blisters and reserve antibiotics for identified infections. A 2005 study reported a lower than expected digit amputation rate when rapid rewarming was followed by treatment with heparin and tissue plasminogen activator (tPA), but to date, this finding has not been confirmed by other studies.⁹⁴

After rewarming, the treatment goals are to prevent further injury while awaiting the demarcation of irreversible tissue destruction. All patients with second- and third-degree frostbite should be hospitalized. The affected tissue should be gently cleansed in a warm (38° C) whirlpool bath once or twice a day; some clinicians add an antiseptic such as chlorhexidine or an iodophor to the bath. On the basis of findings of arachidonic acid metabolites in the blisters of frostbite victims, some authors advocate the use of topical aloe vera (a thromboxane inhibitor) and systemic ibuprofen or aspirin. After resolution of edema, digits should be exercised during the whirlpool bath, and physical therapy should begin. Tobacco, nicotine, and other vasoconstrictive agents must be withheld.

Numerous adjuvants have been suggested and tried in an effort to restore blood supply to frostbitten areas. Because of the intense vasoconstrictive effect of cold injury, attention has been focused for many years on increased sympathetic tone. Sympathetic blockade and even surgical sympathectomy have been advocated as early therapy, the theoretical rationale being that sympathetic blockade should release the vasospasm that may precipitate thrombosis in the affected tissue. Unfortunately, this method of treatment has produced inconsistent results in experimental studies and is difficult to evaluate clinically.^{89,95} Experience with intra-arterial vasodilating drugs such as reserpine and tolazoline has also failed to verify this hypothesis. In a controlled clinical study, immediate (mean, 3 hours) ipsilateral intra-arterial reserpine infusion coupled with early (mean, 3 days) ipsilateral operative sympathectomy failed to

alter the natural history of acute frostbite injury.⁸⁹ Sympathectomy may, however, mollify the chronic pain, hyperhidrosis, and vasospasm of cold injuries; some clinicians also suggest that it reduces the risk of subsequent cold injury. Heparin, low-molecular-weight dextran, thrombolytic agents, and hyperbaric oxygen have failed to demonstrate any substantial treatment benefit (despite the suggestive results of the 2005 study by Twomey and associates⁹⁴).

The difficulty in determining the depth of tissue destruction in cold injury has led to a conservative approach to the care of frostbite injuries. As a general rule, amputation and surgical debridement are delayed for at least 1 month unless severe infection with sepsis occurs. The natural history of a full-thickness frostbite injury leads to the gradual demarcation of the injured area; dry gangrene or mummification clearly delineate nonviable tissue. Often, the permanent tissue loss is much less than originally suspected. In one review, only 39% of urban frostbite victims required debridement and skin grafting or amputation.⁸⁴ Emergency surgery is unusual, but during the rewarming phase, vigilance should be maintained to detect the development of a compartment syndrome necessitating fasciotomy. Open amputations are indicated in patients with persistent infection and sepsis that is refractory to debridement and antibiotics.

Frostbitten tissues seldom recover completely. Some degree of cold insensitivity invariably remains. Hyperhidrosis (occurring in as many as 72% of patients), neuropathy, decreased nail and hair growth, and persistent Raynaud phenomenon in the affected part are frequent sequelae of cold injury.⁹⁶ The affected tissue remains at risk for reinjury and should be carefully protected during any cold exposure. Treatment with antiadrenergics (e.g., prazosin hydrochloride, 1 to 2 mg/day) or calcium channel blockers (e.g., nifedipine, 30 to 60 mg/day) and careful protection from further exposure are often helpful. However, there is little that appears to afford significant relief to the chronic symptoms that follow tissue freeze injury; sympathectomy, beta- and alpha-adrenergic blocking agents, calcium channel blockers, topical and systemic steroids, and a host of home remedies have all been tried, with only occasional individual success.⁷⁸

Toxic Epidermal Necrolysis

Toxic epidermal necrolysis (TEN) is a devastating, though (fortunately) rare, exfoliative disease of the skin and mucous membranes that results in full-thickness epidermal necrosis. The first published report of adult TEN appeared in 1956, when Lyell, in Lyon, France, compared four cases to scald burns.⁹⁷ Some authors describe a similar skin sloughing but with lesser involvement, termed the Stevens-Johnson syndrome. In reality, the two diseases are exactly the same: Stevens and Johnson anticipated Lyell by 34 years when they described the same pathology in two children in South Africa.⁹⁸ Dermatologists have long known the disease as erythema multiforme majus exudativum. Thus, even though only one disease process is involved, various names continue to be used: Europeans refer to this condition as Lyell disease, pediatricians call it the Stevens-Johnson syndrome, dermatologists refer to it as erythema multiforme majus, and American surgeons and internists call it TEN.

TEN can be precipitated by the administration of medications, most commonly sulfonamides, antibiotics, and anticonvulsants. It can also be caused by events such as immunizations, systemic diseases, and viral illnesses. Some cases have no known precipitating cause.

The molecular etiology of TEN remains unclear. According to

one theory, certain offending drugs that should be metabolized are instead deposited in the epidermis, leading to an immune response, which causes the body to reject the skin. In 1998, Viard pointed out that keratinocytes normally express the death receptor Fas (CD95); keratinocytes from TEN patients were found to express lytically active Fas ligand (FasL). Antibodies present in pooled human intravenous immunoglobulins (IVIg) blocked Fas-mediated keratinocyte death in vitro. In a pilot study, 10 consecutive individuals with clinically and histologically confirmed TEN were treated with IVIg; disease progression was rapidly reversed, and the outcome was favorable in all cases. The implication was that Fas-FasL interactions were directly involved in the epidermal necrolysis of TEN and that IVIg might be an effective treatment.⁹⁹ This report sparked numerous small clinical series, the results of which have been, at best, inconclusive.¹⁰⁰⁻¹⁰⁴ A 2005 study of the effect of IVIg on ocular complications was unable to demonstrate any benefit.¹⁰⁵ There may be a role for γ -globulin, but current data indicate that it is no miracle cure. Because of the high cost of γ -globulin and its potential for inducing renal damage, we no longer use it to treat TEN at the UW Burn Center.

TEN should be distinguished from a somewhat similar disease, staphylococcal scalded skin syndrome (SSSS). This entity is caused by a bacterial exotoxin, which splits the epidermis above the dermal-epidermal junction. Although patients with SSSS experience severe erythema, the skin exfoliates rather than blisters. SSSS does not involve mucosa, and the patients are in a septic state from the underlying staphylococcal infection. SSSS usually affects newborns, becoming much less common as people get older. This unusual disease is treated with antibiotics directed against staphylococci.¹⁰⁶

The TEN-induced areas of denudation are comparable to those affected by a very shallow second-degree burn. Oropharyngeal, esophageal, anal, urethral, and vaginal^{107,108} mucosal sloughing are also characteristic of TEN. The disease attacks squamous epithelium, so the remainder of the GI tract is usually spared. There is only one case report of intestinal epithelial sloughing.¹⁰⁹ Complications such as infection, malnutrition, negative nitrogen balance, severe wound pain, and MODS are identical to those seen in patients with major burns. The most common causes of death in TEN patients are systemic infection and pneumonia. The potential mortality from TEN is high, but it is reduced by treatments and protocols common in burn centers (e.g., wound coverage with biologic dressings). There is good evidence that patients affected with TEN should be referred early for management in a burn center.¹¹⁰⁻¹¹² The role of the dermatologist is to define the diagnosis and determine the potential cause.

CLINICAL MANIFESTATIONS

A prodrome of TEN usually consists of fever, sore throat, and malaise; 1 to 2 days after these symptoms appear, the skin of the face and extremities usually becomes tender and erythematous. Lesions appear either as large areas of red skin or as target lesions that are about 2 cm in diameter and consist of concentric rings of erythema. At the same time, ulcerations in the lips and mouth appear, making oral intake painful.

In 24 to 96 hours, the involved skin begins to form both small blisters and bullae. Moderate traction of the erythematous skin results in separation of the epidermis from the dermis—a positive Nikolsky sign.¹¹³ When the bullae rupture, large denuded areas of skin become apparent. Fingernails, toenails, and the skin of the palms and soles may also slough.

One hallmark of this disease is severe inflammation of the mouth. Blisters develop on the oral mucosa, leaving a very raw, red

surface. The lips quickly become swollen and crusted with clotted blood. The oral lesions may be confined to the oral cavity or may extend to the larynx or even to the trachea and the esophagus. The patient is usually unable to eat. The eyelids swell as conjunctival inflammation develops. Conjunctival infection, usually caused by *Staphylococcus aureus*, may lead to scarring and permanent blindness.¹¹⁴ The nasal and urethral mucosa may also become inflamed, and erosions can develop on the genital and perianal skin.

Renal failure can occur as a result of hypovolemia, the septic response, or membranous glomerulonephritis. In as many as 50% of cases, there are abnormalities in liver enzymes, including modest increases in aspartate aminotransferase (AST) and alanine aminotransferase (ALT). Bilirubin levels often show modest to severe increases.¹¹⁵ The mechanism of these increases, which appear to be a part of the toxic component of TEN, is unknown.

TREATMENT

The initial focus of treatment is on restoration and maintenance of cardiopulmonary stability. Because TEN does not induce the intense cytokine reaction that is associated with similar-sized burns, massive anasarca is unusual; resuscitation need not proceed in the manner recommended for burns. Maintenance of normal vital signs and adequate urinary output (0.5 ml/kg) is satisfactory. Because of the high incidence of catheter infection in the absence of epidermis, use of Swan-Ganz catheters is usually avoided when possible.¹¹⁶

Treatment involves aggressive wound management, similar to that of a massive second-degree burn, in which the emphasis is on optimizing healing and controlling infection. A crucial feature of TEN is an intact and uninjured dermis, which, if protected, rapidly reepithelializes from sweat glands and hair follicles, which appear to remain intact. Treatment must, therefore, protect the dermis from desiccation and infection. Routine use of ointments and salves not only creates intense pain but also increases the risk of the formation of a "pseudo eschar" of crusts and devitalized dermis that impairs wound healing.

Biologic or manufactured covers have formed an important role in wound treatment.^{111,117,118} Emergency operative wound cleansing and application of commercially available pigskin (porcine xenograft) has been the standard of care at the University of Washington Burn Center in more than 130 cases. The pigskin is stapled in place, the patient is treated for several days in a fluidized bed, and the pigskin is removed as the denuded areas heal. The pigskin is relatively inexpensive, adheres well, is nontoxic, and probably provides some growth factors to hasten healing. With this management plan and meticulous systemic care, mortality at the UW Burn Center has been below 20% for the past 15 years.¹¹⁹ Alternative covers include Acticoat¹²⁰ (Smith & Nephew, London, United Kingdom) and Biobrane¹²¹⁻¹²⁴ (Mylan Laboratories, Canonsburg, Pennsylvania), which follow the same principle of dermal protection to permit uninfected healing.

In addition, associated physiologic and psychological care must be meticulous. Lung function is often impaired as a result of the aspiration of secretions from involved oral mucosa and a reduction in the clearance of secretions as a result of oral pain and overall weakness. Pain control and aggressive pulmonary toilet to assist the patient's cough are the first line of defense. Suctioning can lead to significant bleeding and should be used either sparingly or only after an endotracheal tube is in place. The patient should be intubated if lung function is progressively impaired. If the patient is intubated, partial ventilatory assistance is often required because chest wall pain, systemic toxicity, and weakness can severely impair spontaneous ventilatory efforts.

Cardiovascular function is initially impaired as a result of hypovolemia caused by plasma leaking from the blisters, increased skin evaporative losses, and decreased oral intake. Controlling the febrile response will also help decrease fluid losses, vasodilatation, and the resulting hyperadrenergic response. Careful use of NSAIDs is often necessary to keep the patient's temperature below 102° F (38.9° C). Adequate pain control is essential. Methadone is effective for long-acting pain control, and morphine is a good choice for procedural pain.

Aggressive oral care is critical because of the high risk of local mouth infection and consequent wound and lung infection. Early and continued assessment and aggressive management of corneal involvement are required. Administration of ophthalmic antibiotic ointments and gentle breaking of adhesions between conjunctiva and eyelids with a small glass rod are the standard treatment.¹²⁵

OPTIMIZING NUTRITION

Nutrition is a major component of care, and it often cannot be delivered orally because of oral lesions. A small gastric feeding tube is preferred, as the GI tract between stomach and anus is usually intact and is normally functional.¹²⁶ In general, standard tube-feeding formulas for an individual under moderate stress are sufficient because the full ravages of postburn hypermetabolism are probably not present. When sepsis is avoided, it is very unusual for the gut to fail and for intravenous parenteral nutrition to be needed.

The role of corticosteroids in the treatment of TEN remains unclear. Although some patients who were receiving steroids before the development of TEN still get severe disease,¹²⁷ a number of dermatologists feel that the administration of steroids when the disease process is just beginning, before skin sloughing occurs, can attenuate the process and thereby reduce subsequent sloughing. However, once vesicles have formed and the separation has occurred, corticosteroids no longer effectively attenuate skin sloughing; in fact, the use of corticosteroids retards the rate of healing. In one study, the complication rate was found to be higher in patients who received steroids.¹²⁸ This study, however, did not take into account the patients whose disease might have been sufficiently limited by steroid use to make burn center treatment unnecessary.

FOLLOW-UP CARE

Fortunately, when treatment is successful, the disease usually resolves without hypertrophic scarring, though some mismatching of epidermal pigmentation may be evident. Nails may remain deformed, and eyes are usually dry, requiring periodic lubrication. Obviously, patients must not again contact the medication that caused the disease; for common medications, a Medic Alert bracelet is useful.

Ionizing Radiation Burns

The burn surgeon may encounter ionizing radiation injuries in three settings. Of these, by far the most common involves deliberate exposure to radiation (i.e., radiation used in treatment) or accidental radiation in a hospital, a laboratory, or an industrial complex. In such settings, a single individual is likely to be injured. The second scenario involves failure of a nuclear energy plant, such as occurred at Chernobyl; in this scenario, dozens to hundreds of exposures may occur. The third setting is that resulting from a nuclear explosion through military or terrorist action. In such a scenario, thousands of casualties will immediately overwhelm all resources.

LOCALIZED INJURY

A gray (Gy) is the current unit of radiation, defined as 1 joule (J) of energy deposited in 1 kg of tissue; 1 Gy is the equivalent of 100 rads.

Localized injury is produced by local irradiation of a small area; no systemic effects are produced. As with thermal burns, the degree of injury is dependent on the type of radiation encountered, the radiation dose delivered, and the susceptibility of the tissue. An initial erythema appears within minutes or hours of exposure and subsides over 2 to 3 days. Secondary erythema occurs 1 to 3 weeks after exposure and is associated with hair loss and desquamation of the epidermis. At about 3 weeks, blisters (after doses of about 20 Gy) or ulcerations (after doses in excess of 25 Gy) may occur. Ulceration may recur months to years after injury. Blood vessels become telangiectatic, and deeper vessels become occluded, leading to fibrosis, atrophy, and necrosis.¹²⁹

Wounds are generally treated in a manner similar to the treatment of thermal burns, with the additional caveat that radiation sickness is accompanied by immunosuppression, and that endarteritis obliterans will markedly diminish the blood supply. Infection is common, and the optimal timing of excision and grafting of deep ulcers is not known.

WHOLE-BODY IRRADIATION AND RADIATION SICKNESS

A detailed description of whole-body radiation exposure and its treatment is beyond the scope of this chapter. Radiation sickness, also known as the acute radiation syndrome, may begin within hours of exposure. It is initially characterized by nausea, vomiting, diarrhea, and lethargy; this is followed by the hematopoietic syndrome (neutropenia and thrombocytopenia) and the gastrointestinal syndrome (severe diarrhea, bowel ischemia, bacterial translocation, and sepsis).¹³⁰ Treatment is mainly supportive.

A nuclear explosion is characterized by a supersonic blast, a fireball extending miles from the epicenter, and immense amounts of ionizing radiation. These three components interact, causing severe mechanical injury, flash and flame burns from the ignition of clothing, and, of course, severe radiation exposure.¹³¹ The flash has been described as being so intense that the side of a victim facing the flash will be charred to bone while the opposite side is unburned. Doctors in Hiroshima after the atomic bombing there observed that for a time, thermal burns appeared to be healing, but in the second and third weeks, the wounds broke down and infection set in as the acute radiation syndrome became manifest.

16 REHABILITATION OF THE BURN PATIENT

Lee D. Faucher, M.D.

Of all the different processes that a burn patient undergoes, rehabilitation lasts the longest: it begins on the day of the injury and never truly ends. With current methods of burn care, patients are increasingly able to survive larger, more debilitating burns; accordingly, the main objective (and primary measure of success) of quality burn care has shifted from survival per se to restoration of burn patients to their preinjury level of function, with the best possible cosmesis. Achieving this objective requires a team of highly trained and knowledgeable physical and occupational therapists, under the direction of rehabilitation physiatrists.

The specific objectives of a rehabilitation program change over time. In the early stages, rehabilitation focuses on restoring baseline cardiopulmonary status and preventing musculoskeletal dysfunction. In the later stages, rehabilitation focuses on regaining baseline function, returning to work or school, and adjusting to possible aesthetic and psychological changes. This changing focus underscores the need for an integrated team approach.

The qualifications and capabilities of rehabilitation programs for burn patients, as well as similar programs for other injuries and neurologic disorders, are determined by the Commission on Accreditation of Rehabilitation Facilities (CARF). This independent, not-for-profit organization is responsible for reviewing and granting accreditation requests from facilities. CARF-accredited programs and services have demonstrated that they meet internationally recognized standards and have made a commitment to continual enhancement of the quality of their services and programs. More information and a complete list of accredited providers can be found at the CARF web site (<http://www.carf.org>).

A national agenda for addressing rehabilitation and recovery has been developed, spearheaded by the National Institute on Disability and Rehabilitation Research (NIDRR). NIDRR is one of the three components of the Office of Special Education and Rehabilitative Services at the U.S. Department of Education; it operates in concert with the Rehabilitation Services Administration and the Office of Special Education Programs. The mission of NIDRR is to generate, disseminate, and promote new knowledge so as to improve the options available to disabled persons, with the ultimate goal of returning individuals to their preinjury status as integrated members of their community. NIDRR is a national leader in sponsoring research: in 2001, it supported 344 projects and had a total annual budget of \$141 million.¹ More information can be found at the NIDRR web site (<http://www.ed.gov/offices/osers/nidrr>).

Quality of Life after Burn Injury

Better acute management of patients with massive burns has been one of the major advances in trauma care over the past two decades. Before 1970, persons who sustained a burn covering more than 30% of their total body surface area (TBSA) nearly always died; today, only about 12% of those who sustain burns of this magnitude die.²

It is not surprising that patients with larger injuries have longer hospital stays, incur more expenses, and usually require years of rehabilitation. This being the case, it is reasonable to consider whether a person who sustains a massive burn injury and who may suffer irreparable loss of function as a result can be said to have a good quality of life after recovery. Unfortunately, data comparing the perceived quality of life of severely burned individuals to that of unburned healthy individuals are scarce.³

A massive burn injury has both physical and psychological consequences. The physical consequences include pain, itching, and loss of function; the psychological consequences include (but are not limited to) depression, anxiety, loss of self-esteem, and inability to socialize. An accurate assessment of quality of life would take account of both types of consequences. In 1982, the Burn Specific Health Scale (BSHS) was developed in an attempt to quantitate and evaluate quality of life for all burn survivors.⁴ In 1987, this 114-item inquiry was shortened to an 80-item questionnaire,⁵ and in 1992, it was again revised and renamed the Revised Burn Specific Health Scale (BSHS-R).⁶ The BSHS-R measures seven domains—simple functional abilities, work, body image, interpersonal relationships, affect, heat sensitivity, and treatment regimens [see Table 1]—and has proved to be a valid and reliable outcome scale for burn patients. It has also been translated into Finnish and Spanish and has proved reliable and valid in those languages as well. The results of the BSHS-R give a clinician an idea of how an individual patient is affected by the injury and where to focus therapy and treatment. Follow-up evaluations can be used to quantify improvements in quality of life, as was shown in a 2002 study that analyzed 110 burn-injured patients with the BSHS.⁷ In this study, patients had an improved quality of life when overall stress was reduced and the level of pain lowered. Physical quality of life was better at 6 months from the time of injury than at 2 months.

Fewer than 50% of patients who experience a major burn injury return to the same job with the same employer without accom-

Table 1 Selected Items from the BSHS-R⁶

Sample Items	Response Format
Heat sensitivity	0—Extremely 1—Quite a bit 2—Moderately 3—A little bit 4—None (not at all)
Being out in the sun bothers me	
Hot weather bothers me	
I can't get out and do things in hot weather	
It bothers me that I can't get out in the sun	
My skin is more sensitive than before	
Work	
My burn interferes with my work	
Being burned has affected my ability to work	
My burn has caused problems with my working	
I'm working in my old job performing old duties	

modations having to be made.⁸ Because most health insurance is connected with employment, prolonged time off work can cause significant hardship to patients and their families. Little information is available on the factors that influence return to work after burn injury. This is unfortunate, because such information could have a positive impact on quality of life after injury.

Quality of life remains difficult to measure. Several studies have demonstrated that many burn survivors are able to return to their preinjury functional status.^{3,7,9,10} The chances of achieving a positive outcome are enhanced if the patient is free of emotional and physical distress and resumes involvement in some of the same activities enjoyed before the injury.^{7,11} Outcome can also be positively affected by comprehensive multidisciplinary aftercare¹⁰ and supportive and healthy family dynamics.⁹

Components of Rehabilitation

EXERCISE AND AMBULATION

As noted, rehabilitation is a long and typically painful process. To get patients through this process, it is essential to inculcate in them a solid understanding of the importance of exercise. The underlying principle of the recovery of the burn patient is return to normal function. Through exercise, the patient can attempt to maintain normal activity from admission through hospital care and beyond. The specific goals of exercise are to reduce the effects of edema, maintain range of motion, stretch the eschar and scar, and achieve an optimal level of function.¹² An aggressive exercise program has been shown to improve pulmonary function in severely burned children,¹³ reduce the need for scar release after burn,¹⁴ and also improve muscle strength, power, and lean body mass.¹³

Scar is the limiting factor for proper range of motion. Some scar is always made as burns or grafted areas heal. Burns and burn scars lead to contractures, and the skin that overlies joints is at the highest risk for loss of function.¹⁵ A patient with full range of motion can lose a great deal of range overnight after a burn. Monitoring of range of motion in all joints should be done on a daily basis so that attention can be directed to specific joints at risk. Trained therapists should be brought in to provide instruction about exercise methods tailored to individual patients and varying levels of understanding.

Range-of-motion exercises should begin on the day of admission. Ideally, they should be done twice daily on all joints of the upper and lower extremities [see Figure 1]. Care must be taken with especially painful and newly grafted areas. Patients with large burns may be incapacitated and unable to participate in these exercises. Passive stretching of all extremities should be done during times when patients cannot perform the range-of-motion exercises.

It is often helpful to coordinate exercise with administration of pain control medications. Patients frequently undergo general anesthesia for excision and grafting several times during the early postburn period. Such occasions provide a good opportunity to evaluate a patient for range-of-motion limitations, in that the activity will not be hindered by pain. As the patient begins to participate in range-of-motion exercises, the therapist can begin passive resistance exercises. This step is the beginning of strength training, in which the amount of resistance is increased until the patient (ideally) returns to his or her preinjury state.

Early ambulation is known to help maintain range of motion, maintain strength in the lower extremities, and prevent thromboemboli; it is also known to maintain bone density and promote functional independence.¹² Patients with large burns are immobi-

lized for substantial periods, ranging from a few days to several weeks, as a consequence of their critical illness. Accordingly, early ambulation, its well-established benefits notwithstanding, is not feasible in this population. Even when a critically ill burn patient's condition improves to the point where such mobilization is possible, he or she still usually requires maximal assistance to perform this task [see Figure 2]. Factors such as severe weakness, impaired motor control, and decreased cognitive status are responsible. Several bed rest studies have determined that the antigravity muscles of the lower extremities are the first muscles to weaken during periods of inactivity.¹⁶ A tilt table can be a bridge to ambulation by allowing a patient to perform a weight-bearing exercise in a gravity-reduced environment.¹⁷

It is important that all wounds be properly dressed and lower-extremity wounds supported with elastic wraps. Wrapping the gravity-dependent areas can decrease edema and thus minimize pain during periods of ambulation.

The patient should be kept well informed of the progress made during exercise and ambulation sessions. Before any intervention is started, the goals of each session should be outlined and the patient told that the goals will be advanced at each session. Many patients do well when there is a visual goal (e.g., a specific location to which they walk). The use of a toy or a game can sometimes help younger patients reach the desired goal.

Many clinicians discontinue range-of-motion exercises and ambulation for 3 to 14 days after autografting to minimize graft trauma. It is my practice to begin range-of-motion exercises 5 days after grafting for hands and faces and 7 days after grafting for other areas. One must remember to weigh the risk of graft loss against the possible loss of function when ordering a period of inactivity.

PRESSURE AND OCCLUSION

Pressure Garments

The use of pressure garments on grafted burns or burns that take longer than 14 days to heal is considered standard care in most burn care centers, despite reports in the literature that question its efficacy.^{18,19} The proponents of the use of pressure assert that it helps reduce hypertrophic scarring by decreasing blood flow and oxygen delivery, thereby lowering the rate of collagen

Figure 1 Shown are range-of-motion exercises being done on the hand.

Figure 2 Patients who have sustained major burn injuries typically cannot be mobilized for days to weeks after their injury. Even when they have improved sufficiently to permit mobilization, they usually require considerable assistance.

deposition in the healing wound. As a result, a balance is reached between production and breakdown of collagen, leading to a flatter scar.²⁰ Clinical studies, however, have not found this to be the case and have shown that pressure garments do not alter wound maturation time.¹⁹ Moreover, patient compliance with the use of pressure garments is generally very poor,^{21,22} and medical insurance often does not cover their cost.²³

Those who elect to use pressure garments in the treatment of burn scars and tissue edema adhere to the following simple plan. If a burn heals in less than 14 days, pressure is not used. If a burn takes 14 to 21 days to heal, pressure is applied only if the wound begins to show signs of hypertrophy. Finally, pressure therapy is always used in grafted burns and those that take longer than 21 days to heal.

Pressure garments deliver pressures ranging from 10 to 40 mm Hg; the usual recommended pressure is about 25 mm Hg, so as to oppose the capillary pressure.²⁴ The garments come in many colors and are custom-made for each patient for use on any part of the body. They conform to body movements and can be worn during therapy or other activities. The garments should be worn 23 hours a day. They are quite durable, lasting about 3 months. When the garments no longer feel tight to the patient, they should be replaced.

Silicone

Topical application of silicone has also been employed to treat burn-related scarring. Of the various forms of silicone available—fluids, gels, and elastomers—elastomer sheets are most commonly used for this purpose today.²⁵ Silicone elastomer sheets easily conform to the contours of the burn wound and can be used either in conjunction with pressure garments or alone. Silicones are not believed to apply any significant pressure to the wound; rather, they are believed to increase the wound temperature and thereby change the oxygen tension, thus reducing scarring.²⁶ An alternative theory is that silicone provides a water barrier that allows the scar to remain hydrated and thus decreases blood flow, thereby reducing collagen deposition and scar hypertrophy.²⁷

Much is known about the effect of topical silicone application, but to date, as with pressure garments, no randomized, controlled

trials have conclusively demonstrated that such therapy minimizes hypertrophic scarring.

SPLINTING

Splinting can be used as an adjunct to range-of-motion therapy throughout all phases of burn care. It is also used postoperatively to protect newly placed autografts. Many ready-made splints are available, but most therapists prefer to customize splints for the needs of each patient; in this way, changes can easily be made as these needs evolve. In every case, the overall medical status of the patient and any associated injuries must be taken into account in the decision process.

Certain positions are generally used for splinting various areas of the body. The neck is splinted in extension; the arms are externally rotated, abducted, and supinated; the trunk is straight; the hip and knee are in neutral rotation and straight; and the feet are in dorsiflexion. Particular patients may have slightly different needs, but this overall plan should be followed.

There are several principles that should be followed in designing a splint [see Table 2]. In particular, the splint should not cause pain and should be easy both to apply and to remove. In addition, it should be lightweight and should allow adequate ventilation so as to minimize the risk of skin breakdown.

The use of continuous passive-motion devices in conjunction with passive splints can provide an additional therapeutic option for increasing the range of motion of certain joints.

PAIN CONTROL

Quantifying pain is notoriously difficult, but it is widely believed that a burn injury may be the most painful trauma a person can sustain. Proper treatment of a burn involves daily wound care, exercise, and ambulation, all of which are painful. Initial care is followed by months of rehabilitation, which often makes patients feel that their pain is unending. All patients have different thresholds for pain and different abilities to cope with pain and long-term rehabilitation. Satisfactory pain control is not always achievable, but it should always be striven for. Poor pain control can render a patient unable to complete required tasks during therapy.

A generalized treatment plan for pain control follows a structured approach that is unique to each burn patient. The plan should cover the three types of pain involved: background pain, breakthrough pain, and procedural pain. Narcotics and anxiolytics should be employed as needed, and nonpharmacologic therapies should be included as appropriate. The plan should also be flexible and capable of conforming to the changing needs of the

Table 2 Purpose of General Splinting Design¹²

- Counteracts gravity to assist in functional activity
- Strengthens weak muscles

patient. Each institution should develop its own guideline-based approach to pain control [see *Table 3*.²⁸

Opioid agonists are the cornerstones of therapy for burn-related pain. These agents provide good flexibility in that they can be administered via different routes and in varying dosages and possess different durations of action. Nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen, though rarely indicated in the acute setting, can be very useful throughout the rehabilitation period.

A number of nonpharmacologic adjuncts to pain control have been studied for use during the acute phase of burn care, including hypnosis, virtual reality, and cognitive interventions. Each of these has proved to offer some benefit in this setting, but there are few data on their use in the rehabilitation and recovery phase. Nevertheless, it would seem logical that learned pain management techniques, such as distraction and relaxation, might assist patients throughout their entire course of therapy, not just in the acute phase of care.

WEIGHT GAIN AND RECOVERY

In no other disease or trauma is the postinsult hypermetabolic response as severe as it is in a major burn injury. A person with a 40% TBSA area burn may have metabolic requirements that are twice normal.²⁹ The hypermetabolic response begins on postburn day 5 and continues for nearly 1 year afterward.³⁰

Severe catabolism and loss of lean body mass are well-recognized complications of major burn injury. Approximately 30% of the calories burned during the hypermetabolic state are from muscle, and weight loss rates as high as 1 lb/day have been described.³¹ Continued loss of lean body mass can lead to further complications from depressed immune function, pneumonia, and impaired wound healing.³²

The mainstay of treatment is prevention of weight loss by giving a diet high in calories and proteins. A typical daily intake ranges from 30 to 35 cal/kg/day, with 1.8 to 2 g/kg/day of protein. Close monitoring of daily intake of nutrition and daily measurement of weight are necessary. A dietitian with special training in the nutritional needs of burn patients can take on the task of daily monitoring and can be a great asset to the burn care team.

Severe catabolism in a burn patient is the result of increased levels of catabolic hormones, decreased levels of anabolic hormones, and direct cell injury caused by inflammatory mediators.³³⁻³⁵ Oxandrolone, an anabolic steroid and testosterone analogue, can increase the rate of weight gain when used in conjunction with an aggressive exercise program and appropriate nutrition,³² and its use is not age-dependent in adults.³⁶ These positive effects have not yet been replicated in children.

SPEECH THERAPY

Speech pathologists also fill an important role in the multidisciplinary burn care team. They possess special skills in the early clinical evaluation and management of dysphagia and can provide an accurate assessment of the efficacy of the pharyngeal phase of swallowing so as to determine the adequacy of airway protection.³⁷ They can also offer useful assistance in stretching and strengthening the facial and oral muscles.³⁸

Dysphagia, defined as the inability of a patient to accept and safely transport food and liquid from the mouth to the stomach, is a consistent and prominent impairment associated with all types of burn injuries.³⁹ Patients with larger burns may also require prolonged mechanical ventilation, in which case the initial dysphagia assessment is delayed until extubation. A retrospective review from 2001 found that the initial dysphagia assessment typically occurred around postburn day 20, that the first safe oral intake

occurred around postburn day 30, and that 90% of patients were able to tolerate a regular diet at discharge.⁴⁰

SKIN CARE

Grafted and healed burn skin is not as durable as uninjured skin. The injury itself depletes the skin of its native ability to remain moisturized, and this depletion increases the likelihood of chapped skin. Liberal use of skin products that contain lanolin can help keep the skin moisturized. These products may also lessen itching and thus reduce the likelihood of trauma from scratching.

Healed and grafted burns are also at risk for hyperpigmentation if exposed to direct sunlight during the postinjury inflammatory phase, which may last as long as 2 years after a burn.⁴¹ A sun block should be used at all times during exposure to sunlight, in combination with clothing that provides appropriate coverage. Clothing by itself does not offer sufficient protection: ultraviolet light can penetrate clothing and cause skin damage.⁴²

Itching

Patients recovering from burn injuries can suffer severe discomfort from itching. Itching does not stop when the wound is closed but continues throughout the healing process. Histamine released during the inflammatory phase of wound healing and during the prolonged phase of collagen deposition is thought to be the main cause of itching, but stress and opioid medications have been implicated as well.

A number of studies have attempted to identify the optimal treatment of itching. Therapies evaluated in these trials include antihistamines, skin moisturizers, distraction therapy, special bath oils, and low-dose antibiotics. To date, none of these treatments, either alone or in combination with others, has been shown to be effective.

Currently, however, the therapeutic picture is beginning to look brighter. There are now two topical creams for which there is promising preliminary data supporting their efficacy against postburn itching. In a 2002 report, topical 5% doxepin cream, applied to healed burn wounds three times daily, significantly decreased burn itching in comparison with oral antihistamines.⁴³ In a pilot study from the same year, topical dapson gel, applied one to four times daily, significantly reduced itching in 84% of patients.⁴⁴ As of October 2003, dapson was being evaluated in phase II trials; it is hoped that further promising results will follow.

MASSAGE THERAPY

Although massage has been a part of burn care for some 400 years,⁴⁵ there is little in the way of high-level evidence to indicate that it is effective in reducing burn scarring. One thorough study found no difference between a group of patients that received massage and a control group that did not,⁴⁶ but the authors admitted that the 10-minute treatments administered may not have been long enough. Massage has, however, been shown to decrease itching,⁴⁷ pain,⁴⁷⁻⁴⁹ anxiety,⁴⁷⁻⁴⁹ anger,⁴⁹ and depression^{47,49} and thus is a useful adjunct in burn treatment and rehabilitation.

BODY TEMPERATURE REGULATION

Core body temperature is regulated through alteration of cutaneous blood flow and dissipation of heat via sweating. A full-thickness burn destroys the dermis and the elements that are the basis of temperature regulation. The body can compensate for this loss through excessive sweating in the unburned areas of the body, but this compensatory response is believed to be limited to patients whose burns cover less than 40% of their TBSA.⁵⁰ There are, however, current data suggesting that improved cardiovascular fitness may allow patients with larger burns to mount such a response.⁵¹

Because healed and grafted burns have less cutaneous blood flow, effective conductive heat loss cannot be achieved through vasodilation.^{50,52} Sweating in these areas does not aid in evaporative heat loss either, because of an isolation effect in the hypovascularized area.⁵³ As a consequence of the impairment of both conductive and evaporative heat loss mechanisms, patients exercising in climates that are both hot and humid have the greatest difficulty in maintaining their thermoequilibrium.

Control of ambient temperature is most critical during the acute phase of burn care and in the operating room. In my experience, burn patients who are in the rehabilitation phase are not uniform in their tolerance to heat and cold: some require more clothing to tolerate the cold, and others have the same exercise tolerance after their burn as they had before it. I know of one burn patient whose temperature tolerance changed so drastically that he had to move to a snow-belt state to get away from the heat, and I know of another who had to move out of a snow-belt state to get away from the cold.

Whenever patient temperature tolerance negatively affects burn rehabilitation efforts, the ambient environment must be changed to meet the individual patient's needs.

Special Problems

HYPERTROPHIC SCARRING

When skin is injured, scar is formed in an attempt to rapidly restore protective covering to the injured area; the reason why scar is formed instead of the original tissues being regenerated is not known. During this attempt to form a new protective covering, new connective tissue is created, which gives the scar strength. When scar formation becomes extensive, it leads to a hypertrophic scar. A hypertrophic scar is a raised, erythematous, pruritic, and inelastic mass of tissue that is the result of a large amount of extracellular matrix whose composition and organization are altered from those of normal dermis. Microscopically, there is a whorl-like pattern of collagen, an abundance of immature connective tissue, and a prolonged chronic inflammatory reaction.⁵⁴ The extracellular matrix is composed of a multitude of cell types that are maintained in a hyperactive state by inflammatory mediators.

Formation of hypertrophic scars is generally considered common after a burn injury; surprisingly, however, published data on the prevalence of hypertrophic scarring after burn injury are scant.⁵⁵ Estimates range from 4% in burns that heal spontaneously⁵⁶ to 75% in grafted burns.⁵⁷ Eventually, all hypertrophic scars undergo some spontaneous resolution, but such resolution is unpredictable.

Tissue contraction is a normal and necessary part of wound healing. Contracture, however, is an abnormal process resulting from long-term shrinkage of a scar. This process can continue indefinitely until it either achieves a comfortable position or meets an equal opposing force.⁵⁸ If allowed to progress uncontrolled, contracture can lead to a loss of function in the affected area.

One way of possibly reducing hypertrophic scarring and contracture is to minimize the period over which wound contraction takes place. Early excision and grafting have been shown to lessen the amount and intensity of inflammation⁵⁹ and reduce the development of hypertrophic scarring by shortening the duration of the inflammatory phase.⁶⁰ In grafting a wound, it is important to use enough tissue to cover all of the wound edges and to use sheet grafts whenever possible.⁵⁹ A full-thickness skin graft results in less skin contraction during healing than a split-thickness graft does. The thinner the split-thickness graft, the greater the degree of contraction.

The main treatment options for hypertrophic scar are aggressive range-of-motion therapy and surgical excision. When therapy fails to stretch the scar and a life-style-limiting contracture develops, surgical excision may become necessary. Often, the scar is excised and the defect covered with another skin graft. Alternatively, the scar may be excised and the wound closed primarily, provided that there is enough tissue to allow coverage of the wound with a tension-free closure. Corticosteroid injection into the wound after scar excision has been studied and found to yield a 30% to 100% reduction in scarring.⁶¹ To date, no prospective, randomized trials have evaluated the use of corticosteroid injections in this setting, but the initial results are undoubtedly promising.

HETEROTOPIC OSSIFICATION

Heterotopic ossification (HO) is a condition in which mature lamellar bone is laid down in tissues that do not usually ossify. HO was first described in the early 20th century and usually occurs in patients who have medical conditions with poor prognoses. As survival rates have increased in patients with major burns, so too has the incidence of HO: it is currently about 3% overall.⁶² HO tends to affect joints underlying areas of full-thickness burns in patients with burns covering more than 20% of their TBSA,⁶² but it can occur anywhere. The most common site is probably the upper extremity, with the elbow the most frequently involved joint.⁶³

At present, how best to treat HO is as uncertain as what causes it. All treatment modalities remain controversial. Surgical treatment yields less than optimal results. Medical treatment incorporates the use of steroids and NSAIDs for prophylaxis and treatment.⁶⁴ Etidronate, an inhibitor of osteoclast bone resorption, has proved effective at reducing HO developing after spinal column⁶⁵ and hip injuries.⁶⁶ This agent has yet to be prospectively studied in burn patients but is widely used to treat HO in this population nonetheless.

PSYCHOLOGICAL PROBLEMS

A burn injury can be the most aesthetically devastating traumatic event a person can experience. Given society's emphasis on youth and beauty, a severely impaired appearance can be socially incapacitating. Furthermore, the very process of being treated for a major burn can cause psychological difficulties. Patients with burn injuries essentially lose control of their lives upon arrival at the burn center. Every moment of every day is planned for them: they undergo therapy, wound care, nutritional supplementation, and operations according to a strict schedule for an indeterminate period.

Accordingly, it is not surprising that psychological problems are identified in a significant number of burn patients. Effective treatment may include psychological debriefing, use of appropriate pharmacologic interventions, exposure therapy, or desensitization.⁶⁷ It is important to provide psychiatric services as soon as the need arises, so that early and effective interventions can support the patient through this traumatic event.

Previous psychiatric diagnoses have been shown both to increase mortality and to prolong length of stay.⁶⁸ Preexisting psychological disorders can be exacerbated during rehabilitation, and

new ones can arise even in the absence of risk factors. Any previous psychiatric diagnosis warrants early and effective intervention in the acute phase of burn care. The clinician, the pharmacist, and the psychiatrist must have a firm understanding of burn physiology and burn pharmacokinetics to ensure that an effective medical treatment plan is established.

Depression, anxiety, and guilt often arise during the early course of rehabilitation. Posttraumatic stress disorder (PTSD) may develop in as many as 43% of patients during the hospital phase of burn care. Alteration of the patient's self-image is thought to be the most common predisposing factor for PTSD; other factors include poor pain control and associated physical impairments. Often, PTSD develops only after hospital discharge, and it is difficult to identify patients at risk.⁶⁹ Therefore, it is imperative for clinicians to provide education and psychological intervention to all patients during the hospital course and maintain aggressive follow-up after discharge.

The most effective way of treating PTSD is to attempt to minimize its occurrence. To this end, control of pain and anxiety is essential. As stated (see above), opioids are the cornerstone of pain management. The addition of benzodiazepines can facilitate pain control considerably. Withdrawal from these medications can produce symptoms similar to those of PTSD, but this concern should not dissuade clinicians from using them when appropriate. Nearly every psychotropic medication has been tried as therapy for PTSD; none has yet proved more effective than any of the others.

NEUROLOGIC COMPLICATIONS

Peripheral neuropathy is a well-known complication after major burn injury, but its incidence is unknown. In 1971, when this complication was first described, the incidence was reported to be 15% in the 249 burn patients studied.⁷⁰ Since then, multiple studies have been done, reporting incidences ranging from 2% to 84%.⁷¹⁻⁷⁵ In all of these studies, peripheral neuropathy was correlated with increased length of stay, increased percentage of TBSA burned, and electrical injury.

In a 2001 retrospective review of cross-sectional data from 572 patients with major burn injuries, the incidence of peripheral neuropathy was 11%.⁷⁶ The patients who were more likely to exhibit peripheral neuropathy were those whose burns covered more than 15% of their TBSA, those who spent more than 20 days in the intensive care unit, and those who sustained electrical injuries.⁷⁶

Precisely what causes peripheral neuropathy is not known. It is important that all burn patients, especially those with known risk factors, receive comprehensive neurologic examinations aimed at detecting this devastating complication. It is often possible to limit the progression of peripheral neuropathy—and sometimes to prevent it—by paying particular attention to (1) prevention of compartment syndrome, (2) proper patient positioning (to prevent nerve compression), (3) use of the shortest feasible tourniquet times, and (4) avoidance of prolonged use of compressive dressings.

Burn Wound Reconstruction

Reconstruction of a burn wound is postponed until the wound is fully matured, which can take as long as 2 years.⁵⁹ If, however, contracture is causing a severe functional deficit, early reconstruction is indicated to correct the problem.

The first priority in burn reconstruction is to obviate further reconstruction by providing proper postoperative care. The second priority is to restore active function, and the third is to restore passive function. To address these priorities requires a systematic approach that includes all members of the multidisciplinary burn team, as well as the patient. By following a rational and orderly plan of possible reconstruction and considering the patient as a whole, the question of what is to be reconstructed and in what order can be clarified.

Primary closure is preferred with any wound, whether the wound is being repaired directly or is undergoing reconstruction. In many burn patients, however, the wound is too large to allow primary closure. Occasionally, large hypertrophic scars that are surrounded by uninjured tissue can be excised through multiple excisions and primary closure. This is a time-consuming process but will lead to a good result.

Z-plasty may be employed to gain length along a scar or skin fold at the expense of surrounding tissues [see 3:7 *Surface Reconstruction Procedures*]. The angles of the limbs of the Z dictate how much length can be gained over the original scar: approximately 25% for 30° angles, 50% for 45° angles, and 75% for 60° angles.

If these approaches are not feasible, the alternative is excision of the scar or contracture with placement of a skin graft [see 3:7 *Surface Reconstruction Procedures*]. After excision of the scar, the wound usually retracts quite widely, leaving a much larger skin deficit. The thickness of the graft depends on the need for the reconstruction. Thinner grafts are more likely to survive but are at higher risk for wound contracture during the maturation phase. Full-thickness grafts have the best color matching and hair pattern, but they require near-perfect conditions to survive, and the donor sites do not heal spontaneously. If a full-thickness graft is needed for reconstruction and the donor site cannot be closed primarily, the donor site can be closed with a split-thickness skin graft.

A flap may be used for reconstruction when primary closure and skin grafting either are not possible or are undesirable. Exposed bones or tendons must be covered with a vascularized section of tissue because they lack the vascular supply required to support a skin graft. Contour defects are also managed with flaps.

Several types of flap are used in burn wound reconstruction [see 3:7 *Surface Reconstruction Procedures*]. A random flap receives its blood supply from the musculocutaneous arteries penetrating its base; the Z-plasty (see above) is an example of this type of flap. An axial flap receives its blood supply from a direct cutaneous artery; the pivot point of the flap is the artery itself. A radial forearm flap is the classic example of this type of flap. Axial flaps are very useful in burn reconstruction, but an exact knowledge of cutaneous arterial anatomy is necessary to design one. A free flap can be divided from its vascular pedicle and used to cover a distant defect. Free flaps are highly useful in burn patients because very often, the tissue surrounding a defect is also damaged and cannot be used for reconstruction.

Tissue expanders may also be used to achieve wound coverage. An expandable device is surgically placed beneath the skin and gradually increased in size, thus stretching the uninjured skin so that it may be used to cover the defect. This technique is best suited to parts of the body with a bony background (e.g., the skull or the chest wall).

17 INJURIES TO THE PERIPHERAL BLOOD VESSELS

Todd R. Vogel, M.D., M.P.H., and Gregory J. Jurkovich, M.D., F.A.C.S.

Before and during World War II, management of extremity vascular trauma consisted of vessel ligation, which resulted in amputation rates as high as 70%. As surgical techniques improved and primary arterial repair became standard, amputation rates declined to approximately 30%. By the time of the Vietnam War, the use of routine angiography and repair had reduced amputation rates to 15%.¹ On the modern battlefield, the incidence of extremity injury remains high, with 88% of vascular injuries occurring in the extremities.² Current management of extremity arterial trauma yields amputation rates ranging from 5% to 20%.²⁻⁴

In this chapter, we outline the current standard of care for vascular injuries in the extremities. Management of such injuries requires knowledge of mechanisms of injury, awareness of high-risk injury patterns, familiarity with modern diagnostic techniques and their indications, and comprehensive understanding of the assessment, triage, and management decisions that influence outcome in this setting.

Mechanisms and Sites of Extremity Vascular Injury

BLUNT VERSUS PENETRATING TRAUMA

Arterial trauma is typically classified according to the general mechanism of injury—that is, blunt or penetrating—because different mechanisms tend to produce different types of injuries. After blunt trauma, the vascular injury most commonly seen is avulsion, in which the artery is stretched. This stretching results in disruption either of the tunica intima alone or of both the tunica intima and the tunica media, leaving the highly thrombogenic tunica externa to maintain temporary vessel continuity [see Figure 1]. Complete occlusion typically occurs when significant intimal damage leads to thrombosis of the artery. Injuries that do not produce occlusion

may give rise to an intimal flap, a pseudoaneurysm (secondary to partial arterial injury), or an arteriovenous (AV) fistula.

Penetrating trauma may transect the vessel completely and may be manifested as thrombosis resulting from vessel spasm or frank bleeding. If the vessel is only partially transected, it may contract and continue to bleed; even if it is initially controlled, it may rebleed as the patient is resuscitated and arterial pressure rises toward normal. In many cases of penetrating trauma, the location of a presumed vascular injury may be determined simply by following the path of the penetrating object. If there is evidence of ongoing bleeding from a penetrating vascular injury, prompt operative intervention, without further evaluation, is indicated. The risk of amputation varies: stab wounds are unlikely to lead to amputation, whereas high-velocity firearm injuries with concomitant blast effect and tissue loss are considerably more likely to do so.⁵ In modern military contexts, blast injuries account for 50% to 70% of cases of vascular trauma.² Vascular trauma from blast wounds may present as thrombosis (related to intimal injury resulting from the application of kinetic force to the tissue) or as deep cavitary injuries with vessel disruption and even segmental arterial loss.

LOCATION OF INJURY AND RISK OF AMPUTATION

Extremity vascular trauma is commonly encountered by surgeons in both urban and rural practices. In urban settings, upper- and lower-extremity injuries account for 40% and 20% of all vascular injuries, respectively.⁶ In rural settings, extremity injuries account for approximately 50% of all vascular injuries.³

Current military data indicate that the most frequently injured lower-extremity vessel in the setting of penetrating trauma is the superficial femoral artery (SFA), followed by the popliteal artery, the profunda femoris, the tibial arteries, and the common femoral artery (CFA); the most frequently injured upper-extremity vessel

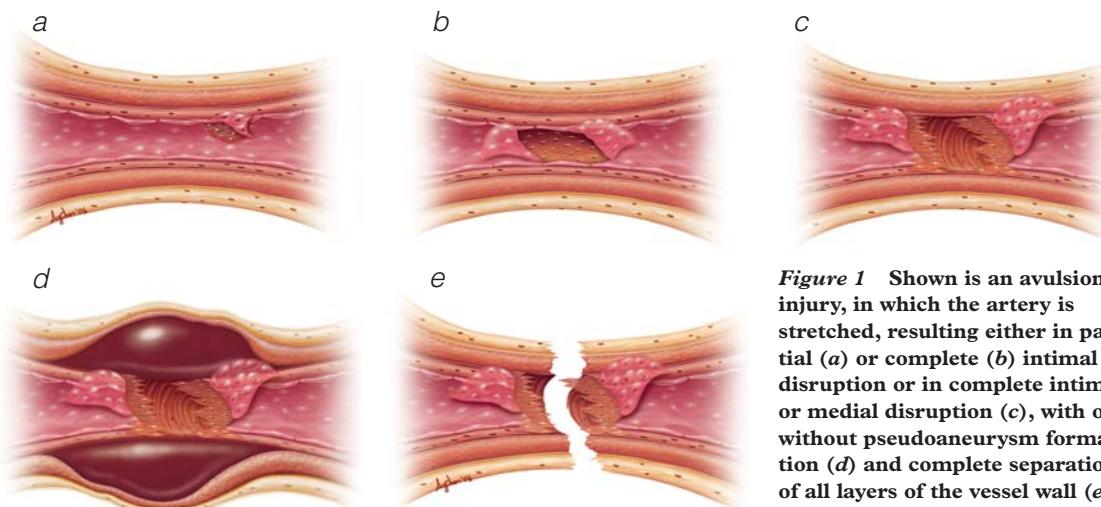

Figure 1 Shown is an avulsion injury, in which the artery is stretched, resulting either in partial (a) or complete (b) intimal disruption or in complete intimal or medial disruption (c), with or without pseudoaneurysm formation (d) and complete separation of all layers of the vessel wall (e).

is the brachial artery, followed by the radial artery and the ulnar artery.² In civilian settings, injuries leading to limb loss often include damage to bones and nerves.

Stepwise logistic regression analysis demonstrates that the following are independent risk factors for amputation: occluded grafts, combined above-the-knee and below-the-knee injury, tense compartments, arterial transections, and associated compound fractures.⁵

Initial Assessment

HISTORY

Assessment of an injured extremity starts with a history, which can be obtained in parallel with the physical examination. The information that should be collected includes the patient's bleeding history at the scene, the time of injury, and the mechanism of injury.

PHYSICAL EXAMINATION

The physical examination is the most important part of the assessment. A careful evaluation of the extremities can provide information on the location and severity of vascular injuries; identify the trajectory and the entrance and exit points of wounds; and suggest appropriate triage and management of vascular injuries.

The initial part of the examination should follow advanced trauma life support (ATLS) guidelines, with attention paid to the ABCs (*Airway, Breathing, and Circulation*). Areas of obvious hemorrhage should be addressed in the primary survey; more specific evaluation of the extremities for vascular injury can be carried out during the secondary survey. Blood pressure, temperature, and distal pulses are evaluated. Side-to-side symmetry is important; thus, injured extremities should be compared with their uninjured counterparts.

If pulses are absent and a joint dislocation or fracture-dislocation is present, then reduction should be done. Frequently, a pulseless extremity regains pulses once the fracture or dislocation is reduced. If pulses return after reduction, the assessment may move on to the next priority. If pulses do not return, vascular injury is assumed, and treatment of such injury becomes the immediate priority.

Once the initial part of the examination has been carried out, a neurologic examination should be done. Motor and sensory function should be assessed in a distal-to-proximal direction on each extremity. Any gross limb deformities should be reduced and splinted to yield a more anatomic alignment of the extremity and relieve any compromise of neural or vascular structures.

CLINICAL CATEGORIZATION OF VASCULAR INJURY

Traditionally, clinical evidence of vascular injury has been divided into hard and soft signs. Hard signs of extremity vascular injury include arterial bleeding, ongoing hemorrhage with shock, an expanding or pulsatile hematoma, a palpable thrill or audible bruit over the injured area, absent distal pulses, and limb ischemia. When a patient presents with hard signs of vascular injury, immediate surgical exploration and vascular repair are warranted. The exception to this rule is the case where the patient presents with multilevel trauma to an extremity and the level of arterial injury is in question. In this situation, arteriography is indicated—preferably intraoperative angiography to minimize delay in repairing the injury and to facilitate intraoperative decision making.

Soft signs of vascular injury include a history of severe hemorrhage at the scene; hypotension; a stable, small hematoma that is not expanding or pulsatile; diminished or unequal pulses; a neurologic deficit (primary nerve injury occurs immediately after

injury, whereas the onset of ischemic neuropathy may be delayed for minutes to hours); and a wound that is in proximity to vascular structures.⁷ Management of patients with soft signs of injury presents a more difficult diagnostic dilemma and is discussed in more detail elsewhere (see below).

It is important to keep in mind that palpation of a pulse is a subjective measure and is thus prone to wide interobserver variation. Furthermore, pulses may be palpable distal to major arterial lesions, including complete arterial disruptions.^{7,8} These limitations notwithstanding, a precise and well-documented physical examination is an appropriate screening tool for vascular injuries.

NONINVASIVE EVALUATION IN CONJUNCTION WITH PHYSICAL EXAMINATION

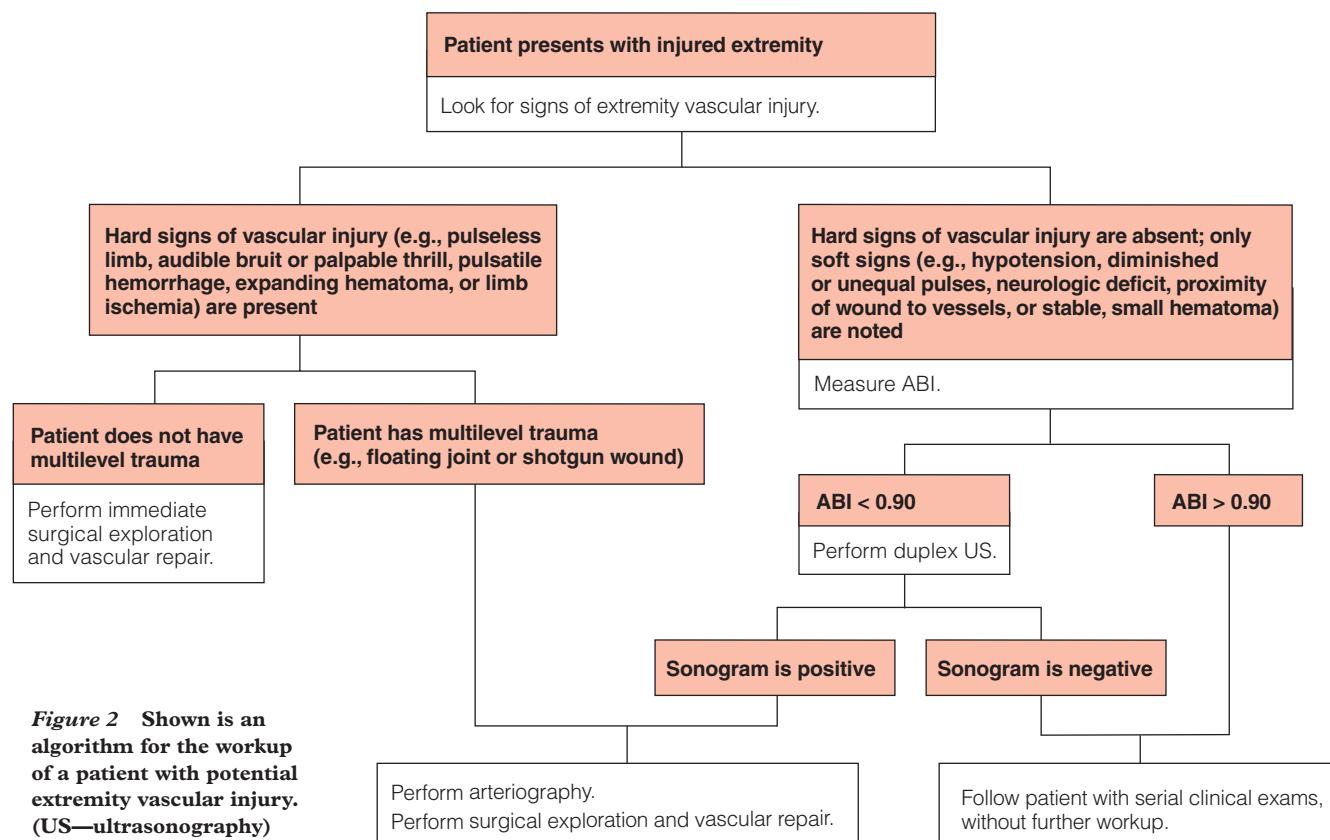

In patients with soft signs of arterial injury, the ankle-brachial index (ABI)—also known as the arterial pressure index (API), the Doppler pressure index (DPI), or the ankle-arm index (AAI)—is a highly useful adjunct to the physical examination. The ABI is obtained by placing a blood pressure cuff on the supine patient proximal to the ankle or wrist of the injured limb. The systolic pressure is determined with a Doppler probe at the respective posterior tibial and dorsalis pedis arteries or at the ulnar and radial arteries. The ratio of the highest systolic pressure obtained in the affected extremity to the systolic pressure in an unaffected extremity (most often a brachial artery) is the ABI [see Figure 2].

A 1991 study assessed the sensitivity and specificity of Doppler-derived arterial pressure measurements in trauma patients undergoing evaluation for possible extremity vascular injury.⁹ An ABI was obtained in 100 consecutive injured limbs, and all patients then underwent contrast arteriography. An ABI lower than 0.90 was 87% sensitive and 97% specific for arterial injury. The authors concluded that in the absence of hard signs of arterial injury, ABI is a reasonable substitute for screening arteriography, particularly if continued observation can be ensured.

The use of the ABI has been extended to the management of blunt extremity trauma associated with high-risk fractures and dislocations. In a controlled trial that included 75 consecutive patients with blunt high-risk orthopedic injuries, the negative predictive value of a Doppler-derived ABI higher than 0.9 was 100%. In the 70% of patients who had an ABI higher than 0.9, clinical follow-up revealed no major or minor arterial injuries. Of the 30% who had an ABI lower than 0.9, 70% had an injury that was diagnosed by arteriography, and 50% of these injuries necessitated operative repair.^{10,11}

It is important to remember that there are several situations in which a vascular injury may not lead to an abnormal ABI. For example, an injury that is considered nonaxial (e.g., an injury to the profunda femoris in the thigh or the profunda brachii in the arm) may not lower the ABI and thus may be missed. In addition, a lesion that does not disrupt arterial flow (e.g., an intimal flap or a transected artery that is maintained in continuity by connective tissue) may yield a normal ABI. Finally, an AV fistula may be associated with a normal ABI.

Certain patient characteristics may affect the ABI as well. For example, noninvasive measurement of the ABI may fail to detect an injury if the patient is severely hypotensive or in shock and the clinical circumstances do not permit placement of a cuff around an injured site or extremity. Moreover, elderly patients may have abnormal preinjury ABIs as a consequence of atherosclerosis. In these situations, the concept of symmetry is crucial. It is also important to consider the possibility that the patient may have previously undergone peripheral vascular surgery, though this is rarely the case in the typical trauma population.

IMAGING

Diagnostic Angiography

Arteriography has a sensitivity of 95% to 100% and a specificity of 90% and 98% and is therefore considered the gold standard for evaluation or confirmation of arterial injury.^{12,13} In the setting of extremity injury, however, nonselective angiography has not been found to be cost effective, and it is often overly sensitive, detecting minimal injuries that do not call for further management.^{14–16} Furthermore, arteriography can be time consuming, can delay definitive treatment, and can give rise to complications of its own, including renal contrast toxicity and pseudoaneurysm formation.¹⁶

Angiography should be reserved for patients with soft signs of vascular injury and an abnormal ABI; there is little reason to perform angiography in a patient with hard signs of injury, unless an intraoperative angiogram is needed to delineate the anatomy. In no case should transport to the OR for definitive treatment be delayed so that arteriography can be performed. Several reviews have supported reserved use of arteriography in this setting. A 2002 report concluded that physical examination in conjunction with measurement of the DPI (i.e., the ABI) was an appropriate method of identifying significant vascular injuries caused by penetrating extremity trauma.¹⁷ Patients with normal physical examinations and normal DPIs could safely be discharged; angiography was indicated only for asymptomatic patients with abnormal DPIs.¹⁷

Duplex Ultrasonography

Several studies have evaluated the efficacy and accuracy of duplex ultrasonography in the setting of extremity vascular trauma. The sensitivity of duplex ultrasonography is between 90% and 95%, the specificity is in the range of 99%, and the overall accuracy is between 96% and 98%. These figures approach those report-

ed for arteriography in the evaluation of similar vascular trauma patients. Duplex ultrasonography has no inherent risks, and it may be more cost-effective for screening certain injuries than either arteriography or exploration. Duplex ultrasonography has been shown to be a reliable method of diagnosis in patients with potential peripheral vascular injuries.^{18,19}

The advantages of duplex ultrasonography notwithstanding, it is important to remember that this imaging modality may not be equally appropriate in all scenarios. As an example, given that duplex ultrasonography is highly operator dependent, the results of duplex examination may not be reliable in situations where the examiner has not had sufficient access to the technology or experience with the technique. As another example, injuries in certain anatomic locations (e.g., injuries in regions where bone structures interpose themselves, injuries in areas with concomitant soft tissue injuries, injuries that dive into the pelvis or chest, and injuries in patients with a large body habitus) may not be well visualized by duplex ultrasonography. Such considerations are important in assessing patients with potential extremity vascular injuries; if either applies in a given case, angiography may be required.

Computed Tomographic Angiography

Ongoing radiologic advances have led some centers to consider using computed tomographic angiography (CTA) to evaluate arterial injury. To date, this approach has been formally evaluated in only a modest number of studies, though there is reason to believe that it will be more widely used in the future. A few small series found CTA to have a sensitivity and specificity of approximately 90% in the evaluation of large arteries; other studies suggested that this modality might be a reasonable alternative to conventional arteriography for diagnosis of traumatic arterial injuries. Before CTA can be considered equivalent to the gold standard, large randomized trials will have to be performed.^{20,21}

MANAGEMENT ALGORITHMS

On the basis of the data available on noninvasive assessment and diagnostic imaging, an effective management algorithm can be created [see Figure 2].^{22,23} If the ABI is higher than 0.9, the patient may be followed clinically without further workup. If the ABI is lower than 0.9, arteriography or duplex ultrasonography

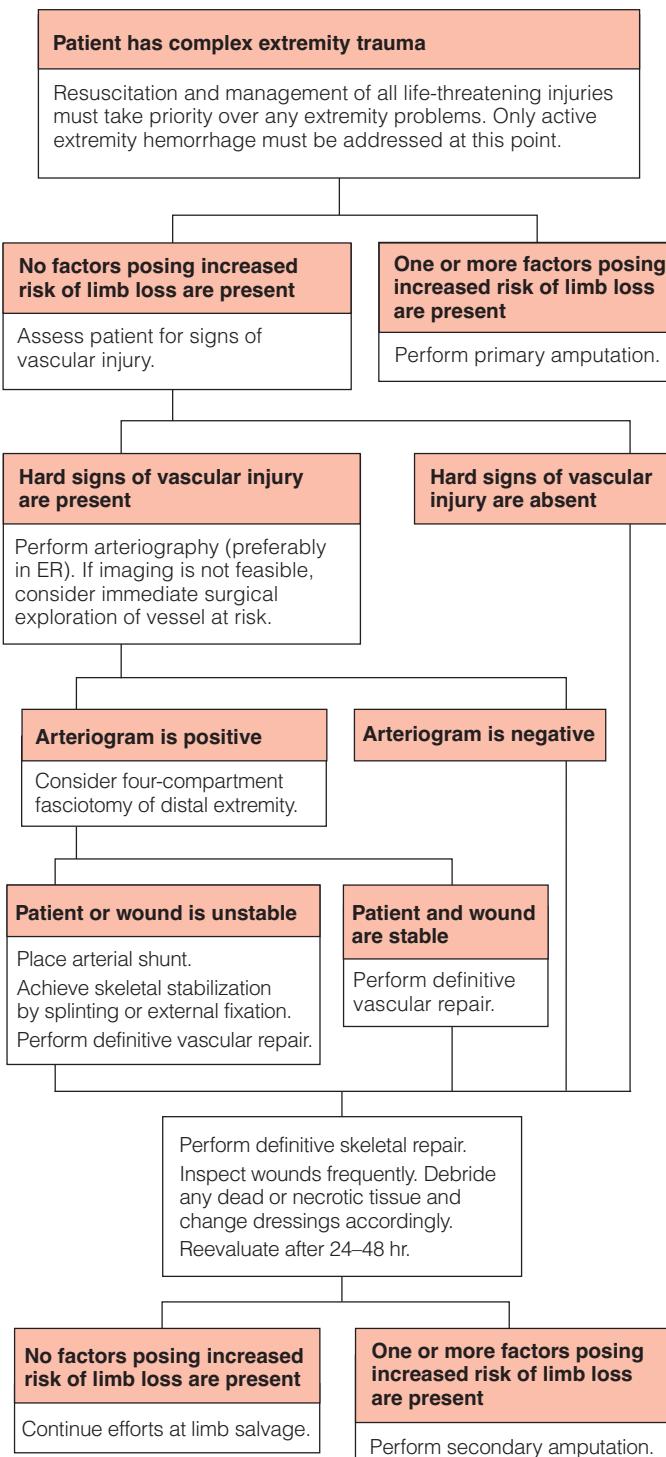

Figure 3 Shown is an algorithm for the management of complex extremity trauma, adapted from an algorithm developed by the ACS Committee on Trauma. The full annotated version of the ACS algorithm is available at the ACS Web site (<http://www.facs.org/trauma/publications/mancompxttrauma.pdf>).

should be performed, the results of which will dictate the final plan of action. It is impossible to define every single clinical scenario that could possibly give rise to arterial trauma. The ABI fulfills the requirements of a useful screening tool, in that it is sensitive, specific, reproducible, noninvasive, and inexpensive.

Management of complex extremity trauma involving soft tissue, nerve, and arterial injury must include consideration of primary amputation to increase patient survival. This issue is well addressed by an algorithm for complex extremity trauma created by the Committee on Trauma of the American College of Surgeons (ACS) [see Figure 3].²⁴ The algorithm incorporates the environment, the type of injury sustained, and the stability of the patient into the process of deciding whether to attempt limb salvage or perform amputation.

HIGH-RISK LOWER-EXTREMITY INJURIES

Certain lower-extremity injuries—such as knee dislocations, displaced medial tibial plateau fractures and other displaced bicondylar fractures around the knee, open or segmental distal femoral shaft fractures, floating joints, gunshot wounds in proximity to neurovascular structures, and mangled extremities—are associated with a particularly high incidence of vascular trauma.²⁵ The most commonly injured lower-extremity artery in the setting of blunt trauma is the popliteal artery, which starts below the adductor hiatus and ends at the soleus arch. Because the vessel's start and end points areas are relatively fixed, there is a potential for significant stretch injury at the knee joint. A purely ligamentous knee dislocation is associated with a high risk of arterial injury, despite the lack of sharp fracture fragments. The risk of popliteal injury may be as high as 40% in patients with knee dislocations. Although the arterial disruption may be only a minor intimal tear and examination may reveal no evidence of injury, such internal tears are thrombogenic and may result in delayed thrombosis. Because lower extremities are often splinted and covered during stabilization, delayed thrombosis may not be recognized in a timely fashion.

Workup of a patient with a posterior knee dislocation may or may not require angiography. Some authors maintain that angiography is unnecessary in routine evaluation of patients with blunt lower-extremity trauma who present with a normal neurovascular examination and that angiography or duplex ultrasonography should be used selectively for patients with diminished pulses who lack associated indications for mandatory operative exploration.²⁶ In addition, the use of the ABI has been validated in the setting of blunt lower extremity trauma. The ABI has proved to be a rapid, reliable, noninvasive tool for diagnosing vascular injury associated with knee dislocation. At present, the evidence suggests that routine arteriography for all patients with knee dislocation is not indicated but that a secondary study should be ordered when the ABI is low or the neurovascular examination yields abnormal results.^{10,12,27} When managing a posterior knee dislocation, one should have a high index of suspicion for vascular injury and a low threshold for obtaining secondary studies.

Management

INITIAL TREATMENT CONSIDERATIONS

Time to Repair

A warm ischemia time of less than 6 hours is generally accepted as the standard interval within which arterial continuity must be restored to prevent permanent damage to the soft tissues.^{28,29}

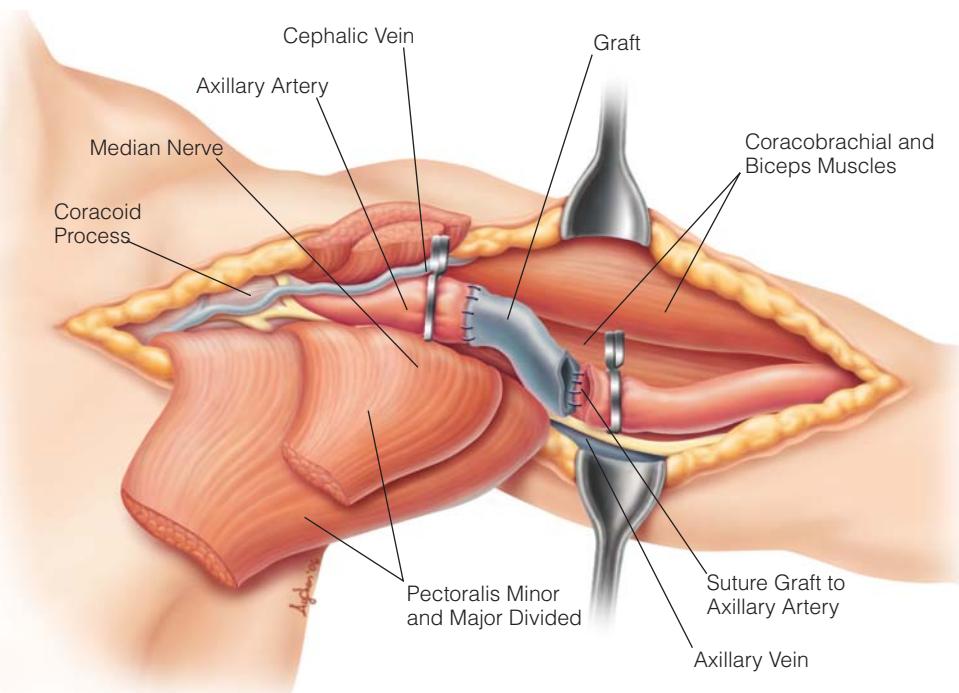

Figure 4 Depicted is exposure of the axillary artery.

This interval may vary depending on several factors, including the level of injury, previous vascular disease, the presence of collateral vessels, and previous extremity surgery.

Vascular Control

As has long been a dictum in vascular surgery, it is important to gain proximal control of the injured vessel—meaning control at a point one level higher than the injured area—before assessing the site of the injury. This maneuver reduces blood loss from the injury during repair and minimizes hematoma formation and subsequent loss of tissue planes. Entering an injured area without first obtaining proximal control can be dangerous, can cause additional injury to other neurovascular structures, and can result in belated attempts to gain proximal control in a hurried fashion, which may cause secondary injury to the vessel. In situations where proximal control has not yet been obtained or cannot be obtained, an intra-luminal or intra-arterial balloon (e.g., a Fogarty catheter or even a Foley catheter, in larger arteries) may be used to achieve temporary control. This simple technique sometimes proves to be lifesaving.

Use of Tourniquets

Surgeons have long debated the use of tourniquets in the management of vascular trauma. Undoubtedly, the tourniquet can be a lifesaving addition to the surgeon's armamentarium if used correctly and appropriately. Proximal application of a tourniquet may facilitate examination, permit definitive control of a bleeding point, and help determine whether significant nerve, muscle, or tendon injury has occurred. Even if a tourniquet is kept in place for only a short period, it may be invaluable for the control of hemorrhage.

When a tourniquet is used, it must be applied correctly. Incorrectly applied tourniquets actually increase bleeding from an extremity wound and increase the risk of early exsanguination. This paradoxical effect results from occlusion of the lower-pressure venous outflow and inadequate occlusion of the higher-pressure arterial inflow. A properly applied tourniquet causes substantial pain, which should be managed with intravenous or intramuscular analgesics.³⁰

Tourniquets are often placed on hypotensive patients before resuscitation, and these patients sometimes start bleeding through their tourniquets when resuscitation is initiated. Accordingly, tourniquets should be continuously monitored and tightened for maximal effectiveness during resuscitation. In the hospital setting, pneumatic tourniquets may be used as temporizing proximal clamps in patients with multiple injuries, as well as patients with blast injuries, massive soft-tissue destruction, or mangled extremities.³⁰

EXPOSURE OF INJURY

Once the decision has been made to transport the patient to the operating room, the next step is to determine the operative approach that will optimize exposure of the injury. Often, exposures of upper-extremity arteries prove more challenging than exposures of lower-extremity vessels, primarily because they are performed less frequently. A thorough discussion of all extremity vascular exposures is beyond the scope of this chapter. Accordingly, in what follows, we discuss those exposures of the upper and lower extremities that are particularly useful in the trauma setting.

Upper Extremity

Operative exposure of potential vascular injuries in the upper extremity requires detailed knowledge of the anatomy of the axillary and brachial arteries. The axillary artery is surrounded by muscle on all sides, including the chest wall, the pectoral girdle, and the brachium. The vessel itself is divided into three segments by the pectoralis minor: the medial segment, the posterior segment, and the lateral segment. The specific operative approach depends on which of these three segments has been injured.

To gain access to the first (medial) segment of the axillary artery, the infraclavicular region must be exposed [see Figure 4]. This approach may also be useful for proximal control of more distal injuries, depending on the location and type of injury being treated. A horizontal incision is made 2 cm below the middle third of the clavicle, and dissection continues through the subcutaneous fascia, the pectoral fascia, the pectoralis fibers, and the clavipectoral fascia. At this level, the neurovascular bundle can be identified,

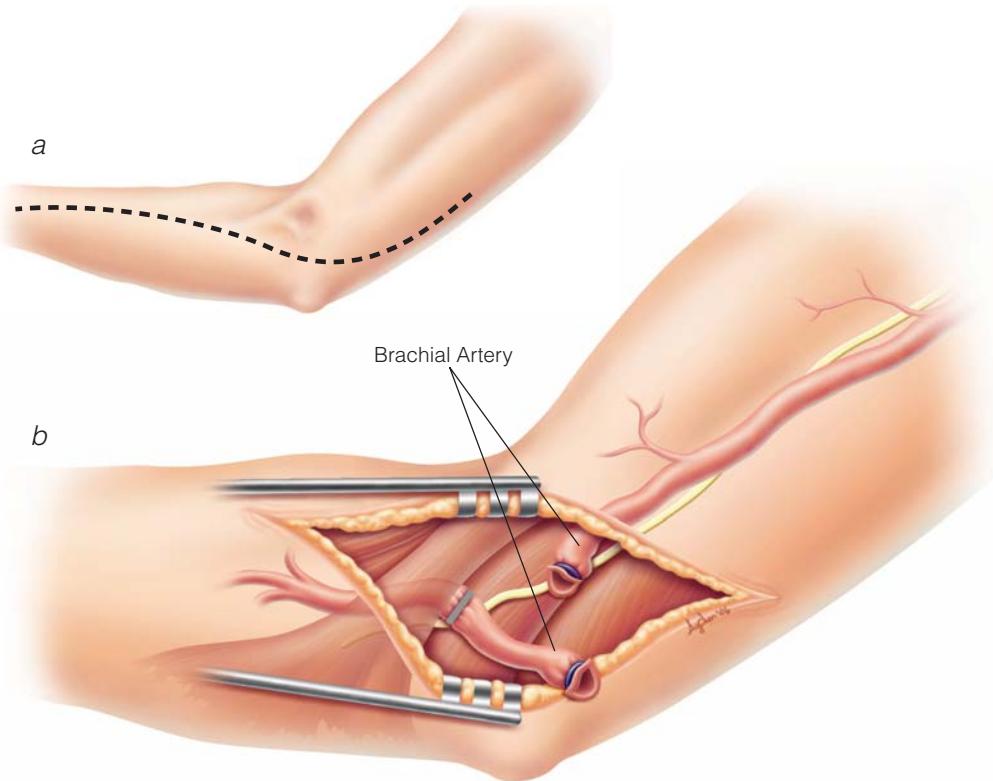

Figure 5 (a) Depicted is exposure of the brachial artery, with removal of an occluded segment to restore blood flow to the hand and forearm. (b) The incision is extended onto the forearm in an S shape to afford complete exposure.

with the artery lying superior and deep to the axillary vein. Exposure and control of the artery are obtained by means of sharp dissection. To gain access to the second (posterior) and third (lateral) portions of the axillary artery, an incision is made along the lateral border of the pectoralis major from the chest wall to the biceps. The coracobrachialis can then be identified; the neurovascular sheath is located at the posterior border of this muscle.³¹

As an alternative, the deltopectoral approach may be employed to gain access to any of the segments of the axillary artery. An incision is made from the midpoint of the clavicle along the anterior border of the deltoid muscle. The incision is deepened through subcutaneous tissue to reach the intramuscular groove. The cephalic vein is retracted, and the axillary artery may then be traced proximally and distally.

To expose the brachial artery, a longitudinal incision is made in the medial arm between the biceps and the triceps [see Figure 5], and dissection is carried out through the subcutaneous tissue. The basilic vein can then be identified. This vein is retracted inferiorly, and the neurovascular bundle is exposed by opening the deep fascia at the medial border of the biceps. To expose the brachial artery along with the arteries in the forearm, an S-shaped incision is made over the antecubital fossa. The superior portion of the incision follows the medial border of the biceps muscle and extends horizontally in the antecubital fossa; the inferior portion is made laterally on the volar forearm. Such an incision affords complete exposure of all of the target vessels. On subcutaneous dissection, multiple veins can be seen, including the median cubital vein, the cephalic vein, and the basilic vein. Exposure of the deep fascia and entrance into the bicipital aponeurosis allows exposure of the median nerve, the brachial artery, and two deep veins. The incision can be extended to track the radial and ulnar arteries.³¹

Lower Extremity

In addressing potential vascular injuries in the lower extremity, it is essential to be able to expose the CFA and the popliteal artery.

To gain access to the femoral artery, a vertical skin incision is made midway between the superior iliac spine and the pubic tubercle [see Figure 6]. This incision is opened to expose the superficial epigastric and superficial circumflex branches. The fascia lata is incised along the medial portion of the sartorius up to the inguinal ligament, and the femoral sheath is exposed and opened. (In an emergency situation where retroperitoneal or abdominal exposure is not warranted, the inguinal ligament can also be divided if necessary for more proximal control). The CFA can then be identified lateral to the femoral vein and can be tracked downward to the point where it bifurcates into the profunda femoris and the SFA. Typically, the profunda femoris branches laterally off of the CFA 3 to 5 cm distal to the inguinal ligament; the SFA lies superior to the profunda femoris. The incision may be extended inferiorly as necessary to locate more distal vascular injuries.³¹

In the setting of trauma, exposure of the popliteal artery is best accomplished via a medial approach. To expose the proximal (supragenicular) popliteal artery, an incision is made in the distal portion of the thigh along the anterior border of the sartorius [see Figure 7]. The fascia can be incised, the muscle retracted posteriorly, and the popliteal vessels may be identified. It may be necessary to divide the adductor tendon or the semimembranosus muscle for exposure. If necessary, this incision can be extended down the leg for exposure of the tibial vessels. To expose the distal (infragenicular) popliteal artery, an incision is made just behind the posteromedial surface of the tibia [see Figure 8]. The gastrocnemius is retracted posteriorly, and the semitendinosus, gracilis, and sartorius muscles are retracted superiorly. (These muscles may also be divided if more exposure is needed.) The popliteal vein is the first and most superficial portion of the neurovascular bundle. The tibial nerve is posterior and medial to the popliteal artery and should always be identified and protected during the dissection. If necessary, this exposure can be extended inferiorly to the tibial peroneal trunk for control of the distal arteries.³¹

DEFINITIVE REPAIR OF INJURY

Primary Repair versus Grafting

Once the need for operation has been established and the exposure chosen, the next step to determine which type of repair will be performed. Primary repair is preferred when possible; substantial proximal and distal mobilization of the artery may be required to allow a tension-free anastomosis.

Choice of Conduit

Often, the extent of the injury is such that primary repair is impossible and a conduit (autogenous or prosthetic) must be placed. It is crucial that the contralateral leg be prepared, so that a venous segment can be harvested if needed. In view of the possibility that the extremity arterial injury may be accompanied by significant venous injury, harvesting vein from the ipsilateral leg is discouraged. The most commonly used conduit is the great saphenous vein (GSV), which can be cut and

made to form a larger conduit by using a spiral technique or a panel graft technique.³² The superficial femoral vein (SFV) may also be used as a conduit,³³ but the dissection required is tedious and time-consuming and may be associated with significant morbidity.

Autogenous conduits should be used in contaminated wounds when direct vascular repair is not feasible. Nonautogenous conduits (e.g., polytetrafluoroethylene [PTFE] or Dacron grafts) may also be employed, but as a rule, they should be reserved for extreme situations in which native vein is not available. For patients with severe peripheral vascular injuries but without adequate available vein, PTFE appears to be an acceptable choice for primary reconstruction; graft infection is rare if the graft is covered with healthy tissue.^{34,35}

Management of Arteries in Distal Extremity

On occasion, arteries in the distal extremities (e.g., the radial, ulnar, or tibial arteries) may have to be repaired or ligated after

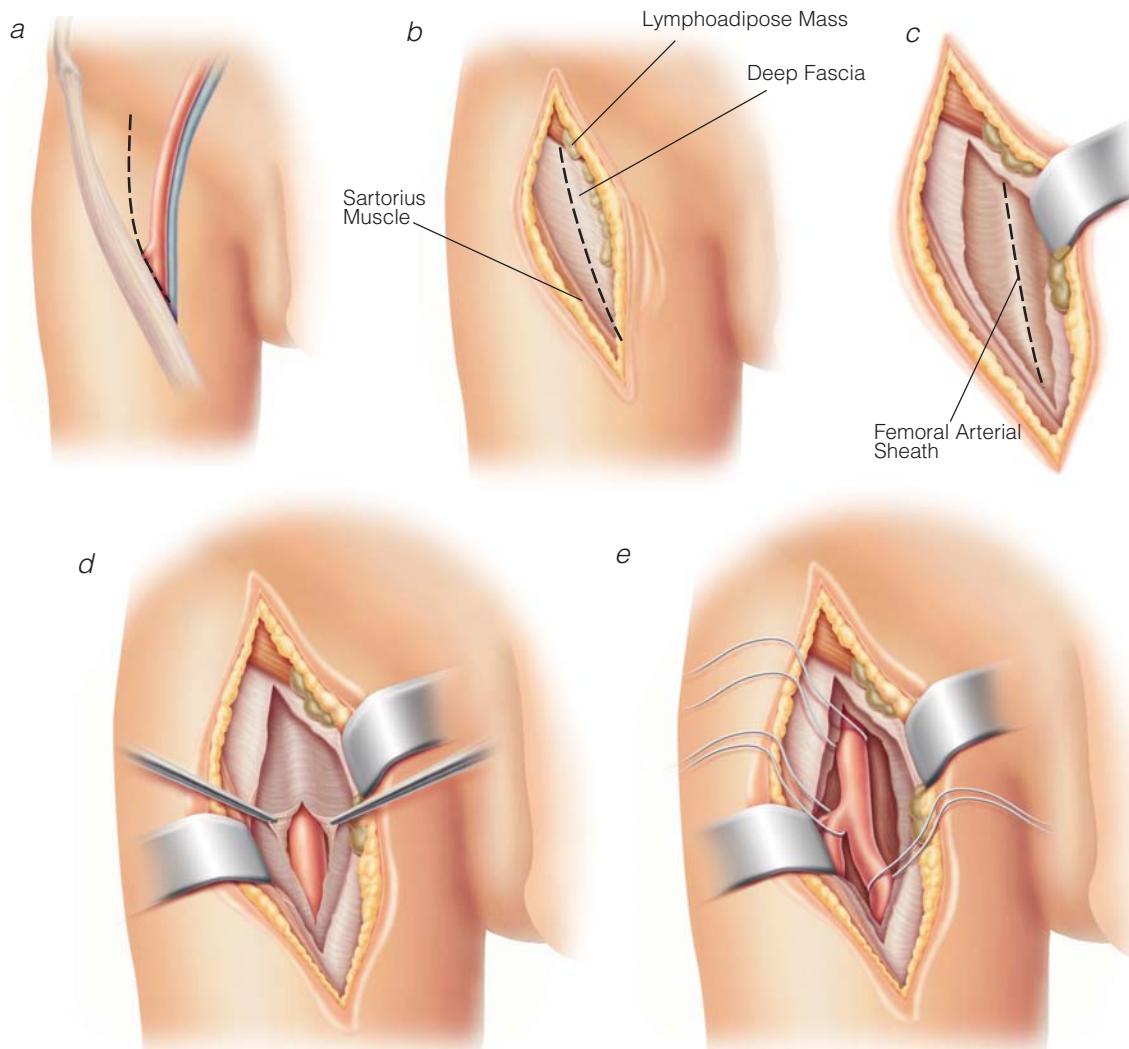

Figure 6 Depicted is exposure of the femoral artery. (a) A curved 10 to 12 cm. skin incision is made slightly lateral to the pulsation of the femoral artery. (b) Lymphoadipose tissue is retracted to expose the deep fascia overlying the course of the femoral artery. (c) The deep fascia is incised, exposing the femoral arterial sheath, which is then opened along its axis (d). (e) The common and superficial femoral arteries are mobilized and encircled with Silastic vessel loops.

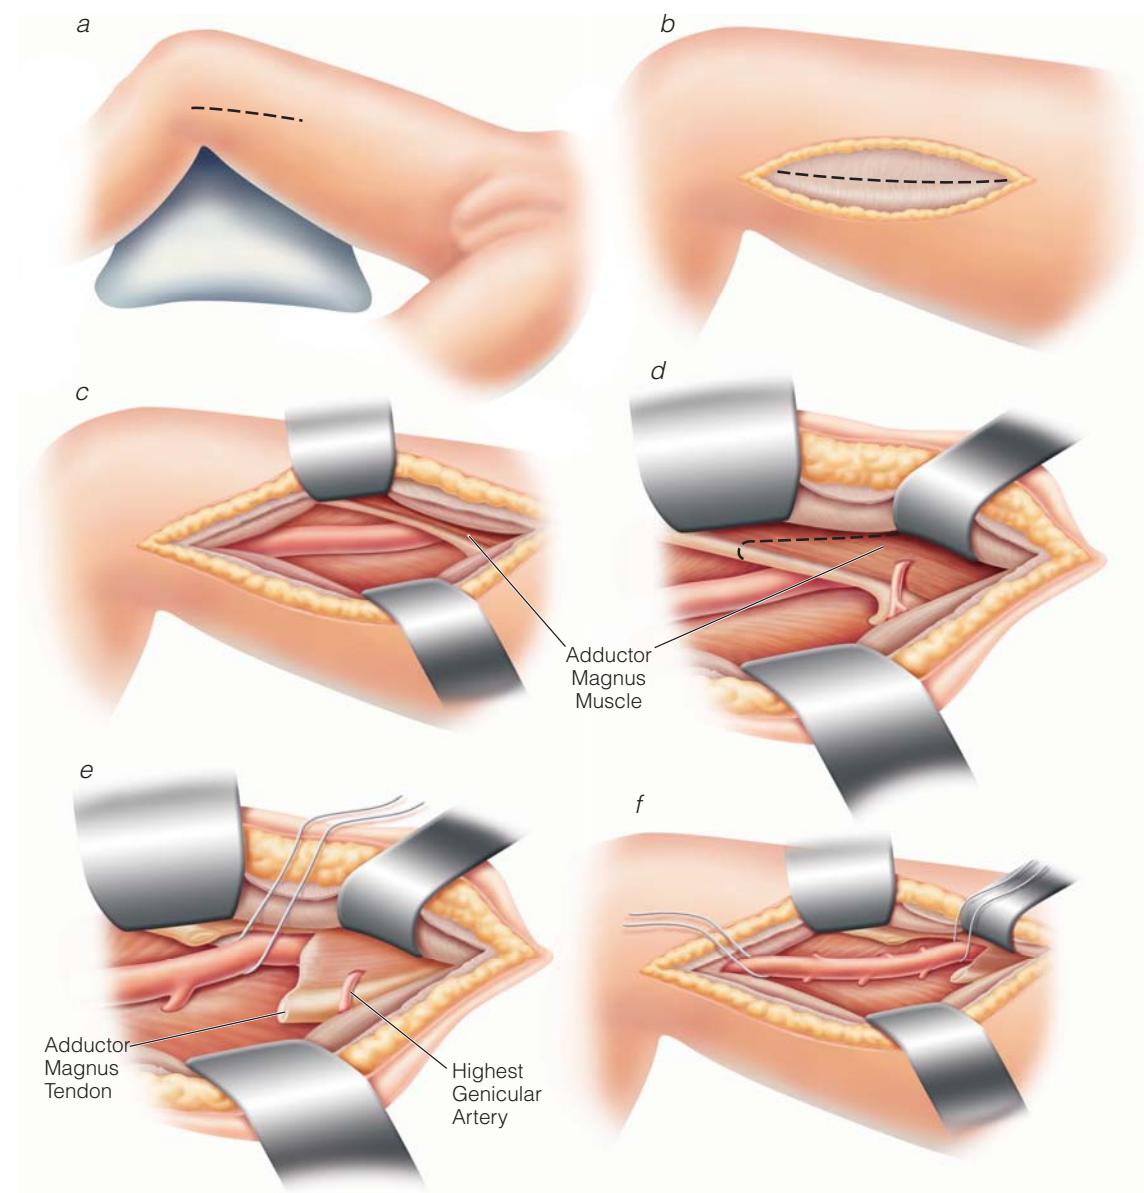

Figure 7 Depicted is medial exposure of the proximal popliteal artery. (a) An incision is made in the lower third of the thigh, anterior to the sartorius muscle. (b) The deep fascia is incised, and the sartorius muscle is retracted posteriorly, allowing the popliteal artery to be readily palpated. (c) The popliteal arterial sheath is opened, exposing the vessel and its surrounding venules. The adductor magnus tendon may be seen covering the proximal end of the artery (d), and it may have to be divided (e) to provide better exposure of the artery. (f) The popliteal artery, freed of the venous plexus, is mobilized between two vessel loops.

trauma. In most patients, there is little need for repair of these arteries, which can typically be ligated without deleterious effects. The safety of ligation is predicated on the presence of adequate arterial flow from the nonaffected arteries, as well as retrograde blood flow from an intact palmar or plantar arch.^{36,37} Repair of injuries to these arteries is associated with the possibility of embolization or other surgical problems. In addition, the patency rate for grafts in the distal extremities tends to be low.³⁸

Repair of Venous Injuries

In most regions of the extremities, repair of any concomitant venous injuries is recommended, on the grounds that it may help keep an arterial repair open and prevent postoperative edema. Primary repair involves closing the venotomy transversely; this may be facilitated by mobilizing the proximal and distal venous

structures. If primary repair is not possible, a patch is recommended. To augment venous flow and help maintain patency, an AV fistula may be created, then ligated at a later point. The administration of heparin and the use of a foot pump may also help maintain the patency of a venous repair, as well as reduce the hypercoagulability associated with Virchow's triad and venous occlusion.

If the vein cannot be repaired, it may have to be ligated. For injuries to the tibial vein and some injuries to the brachial vein or a more distal arm vein, ligation may be chosen over repair, with few deleterious consequences. For injuries to the popliteal vein or the SFV, repair is recommended when possible to optimize continued venous drainage of the extremity. As noted [see Choice of Conduit, above], if vein is harvested, it should come from the contralateral leg so as to permit continued outflow from the injured lower extremity.^{39,40}

If proximal ligation of a lower-extremity vein is required, it should be performed on the common iliac vein rather than the external iliac vein. Higher ligation allows cross-pelvis collateral circulation via the internal iliac veins. In addition, ligation of the external iliac vein is fraught with difficulty. Every attempt should be made to repair the vein to prevent major morbidity, including poor venous return and resultant severe edema. Ligation of the common femoral vein (CFV) is also not ideal, because of the risk of leg edema; however, if ligation at the level of the CFV proves necessary, it does allow some venous return flow via the cruciate collateral vessels, the obturator vein (from the medial circumflex femoral vein), and the gluteal vein (from the lateral circumflex femoral vein).

Postoperative Care

After repair of a vascular injury, patients require 24 hours of monitoring in the intensive care unit for serial pulse and Doppler assessments, monitoring of hemodynamic status, and evaluation of the site of the repair. In addition, patients must be watched for the development of metabolic derangements (e.g., metabolic acidosis, hyperkalemia, myoglobinuria, and renal failure) after hemorrhagic shock and reperfusion of ischemic limbs. Changes in the findings from physical examination, the neurologic status of the extremity, or the ABI warrant immediate investigation, usually beginning with duplex ultrasonography. Typically, a duplex examination is also performed in the early postoperative period to establish a baseline for subsequent surveillance of the graft or repair.

MANAGEMENT OF COMPARTMENT SYNDROME

Compartment syndrome is a condition characterized by abnormally high pressure within a closed space. The elevated tissue pressure leads to venous obstruction within the space. When the pressure continues to increase, the intramuscular arteriolar pressure is eventually exceeded. At that point, blood can no longer enter the capillary space, and the result is shunting within the compartment. If the pressure is not released, muscle and nerve ischemia occurs, leading to irreversible damage to the contents of the compartment.⁴¹

Underlying pathologic processes that reduce the size or increase the contents of a compartment include hemorrhage, reperfusion edema, a tight cast, constrictive dressings, and pneumatic antishock garments. Crush injury may be associated with rapid development of swelling and rigid compartments. The key to the diagnosis of compartment syndrome is continuous assessment of any extremity injury in which elevated pressures may develop. It must always be remembered that the diagnosis is a clinical one; although compartment pressures may be measured, clinical suspicion and findings suggestive of compartment syndrome on physical examination should suffice to mandate therapy.

Current management of compartment syndrome is derived from a 1970 review by Patman and Thompson, in which fasciotomy was performed after arterial reconstruction in 164 patients with peripheral vascular disease.⁴² The investigators concluded that fasciotomy could result in limb salvage and implied that it should be considered after restoration of arterial inflow to an extremity. Indications for fasciotomy included pain on palpation of the

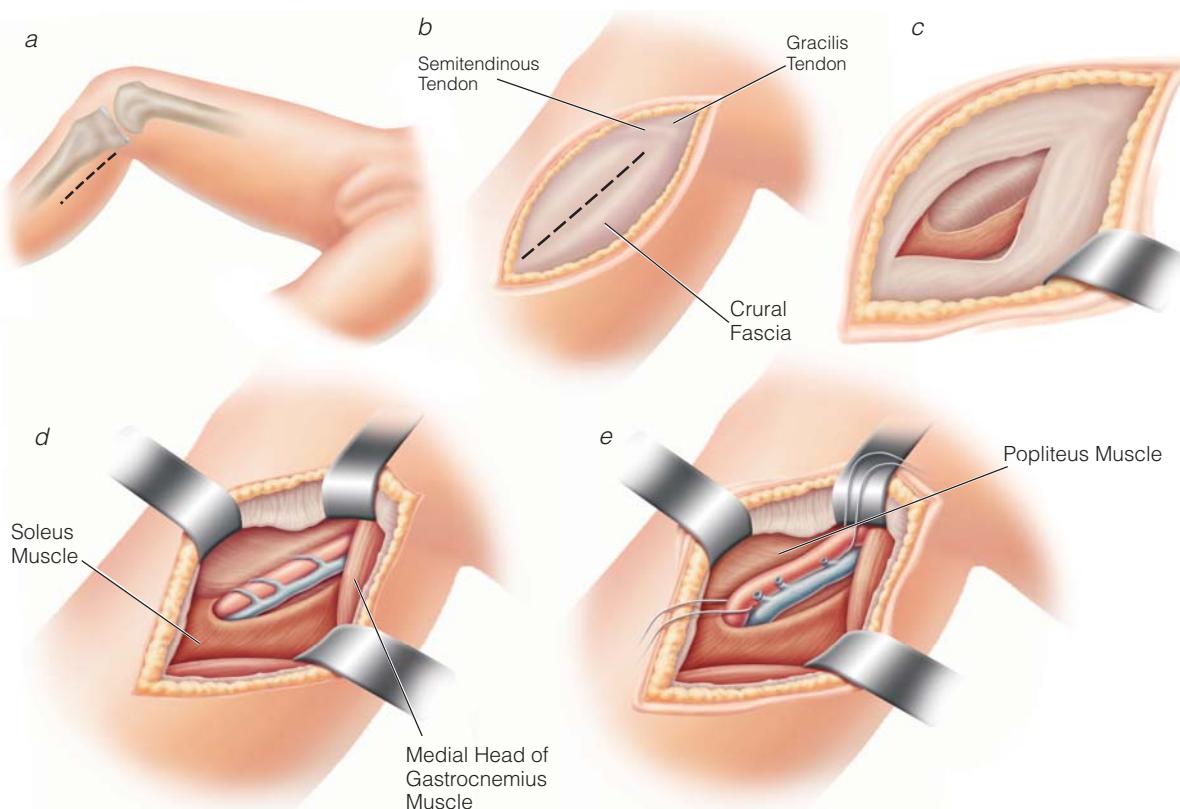

Figure 8 Depicted is medial exposure of the distal popliteal artery. (a) An incision is made just behind the posteromedial surface of the tibia. (b) The crural fascia is exposed. (c) The fascia is incised, exposing the vascular bundle. (d) The medial head of the gastrocnemius muscle is retracted posteriorly, exposing the distal popliteal vessels and the arcade of the soleus muscle. (e) The distal popliteal artery is freed and mobilized between vessel loops.

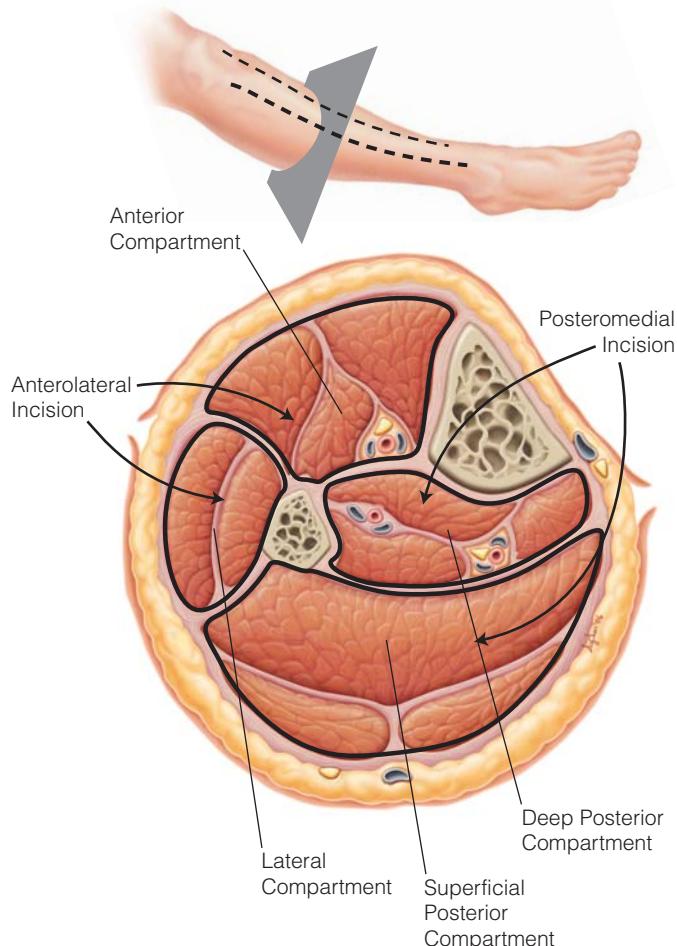

Figure 9 (a) Illustrated is the two-incision technique for lower leg decompression in compartment syndrome. Two vertical skin incisions are made from knee to ankle, separated by a skin bridge at least 8 cm wide. (b) Fasciotomies are then performed in all four compartments along the dashed lines.

swollen compartment, reproduction of symptoms with passive muscle stretch, a sensory deficit in the territory of a nerve traversing the compartment, muscle weakness, diminished pulses (a very late sign), and compartment pressure exceeding 30 to 35 mm Hg.

It has been noted that the difference between the diastolic pressure and the measured compartment pressure may be a more reliable clinical indicator of compartment syndrome than the compartment pressure by itself. A difference of less than 30 mm Hg between the two pressures is significant and may be the most reliable indicator of when fasciotomy is warranted.

There are a number of clinical situations in which fasciotomy should be considered: when there is a 4- to 6-hour delay before revascularization, when arterial injuries are present in conjunction with venous injuries, when crush injuries or high-kinetic energy injuries have been sustained, when vascular repair has already been performed (reperfusion), when an artery or vein has been ligated, when a patient is comatose or has a head injury and physical examination is impossible, and when a patient has tense compartments or elevated compartment pressures. In these scenarios, fasciotomy should be considered as a prophylactic maneuver.

Fasciotomy

The lower leg contains four osseofascial compartments: the anterior compartment, the lateral compartment, the superficial

posterior compartment, and the deep posterior compartment. The thigh contains three osseofascial compartments: the quadriceps, the hamstrings, and the adductors. For fasciotomies of the lower leg, there are two techniques: perifibular fasciotomy and the double-incision technique. Perifibular fasciotomy affords access to all four compartments of the leg via a single lateral incision that extends from the head of the fibula to the ankle, following the general line of the fibula. The double-incision technique employs two vertical skin incisions that are separated by a bridge of skin at least 8 cm wide [see Figure 9]. The first incision extends from knee to ankle and is centered over the interval between the anterior and lateral compartments; the second also extends from knee to ankle and is centered 1 to 2 cm behind the posteromedial border of the tibia.⁴¹ Although decompression in the lower extremity may be achieved via either of the two techniques, the double-incision technique is preferred in the setting of trauma because it readily ensures that all four compartments have been decompressed.

The forearm consists of three osseofascial compartments: the superficial flexor compartment, the deep flexor compartment, and the extensor compartment. To decompress the upper extremity, a volar fasciotomy, a dorsal fasciotomy, or both may be performed. A volar fasciotomy decompresses the superficial and deep flexor compartments of the forearm via a single skin incision.⁴¹ This incision begins medial to the biceps tendon, crosses the elbow crease, proceeds toward the radial side of the forearm, and extends distally along the medial border of the brachioradialis, finally continuing across the palm along the thenar crease [see Figure 10]. After the superficial and deep flexor compartments of the forearm are decompressed, intraoperative pressure measurements may be obtained to help determine whether fasciotomy is necessary to decompress the extensor compartment. If the pressure continues to be elevated in the extensor compartment, a dorsal fasciotomy should be performed. With the arm pronated, a straight incision is made from the lateral epicondyle to the midline of the wrist.⁴¹

After fasciotomy, both the fascia and the skin are left widely open. The skin defects may be closed with skin grafts at the time of original operation, provided that this can be done without excessive tension or pressure. Alternatively, the patient may be returned to the OR after the swelling resolves for delayed skin closure (with the fascia left open) or split-thickness skin grafting, as indicated.

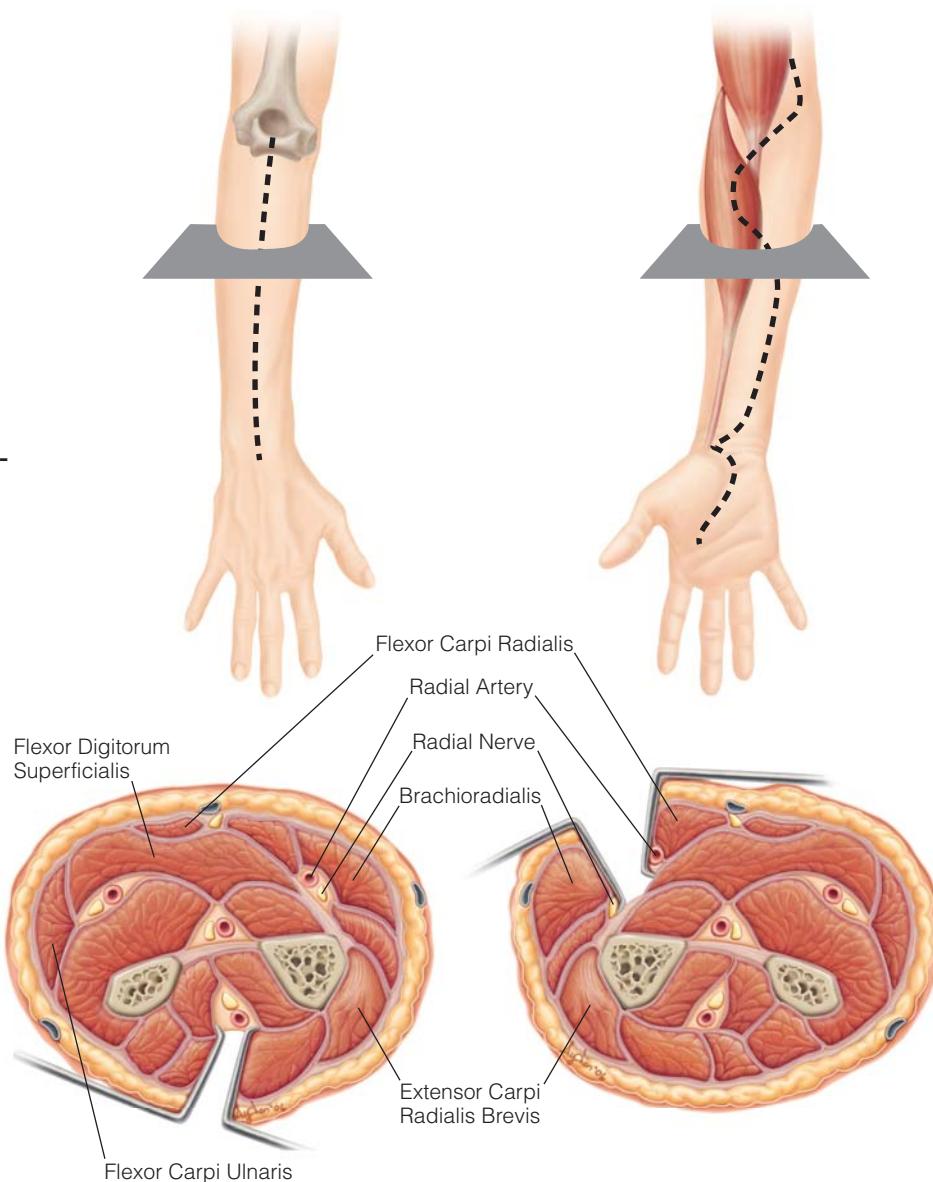

It is important to consider fasciotomy in patients with arterial injuries associated with crush injury and venous injury or occlusion. These secondary injuries may be associated with a higher risk of compartment syndrome than either isolated arterial injuries or ischemia-reperfusion alone.⁴³ In any setting, the most important concerns in performing a fasciotomy are that the procedure must be done in a timely manner and that all of the compartments must be completely decompressed.

Special Considerations

MANAGEMENT OF INTIMAL INJURIES

How best to manage small traumatic intimal injuries identified by means of angiography has been the subject of considerable debate. In general, patients who have injuries shorter than 2 mm and involving less than 50% of the vessel circumference, with no noted pulse deficits, may be placed on an antiplatelet regimen and followed clinically; evidence from animal studies supports this approach.⁴⁴ There is some clinical evidence to suggest that antiplatelet medication (e.g., acetylsalicylic acid) and observation alone may be adequate treatment in such patients; however, addi-

Figure 10 Shown are incisions for forearm decompression in compartment syndrome.

tional follow-up studies are required before this recommendation can be confirmed.⁴⁵

Even though some cases can be treated conservatively, it is important not to underestimate the potential importance of angiographically identified intimal injuries. Patients with such injuries are at risk for the development of a pseudoaneurysm, AV fistula, dissection, or even thrombosis.^{44,46,47}

ANTICOAGULATION

Whether anticoagulation is indicated in patients with vascular trauma is also debatable. It has been suggested that early administration of systemic anticoagulant therapy (heparin, 100 U/kg) may reduce amputation rates by preventing microvascular thrombosis. There is some evidence that anticoagulation may improve limb salvage rates while posing only a minimal risk of bleeding complications.⁴⁸ Systemic anticoagulation may be contraindicated in certain situations, such as active hemorrhage, coagulopathy, and craniocerebral injury. If heparin cannot be given systemically, it may be administered locally during the operation, at the site of the arterial repair.

ENDOVASCULAR INTERVENTION

At present, although there are several potential uses for endovascular techniques in the trauma setting, there are no clear indications for such interventions in the management of extremity vascular injuries. The reality is that there are few long-term data on the use of stents in the peripheral arteries even in nontrauma settings. For example, the patency rate for endoluminal stents in the SFA is between 60% and 80% at 2 years, a range lower than that of primary repairs or interposition grafts.⁴⁹ In addition, many patients who sustain extremity trauma are younger than the average vascular stent patient and have poorer access to health care; consequently, close long-term follow-up after an endovascular intervention may be harder to carry out in this population.

Endovascular therapy may be considered in certain instances of extremity vascular trauma, such as when systemic conditions rule out operative repair and a temporizing measure is warranted. It should be kept in mind, however, that endovascular repair of peripheral vascular injuries is still a developing form of treatment and not the standard of care.^{50,51}

TIMING OF ORTHOPEDIC REPAIR VIS-À-VIS VASCULAR REPAIR

Another issue that continues to evoke controversy is the timing of repair of concomitant vascular and orthopedic injuries—in particular, the order in which these injuries should be repaired. In general, vascular repair should take precedence over orthopedic reconstruction when possible. Vascular surgeons have long been concerned about the instability of knee dislocations and distal femoral or proximal tibial fractures, fearing that a fragile vascular reconstruction might be undone by subsequent orthopedic maneuvers; however, the data do not support this fear. There is some evidence that in patients with combined injuries, giving priority to revascularization over orthopedic fixation leads to shorter hospital stays and a trend toward lower fasciotomy rates. In a 2002 study, revascularization before fracture fixation was not found to result in iatrogenic disruption of the vascular repair.⁴³

When an extremity has been substantially destabilized as a consequence of bony injury, short-term external fixation may be employed to facilitate vascular repair. A temporary intraluminal shunt is often used to maintain perfusion during initial orthopedic stabilization. One study demonstrated that routine use of intraluminal shunts in patients with complex extremity vascular injuries had the potential to reduce excessive morbidity (e.g., the need for fasciotomy and the resultant prolonged hospital stay) from prolonged arterial insufficiency.⁵² In selected patients with combined skeletal and vascular injuries to the upper or lower limb, temporary vascular shunting may reduce complications resulting from prolonged ischemia and permit an unhurried and reasonable sequence of treatment.⁵³

SALVAGE OF SEVERELY INJURED OR MANGLED EXTREMITIES

When an extremity is severely injured or mangled, a decision must be made whether to attempt salvage or perform amputation. Because of the need to take the patient's emotional and medical concerns into account, evaluation of an extremity for potential salvage is a difficult undertaking. Several scoring systems have been developed to help make this decision-making process somewhat easier. The most commonly used system is the Mangled Extremity Scoring System (MESS), which uses four objective criteria to predict the likelihood of amputation after lower-extremity trauma: skeletal/soft tissue injury, limb ischemia, shock, and patient age. A MESS score of 7 or higher predicts amputation with an accuracy approaching 100%. However, it is essential to remember that each patient must be carefully evaluated and that attempts at limb salvage must not be base solely on a high MESS score.^{54,55}

The need for amputation may be best predicted by the occurrence of severe injuries to the sciatic or tibial nerves, the presence of associated fractures, and the failure of arterial repair.⁵ Often, the decision to amputate is not made at the time of presentation or during the initial operation. If, after revascularization and skeletal stabilization, the extremity is clearly nonviable or remains insensate, then delayed amputation may be performed under more controlled circumstances.⁵⁶

The optimal approach to evaluating a severely injured extremity involves a multispecialty group, including the trauma surgeon, the vascular surgeon, and the orthopedic surgeon. With full knowledge of the patient's condition, an attempt at limb salvage may be appropriate. In some cases, though, amputation may be preferable to preservation of an insensate, nonfunctional limb.

1 CARDIAC RESUSCITATION

Terry J. Mengert, M.D.

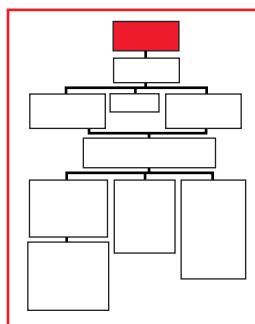

Approach to Cardiovascular Resuscitation

Out-of-hospital sudden cardiac arrest claims the lives of more than 300,000 persons in the United States each year, making it the leading cause of death.¹⁻⁴ In fact, approximately 50% of all cardiac deaths are sudden deaths.⁵ In hospitals, a minimum of 370,000 patients also suffer a cardiac arrest, followed by an attempted, but only sometimes successful, resuscitation.⁶ Although most victims of sudden death have underlying coronary artery disease (70% to 80%), sudden death is the first manifestation of the disease in half of these persons.² Other causes and contributing factors include abnormalities of the myocardium (i.e., chronic heart failure or hypertrophy from any cause), electrophysiologic abnormalities, valvular heart disease, congenital heart disease, and miscellaneous inflammatory and infiltrative disease processes (e.g., myocarditis, sarcoidosis, and hemochromatosis).⁷⁻⁹

The pathophysiology that culminates in a sudden cardiac death is complex and poorly understood. It likely represents a mix of electrical abnormalities combined with acute functional triggers, such as myocardial ischemia, central and autonomic nervous system effects, electrolyte abnormalities, and even pharmacologic influences.¹ Classically, most sudden deaths that occur in adults in the community are thought to be secondary to ventricular tachycardia (VT) that quickly degenerates into ventricular fibrillation (VF). In a 10-year study in the Seattle area, the different arrhythmias found in prehospital cardiac arrest patients presumed to have underlying cardiovascular disease were VF (45%), asystole (31%), pulseless electrical activity (PEA; 10%), VT (1%), and other arrhythmias (14%).³ Studies indicate that the out-of-hospital incidence of VF has decreased in recent years, probably because of the decrease in mortality from coronary artery disease.¹⁰

The Chain of Survival

The resuscitation of an adult victim of sudden cardiac arrest should follow an orderly sequence, no matter where the patient's collapse occurs. This sequence is called the chain of survival.¹¹ It comprises four elements, all of which must be instituted as rapidly as possible: activation of the emergency medical service network, cardiopulmonary resuscitation (CPR), early defibrillation, and provision of advanced care.

ACTIVATION OF EMERGENCY MEDICAL SERVICES

A person in cardiac arrest is unresponsive and pulseless, although agonal respirations may last for minutes. Confirm unresponsiveness by speaking loudly and gently shaking the patient. If the patient is truly unresponsive, immediately call for help by activating the emergency medical service in the community (in most locales, this means calling 911); or if the patient is already in the hospital, call a code (e.g., code blue, code 199). If an automated external defibrillator (AED) is available, have it brought to the resuscitation scene. AEDs are both easily used and lifesaving.¹²⁻¹⁶

INITIATION OF CPR

While awaiting the arrival of a defibrillator and advanced help, the rescuer assesses the patient's airway, breathing, and circulation [see The Primary Survey, below] and initiates CPR [see Table 1]. When CPR is started within 4 minutes of collapse, the likelihood of patient survival at least doubles.^{17,18}

INITIATION OF DEFIBRILLATION

When the AED or monitor-defibrillator arrives, attach it appropriately to the patient and analyze the patient's rhythm; if the patient is in VF or pulseless VT, a defibrillatory shock should be rapidly applied [see Tables 2 and 3]. If required, two additional shocks may be administered sequentially. The importance of rapid access to defibrillation cannot be overemphasized. In a patient who is dying from a shockable rhythm, the chance of survival declines by 7% to 10% for every minute that defibrillation is delayed.¹⁹

INITIATION OF ADVANCED CARE

If the patient remains pulseless despite the steps described above, resume CPR; establish a definitive airway, confirm its correct placement, and then secure it; establish intravenous access; then administer appropriate medications as determined by the rhythm and the arrest circumstances. If the patient is in VF or pulseless VT, repeated attempts at defibrillation are interspersed with delivery of vasoactive and antiarrhythmic drugs [see Table 4].

RESUSCITATION OUTCOME

When every link in the chain of survival is quickly and sequentially available, the patient is provided an optimal opportunity for return of spontaneous circulation.¹⁹⁻²² In the United States, individual communities report survival rates of 4% to 40% or more in cases of sudden cardiac death.²³⁻²⁷ Prehospital victims of VF have had survival rates to hospital discharge of greater than 50% when an AED was expeditiously used.²⁸ Many other factors also influence patient survival, however; these include whether the patient's collapse was witnessed, the rapidity and effectiveness of bystander CPR, the rhythm associated with the cardiac arrest, and underlying comorbidities.^{29,30} With inpatient cardiac arrest, for example, overall survival rates vary from 9% to 32%,³¹⁻³⁷ but in one study, survival to hospital discharge was 30% for patients with primary heart disease, 15% for patients with infectious diseases, and only 8% for patients with other end-stage diseases (e.g., cancer, lung disease, liver failure, or renal failure).³⁸

Such statistics underline the importance of using cardiac resuscitation appropriately and with discrimination. Cardiac resuscitation provides rescuers with powerful tools that save the lives of thousands of people every year. These techniques are capable of returning patients who would otherwise die to productive and meaningful lives. However, cardiac resuscitation should not be employed to reverse timely and natural death. Under those circumstances, it has the potential to lengthen the dying process and to increase human suffering. All practitioners are well advised to remember that "death is not the opposite of life, death is the opposite of birth. Both are as-

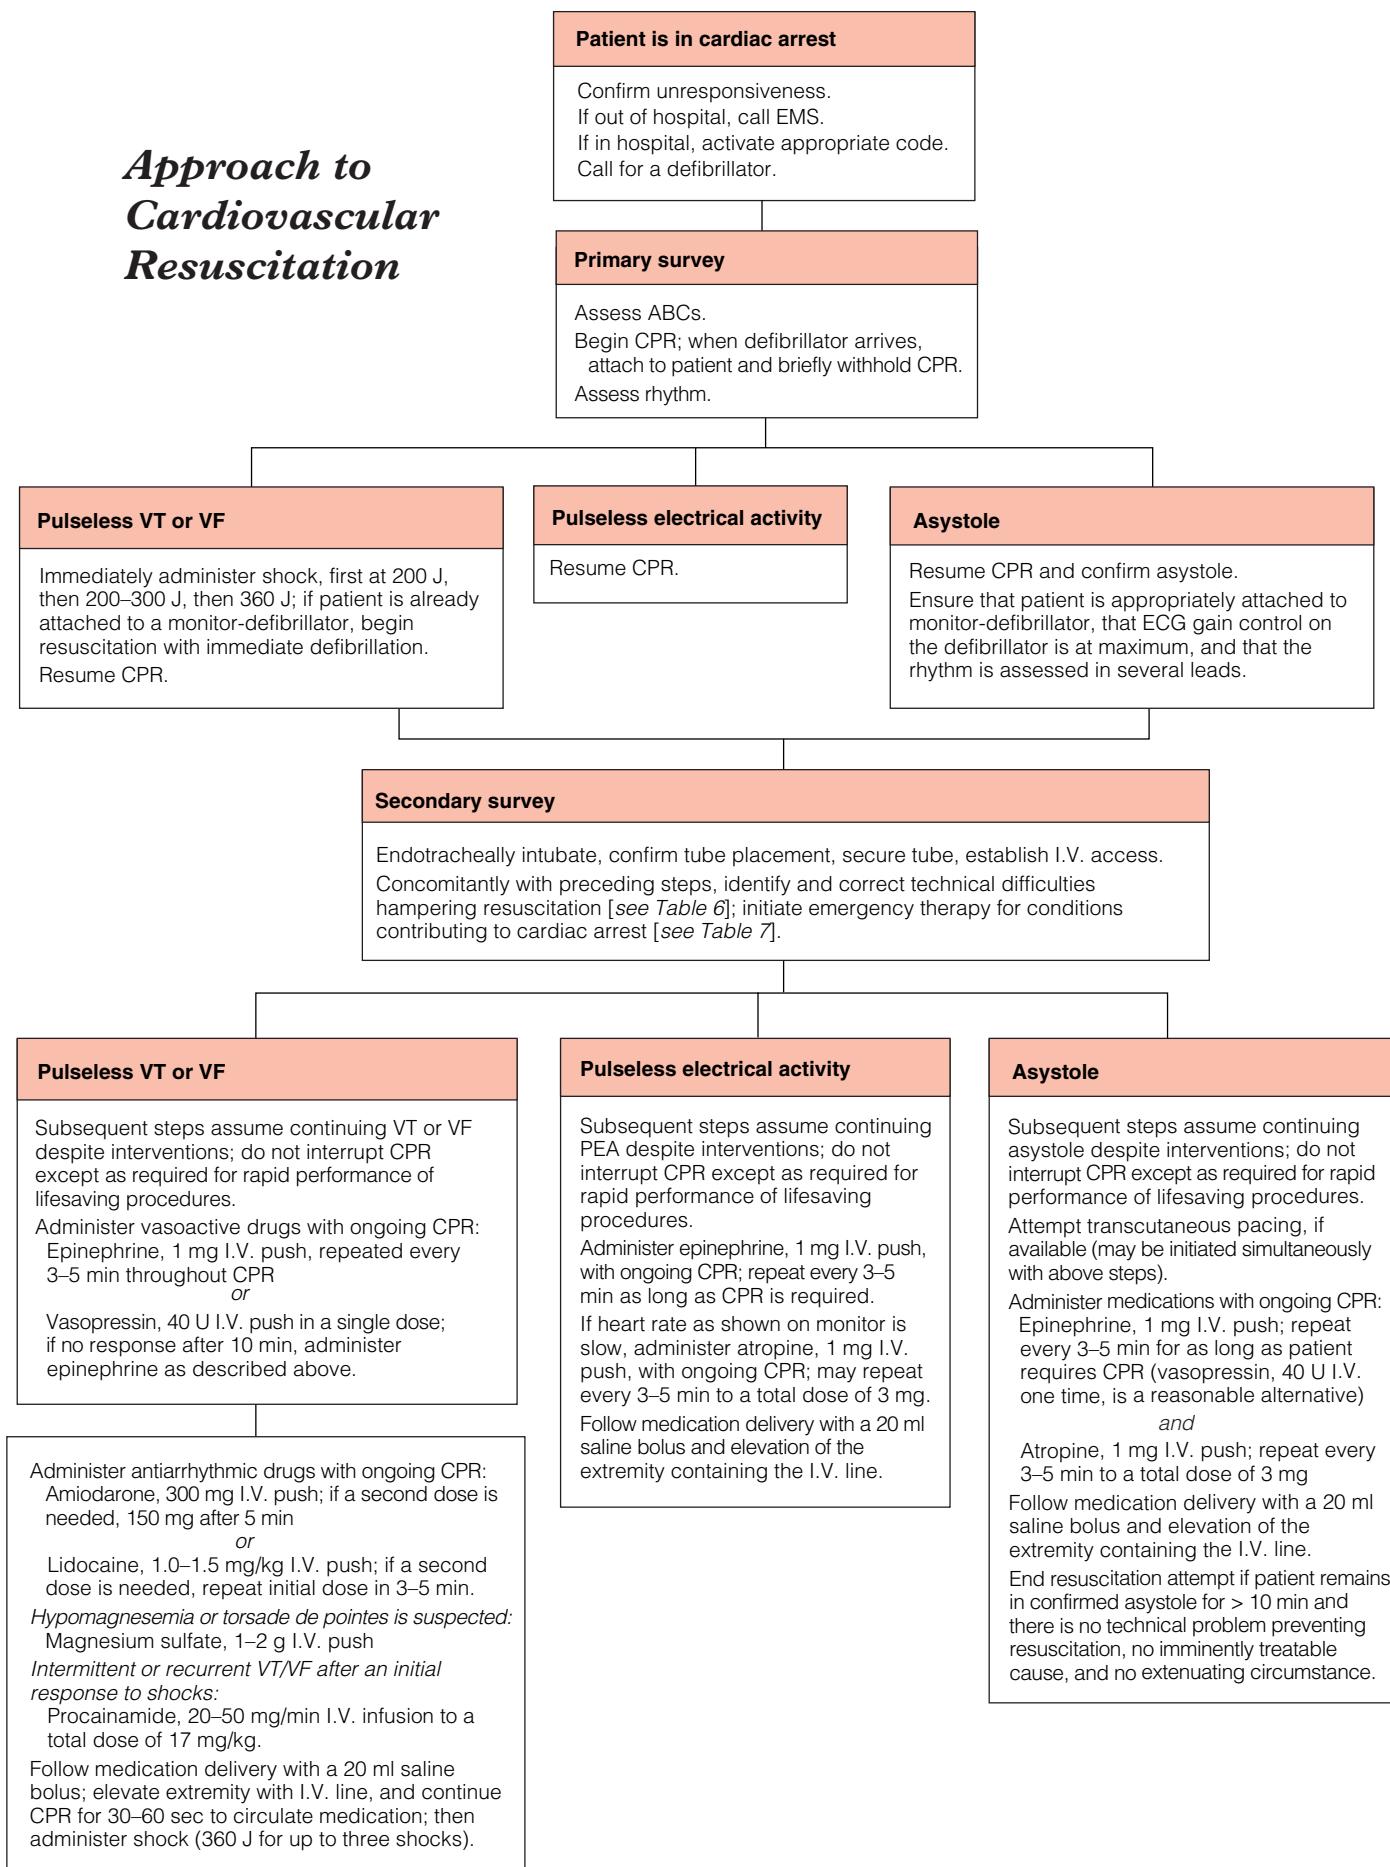

Table 1 Initial Resuscitation Steps in the Unresponsive Patient

- Confirm unresponsiveness
- Activate the emergency medical system
 - In most community locales, call 911
 - In the hospital, activate the appropriate code response
- Call for an automatic external defibrillator (AED)
- Begin basic life support (CPR)
 - Open airway
 - Check breathing; if not breathing, deliver two initial breaths
 - Check for a carotid pulse; if pulseless, do the following:
 - Begin chest compressions at the rate of 100 compressions/min, depressing the sternum 4–5 cm per compression in patients older than 8 yr
 - Intersperse ventilations with chest compressions: in nonintubated patients, deliver 15 compressions, pause for two breaths, then repeat; in intubated patients, deliver one breath every 5 sec, with no pause in compressions
 - Reassess for return of spontaneous circulation every 1–3 min
- When defibrillator arrives, immediately analyze and treat arrhythmia
 - Attach patient to AED [see Table 2] or the monitor-defibrillator [see Table 3]
 - Analyze arrhythmia and treat as appropriate

pects of life.”³⁹ It is untimely death that requires immediate intervention with cardiac resuscitation.

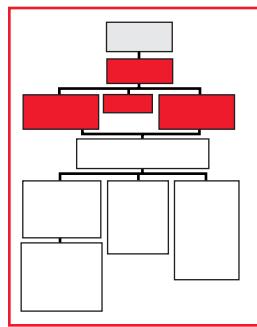

The Primary and Secondary Surveys of Cardiac Resuscitation

A cardiac resuscitation is a stressful event for everyone involved. Too often, clinic and inpatient cardiac arrests and their management are episodes of chaos in the busy lives of resident and attending physicians. Yet, it has been eloquently stated that a good resuscitation team should function like a fine symphony orchestra.⁴⁰ Such skill levels require dedicated individual and team practice and careful code-team organization. Mastery in cardiac resuscitation is in fact a lifelong pursuit that requires training and retraining in advanced cardiac life support (ACLS); regular practice and review; and leadership and team skill development. Its key elements include not only the resuscitation itself but the response to the announcement of a code, postresuscitation stabilization of the patient, notification of the family and primary care provider, and code critique and debriefing. To help practitioners learn and apply some of the most essential techniques used in cardiac resuscitation more easily and effectively, the American Heart Association (AHA) has developed the concepts of primary and secondary surveys of a patient in atraumatic cardiac arrest.⁴¹

THE PRIMARY SURVEY

The primary survey for the victim of sudden cardiac arrest consists of the appropriate assessment of the patient’s airway (A), breathing (B), and circulation (C) and the simultaneous application of expert CPR until defibrillation (D) becomes possible (assuming the patient is in VF or pulseless VT). Thus, the primary survey includes the second and third links in the chain of survival (see above).

In 1958, Kouwenhoven noted that when his research fellow forcefully applied external defibrillating electrodes on a dog’s chest

in the laboratory, an arterial pressure wave occurred.⁴² Further study and refinements led to the technique of closed-chest CPR, the careful description of which was published in 1960.⁴³ The first report of the use of this technique in patients was in 1961.⁴⁴ Since those early days, the fundamentals of closed-chest CPR have remained relatively unchanged. Mouth-to-mouth, mouth-to-mask, or bag-valve-mask ventilation oxygenates the blood. Chest compressions produce forward blood flow. This flow appears to result from a combination of direct compression of the heart and intrathoracic pressure changes.^{45,46}

CPR in isolation does not defibrillate the heart. Its main benefit is to extend patient viability until a defibrillator and advanced interventions become available and, one hopes, succeed in restoring spontaneous circulation in the patient. CPR is not nearly as effective as a contracting heart; systolic arterial pressure peaks of 60 to 80 mm Hg may be generated, but diastolic blood pressure remains low, and a cardiac output of only 25% to 30% of normal can be achieved even under optimal conditions.⁴⁷ Still, effective CPR is critical to keeping the patient alive. It is worth remembering that the most important rescuers at a cardiac resuscitation are those who are performing expert CPR, because it is only through their efforts that the patient’s heart and brain are kept viable until defibrillation and other advanced interventions can restore spontaneous circulation.

After unresponsiveness is confirmed, the emergency medical system is activated and an AED is called for; the primary survey (A, B, C, and D) proceeds as described (see below) until the AED arrives.

Airway Optimization

Open the patient’s mouth and optimize the airway in the non-trauma patient by use of the head-tilt and chin-lift maneuver. A jaw-thrust maneuver should be used instead of the head-tilt technique if cervical spine injury is suspected. In patients with suspected spine injury, proper spine alignment must be maintained throughout all phases of the resuscitation. In such circumstances, as

Table 2 Using an Automatic External Defibrillator in Patients Older than 8 Years

- Automatic external defibrillator (AED) arrives (CPR is in progress)
- Place AED beside patient.
- Turn on the AED.
- Attach the electrodes to the AED (they may be preattached).
- Attach the electrode pads to the patient (as diagrammed on the pads).
- AED analyzes patient’s rhythm
- Stop CPR (and ensure no one is touching the patient).
- Press the Analyze button on the AED (some devices analyze the rhythm automatically as soon as the pads are placed on the patient).
- AED instructs rescuers (via an audible voice prompt and/or on-screen instructions)
- Shock is indicated: clear the patient (ensure no one is touching the patient) and push the Shock button.
- After delivering shock, press the Analyze button again; the sequence of analysis followed by shock (if so indicated) may be performed a total of three times.
- or
- Shock not indicated: reassess the patient for signs of circulation; if present, assess the adequacy of breathing; if there are no signs of circulation, resume CPR for 1–2 min. After 1 min of CPR, assess the patient again for signs of circulation; if present, assess the adequacy of breathing. If the patient is still pulseless, repeat analysis, followed (if indicated) by shock steps.

Table 3 Using a Manual Defibrillator^{52,89}

Defibrillator arrives (CPR is in progress)

Place defibrillator beside patient.

Turn defibrillator on (initial energy level setting is typically 200 J).*

Set Lead Select switch to Paddles. Alternatively, if patient is already attached to monitor leads, set Lead Select switch to lead I, II, or III; ensure all three leads are correctly attached to the patient and the defibrillator: white to right shoulder, black to left shoulder, red to ribs on left side.

Apply gel to paddles or place conductor pads on patient's chest. Some devices use disposable electrode patches that are prepasted with a conducting gel. In either case, the appropriate positions of the paddles with applied gel, conductor pads, or disposable paddles are as follows: sternal paddle is placed to the right of the sternum, just below the right clavicle; apex paddle is placed to the left of the left breast, centered in the left midaxillary line at the fifth intercostal space.

Analyze rhythm

Briefly withhold CPR

If using paddles to assess rhythm, apply paddles as described with firm pressure (25 lb of pressure to each paddle) and visually assess rhythm on monitor (if using leads, briefly withhold CPR and assess rhythm in leads I, II, or III). If rhythm is either pulseless VT or VF, proceed as follows:

Defibrillate, then reassess

Announce to resuscitation team, "Charging defibrillator, stand clear!" and press Charge button on either paddles or defibrillator (initial energy, 200 J, not synchronized).*

Warn resuscitation team that a defibrillatory shock is coming:

"I am going to shock on three! ONE, I'm clear; TWO, you're clear, THREE, everybody's CLEAR!" Simultaneously with these statements, visually ensure that no resuscitation team member is in contact with patient.

Press the Discharge buttons on both paddles simultaneously to deliver a defibrillatory shock.

Reassess rhythm on monitor; if patient is still in VT or VF, recharge defibrillator (now 300 J)* and repeat process of loudly informing team members by giving the warning statements as above, and then apply defibrillatory shock.

Reassess rhythm on monitor; if patient is still in VT or VF, recharge defibrillator (now 360 J)* and repeat process of loudly informing team members by giving the warning statements as above, and then apply defibrillatory shock.

Reassess rhythm on monitor; if patient is still in VT or VF, resume CPR and continue with resuscitation sequence.

*Note: if using a biphasic defibrillator, a lower initial defibrillatory energy level (< 200 J) without energy escalation on subsequent shocks is acceptable.

VF—ventricular fibrillation VT—ventricular tachycardia

equipment becomes available, the patient's spine requires immobilization with a padded backboard, hard cervical collar, appropriate bolstering around the patient's head to prevent movement, and strapping of the patient to the backboard.⁴⁸

Breathing Assessment

To assess breathing, the rescuer places his or her cheek close to the patient's mouth and looks, listens, and feels for patient respirations. If the respirations are agonal or the patient is apneic, the rescuer then delivers two initial breaths. Each breath is delivered over 1.5 to 2.0 seconds. The patient's chest should rise with each delivered breath, and exhalation is allowed for between breaths. Breaths may be delivered using the mouth-to-mouth technique with appropriate barrier precautions (the patient's nose should be pinched if the mouth-to-mouth technique is used) or mouth-to-mask technique. The ideal device, if available, is a bag-valve-mask device attached to high-flow oxygen; this allows the delivery of a substantially higher oxygen concentration to the patient. If the patient cannot be ventilated, the rescuer repositions the airway and attempts the technique again. If the airway is still obstructed, up to five abdomi-

nal thrusts are then applied, followed by a finger sweep of the oropharynx to relieve suspected obstruction, and then ventilation attempts are repeated. Definitive intervention for an obstructed airway in the hospital setting may involve laryngoscopic visualization of the cause of obstruction and foreign-body removal. If an adequate airway cannot be established by less invasive means, cricothyrotomy may be required.

CPR Initiation

The health care rescuer next checks for a carotid pulse in the unresponsive patient but should allow no more than 10 seconds to do so. (The AHA no longer recommends pulse checks for rescuers who are not health care providers.⁴⁹ Instead, lay rescuers should initiate chest compressions if the patient is not breathing, coughing, or moving after the initial two breaths.) If the patient has no carotid pulse, begin chest compressions. The patient should be on a firm surface, and the heel of the rescuer's hand should be in the center of the inferior half of the patient's sternum (but cephalad to the xiphoid process). The rescuer's other hand is placed on top of the lower hand, with the fingers interlocked.

The rescuer's arms are held straight, with the force of each compression coming from the rescuer's trunk. In patients older than 8 years, the sternum is smoothly compressed by 1.5 to 2.0 inches, then released. The duration of the compression-release cycle is divided equally between compression and release. The rate of chest compression is 100 compressions/min in patients older than 8 years. The chest should be allowed to rebound to its precompression dimensions between compressions, but the resuscitator's palm closest to the patient should remain in contact with the sternum.

In nonintubated patients, chest compressions are regularly interrupted for the delivery of ventilations. The sequence is the same, regardless of whether one-rescuer or two-rescuer CPR is being performed: the rescuer delivers 15 compressions, pauses for two breaths (each given over 2 seconds), then resumes compressions. In endotracheally intubated patients, no pause for ventilation is necessary; every 5 seconds, one ventilation is delivered over a period of 1 to 2 seconds, while compressions continue.¹⁸

The optimal timing and ratio of ventilations to compressions in CPR is an ongoing area of research, which may lead to changes in the current recommendations. In the porcine model, for example, optimal neurologic outcome was achieved with the use of only compressions for the first 4 minutes, followed by a compression-ventilation ratio of 100:2.⁵⁰ In the prehospital setting, when rapid advanced care is available within minutes, bystander-initiated mouth-to-mouth ventilation combined with chest compressions offers no advantage over chest compressions alone.⁵¹

Good technique is critical throughout CPR delivery. The patient should have carotid pulses with chest compressions and should have appropriate breath sounds and chest movement with ventilations. Interestingly, femoral pulsations with CPR do not necessarily indicate effective CPR; these pulsations often are venous rather than arterial. Quantitative end-tidal carbon dioxide levels can be monitored, if practical. Higher levels correlate with more effective CPR and increased survival.⁵² The patient should be reassessed for return of spontaneous circulation every 1 to 3 minutes [see Table 1].

Defibrillation

When the monitor-defibrillator or AED arrives, it is attached to the patient; the rhythm is analyzed, and if the patient is in VF or pulseless VT, defibrillation is provided [see Tables 2 and 3].

Defibrillation is thought to work by simultaneously depolarizing a sufficient mass of cardiac myocytes to make the cardiac tissue ahead of the VT or VF wavefronts refractory to electrical conduction. Subse-

Table 4 Drugs Useful in Cardiac Arrest^{3,90}

Category	Drug and Doses Supplied	Indications in Cardiac Arrest	Adult Dosage	Comments
Vasopressors	Epinephrine, 1 mg in 10 ml emergency syringe; 1 mg/ml (1 ml and 30 ml vials)	Pulseless VT or VF unresponsive to initial defibrillatory shocks; PEA; asystole	1 mg I.V. push; may repeat every 3–5 min for as long as patient is pulseless; can also be given via the endotracheal route: 2–2.5 mg diluted with normal saline (NS) to 10 ml total volume	I.V. boluses of epinephrine (1 mg) are appropriate only in pulseless cardiac arrest patients; if continued epinephrine is required after resuscitation, a continuous infusion should be started (1–10 µg/min). High-dose epinephrine (up to 0.2 mg/kg I.V. per dose) does not improve survival to hospital discharge in cardiac arrest patients and is no longer recommended in adults.
	Vasopressin, 20 IU/ml (1 ml vial)	Pulseless VT or VF unresponsive to initial defibrillatory shocks	40 IU I.V. push, single dose only; can also be given via endotracheal tube: same dose, diluted with NS to 10 ml total volume	If no response after 10 min of continued resuscitation, administer epinephrine, as above.
Antiarrhythmics	Amiodarone, 50 mg/ml (3 ml vial)	Pulseless VT or VF unresponsive to initial defibrillatory shocks and epinephrine plus shock(s)	VT/VF: 300 mg diluted in 20–30 ml; NS or D5W rapid I.V. push; a repeat dose of 150 mg may be given if required in 5 min; maximum dose in 24 hr should not exceed 2,200 mg	Side effects may include hypotension and bradycardia in the postresuscitation phase.
	Lidocaine, 50 mg or 100 mg in 5 ml emergency syringes; pre-mixed bag, 1 g/250 ml or 2 g/250 ml	Pulseless VT or VF unresponsive to initial defibrillatory shocks and epinephrine plus shock(s)	Initial dose: 1–1.5 mg/kg I.V.; for refractory VF or unstable VT, may repeat 1–1.5 mg/kg I.V. in 3–5 min; maximum dose, 3 mg/kg May also be given endotracheally: 2–4 mg/kg diluted with NS to 10 ml total volume	If lidocaine is effective, initiate continuous I.V. infusion at 2–4 mg/min when patient has return of a perfusing rhythm (but do not use if this rhythm is an idioventricular rhythm or third-degree heart block with an idioventricular escape rhythm). Continuous infusion should begin at 1 mg/min in congestive heart failure or chronic liver disease or in elderly patients.
	Magnesium sulfate, 500 mg/ml (2 ml and 10 ml vials), or 10 ml emergency syringe	Pulseless VT or VF unresponsive to initial defibrillatory shocks and epinephrine plus shock(s) if suspected hypomagnesemic state	Administer 1–2 g diluted in 100 ml D5W I.V. over 1–2 min Total body magnesium deficits should be replaced gradually after initial therapy has stabilized the emergency: administer 0.5–1 g/hr for 3–6 hr, then reassess continued need	Measured magnesium levels correlate only approximately with the actual level of deficiency. Patients with renal insufficiency are at risk for dangerous hypermagnesemia; use appropriate caution. Side effects may include bradycardia, hypotension, generalized weakness, and temporary loss of reflexes.
	Procainamide, 100 mg/ml (10 ml injection); 500 mg/ml (2 ml vial)	Recurrent or intermittent pulseless VT or VF	20–30 mg/min I.V. (up to 50 mg/min if situation is critical); maximum dose is 17 mg/kg over time (but maximum dose is reduced to 12 mg/kg in setting of cardiac or renal dysfunction) Maintenance infusion is 1–4 mg/min	Administer procainamide during a perfusing rhythm. Stop procainamide administration when arrhythmia is adequately suppressed, hypotension occurs, QRS widens to > 50% of original duration, or maximum dose is administered.
Anticholinergic	Atropine, 1 mg in 10 ml emergency syringe	Asystole or PEA (if rate of rhythm is slow)	For asystole or PEA: 1 mg I.V. every 3–5 min up to 3 mg May be given via ET tube: 2–3 mg diluted with NS to 10 ml	Minimal adult dose is 0.5 mg. Avoid use in type II second-degree heart block or third-degree heart block.
Miscellaneous	Bicarbonate, 50 mEq in 50 ml emergency syringe	Significant hyperkalemia Significant metabolic acidosis unresponsive to optimal CPR, oxygenation, and ventilation Certain drug overdoses, including tricyclic antidepressants and aspirin	Hyperkalemia therapy: 50 mEq I.V. Metabolic acidosis: 1 mEq/kg slow I.V. push; may repeat half initial dose in 10 min; ideally, ABGs should help guide further therapy Use in overdose: discuss with toxicologist	In non-dialysis-dependent hyperkalemic patients, bicarbonate is most useful if metabolic acidosis is also present; bicarbonate is less effective in dialysis-dependent renal failure patients. The use of bicarbonate in metabolic acidosis management in cardiac arrest patients is controversial. Side effects may include sodium overload, hypokalemia, and metabolic alkalosis.
	Calcium chloride, 100 mg/ml in 10 ml prefilled syringe	Significant hyperkalemia Calcium channel blocker drug overdose Profound hypocalcemia of other causes	In hyperkalemia: 5–10 ml slow I.V. push; may repeat if required In calcium channel blocker overdose: discuss with toxicologist	Do not use if suspected cause of hyperkalemia is acute digoxin poisoning. Do not combine in same I.V. with sodium bicarbonate. Calcium chloride is not a routine medication in cardiac arrest.

Note: All medications used during cardiac arrest, when given via a peripheral venous site in an extremity, should be followed by a 20 ml I.V. saline bolus and elevation of the extremity for 10 to 20 sec.

ABG—arterial blood gases D5W—5% dextrose in water ET—endotracheal PEA—pulseless electrical activity VF—ventricular fibrillation VT—ventricular tachycardia

quently, the sinus node or another appropriate pacemaker region of the heart with inherent automaticity can resume orderly depolarization-repolarization, with return of a perfusing rhythm.^{15,53} The sooner defibrillation occurs, the higher the likelihood of resuscitation. When defibrillation is provided immediately after the onset of VF, its success rate is extremely high.⁵⁴ In a study of sudden cardiac arrest patients in Nevada gambling casinos, the survival rate to hospital dis-

charge was 74% for patients who received their first defibrillation no later than 3 minutes after a witnessed collapse.²⁸ In this study, defibrillation was delivered via an AED operated by casino security officers.

Early defibrillation is so critical that if a defibrillator is immediately available, its use traditionally takes precedence over CPR for patients in VF or pulseless VT of recent onset. If CPR is already in progress, it should of course be halted while defibrillation takes place. Newer de-

fibrillators can compensate for thoracic impedance, ensuring that the selected energy level is in fact the energy that is delivered to the myocardial tissue. In addition, defibrillators that deliver biphasic defibrillation waveforms instead of the standard monophasic damped sinusoidal waveforms allow effective defibrillation at lower energy levels (< 200 joules) and without the need for energy-level escalation during subsequent shocks.^{15,55-58} In the Optimized Response to Cardiac Arrest (ORCA) study, which involved 115 patients with prehospital VF, the 150-joule biphasic-shock AED was more effective than the traditional high-energy monophasic-shock AED in four respects: it was more successful in producing defibrillation with the first shock (96% versus 59%); it led to a higher rate of ultimate success with defibrillation (100% versus 84%); it had a better rate of return of spontaneous circulation (76% versus 54%); and its use was associated with a higher rate of good cerebral performance in the survivors (87% versus 53%).⁵⁹ There were no differences, however, in terms of survival to hospital admission or discharge, and replication of the ORCA findings is lacking at this time. Current AHA guidelines state that lower-energy biphasic waveform defibrillators are safe and have equivalent or higher efficacy for termination of VF, as compared with the standard monophasic waveform defibrillator.^{15,49}

Ongoing research suggests that the duration of VF is a consideration in deciding whether to defibrillate immediately and as soon as a defibrillator is available or to perform CPR for a brief period first to “prime the pump” before proceeding to defibrillation. In the porcine model in the setting of prolonged VF (> 10 minutes), CPR before countershock provides several physiologic benefits.⁶⁰ Studies have found that patients with VF of longer than 5 minutes’ duration had better return of spontaneous circulation, survival to hospital discharge, and 1-year survival if ambulance personnel provided 3 minutes of CPR before performing defibrillation than if ambulance personnel performed defibrillation immediately after arriving at the scene; however, some experts question the validity of these results, on the basis of study design.^{61,62}

THE SECONDARY SURVEY

The secondary survey for a victim of persistent cardiac arrest takes place after completion of the primary survey. Like the primary survey, the secondary survey follows an ABCD format, which in this case consists of advanced airway interventions (A); optimized oxygenation and ventilation by confirmation of endotracheal (ET) tube placement and repeated reassessment of the adequacy of delivered breaths (B); intravenous access and appropriate medication delivery to the patient’s circulation (C); and definitive therapy (D), based on a differential diagnosis that considers the specific disease processes thought to be responsible for, or contributing to, the cardiac arrest. The secondary survey includes the fourth link in the chain of survival, rapid advanced care (see above).

Placement of an Advanced Airway

Patients who remain in cardiac arrest after completion of the primary survey require placement of an advanced airway. Depending on the setting and the experience of the rescuers, this advanced airway may be a laryngeal mask airway, an esophageal-tracheal Combitube (a tracheal tube bonded side by side with an esophageal obturator), or an ET tube.^{36,63,64} The laryngeal mask airway and the Combitube can be placed by personnel with less training than that required for endotracheal intubation, and they do not require additional special equipment or visualization of the vocal cords. Never-

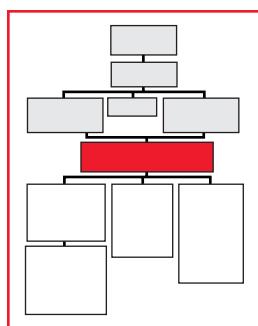

Table 5 Confirmation of Endotracheal Tube Placement

Intubation process

Vocal cords are visualized by intubator

Tip of ET tube is seen passing between the cords

Cuff of ET tube also passes cords by 1 cm

Postintubation checks

Esophageal detector device or end-tidal CO₂ detector confirms ET tube placement in trachea

Breath sounds are symmetrical (auscultate over lateral anterior chest and in midaxillary line bilaterally)

No gurgling with auscultation over epigastrium

Patient’s chest rises and falls appropriately with ventilation

ET tube depth is appropriate: 21 cm at the corner of the mouth in women, 23 cm in men

Secure the ET tube to prevent dislodgment

Reassess the adequacy of oxygenation and ventilation throughout the resuscitation (bedside patient assessment; also obtain ABGs when feasible)

After resuscitation, obtain a portable chest radiograph

ABG—arterial blood gas ET—endotracheal

theless, oral endotracheal intubation is generally the preferred advanced airway technique for cardiac resuscitation, especially in the hospital setting, where experienced intubators are generally present; in the prehospital setting, the evidence supporting endotracheal intubation remains inconsistent. Endotracheal intubation isolates the airway, maintains airway patency, helps protect the trachea from the ever-present risk of aspiration, helps permit optimal oxygenation and ventilation of the patient, allows for tracheal suctioning, and even provides a route for delivery of some medications to the systemic circulation (via the pulmonary circulation) if intravenous access is unobtainable or lost.⁶³

Optimization of Breathing and Ventilation

When a cardiac arrest patient undergoes endotracheal intubation, correct positioning of the ET tube must be immediately confirmed and regularly reconfirmed during and after the resuscitation [see Table 5]. Routine use of an esophageal detector device or end-tidal CO₂ detector is recommended, along with careful patient examination. Caution is necessary with qualitative colorimetric end-tidal CO₂ detectors because both false positive and false negative results have been documented during cardiac arrests.⁶⁵ Breath sounds should be present during auscultation over the anterior and lateral chest walls, and the patient’s chest should rise and fall with delivered ventilations. No gurgling should be heard when the epigastrium is auscultated. The ET tube should be inserted to the appropriate depth marking: for average-sized adults, this is 21 cm at the corner of the mouth in a woman and 23 cm in a man. The patient’s skin color should be reasonable (i.e., not dusky or cyanotic), provided that the patient’s pigmentation allows such assessment.

Once correct positioning is confirmed, the ET tube is then appropriately secured to prevent its dislodgment. When feasible, an arterial blood gas (ABG) measurement will help further confirm the adequacy of oxygenation and ventilation as the resuscitation proceeds.

Establishment of Circulation Access

Access to the patient’s venous circulation is mandatory; such access may be achieved by a code-team member or members simultaneously while other resuscitators pursue steps A and B of the secondary survey. Ideally, a large intravenous cannula is placed in a

Table 6 Technical Problems That May Prevent a Successful Resuscitation

Problem	Patients at Risk	Recommendations
Ineffective CPR	All cardiac arrest patients	Ensure technically perfect CPR. Confirm carotid pulses with CPR. If arterial line was in place before cardiac arrest, confirm adequate arterial waveform with CPR on arterial line monitor. Monitor end-tidal CO ₂ if available (higher levels correlate with better CPR and improved patient survival). Confirm adequate oxygenation with an ABG when feasible.
Inadequate oxygenation and ventilation	All cardiac arrest patients	Ensure optimal airway positioning and control. Have suction immediately available to manage pharyngeal and airway secretions. Ensure use of properly fitting, tightly sealed face mask for bag-valve mask (BVM) ventilation until a definitive airway is established. Apply cricoid pressure to prevent gastric distention during BVM ventilation until a definitive airway is established. Ensure that supplemental oxygen is flowing to BVM at 15 L/min. Deliver an appropriate tidal volume per breath (6–7 ml/kg if oxygen is available) at the rate of 12–15 breaths/min. Confirm bilateral and equal breath sounds with ventilation. Confirm that patient's chest rises with each ventilation. Allow adequate time for exhalation between breaths. Confirm optimal oxygenation and ventilation with an ABG when feasible.
ET tube difficulties	All patients intubated with ET tube	Allow ≤ 20–30 sec/intubation attempt. Intubator should see tip of ET tube and cuff pass between vocal cords at time of intubation. After intubation, immediately confirm correct ET tube placement; regularly reconfirm ET tube placement throughout resuscitation. Confirm adequacy of oxygenation and ventilation with an ABG. After intubation, consider nasogastric tube placement to decompress stomach and optimize diaphragmatic excursions with ventilation.
Intravenous line difficulties	All cardiac arrest patients	Place one or more 18-gauge or larger I.V. cannulas in an antecubital or external jugular vein site. Check for I.V. infiltration regularly throughout the resuscitation. Follow all medications administered through a peripheral I.V. site with a 20 ml saline bolus and elevation of the extremity containing the I.V. for 10–15 sec (if possible). Consider central line placement if the resuscitation is prolonged. Be aware of all I.V. infusions the patient is receiving. Stop all nonessential medications that had been started before the cardiac arrest. During the resuscitation, the only infusions the patient should receive are normal saline, blood products (if clinically indicated), and pertinent medications necessary to assist with return of spontaneous circulation. Pulmonary artery catheters and central lines occasionally act as an arrhythmogenic focus within the right ventricle. If applicable, deflate all relevant balloons on the catheter and withdraw the catheter to a superior vena cava position.
Monitor defibrillator difficulties	All cardiac arrest patients	Make sure Synchronization Mode button is in the off position when defibrillating patients in pulseless VT or VF. Make sure electricity is not arcing over the patient's chest because of perspiration or smeared conducting gel; dry patient's chest with a towel except for areas directly beneath pads or paddles. Do not administer shock through nitroglycerin paste or patches. If the patient has an internal cardioverter-defibrillator (ICD) or a pacemaker, the patient may still be manually defibrillated, but do not shock directly over the internal device. Under these circumstances, place the pads or paddles at least 2.5 cm away from the patient's internal device. If the ICD is intermittently firing but not defibrillating the patient and if the ICD is thought to be compromising the resuscitation, turn the device off with a magnet so that manual defibrillation may take place without interference. Maximize the gain or electrocardiography "size" and check the rhythm in several leads (or change the axes of the paddles if reading the rhythm in Paddles mode) to confirm asystole when the initial rhythm appears to be asystole.

ABG—arterial blood gas ET—endotracheal VF—ventricular fibrillation VT—ventricular tachycardia

prominent upper-extremity vein or the external jugular vein to optimize delivery of needed medications. If a peripheral line is not achievable, additional access possibilities include central line placement via the internal jugular, subclavian (via the supraclavicular approach), or, less ideally, femoral vein; even intraosseous access is possible (intraosseous access is a common emergency vascular access site in pediatric patients, but it is an unusual route of access in adults). It is useful to remember, as already noted, that some important resuscitation medications can be delivered via the ET tube in cases of failed intravenous access; such medications include naloxone, atropine, vasopressin, epinephrine, and lidocaine (mnemonic: NAVEL).

The commonly used medications in cardiac resuscitation may be grouped into the following general categories: vasopressors (epinephrine or vasopressin), antiarrhythmics (amiodarone, lidocaine, magnesium, and procainamide), anticholinergic agents (atropine, if

the arrest arrhythmia is asystole or PEA is slow), and miscellaneous drugs used to treat specific problems contributing to the arrest state, such as sodium bicarbonate (for severe metabolic acidosis, hyperkalemia, and certain drug overdoses), and calcium chloride (for hyperkalemia, calcium channel blocker drug overdose, or severe hypocalcemia) [see Table 4].

Persons in cardiac arrest (which can result from pulseless VT, VF, PEA, or asystole) require a vasopressor for as long as they remain pulseless. Typically, this consists of 1 mg of epinephrine intravenously every 3 to 5 minutes. Epinephrine stimulates adrenergic receptors, which leads to vasoconstriction and optimization of CPR-generated blood flow to the heart and brain. Vasopressin (40 units I.V. once only) is a reasonable alternative to epinephrine, at least initially. Vasopressin in the recommended dose is a potent vasoconstrictor. It also has the theoretical advantage over epinephrine of not increasing myocardial

Table 7 Potentially Treatable Conditions That May Cause or Contribute to Cardiac Arrest³

Condition	Clinical Setting	Diagnostic and Corrective Actions
Acidosis	Preexisting acidosis, diabetes, diarrhea, drugs, toxins, prolonged resuscitation, renal disease, shock	Obtain stat ABG. Reassess technical quality of CPR, oxygenation, and ventilation. Confirm correct endotracheal tube placement. Hyperventilate patient (P_aCO_2 of 30–35 mm Hg) to partially compensate for metabolic acidosis. If pH < 7.20 despite above interventions, consider I.V. sodium bicarbonate, 1 mEq/kg I.V. slow push.
Cardiac tamponade	Hemorrhagic diathesis, malignancy, pericarditis, post cardiac surgery, post myocardial infarction, trauma	Initiate large-volume I.V. crystalloid resuscitation. Confirm diagnosis with emergency bedside echocardiogram, if available. Perform pericardiocentesis. Immediate surgical intervention is appropriate if pericardiocentesis is unhelpful but cardiac tamponade is known or highly suspected clinically.
Hypoglycemia	Adrenal insufficiency, alcohol abuse, aspirin overdose, diabetes, drugs, toxins, liver disease, renal disease, sepsis, certain tumors	Consider clinical setting and obtain finger-stick glucose or stat blood glucose measurements (may be obtained on ABG specimen). If glucose < 60 mg/dl, treat: 50 ml = 25 g of D50W I.V. Follow glucose levels closely post treatment.*
Hypomagnesemia	Alcohol abuse, burns, diabetic ketoacidosis, severe diarrhea, diuretics, drugs (e.g., cisplatin, cyclosporine, pentamidine), malabsorption, poor intake, thyrotoxicosis	Obtain stat serum magnesium level. Treat: 1–2 g magnesium sulfate I.V. over 2 min. Follow magnesium levels over time, because blood levels correlate poorly with total body deficit.
Hypothermia	Alcohol abuse, burns, central nervous system disease, debilitated and elderly patients, drowning, drugs, toxins, endocrine disease, exposure history, homelessness, poverty, extensive skin disease, spinal cord disease, trauma	Obtain core body temperature. If severe hypothermia (< 30° C), limit initial shocks for pulseless VT/VF to three, initiate active internal rewarming and cardiopulmonary support, and hold further resuscitation medications or shocks until core temperature > 30° C [†] . If moderate hypothermia (30°–34° C), proceed with resuscitation (space medications at intervals greater than usual), passively rewarm, and actively rewarm truncal body areas.
Hypovolemia, hemorrhage, anemia	Major burns, diabetes, gastrointestinal losses, hemorrhage, hemorrhagic diathesis, malignancy, pregnancy, shock, trauma	Initiate large-volume I.V. crystalloid resuscitation. Obtain stat hemoglobin level on ABG specimen. Emergently transfuse packed red blood cells (O negative if type-specific blood not available) if hemorrhage or profound anemia is contributing to arrest. Emergently consult necessary specialty for definitive care. Emergency thoracotomy with open cardiac massage is a consideration if experienced providers are available for the patient with penetrating trauma and cardiac arrest.
Hypoxia	All cardiac arrest patients are at risk	Reassess technical quality of CPR, oxygenation, and ventilation. Confirm correct ET tube placement. Obtain stat ABG to confirm adequate oxygenation and ventilation.
Myocardial infarction	Consider in all cardiac arrest patients, especially those with risk factors for coronary artery disease, a history of ischemic heart disease, or prearrest picture consistent with an acute coronary syndrome	Review prearrest clinical presentation and ECG. Continue resuscitation algorithm; proceed with definitive care as appropriate for the immediate circumstances (e.g., thrombolytic therapy, cardiac catheterization/coronary artery reperfusion, circulatory assist device, emergency cardiopulmonary bypass).

(continued)

oxygen consumption or lactate production in the arrested heart.⁶⁶ Despite its potential advantages, however, in a study of 200 inpatient cardiac arrest patients, vasopressin did not provide a better survival rate than epinephrine.⁶⁷ Vasopressin was also found to be comparable to epinephrine in out-of-hospital cardiac arrests when the rhythm was VF or PEA but superior to epinephrine for patients in asystole.^{68,69}

During resuscitation with ongoing CPR, medication delivery through an intravenous cannula needs to be followed by a 20 ml saline bolus; if the cannula is in a peripheral vein, the extremity containing the cannula should then be elevated for 10 to 15 seconds to augment delivery of the medication to the central circulation. This is especially important because of the low-flow circulatory state with closed-chest CPR.

Differential Diagnosis and Definitive Care

The most challenging part of the secondary survey, as well as cardiac resuscitation management in general, is the problem-solving re-

quired when spontaneous circulation does not return despite appropriate initial interventions. This situation poses a critical question to the resuscitators: Why is this patient dying right now? The intellectual challenge of that question, which the resuscitators must try to answer expeditiously and at the bedside, is compounded by the emotional intensity that pervades most cardiac resuscitations.

The solvable problems that may interfere with resuscitation can be grouped into three broad categories: technical [see Table 6], physiologic, and anatomic [see Table 7]. Technical problems consist of difficulties with the resuscitators' equipment or skills; such difficulties include ineffective CPR, inadequate oxygenation and ventilation, ET tube complications, intravenous access difficulties, and monitor-defibrillator malfunction or misuse. The physiologic and anatomic problems consist of life-threatening but potentially treatable conditions that may have led to the cardiac arrest in the first place. This differentiation between physiology and anatomy is admittedly artificial, given that physiology is always involved in a car-

Table 7 (continued)

Condition	Clinical Setting	Diagnostic and Corrective Actions
Poisoning	Alcohol abuse, bizarre or puzzling behavioral or metabolic presentation, classic toxic syndrome, occupational or industrial exposures, history of ingestion, polysubstance abuse, psychiatric disease	Consider clinical setting and presentation; provide meticulous supportive care. Emergently consult toxicologist (through regional poison center) for resuscitative and definitive care advice, including appropriate antidote use. Prolonged resuscitation efforts are appropriate. If available, immediate cardiopulmonary bypass should be considered.
Hyperkalemia	Metabolic acidosis, excessive administration, drugs and toxins, vigorous exercise, hemolysis, renal disease, rhabdomyolysis, tumor lysis syndrome, significant tissue injury	Obtain stat serum potassium level on ABG specimen. Treatment: calcium chloride 10% (5–10 ml I.V. slow push [do not use if hyperkalemia is secondary to digitalis poisoning]), followed by glucose and insulin (50 ml of D50W and 10 U regular insulin I.V.); sodium bicarbonate (50 mEq I.V.); albuterol (15–20 mg nebulized or 0.5 mg I.V. infusion). [†]
Hypokalemia	Alcohol abuse, diabetes, diuretic use, drugs and toxins, profound gastrointestinal losses, hypomagnesemia, excess mineralocorticoid states, metabolic alkalosis	Obtain stat serum potassium level on ABG specimen. If profound hypokalemia ($K^+ < 2.5 \text{ mEq/L}$) is contributing to cardiac arrest, initiate urgent I.V. replacement (2 mEq/min I.V. for 10–15 mEq) then reassess. [§]
Pulmonary embolism	Hospitalized patients, recent surgical procedure, peripartum, known risk factors for venous thromboembolism (VTE), history of VTE, prearrest presentation consistent with acute pulmonary embolism	Review prearrest clinical presentation; initiate appropriate volume resuscitation with I.V. crystalloid and augment with vasopressors as necessary. Attempt emergency confirmation of diagnosis, depending on availability and clinical circumstances; consider emergency cardiopulmonary bypass to maintain patient viability. Continue resuscitation algorithm; proceed with definitive care (thrombolytic therapy, embolectomy via interventional radiology, or surgical thrombectomy) as appropriate for immediate circumstances and availability.
Tension pneumothorax	Post central line placement, mechanical ventilation, pulmonary disease (including asthma, COPD, necrotizing pneumonia), post thoracentesis, trauma	Consider risks and clinical presentation (prearrest history, breath sounds, neck veins, tracheal deviation). Proceed with emergency needle decompression, followed by chest tube insertion.

*Unrecognized hypoglycemia can cause significant neurologic injury and can be life threatening, but caution with I.V. glucose is appropriate in the setting of cardiac arrest. Available evidence indicates that hyperglycemia may contribute to impaired neurologic recovery in cardiac arrest survivors.

[†]Active internal or core rewarming includes warm (42°–46° C) humidified oxygen delivered through the endotracheal tube; warm I.V. fluids; peritoneal lavage; esophageal rewarming tubes; bladder lavage; and extracorporeal rewarming if immediately available. Active external rewarming includes warming beds, hot-water bottles, heating pads, and radiant heat sources applied externally to the patient.

[‡]Glucose is not necessary initially if patient is already hyperglycemic, but glucose levels should be followed closely after administration of I.V. insulin because of the risk of hypoglycemia (especially in patients with renal failure, because of the long duration of action of I.V. insulin in such patients). Sodium bicarbonate is most helpful in patients with concomitant metabolic acidosis; it is less effective in lowering serum potassium in dialysis-dependent renal failure patients. High-dose nebulized albuterol should lower serum potassium by 0.5 to 1.5 mEq/L within 30 to 60 min, but administration during cardiac arrest may be difficult.

[§]In a non-cardiac arrest situation, usual I.V. potassium replacement guidelines for patients requiring parenteral therapy are generally 10 to 20 mEq/hr with continuous electrocardiographic monitoring. If profound hypokalemia is contributing to cardiac arrest, however, these usual replacement rates are not timely enough, given the critical nature of the situation. Under these circumstances, potassium chloride, 2 mEq/min I.V. for 10 to 15 mEq, is reasonable, but reassessment and careful attention to changing levels, redistribution, and ongoing clinical circumstances are essential to prevent life-threatening hyperkalemia from developing.

ABG—arterial blood gas COPD—chronic obstructive pulmonary disease D50W—50% dextrose in water ET—endotracheal VF—ventricular fibrillation VT—ventricular tachycardia

diac arrest, but it has some usefulness as a teaching and problem-solving tool. Physiologic problems classically include hypoxia, acidosis, hyperkalemia, severe hypokalemia, hypothermia, hypoglycemia, and drug overdose. Anatomic problems are hypovolemia/hemorrhage, tension pneumothorax, cardiac tamponade, myocardial infarction, and pulmonary embolism.⁴¹

Whenever possible, the patient's medical and surgical history and the circumstances and symptoms immediately before the cardiac arrest should be sought from family members, bystanders, or hospital staff as the resuscitation proceeds. This information may contain important clues to the principal arrest problem and how it may be expeditiously treated. For example, a patient who presents to an emergency department with chest pain and then suffers a VF cardiac arrest is probably dying of a massive myocardial infarction, pulmonary embolism, or aortic dissection, with tension pneumothorax or cardiac tamponade also being possibilities.

Specific questions to consider include the following: Does the patient have risk factors for heart disease, pulmonary embolism, or aortic disease? What was the quality of the patient's pain and its radiation before the cardiac arrest? What were the prearrest vital signs and physical examination findings? What did the prearrest ECG show (if available)? Can any of this information be used now, at the bedside, to dictate the needed resuscitation interventions during the D phase of the secondary survey? For example, if the prearrest

ECG showed prominent ST segment elevation in leads V1 through V4 consistent with a large anterior myocardial infarction, if the patient's resuscitation is failing despite appropriate interventions, and if there appear to be no technical problems hampering the resuscitation, a working diagnosis of massive myocardial infarction can be made; intravenous thrombolytic therapy may then be a reasonable and needed step in such a resuscitation.⁷⁰

Thoughtful consideration of the possible reasons why a resuscitation is failing will regularly push the code-team captain's and resuscitation team's expertise and clinical skills to the limits. Nevertheless, the failure to consider these formidable issues will deprive the patient of an optimal opportunity to survive the cardiac arrest.

Cardiac Resuscitation Based on Rhythm Findings

When a monitor-defibrillator arrives at the scene of a cardiac arrest, the patient's rhythm is immediately analyzed. This step constitutes the beginning part of the defibrillation stage, or step D, of the AHA's primary survey. There are four rhythm possibilities [see Figure 1]: (1) pulseless VT; (2) VF; (3) organized or semiorganized electrical activity despite the absence of a palpable carotid pulse, which defines PEA; and (4) asystole. The detailed management of these different cardiac resuscitation scenarios is based on the recommendations of the AHA⁴⁹ and the International Liaison Committee on Resuscita-

tion.⁷¹ In following these guidelines, the clinician should remember that, with the exception of early CPR and early defibrillation for VF and pulseless VT, many of the recommendations that form the foundation of modern resuscitation are evidence supported or consensus based (rather than evidence based, as would be ideal). Because of the nature of cardiac arrest and the multiple variables involved, it is exceptionally difficult to perform high-quality research in cardiac resuscitation.

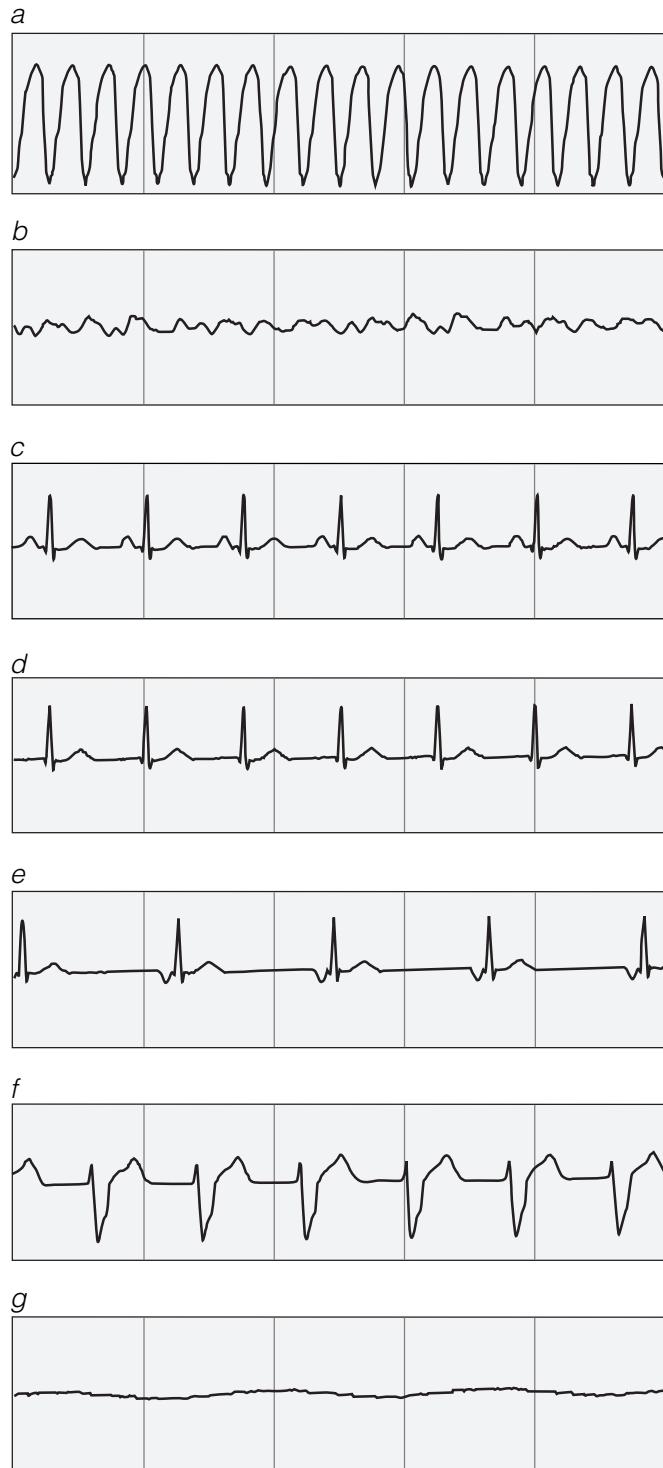

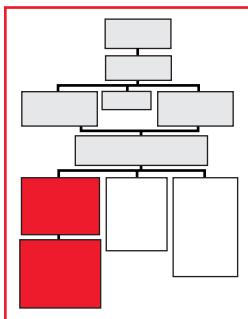

Figure 1 The sudden cardiac arrest arrhythmias. (a) Ventricular tachycardia. (b) Ventricular fibrillation. Pulseless electrical activity encompasses any of several forms of organized electrical activity in the pulseless patient; these include (c) normal sinus rhythm, (d) junctional rhythm, (e) bradycardic junctional rhythm, and (f) idioventricular rhythm. (g) Asystole.

PULSELESS VENTRICULAR TACHYCARDIA OR VENTRICULAR FIBRILLATION

The appearance of either VF or pulseless VT on the rhythm monitor in a patient with ongoing CPR is a relatively favorable finding, because there is reasonable hope for a successful outcome with these rhythms. In addition, the interventions and medications sequentially used in the resuscitation are plainly delineated, and the initial course of action is clear. VF and pulseless VT are managed identically.

Initiation of Defibrillation

Defibrillation with 200 joules should be attempted immediately. However, if the time from onset of arrest to CPR to the availability of defibrillation is estimated to be longer than 5 minutes, it may be reasonable to continue CPR for another 3 minutes before initiating defibrillation [see Defibrillation, above]. If the VF or VT persists after the initial shock, subsequent attempts should be made with 200 to 300 joules and then 360 joules.

A lower, nonescalating equivalent biphasic energy level is acceptable, if the defibrillator offers this option. Manually checking the patient's carotid pulse between shocks is no longer recommended, but the displayed rhythm on the monitor must be carefully assessed after each defibrillation attempt. If there are any doubts concerning the rhythm or if there is suspicion of a dysfunctional lead or paddle cable, then a manual pulse check would be appropriate. If VF or pulseless VT persists, CPR is resumed, the patient endotracheally intubated, correct ET tube placement confirmed, and the tube secured. Simultaneously, intravenous access should be established.

Initiation of Drug Therapy

In patients with ongoing VF, drug therapy begins with the administration of a vasoconstrictor (either epinephrine or vasopressin) [see Table 4]. If there is no intravenous access, the drug can be given endotracheally. After each intravenous dose, drug delivery is followed by a 20 ml saline bolus and the extremity containing the I.V. line is elevated. Rescuers continue CPR for 30 to 60 seconds to allow the drug to reach the heart, then attempt defibrillation again with one to three shocks at 360 joules each. As long as the patient remains pulseless, epinephrine is administered every 3 to 5 minutes, with each dose followed by one to three attempts at defibrillation. When vasopressin is the chosen initial drug, only a single dose is given; if the resuscitation continues 10 minutes or longer after vasopressin is administered, epinephrine should be substituted for vasopressin for the remainder of the code. If VF or pulseless VT persists despite the initial administration of a vasoconstrictor and repeated defibrillation attempts, parenteral antiarrhythmic drug therapy is added; amiodarone or lidocaine is an appropriate agent [see Choice of Antiarrhythmic Drugs, below]. Throughout all of these steps, the code-team leader is also actively looking for and correcting any technical and physiologic or anatomic problems that may be preventing a successful resuscitation [see Tables 6 and 7].

Emergency Laboratory Tests

If spontaneous circulation does not return after the first round of antiarrhythmic drug therapy, the resuscitation team must also endeavor to identify and treat the clinically relevant conditions causing

or contributing to the cardiac arrest [see Table 7]. In theory, the interventions conducted to this point should have resulted in a perfusing rhythm. The code team must ask why this has not occurred and then attempt to answer this question as the resuscitation continues. Emergency laboratory studies that may prove helpful include a stat ABG measurement and measurements of hemoglobin, potassium, magnesium, and blood glucose levels (most of which can be obtained from the ABG specimen).

Choice of Antiarrhythmic Drugs

Four antiarrhythmic drugs are used in cardiac resuscitation: amiodarone, lidocaine, magnesium (if the patient is thought or proved to be hypomagnesemic), and procainamide (for intermittent or recurrent VT or VF that initially responds to defibrillation).⁷² It is not known which one of these drugs or which combination of them will optimize the chances of patient survival to hospital discharge. Despite many years of routine use, there are no controlled studies demonstrating a survival benefit with lidocaine, versus placebo, in the management of VF or pulseless VT. Two studies in patients with shock-refractory prehospital VF showed that survival to hospital admission was better with amiodarone than with placebo (44% versus 34%; $P = 0.03$)⁷³ or with lidocaine (22.8% versus 12.0%; $P = 0.009$).⁷⁴ Neither of these studies demonstrated an improved survival to hospital discharge in the amiodarone groups, but neither study had the statistical power to demonstrate such a difference. Amiodarone is also considerably more expensive than lidocaine.

The optimal role and the exact benefit of antiarrhythmic medications in cardiac resuscitation are yet to be fully elucidated. According to AHA guidelines, either amiodarone or lidocaine is an acceptable initial antiarrhythmic drug for the treatment of patients with VF or pulseless VT that is unresponsive to initial shocks, CPR, airway management, and administration of epinephrine or vasopressin plus shocks. On the basis of available evidence, however, amiodarone may be the antiarrhythmic agent of first choice in the setting of prehospital refractory VF, allowing for optimal survival to hospital arrival.⁷²⁻⁷⁴

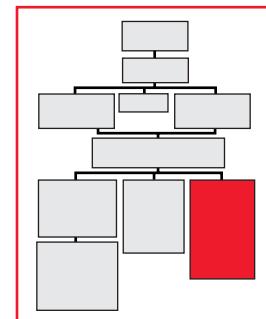

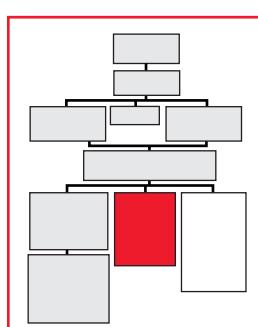

PULSELESS ELECTRICAL ACTIVITY

Community ACLS providers are encountering nonventricular arrhythmias (i.e., PEA and asystole) with increasing frequency. Classically, the prognosis for PEA has been poor, with outpatient survival rates generally reported as 0% to 7%.^{75,76} The sequence of resuscitation steps in the management of PEA is as follows: activation of the emergency medical or code response, primary survey (CPR and rhythm evaluation), and secondary survey (intubation and confirmation of correct ET tube placement, optimal oxygenation and ventilation, establishment of I.V. access, epinephrine administration, and, finally, problem solving for technical difficulties and establishment of the cause of the cardiac arrest). The two core drugs for PEA management are epinephrine (repeated every 3 to 5 minutes for as long as the patient is pulseless) and atropine (up to 3 mg over time if the PEA rhythm on the monitor is inappropriately slow). Although not currently on the AHA PEA algorithm, vasopressin is probably a reasonable alternative to epinephrine. The best hope for a successful resuscitation is to find and treat the cause of PEA; therein lies the exceptionally challenging aspect of PEA resuscitation management [see Tables 6 and 7]. Because coronary artery thrombosis and pulmonary thromboembolism are common causes of cardiac arrest, a trial evaluated the efficacy of tissue plasminogen activator (t-PA) in the setting of PEA of unknown or presumed car-

diovascular cause in 233 patients in prehospital and emergency department settings.⁷⁷ No benefit was found with thrombolytic therapy for PEA in this study; the proportion of patients with return of spontaneous circulation was 21.4% in the t-PA group and 23.3% in the placebo group.

ASYSTOLE

The prognosis for asystole is generally regarded as dismal unless the patient is hypothermic or there are other extenuating but treatable circumstances. The sequence of resuscitation steps in the management of asystole is as follows: activation of the emergency medical or code response, primary survey (CPR, rhythm evaluation, and asystole confirmation), and secondary survey (intubation and confirmation of correct ET tube placement, optimal oxygenation and ventilation, I.V. access with epinephrine and atropine administration, immediate transcutaneous pacing, if available, and problem solving for technical difficulties and establishment of the cause of cardiac arrest). The two core drugs for asystole management are epinephrine (repeated every 3 to 5 minutes for as long as the patient is pulseless) and atropine (up to 3 mg over time). As with PEA, vasopressin appears to be a reasonable and possibly beneficial substitute for epinephrine in asystole. A single dose of aminophylline (250 mg I.V.) may also be beneficial in atropine-resistant asystole.⁷⁸ Potentially treatable causes of asystole include hypoxia, acidosis, hypothermia, hypokalemia, hyperkalemia, and drug overdose. Resuscitation efforts should stop if asystole persists for longer than 10 minutes despite optimal CPR, oxygenation and ventilation, and epinephrine or atropine administration; if extenuating circumstances (e.g., hypothermia, cold-water submersion, or drug overdose) are not present; and if no other readily treatable condition is identified.

Immediate Postresuscitation Care

Even when the resuscitation is successful, the patient's situation remains tenuous and continued meticulous patient care is essential. When the cardiac monitor indicates what should be a perfusing rhythm, the rescuer should immediately confirm that the patient has a palpable pulse. If there is a pulse, the patient's blood pressure is then obtained. Simultaneously, resuscitation team members need to quickly reassess the adequacy of the patient's airway, the ET tube position, oxygenation and ventilation, and the patient's level of consciousness and comfort.

If the patient is hypotensive, appropriate blood pressure management depends on the presence or absence of fluid overload, as judged at the bedside. If the patient is clinically volume overloaded or in frank pulmonary edema and hypotensive, dopamine is started at inotropic doses (5 μ g/kg/min I.V.) and titrated to a target systolic blood pressure of 90 to 100 mm Hg. If the patient's clinical status suggests normovolemia or hypovolemia, intravenous crystalloid boluses (in 250 to 500 ml increments) can be administered instead of dopamine to support adequate tissue perfusion. In patients who are regaining consciousness, their level of comfort mandates careful assessment and administration of analgesia and sedation, as appropriate.

If the arrest rhythm was either VT or VF, the parenteral antiarrhythmic drug used immediately before the return of spontaneous circulation is continued as a maintenance infusion (amiodarone, 1 mg/min for 6 hr, then 0.5 mg/min for 18 hr as blood pressure allows; or lidocaine, 2 to 4 mg/min). If an antiarrhythmic drug has not yet been administered, it is usually started at this point to pre-

vent the recurrence of VF or pulseless VT. There are important exceptions to this guideline, however. If the perfusing postarrest arrhythmia is an idioventricular rhythm or third-degree heart block accompanied by an idioventricular escape rhythm, an antiarrhythmic medication should not be started at this time, because the antiarrhythmic agent could eliminate the ventricular perfusing focus and return the patient to a pulseless state.

Initial postresuscitation studies usually include an ECG; portable chest radiography; and measurement of ABGs, a serum electrolyte panel, fingerstick or blood glucose, serum magnesium and cardiac enzyme levels, and hemoglobin and hematocrit. The resuscitated patient requires urgent transfer to the optimal site for continued definitive care. Depending on the circumstances, this may be either the cardiac catheterization laboratory or the intensive care unit.

Ongoing research continues to look at optimal postresuscitation management strategies to improve neurologic outcome and survival to hospital discharge.⁷⁹ Hyperthermia and hyperglycemia compromise postresuscitation neurologic outcome, whereas mild to moderate induced hypothermia appears to improve neurologic outcome and decrease mortality.⁸⁰⁻⁸³

Ending a Resuscitation Attempt

Throughout the resuscitation, the team leader must speak with calmness and authority, and all resuscitations should be orchestrated with clarity and finesse. If possible, the code captain should make clinical decisions without directly performing specific procedures. Cardiac arrests are emotionally charged, but the leader must insist on a composed, orderly, and technically sound resuscitation. It is appropriate to invite suggestions from team members and to ensure that all members are comfortable with the decision to stop the resuscitation, should that time arrive.

The decision whether to stop a cardiac resuscitation is burdensome. Clearly, the circumstances of the event, patient comorbidities, the nature of the lethal arrhythmia, and the resuscitation team's ability to correctly identify and treat potential contributing causes of the arrest are all important considerations. Resuscitation efforts beyond 30 minutes without a return of spontaneous circulation are usually futile unless the cardiac arrest is confounded by intermittent or recurrent VF or pulseless VT, hypothermia, cold-water submersion, drug overdose, or other identified and readily treated contributing conditions.^{84,85}

With nontraumatic cardiac arrest in the prehospital setting (assuming proper equipment and medications are available and no ex-

tenuating circumstances suggest otherwise), full resuscitation efforts take place at the scene of the arrest in preference to rapid transport to an emergency department. A prehospital resuscitation that has been appropriately conducted but has not resulted in at least temporary return of spontaneous circulation to the patient may be discontinued. It is important that certain criteria are adhered to, however, including the following: high-quality CPR provided, an adequate airway successfully placed, appropriate oxygenation and ventilation delivered, intravenous access established, appropriate medications specific to the arrest scenario administered, and resuscitation attempted for at least 10 minutes; in addition, the patient must not be in persistent VF, and there can be no extenuating circumstances that mandate in-hospital continuation of the resuscitation (e.g., hypothermia, drug overdose). The decision whether to cease resuscitation efforts in the field is bolstered by direct discussion with EMS physicians. It is also essential that social services be available to provide immediate assistance and support to the family and loved ones of the patient who has now died.

Discontinuing in-hospital resuscitations is advisable when three criteria are met: (1) the arrest was unwitnessed, (2) the initial rhythm was other than VF or VT, and (3) spontaneous circulation does not return after 10 minutes of ongoing resuscitation.⁸⁶ In a study of this three-component decision rule, only 1.1% of patients (three out of 269) who met these criteria survived to hospital discharge, and none of the three survivors were capable of independent living.⁸⁷ In a study of 445 prospectively recorded resuscitation attempts in hospitalized patients, no patient survived who suffered a cardiac arrest between 12 A.M. and 6 A.M. if the arrest was unwitnessed and if it occurred in an unmonitored bed.³⁸

A resuscitation attempt in a persistently asystolic patient should not last longer than 10 minutes, assuming all of the following conditions apply: asystole is confirmed through proper rhythm monitoring and assessment; high-quality CPR is taking place; ET intubation is correctly performed and confirmed; adequate oxygenation and ventilation are provided; intravenous access is secured; appropriate medications (epinephrine or vasopressin and atropine) have been administered; and the patient is not the victim of hypothermia, cold-water submersion, drug overdose, or other readily identified and reversible cause.

After all resuscitation attempts, the code-team captain should debrief the team so that all may learn from the experience. Finally, marked empathy and skill are needed to carefully and compassionately inform family members about the outcome of the resuscitation.⁸⁸

2 ACUTE CARDIAC DYSRHYTHMIA

Caesar Ursic, M.D., and Alden H. Harken, M.D.

Management of Acute Dysrhythmias

After successful cardiopulmonary resuscitation (CPR) or any myocardial ischemic event, the most common source of hemodynamic instability is an abnormal heart rhythm. This chapter outlines the approach to a patient with an apparent acute cardiac dysrhythmia.

The purpose of the heart's electrical activity is to induce mechanical activity. Abnormal electrical activity that occurs in the absence of hemodynamic compromise should be examined but treated with forbearance because therapy itself poses some hazards: all antidysrhythmic agents, except oxygen, are negatively inotropic. In the evaluation of a patient who appears to exhibit an acute cardiac dysrhythmia, four questions should be asked:

1. Does the patient actually have a cardiac dysrhythmia?
2. Does the patient require any therapy (i.e., is the patient sufficiently stable that treatment is NOT indicated)?
3. How soon should therapy be started (i.e., how unstable is the patient)?
4. Which therapy is the safest and most effective?

Patient Is Hemodynamically Unstable

The choice of therapy is determined by the stability of the patient and the origin of the dysrhythmia. An electrocardiogram is helpful but not required. Patients with asystole require CPR [see **8.1 Cardiac Resuscitation**]. All hemodynamically unstable patients who have a dysrhythmia other than asystole should be treated immediately by cardioversion. Actually, cardioversion of asystole will do no harm; it just will not help, because there is no underlying rhythm to reorganize. If in doubt, therefore, one should proceed with cardioversion.

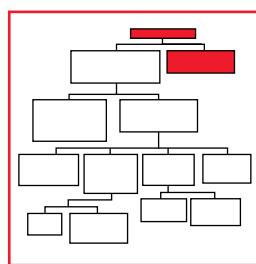

The two primary goals in the management of an acute dysrhythmia are to control the ventricular rate and to maintain a normal sinus rhythm. It is important to note that hemodynamic instability in a patient who has a ventricular rate between 60 and 100 beats/min is almost certainly not the result of a cardiac rhythm disturbance. Furthermore, heart rates in excess of 100 beats/min do not necessarily require therapy. Most patients can remain hemodynamically stable—and, in fact, increase their cardiac output—while raising their heart rate to 220 beats/min minus their age. In addition, it is not critical to reestablish normal sinus rhythm in all cases.¹ In a young, healthy patient with a nor-

mal heart, the so-called atrial kick adds almost nothing to cardiac output.² If normal sinus rhythm is abolished and atrial fibrillation is electrically induced in a young healthy patient, the ventricles and the rest of the cardiovascular system compensate almost immediately to prevent a fall in cardiac output.³ On the other hand, loss of synchronous atrial activity in patients with end-stage cardiac decompensation may decrease cardiac output by as much as 40%; fortunately, such a degree of end-stage cardiac compromise is rare.

CARDIOVERSION

Cardioversion delivers sufficient electrical energy to the pre-cordium (or directly to the heart) to depolarize cells, even those in a relatively refractory state. Cardioversion imposes electrical reorganization on the heart. In theory, after this massive depolarization, all the myocardial cells will repolarize simultaneously and then reinstitute a synchronous beat [see *Sidebar The Intracardiac Cardioverter Defibrillator*].

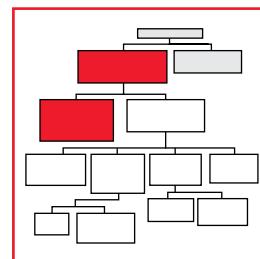

Certain precautions are necessary with cardioversion. The procedure is of no use in patients who are in asystole or who have fine ventricular fibrillation (VF), because these patients have no cardiac activity to organize—though, again, cardioversion does no harm in such cases (as it is said, “you cannot fall off the floor”). Supraventricular dysrhythmias such as atrial flutter can be converted with extremely low energy levels (e.g., ≤ 5 joules), but such low levels should not be employed in emergency situations. For a hemodynamically unstable patient, the initial cardioversion should be with 100 joules; if the dysrhythmia is not abolished, the voltage should be increased rapidly (to a maximum of 360 joules).

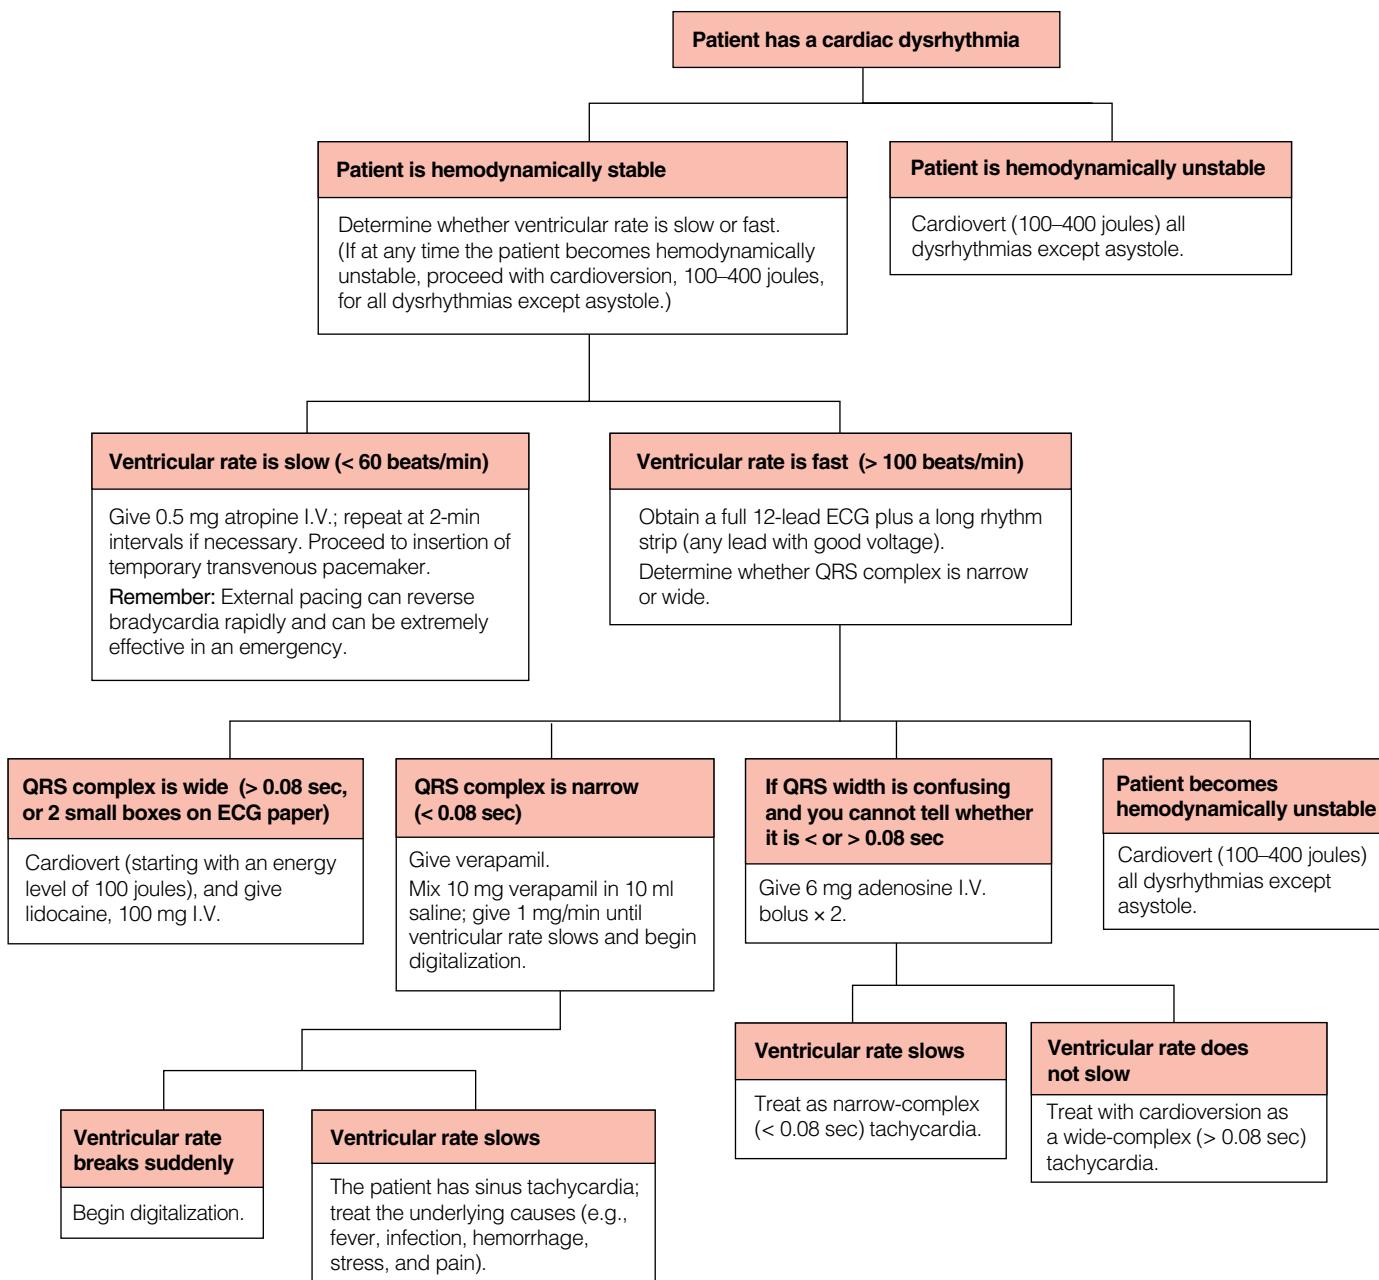

Patient Is Hemodynamically Stable

VENTRICULAR RATE IS SLOW

If the patient is bradycardic before or after cardioversion, atropine should be administered in a 0.5 mg I.V. push. This dose may be repeated at 2-minute intervals. Because the effects of atropine are transient, a temporary internal or external pacemaker should be used to maintain the heart rate. Insertion of an internal pacemaker consistently takes longer than predicted; an external pacemaker is a very effective temporizing maneuver [see *Sidebar Troubleshooting a Pacemaker*].

Management of Acute Dysrhythmias

The Intracardiac Cardioverter Defibrillator

Over 30 years ago, Michel Mirowski developed the first automatic intracardiac cardioverter defibrillator (ICD), a device that detects dangerous tachyarrhythmias and delivers a cardioverting shock.⁵⁵ In the intervening time, it has become abundantly clear that some of the 400,000 Americans who die "suddenly" of tachyarrhythmias each year could have been identified as high risk, although they could not have been saved by pharmacologic or surgical treatment. For these patients, an ICD can be lifesaving.⁵⁶

The ICD identifies dangerous rhythm patterns by means of two algorithms. The first of these algorithms analyzes the patient's heart rate. The patient's maximum attainable sinus rate must be determined by exercise testing before the device is implanted; the ICD is then programmed to detect heart rates above this value. (The ICD can be externally programmed to detect rates between 155 and 200 beats/min.⁵⁷)

Using rate criteria alone, however, the ICD cannot discriminate between sinus tachycardia and ventricular or supraventricular tachycardia. Inappropriate shocks are the Achilles heel of the ICD: almost one third of patients experience at least one inappropriate shock annually, when the device detects an episode of sinus tachycardia in which the rate exceeds the threshold programmed earlier. The ICD misinterprets the event as ventricular tachycardia and delivers a shock to the hemodynamically stable patient.⁵⁸ Patients liken this to being punched hard in the chest. Although rarely of electrophysiologic significance, an inappropriate shock can be psychologically crippling.⁵⁹

Although computer circuitry is facile and rapid, an ICD recognizes patterns poorly. Fine (or even coarse) VF may not exhibit enough positive spikes to be recognized as a tachyarrhythmia by the ICD. A second algorithm (the probability density function algorithm) was developed to analyze electrophysiologic data and improve the specificity of the ICD's sensing circuitry. A unique feature of ventricular fibrillation is the virtual absence of isoelectric time. Conversely, during sinus tachycardia and supraventricular tachycardia, the ECG is at the isoelectric baseline much of the time. The probability density function algorithm enables the ICD to determine the proportion of time that the ECG is spending at the isoelectric baseline and thereby to detect ventricular fibrillation.

The ICD typically requires more than 5 seconds to appreciate ventricular tachycardia or fibrillation. It then charges its energy storage capacitors for 15 seconds and delivers a 30-joule cardioverting shock. If necessary, the device will deliver a second, third, fourth, and fifth countershock. If the rhythm disorder persists after the fifth countershock, the device will not recycle.

ICD systems are not complex. The device consists of a battery, which is

heavy (though newer batteries are becoming lighter), and circuitry, which is light, with a total weight of less than 100 g. Most implanted defibrillators are currently placed without a thoracotomy. A sensing and defibrillating lead system (14 French) is inserted percutaneously via the subclavian vein into right ventricular-right atrial position. The distal electrode tip senses ventricular fibrillation and tachycardia. The cardioverting energy is then discharged between a coil electrode on the diaphragmatic surface of the right ventricle and another coil electrode positioned in the superior vena cava.

It is now clear that ICDs really do work and are capable of extending life. The most effective predictor of outcome in patients with ICDs is the severity of heart failure.⁶⁰ The ICD does not prevent malignant arrhythmias: it is, in essence, a safety net that cardioverts ventricular tachycardia or VF when it occurs. Therefore, it must still be used in conjunction with antidysrhythmic drugs.^{61,62}

It is easy for a surgeon to become spooked by an ICD. The most effective strategy for managing a patient with an ICD is simply to ignore the ICD. If such a patient is being transported to the OR, however, the device should be inactivated before the electrocautery is used: the ICD will misinterpret the cautery current as VF and respond by delivering a shock to the patient.

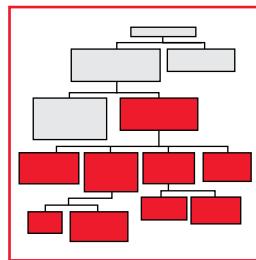

The aura of mystery surrounding the ICD may be instantly eliminated by turning off the device (see below). Once the ICD is inactivated, the patient can be treated as any other patient would be. If external cardioversion is indicated, the ICD can be disregarded; external cardioversion will not harm or activate it.

How to Turn the ICD Off

1. If you can find the industry representative to program the device to remain off, do so. Then treat the patient exactly as you would if the ICD were not present.
2. If you cannot find the representative or the situation is urgent:
 - a. Palpate the ICD generator, which is typically implanted in the left subcostal region.
 - b. Place a heavy pacemaker (or, better yet, an ICD magnet) over the upper corner of the device, toward the patient's left shoulder. Older devices used to emit a soft beep (synchronous with the heartbeat) in response to a magnet when they were active. Unfortunately, that feature has since been engineered out, and newer ICDs are silent.
 - c. Tape the magnet in place over the upper border of the device. As long as the magnet is in place, the ICD is off and the electrocautery can be used safely.

VENTRICULAR RATE IS FAST

If a patient is hemodynamically stable, a full 12-lead electrocardiogram is helpful; a long rhythm strip should be obtained as well. The best ECG lead to use for evaluating acute dysrhythmias is one that has good-voltage QRS complexes and maximal P waves, if the latter are present at all.

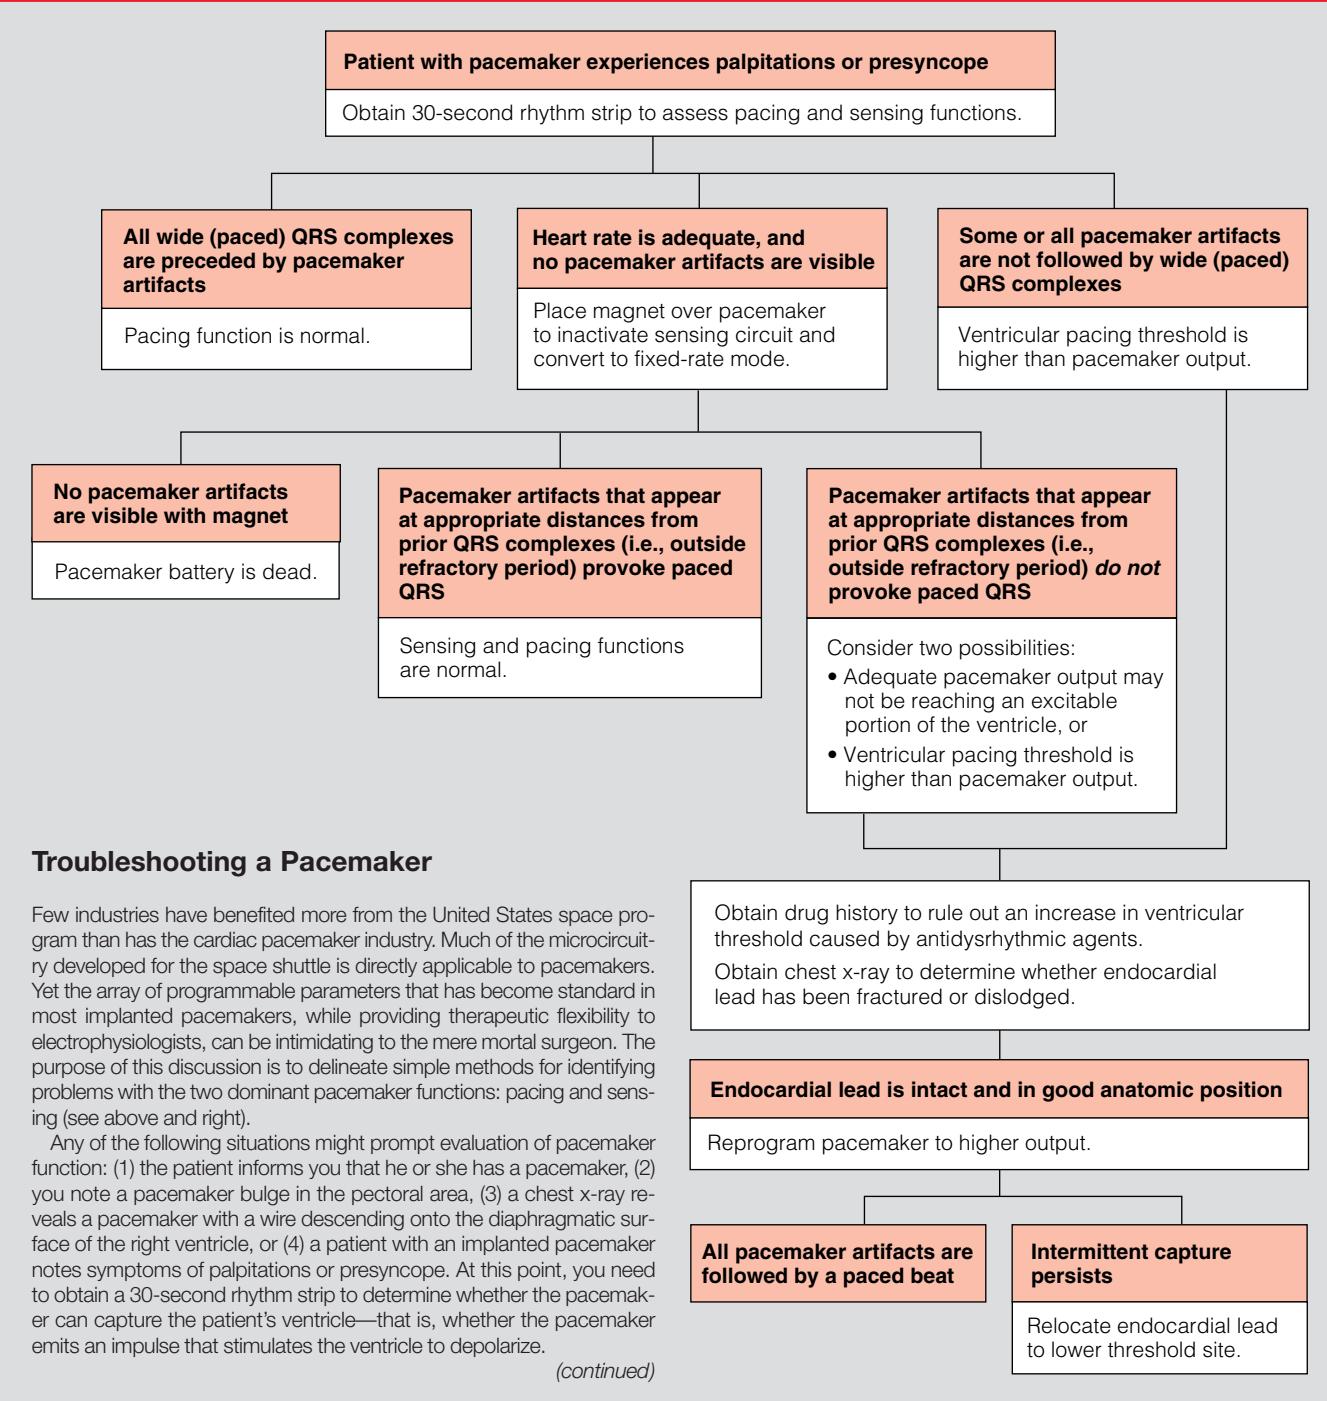

Electrocardiography

A cardiac impulse produces a positive, or upward, deflection on the monitor or oscilloscope as it approaches an ECG electrode and a negative, or downward, deflection as it moves away from the electrode. The important factor in dysrhythmia recognition, however, is not the direction of the impulse but its duration and location. Normal conduction velocity is fast: an impulse is transmitted by healthy Purkinje fibers at a rate of 2 to 3 m/sec.³ Hence, when an impulse that arises in the atrium (supraventricular) is transmitted via the atrioventricular (AV) node to the high-velocity Purkinje system, the entire ventricle is electrically activated in 0.08 second (80 milliseconds; or two small boxes on ECG paper). An impulse that is generated at an ectopic ventricular site, however, cannot

access the high-velocity Purkinje fibers as rapidly as a normal impulse, and ventricular activation is delayed. The QRS complex arising from an ectopic ventricular locus is therefore wider, signifying aberrant ventricular conduction [see Figure 1].

Because dysrhythmias of supraventricular origin typically display a narrow QRS complex, the width of the QRS can generally be used to distinguish dysrhythmias of ventricular origin from those of supraventricular origin [see Figure 2]. A wide QRS, however, may also be produced by an impulse that originates in the atrium and is aberrantly conducted to or through the ventricles (supraventricular rhythm with aberrancy). Such rhythms are relatively uncommon, constituting approximately 10% of all wide-complex tachycardias; more important, these patients will not suffer if their dysrhythmias are treated as though they were of ventricular origin.

When the ventricular rate is fast and the QRS is narrow, the 12-lead ECG should be searched for P waves, which indicate the presence of atrial activity. If P waves are absent and the QRS complexes occur at irregular intervals [see Figure 3], the patient probably has atrial fibrillation. It is not crucial to know this, however; the focus should be on the width of the QRS complex. A calcium channel blocker (verapamil or diltiazem) should be administered to control the ventricular rate. For verapamil, 10 mg is

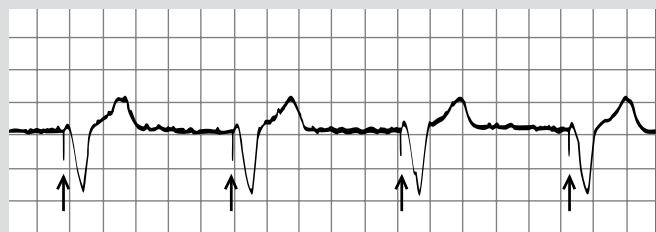

mixed into 10 ml of saline, and 1 mg/min is given until the ventricular rate slows. For diltiazem, 0.25 mg/kg—15 to 20 mg is a reasonable dose for the average patient—is given over 2 minutes; the dose can be repeated in 15 minutes at 20 to 25 mg (0.35 mg/kg) over 2 minutes. A patient with a wide-complex tachycardia—or any patient who is hemodynamically unstable—is treated by cardioversion (see above), commonly followed by administration of lidocaine, 100 mg I.V., whereas a patient with a narrow-complex tachycardia should be treated with verapamil^{3,5} or diltiazem to retard impulse conduction through the AV node. Therefore, it is not necessary to identify the specific type of dysrhythmia in order to treat it effectively.

Verapamil and diltiazem act by producing profound AV nodal blockade (see below); however, they are also peripheral vasodilators.⁶ Moderate to profound systemic hypotension can be anticipated until the patient converts to sinus rhythm.

Much has been written about the risks of using calcium channel blockers in patients who are already receiving beta blockers. Abrupt and complete AV block rarely occurs, however, and in the vast majority of patients, persistent supraventricular tachycardia poses a greater risk than the possibility of third-degree heart block. Therefore, previous beta blockade should not be considered a contraindication to the use of a calcium channel blocker. Some clinicians may prefer to use adenosine.

Troubleshooting a Pacemaker (continued)**Ventricular Capture**

a

Note the pacemaker artifact (\uparrow) that precedes each wide QRS complex in rhythm strip a, above. The QRS complex is wide because ventricular activation does not originate from the AV node, and ventricular conduction is therefore aberrant. At this point, you know that your patient is pacing, and you can determine the pacing rate. You do not, however, know the pacing threshold (i.e., the minimum voltage required for ventricular capture) or the safety margin between pacemaker output and pacing threshold. At this moment (and presumably yesterday and tomorrow), this pacemaker is appropriately discharging its most important function—pacing the heart and maintaining an adequate rate.

Ventricular Sensing

b

In rhythm strip b, above, normal P waves are followed by regular QRS complexes, and no pacemaker artifacts are evident. It is most likely that this patient's pacemaker has been programmed to fire at a paced rate that is slower than this patient's intrinsic heart rate, and the pacemaker is thus appropriately sensing each QRS complex. It is unlikely but possible, however, that the pacemaker is not sensing appropriately. Instead, one of the following problems may be occurring: (1) the pacemaker battery is dead, which is unlikely unless the battery was implanted more than 5 years ago, (2) the intracardiac electrode has been fractured, which is also unlikely, because current leads are remarkably durable, (3) the intracardiac electrode has been dislodged (this is an uncommon late problem that typically results in pacemaker artifacts unrelated to each QRS complex), or (4) the patient is taking an antidysrhythmic drug that has profoundly depressed ventricular excitability below threshold level for capture (this problem is very rare and can be excluded by taking a drug history). It is overwhelmingly likely, therefore, that rhythm strip b simply demonstrates that the pacemaker is sensing appropriately.

Assessing Ventricular Capture When the Spontaneous Heart Rate Is High

Typically, by the time you see the syncopal patient in the emergency department or recovery room, the patient is sufficiently excited that his or her

heart rate has recovered, and the rhythm strip will look like rhythm strip b. In a patient in whom heart rate is adequate and no pacemaker artifacts are visible, it is necessary to override the pacemaker's sensing circuit to determine whether the pacemaker is capable of emitting a pacing impulse that will capture the ventricle. The pacemaker's sensing circuit may be inactivated by placing a magnet over the pacemaker. Alternatively, the pacemaker may be reprogrammed to a paced rate that is faster than the patient's intrinsic heart rate. In this fashion, capture may easily be assessed. (Unfortunately, the programmers are expensive and are therefore often locked in some inaccessible closet. Programmers have great theoretical value but very little practical value to the surgeon.)

c

In rhythm strip c, above, a magnet has converted the patient's pacemaker from the demand mode to the fixed-rate mode. The pacemaker artifacts that precede the wide (paced) QRS complexes in this rhythm strip (black arrows) show that the pacing function of this pacemaker is intact. Occasionally, a pacemaker artifact occurs during the electrical refractory period that immediately follows the QRS complex (red arrows). Pacing during the refractory period will not result in ventricular capture. Pacing during the refractory period should not result in ventricular capture and must not be interpreted as intermittent capture. In a patient whose pacemaker seems to be sensing appropriately (as in rhythm strip b), the magnet permits assessment of ventricular capture. Rhythm strip c demonstrates normal ventricular capture in the presence of a magnet.

Some or All Pacemaker Artifacts Are Not Followed by Wide QRS Complexes

If a pacemaker impulse that occurs outside the refractory period is not followed by a wide QRS complex, two possibilities should be considered. First, an adequate pacemaker impulse may not be reaching an excitable portion of the ventricle because of fracture or dislodgment of the endocardial lead. This problem can usually be identified by a chest x-ray. Second, if the chest x-ray shows that the lead is intact and in good anatomic position, the pacemaker output is not sufficient to reach the pacing threshold. Occasionally, this problem is caused by fibrosis at the endocardial electrode tip. If the pacemaker can be reprogrammed to a higher output, the capture problem should resolve. Otherwise, the lead must be repositioned to a site at which the pacing threshold is lower.

Occasional Pacemaker Artifacts Closely Follow a Spontaneous QRS Complex

If the patient's rhythm strip looks like rhythm strip c, *in the absence of a magnet*, the pacemaker is not sensing properly. In the demand mode, most pacemakers require at least a 2.5 mV signal to suppress output. Thus, if the pacemaker emits stimuli in spite of a normal spontaneous heart rate, an adequate QRS signal either is not being sensed (the lead tip may be lodged at the site of a prior myocardial infarction or scar) or is not being transmitted to the pacemaker (because of lead fracture or dislodgment).

Adenosine (see below) produces conduction delay in the AV node and deserves recognition as a second very good option (albeit only a transiently effective one) for treatment of paroxysmal narrow-complex tachycardia or for diagnosis of supraventricular tachycardia with aberrancy (including Wolff-Parkinson-White syndrome). Adenosine is given in a 6 mg I.V. push, followed 2 minutes later by a 12 mg I.V. push and then, after another 2 min-

utes, by a final 12 mg I.V. push over 2 seconds.^{2,7}

Patients receiving adenosine complain of a frightening feeling of breathlessness and pressure that is not angina or dyspnea. This feeling typically resolves within 30 seconds. Facial flushing is also common. Unlike verapamil, adenosine is associated with hypotension in fewer than 1% of patients. Transient atrial or ventricular ectopy, with varying degrees of AV block, occurs in more

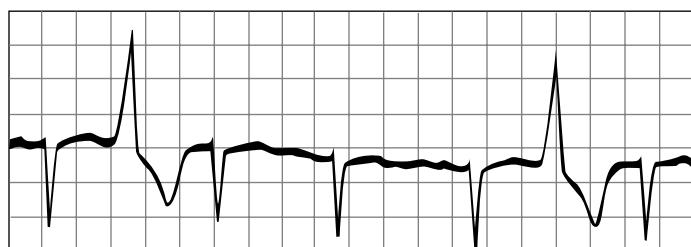

Figure 1 This tracing depicts frequent ventricular ectopic depolarizations interspersed among depolarizations from a supraventricular source. Note that the QRS depolarizations of supraventricular origin are narrow, whereas the QRS complexes of ectopic ventricular origin are wide.

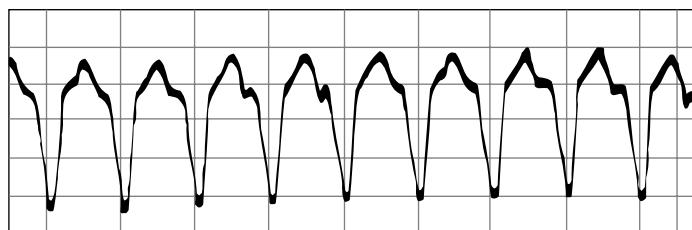

Figure 2 In a wide-complex tachycardia, each impulse is conducted aberrantly through the ventricles. The QRS complex is therefore prolonged to more than 0.08 second and occupies more than two small boxes on the ECG tracing.

than half of patients. None of the side effects of adenosine necessitate therapy.

Compared with calcium channel blockers, adenosine has certain advantages. Because of its rapid onset and short duration of action, and because its side effects are trivial and self-limited, adenosine can be used diagnostically. If, as is often the case, the QRS width is confusing and it is therefore uncertain whether the rhythm disorder is supraventricular ($\text{QRS} < 0.08$ second) or ventricular ($\text{QRS} > 0.08$ second), a 6 mg I.V. bolus of adenosine may be infused, and repeated if necessary. If the dysrhythmia slows or breaks, it was supraventricular. If it does not break, proceed to cardioversion (see above). On the other hand, even if a dysrhythmia responds to adenosine, the profound neuroendocrine and electrolyte perturbations that provoked the dysrhythmias in the first place—perturbations that are very common in the surgical intensive care unit—are likely to persist, and the dysrhythmia disorder typically recurs. Continuous (therapeutic) infusion of adenosine (150 to 300 $\mu\text{g}/\text{kg}/\text{min}$) is rational from a physiologic standpoint but is frighteningly expensive. Therefore, if adenosine works transiently, it is appropriate to follow with one of the longer-acting calcium channel blockers.

Calcium Channel Blockers

Both the sinoatrial (SA) node and the AV node are activated by the movement of calcium through the so-called slow calcium channels.⁸ Calcium channel blockers are the most powerful agents currently available for blocking the transmission of impulses across the AV node. A supraventricular dysrhythmia produces an acceleration in the ventricular rate because impulses generated by an ectopic source above the AV node are transmitted too rapidly to the ventricle [see Figure 4]. Calcium channel blockers produce a pharmacologic blockade of the AV node, reducing the number of impulses reaching the ventricles and thereby controlling the ventricular rate (Remember, keeping the

ventricular rate between 60 and 100 beats/min is the ultimate goal of antidysrhythmic therapy).

Adenosine

Adenosine is an endogenous nucleoside that has differential antidysrhythmic effects in both supraventricular and ventricular tissue. The appeal of adenosine as a therapeutic and diagnostic tool is that it depresses automaticity and conduction within the SA and AV nodes.⁹ Two clinically relevant types of adenosine receptors are present in cardiac tissue: (1) A_1 receptors, which are present on AV nodal tissue and cardiomyocytes and which thus mediate AV block and even bradycardia; and (2) A_2 receptors, which reside on vascular endothelial and smooth muscle cells and mediate coronary vasodilatation.¹⁰ A_3 receptors are present in the myocardium, and selective activation of these has a cardioprotective (cardiac preconditioning) effect; however, these receptors are not relevant in antidysrhythmic therapy.¹¹

Adenosine and acetylcholine exhibit identical cardiac effects and share similar receptor-effector coupling systems. Adenosine and acetylcholine provide an opposing balance to the sympathetic neurotransmitters norepinephrine and epinephrine. Thus, predictably, the adenosine antagonists caffeine, theophylline, and aminophylline provoke tachycardia and ectopy.

Because of the rapid intravascular metabolism of adenosine (half-life, 6 seconds), an intravenous bolus of adenosine (6 mg or 100 $\mu\text{g}/\text{kg}$) produces a negligible effect on systemic blood pressure, as confirmed by multiple clinical studies. Thus, adenosine is safe, but its effects are transient.

Adenosine is useful in blocking AV nodal conduction. Intracardiac recordings exhibit prolongation of the A-H interval with no alteration in conduction distal to the His bundle and on into the ventricular myocardium (the His-Purkinje system is unaffected).

In more than 90% of cases, adenosine is effective in terminating supraventricular tachycardia. Interestingly, adenosine has proved as effective at terminating atrioventricular reentry (85%) as at terminating atrioventricular node reentry (86%).⁹ Because of adenosine's short half-life, however, the supraventricular dysrhythmia is likely to recur within minutes in up to one third of patients. For that reason, adenosine is often used diagnostically, to discriminate supraventricular from ventricular dysrhythmias (see above).

Several clinical studies have compared adenosine with verapamil for therapeutic AV nodal blockade, with predictable results. Both agents block the AV node and control the ventricular rate: cumulative efficacy with either agent is more than 90%. Postconversion dysrhythmias in the two groups were similar. Spontaneous reinitiation of supraventricular dysrhythmias occurs more frequently with adenosine, whereas systemic hypotension is more commonly associated with verapamil (at least until the dysrhythmia breaks). Thus, for help in seconds (approximately 20 seconds), use adenosine (6 mg I.V. bolus, may be repeated); for help in minutes (3 to 5 minutes), use verapamil (1 mg/min I.V. up

Figure 3 P waves are absent and the QRS complexes are narrow and irregular in this ECG tracing from a patient with atrial fibrillation.

Figure 4 In a narrow-complex tachycardia, the entire ventricle is activated in less than 0.08 second. Presumably, the impulse originated at a supraventricular source and accessed the ventricle via the high-velocity Purkinje system.

to 10 mg); and for help in hours, infuse digoxin, 0.5 mg I.V. Although digitalis effectively blocks the AV node, it should be remembered that digitalis actually increases automaticity and excitability in both the atrium and the ventricle. The calcium channel blockers are superior to digoxin in controlling the ventricular rate.⁸

The adverse effects of adenosine, like the beneficial effects, are transient.⁹ Facial flushing, chest pressure (adenosine has been implicated in the sensation of angina), and transient third-degree heart block are very common. Significant side effects are rare. Nebulized adenosine can cause bronchoconstriction, especially in asthmatic patients. Bronchoconstriction has not been reported after intravenous administration of adenosine.

Magnesium

Magnesium is the second most abundant cation in humans. It is involved in many enzymatic reactions that influence the production and utilization of cellular energy. Abnormalities in electrolyte homeostasis (potassium and calcium in particular) are associated with a robust increase in cardiac myocellular excitability and automaticity, especially when these abnormalities are concurrent with myocardial ischemia.¹² Multiple clinical studies confirm the efficacy of intravenous magnesium infusion even when the measured serum values are normal. The mechanism is unknown. When confronted with a patient exhibiting either supraventricular or ventricular ectopy, it is safe (and often effective) to administer magnesium chloride at a dosage of 7 g or 100 mg/kg I.V. over 1 to 3 hours. It is not necessary to measure the serum magnesium concentration first; the serum value will not influence therapy.

Amiodarone

Amiodarone is a class III antiarrhythmic drug that exerts its primary effect by prolongation of the myocardial action potential and refractory period and by delay of both SA node function and AV conduction. Amiodarone is also unique among these compounds by virtue of exhibiting, to varying degrees, the pharmacologic traits of all four classes of antiarrhythmic drugs [see Discussion, Antidysrhythmic Agents, below].¹³ Among these is its ability to inhibit alpha- and beta-adrenergic stimulation without the classic side effects associated with beta receptor blockade. It also reduces transmural proarrhythmic heterogeneity (which predisposes to arrhythmias) in the human heart [see Discussion, Pathophysiology of Cardiac Dysrhythmias, Reentrant Dysrhythmias, below].¹⁴

Intravenous amiodarone was approved in the United States for use against malignant ventricular tachyarrhythmias in 1995. Rates of effective suppression for ventricular arrhythmias have been reported to be as high as 91% in uncontrolled trials.¹⁵ Intravenous amiodarone has also proved effective against refractory ventricular tachycardia and VF. In one double-blind, randomized, placebo-controlled trial, amiodarone significantly improved survival in patients suffering out-of-hospital cardiac

arrest.¹⁶ Amiodarone also proved superior to lidocaine (78% versus 27%) for termination of ventricular tachycardia in a randomized, prospective study of 29 patients with ventricular tachycardia refractory to external shock therapy.¹⁷

Another prospective, double-blind study comparing amiodarone with ibutilide (another class III antiarrhythmic agent) showed the drugs to be equally efficacious in the conversion of atrial fibrillation to sinus rhythm and in the subsequent maintenance of sinus rhythm.¹⁸ Although two patients (10%) in the amiodarone group experienced hypotension during treatment, long-term maintenance therapy using the oral form of amiodarone may make it the drug of choice for this purpose, given ibutilide's lack of oral bioavailability. Amiodarone was also found superior to both sotalol and propafenone in preventing the recurrence of atrial fibrillation in a randomized, prospective multicenter study of 403 patients with a mean follow-up period of 16 months.¹⁹

Although gratifyingly effective, amiodarone has significant side effects.²⁰ In trials of low-dose amiodarone (200 mg/day), thyroid, neurologic, cutaneous, ocular, bradycardic, and hypotensive problems were statistically more frequent; interestingly, pulmonary fibrosis was not.²¹

For the first 24 hours, the recommended dosages for adults are a loading dose of 150 mg I.V. over the first 10 minutes (15 mg/min) followed by 360 mg I.V. over the next 6 hours (1 mg/min); a maintenance infusion of 540 mg (0.5 mg/min) is given over the remaining 18 hours. The maintenance infusion may be continued for up to 3 weeks, at the rate of 0.5 mg/min, or the patient may be converted to oral dosing at 400 to 1,600 mg daily, depending on the duration of the preceding I.V. infusion.

Cardiac Dysrhythmias during Pregnancy

Fortunately, cardiac dysrhythmias are not frequent in young women of childbearing age. When rhythm problems do occur, they tend not to be hemodynamically destabilizing. The most commonly used obstetric drug with electrophysiologic side effects is magnesium sulfate.²² When magnesium is infused intravenously into the mother, the fetus may exhibit a dose-dependent bradycardia and a progressive decrease in healthy heart rate variability.^{23,24} Antidysrhythmic (indeed, any) drugs should be avoided during the first trimester of pregnancy, although most antidysrhythmic agents carry relatively little risk.²² Quinidine, procainamide, lidocaine, digoxin, adenosine, and beta blockers all have a long record of safety during pregnancy. Flecainide has proved to be effective in treating fetal supraventricular tachycardia complicated by hydrops. Phenytoin and amiodarone have been associated with congenital abnormalities.²²

The important point is that if the mother is hemodynamically unstable and exhibits a dysrhythmia, direct current cardioversion is safe and effective.

Proarrhythmia with Antidysrhythmic Drugs

Proarrhythmic manifestations of ostensibly antiarrhythmic drugs have been linked primarily to agents that prolong repolarization. Early afterdepolarizations associated with agents that retard repolarization or an increase in spatial and temporal dispersion of repolarization are the putative mechanisms of drug-induced or drug-enhanced arrhythmias.^{25,26}

The class III antidysrhythmic agents have traditionally been the agents most likely to cause dysrhythmias.²⁶ The best way of preventing dysrhythmias, however, is to follow the general policy of not using drugs at all if they are not needed.²⁷

Discussion

Antidysrhythmic Agents

Verapamil (or another calcium channel blocker), lidocaine, and adenosine are the only drugs essential for the acute treatment of cardiac dysrhythmias. Because patients may already be taking oral agents for chronic dysrhythmias, however, it is important to be aware of the actions and side effects of these drugs when treating an individual with an acute dysrhythmia. Antidysrhythmic drugs have been classified on the basis of their dominant electrophysiologic effect²⁸; this classification has been reviewed and placed in a clinical context.⁵ Adenosine has a unique receptor that modulates cyclic adenosine monophosphate (cAMP), resulting in cholinergic activity. It is not similar to other antidysrhythmic agents and is therefore unclassified.

CLASS I AGENTS (MEMBRANE ACTIVE)

Class I agents are fast sodium channel blockers. All class I agents—which include lidocaine, procainamide, quinidine, and disopyramide—are local anesthetics. These agents block the fast inward sodium current and thereby decrease both the amplitude of the action potential, or phase 0 depolarization (see below), and conduction velocity. These agents also depress the rate of spontaneous phase 4 depolarization, or automaticity, and thus are useful for abolishing premature ventricular contractions (PVCs); class I agents are sometimes termed PVC killers. Because these agents slow the conduction velocity, they can actually increase the likelihood of reentrant cardiac dysrhythmias in some patients.^{25,27}

CLASS II AGENTS (BETA BLOCKERS)

Class II agents are beta blockers and include such drugs as propranolol. Sympathetic hyperactivity, marked by increased release of catecholamines, is one of the major causes of cardiac dysrhythmias that result from increased automaticity (hyperexcitability).^{25,27,29} Beta-adrenergic blockade has produced a decrease in such automatic dysrhythmias under both clinical and experimental conditions.²⁹

CLASS III AGENTS (TO PROLONG REPOLARIZATION)

Class III agents, such as bretylium, act directly on the myocardial cell membrane to delay phases 2 and 3 of repolarization and thereby prolong refractoriness. Bretylium is effective in terminating reentrant dysrhythmias because it prolongs the refractory period of the ectopic focus to beyond the point at which an impulse reenters the circuit.^{1,2} Bretylium apparently has no effect on either automaticity or conduction velocity.³⁰

CLASS IV AGENTS (CALCIUM CHANNEL BLOCKERS)

Class IV agents, of which verapamil and diltiazem are the most effective, block the movement of calcium across the slow calcium channels but have virtually no effect on the so-called fast sodium channels.²⁸ Because both the SA node and the AV node are composed of slow-response fibers that are activated by the movement of calcium ions across the slow channels, the class IV agents are particularly effective in preventing unwanted supraventricular impulses from reaching the ventricles. These agents decrease the conduction velocity through the AV node and increase the refractory period of the AV node.

CLASS V AGENTS (UNCLASSIFIED)

The vagus nerve innervates the SA node, the atria, and the AV node, but it has almost no influence over the His-Purkinje system

or ventricular muscle. At therapeutic levels, digitalis has an antidysrhythmic action that is mediated almost exclusively via the vagus nerve. Toxic doses of digitalis, however, may produce an increased automaticity characterized by multifocal premature ventricular depolarizations [see Pathophysiology of Cardiac Dysrhythmias, below]. Caution must be observed in digitalizing a patient who is prone to atrial dysrhythmias, because digitalis increases atrial excitability and hence increases the risk of atrial ectopy. Because digitalis also induces AV nodal blockade mediated by the vagus nerve, however, any atrial dysrhythmias produced by digitalization will be less clinically significant.^{31,32}

Cellular Electrophysiology

Electromechanical activity of all muscle, including the heart, is determined by the concentration and flow of ions, particularly calcium, potassium, and sodium. Knowledge of cardiac electrophysiology can serve as a conceptual framework on which to build a rational therapeutic program. Direct observation of cellular electrical activity using a glass microelectrode reveals that the cell membrane is semipermeable: it permits easy passage of cations such as sodium, potassium, and calcium but provides a barrier to anions and proteins. Negatively charged intracellular proteins that cannot cross the cell membrane create a transmembrane potential in which the interior of the cell is negatively charged relative to the exterior. The membrane potential of a cell, E_K , is proportional to the difference between the logarithms of the intracellular potassium concentration, $[K]_i$, and the extracellular potassium concentration, $[K]_o$:

$$E_K = c(\log [K]_i - \log [K]_o)$$

The proportionality constant, c , varies with temperature, but at 37° C it is -60 mV. Thus, under physiologic conditions,

$$E_K = -60 \text{ mV} \times \log [K]_i / [K]_o$$

This relation, termed the Nernst equation, can be used to calculate the myocardial cell membrane potential if the potassium concentrations are known. For example, if the potassium concentration is normal—that is, 150 mEq/L intracellularly and 3.8 mEq/L extracellularly—then the membrane potential is

$$E_K = -60 \text{ mV} \times \log 150 / 3.8 \\ E_K = -90 \text{ mV}$$

If, however, the serum potassium concentration rises to 6.0 mEq/L, then the membrane potential also changes:

$$E_K = -60 \text{ mV} \times \log 150 / 6.0 \\ E_K = -80 \text{ mV}$$

Thus, the resting membrane potential is determined primarily by the concentration gradient for potassium across the cell membrane. The transmembrane potential can be calculated if the transmembrane potassium concentrations are measured with a glass microelectrode. Under clinical conditions, however, only the serum potassium level can be measured. This value does not provide an adequate guide to the transmembrane electrical voltage, because many physiologic factors are capable of altering the intracellular potassium concentration.¹³ Such factors include electrolyte and acid-base balance, the level of osmotic and metabolic activity, and the serum levels of glucose and insulin.

Any factor that causes osmotic movement of water into the cell

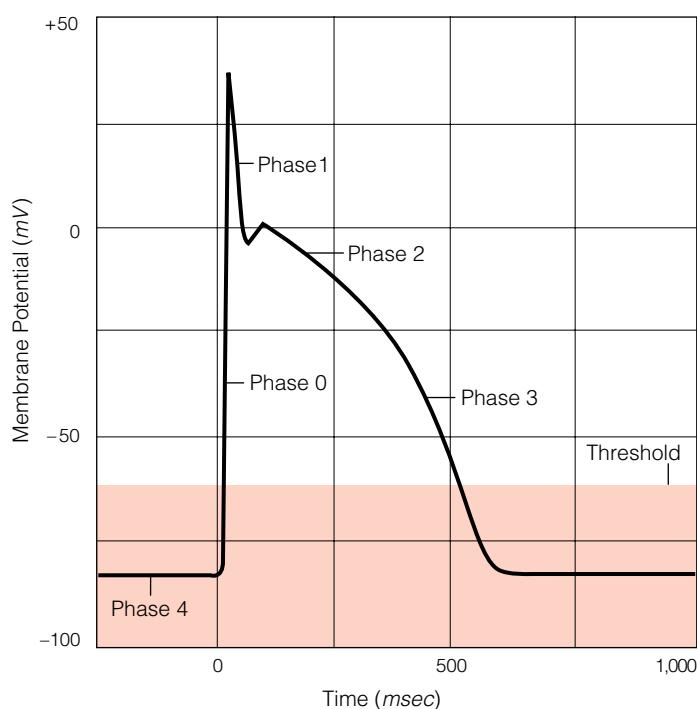

Figure 5 The standard Purkinje (or ventricular muscle) action potential has five distinct phases: phase 0, rapid depolarization; phase 1, early repolarization; phase 2, plateau; phase 3, rapid repolarization; and phase 4, diastole.

will dilute and thus decrease the intracellular potassium concentration. The transmembrane gradients of sodium and calcium are maintained by energy-requiring pumps in the cell membrane. When these pumps are inactivated, as during myocardial ischemia,¹² sodium and calcium can leak into the cell. If, as often occurs, sodium leaks into the cell faster than potassium leaks out, water will be drawn in, producing myocardial edema. Tissue acidosis can also alter the transmembrane potassium gradient. In acidosis, hydrogen ions can leak into the cell in exchange for potassium, thereby decreasing the intracellular potassium concentration and increasing the membrane potential. Variations in glucose transport can also affect the potassium gradient. Under the influence of insulin and epinephrine, glucose may move across the membrane into the myocardial cell, drawing in water by osmosis. The decline in intracellular potassium concentration stimulates the sodium pump to exchange extracellular potassium for intracellular sodium. Concurrent administration of glucose and insulin is the standard method for treating hyperkalemia because it shifts potassium from the extracellular fluid back into the cells.

ACTION POTENTIAL GENERATION

Stimulation of either cardiac muscle or skeletal muscle produces an action potential. Unlike a skeletal muscle action potential, which lasts only several milliseconds, a cardiac action potential may persist for as long as several hundred milliseconds.³³ The standard Purkinje, or ventricular muscle, action potential has five discernible phases [see Figure 5].

Phase 4

In phase 4, the resting membrane potential, or diastolic potential, of the cell is generated by active metabolic processes that produce substantial transmembrane potassium and sodium gradi-

ents. An energy-dependent (ATP-dependent) sodium-potassium pump counteracts a significant influx of sodium and efflux of potassium in the resting cell to maintain this resting membrane potential. As noted, when the extracellular potassium concentration rises from a typical value of 3.8 mEq/L to 6.0 mEq/L, the resting membrane potential increases from -90 mV to -80 mV. This effect would tend to increase automaticity, but it is superseded by the effect of hyperkalemia on the sodium current. A rise in the extracellular potassium level progressively impairs the flux of sodium through sodium-specific channels, leading to an overall decrease in myocardial excitability.³⁴

Phase 0

During phase 0, an electrical stimulus causes the sodium-specific fast channels and the calcium-specific slow channels to open, usually for no longer than 1 msec. As positive ions rush in, depolarization occurs as the membrane potential rises to threshold, or -60 mV, and an action potential is generated [see Figure 5]. Under normal physiologic conditions, the stimulus that produces an action potential is electrical, but any stimulus—electrical, physical (such as a precordial thump), or chemical—that depolarizes a membrane up to threshold (again, -60mV) can generate an action potential. There are various abnormalities that can cause the resting membrane potential to move toward threshold. For example, conditions that produce a decrease in energy supply (or, alternatively, an increase in energy demand) will have this effect because energy is required to maintain the potassium and sodium gradients across the resting membrane. Under such conditions, automaticity is enhanced because lesser stimuli can achieve the threshold potential, and the cardiac muscle is said to be hyperexcitable, or irritable.

Phases 1 and 2

Phase 1 is characterized by repolarization to the plateau phase, or phase 2. During phase 2, the slow calcium channels as well as the fast sodium channels are activated, and the membrane potential remains relatively constant for as long as 100 msec.³⁵ The long duration of this plateau phase is the most dramatic difference between an action potential in cardiac muscle and one in skeletal muscle. During this interval, termed the effective refractory period, the myocardium is relatively resistant to further excitation.

Phase 3

During phase 3, potassium channels reopen to promote efflux of potassium from the cell. Rapid repolarization ensues, and the resting membrane potential is reestablished at -90 mV.

Spontaneous Phase 4 Depolarization

Unlike ordinary atrial and ventricular muscle, the Purkinje fibers do not have a stable phase 4 diastolic potential [see Figure 6]. Instead, these fibers undergo continuous depolarization during diastole as a result of deactivation of the potassium efflux current.^{35,36} If the Purkinje fibers reach the threshold voltage, they will fire an action potential. Under normal conditions, however, the SA and AV nodes exhibit faster diastolic depolarization and reach threshold sooner than the Purkinje fibers. Because the cells in the SA node normally reach threshold first—winning the race, so to speak—the SA node typically assumes the pacemaker function of the heart. Premature ventricular contractions develop when a hyperexcitable cell or fiber in ventricular myocardium undergoes rapid diastolic depolarization and reaches threshold before the cells in the SA node. This cell or fiber then assumes the pacemaker function of the heart for that beat. The PVCs (or,

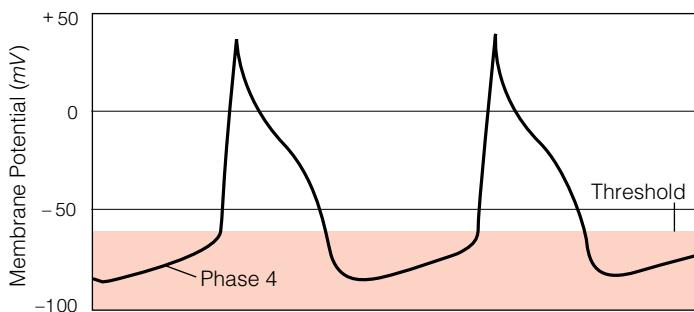

Figure 6 In normal cardiac Purkinje fibers, the membrane potential does not remain flat during phase 4 but instead rises gradually. This spontaneous phase 4 depolarization is the result of a resting potassium current.

more accurately, premature ventricular depolarizations) that result from such ventricular ectopy can be abolished by overdrive pacing. In this situation, a mechanical pacemaker is used to pace the heart at a rate faster than that of the PVC (i.e., the R-R interval is shorter). The artificial device thereby wins the race; it assumes the pacemaker function and regularizes the heart rate, producing a beneficial cosmetic effect on the ECG without altering the hyperexcitability of the diseased cell.

Pathophysiology of Cardiac Dysrhythmias

All dysrhythmias are caused by enhanced automaticity, reentry, or a combination of these two mechanisms.

AUTOMATIC DYSRHYTHMIAS

Any area of myocardial tissue that independently depolarizes, reaches threshold, and fires is termed automatic, and the electrical impulse that activates the adjacent myocardium generates an automatic rhythm. Acute dysrhythmias tend to be automatic; such automatic dysrhythmias are frequently seen in patients in emergency departments and coronary care units and in patients undergoing surgery. Five common clinical phenomena that tend to increase automaticity have been identified: local myocardial hypoxia, hypokalemia, hypercalcemia, increased catecholamine levels, and drugs (most commonly digitalis).

Local Myocardial Hypoxia

Energy-dependent cell membrane pumps maintain the resting membrane potential, and when oxygen supply to myocardial tissue is inadequate because of ischemia, the pumps fail to function properly. Consequently, the potassium gradient declines, and the membrane potential drifts closer toward threshold. Small membrane potential fluctuations or stimuli of less than normal magnitude are then sufficient to bump the membrane potential up to threshold and initiate an action potential. Ventricular muscle cells, not only those cells in specialized conduction tissue, can spontaneously generate electrical fluctuations, or oscillations, in membrane potential [see Slow Afterdepolarizations, below]. If the resting membrane potential is initially closer to normal because of local myocardial hypoxia, then these spontaneous oscillations are more likely to achieve threshold and fire an action potential.³⁷

Hypokalemia

Extracellular hypokalemia increases the resting membrane potential, drawing it further away from threshold and producing hyperpolarization. This effect tends to decrease tissue excitability,

or automaticity.^{37,38} Hypokalemia also increases the size of the sodium channels, however, thereby promoting more rapid influx of sodium during phase 0. Because the net result of hypokalemia is increased automaticity, the effect of hypokalemia on sodium influx appears to override its effect on membrane hyperpolarization. Hypokalemia is one of the most easily treated (and overtreated) forms of hyperexcitability.

Hypercalcemia

Calcium is a potent inotropic agent, mediating the interaction between actin and myosin that produces muscle contraction.³⁵ High extracellular calcium levels may cause myocardial work to exceed the energy supply and thus impair the function of the membrane pump. As a result, the resting membrane potential drifts up toward threshold, enhancing automaticity. Excess calcium also appears to promote spontaneous oscillations in membrane potential [see Slow Afterdepolarizations, below].³⁹ Because of calcium's inotropic effect, such oscillations are accompanied by muscle activity.

Elevated Catecholamine Levels

Increased catecholamine levels also appear to predispose to automaticity, as evidenced by an increase in the incidence of multiple PVCs reported in patients who have been infused with high doses of catecholamines, such as epinephrine or dopamine. Catecholamines increase both heart rate and contractility. As with hypercalcemia, elevated catecholamine levels may increase cardiac work beyond the limits of energy supply and cause the membrane potential to move closer to threshold. This effect on the energy-dependent membrane pumps has been observed in isolated preparations of Purkinje muscle fibers. The addition of catecholamines to preparations of Purkinje muscle fibers has decreased the outward potassium current to the point that the resting membrane potential was shifted as much as 25 mV toward depolarization, enhancing automaticity.^{36,37} In addition to affecting the operation of the membrane pumps, catecholamines can produce large spontaneous oscillations in membrane voltage.^{36,40} Catecholamines are elaborated endogenously; a patient who is in pain, for example, may be releasing large amounts of epinephrine into the circulation. In such cases, morphine can be used effectively as an antidysrhythmic agent.⁴⁰

Drugs

Digitalis is the prototypical cardiac stimulant. Typically, any

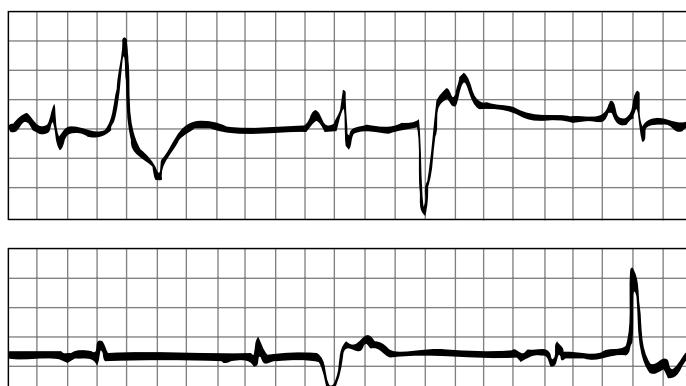

Figure 7 ECG demonstrates multifocal PVCs, indicating a diffuse hyperexcitability of the ventricles. Such hyperexcitability may arise from a metabolic abnormality such as hypokalemia or a pharmacologic cause such as digitalis toxicity.

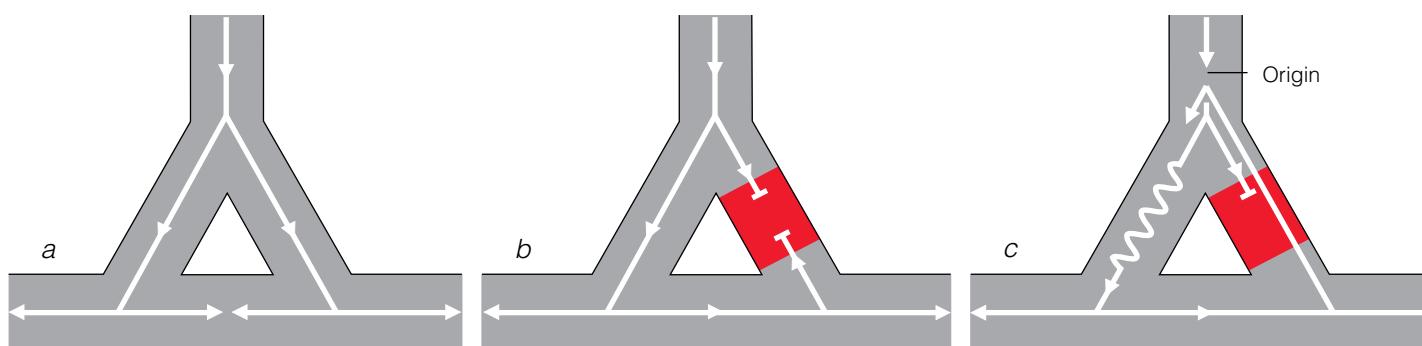

Figure 8 Schematic diagram portrays a conceptual framework for understanding the generation of reentrant dysrhythmias. In normal conduction (*a*), as in sinus rhythm or ventricular pacing, an impulse is propagated along two different anatomic pathways and is extinguished at the bottom. In (*b*), one pathway has a region of slow conduction (red area), which results in a rate-dependent block. In (*c*), the impulse is also blocked in the right limb (red area), but it travels over the alternative pathway sufficiently slowly (zigzag line) for the origin to be able to repolarize before the initial impulse returns; the conducted impulse then depolarizes the origin and reenters the circuit.

agent other than oxygen that causes the heart to pump harder and faster also increases cardiac excitability. Digitalis toxicity can produce diffuse myocardial hyperexcitability, manifested by so-called automatic ventricular ectopy. In this condition, the cardiac impulse originates from multiple sites in the ventricle. In patients with ventricular ectopy caused by digitalis intoxication, the whole myocardium becomes hyperexcitable and spontaneous depolarizations derive from multiple different sites. When the QRS complex originates at multiple loci, the ECG will exhibit multiple morphologies, and multifocal PVCs are apparent on the ECG—the classic multifocal ectopy of digitalis toxicity [see Figure 7].^{41–43}

REENTRANT DYSRHYTHMIAS

In the normally functioning heart, the rich cell-cell conduction pathways promote uniform activation of the atria or ventricles in waves. Because activation occurs by means of large electrical wave

fronts and because all cardiac tissue has a long refractory period, it is highly unlikely that any cells will remain excitable at the completion of each beat. However, disorders such as myocardial ischemia, fibrosis, and necrosis slow electrical conduction and also produce nonconductive areas that interrupt the normal electrical wavefront.⁴⁴ These conditions set up one of the requirements for reentry: areas of differential myocardial polarization.⁴⁵

A circuit whose length exceeds the duration of the reentrant impulse circuit is required for the initiation of reentry (i.e., in order to sustain continuous conduction); such a circuit may develop because of anatomic or physiologic heterogeneity in myocardial tissue.^{44,45} Slow conduction, a shortened refractory period, and anatomic heterogeneity all favor reentry [see Figure 8]. The circuit wavelength of an impulse is the product of the conduction velocity and the duration of the longest refractory period in the circuit.⁴⁶ For example, for normal myocardium, the

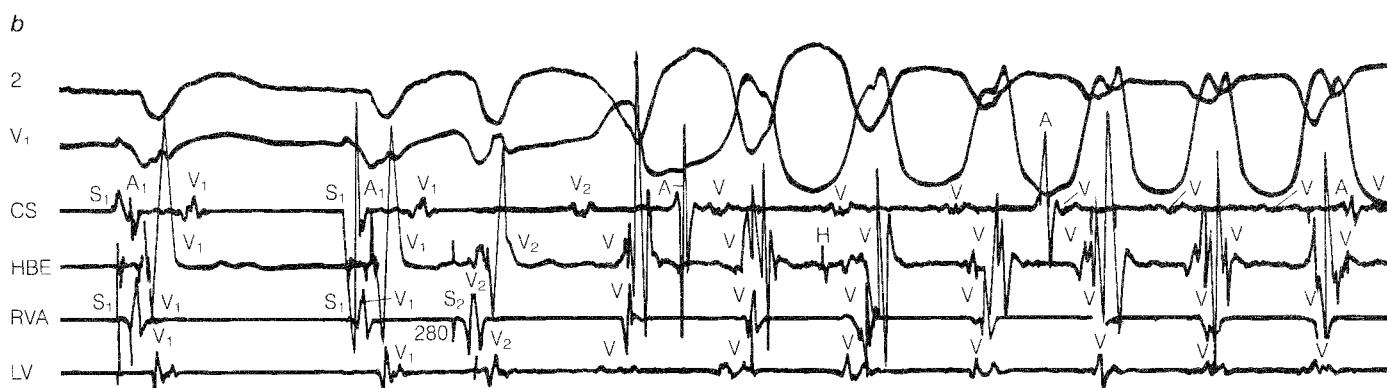

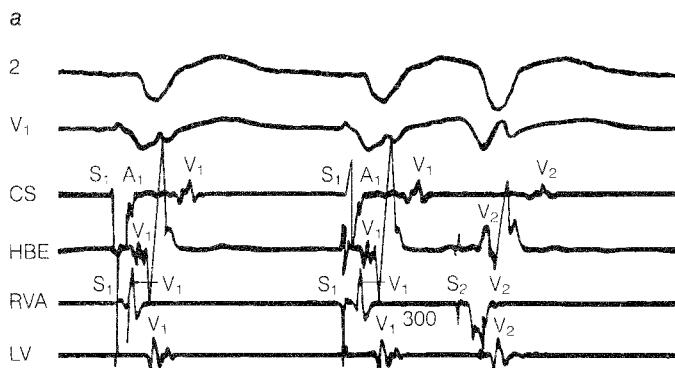

Figure 9 In electrophysiologic testing, the electrical complexes are spread out to facilitate the recognition of ventricular electrical morphology. In (*a*), critically timed paced stimuli capture one ventricle, but when pacing is stopped, the rhythm reverts to sinus rhythm. In (*b*), critically timed paced stimuli achieve rate-dependent block in one arm of a reentrant circuit. When the activation wave front returns to the origin, this tissue is no longer refractory and undergoes depolarization. With reexcitation, the conditions for reentry are met, and the impulse continues after pacing stops.

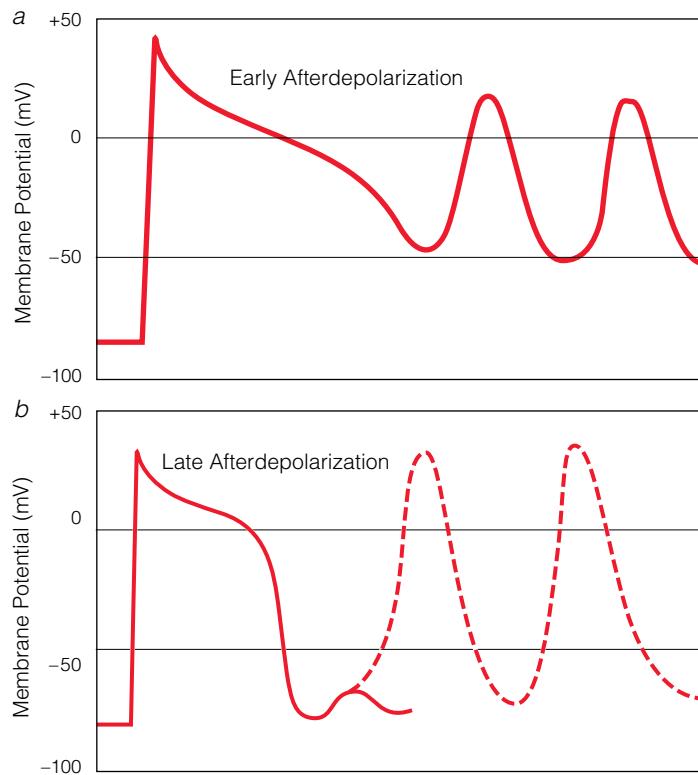

Figure 10 Membrane oscillatory instability may be manifested by either (a) early afterdepolarizations or (b) late afterdepolarizations. If the late afterdepolarizations achieve the threshold voltage, they can fire an action potential (dotted lines).

conduction velocity is 200 cm/sec and the refractory period is 0.4 second; therefore, the circuit length for a normally conducted myocardial impulse would have to be 80 cm. Because the reentrant circuit would have to be extraordinarily tortuous to encompass 80 cm, it would appear that concomitant slow conduction is essentially mandatory to shorten the circuit wavelength and permit initiation of a reentrant dysrhythmia. Regions such as the AV and SA nodes normally exhibit slow conduction, and therefore, any disturbance that produces minor additional slowing in these areas predisposes to reentry. It has also been suggested that extreme anatomic heterogeneity might permit microreentry.⁴⁵ For example, a tortuous path over stunned, slowly conducting ventricular muscle in an individual with heterogeneous myocardial infarction might achieve the prerequisites for reentry.

In vitro studies have investigated physiologic factors that might produce changes in conduction and excitability that predispose to reentrant dysrhythmias. For example, abnormal conduction has been observed in a Purkinje network subjected to local changes in potassium concentration.^{33,40} The decrease in conduction velocity can vary in different areas of the Purkinje network, leading to functional conduction block.^{37,38} In T- or X-shaped Purkinje preparations, the impulses either summate electrically or, conversely, inhibit each other when they arrive at the same junction simultaneously. It is difficult to study the cardiac microenvironment in living animals or humans, but in these studies,⁴⁷ electrical instability results when the Purkinje network is subjected to potassium fluctuations (which certainly occur with induced cardioplegia during cardiac surgery, and probably occur in myocardial ischemia).

Electrophysiologic testing with programmed stimulation in a

patient with a history of cardiac dysrhythmias can reveal whether latent substrates of reentry are present. Because organized ventricular reentry does not occur in normal myocardium, all reentrant dysrhythmias, whether they are induced or spontaneous, are pathologic. Rapidly paced stimuli may provoke a decrease in action potential duration and shorten refractoriness in myocardium in which the conduction velocity has already been reduced. Critically timed premature paced stimuli may then penetrate selective zones of myocardium, leading to a reentrant dysrhythmia [see Figure 9].⁴⁸ A ventricular tachydysrhythmia that can be induced by programmed stimulation carries an ominous prognosis unless it can be abolished by pharmacotherapy or surgery.⁴⁸

SLOW AFTERDEPOLARIZATIONS

Damaged atrial and ventricular muscle exhibits resting membrane potential instability.⁴⁹ The oscillations in membrane potential may at times be large enough to raise the membrane voltage to threshold level and cause the cell to fire. The phenomenon of oscillatory instability, which was first recognized in the 1940s,⁵⁰ is now thought to play an important role in the genesis of cardiac dysrhythmias. Injury,⁴⁹ elevated calcium levels,³³ digitalis,^{41,42} and catecholamines all promote membrane oscillatory instability, which may be manifested as either early or late afterdepolarizations. Both phenomena occur after an action potential; however, an early afterdepolarization occurs before repolarization of the cell, whereas a late afterdepolarization occurs after repolarization [see Figure 10]. Both early and late afterdepolarizations may be followed by extreme membrane oscillatory instability that leads to slow-response action potentials [see Figure 11]. If any of these slow potentials reach threshold, they may result in either organized electrical activity (premature ventricular depolarization) or disorganized electrical activity (fibrillation).

The recognition of slow potentials, depressed fast responses, and very slow conduction was originally based on *in vitro* studies of cardiac tissue.⁵¹ For example, bathing superfused Purkinje fibers in a solution with a high potassium concentration inactivates the fast sodium channels and markedly alters normal phase 0 depolarization. Under such circumstances, slow potentials that are less than 80 mV in amplitude, that depolarize at a rate of 1 to

Figure 11 Early afterdepolarizations may lead to slow-response action potentials. If any of these potentials reach threshold, they may lead to either organized electrical activity (premature ventricular depolarization) or disorganized electrical activity (fibrillation).

2 V/sec, and that last for up to 1 second are frequently documented.^{40,51} The amplitude and the overshoot of these slow potentials can be magnified by increasing the extracellular calcium concentration and can be abolished by adding manganese, an agent that blocks the slow calcium channels. These results suggest that the slow potentials are mediated by the slow calcium channels rather than by the fast sodium channels responsible for routine phase 0 depolarization. Although extraordinary nonphysiologic conditions are employed to induce such slow potentials in the laboratory, the myocardial microenvironment during the peri-infarction and postinfarction periods as well as after cardio-plegia may well be similarly bizarre and equally nonphysiologic.

For example, even after extensive myocardial infarction, there are often healthy Purkinje fibers overlying areas of damaged, ischemic myocardium.⁵² Slow conduction and slow potentials are characteristic of stunned myocardium.^{53,54}

Slow potentials have been incriminated in the generation of reentrant dysrhythmias for three reasons: (1) because they are caused by an active calcium influx that produces 40 to 80 mV depolarizations, they may be conducted long distances; (2) because the conduction velocity may be 1,000 times slower than normal, the circuit wavelength is reduced accordingly; and (3) because slow potentials leave a long refractory wake, they set up zones of functional conduction block.^{53,54}

3 SHOCK

James W. Holcroft, M.D., F.A.C.S., John T. Anderson, M.D., F.A.C.S., and Matthew J. Sena, M.D.

Approach to Management of Shock

Like a Carnot engine, the heart generates power (the product of pressure and flow), and under normal conditions, it does so in an extremely efficient manner. The generated power is used to deliver nutrients to and remove waste products from metabolizing tissues, to carry heat from these tissues to the surface of the skin (where the heat is dissipated into the environment to help keep body temperature under control), and to transport hormones from one part of the body to another. If a patient's heart becomes incapable of carrying out these functions, he or she is said to be in shock.

For the purposes of treatment, it is helpful to classify shock into six main types on the basis of the underlying processes responsible for the shock state. Most cases of shock fall readily into one of these six categories; however, some cases involve more than one underlying process and thus belong to more than one category.

Classification

HYPVOLEMIC SHOCK

In hypovolemic shock, small ventricular end-diastolic volumes lead to inadequate cardiac generation of both pressure and flow (and thus of power). Causes include bleeding, protracted vomiting or diarrhea, fluid sequestration in obstructed gut or injured tissue, excessive use of diuretics, adrenal insufficiency, diabetes insipidus, and dehydration.

INFLAMMATORY SHOCK

Inflammatory shock arises from the release of inflammatory and coagulatory mediators. It can be caused by ischemia-reperfusion injury, trauma, or infection (in which case it is sometimes referred to as septic shock). Clinical conditions capable of causing inflammatory shock include pneumonia, peritonitis, cholangitis, pyelonephritis, soft tissue infection, meningitis, mediastinitis, crush injuries, major fractures, high-velocity penetrating wounds, major burns, retained necrotic tissue, pancreatitis, anaphylaxis, and wet gangrene.

For inflammatory shock to develop, the infected or traumatized or reperfused tissues must be in proximity to a robust drainage of blood from the tissues. An avascular infection (e.g., a contained abscess), in which the inflammatory mediators do not have access to the circulation, will not cause inflammatory shock, whereas an uncontained abscess (e.g., a ruptured appendiceal abscess or an acutely drained subphrenic abscess), which allows vascular dissemination of the mediators, can do so. Similarly, dry gangrene, because of its poor vascular supply, will not cause inflammatory shock, whereas wet gangrene can.

The hemodynamic problems in inflammatory shock are caused by two basic mechanisms. The first mechanism is disruption of the microvascular endothelium, both at the inflammatory site and distally. On the one hand, the increased permeability of the endothelial

lum gives inflammatory mediators access to the injured or infected tissues and helps promote wound healing and control of infection; on the other, it also leads to leakage of plasma into the interstitium, which results in hypovolemia and inadequate ventricular end-diastolic volumes. The second mechanism, which arises from the need to offload heat generated by the inflammatory process, is a severalfold increase in blood flow to the skin. Blood pressure falls because of cutaneous arteriolar dilation and because of sequestration of blood in the cutaneous venules and small veins.

Other problems can arise from these two basic mechanisms. Myocardial contractility may decrease, either as a result of inadequate coronary perfusion or as a direct cardiodepressant effect of the inflammatory mediators. The afterload may fall even further, presumably in an effort to produce the residual cardiac power more efficiently. The heart rate may rise in an effort to increase the cardiac output; alternatively, it may remain largely unchanged in an effort to allow more time for ventricular filling and perfusion of the coronary vasculature during diastole.

If the predominant feature of the shock state is loss of plasma volume into the interstitium through a permeable microvasculature, the patient's skin will be cool and clammy (hence the terms cold septic shock and cold inflammatory shock). The mean blood pressure and the cardiac output will both be inadequate. If, however, the blood volume has been restored or the predominant feature of the shock state is cutaneous vasodilatation, the patient's skin will be flushed and warm (hence the term warm inflammatory shock). The mean blood pressure will be low, but the cardiac output may be high as a consequence of the cutaneous arteriolar dilatation and the reduced afterload.

COMPRESSIVE SHOCK

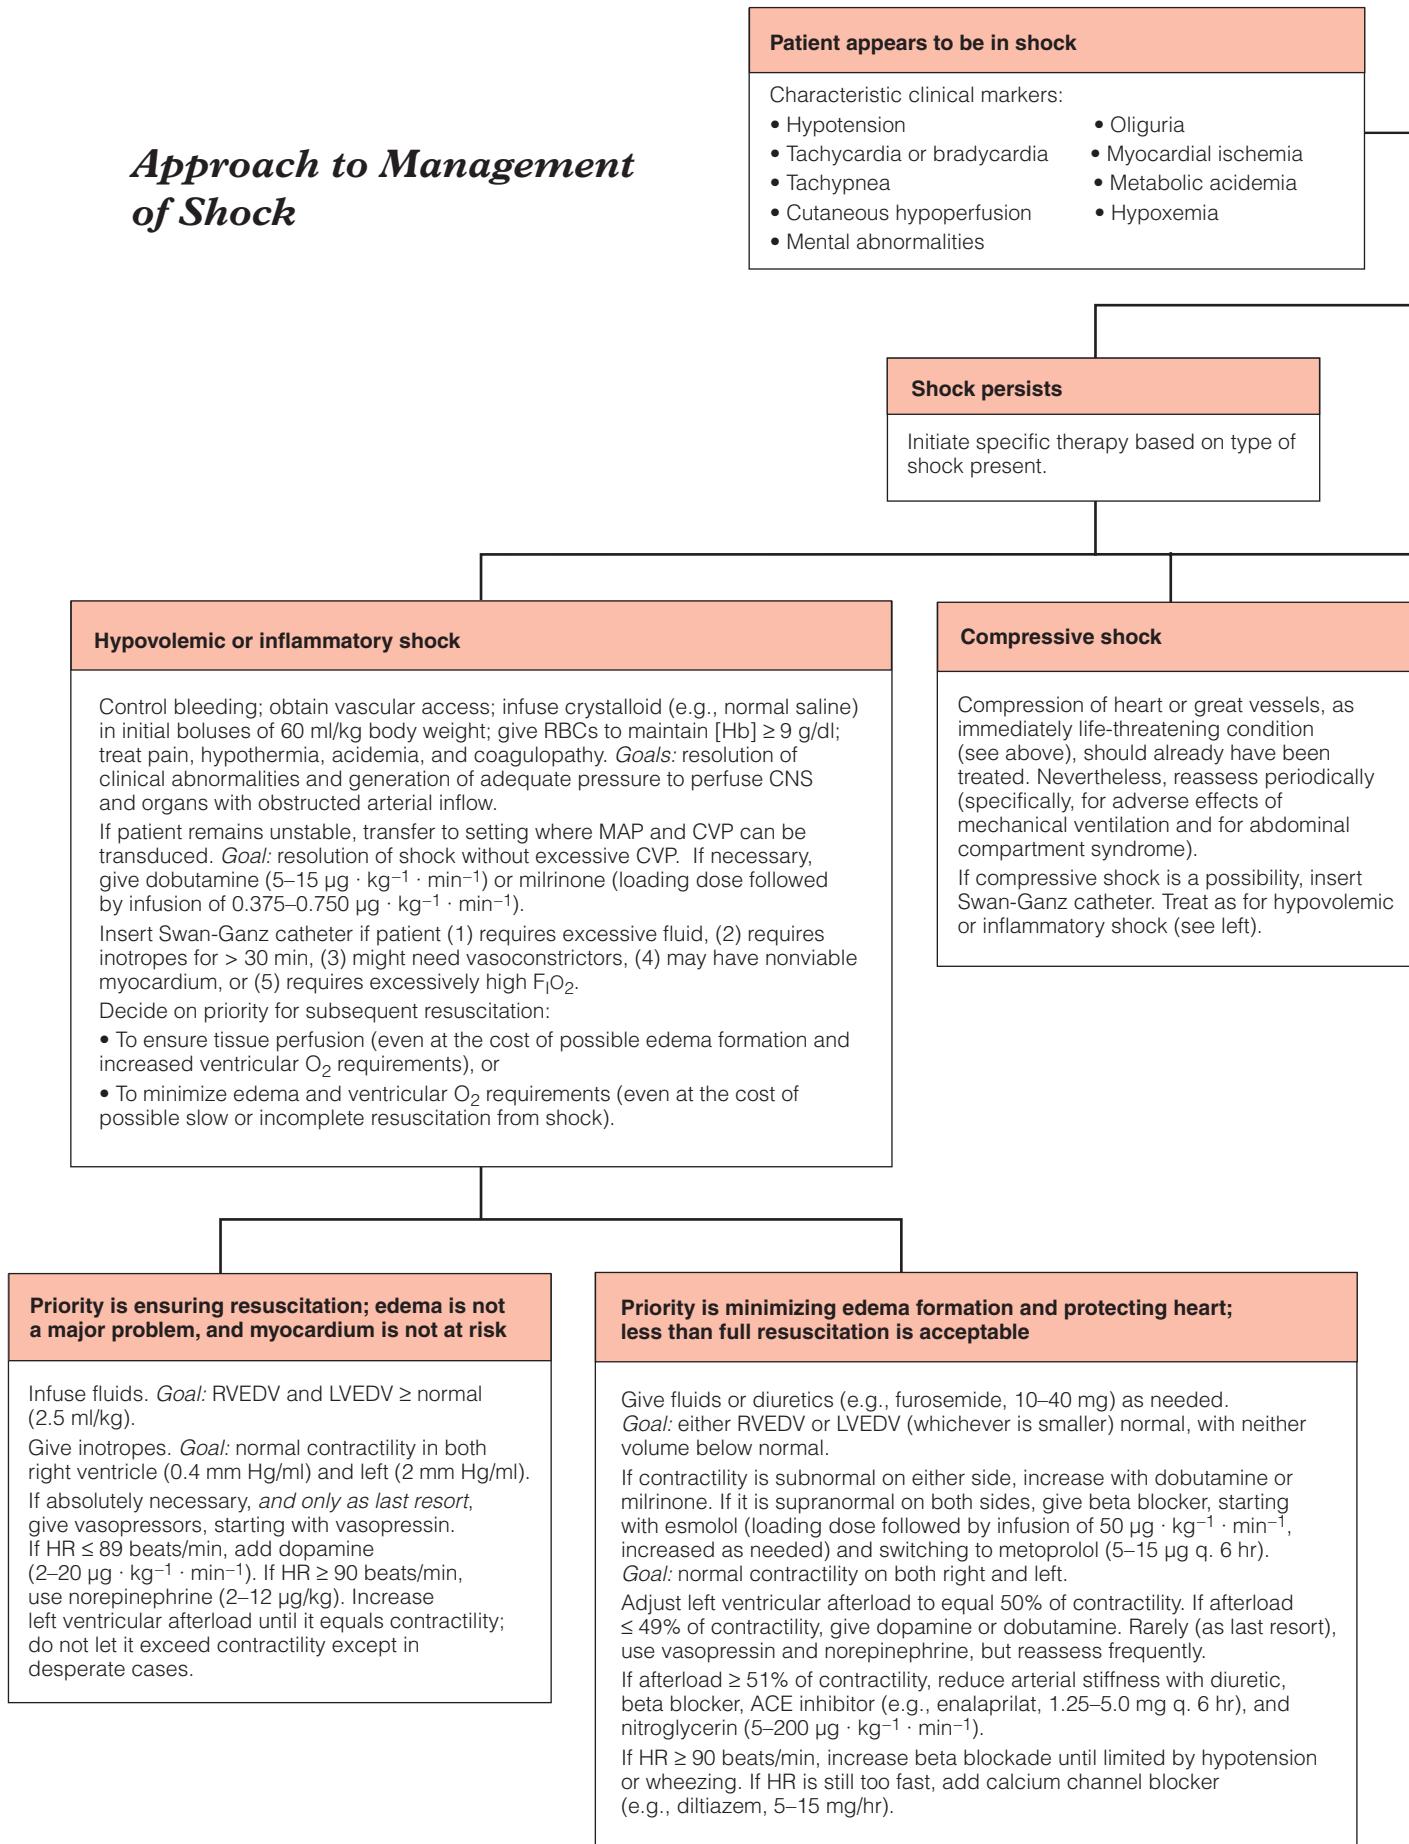

In compressive shock, external forces compress the thin-walled chambers of the heart (the atria and the right ventricle), the great veins (systemic or pulmonary), the great arteries (systemic or pulmonary), or any combination of these. Compression of any of these structures can drastically decrease ventricular production of both pressure and flow.

Clinical conditions capable of causing compressive shock include pericardial tamponade, tension pneumothoraces, positive pressure ventilation with large tidal volumes or high airway pressures (especially in a hypovolemic patient), an elevated diaphragm (as in pregnancy), displacement of abdominal viscera through a ruptured diaphragm, and the abdominal compartment syndrome (e.g., from ascites, abdominal distention, abdominal or retroperitoneal bleeding, or a stiff abdominal wall, as in a patient with deep burns to the torso).

INTRAVASCULAR OBSTRUCTIVE SHOCK

Intravascular obstructive shock results when intravascular obstruction, excessive stiffness of the arterial walls, or obstruction of

Approach to Management of Shock

Identify and treat any immediately life-threatening conditions:

- Dysrhythmias
- Airway compromise, inadequate ventilation or compression of heart and great vessels (or both)
- Bleeding
- Medical emergencies

Shock resolves

Intravascular obstructive shock

Reduce RVESP and LVESP by decreasing arterial stiffness with diuretics, beta blockers, ACE inhibitors, and nitroglycerin. If pressures remain too high, insert Swan-Ganz catheter. Treat as for hypovolemic or inflammatory shock (see left). If pulmonary vasculature is obstructed, ventilator mode may have to be changed. If systemic vasculature is obstructed, aortic counterpulsating balloon pump may be needed.

Neurogenic shock

Place in Trendelenburg position. Infuse fluids as necessary, and give vasoconstrictors (dopamine if $HR \leq 89$ beats/min; norepinephrine if $HR \geq 90$ beats/min). Periodically reassess for possibility of hypovolemia or other cause of inadequate end-diastolic volume (e.g., cardiac compression). If such possibility is significant, insert Swan-Ganz catheter. Treat as for hypovolemic or inflammatory shock (see left).

Cardiogenic shock

If RVEDV and LVEDV seem too large, initiate diuresis. Initiate beta blockade to keep $HR \leq 89$ beats/min unless patient is hypotensive or wheezing. Control LVESP. Reduce arterial stiffness with more aggressive diuresis, increased beta blockade, ACE inhibition, and nitroglycerin. *Goals:* adequate MAP, adequate peripheral perfusion, and $HR \leq 89$ beats/min, with no sign of myocardial ischemia. If efforts are unsuccessful, insert Swan-Ganz catheter. Adjust left ventricular afterload to equal 50% of contractility. Balloon pump, coronary angioplasty, or cardiac surgery may be required. If problem is with right ventricle, adjustment of ventilator may help.

the microvasculature imposes an undue burden on the heart. The obstruction to flow can be on either the right or the left side of the heart. Causes include pulmonary valvular stenosis, pulmonary embolism, air embolism, acute respiratory distress syndrome (ARDS), aortic stenosis, calcification of the systemic arteries, thickening or stiffening of the arterial walls as a result of the loss of elastin and its replacement with collagen (as occurs in old age), and obstruction of the systemic microcirculation as a result of chronic hypertension or the arteriolar disease of diabetes. The blood pressure in the pulmonary artery or the aorta will be high; the cardiac output will be low.

NEUROGENIC SHOCK

Neurogenic shock arises from the loss of autonomic innervation of the vasculature. The arterioles, the venules, and the small veins are the vessels most strongly affected by this denervation; the arteries may be affected as well, but not to the same extent. In some cases, the denervation also involves the heart. Causes include spinal cord injury, regional anesthesia, administration of drugs that block the adrenergic nervous system (including some systemically administered anesthetic agents), certain neurologic disorders, and fainting.

In some patients (e.g., those who have a spinal cord injury or have received a regional anesthetic), the denervation is localized, which means that only the vasculature in the denervated areas will be blocked. In other patients (e.g., those who have received a general anesthetic), the vasculature throughout the body will be blocked.

All patients in neurogenic shock have small ventricular end-diastolic volumes because of the pooling of blood in the denervated venules and small veins. If the blockade is generalized or at a high enough level, the denervation can also reduce myocardial contractility and lower the heart rate. All patients also have low blood pressures because of the arteriolar denervation and the depletion of the ventricular end-diastolic volumes. In cases of distal denervation, in which the heart is not involved, the cardiac output may be high, depending on the offsetting effects of the decreased afterload and the decreased end-diastolic volumes. In cases of generalized denervation, however, the cardiac output is low.

CARDIOGENIC SHOCK

In cardiogenic shock, the heart itself, because of an intrinsic abnormality, is incapable of delivering blood into the vasculature with adequate power. Sometimes, the problem is with the muscle; sometimes, it is with the rhythm. Causes include bradycardia, tachyarrhythmia, myocardial ischemia, myocardial infarction, cardiomyopathy, myocarditis, myocardial contusion (rare), cardiac valvular insufficiency, papillary muscle rupture, and septal defects. The mean arterial pressure (MAP) is usually low, depending on the degree of compensatory constriction of the systemic arterioles; the cardiac output is always low.

Characteristic Clinical Markers

The presence of a shock state is typically signaled by one or more characteristic clinical markers [see Table 1].

HYPOTENSION

In the initial assessment and resuscitation of a patient in shock, it is usually necessary to rely on the brachial systolic pressure as measured by sphygmomanometry, with the manometer zeroed

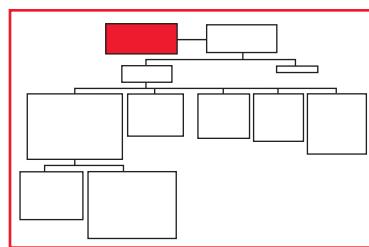

Table 1 Clinical Markers of Possible Shock State

Clinical Marker	Value or Findings Indicative of Shock
Systolic blood pressure	
Adult	≤ 110 mm Hg
Schoolchild	≤ 100 mm Hg
Preschool child	≤ 90 mm Hg
Infant	≤ 80 mm Hg
Sinus tachycardia	
Adult	≥ 90 beats/min
Schoolchild	≥ 120 beats/min
Preschool child	≥ 140 beats/min
Infant	≥ 160 beats/min
Cutaneous vasoconstriction	Pale, cool, clammy skin with constricted subcutaneous veins
Respiratory rate	
Adult	≤ 7 or ≥ 29 breaths/min
Child	≤ 12 or ≥ 35 breaths/min
Infant	≤ 20 or ≥ 50 breaths/min
Mental changes	Anxiousness, agitation, indifference, lethargy, obtundation
Urine output	
Adult	≤ 0.5 ml·kg ⁻¹ ·hr ⁻¹
Child	≤ 1.0 ml·kg ⁻¹ ·hr ⁻¹
Infant	≤ 2.0 ml·kg ⁻¹ ·hr ⁻¹
Myocardial ischemia or failure	Chest pain, third heart sound, pulmonary edema, abnormal ECG
Metabolic acidemia	[HCO ₃ ⁻] ≤ 21 mEq/L Base deficit ≥ 3 mEq/L
Hypoxemia (on room air)	
0–50 yr	≤ 90 mm Hg
51–70 yr	≤ 80 mm Hg
≥ 71 yr	≤ 70 mm Hg

at the midaxillary line and with the pressures referenced to the atmosphere (as all physiologic pressures are unless otherwise specified).

The brachial systolic pressure has several advantages in this context: it is easy to measure and understand, it can be measured in almost any setting, and its measurement does not require expensive, complicated, or difficult-to-calibrate equipment. Moreover, in the treatment of shock, it is the pressure with which most physicians feel most comfortable. Nonetheless, the brachial systolic pressure is not the most pertinent variable in the early stages of resuscitation. The mean aortic root pressure is more relevant [see Figure 1]. This pressure, however, usually is not available until a later stage of resuscitation, when it is possible to cannulate and directly monitor the intra-arterial pressures (see below).

A low brachial systolic pressure can serve as an indicator of shock, though what constitutes a significantly low value depends to an extent on the age of the patient [see Table 1]. In an adult, a low brachial systolic pressure (≤ 110 mm Hg) frequently indicates shock; a very low brachial peak-systolic pressure (≤ 89 mm Hg) almost always does, especially in a patient who is under stress. (Admittedly, many normal patients, especially young women, may have a systolic pressure of 89 mm Hg or lower when supine, but only when in an unstressed state.)

The pain or stress associated with an injury or acute illness will drive that normally low pressure to much higher levels, particularly in well-conditioned patients who are ideally suited to deal with threats to the cardiovascular system. A patient whose brachial systolic pressure is low in the presence of stress can be assumed to be in shock.) A sustained (> 30 seconds) systolic pressure drop greater than 10 mm Hg in a patient who has arisen from a supine to an upright position can also be an indicator of underlying shock.

The absence of hypotension does not, however, rule out shock. Adrenergic discharge and the release of circulating vasoconstrictors (e.g., vasopressin and angiotensin) and locally produced vasoconstrictors (e.g., endothelin) often sustain blood pressure during shock despite volume depletion or depressed myocardial contractility. As a result, visceral hypoperfusion may precede clinically evident changes in the supine blood pressure. In addition, some forms of shock can even be associated with hypertension (as in a hypertensive crisis). Finally, the definition of hypotension can vary, depending on the patient's usual blood pressure, which the physician may not know. For example, in a patient with severe preexisting hypertension, a brachial systolic pressure of 120 mm Hg might be an indicator of shock.

TACHYCARDIA OR BRADYCARDIA

The pulse rate—perhaps the most evident of all the physical findings in clinical medicine—can increase in shock, and the possibility of shock should be considered in any patient with a tachycardia. An abnormally high pulse rate—with “high” determined in

relation to the patient's age [see *Table 1*]—can serve as an indicator of shock.

The absence of tachycardia should not, however, be taken as a sign that the patient is not in shock. A slow or normal heart rate may even indicate that decompensation is imminent. In severe shock, the pulse rate may have to slow down to allow more time both for ventricular filling and for coronary perfusion of the myocardium.

TACHYPNEA AND BRADYPNEA

Any patient with tachypnea must be promptly evaluated not only for possible pulmonary insufficiency but also for possible shock. The rapid respiratory rate may be a response to a metabolic acidemia; it may also be a means of compensating for inadequate filling of the ventricles, in that it will lower the mean intrathoracic pressure and facilitate the influx of blood into the heart from the capacitance venules and small veins in the periphery. In severe decompensated shock, the respiratory rate may fall to very low levels, perhaps because of ischemia in the muscles providing the ventilation.¹

CUTANEOUS HYPOPERFUSION

Diminished skin perfusion is often the first sign of shock. In all types of shock other than warm inflammatory shock and neurogenic shock, blood flow to the skin is reduced because of adrenergic discharge and high circulating levels of vasopressin and angiotensin II. The result is the pale, cool, and clammy skin of a person exhibiting the fight-or-flight reaction. Cutaneous hypoper-

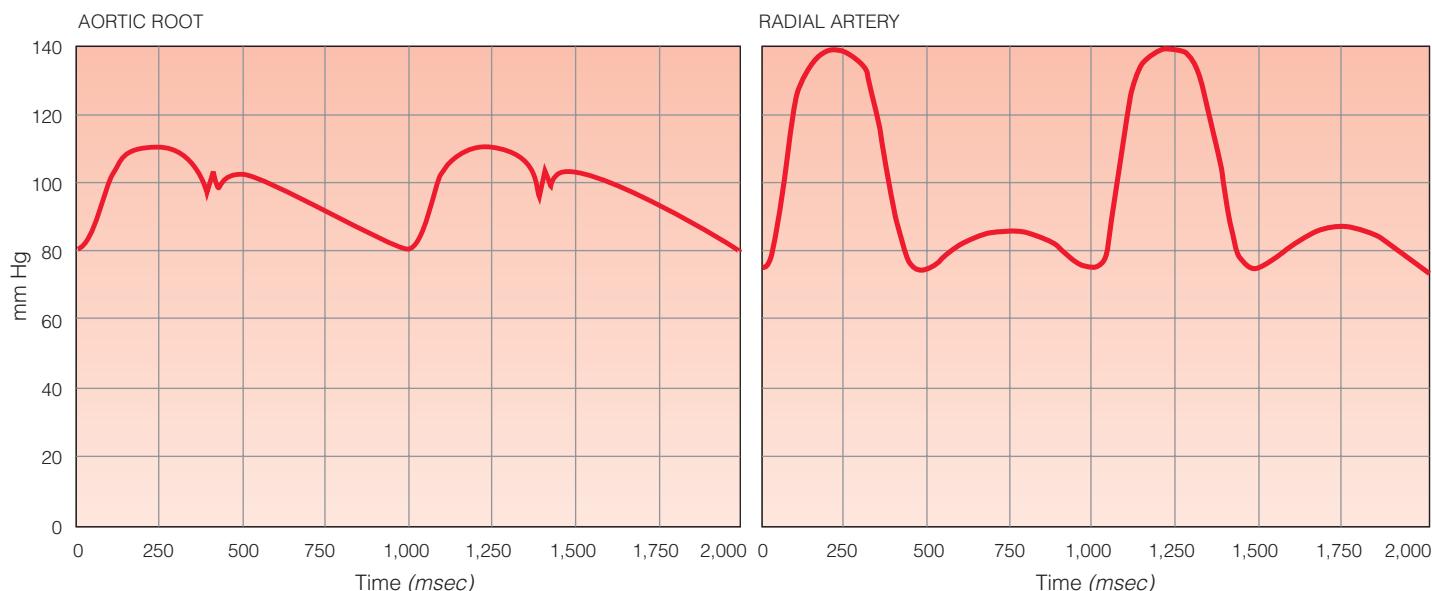

Figure 1 The mean pressure is defined as the area under a pressure tracing divided by the time needed to produce the tracing. A pressure wave in the ascending aorta with a blood pressure of 110/80 mm Hg will have the same mean pressure as a pressure wave in the radial artery of the same patient, even though the radial artery pressure might be 140/75 mm Hg. The systolic pressure in the radial artery is usually inscribed more rapidly. Therefore, even though the peak pressure in the radial artery is greater than that in the aorta, the areas under the tracings will be the same for the two vessels. Sometimes, the mean pressure can be approximated by taking one third of the difference between the systolic and diastolic pressures and adding that value to the diastolic pressure. Frequently, however, the formula does not work. In this example, the mean aortic pressure would be approximated at 90 mm Hg, whereas the mean radial artery pressure would be approximated at 97 mm Hg. Such results would be impossible: if the mean pressure in the radial artery were greater than the mean pressure in the aorta, blood would flow backward. This confusion is avoided by measuring the area under the curve and calculating the mean pressure exactly, which can be done with computer circuits that are available in all modern pressure-monitoring systems. It should also be noted that the systolic pressure in the radial artery is about 30 mm Hg higher than the systolic pressure in the aortic root. In extreme cases, it can be as much as 80 mm Hg higher.

fusion is not specific for shock—it can also be the result of hypothermia, for example—but it can be a warning that the patient may decompensate at any time.

MENTAL ABNORMALITIES

Patients in severe shock frequently exhibit mental abnormalities, which can range from anxiousness to agitation to indifference to obtundation. These findings are not sensitive—indeed, they develop only in the late stages of shock—nor are they specific. They are, however, a strong warning to the physician that something must be done quickly. The body protects the blood supply to the brain at all costs. Changes in mental status as a result of severe shock suggest impending circulatory collapse.

OLIGURIA

The stress imposed by all forms of shock—in the absence of diuretic use, high alcohol levels, or administration of radiographic contrast agents—stimulates the release of vasopressin (antidiuretic hormone) and aldosterone (through activation of the angiotensin system).^{2,3} The result is oliguria, which is a sign of stress at the very least and a sign of decreased blood flow to the kidneys in extreme cases.

Whenever the diagnosis of shock is being entertained, a Foley catheter should be placed. Successful treatment should reduce the stress and decrease the plasma levels of vasopressin and aldosterone. It should also increase renal blood flow if the shock is indeed so severe that inadequate blood flow to the kidneys is compromising their viability. With successful treatment, the urine output should improve; if it does not, further therapeutic measures are probably necessary.

MYOCARDIAL ISCHEMIA

Electrocardiography is indicated whenever the suspicion of shock arises. The electrocardiogram may show signs of ischemia, which may be caused either by a primary myocardial problem or by a secondary extracardiac problem (e.g., hypotension resulting from hemorrhage). In either case, the presence of myocardial ischemia should prompt quick action.

METABOLIC ACIDEMIA

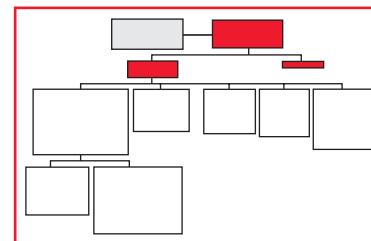

Metabolic acidemia, as a sign of shock, may be manifested by an increased respiratory rate. Serum chemistry may also demonstrate a decrease in the total concentration of carbon dioxide (bicarbonate plus dissolved CO₂), but analysis of blood gases is usually required for confirmation. The acidosis may take the form of either a low calculated bicarbonate level or a base deficit. Often, it does not become evident until after the shock has been recognized and treatment is under way. In severe, untreated shock, the anaerobic products of metabolism are confined to the periphery; they may not be washed into the central circulation until resuscitation has reestablished some flow to the ischemic tissues. The degree of acidosis after resuscitation can, however, provide information about the duration and severity of the initial insult.

HYPOXEMIA

Shock may be associated with significant arterial hypoxemia. Low flow results in marked desaturation of the blood leaving the metabolizing peripheral tissue, which eventually ends up in the pulmonary artery (yielding a low mixed venous oxygen saturation [S_{mvO₂}]). In patients with coexisting pulmonary dysfunction and an intrapulmonary shunt, the markedly desaturated pulmonary arterial blood is only partially saturated as it passes through the lungs, ultimately mixing with fully saturated blood. The increased

admixture of oxygen-poor blood results in a reduced oxygen saturation in the systemic arterial blood.

Identification and Treatment of Immediately Life-Threatening Conditions

If the patient shows signs suggestive of shock, the next step is to search for and treat any conditions that could be immediately fatal, such as (1) dysrhythmias; (2) compromise of the airway, inadequate ventilation, compression of the heart, compression of the great vessels, or any combination of these conditions (they often go together); (3) acute intravascular obstruction of the great vessels; (4) bleeding; and (5) certain life-threatening medical conditions (e.g., anaphylaxis, severe electrolyte disturbances, and life-threatening endocrine abnormalities).

There are roughly 10 to 20 clinical entities (depending on how one categorizes them) that can kill a patient quickly. Identification and management of these conditions requires early and continuous patient assessment and depends heavily on pattern recognition. Although not all of these entities are immediately fatal, all are life-threatening. Delays in recognition will increase the duration of hypoperfusion and may result in significant late morbidity and mortality related to multiple organ failure.

DYSRHYTHMIAS

Given that an ECG should be obtained promptly in any case of suspected shock, any dysrhythmia present is usually recognized early in the course of resuscitation. If the patient is agonal, cardioversion should be performed. If the patient turns out to be in ventricular fibrillation, ventricular tachycardia, or atrial fibrillation, cardioversion may restore him or her to life with full neurologic function. Cardioversion takes precedence over all other resuscitative efforts, including gaining airway control and obtaining I.V. access (though if the team taking care of the patient can perform cardioversion, secure the airway, and gain I.V. access at the same time, it should do so). The goal is to get blood flowing again to the brain. Even if the initial reperfusion is with desaturated blood, it is better than no perfusion at all. If the agonal patient turns out to be in asystole, cardioversion will be of no value. It is likely, however, that no other treatment will restore an asystolic patient to life with full neurologic function either. In the case of asystole, it rarely makes any difference what mode of therapy is attempted—or, indeed, whether therapy is attempted at all.

A nonagonal patient should be treated in accordance with standard resuscitation routines [see 8:1 Cardiac Resuscitation and 8:2 Acute Cardiac Dysrhythmia].

COMPROMISE OF AIRWAY, INADEQUATE VENTILATION, AND COMPRESSION OF HEART OR GREAT VESSELS

If a patient can talk in a full voice without undue effort, the airway can be assumed to be intact. Supplemental oxygen should be given via a mask or nasal prongs; nothing else need be done.

If the patient cannot talk in a full voice, possible compromise of the airway and possible inadequate ventilation must be assumed. Causes range from loss of protective reflexes to mechanical obstruction to a host of other problems that can limit ventilation. Sometimes, a jaw thrust is all that is needed for diagnosis and treatment of the problem. In cases of profound shock, however,

Table 2 Selected Cardiopulmonary Variables in Resting Subjects of Different Age-Adjusted Weights

Height (ft, in)	Lean Weight (kg)	Approximate Lean Weight (kg)	O ₂ Consumption (ml/min)	Cardiac Output (L/min)	Tidal Volume (ml)
5'0"	48.9	50	175	5.0	350
5'6"	59.1	60	210	6.0	420
6'0"	70.4	70	245	7.0	490
6'6"	82.6	83	290	8.3	580

the patient should be intubated. Initially, the patient should be ventilated by using an Ambu bag with 100% oxygen; later, when the situation has stabilized sufficiently, the patient should be switched to mechanical ventilation.

In the mechanical ventilation of a patient in severe shock, the goal is to achieve ventilation and oxygenation without unduly compromising cardiac production of pressure and flow. The ventilator should be set so as to produce ventilation with a minimal mean airway pressure (mean pressure being defined as the integral of the pressure over time divided by the time over which the pressure is produced). A respiratory rate of 12 to 15 breaths/min and an initial tidal volume of approximately 7 to 8 ml/kg lean body weight should result in sufficient alveolar ventilation to normalize the carbon dioxide tension (mild hyperventilation is acceptable if the patient has a profound acidemia) [see Table 2 and Sidebar Expectations for Cardiopulmonary Values in Patients of Different Sizes and Ages]. Although a lung-protective ventilation strategy may ultimately be desirable in certain patients who have sustained lung injury, the initial ventilatory settings should be adjusted so that respiratory acidosis is avoided during the acute resuscitation phase.⁴ The end-expiratory pressure should be set at 0 mm Hg. Oxygenation should be assured with a fractional concentration of inspired oxygen (F_1O_2) of 1.00.

When blood gas analysis becomes available, the ventilator should be adjusted to ensure adequate arterial oxygen saturation (S_aO_2) and adequate alveolar ventilation. Managing the ventilator during the acute resuscitation of a patient in severe shock is a dynamic process. Close attention to the tidal volume and the airway pressure is necessary to ensure adequate gas exchange and avoid unnecessary cardiovascular sequelae and potential lung injury [see 8.5 Mechanical Ventilation and 8.4 Pulmonary Insufficiency].

Even when intubation appears to have been successful and the ventilator seems to be functioning normally, there are still many things that can go wrong. Misplacement or displacement of the endotracheal tube and malfunction of the ventilator can be hard to detect. If the chest wall does not rise with inspiration, the patient should be removed from the ventilator, and the almost foolproof Ambu bag should again be used to ensure adequate airflow through the endotracheal tube. Malfunction is rare with modern ventilators, but it remains a potential problem that must be eliminated. The easiest way of dealing with ventilator malfunction is to change the ventilator.

If increasing abdominal distention is apparent, the possibility of esophageal intubation or displacement of the endotracheal tube into the hypopharynx should be considered. Whenever the placement of the tube is questionable, reintubation is mandatory. Reintubation is obviously hazardous in these circumstances, but it is clearly preferable to leaving a misplaced endotracheal tube in place. If breath sounds are absent on the left, right mainstem

bronchial intubation is a possibility. The tube should be withdrawn into the trachea (or what one believes to be the trachea).

If the endotracheal tube is obstructed by clotted blood or inspissated secretions, the obstruction can usually be cleared by suctioning. If this measure is unsuccessful, the patient should be reintubated.

Bleeding in the tracheobronchial tree (from injuries or from friable bronchial mucosa or tumor tissue) can eliminate ventilation from the lung segment supplied by the injured or obstructed bronchus and flood the initially uninjured lung with blood. If the bleeding is thought to be coming from the left lung, the endotracheal tube should be advanced into the right mainstem bronchus. Bleeding from the right lung is more problematic. Selective left mainstem intubation is usually impossible under emergency conditions. If selective mainstem intubation is not feasible or substantial bleeding continues on either side, definitive control of the bleeding will have to be obtained by means of either endobronchial techniques or open surgical intervention.

Bleeding into the pleural cavity can eliminate ventilation of the affected side and push the mediastinum into the nonbleeding side. This problem is treated with insertion of a chest tube and, if necessary, surgical intervention.

Pneumothoraces may arise from injuries to the lung, from attempts to place a central venous line, or from positive pressure ventilation. They are treated by inserting a chest tube.

Tension pneumothoraces sometimes develop in a patient who is breathing spontaneously; more often, however, they are created by superimposition of positive pressure ventilation on a previously existing pneumothorax. The tension pneumothorax not only eliminates ventilation on the side of the pneumothorax but also limits ventilation on the uninjured side and compresses the heart and great vessels. Characteristic signs include decreased or absent breath sounds on the involved side, a hyperresonant hemithorax, and, if the patient is normovolemic, distended neck veins. (A tracheal shift—a commonly described feature in patients with tension pneumothoraces—is hard to detect and, in our experience, rarely helpful in making the diagnosis.) A tension pneumothorax should be the first diagnosis considered in any patient who suddenly decompensates when placed on positive pressure ventilation. Treatment consists of needle decompression followed by tube thoracostomy.

Air leaks almost always mean loss of ventilation on the side of the leak. If they are large, they also mean loss of ventilation on the uninjured side, in that the administered air preferentially exits the airway through the chest wall defect or the chest tube on the injured side. A left-side leak can sometimes be treated by advancing the endotracheal tube into the right mainstem bronchus; a right-side leak usually necessitates surgical intervention, as does any large leak that does not close quickly.

Acute pericardial tamponade is usually manifested by muffled heart tones and occasionally by an exaggerated (> 10 mm Hg)

Expectations for Cardiopulmonary Values in Patients of Different Sizes and Ages

Some numerical descriptors of physiologic variables that can be altered in shock (e.g., blood pressure, body temperature, and arterial pH) are independent of the amount of metabolically active tissue the patient has; others (e.g., tidal volume, minute ventilation, ventricular end-diastolic volumes, stroke volume, cardiac output, oxygen consumption, carbon dioxide production, and caloric needs) are not.

The question of how to interpret, or index, these size-dependent variables dates back at least to the 1800s. It seemed logical at that time (and still seems so today) to index the variables to body surface area.⁶⁹ The body surface, as the site where the body dissipates its heat into the environment, plays a critical role in keeping the body from becoming overheated. The amount of heat produced by the body in a resting condition depends on the mass of the metabolizing tissue. (During exercise or illness, more heat is generated from the same mass of tissue. Presumably, humans evolved so as to be able to deal with both resting and stressful conditions. In either type of condition, however, some surface area through which heat can be dissipated is necessary.) The amount and activity of metabolically active tissue correlates with oxygen consumption. Thus, a patient's body surface area should correlate with the amount of heat generated by his or her metabolizing tissue, the mass and activity of the metabolizing tissue, and the oxygen consumption.

In the 1920s, when it became possible to measure cardiac output as part of metabolic studies, many investigators began to express cardiac output, as well as metabolic rate, in terms of body surface area, on the grounds that these two quantities should also be correlated. Although it was recognized that the relation was not necessarily a linear one, this approach to indexing worked, in the sense that it minimized some of the inherent variability observed in nonindexed values. By the end of the 1920s, body surface area had become the most commonly used parameter for indexing both metabolic rate and cardiac output to body size.^{70,71}

In the 1930s, however, Max Kleiber made the empirical observation that the metabolic rates—and presumably the cardiac outputs and some of the ventilatory parameters—of members of one species of animals

could best be compared with those of another species by indexing to body weight raised to the three-fourths power. Such indexing seemed to reduce variability even more effectively than indexing to body surface area did, though it was difficult to explain why.⁷²

Over the ensuing six decades, more and more accumulated evidence came to support Kleiber's contention, but only in the past two decades have his observations been satisfactorily explained. It now seems established that the Kleiber hypothesis can be proved by using a mathematical model that takes into account not only the thermodynamic considerations just described but also the fractal geometry of the vasculature in metabolizing organs and the thermodynamic constraints placed on such systems.⁷³

Thus, the problem of correlating size-dependent cardiopulmonary variables between species seems to be settled, and the different metabolic rates, cardiac outputs, and minute ventilations in different species appear to be well explained. However, the practice of using body weight raised to the three-fourths power does not solve the problem of how to make comparisons between members of the same species (e.g., between a large mouse and a small one or between a linebacker and a ballerina). In addressing this second problem, some clinicians, particularly those with a primary interest in the cardiovascular system, continue to index cardiopulmonary variables to body surface area. Others, particularly those with a primary interest in the respiratory system, favor indexing to body weight instead. A few prefer to use body weight raised to the three-fourths power. Still others choose not to index at all.

Not only is there no consensus on the preferred indexing method, but there also is no agreement on how and whether to adjust for obesity and aging. Body surface area is typically calculated on the basis of height and weight. Usually, the measured weight is used, which includes the weight of the fat. Thus, the calculation gives equal emphasis to metabolically active muscle and to metabolically inactive fat. Old age introduces a similar problem: for a given weight, older patients have less lean muscle mass and more fat than younger patients do. Some authors make an adjustment for age; others do not.

(continued)

decrease in systolic blood pressure on spontaneous breathing. If the patient is not hypovolemic, the neck veins are typically distended. Nowadays, the diagnosis is frequently confirmed by echocardiography (if that modality is immediately available). Treatment consists of needle decompression or surgical creation of a pericardial window. Chronic tamponade can also cause shock but may not give rise to the findings characteristic of acute tamponade. The diagnosis usually is made by means of echocardiography. Treatment is the same as for acute tamponade.

Diaphragmatic rupture and the ensuing intrusion of abdominal viscera into the chest can compress the venae cavae, the heart, the pulmonary arteries, the pulmonary microvasculature, the pulmonary veins, the left atrium, and the lungs. Treatment consists of operative reduction and repair.

The abdominal compartment syndrome can be caused by ascites, intestinal distention or edema, intra-abdominal or retroperitoneal bleeding, or noncompliance of the abdominal wall (as in patients with deep burns of the torso). The result is compression of the vasculature of the organs within the abdomen and intrusion of the diaphragm into the chest, which compromise ventilation and decrease ventricular end-diastolic volumes. If the patient is also hypovolemic, the hemodynamic consequences can be devastating. Infusion of fluid can restore ventricular end-diastolic volumes but can also worsen the underlying problem, either by increasing the central venous pressure (CVP) and encouraging the development

of ascites or edema or by exacerbating bleeding.⁵⁻⁷ The situation is made even worse because the increased venous pressures further reduce the perfusion pressures (calculated as MAP minus the venous pressure) in the organs at risk.

Initial treatment of ascites consists of paracentesis of just enough fluid to decrease the abdominal pressure, but no more. Treatment of intestinal edema may necessitate opening the abdomen. Bleeding may be controllable by operative or endovascular means; if such measures fail to control bleeding, the abdomen may have to be opened and left open. Treatment of the burned abdominal wall may involve escharotomies.

Pregnancy can elevate the diaphragm and complicate a shock state. If a woman in the late stages of pregnancy is thought to be in shock, she should be turned onto her left side to relieve compression of the right common iliac vein and the inferior vena cava. If shock persists, one may consider attempting to induce labor or perform a cesarean section.

INTRAVASCULAR OBSTRUCTION OF GREAT VESSELS

To treat pulmonary thromboembolism, aggressive anticoagulation with heparin, at the very least, is required; fibrinolitics, sometimes infused through a pulmonary arterial catheter, may also be necessary [see 6:6 *Venous Thromboembolism*].

Right-side air embolism can arise either from penetrating injuries to large veins in the upper part of the body or from percutaneous

Expectations for Cardiopulmonary Values in Patients of Different Sizes and Ages (*continued*)

Even though there is, at present, no unanimity on how best to deal with these issues, it is obvious that some form of indexing (or nonindexing) is necessary, both for the management of patients and for the creation of written reference sources. Our current practice is to start with the assumption that lean persons (e.g., those with a body mass index [BMI] of 21 or so) do not have very much body fat. Assuming a BMI of 21, we then use the patient's height to assign a weight, which we assume is mostly metabolically active tissue. This assigned weight is employed in interpreting the size-dependent variables. For patients 50 years of age or younger, we use the assigned weight as is. For patients 51 years of age or older, we calculate an age-adjusted lean weight based on the assumption that 1% of body weight has been lost each year after the age of 50.⁷⁴ (Although this loss is in fact exponential in nature, we have not found it necessary to reflect this fact in the calculation.) As an example, with an 83-year old patient, we subtract 33% from the lean weight that the patient would have had at 50 years of age. For older subjects who have kept themselves in particularly good condition, we assume that 0.5% of body weight has been lost each year after the age of 50. Finally, we make subjective adjustments if muscle mass appears to be either abnormally large (as in male patients who worked out extensively when young) or abnormally small (as in malnourished patients or patients with a preexisting prolonged critical illness).

This practice means that we do not use the patient's actual weight when setting up the ventilator or when managing the patient on the basis of other size-dependent variables. The weight at the time of measurement can be inflated by fluid resuscitation, the hardware used for fracture fixation, bedclothes, or obesity. It can also be difficult to measure accurately in critically ill patients, who often cannot easily be moved to a bedside scale. We also do not adjust for gender. For longevity and freedom from debilitating illnesses, a BMI of 21 is close to ideal for both men and women (though it appears that a slightly higher fat percentage may be appropriate for women). The value we use is also conveniently close to

the predicted body weight that has been advocated for use in setting tidal volumes.^{4,75}

We have found it useful to assign expected values for size-dependent cardiopulmonary variables in subjects of different age-adjusted lean weights who are resting, fasting, well conditioned, supine, spontaneously breathing, and in a thermoneutral environment [see *Table 2*]. We make three assumptions in assigning these values, using the age-adjusted lean weight for all of the calculations:

1. The normal resting oxygen consumption is $3.5 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$.
2. The normal resting cardiac output is $100 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$.
3. The normal resting tidal volume is 7 ml/kg .

In practice, we usually approximate the height to the nearest half-foot [see *Table 2*], then approximate the lean weight for that approximate height. Once this is done, the values for oxygen consumption, cardiac output, and tidal volume tend to come out in a pleasing, almost linear way. We then make any additional adjustments necessary—in particular, for age and cardiovascular variables.

An example will demonstrate how use of the age-adjusted lean weight can influence assessment and treatment. The hypothetical patient is an 83-year-old man with an admission weight of 80 kg and a height of 5 feet 6 inches. If a Swan-Ganz catheter were in place, one would expect a cardiac output of 8 L/min. The patient's age-adjusted lean weight, however, is 40 kg (60 kg was the lean weight at 50 years of age, minus 33% for the subsequent 33 years—on the assumption the patient did not work out much over the past few decades). One would expect a resting cardiac output of 4 L/min. (We would accept this value unless the patient had excessive metabolic needs.) This is not an unusual example; one could easily think of more extreme cases. The patient in this example has a BMI of 28, and there are many patients in the ICU today with indices that exceed this level.

puncture of a large central vein in the upper part of the body with a large-bore needle (if the needle is unintentionally left open to atmospheric pressure and air). In both situations, the air typically gains access to the venous system during spontaneous deep breathing. Patients are particularly vulnerable when upright. Right-side air embolism can also arise as a complication of insufflation of gas into the peritoneal cavity during laparoscopy.⁸

In all of these situations, the air that gains access to the veins can form an obstructing air bubble in the outflow tract of the right ventricle. Treatable sources of air should be searched for and eliminated, and 100% oxygen should be administered to wash out residual nitrogen in the trapped air. The patient should be placed in the Trendelenburg position with the left side down to induce translocation of air from the outlet of the right ventricle to the apex of the chamber. A long central venous catheter should then be advanced centrally to allow aspiration of any air that may be present.

Left-side air embolism can arise from right-side air embolism if the right-side air embolizes to the pulmonary microvasculature, backs up blood in the right side of the heart, increases pressures in the right atrium, and opens up a potentially patent foramen ovale. It can also be the consequence of a penetrating injury to the lung parenchyma (either from trauma or from a needle puncture) in a patient placed on positive pressure ventilation: the positive airway pressure can push air from an injured bronchus into an adjacent injured pulmonary vein. The air and its contained nitrogen can occlude the vasculature of the brain and heart, as well as that of other organs. The diagnosis is usually made when a patient with a

penetrating thoracic injury suddenly and catastrophically decompensates after initiation of positive pressure ventilation. (The differential diagnosis in this case consists of tension pneumothorax and air embolism. Accordingly, the first therapeutic measure is to insert chest tubes on both the right and the left. If it turns out that the patient has not had a tension pneumothorax, the diagnosis of possible air embolism should be kept in mind as other conditions are ruled out.)

Treatment consists of surgical control. In the case of a penetrating injury, the chest should be opened through an anterolateral thoracotomy on the side with the suspected injury. The hilum of the injured lung should be cross-clamped. Then, if the right side was opened first, the incision should be extended into the left chest. The heart should be massaged while the descending thoracic aorta is compressed. Vasoconstrictors should be given to increase the aortic pressure and to drive the air bubbles through and out of the arterial circulation. If neither side of the chest is known to have had a penetrating injury, the left side should be opened first. The primary goal of treatment is to prevent further embolism. Thus, if the left chest is opened first and no injury to the lung is detected, yet the diagnosis is certain (based on the finding of bubbles of air in the coronary arteries), the incision should be carried into the right chest in an effort to find a treatable injury there.

BLEEDING

Bleeding should be controlled by any means necessary. In some cases (e.g., bleeding from an easily accessible site in an

extremity), compression will suffice; in others, immobilization of a fracture may be enough; in still others, operative control (e.g., for a ruptured spleen), endoscopic control (e.g., for GI hemorrhage), or endovascular control (e.g., for arterial hemorrhage after a severe pelvic fracture) may be possible. In any case, control is paramount: it makes no sense to infuse fluid or blood or to persist with ancillary measures while controllable bleeding continues unabated.

MEDICAL EMERGENCIES

In the appropriate clinical circumstances, early consideration should be given to certain medical conditions that may cause shock. In diabetic patients, severe hypoglycemia should always be considered. Rapid assessment with a bedside glucose monitor or empirical I.V. dextrose therapy may prevent the neurologic consequences of prolonged hypoglycemia. Anaphylaxis can be addressed with I.V. or subcutaneous epinephrine and antihistamine therapy and may help prevent life-threatening airway and circulatory compromise. In patients with significant renal dysfunction, life-threatening electrolyte abnormalities should always be considered. Finally, whenever standard resuscitative measures are unsuccessful in reversing shock, severe endocrine abnormalities (e.g., addisonian crisis and myxedema), though often difficult to diagnose, should be considered.

Specific Treatment Based on Category of Shock

If shock persists after immediately life-threatening conditions have been treated, the next step is to categorize the shock state on the basis of the underlying physiologic abnormality and treat the patient accordingly.

As a rule, all that is needed to make this preliminary classification is the history, the physical examination, a chest x-ray, an ECG, and, in some cases, a complete blood count, electrolyte concentrations, a glucose level, and arterial blood gas analysis. The categorization is seldom neat: more than one cause of cardiovascular inadequacy is usually present, as when a patient with a myocardial infarction requires mechanical ventilation or when a patient with a ruptured abdominal aortic aneurysm has a distended and tight abdomen. Nevertheless, classification is useful, in that it focuses the physician's attention on the primary problem, which should be treated first.

Management of Hypovolemic or Inflammatory Shock

CONTROL OF BLEEDING AND ONGOING INFLAMMATION

At first glance, it might seem obvious that treatment of the underlying causes of shock should have the highest priority. This is indeed the case with hypovolemic shock caused by hemorrhage; however, with inflammatory shock, a temporary delay in source control (e.g., abscess drainage or tissue debridement) may be warranted until the patient has been adequately resuscitated. This is a particularly important consideration when the process of source control is likely to result in further cardiovascular compromise. An obvious example is the patient who requires a laparotomy for a hollow viscus perforation. In this situation, briefly delaying administration of a vasodilating inhaled anesthetic while intra-

vascular volume is restored may prevent cardiovascular collapse during anesthetic induction.

At the risk of belaboring the obvious again, it must be emphasized that early resuscitation should be the goal. Delaying recognition and treatment by as little as several hours may result in increased mortality.⁹ Once resuscitation has been initiated and the physiologic abnormalities addressed, source control becomes the priority. From a practical standpoint, these two processes are frequently performed in parallel—that is, resuscitation continues while the infectious or inflammatory source is being addressed.

VASCULAR ACCESS

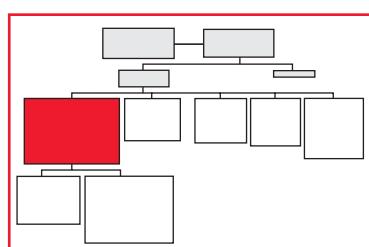

On the assumptions that an airway has been established, that the patient is being ventilated, and that bleeding is being controlled, the next step is to obtain vascular access (this is frequently done simultaneously). If possible, superficial veins in the upper extremities should be percutaneously cannulated with two large-bore catheters. If this is impossible, venous access can be achieved by means of cutdown on veins in the extremities or percutaneous puncture of central veins; access to the bone marrow can be obtained by means of percutaneous insertion of a thick needle through cortical bone.

Cutdowns in the upper extremity cause little morbidity. They sometimes take time to perform, however, and the veins may be thrombosed from earlier use. The cephalic vein at the shoulder is less likely to be thrombosed, but it lies below the deep fascia and is sometimes difficult to isolate. The external jugular vein is deep to the platysma and can be difficult to identify when the lighting is poor. The saphenous vein at the ankle is readily exposed by cutdown and is large and easy to cannulate; however, it cannot be used if there is extensive trauma to the extremity, and if the cannula is left in place for more than 24 hours, superficial thrombophlebitis is likely to develop. The saphenous vein in the groin is large and easy to cannulate, but the end of the catheter will lie in the external iliac vein. Iliofemoral deep vein thrombosis (DVT) or even septic DVT is common; either can be a potentially fatal complication in a patient who becomes critically ill.

Percutaneous cannulation of the internal jugular vein or the subclavian vein not only affords access for infusion of fluids and drugs but also provides a port for central venous monitoring. Obtaining central venous access with percutaneous techniques, however, can be difficult and risky, particularly in a hypovolemic patient with collapsed central veins. The puncture can cause a pneumothorax. An artery adjacent to the vein may be punctured. At times, an arterial puncture may not be recognized, and the artery may even be dilated and cannulated. Once the vessel is cannulated, the problem may initially go undetected. Furthermore, blood drawn from a cannulated artery in a shock patient may be flowing in a nonpulsatile fashion, giving the impression that the targeted vein has been successfully accessed. In severe shock, the arterial blood may be blue, thereby supporting this mistaken impression. A damaged artery can also bleed into the pleural cavity, an untamponaded space. If this occurs in a patient who is already compromised, the patient will probably die.

Percutaneous puncture of the common femoral vein is among the easiest of all venous access techniques and avoids the problems of pneumothorax and bleeding into a pleural cavity. If this vein is cannulated, the access site should be changed to a vein in the upper body as soon as the patient is stable. The incidence of DVT and septic complications is relatively high with femoral venous cannulation, and long-term use of this site should be avoided if possible.¹⁰⁻¹²

If the adjacent femoral artery is unintentionally cannulated, it is sometimes best to use this vessel for vascular access. Intra-arterial

infusion of fluids is as effective as I.V. infusion. Care must be taken, however, to ensure that no air enters the system. The catheter should be removed as soon as other access is gained.

In pediatric patients, intraosseous access (e.g., via the proximal tibia, the distal femur, the iliac crest, or the sternum) is a useful means of gaining vascular access under difficult conditions. On rare occasions, this approach may be used in adults when other sites are unavailable or in special situations.¹³⁻¹⁶

The first attempts at obtaining vascular access should be made in the upper extremities with a percutaneous technique. If these attempts fail, one should fall back on a technique with which one is comfortable. There is no single best approach.

INITIAL FLUID RESUSCITATION

Once vascular access is obtained, a 20 ml/kg bolus of normal saline should be infused. If the patient is in profound shock, the fluid bolus should be given within 5 minutes if possible, and the use of a rapid infusion device should be considered; if the situation is less urgent, the bolus may be given over a period of 15 minutes or so. If the shock does not resolve, two more boluses should be given.

We consider normal saline (NS) the fluid of choice for initial resuscitation in most shock patients. The sodium concentration of NS (154 mmol/L) is close to that of normal serum. Its chloride concentration (also 154 mmol/L) can induce hyperchloremic metabolic acidemia; however, this state is generally well tolerated and usually clears as renal perfusion is restored and bicarbonate is regenerated.

If the patient already has significant lactic acidosis or the chloride concentration exceeds 115 mmol/L, lactated or acetated Ringer solution is used. Some favor initial use of lactated Ringer solution to reduce the chance that a hyperchloremic acidosis will develop in the first place. Both lactate and acetate accept a proton to form an organic acid, which is converted in the liver to CO₂ and water. The CO₂ is excreted by the lungs; the water, by the kidneys. As long as hepatic function and pulmonary function are adequate, which is usually the case, the result of this process is buffering of the acidemia that can accompany the shock state. Both lactated and acetated versions of Ringer solution, however, are hyponatremic and hypoosmotic; the latter is a potential problem in patients at risk for increased intracranial pressure.

Solutions containing glucose should not be used in the initial stages of resuscitation unless the patient is known to be hypoglycemic. Most patients in shock, in fact, are hyperglycemic as a result of high plasma levels of epinephrine and cortisol. Excessively high plasma glucose concentrations can induce an inappropriate diuresis.

Colloid and Hypertonic Solutions

Although crystalloid solutions have been the primary resuscitation fluid in the United States for many years, the use of colloid solutions in the resuscitation of critically ill patients is still the subject of debate. Factors such as the type of colloid used (albumin or hydroxyethyl starch), the timing of administration (early versus delayed), and the environment of care (prehospital, battlefield, or hospital) continue to be explored in laboratory, bedside, and field settings. Colloid solutions have the advantage of producing a much greater intravascular volume expansion for a given volume of fluid infused than crystalloid solutions do, and this advantage may be significant in prehospital, mass-casualty, or battlefield environments. In addition, colloid solutions theoretically increase colloid osmotic pressure (in the absence of increased permeability) and may decrease interstitial and cellular edema.^{17,18}

The colloid solution that has probably been the object of the greatest amount of interest is albumin. Until comparatively recently, no large, randomized trials of albumin had been done, and thus, there was an ongoing controversy as to whether albumin should be given to critically ill patients.^{19,20} In 2004, however, the Saline versus Albumin Fluid Evaluation (SAFE) study, which randomly assigned nearly 7,000 critically ill patients to receive either 4% albumin or NS, found outcomes to be identical in the two groups.²¹ In the light of these data, coupled with the relatively low availability and high cost of albumin, the use of albumin solution as a resuscitation fluid is probably not warranted unless logistical or environmental constraints limit the use of crystalloid solutions.

Hydroxyethyl starch solutions share the same theoretical advantages as albumin, but they are less expensive and are therefore a more attractive alternative. They may have additional properties affecting inflammation and coagulation, the clinical significance of which is unknown.²²⁻²⁵ To date, no large, randomized trials have shown these solutions to have a significant beneficial effect on outcome when used in place of isotonic crystalloid. A 2004 meta-analysis (which, admittedly, included a relatively small number of patients) was unable to demonstrate any significant effect.²⁶ Accordingly, the role of hydroxyethyl starch solutions in the resuscitation of critically ill patients remains to be determined.

Hypertonic saline solutions containing up to 7.5% sodium chloride (compared with 0.9% for normal saline) show promise for resuscitating patients in situations where large-volume resuscitation with isotonic solutions is impossible (e.g., combat, events involving mass casualties, and prehospital trauma care).²⁷ Hypertonic solutions provide far more blood volume expansion than isotonic solutions and result in less cellular edema. In addition, they may have favorable effects on the inflammatory response to injury.²⁸⁻³³ These solutions are approved for use and commercially available in Brazil (where the idea originated), Chile, Argentina, and Europe; they are not currently approved for use in the United States or Canada. Both hypertonic saline and hydroxyethyl starch have been recommended as first-line solutions for the resuscitation of U.S. combat casualties in the field.³⁴

TRANSFUSION

Transfusion of red blood cells (RBCs) restores intravascular volume and increases hemoglobin concentration, both of which improve oxygen delivery. Accordingly, it is ideal for resuscitation of a patient in shock. Unfortunately, allogeneic blood falls far short of being the ideal resuscitation fluid. Factors such as the age of the blood, the presence of allogeneic leukocytes, and the presence of soluble factors have been implicated in the observed association between RBC transfusions and poor patient outcomes.³⁵⁻⁴⁰ The data suggest that limiting RBC transfusions in critically ill patients may lead to better patient outcomes. When this more restrictive approach to transfusion was prospectively evaluated against a more liberal transfusion strategy in critically ill patients, it resulted in equivalent or better patient outcomes.⁴¹

These findings provide useful guidance as to what an appropriate transfusion strategy might be for the average critically ill patient who is euvolemic, but they may not be applicable to the patient who is in shock. With shock patients, the first priority is restoration of intravascular volume. Volume replenishment should be initiated with isotonic crystalloid; when clinical or laboratory findings suggest significant anemia (hemoglobin concentration < 10.0 g/dL), transfusion of packed RBCs should be considered. In general, packed RBCs, reconstituted with normal saline, should be given to ensure that the patient's hemoglobin concentration is

at least 7 g/dl, if not substantially higher. Certain patients require higher concentrations.

The following guidelines provide a reasonable approach to patients in all classes of shock, with the key variables being (1) the possibility of a continued decrease in the hemoglobin concentration (from bleeding or hemolysis) and (2) the estimated or measured values for the relation between oxygen supply and oxygen demand (determined via mixed venous or central venous oximetry).

1. A hemoglobin concentration of 7 g/dl is adequate in a young patient whose coronary arteries are in good shape and whose bleeding is known to be under control.
2. A hemoglobin concentration of 8 g/dl is adequate in a young patient who may be at slight risk for further bleeding.
3. A hemoglobin concentration of 9 g/dl is required if the risk of bleeding is substantial.
4. A hemoglobin concentration of 10 g/dl should be the goal if overt ischemia is present or there is a significant risk of occult ischemic disease (e.g., in a patient with peripheral vascular disease), even in the absence of ongoing myocardial ischemia.

In an emergency, O-negative RBCs should be given. There is no need for typing or crossmatching, and in the case of the confusion that can attend the treatment of multiple casualties, there is no danger that a patient will receive the wrong type of blood. However, with multiple casualties, there is a danger that the blood bank will be rapidly depleted of O-negative cells. If the patient can wait a few more minutes and if there is minimal risk of giving the wrong type of blood, type-specific blood should be given so as to conserve the supply of O-negative blood.

Although whole blood can be administered more quickly than packed RBCs can, its use in the civilian setting has almost become a matter of purely historical interest. Use of packed RBCs has the advantage of conserving the blood bank's supply of fresh frozen plasma and platelets. Under austere conditions, however, whole-blood transfusions may be more practical.^{42,43}

From a conceptual perspective, the use of blood substitutes for resuscitation is an attractive option. Multiple preparations of hemoglobin-based oxygen carriers (HBOCs) have been developed, several of which have been tested clinically. Although the results obtained with an early HBOC were disappointing, those obtained with newer, polymerized HBOCs have been encouraging. In the light of the potential risks and the limited availability of allogeneic blood, HBOCs appear to be a promising alternative to RBC transfusion that will play a growing role in the future.^{44,45}

MANAGEMENT OF PAIN, HYPOTHERMIA, ACIDEMIA, AND COAGULOPATHY

Once blood volume has been at least partially replenished, pain should be treated with small I.V. doses of narcotics. On the one hand, pain relief can reduce the stress response associated with shock and perhaps mitigate the severity of its late sequelae.⁴⁶ On the other, narcotics can also decrease tone in the venules and small veins, thereby exacerbating the shock state. Accordingly, one should titrate the doses and be ready to reverse the effect with a narcotic antagonist if necessary. A drop in blood pressure after administration of a narcotic suggests that the patient may still be hypovolemic, in which case more aggressive resuscitation may be indicated.

If hypothermia is present initially, it should be corrected; if not, it should be kept from developing. Hypothermia slows metabolic processes. In some situations (e.g., cold-water drowning), this effect may be beneficial, but in most cases, it is better for the

patient to have a normal body temperature, normal myocardial contractility, and intact coagulatory and immune function.

The patient must be unclothed during the initial evaluation but should be covered afterward, with particular attention paid to covering the head. The room should be kept warm, and any fluids administered should be prewarmed either in an oven or with heating devices.

If the arterial pH is low, it should be raised to 7.20 by means of either modest degrees of hyperventilation or administration of bicarbonate. (Although agents other than bicarbonate can be given to correct a metabolic acidemia, it is not clear that they have any more to offer than bicarbonate does.) No efforts should be made to raise the pH above 7.20. Moderate degrees of acidemia are well tolerated, and excessive administration of bicarbonate may worsen intracellular acidosis [see Initial Fluid Resuscitation, above].⁴⁷ Instead, efforts should continue to be directed toward managing the underlying cause of shock.

Coagulopathy should be treated with fresh frozen plasma and platelets [see 1:4 Bleeding and Transfusion]. The decision whether to use these components should be based on observation of bleeding and clotting in the patient, not on laboratory measurements of coagulation or platelet counts, which can be normal even during exsanguination.

MODULATION OF INFLAMMATORY RESPONSE

In the case of inflammatory shock, there has long been interest in therapeutic approaches aimed at blocking or counteracting inflammatory and coagulatory mediators released from the inflamed tissues. To date, almost all of these approaches have failed to show any benefit, and some have proved dangerous. A study published in 2001 yielded apparently more promising results, concluding that infusion of activated protein C seemed to improve survival in some patients with severe sepsis. Since that study was published, several other trials have been carried out in an attempt to define the role of activated protein C in the treatment of severe sepsis with more precision.^{48–50} Taken as a whole, the current data suggest that in view of the side-effect profile and potential complications of activated protein C, its use should be considered only in patients who have severe sepsis and are at high risk for death.⁵¹ We do not currently use this agent in the treatment of surgical patients with severe sepsis.

The use of corticosteroids in the treatment of sepsis has been studied extensively over the past several decades. Older regimens frequently involved administering these agents in high doses, and the bulk of the evidence suggested that such regimens were not beneficial and might actually have had an adverse effect.⁵² Newer regimens have been developed that employ lower steroid doses, and the results have been encouraging. A multicenter study published in 2002 found that administration of modest doses of hydrocortisone and fludrocortisone to patients in septic shock with impaired adrenal function led to improvements in mortality.⁵³ Although these data are compelling, it remains the case that corticosteroids have well-established potential side effects in this setting. Further study will be required before the role of steroids in the management of critically ill patients can be fully defined.

ASSESSMENT OF AND GOALS FOR CARDIOVASCULAR VARIABLES

In most cases of shock, regardless of category, the initial approach just described is all that is needed. Some patients, however, will not respond. These patients should be transferred to a setting in which cardiovascular pressures can be transduced and monitored. A systemic artery, usually a radial artery, should be cannulated, and central venous access should be obtained. An attempt should be made to assess the cardiac output.

Mean Arterial Pressure

Arterial cannulation provides blood for analysis of blood gases and allows reliable measurement of the MAP [*see Figure 1*], which is more useful in managing shock than the peak systolic brachial pressure is. The MAP is the pressure that drives the perfusion of the noncardiac tissues. It is close to the mean diastolic aortic root pressure and is thus a good approximation for the pressure that perfuses the myocardium. Finally, it is the pressure that provides the energy required to drive the blood back to the right atrium and ventricle.

The mean pressure in the transducer used to monitor the arterial pressure is the same as the mean pressure in the monitored artery. Furthermore, the mean pressure in the monitored artery is the same as the mean pressure in the aortic root, unless there is arterial obstruction between the aortic root and the monitored artery or spasm of the proximal conducting arteries (as may be the case in severe shock). Thus, knowing the MAP is as close as one can get to knowing the pressure that is providing perfusion for the body. Accordingly, one should focus on the MAP, once it can be accurately determined by intra-arterial monitoring.

In treating a patient who is unresponsive to initial care, the goal is to generate an adequate MAP and an adequate cardiac output without producing an undue degree of peripheral edema (i.e., without driving the CVP to unnecessarily high levels). However, it can be difficult to determine what constitutes an adequate MAP. To begin with, the MAP must be high enough to perfuse the CNS. The brain and the spinal cord have high metabolic rates, and their vasculature is chronically dilated. (An injured CNS is capable of autoregulation, but only over a relatively narrow range of blood pressure.) A fall in the perfusion pressure can lead to a profound loss of flow.

In addition, the MAP must be high enough to perfuse organs supplied by arteries obstructed by preexisting disease. The microvasculature of the gut in a patient with an occluded superior mesenteric artery is maximally dilated, and thus, a fall in proximal pressure can shut off critical perfusion. The same is true in the case of a kidney with an obstructed renal artery, an extremity with obstructed proximal arteries, or a heart with obstructed coronary arteries. However, if these non-CNS organs have an unobstructed arterial supply, they are protected from hypotension, unless the hypotension is profound. All of the organs in the body, except for the brain and the spinal cord, have some degree of chronic resting arteriolar constriction. A fall in the perfusion pressure, in conjunction with the expected production of local ischemia and accumulation of waste products of metabolism, causes reflex dilation of the arterioles in the organ at risk. Unless the hypotension is extreme, this dilation permits compensatory flow. As noted, the CNS does not enjoy this luxury, but then, the cardiovascular system is designed to maintain a normal pressure for the brain: it is no accident that the primary baroreceptors are placed at the carotid bifurcations.

If a patient is alert and able to move all extremities, and if there is no reason to suspect that any of the major arteries are obstructed by preexisting disease, any MAP that is high enough to maintain full neurologic function is adequate. Determining the adequacy of the MAP in obtunded, sedated, or anesthetized patients, however, can be a challenge.

In certain cases, one might know that at some previous point, perhaps during the same hospitalization, the patient was alert and neurologically intact with a given MAP (e.g., 50 mm Hg). If so, it can be assumed that the same pressure would still be adequate now. If, however, one does not have this information, one must err on the

side of giving more fluids to keep the blood pressure high. In the case of an obtunded patient with no indications of possible carotid disease or obstructed blood supply to the spinal cord, an arbitrary value can be assigned. A reasonable MAP might be 60 mm Hg for a younger patient (or somewhat higher for an older patient).

If it is possible that the arterial supply to an actively metabolizing organ is obstructed, some assessment of the organ must be made. For the heart, the absence or resolution of chest pain with resuscitation and the absence of ischemic changes on the ECG suggest that pressure and perfusion are adequate. For the gut, the absence of pain and the presence of bowel activity are reassuring. For the kidneys, adequate urine output and excretion of creatinine are generally indicative of acceptable pressure and perfusion. For the extremities, physical examination of the skin usually suffices.

Mean Central Venous Pressure

As a rule, the tip of the catheter used to measure the CVP ends up in either the superior vena cava or the right atrium. The pressures at these sites vary both with the cardiac cycle and with ventilation. These variations can be substantial, depending on atrial activity and on the pressures produced by the labored breathing of the critically ill patient or by the effects of mechanical ventilation.

With respect to prevention of unnecessary edema, the mean CVP is the most pertinent variable. In addition, we consider the mean CVP the most useful measurement for assessing the right ventricular end-diastolic volume (RVEDV) (i.e., for making an initial assessment of the adequacy of volume restoration). The mean CVP is close to the ventricular end-diastolic pressure averaged over the ventilatory cycle. It is also the simplest central pressure to obtain. Typically, the number is read directly off the digital readout on the monitor; if the transducer is calibrated and zeroed properly, interobserver variation should be nonexistent.

Care must be exercised, however, in extrapolating from the mean CVP (or the ventricular end-diastolic pressure) to the ventricular end-diastolic volume. All measurements of central or vascular pressures, whether mean or end-diastolic, are measured with respect to the atmosphere (i.e., to the outside of the body). It would be useful to know the transmural pressure—the pressure inside the ventricle minus the pressure immediately outside—because the end-diastolic transmural pressure correlates best with the end-diastolic volume. Unfortunately, it is not possible to determine the transmural pressure accurately in this setting, because the extramural pressure is not known.

Some assumptions can, however, be made about the extramural pressure. In a normal, supine, spontaneously breathing person, the mean pressure immediately outside the heart, measured with respect to the atmosphere, is usually on the order of -3 mm Hg. The intracavitory right ventricular end-diastolic pressure (RVEDP), measured with respect to the atmosphere, is approximately 5 mm Hg. Thus, the end-diastolic transmural pressure will be about 8 mm Hg. This level of transmural pressure is usually enough to generate an adequate RVEDV. In a normal patient who is undergoing mechanical ventilation, the mean pressure outside the heart is on the order of 4 mm Hg; an RVEDP of 12 mm Hg produces a transmural pressure of 8 mm Hg and usually suffices to produce an adequate RVEDV.

These values work for patients with essentially normal lungs. Unfortunately, most patients on mechanical ventilators do not have normal lungs. In such patients, the lungs can form a stiff compartment around the heart that does not give. The problem is

compounded when the diaphragm is elevated, as it is in many surgical patients. The heart can be trapped between the inflated stiff lungs and the elevated stiff diaphragm, and the extramural pressures can be very high.

Furthermore, the stiffness of the ventricular wall during diastole must be taken into account. A ventricle with stiff musculature (or low compliance) during diastole needs a high intracavitory pressure to achieve an adequate end-diastolic volume. The conditions that can increase diastolic stiffness are manifold and include myocardial ischemia, tachycardia in a patient with preexisting coronary artery disease, edema, fibrosis, and hypertrophy.

Thus, to extrapolate from the intracavitory mean CVP to the RVEDV (and to an initial assessment of the adequacy of volume resuscitation), one must consider not only the measurement recorded but also the patient's clinical condition. In some patients, the intracavitory CVP may have to be as high as 20 mm Hg to achieve adequate filling of the ventricle.

Cardiac Output

In two clinical scenarios—warm inflammatory shock and neurogenic shock—the adequacy of cardiac output can be assessed by means of physical examination, as long as the MAP is adequate. Physical examination will determine whether the cutaneous arterioles are dilated. If they are, there will be a short circuit in the vasculature. Hindrance to ventricular contraction will be minimal; cardiac output will be robust. In other scenarios, however, one cannot be sure about the cardiac output without more sophisticated monitoring.

INDICATIONS FOR ADDITIONAL MEASURES

Fluids

If the patient is still in shock—that is, if it appears that the MAP, cardiac output, or both may be inadequate for tissue perfusion—additional fluids should be infused until, in one's best judgment, the RVEDV is probably normal.

Inotropes

If the patient is still in shock and further fluid administration is unlikely to be beneficial, an inotropic should be given. Dobutamine is a good first choice in this situation. The dosage should be $5 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ initially, then be increased as needed, to an upper limit of $15 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. If necessary, milrinone may be added, administered in a 50 μg loading dose followed by infusion of 0.375 to 0.75 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. Neither agent has any vasoconstrictor effects, and both are safe, at least for a short time. The goal is to achieve an adequate MAP without producing signs of peripheral constriction (e.g., cutaneous hypoperfusion) or causing tachycardia (defined as a heart rate exceeding 110 beats/min in a young patient, exceeding

90 beats/min in an older patient, or exceeding 75 beats/min in a patient with coronary artery disease).

Swan-Ganz Catheter

In this setting, inotropes can usually be used safely for 30 minutes or so. If it appears that inotropes may be needed for a longer period, that more fluids will have to be given despite a high CVP, that the myocardium is at risk (as suggested by chest pain or signs of ischemia on ECG), that a vasoconstrictor may be needed, or that the patient requires an excessively high F_1O_2 , then a decision must be made about what the goals of resuscitation will be from this point forward. There is no general agreement on precisely how this decision should be made, but we believe that the decision-making process frequently benefits from considering measurements obtained by means of a Swan-Ganz catheter.

Measurements and derived values obtained via Swan-Ganz catheter The Swan-Ganz catheter can provide an enormous amount of information about the cardiovascular system. Insertion of the catheter is described elsewhere [see 8:26 *Cardiopulmonary Monitoring*], as are details and caveats about the measurements that can be made with it.

The $S_{mv}O_2$ can be directly measured by an oximeter on the end of the catheter. An excessively low value (< 60%) is cause for concern. It can arise from an inadequate cardiac output, an excessively low hemoglobin concentration, marked desaturation of systemic arterial blood, or, in rare cases, from excessive and unnecessary consumption of oxygen (as in a patient who is shivering).

The cardiac output can be measured directly with thermodilution technology,⁵⁴ and the stroke volume can be calculated by dividing the cardiac output by the heart rate.

The intracavitory mean CVP can be measured through a port in the superior vena cava or the right atrium. It can be taken as a very close approximation of the mean pressure in the right ventricle and of RVEDP. The RVEDV can be measured directly with thermodilution technology.⁵⁵ The end-systolic pressure in the root of the pulmonary artery and the right ventricular end-systolic pressure (RVESP) can be approximated as 90% of the directly measured peak systolic pressure in the pulmonary artery, measured through the port on the end of the catheter (provided that the catheter monitoring system is properly set up [see 8:26 *Cardiopulmonary Monitoring*]). The mean pulmonary arterial pressure (MPAP) can be directly and accurately measured through the same port.

The LVEDP can be approximated from the pulmonary arterial wedge pressure (PAWP) [see 8:26 *Cardiopulmonary Monitoring*]. To smooth out variations introduced by both ventilation and the cardiac cycle, we use the mean value for the pressure, which is typically 1 or 2 mm Hg lower than the end-diastolic pressures aver-

Table 3 Influence of Body Size on Selected Cardiovascular Parameters*

Weight (kg)	End-Diastolic Volume (ml)	Stroke Volume (ml)	End-Systolic Volume (ml)	Contractility (mm Hg/ml)	Afterload (mm Hg/ml)
50	125	83	42	2.4	1.2
60	150	100	50	2.0	1.0
70	175	117	58	1.7	0.85
80	200	133	67	1.5	0.75

*On the assumptions that (1) ventricular end-diastolic volume is 2.5 ml/kg, (2) stroke volume is 1.67 ml/kg, and (3) ventricular end-systolic pressure is 100 mm Hg.

aged over several ventilatory cycles. The LVEDV can be estimated on the basis of the PAWP, in conjunction with all the available clinical information (including physical examination, chest x-ray, and ventilator settings). It must be kept in mind that the PAWP and the LVEDP are both intracavitory pressures. For extrapolation to the LVEDV, the pressure applied to the outside of the heart and the stiffness of the ventricular wall during diastole must be taken into account.

The information from the right ventricle can be used to estimate the pressure outside the left ventricle. If a reasonably low CVP generates a reasonably large directly measured RVEDV, it follows that the extracardiac pressures are not excessively high. The information from the right ventricle can also be (cautiously) used to estimate the stiffness of the left ventricular wall during diastole (i.e., ventricular diastolic compliance). If a low CVP generates a generous RVEDV, it follows that the right ventricular diastolic compliance is large. Often, one can tentatively assume that the values measured in the right ventricle reflect the status of the left ventricle as well. This is not always the case, however: many patients with ischemic heart disease have a stiff diastolic left ventricle and a normal right ventricle.

The estimates of end-diastolic volume can sometimes be confirmed by increasing the filling pressures of the heart with a fluid bolus and assessing the cardiovascular response. The fluid should be given rapidly, in an amount sufficient to effect changes in the filling pressures. Increases in stroke volume, especially if associated with increases in pulmonary and systemic arterial pressures, suggest that the initial end-diastolic volumes were small.

If increases in filling pressures have minimal effects on the stroke volume and pressures, there are two possibilities. The first is that the end-diastolic volumes were already generous. If so, a diuretic can be given; if stroke volumes and blood pressures do not decrease, further diuresis is indicated. The second possibility is that the volumes were small but the diastolic compliances were poor or the extramural pressures large. In either case, caution should be exercised in giving additional fluid (though there may be little choice). In the case of poor diastolic compliance, it may be possible to find and treat a potentially correctable cause of the stiffness (e.g., myocardial ischemia). In the case of high extramural pressures, it may be possible to find and treat the underlying causative condition. (Admittedly, neither problem is easy to deal with, but the effort should be made nonetheless.)

It cannot be assumed that the LVEDV is the same as the directly measured RVEDV. In fact, the two volumes are frequently different in critically ill patients. Studies comparing RVEDVs (measured with a fast thermistor) with LVEDVs (measured with transesophageal echocardiography) have shown that right ventricular values are often larger than left ventricular values in patients in inflammatory shock, sometimes by a factor of 3.⁵⁶ In patients with left-side congestive heart failure, however, left ventricular values can be substantially larger than right ventricular values. Thus, the volume of one chamber is not necessarily an accurate indicator of the volume of the other chamber, though the clinical scenario can provide some guidance in this regard.

The aortic root end-systolic pressure (or the left ventricular end-systolic pressure [LVESP]) is the most important pressure to consider in estimating left ventricular oxygen requirements and in assessing the left ventricular afterload. The LVESP can be roughly approximated as 90% of the estimated peak pressure in the aortic root.⁵⁷

Estimating the peak aortic root pressure can be a difficult process. One approach is to measure the peak systolic pressures

in the radial artery, then cautiously extrapolate back to the corresponding pressures in the root of the aorta. To this end, the equipment used to measure the radial artery pressure must be satisfactorily matched to the physical characteristics of the artery [see 8:26 *Cardiopulmonary Monitoring*]. Once the peak systolic pressure in the radial artery is known, several clinical scenarios may be considered.

If the arteries supplying the upper extremity are stiff or calcified (as they will be in many older patients or in diabetics), the peak systolic pressure in the radial artery will be as much as 80 mm Hg higher than that in the root of the aorta. If the arterioles in the hand are constricted (as they may be in hypovolemic, compressive, obstructive, or cardiogenic shock), the peak systolic pressure in the radial artery may be 40 mm Hg higher than that in the aortic root. If the arteries are in spasm, the difference may be greater; in severe spasm, all of the pressures in the radial artery are lower than the central pressures. If the microvasculature in the hand is dilated (as in warm inflammatory shock), the proximal and distal systolic pressures will be nearly the same.

The peak aortic root pressure can also be estimated by extrapolating from the MAP, which will always be less than the systolic pressure.⁵⁸ In young patients with compliant arteries and no abnormal arteriolar constriction, the peak systolic pressure in the aortic root is usually about 20 mm Hg higher than the MAP. In patients with stiff or calcified arteries, the central peak systolic pressure can be much higher than the MAP. In patients who are in warm inflammatory shock or neurogenic shock, the central systolic pressure may be only 10 mm Hg higher than the MAP.

Thus, although it is necessary to estimate the LVESP so that ventricular oxygen requirements and left ventricular afterload can be assessed, one must be wary in doing so, just as one must be careful in treating a patient on the basis of the estimated LVEDV.

The mean aortic root pressure is usually the same as the mean pressure in the radial artery. It can be misleading if the patient has an obstruction in a proximal artery. To rule out the possibility of a subclavian stenosis, the pressures in the two arms should be measured at the beginning of hospitalization. In severe shock, the arteries may go into spasm that is severe enough to narrow the lumina; if this occurs, the mean pressures in the extremities will be lower than those in the aortic root. Otherwise, however, the MAP in the extremities, as a surrogate for the mean aortic root pressure, is one of the most reliable measurements made in clinical medicine.

Right ventricular contractility, in the absence of congestive failure, can be approximated as the RVESP divided by the right ventricular end-systolic volume (RVESV), which is obtained by subtracting the stroke volume from the RVEDV. A normal value for a 60 kg person is 0.4 mm Hg/ml [see Table 3]. Contractility can rise to double that value with full adrenergic stimulation, and it can probably fall to levels as low as 50% of normal.

The right ventricular afterload can be approximated as the RVESP divided by the stroke volume. Because only a few conditions need be met to obtain these two measurements, the approximation is quite accurate. A normal value is 0.2 mm Hg/ml [see Table 3]. With severe respiratory failure, the right ventricular afterload can increase by a factor of 5.

Left ventricular contractility, in the absence of congestive failure, can be approximated as the LVESP divided by the left ventricular end-systolic volume (LVESV). A normal value for a 60 kg person is 2.0 mm Hg/ml. This value is approximately five times

greater than the corresponding value for the right ventricle, which is to be expected, given that the wall of the left ventricle is approximately five times thicker [see Table 3]. Left ventricular contractility can double with adrenergic stimulation and can fall to levels as low as 50% of normal in severe congestive failure.

Frequently, the clinical scenario gives the physician some idea of the state of left ventricular contractility. In most cases of mild or moderate shock (except cardiogenic shock), it can be assumed that contractility is normal or slightly above normal. In cases of severe shock, however, this assumption cannot be made. Often, contractility is reduced as a consequence of poor perfusion of the coronary vasculature or downregulation of the beta receptors in the myocardium.

The calculated value for left ventricular contractility must always be considered in terms of the clinical context. It is not as reliable as the calculated value for right ventricular contractility, because the approximations for the LVESP and the LVESV are not highly accurate. Potential inaccuracies notwithstanding, the calculated left ventricular contractility can be useful for following upward or downward trends.

The left ventricular afterload can be approximated by dividing the LVESP by the stroke volume. A normal value is 1.0 mm Hg/ml [see Table 3]. With normal physiologic adjustments in intense isometric exercise, the left ventricular afterload can temporarily increase by a factor of 4. It can also rise by a similar factor in patients who have hypertensive disease or who have received excessive doses of vasoconstrictors. Under less extreme circumstances (e.g., aerobic exercise), it increases by no more than a factor of 2.

The power available for perfusing the lungs and filling the left atrium and ventricle during diastole is the MPAP multiplied by the product of the heart rate and the stroke volume (i.e., cardiac output). The power available for perfusing the systemic tissues, including the heart (on the assumption that the MAP is approximately equal to the mean diastolic pressure in the aortic root), and for filling the right atrium and ventricle during diastole is the MAP multiplied by the product of the heart rate and the stroke volume (i.e., cardiac output).

DETERMINATION OF PRIORITIES FOR SUBSEQUENT RESUSCITATION

Increases in heart rate, ventricular end-diastolic volume, contractility, and afterload all increase ventricular oxygen requirements. They also increase the power production of the ventricle, as long as afterload is not allowed to exceed contractility. If afterload is allowed to exceed contractility, the power production falls off. That is, increased ventricular power production almost always means increased myocardial oxygen requirements. There is no thermodynamic free lunch.

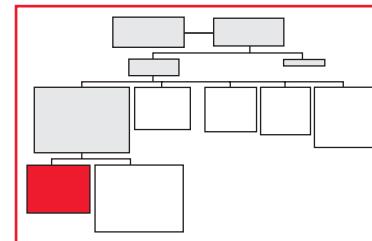

At this point, therefore, if the patient still has not responded to resuscitative measures, one must decide whether the priority for subsequent treatment should be (1) to increase ventricular power production, at the cost of possible edema and increased myocardial oxygen requirements, or (2) to minimize edema formation and myocardial oxygen requirements, at the cost of possible compromise of ventricular power production.

This fundamental decision must be made on clinical grounds. Occasionally, the decision is straightforward, as in a young trauma patient with extensive noncardiac injuries and a robust myocardium or in an older patient with an uncomplicated MI. More often, however, the choice is not so clearcut, because most initially nonresponding patients do not fall cleanly into either category. Nevertheless, it is necessary to choose one priority or the other.

Once a priority is decided on, the planned treatment should be adjusted to take into account the particular needs of individual patients.

Priority Is Ensuring

Resuscitation: Edema Not a Major Problem and Myocardium Not at Risk

Fluid infusion If priority is given to the periphery, fluid administration is probably necessary. The initial goal should be to achieve

a CVP in the low teens and a PAWP in the midteens (on the assumption that the patient is undergoing mechanical ventilation). As therapy progresses and more measurements are made, this goal may have to be modified. Ultimately, however, the goal is not to produce any specific filling pressures but, rather, to produce generous right and left ventricular end-diastolic volumes.

Administration of inotropes Inotropes (e.g., dobutamine and milrinone) can be safely used for a few days if necessary, provided that the patient is being monitored with a Swan-Ganz catheter. These agents increase myocardial oxygen requirements, but this is not a problem in a patient with a strong heart. The goal is to increase ventricular contractility to normal or slightly supranormal levels. Supranormal contractility leads to increased ventricular production of power, but the additional power is rarely needed. The dosages should be kept low enough that the heart rate does not exceed 110 beats/min in younger patients or 90 beats/min in older patients.

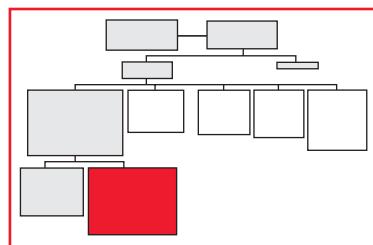

Administration of vasoconstrictors: last resort There are only two indications for the administration of vasoconstrictors to patients in whom the primary concern is perfusion of the periphery: (1) a MAP that may be inadequate for perfusion of the CNS and (2) hypotension in a patient who has a critical stenosis in the cerebral, coronary, hepatic, mesenteric, or renal arteries or in the arteries supplying the spinal cord or an ischemic limb. If a vasoconstrictor is indicated, low-dose I.V. vasopressin should be given first. If the heart rate is 89 beats/min or slower, dopamine, 2 to 20 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$, should be added. The heart rate should not be driven above 110 beats/min, even in young patients. If the initial heart rate is 90 beats/min or higher, norepinephrine, 2 to 12 $\mu\text{g}/\text{kg}$, may be given.

In either ventricle, the afterload should not be allowed to exceed the contractility, except in desperate circumstances. Matching the afterload to the contractility produces the maximum attainable work on the aortic root for a given end-diastolic volume. Allowing the afterload to exceed the contractility causes a rise in the blood pressure but a sharp fall in the stroke volume. The afterload should be increased to this degree only if there appears to be no other way to perfuse the CNS or organs with an obstructed arterial supply. If this is the case, the vasoconstrictor should be given and the effect on the perfusion of the organ in question evaluated. If the increased pressure does not produce the desired effect, the vasoconstrictor dosage should be reduced. Again, the goal is to achieve adequate perfusion, not to reach an arbitrary numerical pressure value. The great fear in using vasoconstrictors is that they can lead to ischemia and even necrosis of the skin, the kidneys, the gut, and

the liver. Accordingly, they should be used in this context only as a last resort.

Priority Is Minimizing Edema and Protecting Heart

Fluid administration versus diuresis Fluid management must be finely tuned in patients who have both inadequate peripheral perfusion and marginal myocardial reserve. On the one hand, too-large end-diastolic volumes unnecessarily increase myocardial oxygen requirements and produce edema; on the other, too-small end-diastolic volumes make it impossible for the ventricles to produce adequate pressure and stroke volumes. In some patients, diuresis (e.g., with furosemide, 10 to 40 mg I.V.) is indicated; in others, fluids should be given. Sometimes, it is necessary to rely on trial and error.

Adjustment of contractility If pressures and stroke volumes are still inadequate after end-diastolic volumes have apparently been optimized, measures for adjusting contractility may be considered.

If contractility seems to be reduced on either side, inotropes such as dobutamine or milrinone should be tried (cautiously, in view of their effect on myocardial oxygen requirements). If, by chance, contractility seems to be excessively high in either ventricle (or both), a beta blocker should be given. Esmolol is a good first choice because it has a short duration of action. A 500 µg/kg loading dose is given, followed by a $50 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ infusion, which is increased as necessary. Metoprolol, 5 to 15 mg every 6 hours, may be given later if it is clear that beta blockade was needed and still is. The goal is normal contractility on both the right side and the left.

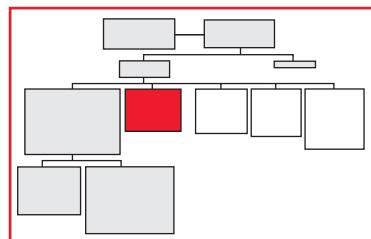

Adjustment of afterload with respect to contractility Left ventricular afterload should be adjusted so that it is 50% of left ventricular contractility. This ratio does not produce the maximum transfer of energy to the aortic root, but it is efficient, in that it produces the greatest amount of work per milliliter of oxygen required by the ventricular musculature.

If left ventricular afterload is less than or equal to 49% of left ventricular contractility, vasopressin, dopamine, and norepinephrine should be given as necessary. The heart rate should not be driven above 90 beats/min. As with any patient receiving vasoconstrictors, frequent reassessment is essential. The goal is to wean the patient from the drugs as soon as possible. If left ventricular afterload is equal to or greater than 51% of left ventricular contractility, the stiffness of the arteries should be decreased by performing further diuresis, by increasing the beta blocker dosage, by adding an angiotensin-converting enzyme (ACE) inhibitor (e.g., enalaprilat, 1.25 to 5 mg every 6 hours), or by adding nitroglycerin, 5 to 200 µg · kg⁻¹ · min⁻¹.

If the heart rate exceeds 90 beats/min after these adjustments, the beta-blocker dosage should be increased, and a calcium channel blocker (e.g., diltiazem, 5 to 15 mg/hr) should be added. Maintenance of a slow heart rate is the single most important factor for minimizing myocardial oxygen requirements, but as with the other interventions mentioned (see above), it usually can be achieved only at the cost of decreased pressures and stroke volumes.

Management of Compressive Shock

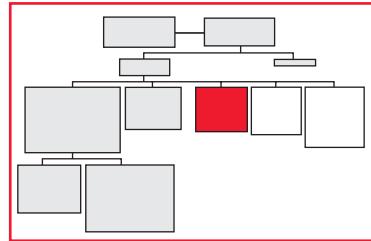

In many cases, extracardiac compressive and extracardiac obstructive shock, being conditions that can kill quickly, will already have been treated by this point in management.

It is wise, however, to keep these two causes of shock in mind as workup proceeds: they often develop secondarily. Examples of problems that can arise as treatment progresses are a tension pneumothorax that develops in a mechanically ventilated patient who is being worked up or treated for some nonpulmonary problem and an abdominal compartment syndrome that develops in a patient who is being resuscitated after a major injury or burn. In patients with more complicated problems (e.g., possible abdominal compartment syndrome), a Swan-Ganz catheter should be inserted. When dealing with the conflicting demands made on the cardiovascular system in compressive shock, one needs all the information one can get.

Management of Intravascular Obstructive Shock

The immediately life-threatening problems caused by intravascular obstruction should already have been treated by this point. The pharmacologically treatable problems (e.g., systemic hypertension) should be treated with diuresis, beta blockade, ACE inhibition, and nitroglycerin, as described (see above). If hypertension persists and inadequate ventricular production of power is a possibility, a Swan-Ganz catheter should be inserted. The goal is to adjust the afterload for each ventricle so that it is approximately 50% of the contractility.

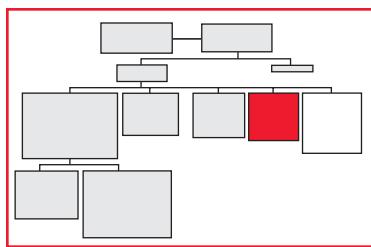

This goal can be particularly difficult to achieve for the right ventricle and the pulmonary vasculature. In patients with severe ARDS, there is some evidence to suggest that administration of prostacyclin or inhaled nitrous oxide may help reduce excessive right ventricular afterload,⁵⁹ though these interventions have not been particularly successful in our own experience. In any case, one should always attempt to address the underlying problem causing the ARDS. One can try to adjust the ventilator in an effort to relieve the potentially confounding problem of extravascular obstruction of the vasculature.

To achieve the desired goal in the systemic vasculature, it may be necessary to employ aortic balloon counterpulsation to deal with the reflected waves generated by the transmission of energy into these vessels. This measure can be extremely effective; however, it puts the perfusion of the limb with the cannulated artery at risk. Furthermore, it is only a short-term solution: the underlying problem will have to be dealt with eventually [see Management of Cardiogenic Shock, below].

Management of Neurogenic Shock

The initial management of neurogenic shock is much the same as that of hypovolemic and inflammatory shock, with two

exceptions: the use of the Trendelenburg position and the use of vasoconstrictors.

TRENDELENBURG POSITION

Patients in neurogenic shock often benefit from being placed in the Trendelenburg position. Autonomic denervation of the systemic venules and small veins leads to pooling of blood in these capacitance vessels. The Trendelenburg position causes this blood to be translocated to the vascular structures in the chest, including the heart, thereby helping to restore ventricular end-diastolic volumes.

Patients with other forms of shock, however, derive no benefit from the Trendelenburg position.⁶⁰ In hypovolemic shock, for example, the systemic venules and small veins are already depleted of blood as a consequence of both volume loss and adrenergic constriction of the vessel walls. In cardiogenic shock, the end-diastolic volumes are already too large, and there is no point in trying to increase them.

ADMINISTRATION OF VASOCONSTRICATORS

As noted (see above), vasoconstrictors should play almost no role in the initial management of hypovolemic or inflammatory shock. For these forms of shock, fluid replenishment is the crucial initial measure, and these agents can shut off residual flow to organs already rendered ischemic by the shock state. For the initial management of neurogenic shock, however, vasoconstrictors are often beneficial. In neurogenic shock, the denervated arterioles are fully dilated, leading to substantial (and sometimes profound) drops in the central arterial pressure. Cerebral or myocardial infarction may occur. Constriction of the arterioles increases the pressure and offers protection. In addition, constriction of the denervated systemic venules and small veins causes translocation of blood back into the chest and helps restore depleted ventricular end-diastolic volumes.

If the heart rate is slow, as it may be if denervation extends high enough to block the sympathetic nerves going to the heart, dopamine may be given. If the heart rate is rapid, norepinephrine or phenylephrine (in an initial dosage of 100 to 180 µg/min, which is then decreased to 40 to 60 µg/min) may be used.

The danger in giving a vasoconstrictor to a patient in neurogenic shock is that the underlying condition that caused the shock state may also have caused occult bleeding. Thus, the vasoconstrictor may maintain the blood pressure, reassuring the physician while the patient bleeds to death. Vasoconstrictors should be employed to treat neurogenic shock only after it has been established that the shock state has no hypovolemic component. If there is a possibility that hypovolemia or another abnormality (e.g., cardiac compression) may be contributing to the shock state, a Swan-Ganz catheter should be inserted. Treatment should then be governed by the information gathered by means of the catheter.

Management of Cardiogenic Shock

If the priority is the heart and there is comparatively little reason for concern about noncardiac tissues, treatment is usually straightforward, though the results may be less

than might be hoped for. The approach to treatment of a patient in cardiogenic shock should be patterned on the approach to treatment of a patient in hypovolemic or inflammatory shock in whom there are grounds for concern about myocardial viability or formation of edema (see above).

If the ventricular end-diastolic volumes seem excessively large, either diuresis should be initiated or morphine sulfate, 1 to 4 mg/hr, should be given, both to relieve pain and stress and to allow pooling of blood in the systemic capacitance vessels.

If the heart rate is excessively rapid, beta blockade is indicated, accompanied, if necessary, by calcium channel blockade. If myocardial ischemia is a possibility, the heart rate should not be allowed to exceed 75 beats/min. If myocardial damage is unlikely, as in a patient with uncomplicated valvular problems, the heart rate should not be allowed to reach or exceed 90 beats/min.

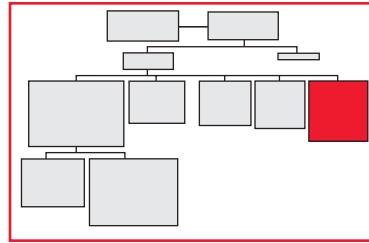

If the ventricular end-systolic pressure seems excessively high, more aggressive attempts should be made to reduce arterial stiffness with diuresis and beta blockade. An ACE inhibitor and nitroglycerin should be added as needed. As a rule, hydralazine should not be used. Because its principal effects are on the arterioles, not the arteries, it lowers the MAP without reducing the stiffness of the arteries (which is more important for decreasing the ventricular oxygen requirements). Hydralazine can also increase the heart rate and thereby markedly increase myocardial oxygen requirements, thus defeating the very purpose for which it was originally given. The use of clonidine should also be avoided if possible. It, too, works mainly on the arterioles instead of the arteries, and it can cause nightmares and disorientation, side effects that can be a major problem in critically ill patients.

The goal of treatment is to achieve an acceptable LVESP, an adequate MAP, adequate peripheral perfusion, and an acceptable heart rate, with no sign of myocardial ischemia. If this goal cannot be achieved, the next step is to insert a Swan-Ganz catheter and manage the patient so that the left ventricular afterload is 50% of the attainable contractility. Some degree of compromise may prove necessary, but every effort should be made to keep the afterload from exceeding this value. A high afterload will indeed produce a higher blood pressure, but only at the cost of increased myocardial oxygen requirements, which are rarely desirable in a patient with a compromised myocardium.

In some patients with acute myocardial ischemia and shock, all of the aforementioned treatments will fail. Such patients should undergo emergency coronary angiography, as should any patient with an acute coronary syndrome that becomes unstable or that is associated with ST-T segment elevation. The purpose of the angiography is to find a correctable lesion that can be treated with coronary angioplasty, stenting, or surgical revascularization. If necessary, an intra-aortic balloon pump may be placed before or at the time of angiography, angioplasty, or stenting. This pump can be left in place while the underlying problem awaits possible surgical correction (if indicated).

Treatment of primary right-side cardiogenic shock is the same as that of primary left-side cardiogenic shock, except that in right-side failure, it may be possible to adjust the ventilator so as to reduce the right ventricular afterload.

The hemoglobin concentration should probably be maintained at a generous level (i.e., 10 to 11 g/dl) in patients with cardiogenic shock, especially if the higher levels obliterate symptoms of ischemia.

Discussion

Contractility

Defining a numerical descriptor for contractility has been a challenge since the beginning of the 20th century. Of the many descriptors that have been suggested since Starling's Linnacre lecture, the one we and many others have come to prefer is ventricular end-systolic stiffness, or elastance (the engineering term for this characteristic). The elastance of a chamber with a given volume and pressure is the slope of the line that is drawn tangentially to the pressure-volume relation in the chamber around that point. In terms of the calculus, it is the first derivative with respect to volume of the pressure-volume relation. If the pressure-volume relation in the chamber is a straight line, the elastance is equivalent to the difference between the pressures at any two points on the line divided by the difference between the volumes associated with those two pressures.

Elastance (or stiffness) is the inverse of compliance (or distensibility or elasticity). The term compliance and its synonyms refer to the first derivative of the volume of a chamber with respect to pressure. Thus, all of these terms are dealing with the same fundamental physical property of elastic materials: the tendency of the pressure inside a chamber to be related to the volume within the chamber. Usually, the relation is a direct one. In the case of the heart, however, the relation is not linear and varies with time.^{61,62} The ventricle is much stiffer during systole than during diastole, and its stiffness varies during systole and diastole—hence the concept of systolic function as opposed to diastolic function.

Traditionally, in plotting the pressure-volume relation, physicists, engineers, and cardiovascular physiologists have preferred to assign volume to the x-axis as the independent variable and to assign pressure to the y-axis as the dependent variable. Pulmonary physiologists, however, have generally preferred to reverse this assignment. Neither way is right or wrong; the assignment of variables to axes is essentially arbitrary. Nevertheless, for the purposes of consistency and clarity, one must make a decision about how these concepts are to be represented. Accordingly, in the ensuing discussion, we will treat volume as the independent variable and, for the most part, will address stiffness or elastance rather than compliance, distensibility, or elasticity.

The pressure-volume relation in the left ventricle can be determined by simultaneous measurement of ventricular volume (with implanted microsonographic crystals, conductance catheter techniques, contrast ventriculography, or echocardiography) and intraventricular pressure. These measurements are then repeated while either the LVEDV or the afterload is altered, thereby yielding a "family" of pressure-volume relations. From this family, the elastances of the ventricle during an entire cardiac cycle can be calculated.^{61,62}

How ventricular elastance varies during a single cardiac cycle can be illustrated by considering typical values for a normal 60 kg woman in a resting state [see Figure 2]. At the end of diastole (or the beginning of systole), the elastance is 0.2 mm Hg/ml. When systole begins, this value increases rapidly (within about 50 milliseconds) to 1.0 mm Hg/ml. At this point in the cardiac cycle, the pressure inside the ventricle is high enough to open the aortic valve. The elastance continues to increase as the ventricle pushes its blood into the aortic root, reaching its maximum at the end of systole. Typically, the end-systolic elastance is some 10 times greater than the end-diastolic elastance, or about 2.0 mm Hg/ml.

The elastance rapidly decreases during isovolumic relaxation until the beginning of diastolic filling of the ventricle; it then gradually and slightly increases until the end of diastole, returning to the initial value of 0.2 mm Hg/ml.

It is worthwhile to compare these variations in elastance with those seen in a person with maximal adrenergic stimulation of the heart and in a person with profound beta blockade [see Figure 2]. In the former, the end-systolic elastance is double the normal value, or 4.0 mm Hg/ml, and the ventricle reaches its maximal elastance more quickly. In the latter, the end-systolic elastance is half the normal value, or 1.0 mm Hg/ml, and the ventricle reaches its maximal elastance more slowly.

Thus, the end-systolic elastance can serve as a reasonably complete and simple measure of ventricular function. It provides a single-number quantitative description of the concept of contractility; it can be precisely measured, at least in the catheterization laboratory; it has been shown to be independent of end-diastolic volumes and afterload in experimental animals; and it is ideally suited for dealing with one of the fundamental problems in managing

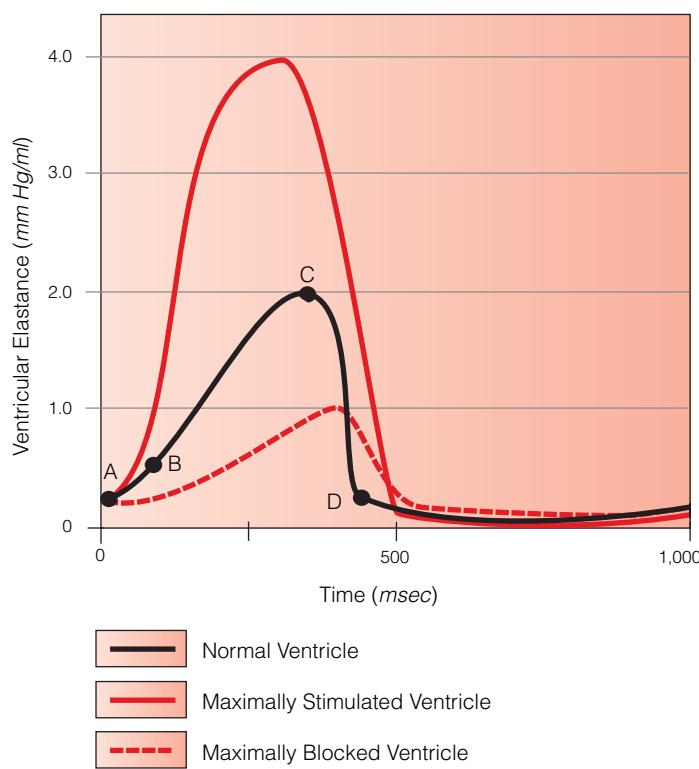

Figure 2 Illustrated is the elastance (stiffness) of the left ventricle over a cardiac cycle in a 60 kg person, as seen in a normal person under resting conditions, a person with a maximally contractile ventricle, and a person with profound beta blockade or congestive heart failure. Point A is the beginning of systolic contraction; point B is the opening of the aortic valve; point C is end-systole; and point D is the beginning of diastolic filling. With maximal contractility, elastance rises more quickly than normal, and maximal stiffness, at end-systole, is twice the normal value. With congestive failure, elastance rises more slowly, and maximal stiffness is half the normal value. The elastance during diastole is lowest under conditions of maximal contractility, at least in this example.

critically ill patients—namely, the problem of predicting how a ventricle with a given contractility will interact with a vasculature with a given afterload [see Ventricular-Arterial Coupling, below].

Afterload

As with contractility, defining a numerical descriptor for afterload has proved challenging since the early 1900s. In our view and that of many others, the impedance faced by the ventricle is a good choice for this purpose. We use the impedance as the descriptor for afterload for many of the same reasons that we use the ventricular end-systolic elastance as the descriptor for contractility. The impedance can be precisely defined by making precise measurements of flow and pressure in the aortic root in the cardiac catheterization laboratory; it can, with reservations, be expressed as a single number; it can, with reservations, be approximated with values obtained from measurements made with a Swan-Ganz catheter; and it is ideally suited for dealing with ventricular-arterial coupling.

The impedance (or hindrance) faced by the ventricle during emptying has three components. (We use the left ventricle as an example here, but the same concepts apply to the right ventricle.) The first component is the elastance (or stiffness) of the named arteries, including the aorta, which hinders the accommodation of blood in the arteries as the ventricle empties during systole. The second component is the resistance to steady-state flow offered by the arterioles throughout the body. The third component is the resistance to flow offered by the large veins as they enter the chest, coupled with the stiffness of the right atrium and ventricle as they accept blood returning from the body.

At first glance, the way in which these components relate to impedance appears simple. The stiffer the arteries, the higher the impedance; the greater the arteriolar constriction, the higher the impedance; and the greater the hindrance to the filling of the contralateral heart, the higher the impedance. The concept becomes more complex, however, when one tries to understand how these components interact with one another, as they do when connected to a pulsatile energy source (e.g., a contracting ventricle). One way of exploring this interaction is to consider the pressure wave that is propagated throughout the vasculature when the ventricle pumps blood into the aortic root.

When the left ventricle contracts, it pushes the blood it contains into a standing column of blood in the aortic root. Initially, this column of blood remains stagnant; however, the energy impulse imparted to it by the inrush of ventricular blood generates a pressure wave that propagates throughout the arteries until it reaches the arterioles, which are situated throughout the body at differing distances from the heart. Part of the propagated wave bounces off the arterioles, generating reflected waves that return to the aortic root and the heart.

The amplitude of the reflected waves depends on the degree to which the arterioles are constricted: the greater the constriction, the higher the amplitude. Some of the reflected waves return during systole, some during diastole. The timing, as one might expect, depends to a large extent on the spatial distribution of the arterioles: waves from nearby arterioles return sooner, and waves from distant arterioles return later. The timing also depends on the propagation velocity of the waves, which itself depends on the elastance of the walls of the arteries through which the waves pass. Finally, the timing depends to an extent on the viscoelastic properties of the conducting medium (i.e., the blood), but aside from limiting blood transfusions and keeping the patient warm, there is little that the physician can do to influence these properties. There is, however, a great deal that the physician can do to influence arterial elastance (see below).

The velocity of the propagating pressure wave can be measured quite simply in humans by means of Doppler technology. On average, it is about 4 m/sec in young children and 18 m/sec in octogenarians.^{63,64} The increased velocity in older persons is caused by the replacement of elastin in the arterial walls with collagen as part of the aging process. The velocities in the upper part of the body are slower than those in the lower part because the arterial walls in the upper extremities are thinner and more compliant than those in the lower extremities. Arterial walls possess receptors for norepinephrine, vasopressin, and angiotensin II; activation of these receptors increases the stiffness of the walls and the velocity of the pressure wave. Stretching of the walls also increases their stiffness and the velocity of the pressure wave, as does arterial mural calcification (e.g., in patients with diabetes).

A key point is that the propagation velocities of the pressure waves are much faster than the velocities with which the blood moves through the arteries. Blood flow velocities, unlike pressure wave propagation velocities, are not affected by changes in arterial wall elastance. During a cardiac cycle, blood flow velocity ranges from 0 to 50 cm/sec, with a mean value of about 15 cm/sec. Thus, for a child, pressure wave propagation velocity (4 m/sec) is more than 25 times faster than mean blood flow velocity, whereas for an 80-year-old, pressure wave propagation velocity (18 m/sec) is more than 100 times faster. The differences between pressure wave propagation velocity and blood flow velocity indicate that although the blood is indeed moved by the energy waves generated by ventricular contraction, it has inertia. The blood does accelerate and gain speed as the pressure wave moves through it, but it cannot be expected to keep up with the wave.

As a general rule, a patient is better off with compliant arteries and slow propagation velocities. With high velocities, the waves return too rapidly to the aortic root, arriving even before the ven-

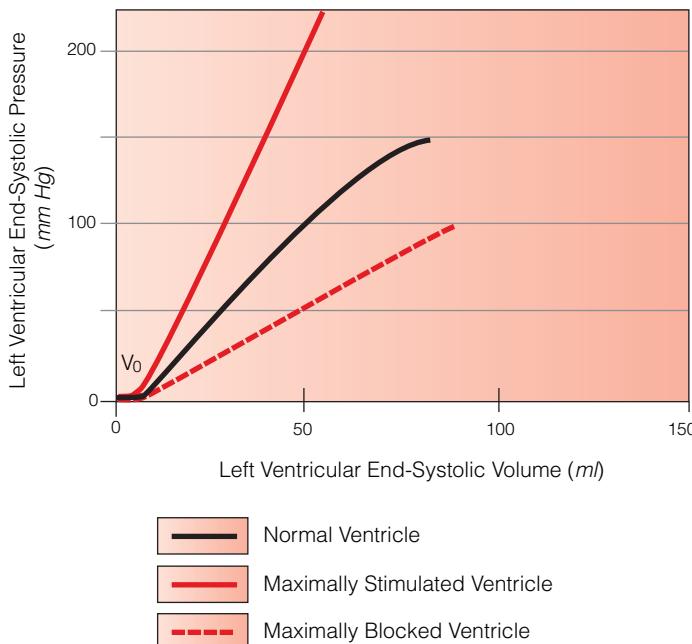

Figure 3 Shown is LVESP plotted against LVESV at end-systole, as seen in a normal ventricle, a maximally stimulated ventricle, and a maximally blocked ventricle. Once the LVESV exceeds the unstressed volume (V_0), the LVESP increases in a fairly linear way. The contractilities of the three ventricles can be taken as the slopes of the relations: 2.0, 4.0, and 1.0 mm Hg/ml, respectively [see Figure 1].

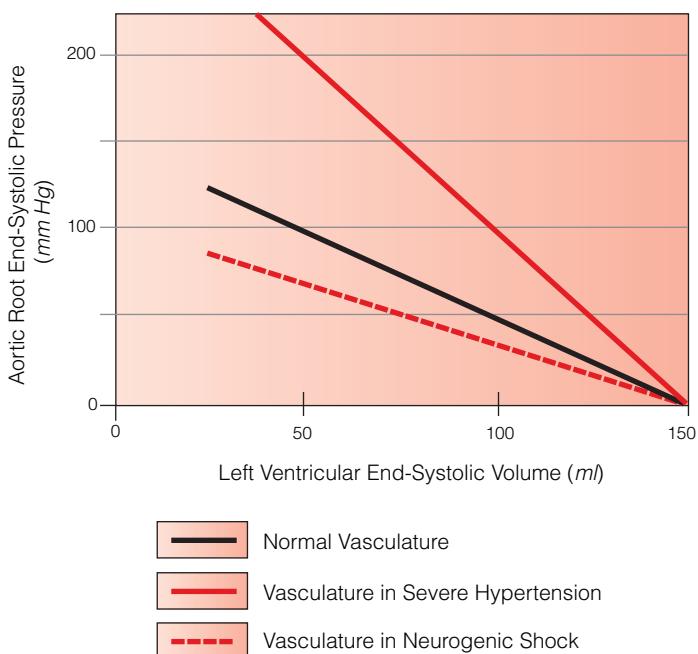

Figure 4 Shown is aortic root end-systolic pressure plotted against LVESV, as seen in a normal vasculature, the vasculature of a patient with severe hypertension, and the vasculature of a patient in neurogenic shock. The LVESV is assumed to be 150 ml. The magnitudes of the slopes of the relations for the three vasculatures (1.0, 2.0, and 0.75, respectively) can be taken to represent the afterloads.

tricle has finished contracting; as a result, the ventricle fights itself, pumping against the pressure wave that it generated. Another problem with high propagation velocities is that the waves die out before diastole, and thus, pressure that could have been used for perfusion of the coronary vasculature is lost. The mean aortic root pressure may even fall, compromising peripheral perfusion.

In a young, unstressed patient, the propagation velocities are slow, and the waves return during diastole. The heart benefits enormously. Because the waves arrive back at the heart after the aortic valve has closed, the ventricle does not have to pump against its own energy impulse, and the perfusion pressure of the coronary arteries is maximized. The augmented diastolic and mean pressures maintain peripheral perfusion.

The behavior of these reflected waves is not merely of theoretical interest but has several clinical implications. If a patient's arteries are abnormally stiff (e.g., as a result of age, calcification, distention, activation of vessel wall receptors, or external compression), the propagation velocity will be high, which means that the waves will return early, the systolic pressure at the aortic root will rise, and the diastolic pressure will fall. The elevated systolic pressure will increase ventricular oxygen requirements; the unaffected MAP will do nothing for tissue perfusion. If the propagation velocity can be reduced, the systolic pressure will come down and the MAP will stay the same. This is usually a desirable result for a shock patient, in that myocardial oxygen requirements will decrease while perfusion pressures are maintained. Accordingly, in the treatment of shock, there is often a real clinical benefit to be gained from interventions aimed at reducing arterial stiffness.

Several options are available for decreasing arterial stiffness, including diuresis or fluid restriction, beta blockade, ACE inhibition, and the use of agents that increase the production of nitric oxide near the arterial walls (and, admittedly, at the arteriolar and

venular walls). The aortic counterpulsating balloon pump can be extremely effective in dealing with systemic arterial stiffness. (In fact, that is its only function.) Options for treating stiff arteries on the right side of the circulation are more limited, though the pharmacologic interventions just mentioned are sometimes helpful. One may also adjust the ventilator.

The impedance facing the ventricles can be determined with precision in the catheterization laboratory by using catheters that can precisely measure pressures and flows at the roots of the arteries. To describe this complex interplay of wave propagation and reflection with a single number, to quantify responses to interventions, and to do both of these things with numbers available in the intensive care unit, one can calculate the hindrance facing the left ventricle as the LVESP (or, equivalently, the aortic root end-systolic pressure) divided by the stroke volume. The resulting value—the effective aortic root elastance—will be high if a given stroke volume creates a high systolic pressure and low if the stroke volume creates a low pressure. (It is worth mentioning that although this value is an elastance and is expressed in the units used for elastance, it reflects not only the properties of the arteries but also the properties of the arterioles. After all, the amplitude of the reflected waves depends on the arterioles. The value for effective elastance takes into account all of the factors that may hinder ventricular emptying.)

Ventricular-Arterial Coupling

In addressing the problem of ventricular-arterial coupling, it is useful to start by considering the pressure-volume relations in the left ventricle and the aortic root. One could just as well start by considering the right side of the heart, which in some surgical patients is the critical side; however, there is far more information in the literature about the left side, and more options are available for intervention on that side. Regardless of which side of the heart is considered, the essential concepts are the same.

The left ventricle is stiffest at end-systole. If the intraventricular pressure is plotted as a function of the intraventricular volume at end-systole, a fairly straight line will be generated [see Figure 3]. The slope of this line is the end-systolic elastance (or stiffness), which, as noted [see Contractility, above], serves as a descriptor for contractility.⁶²

It is noteworthy that the x-intercept of the relation is not 0 but a value slightly greater than 0. This is because a ventricle can contain a small amount of blood without generating any pressure at all; it is only when the volume exceeds a certain threshold—the so-called unstressed volume (V_0)—that the pressure starts to increase as the volume increases.^{61,62} A typical value for the end-systolic unstressed volume in a 60 kg person is quite low, on the order of 0.1 ml/kg, or 6 ml. In patients with severe congestive heart failure, the unstressed volume can be as high as 60 ml, as a manifestation of a globally flabby heart, but in most patients, it can be assumed to be close to 0 ml.

The slope of the line can then be approximated as the LVESP divided by the LVESV. Other points on the line can also be used to make this calculation, but they will not be known unless one is in the catheterization laboratory and can make sophisticated measurements of both pressure and volume as end-diastolic volumes or afterloads are altered. Accordingly, the aforementioned approximation is the most clinically useful calculation. As with ventricular elastance, the plot will look quite different in a person with maximal beta-adrenergic stimulation or a person with maximal beta blockade [see Figure 3].

The pressure-volume relation for the aortic root can be plotted on a graph in a similar fashion [see Figure 4]. In this case, the LVESV is still plotted on the x-axis, whereas the end-systolic pres-

sure in the aortic root is plotted on the y-axis. This relation depends on the LVEDV. For example, in a 60 kg person with an LVEDV of 150 ml, if the LVESV is 150 ml, the stroke volume will be 0 ml. If the stroke volume is 0 ml, the heart will generate no pressure for filling the aortic root, and the aortic root pressure will be 0 mm Hg. If, however, the LVESV is 50 ml (a normal value) and the LVEDV is held constant at 150 ml, the stroke volume will be 100 ml. A stroke volume of 100 ml will generate an LVESP of 100 mm Hg.

If points representing these two scenarios are plotted on the graph, a line can be drawn between them to represent the relation between the end-systolic pressure in the aortic root and the LVESV. The magnitude of the slope of this line is calculated by dividing the LVESP by the stroke volume. In this case, the calculation yields a value of 1.0 mm Hg/ml. This value can be taken as the effective elastance of the aortic root at end-systole, which, in turn, can be taken as a single-number representation of the hindrance facing the left ventricle (*i.e.*, the impedance).^{61,62} Different values will be obtained in a patient with severe hypertension or a patient in warm septic shock [*see Figure 4*], even when the LVEDV is the same.

To deal with the problem of ventricular-arterial coupling, one then plots the two pressure-volume relations (for the left ventricle and the aortic root) at end-systole on the same graph [*see Figure 5*]. The LVESP must equal the end-systolic pressure in the aortic root. (In fact, the pressures throughout most of systole, with the exception of isovolumic contraction, are about the same.) The only point on the graph where the two pressures are equal is the point where the two lines intersect. This point defines the specific end-systolic volume and pressure for a patient with a specific unstressed ventricular end-systolic volume, a specific contractility, a specific end-diastolic volume, and a specific afterload. That is, this graphic analysis allows one to predict how a particular ventricle with particular characteristics will interact with an arterial system with a particular afterload.

Pressure-Volume Loops and Thermodynamics of Ventricular Contraction

The next step is to draw a pressure-volume loop for the ventricle, working on the assumption that the unstressed end-systolic volume, the contractility, the end-diastolic volume, and the afterload are known. Typical values would be 6 ml, 2 mm Hg/ml, 150 ml, and 1 mm Hg/ml, respectively. From the analysis previously described (*see above*), it follows that the end-systolic volume will be 50 ml and the end-systolic pressure will be 100 mm Hg [*see Figure 6*].

At the beginning of systole (point A), the ventricle has a volume of 150 ml and an end-diastolic pressure of 8 mm Hg (*if the patient is breathing spontaneously*). The ventricle then contracts until the pressure in the chamber exceeds the pressure in the aortic root and the aortic valve opens (point B).

As the blood contained in the ventricle is pushed into the aortic root, ventricular volume decreases until end-systole (point C) is reached. It should be kept in mind that the pressure inside the ventricle at any point during ventricular emptying is determined by the balance between the volume and the stiffness of the chamber at that point. The pressure increases from the beginning of ventricular emptying to, roughly, the midportion of systole. That is, the effect of the rapidly increasing stiffness of the ventricle [*see Figure 2*] overcomes the effect of the decreasing volume as the ventricle empties. From the midportion of systole to end-systole, the effect of the decreasing volume starts to dominate as it overcomes the still-increasing stiffness, and the pressure gradually falls.

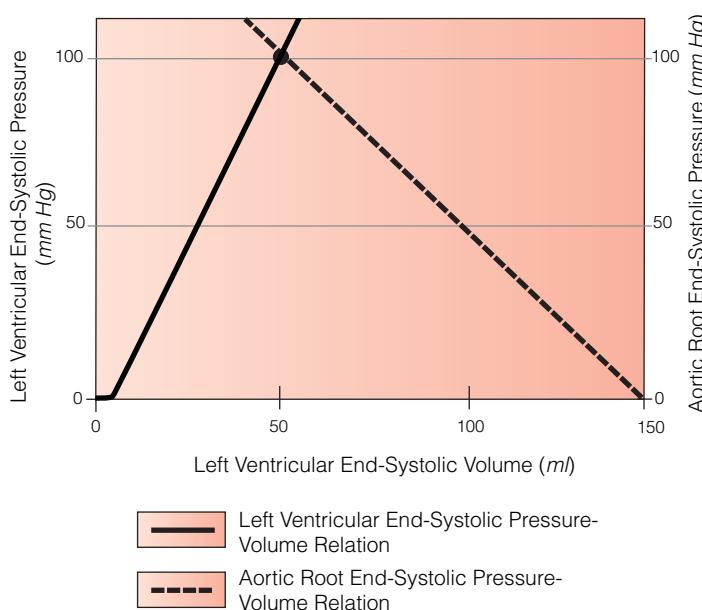

Figure 5 Illustrated is the superposition of the normal pressure-volume relation for the left ventricle at end-systole [*see Figure 3*] onto the normal pressure-volume relation for the aortic root at end-systole [*see Figure 4*]. The two pressures must be the same. Thus, in this case, the LVESV must be 50 ml, and both the LVESP and the aortic root end-systolic pressure must be 100 mm Hg (point C). That is, the end-systolic point is determined by the end-systolic unstressed volume, the contractility, the end-diastolic volume, and the afterload.

At end-systole (point C), the actin and myosin myofilaments suddenly disengage, and the ventricle switches from its maximally contracted state to an increasingly compliant one. The ventricle then goes through another isovolumic phase as its pressure drops to its lowest value during the cardiac cycle, at the beginning of diastolic filling (point D). Finally, the chamber fills again and returns to its initial state.

The work done on the ventricle during diastole is represented by the area under the diastolic pressure-volume curve and the x-axis, which is approximately equal to the mean diastolic pressure multiplied by the stroke volume.^{61,62} The work done on the aortic root by the contraction of the ventricle is represented by the area contained within the curve, or the difference between the end-systolic and mean diastolic pressures multiplied by the stroke volume. The total work done on the aortic root with each cardiac cycle is represented by the entire area under the curve, down to the x-axis. It can be approximated as the end-systolic pressure multiplied by the stroke volume.

Also illustrated is the wasted energy associated with the loop (*i.e.*, the heat dissipated in the ventricular wall during isovolumic relaxation). This variable is represented by the area contained within a triangle whose apices are the points V₀, D, and C (*i.e.*, the unstressed volume, the beginning of diastolic filling, and end-systole). Under normal circumstances, this area can be ignored. It can become substantial, however, if the afterload comes to exceed the contractility (*see below*).

The total amount of energy transmitted into the aortic root per minute is the total work done on the root per heartbeat multiplied by the heart rate. The total amount of heat dissipated in the ventricular wall during isovolumic relaxation is the area of the aforementioned triangle multiplied by the heart rate. The left-side oxy-

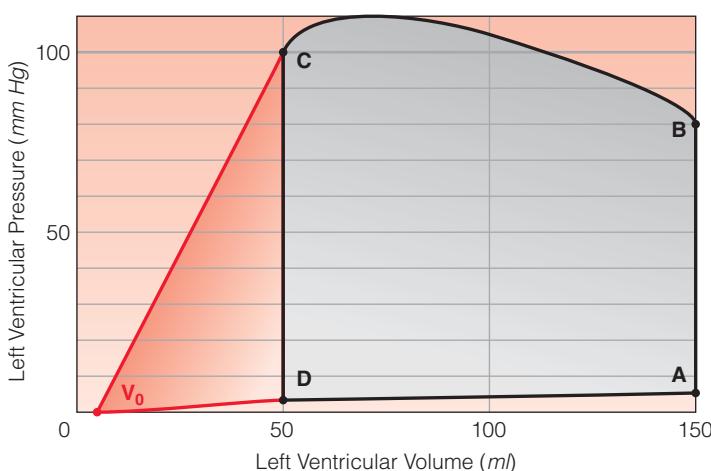

Figure 6 Illustrated is the pressure-volume relation for the left ventricle over an entire cardiac cycle. The work done on the left ventricle during diastole (or, equivalently, the energy added to the ventricle during systole) is the area under the curve DA. The energy added to the aortic root by virtue of ventricular contraction is the area contained within the loop ABCD. The total energy added to the aortic root during a single heartbeat is the sum of these two areas. The heat dissipated in the ventricular wall during isovolumic relaxation is equal to the area contained within the triangle CV_0D .

gen requirements for the myocardium are directly proportional to the sum of the total amount of power produced and the total amount of heat dissipated in the ventricular wall.

The goal of resuscitation in a patient in shock is to achieve adequate cardiac production of power while minimizing myo-

cardial oxygen requirements. If the effective arterial elastance is adjusted so that it equals the contractility, maximum work per heartbeat will be achieved, but a substantial amount of heat will be dissipated in the ventricular wall during isovolumic relaxation [see Figure 7]. If the afterload is adjusted so that it is approximately half the contractility, some work will be lost, but substantially less heat will be dissipated; thus, power will be produced much more efficiently. If the afterload is allowed to exceed the contractility, the work produced will fall off and the myocardial oxygen requirements will increase—a situation that is rarely good for the patient.

These conclusions can be demonstrated by graphing the pressure-volume relations for ventricles and aortic roots at end-systole under these different conditions. The predicted end-systolic values for the ventricular volumes and pressures can then be used to generate the different pressure-volume loops. The conclusions can also be proved by means of mathematical analysis.

Although there is no thermodynamic free lunch, there are certainly more expensive and less expensive lunches. To make the thermodynamic lunch as inexpensive as possible, one should avoid letting the afterload exceed the contractility, and one should try to minimize the systolic pressures while maintaining the mean pressures.

Goals for Cardiovascular Resuscitation in Treatment of Shock

Efforts have been made to avoid using any invasive cardiovascular measurements in resuscitation from severe shock (e.g., by using gastric mucosal pH as an end point for resuscitation), but to date, such efforts have not proved helpful outside carefully controlled research environments. There is wide agreement that invasive monitoring is still needed in the treatment of severe shock;

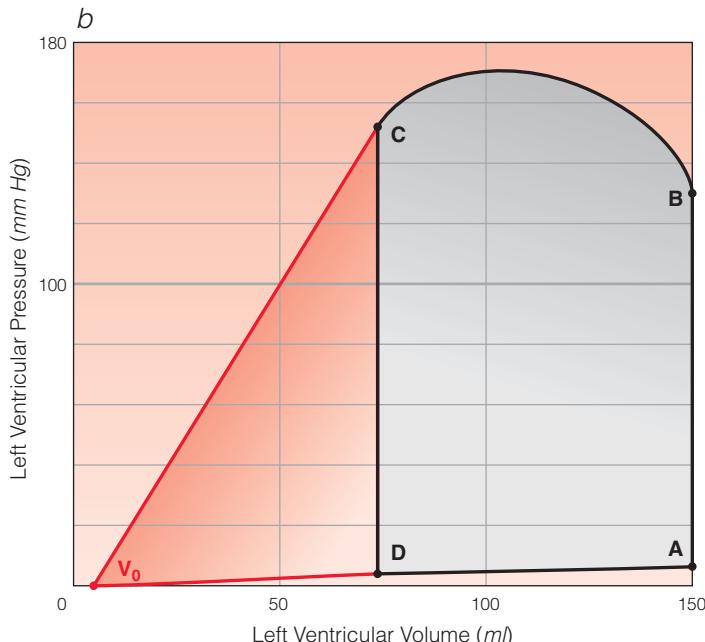

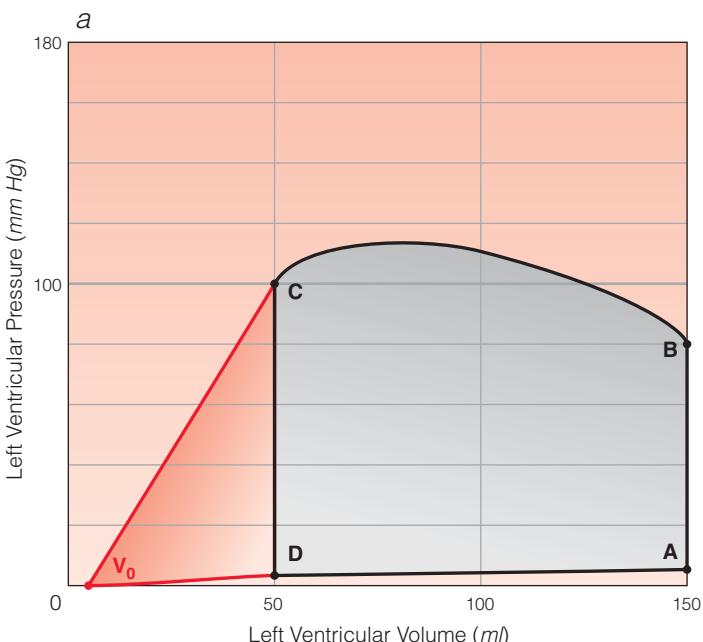

Figure 7 Shown are pressure-volume loops generated by different ratios of afterload to contractility. If the afterload is approximately half the contractility (a), as in a patient in septic shock who has reduced contractility and afterload, the ventricle will produce its work with optimal efficiency. If the afterload equals the contractility (b), as when the same patient is given a vasoconstrictor, the pressure will increase and the ventricle will produce slightly more work, but substantially more energy will be wasted in the form of heat dissipation during isovolumic relaxation. If the vasoconstrictor is given to produce a higher pressure, the work will begin to fall off, and the heat dissipated in the ventricular wall will continue to increase.

Table 4 Effects of Position and Strenuous Exercise on Cardiovascular Volumes and Pressures in a Young, Well-Conditioned 60 kg Woman

Variables	Supine (Resting)	Upright (Resting)	Upright (Exercising)
Lower body venular volume (ml)	1,920	> 1,920	< 1,920
Lower body venular pressure (mm Hg)	20	> 20	< 20
Upper body venular volume (ml)	960	< 960	> 960
Upper body venular pressure (mm Hg)	10	< 10	> 10
Right ventricular end-diastolic volume (ml)	150	133	145
Right ventricular end-diastolic pressure (mm Hg)	5	5	5
Right ventricular and pulmonary arterial end-systolic pressure (mm Hg)	22.5	22.5	35
Mean pulmonary arterial pressure (mm Hg)	15	15	20
Left ventricular end-diastolic volume (ml)	150	133	145
Left ventricular end-diastolic pressure (mm Hg)	8	8	8
Left ventricular and aortic root end-systolic pressure (mm Hg)	100	100	145
Mean aortic pressure (mm Hg)	90	90	110

however, there is no consensus on what to do with the values obtained from monitoring.

One approach is to try to find a single parameter that can serve as the goal of resuscitation. The best candidate parameter is probably the $S_{mv}O_2$, measured with a pulmonary arterial catheter. This value can be quite helpful in minute-to-minute management during resuscitation from hemorrhagic shock. It is considerably less helpful, however, in patients in inflammatory shock, who often have quite high venous saturations, partly because of peripheral shunting through the cutaneous vasculature and partly because of functional shunting by cells that cannot metabolize the oxygen presented to them. In the setting of inflammatory shock, a high $S_{mv}O_2$ may even indicate a severe metabolic derangement rather than resolution of shock.

Another approach is to attempt to determine whether the patient's oxygen consumption (measured with a pulmonary arterial catheter and based in part on measurements of cardiac output) depends on oxygen delivery (the product of cardiac output, hemoglobin concentration, and S_aO_2). Unquestionably, at very low levels of oxygen delivery, oxygen consumption must decrease. At excessively high levels, however, oxygen consumption may continue to rise if oxygen delivery is increased by the administration of inotropes. These agents usually have beta-adrenergic effects and can increase peripheral oxygen metabolism; they also increase myocardial oxygen requirements. Thus, the act of increasing delivery can increase overall consumption.

Yet another approach is to maintain all patients at very high levels of oxygen delivery without making any attempt to ascertain whether there is a correlation between delivery and peripheral consumption. Two randomized trials evaluated this approach; neither found any evidence of benefit.^{65,66}

Our approach is to start, as any clinician would, by attempting to resolve the clinical abnormalities observed without subjecting the patient to invasive monitoring. If this attempt is unsuccessful, we insert monitoring catheters and use the information obtained from them to try to achieve reasonable ventricular power production with acceptable efficiency while minimizing the formation of edema. This approach is supported by a compelling study that underscored the value of taking a thermodynamic approach to resuscitation and indicated that the goal for resuscitation of the typical shock patient need be little more than a reasonable blood pressure and a reasonable cardiac output.^{67,68}

Different goals may, however, be appropriate in other patients. For example, cardiovascular conditioning increases the blood vol-

ume, increases the ventricular end-diastolic volumes, increases the stroke volume, and decreases the resting heart rate. In other words, it prepares the body for stress. Accordingly, we aim for a higher cardiac output if we know that a patient was in good car-

Table 5 Effects of Position and Exercise on Organ Blood Flow and Oxygen Consumption in a Young, Well-Conditioned 60 kg Woman

Variables	Supine (Resting)	Upright (Resting)	Upright (Exercising)
Whole body			
Blood flow (L/min)	6.0	5.0	22.0
Venous O ₂ saturation	76%	71.6%	11%
O ₂ consumption (ml/min)	210	210	3,180
Splanchic viscera			
Blood flow (L/min) (% of total)	1.50 (25%)	1.25 (25%)	0.30 (1%)
Venous O ₂ saturation	77%	73%	18%
O ₂ consumption (ml/min)	50	50	40
Kidneys			
Blood flow (L/min) (% of total)	1.20 (20%)	1.00 (20%)	0.25 (1%)
Venous O ₂ saturation	91%	90%	65%
O ₂ consumption (ml/min)	12	12	12
Brain			
Blood flow (L/min) (% of total)	0.90 (15%)	0.75 (15%)	0.75 (3%)
Venous O ₂ saturation	67%	60%	59%
O ₂ consumption (ml/min)	45	45	45
Heart			
Blood flow (L/min) (% of total)	0.24 (4%)	0.20 (4%)	0.80 (4%)
Venous O ₂ saturation	46%	35%	1%
O ₂ consumption (ml/min)	20	20	130
Skeletal muscle			
Blood flow (L/min) (% of total)	1.20 (20%)	1.00 (20%)	19.5 (89%)
Venous O ₂ saturation	61%	54%	8%
O ₂ consumption (ml/min)	70	70	2,940
Skin			
Blood flow (L/min) (% of total)	0.30 (5%)	0.25 (5%)	0.30 (1%)
Venous O ₂ saturation	93%	91%	88%
O ₂ consumption (ml/min)	2	2	2
Other organs			
Blood flow (L/min) (% of total)	0.66 (11%)	0.55 (11%)	0.10 (0%)
Venous O ₂ saturation	87%	85%	31%
O ₂ consumption (ml/min)	11	11	11

diovascular condition before the acute problem developed.

We also aim for slightly higher (but not excessively high) values in patients with major injuries or overwhelming infections. Hyperthermia or systemic inflammation can raise oxygen consumption to values as high as twice those encountered in normothermic, uninjured, or uninjected persons [see 8:22 *Metabolic Response to Critical Illness*]. (To put these changes in perspective, oxygen consumption in a strenuously exercising young subject can increase by a factor of 15 to 20.) In addition, if the environment is cold enough to induce shivering, oxygen consumption can rise to levels several times higher than those observed in a thermoneutral environment. In these situations, a higher cardiac output is to be expected. (In contrast, hypothermia in the absence of shivering decreases oxygen consumption. In this situation, the cardiac output can fall to quite low levels with no detrimental effect on survival. Efforts to increase cardiac output in severely cold patients can even induce fatal ventricular arrhythmias.)

Sometimes, a goal for cardiac output can be arrived at by means of trial and error. For example, if a supranormal cardiac output causes an abnormality (e.g., metabolic acidosis) to resolve when a normal output did not, an effort should be made to keep the cardiac output high for a while.

We also consider values gleaned from the wealth of studies done on both normal and exercising subjects in cardiac catheterization and exercise physiology laboratories, keeping in mind that normal values can vary from subject to subject [see Tables 4 and 5]. Gaining a sense of what the heart and lungs can do in different circumstances can give the clinician a useful perspective on how a patient is likely to respond to shock and what to expect from resuscitation.

Studies have shown that the physiologic responses to standing up are similar to those that come into play in the early stages of

shock (with the exception of neurogenic shock, in which there are very few responses) [see Tables 4 and 5]: activation of the adrenergic system, activation of the renin-angiotensin system, release of vasopressin from the hypothalamus, and release of aldosterone from the adrenal glands. These responses are also similar to those that develop when a patient is placed on mechanical ventilation, a therapeutic intervention that results in small ventricular end-diastolic volumes because of redistribution of blood into the systemic venules and small veins (just as standing up results in redistribution of blood from the ventricles to the dependent venules and small veins). The pressures are maintained with minor stresses, but the cardiac output drops, as does flow to the kidneys and the splanchnic organs.

In strenuous exercise, oxygen consumption can increase by a factor of 15 to 20, and cardiac output can increase by a factor of 3 to 4. Blood flow to the splanchnic viscera and the kidneys falls to levels as low as 20% of normal, with no long-term ill effects. (The organs survive by extracting a higher percentage of the oxygen delivered to them.) Blood flow to the skin during strenuous but not exhausting exercise in a warm environment can increase from a baseline of 300 ml/min to levels as high as 6 L/min in an effort to offload heat and keep body temperature within acceptable limits. (We are not aware of any studies that have measured blood flow to the skin of patients in inflammatory shock, but we suspect that the flow rate may be as high as 3 L/min for a 60 kg person.)

Shock patients cannot be expected to be capable of achieving these sorts of values, but the numbers do give the physician a feeling for what the body can do and thus some idea of what to expect. A patient in shock has an excellent chance of surviving with normal function of all organs if resuscitation can be achieved expeditiously.

4 PULMONARY INSUFFICIENCY

Robert H. Bartlett, M.D., and Preston B. Rich, M.D.

Approach to Pulmonary Insufficiency

Pulmonary insufficiency is the most common complication after surgical procedures. It ranges in incidence from 5% to 50% and in severity from minor atelectasis to lethal acute respiratory distress syndrome (ARDS). The reason why the lung is so vulnerable in the postoperative period is that both of the essential components of lung function—ventilation (anatomy and physiology of breathing) and pulmonary circulation (anatomy and physiology of the pulmonary endothelium and interstitium)—are affected by all the events surrounding tissue injury, anesthesia, and tissue dissection.¹ Abnormal ventilation leads to alveolar collapse, decreased functional residual capacity (FRC), and atelectasis. Abnormal capillary homeostasis leads to lung edema. Bacterial pneumonitis can initiate these events or can be a secondary complication. The term ARDS refers to a combination of atelectasis and edema, with edema predominating; it will be used sparingly in this chapter, primarily to describe the occurrence of pulmonary edema caused by increased capillary permeability.

In what follows, we discuss the care of patients at risk for pulmonary complications, including clinical presentation, pathogenesis, recognition, prevention, and treatment of pulmonary insufficiency. Atelectasis and lung edema are considered as separate events, though it is obvious that both abnormalities can and do occur simultaneously after operation. The emphasis is on disorders of the pulmonary parenchyma as opposed to pulmonary insufficiency secondary to cardiac disease, thromboembolism, CNS depression, and other conditions. The discussion is limited to mild to moderate pulmonary insufficiency because major insufficiency is discussed more fully elsewhere [see 8:5 *Mechanical Ventilator*]. Perioperative problems related to operations for primary pulmonary disease also are not addressed in this chapter.

Preoperative Pulmonary Function Testing

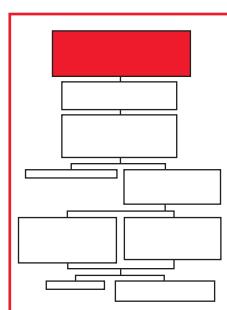

Given that identification of the high-risk patient can reduce the incidence of pulmonary complications, preoperative assessment of respiratory status is clearly important [see CP:4 *Risk Stratification, Preoperative Testing, and Operative Planning*]. The history is the most valuable step. Factors indicating a need for more detailed study of pulmonary function include exercise intolerance, dyspnea on exertion, wheezing, cigarette smoking, cough, and sputum production.

Physical examination should include auscultation and percussion of the lung bases during tidal breathing and maximal inspiration to detect hypoventilation in weak or debilitated patients and

hyperinflation in patients with chronic airway disease. Wheezing, rales, or rhonchi should trigger further examination. Cardiac insufficiency, obesity, clubbing, tobacco stains, and poor oral hygiene are all relative indications for more detailed pulmonary function testing. Chest x-ray should be considered part of the routine physical examination for any patient with an abnormality detected from the history or physical examination, any patient scheduled to undergo a thoracotomy, and any patient older than 40 years. As part of the physical examination, the patient should be instructed to inhale to the maximum, then to perform a vigorous forced expiration. By observing the patient's chest and the sound of forced expiration, one can make a good guess at the volume of inspiration (which should be at least 1 L/50 kg), forced expiratory volume (which should be at least 2 L/50 kg), and expiratory flow (most of the exhaled volume should come out in the first second without wheezing). Forced expiratory volume—or vital capacity (the two are different names for the same thing)—and maximum voluntary ventilation (MVV) can be directly measured with a handheld turbine spirometer.

The ability to climb one or two flights of stairs at a steady pace without dyspnea provides information about the patient that is not available in any other way short of treadmill or exercise testing. A patient who cannot do this simple exercise may have respiratory, cardiac, or joint disease or may be too obese, too weak, too sedentary, or too debilitated to manage mild exertion. Whatever the cause, an elective operation should be delayed if the patient cannot do the exercise.

Simple spirometry should be done whenever the history, the physical examination, or bedside tests yield findings indicating abnormal pulmonary function. Tidal volume, inspiratory capacity, vital capacity (total and timed intervals), and MVV are measured, and the results are compared with tables for normal persons of the same age, sex, and size and then reported as percentages of predicted normal values. Results between 80% and 120% of predicted values are considered normal. If these tests of lung volume and flow are within the normal range, the risk of pulmonary complications is small (though the tests do not address endurance). Abnormally high values are not important; however, abnormal values below 70% of predicted levels indicate small airway or obstructive lung disease (if the expiratory flow rate is low), loss of lung volume (if vital capacity is low), or localized or generalized muscle weakness. If expiratory flow is abnormally low, spirometry should be repeated after the administration of aerosolized bronchodilators. Low expiratory flow that improves after bronchodilation indicates bronchospasm, which will require special management during and after operation. The test result that correlates best with the incidence of postoperative pulmonary complications is an MVV value below 50% of the

Assess pulmonary function preoperatively

Review history; perform physical exam. Evaluate for wheezing, rales, and rhonchi; cough and sputum production; cardiac insufficiency; and obesity. Estimate volume of inspiration, forced expiration, and expiratory flow.

Obtain chest x-ray if abnormality is detected, thoracotomy is planned, or patient is > 40 years.

If pulmonary dysfunction is suspected:

- Measure tidal volume, inspiratory capacity, vital capacity, and maximum voluntary ventilation.
- Obtain baseline blood gas measurements.
- In special circumstances: Measure FRC. Assess for chronic fibrotic disease.
Obtain ventilation-perfusion lung scan if pulmonary resection is contemplated.

Correct abnormalities, and prepare patient before operation

Teach breathing maneuvers, and exercise patient's respiratory muscles.

Reduce risk factors (e.g., smoking, LV failure).

Assess effects of bronchodilators in patients with bronchospasm.

Provide adequate nutrition.

Follow pulmonary prophylaxis regimen during and after operation

Inflate all alveoli regularly:

- Use breathing exercise with incentive spirometer. Use IPPB if necessary.
- Use mechanical ventilation in high-risk patients.
- Use bronchodilators for bronchospasm.

Maintain normal body fluid volume and composition:

- Give blood and fluids as needed, but not excessively.
- If fluid overload is unavoidable, diurese when stable.

Minimize the risk of venous thrombosis and pulmonary embolism.

Postoperative pulmonary insufficiency does not develop**Postoperative pulmonary insufficiency develops (e.g., dyspnea, tachypnea, tachycardia, confusion, cyanosis, abnormal x-ray)**

Rule out mechanical limitation of breathing, bronchospasm, pulmonary embolism, congestive heart failure, and hypovolemia.

Evaluate for atelectasis or pulmonary edema.

General support: Give O₂ during preliminary investigations (10 L/min by cannula or mask).

Treat atelectasis

Establish large-volume inflation via deep breathing exercises. If unsuccessful, try IPPB without intubation.

Initiate chest physiotherapy and postural drainage. Administer hydration, nebulized bronchodilators, and mucolytic drugs via airway. Perform bronchoscopy or tracheal suctioning as indicated.

If ventilation is still inadequate: Intubate and initiate mechanical ventilation. Provide nutritional support. Treat coexisting lung edema and lung infection. Maintain F_iO₂ < 60% and airway pressure < 40 cm H₂O.

Treat increased lung water

Decrease pulmonary hydrostatic pressure by improving LV function pharmacologically. (Monitor changes in cardiac output.) Reduce total extracellular fluid volume by forced diuresis, dialysis, or hemofiltration.

Increase plasma oncotic pressure by administering colloids during diuresis.

Establish and maintain normal pulmonary microvascular integrity by treating any extrapulmonary site of infection or inflammation.

Pulmonary insufficiency resolves**Pulmonary insufficiency progresses to ARDS or pneumonia**

Provide specific treatment for respiratory failure or postoperative pneumonia as indicated.

Approach to Pulmonary Insufficiency

predicted level. MVV may be abnormally low for many reasons, both pulmonary and nonpulmonary.

Arterial blood gas values are obtained only if major pulmonary dysfunction is suspected, and they serve primarily as a baseline for postoperative comparison and for decisions about postoperative ventilation rather than as a screening test for adequacy of pulmonary function. Arterial carbon dioxide tension (P_aCO_2) greater than 45 mm Hg at rest indicates significant alveolar hypoventilation. If the cause is muscle weakness, bronchospasm, or chronic bronchitis, it should be treated before any elective operation is undertaken. If the arterial oxygen tension (P_aO_2) is greater than 70 mm Hg, the patient has significant right-to-left shunting, diffusion block, or ventilation-perfusion mismatch—usually the last, though two or all three of these may occur together. These three causes of hypoxemia can be further identified by the response to breathing 100% oxygen, but this evaluation requires special equipment (a face mask or nasal catheter is not satisfactory), and the information gained is generally not worth the effort for the purposes of preoperative pulmonary assessment.

More detailed tests of pulmonary function are needed only in special situations. The most useful of these is measurement of FRC, which is done in association with simple spirometry using helium dilution or nitrogen washout. FRC is the most difficult lung volume to measure but also the most important: following the FRC is the most specific way of determining when the patient is in optimal pulmonary condition. An abnormally high FRC indicates air trapping from small airway disease or bronchospasm, which should be treated before any elective operation. An abnormally low FRC indicates loss of lung volume that may result from atelectasis, pneumonia, pleural effusion, or congestive heart failure, all of which should be treated until the FRC is normal. Measurement of diffusing capacity by carbon monoxide inhalation is not helpful. Measurement of P_aO_2 during carefully monitored breathing of 100% oxygen is more useful when chronic fibrotic lung disease is suspected. Oxygen consumption, CO_2 production, and respiratory quotient are measures of systemic metabolism rather than of pulmonary function; accordingly, whereas they may be helpful in preoperative screening for the purposes of detecting sepsis or planning nutritional therapy, they generally are not useful guides to pulmonary functional status. Ventilation-perfusion scanning should be added to the regimen of routine preoperative testing in any patient with evidence of compromised pulmonary function in whom resection of pulmonary tissue is contemplated.

In summary, the history, the physical examination, and chest x-ray constitute sufficient preoperative pulmonary assessment in almost all cases. Patients at risk for pulmonary complications, as identified by history or examination, should undergo simple spirometry to identify abnormalities that can be corrected before elective operations. Arterial blood gases should be measured preoperatively in patients with major respiratory dysfunction to serve as a baseline for postoperative management.

Preoperative Measures to Prevent Pulmonary Insufficiency

PREVENTION OF ATELECTASIS AND EDEMA

Given an understanding of how pulmonary insufficiency arises and how patients at high risk for this complication can be detected, one can identify the appropriate steps in prevention. First, measures must be adopted to prevent atelecta-

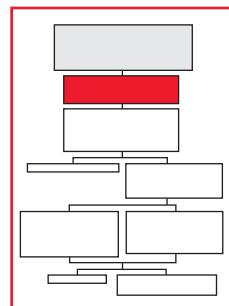

Table 1 Prevention of Atelectasis during and after Operation

Ensure frequent inflation to total lung capacity
Deep breathing exercises facilitated by incentive spirometer
Mechanical ventilation after major operations until alert and awake
Positive pressure breathing for patients who cannot take deep breaths
Minimize respiratory depression
Adequate, but not excessive, narcotic dosage
Local and regional anesthesia
Minimize absorption atelectasis from increased F_iO_2
Add nitrogen (lowest F_iO_2 to keep $S_aO_2 > 90\%$)
Use PEEP if $F_iO_2 > 50\%$
Avoid pulmonary edema
Clear pleural space of air and fluid
Use abdominal viscera to increase lung volume
Sitting or standing position
Avoidance of supine position and high abdominal pressure

F_iO_2 —fraction of inspired oxygen PEEP—positive end-expiratory pressure

S_aO_2 —arterial oxygen saturation

sis [see Table 1]. The most important of these is to maintain a normal pattern of breathing with regular maximal lung inflation. The patient can usually do this voluntarily and spontaneously, taking deep forced inspiratory breaths at least 10 times each hour. The incentive spirometer may be used to encourage the patient's efforts and to measure the volume of inspiration. If the patient cannot take deep breaths spontaneously, mechanical assistance should be employed—usually on an intermittent basis with a mechanical ventilator and mouthpiece (intermittent positive pressure breathing, or IPPB). In high-risk patients who have undergone major operations, postoperative prophylactic intubation and mechanical ventilation are appropriate preventive measures and should be continued until the patient can sustain a normal breathing pattern. Keeping the airway clear with humidification and postural drainage is important in patients with chronic bronchitis. Coughing is not useful for preventing postoperative pulmonary complications.

Second, measures must be adopted to prevent lung edema [see Table 2]. Advising the surgeon to avoid cardiac failure, endotoxemia, and shock is an oversimplified platitude, but it is important to remember that pulmonary insufficiency may be the presenting symptom of these conditions. If preoperative and intraoperative resuscitation has resulted in major fluid overload, diuresis should be instituted when the patient is hemodynamically stable to minimize the potential for symptomatic lung edema and to raise plasma oncotic pressure.

CORRECTION OF ABNORMALITIES

If a patient is scheduled for an elective operation, as much time as is necessary should be spent measuring lung function, correcting abnormalities where present, and changing conditions that may predispose to pulmonary complications. This is particularly true in patients with preexisting cardiopulmonary disease. Patients should be advised to train for a major operation as they would for an athletic event. The respiratory muscles should be exercised and specific breathing maneuvers learned.

Correction of factors that may decrease the efficiency of ventilation includes cessation of smoking, elective weight loss in gross-

Table 2 Prevention of Pulmonary Edema during and after Operation

Avoid extracellular fluid overload

Routine intraoperative fluids limited to 3% of body weight

Low threshold for blood or colloid during resuscitation or blood loss

Treat or prevent left ventricular failure

Optimization of cardiac output with inotropes when filling pressures are elevated

Restore or maintain colloid osmotic pressure

Diuresis to concentrate proteins

Administration of 25% albumin or plasma if pulmonary edema is symptomatic

Minimize pulmonary capillary leakage

Drainage of pus and excision of dead tissue

ly obese patients, and treatment of existing bacterial infection (chronic bronchitis) with culture-specific antibiotics where indicated. Patients with a known tendency for bronchospasm should become accustomed to undergoing bronchodilator treatment preoperatively, and the effect of bronchodilators on pulmonary mechanics should be directly measured, particularly in patients with known bronchospastic disorders (e.g., asthma).

Patients with preexisting lung disease require special consideration beyond the preparation related to bronchospasm or chronic bronchitis (see above). Patients with acute pulmonary insufficiency, increased lung water levels, and atelectasis secondary to an acute disorder such as pancreatitis or sepsis often show improvement during the operation and postoperative mechanical ventilation.

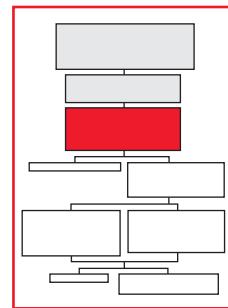

The condition of a patient with severe, chronic obstructive lung disease should be improved as much as possible by means of bronchodilators, treatment of chronic bronchitis (if present), nutritional support, and training in deep breathing. If the pulmonary disorder is very severe (i.e., if $P_{a}O_2$ is less than 50 mm Hg on room air or if CO_2 retention is evident), prolonged postoperative intubation and mechanical ventilation should be anticipated and the patient advised accordingly.

Intraoperative Measures to Prevent Pulmonary Complications

Intraoperatively, several factors may minimize the risk of postoperative pulmonary complications. The operation may directly improve pulmonary function (e.g., by repairing a mitral valve or a large abdominal wall hernia) or may mitigate or eliminate factors that of themselves are causing pulmonary insufficiency (e.g., by draining an empyema, removing a foreign body, or resecting dead tissue).

The operative procedure should be planned so as to simultaneously treat the patient and avoid any factors that may cause postoperative complications. With regard to the pulmonary system, planning includes various components, as follows.

Abdominal incisions should be planned to minimize postoperative pain and to maintain the strength of the abdominal wall for forced inspiration. Transverse incisions should be used whenever possible, particularly in patients with chronic heavy sputum production who will have to cough excessively after operation.

Gastrostomy should be considered to avoid prolonged nasogastric intubation. Bone fragments should be manipulated as gently as possible to prevent possible marrow embolism. Veins under negative pressure (e.g., those in the brain) must be managed carefully to prevent air embolism. If the patient has a history of pulmonary embolism or existing deep vein thrombosis (DVT) in the legs, prophylaxis for these conditions is particularly important.

Ventilation with 100% O_2 before intubation is standard practice, and a fraction of inspired oxygen ($F_{i}O_2$) higher than 90% is commonly used during operation. However, elimination of inert nitrogen in the alveoli leads to absorption atelectasis very rapidly. Accordingly, restoring normal alveolar nitrogen levels and volume through sustained inspiratory pressure with air before extubation is a valuable maneuver.² By the same token, however, maintaining a high $F_{i}O_2$ throughout the operation and during the early postoperative period significantly decreases the risk of a surgical site infection.³

Much of the intraoperative prevention of pulmonary complications is carried out by the anesthesiologist. Maintaining large tidal volume ventilation (10 to 15 ml/kg) at a low respiratory rate during operation helps maintain alveolar inflation. Particularly during long procedures, alveoli begin to collapse unless regularly hyperinflated at least every hour. The anesthesiologist contributes greatly toward preventing pulmonary complications by avoiding crystalloid fluid overload during operation. Blood and protein losses can be replaced intraoperatively with lactated Ringer solution. Generally, blood or plasma lost during operation should be replaced with blood or plasma. Moderate amounts of saline-type solutions are permissible, but caution should be observed.

Mechanical ventilation should be continued postoperatively until adequate spontaneous ventilation has been clearly established. The action of paralytic drugs should be reversed completely, and a voluntary vital capacity at least twice the tidal volume should be documented before extubation.

Postoperative Measures to Prevent Pulmonary Insufficiency**ROUTINE MEASURES**

In the recovery room, the endotracheal tube should be maintained in place as long as is necessary. Patients with preexisting pulmonary dysfunction or those at high risk for pulmonary complications may need to remain intubated and be maintained on mechanical ventilation for hours or days after operation.

Abundant evidence suggests that well-ventilated alveoli are less susceptible to humoral capillary damage than atelectatic alveoli are. Elderly, debilitated patients, patients who have undergone major cardiac procedures, and patients with extensive injuries, multiple fractures, pancreatitis, dead tissue, or severe peritonitis are commonly left intubated and maintained on mechanical ventilation for 12 hours or longer after operation. When the patient is fully alert and awake, when perfusion and cardiac status are stable, and when blood and extracellular fluid volumes are demonstrated to be normal, then the patient is ready for spontaneous ventilation and extubation.

Deep breathing exercises, clearing of sputum and mucus, and avoidance of prolonged periods in the supine position must begin in the recovery room. Profound hypoventilation, ventilation-perfusion imbalance, and resultant hypoxemia are the rule in patients awakening from anesthesia. For this reason, it is common practice to administer moderate amounts (5 to 10 L/min) of supplemental oxygen to all patients in the recovery room. This is a wise precaution

tion for the first hour or two after anesthesia, but it is really prophylactic only against hypoxic arrhythmias, and it may actually impair lung function by suppressing whatever deep breathing may result from moderate hypoxemia. Consequently, supplemental oxygen should not be administered for more than a few hours unless serial blood gas analyses so dictate.

Airway cleaning, suctioning, expectorant drugs, mist inhalation, and mucolytic agents are all useful in patients with preexisting chronic bronchitis or thick, tenacious tracheobronchial secretions. However, these maneuvers and agents may not be necessary in patients who can inflate their lungs adequately by means of inspiratory maneuvers. In the past, a compulsion to force patients to cough dominated much of the thinking on postoperative pulmonary care. Currently, it is generally recognized that coughing maneuvers are painful in thoracotomy or laparotomy patients and should not be necessary if the lung remains well ventilated.

Breathing maneuvers and devices designed to encourage those maneuvers are important adjuncts to postoperative care. Because shallow breathing, the lack of spontaneous deep breaths, and alveolar collapse are the steps that lead to postoperative pulmonary complications, respiratory maneuvers must emphasize maximal lung inflation. Emphasis on breathing out (i.e., with coughing, tracheal stimulation, or so-called blow bottles) does nothing to accomplish alveolar inflation, aside from the preparatory inspiration the patient may take beforehand. The greater the emphasis placed on inhaled volume and inspiratory pressure, the more effective the maneuver will be.

Routine IPPB is not particularly effective in preventing pulmonary complications.⁴ This does not mean that IPPB is not a useful treatment method. On the contrary, it is quite useful for patients who are severely obtunded, those who are too weak to carry out spontaneous breathing maneuvers, and those with already established atelectasis. In such circumstances, however, the device should be used frequently (preferably each hour) and monitored by direct measurement of exhaled volumes, with maximum volume inflation attempted with each breath.

Deep inspiratory maneuvers can be done spontaneously or with the aid of a nurse or physical therapist but are better done with the aid of the incentive spirometer. This device allows the patient to see the inspired volume with each breath, thereby assuring the physician, the nurse, the respiratory therapist, and the patient that the maneuver is being done correctly and frequently enough to maintain alveolar inflation. Regular performance of deep breathing exercises using an incentive spirometer can decrease the incidence of pulmonary complications from about 30% to about 10%.⁵

Another method of preventing postoperative atelectasis is the application of continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP) with a tight-fitting face mask. The potential complications of mask CPAP—gastric distension, vomiting and aspiration, and patient discomfort—are rare but remain a cause for concern. This technique, perhaps combined with mask IPPB, may prove useful in patients who are extubated but cannot or will not breathe deeply.

Whatever method is used to accomplish maximal inflation after operation must be carefully taught to the patient before the procedure: most patients cannot learn breathing exercises in a painful, narcotized, postoperative state.

For patients requiring care in an ICU, keeping the head of the bed elevated at least 30° significantly decreases the risk of developing ventilator-associated pneumonia.⁶⁻⁸ Accordingly, unless

there is a contraindication (e.g., spinal fracture), semirecumbent positioning should be employed routinely. Frequent change of position and early ambulation will minimize fluid collection in the dependent portions of the lung. Postoperative nutrition should be maintained [see 8:23 *Nutritional Support*]. If the patient must go without oral intake for more than 4 or 5 days, total parenteral nutrition is advisable for several reasons, not the least of which is to maintain the strength of the respiratory effort. Fluids must be managed carefully to avoid overloading the extracellular space and diluting the serum proteins.

Pulmonary thromboembolism from the deep veins of the leg or the pelvis is a constant threat after operation [see 6:6 *Venous Thromboembolism*]. Patients older than 40 years and patients with cancer are at particularly high risk. Several methods are used to prevent DVT, including anticoagulation, pharmacologic inhibition of platelet function, and application of pressure to the legs with plastic wraps or stockings. Regular muscle exercise is the easiest preventive maneuver, has the fewest complications, and is advised for all postoperative patients.

MEASURES IN PATIENTS WITH PREEXISTING LUNG DISEASE

Patients with chronic disease of the airways or the pulmonary parenchyma have less pulmonary reserve; consequently, in these patients, acute respiratory failure may develop after a minimal insult to the lung. The patient with emphysema or asthma presents an interesting problem. Because of the primary disease, residual volume and FRC are abnormally expanded. The patient is protected to some extent against alveolar collapse secondary to shallow breathing; however, the involved alveoli are difficult to ventilate, even with maximal effort. The dead space is abnormally large, so that the minute ventilation must be higher than normal just to achieve normal CO₂ excretion. In addition, alveolar destruction, fibrosis, or bullae may be present, decreasing oxygenation as well as CO₂ excretion. The effect of shallow breathing in such a patient will not be atelectasis, as would occur with a normal lung, but rather CO₂ retention and hypoxemia. Supplemental oxygen may reverse the hypoxemia, but CO₂ narcosis may result, particularly if the patient is also sedated with narcotics or anesthetics.

Chronic bronchitis (daily production of purulent sputum) narrows the small airways, increasing susceptibility to inadequate inflation and alveolar collapse. Heavy cigarette smoking has the same effect. In these conditions, treating the airways before elective operation (with antibiotics or cessation of smoking) is advisable. Severe restrictive disease from pulmonary fibrosis, pleural thickening, fibrosis, or chest wall deformities predisposes to atelectasis.

Patients with acute respiratory failure may require operation; in fact, the respiratory failure may exist because of the indication for operation (e.g., abscess, ischemic tissue, or long bone fractures). Such patients come to operation with a decreased FRC and increased pulmonary water, following the pathogenetic sequence of acute respiratory failure [see Discussion, Pathogenesis of Postoperative Pulmonary Insufficiency, below]. The pulmonary problem may be mitigated or eliminated by the operation itself (e.g., when pus is drained or a fracture immobilized), but even if pulmonary function does not improve, these patients cannot afford any worsening of alveolar collapse or pulmonary edema. In such patients, further deterioration of pulmonary function must be prevented by means of prolonged postoperative intubation and mechanical ventilation and fine-tuning of hydrostatic pressure and colloid osmotic pressure in relation to cardiac output and blood volume.

Clinical Presentation of Postoperative Pulmonary Insufficiency

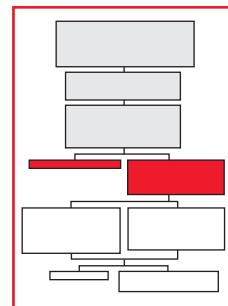

At any time during the first week after a major operation, a patient may manifest dyspnea, tachypnea, tachycardia, confusion, and cyanosis—the syndrome of pulmonary insufficiency. Although the most likely causes of this syndrome are atelectasis and edema, the first step in evaluation is to rule out mechanical limitation of breathing, acute bronchospasm (asthma), pulmonary thromboembolism, congestive heart failure, and hypovolemia.

Mechanical limitation of breathing may be caused by gastric or intestinal distention, ascites, pneumothorax, hydrothorax, or splinting of the chest wall to treat pain or rib fractures. It is diagnosed by physical examination and chest x-ray and treated by removing the limitation.

Bronchospasm occurs in patients with a history of asthma. The diagnosis is made by finding wheezes on physical examination and hyperinflation on x-ray. Treatment consists of bronchodilators.

Pulmonary embolism is the first consideration when the onset of pulmonary insufficiency is sudden, but it is the least common cause. Small (lobar) pulmonary emboli rarely cause symptoms. A patient who is symptomatic from embolism has had a major embolus (or a series of minor emboli) occluding more than 50% of the pulmonary circulation. It is usually easy to differentiate pulmonary embolism from atelectasis on the basis of clinical examination and blood gas measurements [see Table 3].

Congestive heart failure in the postoperative period may be either an exacerbation of a chronic condition or acute cardiac failure secondary to myocardial infarction. In either case, the diagnosis is made by physical and x-ray examination of the chest. In the patient who is fluid overloaded, the use of a pulmonary arterial catheter may be required to differentiate cardiogenic from capillary-injury pulmonary edema. The initial steps in management are the same, however, for the acutely ill patient: diuresis, supplement-

tal oxygen, review of body weight and fluid balance records, and transfer to the ICU for more invasive monitoring.

Hypovolemia is often first manifested by dyspnea associated with metabolic acidosis, and postoperative shortness of breath should always raise the possibility of occult bleeding or third-space sequestration. Clinical examination elicits findings typical of hypovolemia. The chest x-ray is usually clear, and blood gases demonstrate normal oxygenation and CO₂ clearance with metabolic acidosis.

In postoperative pulmonary insufficiency caused by atelectasis and edema, physical examination shows diminished breath sounds over one or both lung bases. Rales and rhonchi may be heard in the middle and lower lung fields. Although tidal volume is normal, vital capacity (judged or actually measured) is abnormally small. Chest x-ray demonstrates incomplete lung inflation, usually with overt collapse or consolidation apparent in the lower lobes. If lung edema is the predominant cause of pulmonary insufficiency, a diffuse increase in lung density is seen, which, when combined with irregular inflation, is often described as diffuse fluffy infiltrates. This radiographic finding will usually differentiate this state from cardiogenic pulmonary edema, which is typically more apparent in the lower and middle lung fields when the x-ray is taken with the patient sitting or standing. Measurement of arterial blood gas values while the patient is breathing air demonstrate hypoxemia, hypocapnia, and respiratory alkalosis.

Supplemental high-flow oxygen (10 L/min) supplied by nasal catheter or face mask supplies approximately 40% inspired oxygen (regardless of the settings on the equipment). Supplemental oxygen substantially mitigates the hypoxemia resulting from ventilation-perfusion mismatch, pulmonary embolism, or cardiogenic pulmonary edema, typically resulting in a P_aO₂ greater than 150 mm Hg. In contrast, supplemental oxygen has a minor effect on hypoxemia caused by atelectasis, yielding a P_aO₂ typically rising from the 40s to the 80s. Fever and mild leukocytosis often accompany atelectasis, and the differential diagnosis between atelectasis and pneumonia is based primarily on con-

Table 3 Differential Diagnosis of Postoperative Dyspnea

	Atelectasis/ Edema	Pulmonary Embolism	Bronchospasm	Congestive Heart Failure
Lung bases	Not aerated	Clear	Wheezes	Rales
Chest x-ray	Consolidation, general edema	Clear ↑ Diameter of main pulmonary artery	Hyperinflated	Hydrostatic edema ↑ Diameter of main pulmonary artery
Central venous pressure	Normal	Elevated	Normal	Elevated
Pulmonary arterial wedge pressure	Normal	Normal or low	Normal or high	High
Arterial P _O ₂ (breathing air) (mm Hg)	40–60	40–80	70–90	40–60
Arterial P _O ₂ (breathing O ₂) (mm Hg)	50–100	100–300	200–300	100–300

Pulmonary angiogram	Normal	Diagnostic	Normal	Normal

tinuing signs of infection without another obvious source, combined with pathogenic organisms on sputum culture. Thickened or copious bronchial secretions may be present in any patient after operation, particularly if the patient underwent endotracheal intubation, general anesthesia, or both during the procedure. Bronchial secretions are neither the cause nor the result of atelectasis. However, sputum samples for a Gram stain and culture should be acquired from every patient with pulmonary complications.

Treatment of Postoperative Pulmonary Insufficiency Caused by Atelectasis or Edema

GENERAL SUPPORT

Beginning during the preliminary clinical and laboratory examinations and the differential diagnosis, supplemental oxygen should be supplied by nasal catheter or face mask at a rate of 10 L/min. If the patient has a history of severe pulmonary disease with hypoxemia and hypercarbia, preoperative supplemental oxygen may correct the hypoxemia but diminish the respiratory drive and result in CO₂ narcosis; accordingly, special precautions should be taken. The patient should be positioned so as to maximize diaphragmatic excursion—that is, sitting but not hunched forward, with care taken to ensure that the stomach and the abdomen are not distended.

TREATMENT OF ATELECTASIS

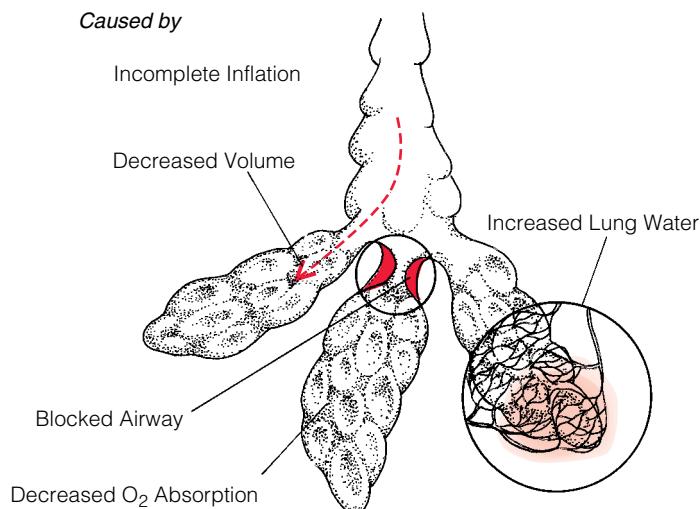

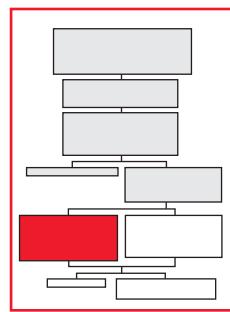

The cornerstone of treatment aimed at alveolar inflation [see *Figure 1*] is to establish large-volume inflation by instituting deep breathing exercises. The patient should be taught to carry out a sustained maximal inspiration (basically a yawn maneuver); as noted, an incentive spirometer will encourage and quantitate the patient's efforts. If adequate volumes cannot be generated in this manner, mechanical assistance is necessary—initially with IPPB with a mechanical ventilator, without intubation. This step must be done with direct measurement of exhaled volume, and it often requires high pressures (30 to 40 cm H₂O) with the IPPB device. All of the inflation techniques of mechanical ventilation (positive end-expiratory pressure [PEEP], sighs, inspiratory hold, CPAP) can be used in nonintubated patients. Again, coughing is not a treatment for pulmonary insufficiency: forced expiration collapses alveoli, does not clear small airways, and is painful and ineffective in the postoperative patient.

When an area of lung is not ventilated, mucus secreted in the bronchi draining from that lung segment may become thickened and impacted, hindering efforts at reexpansion. Chest physical therapy (percussion) and postural drainage should clear this mucus. Hydration and nebulized bronchodilator and mucolytic drugs may be used as well. Although coughing is not effective in preventing atelectasis, it is necessary for expelling mucus from airways that have been inflated distally. Coughing will not dislodge mucus from airways leading to nonventilated areas of lung. In this situation, mucus must be removed directly with tracheal suction or bronchoscopy, preferably the latter.

Tracheal suctioning exacerbates hypoxia if not done properly. The catheter is inserted through the nose, passed through the larynx (with passage confirmed by a change in voice), and connected to oxygen administered at 5 L/min. Then, 5 ml of saline

is injected, and the oxygen is reconnected for several coughing breaths. Suction is applied for no longer than 10 seconds, after which oxygen is resumed. This process is repeated until the suction return is clear (1 to 5 minutes). Electrocardiographic monitoring should be done during and after suctioning. Atropine is given for bradycardia. In adults, the primary value of this technique is the stimulation of deep breathing associated with the vigorous coughing that it induces. However, deep breathing can be easily accomplished by other means without the potential vagal complications associated with tracheal suctioning. Thus, routine tracheal suctioning has no rational place in the care of postoperative adult patients. In infants, who have much narrower airways, even a very small amount of mucus may suffice to cause major tracheal or bronchial occlusion. Infants breathe rapidly, with large ventilation of the dead space; thus, their tracheal secretions tend to dry out, and they may have difficulty coughing material from the lower trachea or from the bronchi. Consequently, endotracheal suctioning can be valuable for infants who have undergone operations on the thorax or the upper abdomen.

ALVEOLAR COLLAPSE

Caused by

- Incomplete Inflation
- Decreased Volume
- Increased Lung Water
- Blocked Airway
- Decreased O₂ Absorption

Leads to

- Ventilation-Perfusion Imbalance
- Hypoxemia
- Decreased FRC
- Decreased Compliance
- Increased Work

Treatment:

- Maximum Inflation
- Yawn, Mechanical Ventilator, IPPB, CPAP
- Maintain Lowest Possible F_iO₂
- Decrease Lung Water
- Treat Infection
- Optimize Nutrition

Figure 1 Illustrated are causes and effects of alveolar collapse in postoperative pulmonary insufficiency.

Flexible fiberoptic bronchoscopy is preferable to blind tracheal suctioning in the management of atelectasis. Bronchoscopy is performed to examine the airways and clear mucus from the atelectatic area. Use of the endotracheal tube facilitates repeated removal and reinsertion of the bronchoscope, which may be necessary if mucus is too thick to be aspirated through the small suction lumen.

If adequate ventilation cannot be established with these methods, respiratory support is warranted. In many cases, endotracheal intubation can be avoided by using noninvasive mechanical ventilation.⁹⁻¹¹ Mechanical ventilation is indicated if the respiratory rate is consistently higher than 30 breaths/min or if the patient is severely hypoxic (oxygen saturation < 92% despite supplemental oxygen via nasal cannula or face mask). If either of these indications cannot be reversed by the measures described, intubation and mechanical ventilation are carried out. Intubation with spontaneous breathing and CPAP (5 to 10 cm H₂O) without mechanical ventilation are standard therapy for the respiratory distress syndrome of the newborn and are commonly employed when that syndrome is complicated by a surgical procedure. CPAP may be useful in some adults with respiratory insufficiency associated with absence of surfactant. Generally, if the patient requires intubation, mechanical ventilation is also indicated.

If supplemental oxygen has been instituted as general support, the amount of oxygen should be kept as low as possible to avoid displacing nitrogen from alveoli and causing absorption atelectasis. Nutritional support should be instituted to achieve a positive nitrogen balance so as to maintain respiratory muscle strength and optimize host defenses. To prevent overfeeding, the amount of nutrients given should be based on measured energy expenditure. Overfeeding with carbohydrate causes an excess CO₂ load that may exacerbate pulmonary insufficiency.

TREATMENT OF EDEMA

The amount of lung water can be reduced by decreasing the entire extracellular fluid space, decreasing the hydrostatic pressure in the pulmonary capillary bed, and increasing plasma oncotic pressure without increasing oncotic pressure in the interstitial fluid of the lung [see Figure 2]. Mechanical positive pressure ventilation is not a means of decreasing lung water. In fact, positive pressure ventilation with PEEP actually increases lung water slightly, probably by stretching the pulmonary tissue.¹² Mechanical ventilation improves gas exchange in patients with pulmonary edema by overcoming the ventilation-perfusion mismatch associated with bronchodilators or alveolar thickening, but it does not decrease lung water itself.

Patients with simple atelectasis need no treatment for increased lung water other than avoidance of fluid overload and cardiac failure. Increased lung water warrants treatment when diffuse interstitial fluid collection is evident from x-rays and the hospital course. For example, patients who have had an episode of severe systemic infection, disseminated intravascular coagulation, or fat embolism; those with peritonitis; those experiencing revascularization of ischemic tissue; and those who received 4 L of lactated Ringer solution during a 3-hour operation are likely to have increased lung water in association with other pulmonary problems.

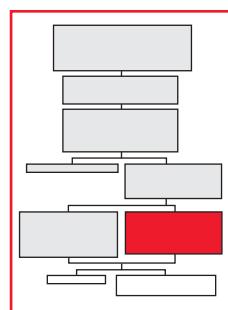

Total extracellular fluid volume is reduced by forced diuresis (or, if the patient is in renal failure, by dialysis or hemofiltration).

Diuresis is induced with a potent agent such as furosemide. The course of diuresis is followed with careful daily measurement of body weight and hourly measurement of fluid intake and output. Usually, a patient with postoperative pulmonary insufficiency is 4 to 5 kg overloaded, primarily with extracellular fluid.

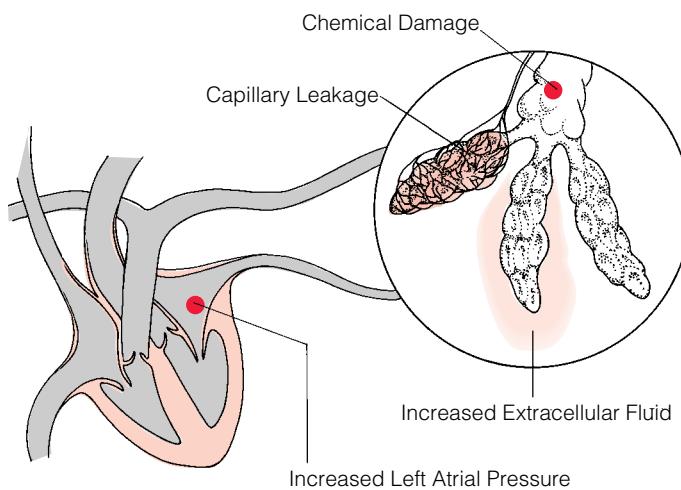

Adequate treatment of increased lung water must include removing excess extravascular fluid (i.e., returning the patient to baseline weight). Diuresis is continued until the patient is close to dry weight and is maintained in this condition. The major decrease in total extracellular fluid volume is accompanied by a minor decrease in pulmonary extracellular fluid volume, but this change is usually enough to improve pulmonary function greatly. Diuretic drugs remove water, sodium, and potassium at differing rates; thus, all of these must be monitored carefully and frequently. Usually, more water is removed than electrolytes, so that extreme forced diuresis leads to a hypernatremic, hyperosmotic state. Serum sodium concentrations should be monitored closely: when they are between 145 and 150 mEq/L, diuresis has reached its limit.

Diuresis concentrates serum proteins, increasing oncotic pressure. It should be combined with colloid loading to further increase plasma oncotic pressure transiently, thereby forcing

INCREASED LUNG WATER

Caused by

Leads to

- Increased Pulmonary Vascular Resistance
- Decreased FRC
- Ventilation-Perfusion Imbalance
- Infection

Treatment:

- Decrease Extracellular Fluid through Diuresis and Decreased Intake
- Increase Plasma Oncotic Pressure
- Treat Capillaries
- Decrease Hydrostatic Pressure

Figure 2 Illustrated are causes and effects of increased lung water in postoperative pulmonary insufficiency.

fluid to move from the extravascular to the intravascular space. Diuresis and colloid loading should be done concomitantly because most agents used for colloid loading (e.g., albumin) have a molecular weight between 50 and 100 kd and will gradually find their way into the extracellular space within 4 to 12 hours of infusion. The advantages of colloid loading come during the first hour or two after infusion and before the colloid load joins the lymphatic system and is metabolized. Although some studies suggest a deleterious effect from albumin loading in this setting, treatment of individuals with colloid loading (and diuresis) is usually highly successful.^{13,14} The technique should be used when capillary integrity has been restored, as determined by response to small initial doses.

Decreasing pulmonary hydrostatic pressure by improving left ventricular function is accomplished pharmacologically; it can and should be done in all patients with major pulmonary insufficiency. A short-acting inotrope (e.g., dopamine) is preferred. The effectiveness of this treatment can be determined only through direct measurement of cardiac output and left atrial (or pulmonary capillary wedge) pressure, for which insertion of a pulmonary arterial catheter is required. Pulmonary arterial pressure monitoring and mixed venous blood sampling are as important as direct arterial blood gas sampling in managing patients with pulmonary insufficiency who have a major increase in lung water. The exact position of the catheter must be carefully determined and the pressure tracings properly interpreted; continuous display on an oscilloscope and careful selection of the end-expiratory point for pressure readings are required.

An effort should be made to establish and maintain normal pulmonary capillary permeability. The most common cause of pulmonary capillary leakage or ARDS is infection or inflammation at a site distant from the lungs. Any postoperative pulmonary insufficiency should trigger a search for wound infection, deep abscess, pancreatitis, and septic phlebitis. Drugs that inhibit the inflammatory response, block mediators of capillary injury, or prevent fibrosis have been investigated for the prevention or treatment of ARDS. Corticosteroids definitely diminish the inflammatory response and appear to be effective against some disorders (e.g., fat embolism), but they have not been confirmed as effective in randomized trials.¹⁵ Drugs such as cyclooxygenase inhibitors, which block production of inflammatory mediators more specifically than steroids do, have been studied.¹⁶ Drugs that inhibit the action of specific mediators—such as antihistamines, superoxide dismutase,¹⁷ catalase, and ketoconazole¹⁸—have been investigated, but none have proved effective in clinical trials.

Progression to Pneumonia, Intubation, or ARDS

Bacterial infection often complicates atelectasis and edema, and it may occur as a primary event after operation. The progression from atelectasis to pneumonia can be difficult to identify because pulmonary infiltration and consolidation, fever, leukocytosis, and sputum production occur in both conditions. This differential diagnosis is one of the most difficult in postoperative

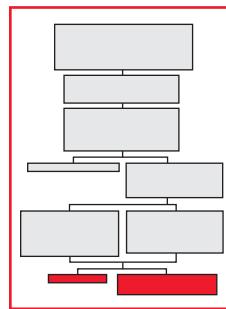

Table 4 Empirical Antibiotic Regimens for Postoperative Pneumonia

Patient Status	Likely Organisms	Empirical Antibiotics
Normal postoperative patients	Pharyngeal organisms; staphylococci; enterococci	Core combination (quinolone plus aminoglycoside)
Postoperative patients with aspirated gastric contents in association with operation	Pharyngeal organisms plus gram-negative organisms and <i>Candida</i>	Core combination plus fluconazole
Immunocompromised patients	Pharyngeal organisms plus <i>Candida</i> and methicillin-resistant staphylococci	Core combination plus vancomycin or fluconazole
Patients with chronic pulmonary infection	Gram-negative organisms (especially <i>Pseudomonas</i> and <i>Klebsiella</i>)	Aminoglycoside plus antipseudomonal agent

care; decisions must be based on repeated examination of the patient and the sputum or bronchoalveolar lavage fluid.

In patients with no preexisting lung disease, the organisms that most commonly cause early (first 3 days) postoperative bacterial pneumonia come from the pharynx during the operation: staphylococci, enterococci, or gram-negative bacteria. The same organisms invariably invade the lower airway in chronically intubated ICU patients. Rarely, streptococcal pneumonia occurs in the postoperative period if the pharynx was colonized at the time of the operation. *Candida* is commonly found in the pharynx but rarely causes pneumonia except in immunosuppressed hosts. Treatment for presumed early postoperative pneumonia includes vigorously treating the edema and atelectasis and giving empirical antibiotics. A Gram stain of the sputum will show the common pharyngeal flora but occasionally identifies one predominant organism, the presence of which guides selection of antibiotics while cultures are pending. Usually, however, the Gram stain is not definitive, and antibiotic treatment is therefore selected to cover the most common bacteria.

In patients with preexisting lung disease (emphysema) or lung infection (bronchitis, cystic fibrosis), pneumonia is usually caused by overgrowth of the bacteria already present in the lower airway. Gram-negative organisms predominate. In this circumstance, it is wise to culture a tracheal aspirate sample at the time of operation and to give culture-specific antibiotics if pneumonia occurs. Several choices for empirical antibiotic coverage for postoperative pneumonia are available [see Table 4].

The combination of atelectasis, edema, and pneumonia may necessitate intubation and mechanical ventilation. The subjective findings of dyspnea and confusion, combined with the objective findings of tachypnea and cyanosis, usually trigger ICU transfer, careful monitoring, and intubation. More precise indicators of the need for intubation and ventilation include (1) respiratory rate higher than 30/min; (2) arterial oxygen saturation (S_aO_2) lower than 92% on supplemental O₂; (3) $P_{a}CO_2$ higher than 45 mm Hg; (4) inspiratory force less than 20 cm H₂O; and (5) vital capacity less than twice tidal volume. Management of severe respiratory failure is discussed more fully elsewhere [see 8:5 Mechanical Ventilator].

Discussion

Normal Pulmonary Physiology

VENTILATION AND PULMONARY MECHANICS

The term pulmonary mechanics refers to the gas volumes in the chest and the gas flow rates during forced inspiration and exhalation. These values are depicted in a normal spirogram [see Figure 3]. As noted, FRC is approximately 2 L in a normal adult. During tidal breathing, the patient inhales about 500 ml, then exhales back to FRC. During a maximal inspiratory maneuver, the patient inhales to total lung capacity (typically twice the FRC). During pulmonary function testing to measure gas flow and volume, the patient inhales to total lung capacity, then breathes out as hard and fast as possible. The volume that the patient exhales is referred to as the forced expiratory volume or vital capacity. The rate at which the gas is exhaled is measured as the timed vital capacity, or the maximal midexpiratory flow rate. The volume of tidal breaths multiplied by the respiratory rate yields the minute ventilation (typically 8 L/min in a normal adult). Approximately one third of this ventilation passes through the conducting airways (dead space), and two thirds reaches the alveoli, where gas exchange takes place. Inspiration occurs when the diaphragm contracts, generating an intrapleural pressure that is negative relative to the atmosphere and resulting in the influx of air through the airway into the alveoli. Exhalation is largely a passive event, involving relaxation of the diaphragm and the accessory muscles of inspiration. Forced expiration requires the exertion of effort by the abdominal muscles.

The relation between gas volume and alveolar inflating pressure is referred to as pulmonary compliance [see Figure 4]. During diaphragmatic contraction, beginning at FRC, an intrapleural pressure of -10 cm H₂O is generated, which results in inspiration. During normal breathing, an inspiratory pressure of -5 to -10 cm H₂O results in inhalation of 500 to 1,000 ml. During forced inhalation against an open airway, intrathoracic pressures of -40 to -50 cm H₂O can be generated, resulting in inhalation to total lung capacity. Exhalation back to atmospheric pressure returns gas volume in the chest to FRC. An inspiratory pressure greater than -40 cm H₂O during spontaneous breathing (or greater than 40 cm

H₂O during mechanical ventilation) causes overdistention of alveoli, stretching of alveolar capillaries, interstitial and pulmonary edema, and potentially severe lung injury.

Compliance relationships obviously depend on the size of the patient [see Figure 4]. The actual volumes for FRC, tidal volume, and total lung capacity related to inflating pressure are low for infants, children, and small adults and relatively high for normal large adults. Patients with alveolar collapse, atelectasis, or interstitial pneumonia have an abnormally small FRC; consequently, their compliance characteristics tend to resemble those of a child. Under these circumstances, if a normal inflating tidal volume is used for such adult patients, high pressures are reached, overstretching occurs, and lung injury results.¹⁹

Minute ventilation (rate and depth of breathing) is controlled by the respiratory center in the brain stem to maintain P_aCO₂ at 40 mm Hg. By definition and in practice, hypoventilation results in a P_aCO₂ higher than 40 mm Hg and hyperventilation in a P_aCO₂ lower than 40 mm Hg. If a patient is hypermetabolic because of exercise or fever, excess CO₂ is produced, and minute ventilation increases proportionately to keep the P_aCO₂ at 40 mm Hg.

GAS EXCHANGE

Although O₂ exchange and CO₂ exchange occur simultaneously and at the same place in the lung, it is worthwhile to consider CO₂ clearance and O₂ uptake as if they were separate physiologic events. CO₂, being highly soluble in water and very diffusible, is readily eliminated from the pulmonary capillary blood to the alveolar gas space, even though the driving gradient is only about 45 mm Hg. The amount of CO₂ removed depends on the amount of alveolar ventilation [see Figure 5]. Minute ventilation (and hence alveolar ventilation) is regulated to remove all metabolically produced CO₂ each minute. Dissolved CO₂ combines with water to become carbonic acid (H₂CO₃), which is in equilibrium with the bicarbonate (HCO₃⁻) in blood at a definite ratio. As long as this ratio is 1:20, the pH will be 7.4 (the Henderson-Hasselbalch equation). In postoperative patients, hypoventilation can be caused by respiratory-depressing drugs (e.g., narcotics and anesthetics), paralysis or

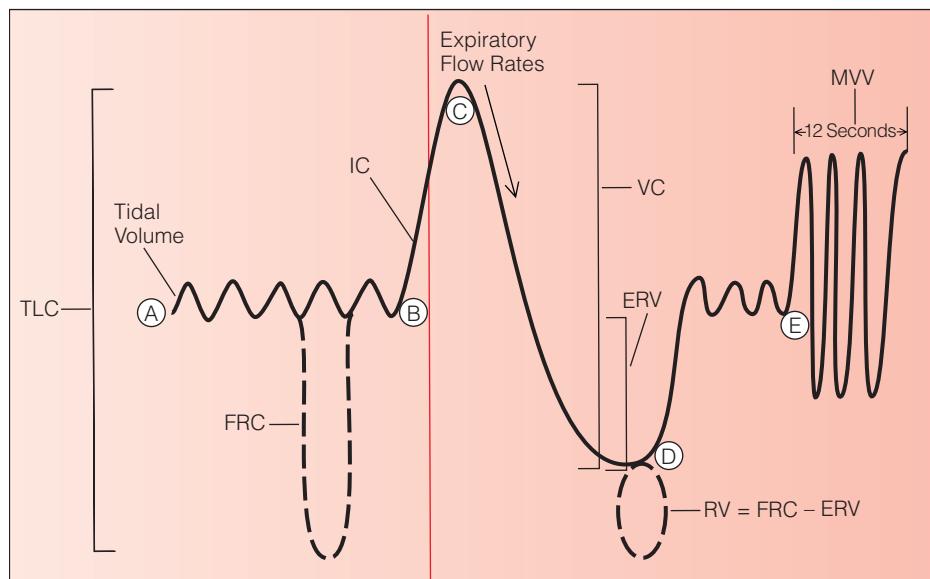

Figure 3 Depicted are gas volume and flow as demonstrated by spirometry. The subject is instructed to (A) breathe normally, (B) inhale as much as possible, (C) blow out as hard and fast as possible, (D) breathe normally, and (E) breathe as hard and fast as possible for 12 seconds. FRC is measured by a separate test, and residual volume (RV) is determined by subtracting expiratory reserve volume (ERV) from FRC.¹ (TLC—total lung capacity; IC—inspiratory capacity; VC—vital capacity)

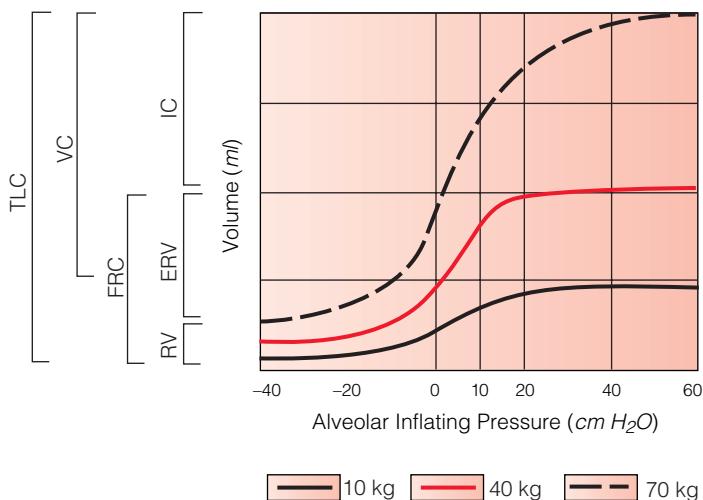

Figure 4 Shown are volume-pressure curves for three subjects. Compliance is quantified as volume per inflating pressure normalized to body size ($80 \text{ ml/cm H}_2\text{O/kg}$). Regardless of subject size, total lung capacity is reached at $40 \text{ cm H}_2\text{O}$.¹

weakness, obesity, and gastric distention, all of which result in CO_2 retention and respiratory acidosis.

Oxygenation of the blood depends more on matching of perfused alveoli to inflated alveoli than on minute ventilation. Under normal conditions, as long as inhaled alveolar gas contains at least 20% oxygen, red blood cells are fully oxygenated and exit the pulmonary capillaries at 100% saturation. During hypoventilation, the concentration of inspired oxygen in the alveoli does not reach 20% unless supplemental oxygen is given at the upper airway. In the recovery room, it is common practice to give supplemental oxygen; thus, a patient may be severely hypoventilated but remain fully oxygenated. The gradient for oxygen transfer from alveolar gas to red blood cells is much higher than that for CO_2 clearance. In a patient breathing room air, the oxygen tension (PO_2) in inhaled gas is approximately 150 mm Hg, and PO_2 in pulmonary capillary blood is approximately 40 mm Hg. Hence, the red cells are oxygenated during a single pass through the pulmonary capillary network. Oxygen in the blood is commonly measured in terms of either saturation (SO_2) or PO_2 , but the most useful measure is actually oxygen content (Co_2) because that is the major determinant of oxygen delivery at the tissue level. It is noteworthy that when CO_2 is plotted against SO_2 and PO_2 at different levels of hemoglobin concentration [see Figure 6], blood that is severely hypoxic because of anemia still exhibits normal SO_2 and PO_2 .

Factors that impair oxygen delivery to blood include hypoventilation causing ventilation-perfusion mismatch, diffusion block caused by chronic lung disease with fibrosis in the interstitial space, and complete atelectasis resulting in transpulmonary shunting of blood from the pulmonary arterial circulation to the venous circulation without participating in gas exchange. The first two generic causes of hypoxemia can be completely corrected by supplemental oxygen breathing, but supplemental oxygen has very little effect on oxygenation when the problem is caused by a transpulmonary shunt.

Pathogenesis of Postoperative Pulmonary Insufficiency

CHANGES IN LUNG FUNCTION

After any major operation, changes occur in lung function. These changes occur in all patients but are not detected on routine exam-

ination. Aside from shallow tidal ventilation and some decreased breath sounds at the lung bases, the patient shows no signs of respiratory abnormality. On direct measurement, lung volumes are decreased (particularly residual volume, expiratory reserve volume, FRC, and vital capacity). Compliance is decreased because of the decrease in FRC. The work of breathing is increased for the same reason: more pressure is required to inhale a given volume into the decreased lung air space. Further evidence that alveoli are not being ventilated is absolute or relative arterial hypoxemia, which occurs with the patient breathing room air or 100% oxygen, indicating that nonventilated alveoli are being perfused (transpulmonary shunting).

These changes in lung function are present immediately after operation, progress slowly over 1 to 2 days, and then return to normal in most patients [see Figure 7]. The extent and duration of abnormality are related to the site of operation, the duration of operation and anesthesia, the quality of postoperative care, and preexisting pulmonary status.

The extent and duration of postoperative pulmonary abnormalities are greatest for operations on the thorax and upper abdomen and progressively decrease as the site of operation moves more distally and more superficially on the body structures. These changes may occur after only 1 to 2 hours of general anesthesia if careful attention is not paid to maximal lung inflation during anesthesia. They are superimposed on the patient's preexisting lung status. If, for example, the patient requires operation for complication of pancreatitis 2 weeks after the onset of disease, he or she may already have pleural effusions, increased pulmonary capillary permeability, and existing transpulmonary shunting and thus may be unable to tolerate any further deterioration of lung function. Likewise, if the patient has preexisting chronic obstructive lung disease with high airway resistance, maximal work of breathing, and minimal functional lung tissue before operation, CO_2 retention may develop if the work of breathing is even slightly increased after the procedure. Advanced age per se does not cause lung dysfunction, but elderly patients may have chronic lung disease or cardiac disease and thus be at higher risk for pulmonary failure. More important, elderly patients may be weak, and weak respiratory muscles predispose to alveolar collapse.

Several factors contribute to these changes in pulmonary function, but shallow breathing with incomplete alveolar inflation is the common denominator. If spontaneous deep breaths to maximal

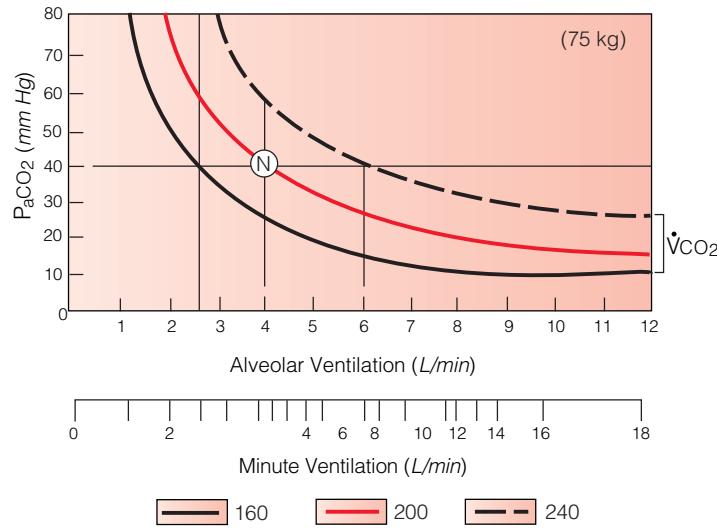

Figure 5 Illustrated is CO_2 excretion ($\dot{V}\text{CO}_2$) related to ventilation for a typical 75 kg adult subject (N = normal).¹

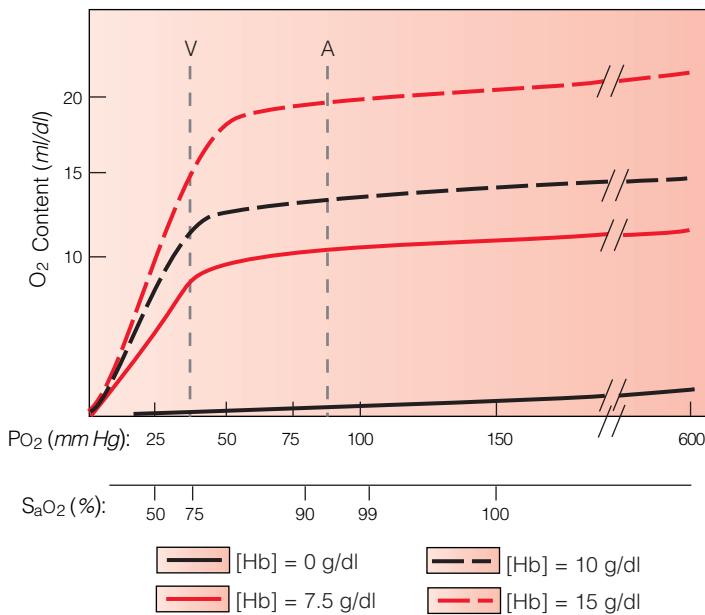

Figure 6 Shown is measurement of oxygen content in blood at four levels of hemoglobin (Hb) concentration. Dotted lines show values for arterial (A) and venous (V) blood. There is much more oxygen in normal venous blood with a PO₂ of 40 mm Hg than there is in anemic arterial blood with a PO₂ of 150 mm Hg.¹

lung inflation are eliminated from the pattern of breathing, alveolar collapse begins within 1 hour and progresses rapidly to produce significant transpulmonary shunting. Several studies have shown that because of severe pain, anesthetics, or narcotic drugs, postoperative patients often lack the normal pattern of spontaneous deep breaths.^{4,20} This finding is further supported by the observation that the postoperative changes in lung function can be returned toward normal by instituting maximal-inflation deep breathing exercises at regular intervals.⁵ Excessive tracheobronchial secretions, aspiration of oral or gastric contents, and intraoperative fluid overload or blood transfusion may also contribute to postoperative changes in lung function.

The effects of an increased F_iO₂ and nitrogen washout are important to consider. The higher the concentration of oxygen in the alveoli, the lower the concentration of nitrogen. Nitrogen accounts for 80% of alveolar gas. Because nitrogen is inert, it merely occupies space, holding alveoli open as O₂ and CO₂ are rapidly exchanged during each breath. When nitrogen is washed out during O₂ breathing, alveoli tend to decrease in volume or collapse altogether with each breath. Major atelectasis can occur with just a few minutes of 100% O₂ breathing. In one study,² chest CT scans during O₂ breathing demonstrated major atelectasis occurring within minutes [see Figure 8]. Because a high F_iO₂ is commonly (and correctly) used during anesthesia with inhalational agents, it is important to minimize the risk of postoperative atelectasis through frequent recruitment of collapsed alveoli by inflation to total lung capacity and restoration of alveolar nitrogen at the end of the operation.

If the pattern of decreased lung volume and shunting is progressing rather than returning to normal, this development becomes clinically evident within 2 to 4 days after operation [see Figure 7]. Decreased lung volume is detectable as decreased breath sounds on physical examination, and atelectatic areas may be visible on chest x-ray. Shunt-produced hypoxemia leads to an increased ventilatory rate and the sensation of dyspnea.

Severe hypoxemia may cause cyanosis. Atelectasis causes fever and pooling of mucus secretions in nonventilated areas, leading to

an apparent increase in sputum production. Against the background of the changes that normally accompany major operations, a more complete picture of pulmonary pathophysiology in the surgical patient can be drawn.

As noted, abnormal ventilation leads to altered pulmonary function; the abnormal pattern of tidal breathing without spontaneous deep breaths after operation is a good example of this phenomenon. A patient supine in bed preferentially ventilates the anterior superior lobes while blood preferentially flows to the posterior dependent lobes. This ventilation-perfusion imbalance itself will result in hypoxemia. If it progresses over time, lower-lobe alveoli begin to collapse in the pathogenetic pathway described earlier. Alveolar collapse will occur in any patient who remains in one position for a prolonged period and in whom the pattern of breathing is that of shallow tidal ventilation. It should be emphasized that 600 ml breaths delivered with a mechanical ventilator will lead to alveolar collapse, just as shallow spontaneous breathing will, if regular maximal inflations are not carried out.

Obesity as a Risk Factor

Obesity is a common risk factor for postoperative pulmonary insufficiency. In the morbidly obese patient, the effort required to lift the chest wall and push the abdominal viscera and omentum aside during inspiration may be more than diaphragmatic contraction can handle. This condition is exacerbated after operation, when the patient may still be partially paralyzed, sedated from anesthetics or narcotics, and lying in the supine position (which allows the abdominal weight to push up on the diaphragm). In addition, obesity narrows the posterior pharyngeal space by the simple accumulation of fat in the submucosal tissues. This combination of factors makes hypoventilation a common problem in the obese patient [see 5:7 *Morbid Obesity*]. The hypoventilation can be profound but may be masked because the patients are receiving supplemental oxygen, so that P_aO₂ remains normal while P_aCO₂ may exceed 100 mm Hg. Moving the obese patient into a sitting position can minimize hypoventilation.

EDEMA AND THE PULMONARY INTERSTITIUM

Increased pulmonary hydrostatic pressure, decreased plasma oncotic pressure, and increased capillary permeability may all occur in the surgical patient. All of these states will cause increased pulmonary extravascular water and deterioration of lung function.

Fluid flux is a net function of the hydrostatic pressure that tends to force fluid out of the vascular space, on one hand, and the oncotic pressure that tends to pull fluid in, on the other hand. High hydrostatic pressure or low plasma oncotic pressure results in accumulation of fluid in the extravascular space. If the pulmonary endothelium is damaged, fluid may leak into the extracellular space at normal hydrostatic or oncotic pressures (as in ARDS) [see Figure 2]. Pulmonary vascular resistance increases because of perivascular cuffing. Ventilation-perfusion imbalance is created by peribronchiolar and alveolar compression. Shunting occurs if the alveoli become completely collapsed or filled with fluid. Finally, boggy atelectatic areas of lung are ideal breeding grounds for bacterial pulmonary infection.

Well-intentioned therapy in the normal course of treatment or resuscitation may cause increased lung water. An example is replacement of lost blood or plasma with crystalloid, which must equilibrate into the entire extracellular space, including that in the lung. Excess exogenous fluid combines with increased endogenous production of the water of metabolism during hypermetabolic states to yield increased total body extracellular fluid—the

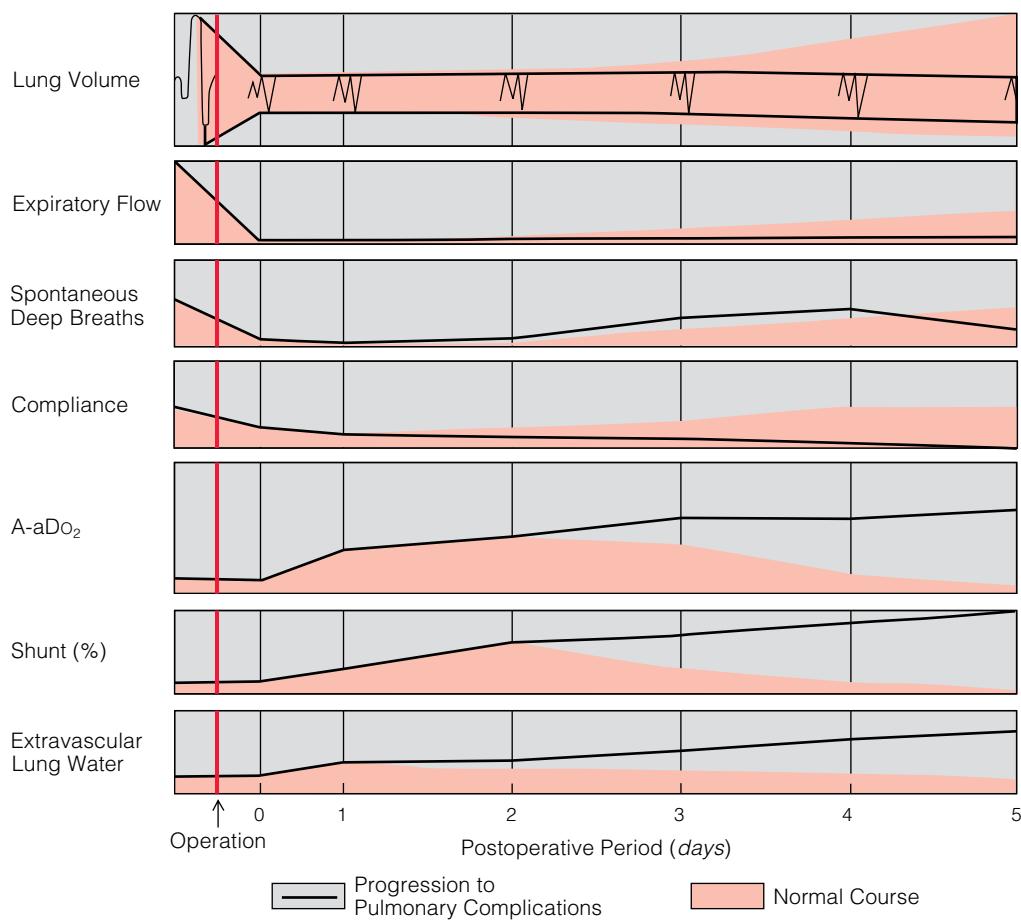

Figure 7 Shaded areas represent normal changes in pulmonary function after an operation. Solid lines represent progression to pulmonary insufficiency. ($A-a\text{DO}_2$ —alveolar-arterial difference in oxygen)

major cause of pulmonary extravascular water collection. The effect is compounded by the decreased oncotic pressure that results when protein is lost or replaced with non-colloid-containing fluids. When plasma proteins are diluted in this way, lung interstitial proteins are also diluted; thus, the oncotic gradients stay unchanged, whereas the entire extracellular space expands.

The pulmonary capillary endothelium is the first major vascular bed to be exposed to any toxic substances arising from peripheral organ metabolism or perfusion of ischemic or infected tissue. The venous effluent from underperfused tissue (whether localized to a single organ, as in arterial embolism, or pervading the entire body, as in any type of shock) arrives directly at the lung, where pulmonary capillary damage occurs. Humoral substances (e.g., lysosomal enzymes and bacterial endotoxin) or particulate materials (e.g., microemboli, major thromboemboli, platelet aggregates, and fat particles) may lodge in the pulmonary capillary bed. As these materials are cleared, leaky pulmonary capillaries are left behind, with the resultant accumulation of extravascular water. If the material trapped in pulmonary capillaries includes large amounts of platelets, secondary effects caused by platelet breakdown products (notably serotonin and thromboxane) are also seen. In major thromboembolism, for example, hypoxemia occurs because of ventilation-perfusion imbalance owing to bronchial spasm, presumably secondary to serotonin released from platelets.

The pulmonary effects of materials released into the venous blood in shock entrain a particularly vicious circle.²¹ Increased

pulmonary vascular resistance and hypoxia resulting from the capillary damage lead to decreased cardiac output and peripheral oxygen delivery, exacerbating the shock state and perpetuating the pulmonary lesion.

Left ventricular failure with increased left atrial pressure results in pulmonary transcapillary transudation, which may be subtle or grossly obvious, as in congestive heart failure with overt pulmonary edema. Left ventricular pressures may waver at the point of high left atrial pressure for short periods—even minutes—resulting in a transient increase in lung water, then return to a balanced state. This situation in itself may not lead to severe pulmonary edema, but it probably makes the lung more vulnerable when minor capillary damage coexists.

The pulmonary interstitium is particularly vulnerable to the events surrounding an operation. Saltwater infusion usually greatly exceeds fluid losses and thus expands the extracellular space. Bleeding and compression of veins by retractors may cause hypotension and necessitate infusion of blood or fluid. Mediators from sterile tissue injury or bacterial invasion may injure pulmonary capillary endothelium. Transient myocardial depression may cause hydrostatic pulmonary edema. With all of these factors, it is remarkable that there is no primary change in lung water volume after uncomplicated operations, even operations including cardiopulmonary bypass. Nonetheless, it should be remembered that the patient usually leaves the OR overloaded with fluid and primed for the development of lung edema.

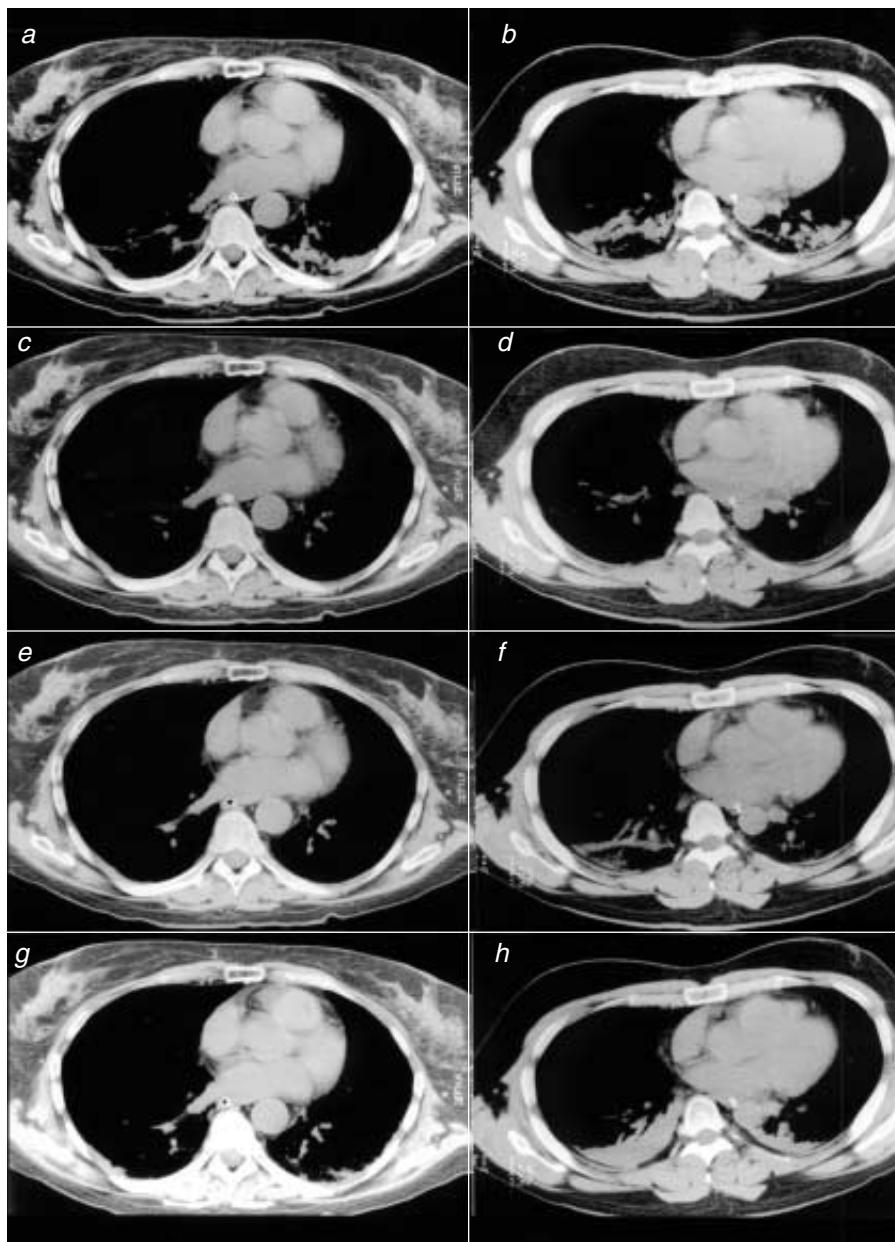

Figure 8 The subject on the left (*a, c, e, g*) is ventilated with 40% O₂; the subject on the right (*b, d, f, h*), with 100% O₂. Atelectasis occurs (posteriorly, of course) after induction and several minutes of tidal breathing (*a, b*) and is completely reversed by inflation to total lung capacity (plateau pressure 40 cm H₂O; *c, d*). Inflation was sustained for 5 and 40 minutes while the patient was breathing 60% nitrogen (*e, g*), but atelectasis recurred by absorption while the patient was breathing 0% nitrogen (*f, h*). Used with permission.²

CONDITIONS AND EVENTS ASSOCIATED WITH PULMONARY INSUFFICIENCY

Fat Embolism

In a small percentage of patients with extensive fractures, the clinical syndrome of fat embolism develops. This syndrome results from pulmonary embolization of neutral fat globules from the marrow cavity and is often associated with embolization of megakaryocytes and other marrow cells. Hypoxemia and bilateral patchy pulmonary infiltrates, beginning 12 to 36 hours after an injury or a bone operation, are typical of this lesion. Associated findings include a falling hematocrit, hemolysis, high fever, cerebral symp-

toms, petechiae (particularly in the anterior axillary folds, the sclerae, and the eyelids), and possibly fat globules in urine, blood, or sputum. Pulmonary capillary damage occurs, apparently as a consequence of sterile inflammation from fatty acids released as the triglyceride particles break down in the lung parenchyma. Steroids have been shown to reduce the inflammation and hence the mortality from the pulmonary lesion, though they must be given early and in large doses to be effective. Intubation and mechanical ventilation are indicated as soon as the syndrome has been diagnosed. Care must be taken to keep the patient's fluid balance as dry as possible because the pulmonary capillaries leak even at normal hydrostatic pressures. This is often difficult in patients with multi-

ple injuries, who may have active bleeding or oliguria concomitantly with the developing pulmonary lesion.

Smoke Inhalation

Several investigators have demonstrated a generalized permeability increase in capillaries (including pulmonary capillaries) after a small burn; the more extensive the burn, the greater the capillary leakage.²² The pulmonary capillary bed shows signs of increased capillary permeability first, in the form of increased lung water. This phenomenon has confused clinicians caring for patients with smoke inhalation syndrome for many years. However, it has now been clarified by work showing that smoke inhalation injury is a relatively mild pulmonary insult in itself but is a major insult when combined with a body surface burn, as is often the case in humans.²³

Toxic components of smoke include carbon monoxide, heat, various aldehydes and other organic materials, and a wide range of vaporized compounds. Materials that are totally combustible (e.g., natural gas and gasoline) burn to yield CO₂ and water, producing few toxic organic compounds and causing minimal lung damage when inhaled in smoke. On the other hand, materials that burn incompletely (e.g., wood, paint, and upholstery), yield a number of toxic vapors in addition to the usual products of combustion, and these vapors damage the respiratory epithelium and the alveoli. The heat carried in smoke is a relatively minor cause of lung damage because air is such a poor heat conductor. Deep lung damage from heat is unusual unless the thermal injury is conveyed by hot steam.

Carbon monoxide is the major toxic material in smoke. It does not damage the lungs but renders the brain hypoxic by associating with hemoglobin, thereby inducing potentially lethal brain damage. Patients with smoke inhalation injury who do not have a body surface burn usually pass through a period of mild pulmonary insufficiency and recover completely unless they have suffered irreversible brain damage or metabolic acidosis as a result of carboxyhemoglobinemia. Patients with the same degree of smoke inhalation injury who also have a moderate body surface burn are subject to serious pulmonary insufficiency with combined atelectasis and increased lung water; intubation, mechanical ventilation, and efforts to reduce lung water usually prove necessary.

Chest Trauma

Direct injury to the chest may cause damage to the chest wall, the lung parenchyma, the diaphragm, the airway, and other intrathoracic structures (e.g., the heart and the great vessels) [see 7:5 *Injuries to the Chest*]. These injuries are usually associated with hemothorax or pneumothorax. Life-threatening hypoventilation may result from injuries to the chest wall or from alveolar collapse caused by fluid or blood in the pleural space. Emergency treatment includes placement of a large chest tube to empty the pleur-

al space and reexpand the lung along with mechanical ventilation if spontaneous breathing is inadequate.

With blunt trauma, fracture of the ribs or sternum may create a segment of the chest wall that moves inward in response to the negative pressure created during spontaneous inspiration (so-called paradoxical motion); this floating segment is referred to as a flail segment, or flail chest. A small amount of paradoxical motion with no physiologic side effects does not warrant specific treatment. If flail chest is associated with hypoxemia or CO₂ retention, then lung contusion is probable and intubation and ventilation are indicated.

If air or fluid is detected in the pleural space, a large chest tube should be placed. If a patient with minor chest injuries requires immediate operation for other problems (e.g., ruptured spleen or head injury), prophylactic chest tubes should be replaced on both sides to eliminate the possibility of a tension pneumothorax or hemothorax developing during anesthesia. Mechanical ventilation is required for patients with major flail segments and lung contusion of chest injury complicating other serious injuries.

Penetrating trauma may result in a sucking chest injury, in which air is inhaled into the pleural space during inspiration, filling the pleural space, eliminating the pressure gradient that would normally cause the lung to inflate, and resulting in atelectasis. If the injury allows air to be inhaled into the pleural space but prevents it from exiting, a tension pneumothorax results, with hypoventilation and blockage of venous return; bleeding into the pleural space from the chest wall or the lung complicates this problem. Placing a chest tube to drain accumulated air and blood, along with appropriate replacement of lost blood, usually returns cardiac output and respiration to normal quite promptly. Because the lung vasculature is a low-pressure system, bleeding from the lung itself usually subsides relatively quickly. Air leaks from the lung usually seal within 1 or 2 days. Prolonged major air leaks suggest the presence of an injury to a large bronchus, the trachea, or the esophagus that requires operative repair.

Thoracotomy and Pulmonary Resection

On the whole, patients experiencing pulmonary problems after thoracic operations are managed in much the same way as those with pulmonary insufficiency from other causes. Special attention should, however, be given to patients who have undergone resection of part or all of a lung as treatment for infection, cancer, congenital abnormalities, or, rarely, trauma. If the remaining lung is normal, removal of lung tissue does not cause a major physiologic deficit. Nevertheless, pulmonary resection does give rise to certain unique concerns. In particular, the empty space formerly occupied by the lung tissue must be managed very carefully, or poor healing and infection may result. If pleural space infection, leakage from the closed bronchus, or pulmonary failure occurs after pulmonary resection, challenging ventilatory problems ensue.

5 MECHANICAL VENTILATION

Matthew J. Sena, M.D., and Avery B. Nathens, M.D., Ph.D., M.P.H., F.A.C.S.

Approach to the Use of the Mechanical Ventilator

Patients requiring mechanical ventilation account for a large percentage of admissions to medical and surgical intensive care units. The initial indications for mechanical ventilation can be divided into two main categories: (1) airway instability necessitating endotracheal intubation (as a consequence of operation, brain trauma, or intoxication) and (2) primary respiratory failure from any of several diverse causes, including the acute respiratory distress syndrome (ARDS), trauma, cardiogenic pulmonary edema, and exacerbation of chronic obstructive pulmonary disease (COPD).¹ In the first category, ventilator management is relatively straightforward, and support is temporary, maintained only until the patient's airway is stabilized. In the second category, a prolonged period of mechanical ventilation (> 2 to 3 days) is frequently required. The majority of ventilated ICU patients fall into this second group,¹ and it is these patients in whom specific attention should be paid to the cause of respiratory failure and the goals of therapy. The ventilator mode and settings can then be appropriately tailored to minimize lung injury and facilitate resolution of the underlying disease.

Proper use of a mechanical ventilator requires a solid understanding of normal and abnormal pulmonary mechanics, gas exchange, and the relation between systemic oxygen delivery and consumption. Mechanical ventilators, along with currently available noninvasive and invasive monitoring devices, allow support of critically ill patients while the acute physiologic derangements that led to respiratory failure resolve. In addition, specific ventilator strategies geared toward minimizing further lung injury and expediting the process of liberation from the ventilator not only yield improved support of patients with respiratory failure but also appear to have an impact on outcome.

Ventilator terminology has become increasingly complex as the technology has advanced, but the basic principles of management remain unchanged: to facilitate gas exchange for tissue oxygen delivery, to provide ventilation for removal of carbon dioxide, and to minimize the detrimental effects of both endotracheal intubation and mechanical ventilation. With these priorities in mind, the clinician can use an evidence-based approach to ventilator management as a component of multimodal therapy to improve patient outcome in the ICU. Such management includes use of a lung-protective strategy for patients with acute lung injury (ALI) or ARDS, performance of daily spontaneous breathing trials (SBTs) to identify patients who are ready for liberation from the ventilator, and, when possible, consideration of a nurse-driven or respiratory therapist-driven protocol to minimize delays in extubation. Newer therapies have been developed that offer attractive alternatives to conventional modes of ventilation. Most such therapies are of unproven efficacy, and must therefore be employed with caution in clinical settings. Nonetheless, they provide the clinician with more options for treating patients with advanced respiratory failure and should be considered in extreme cases.

Ventilation and Oxygenation

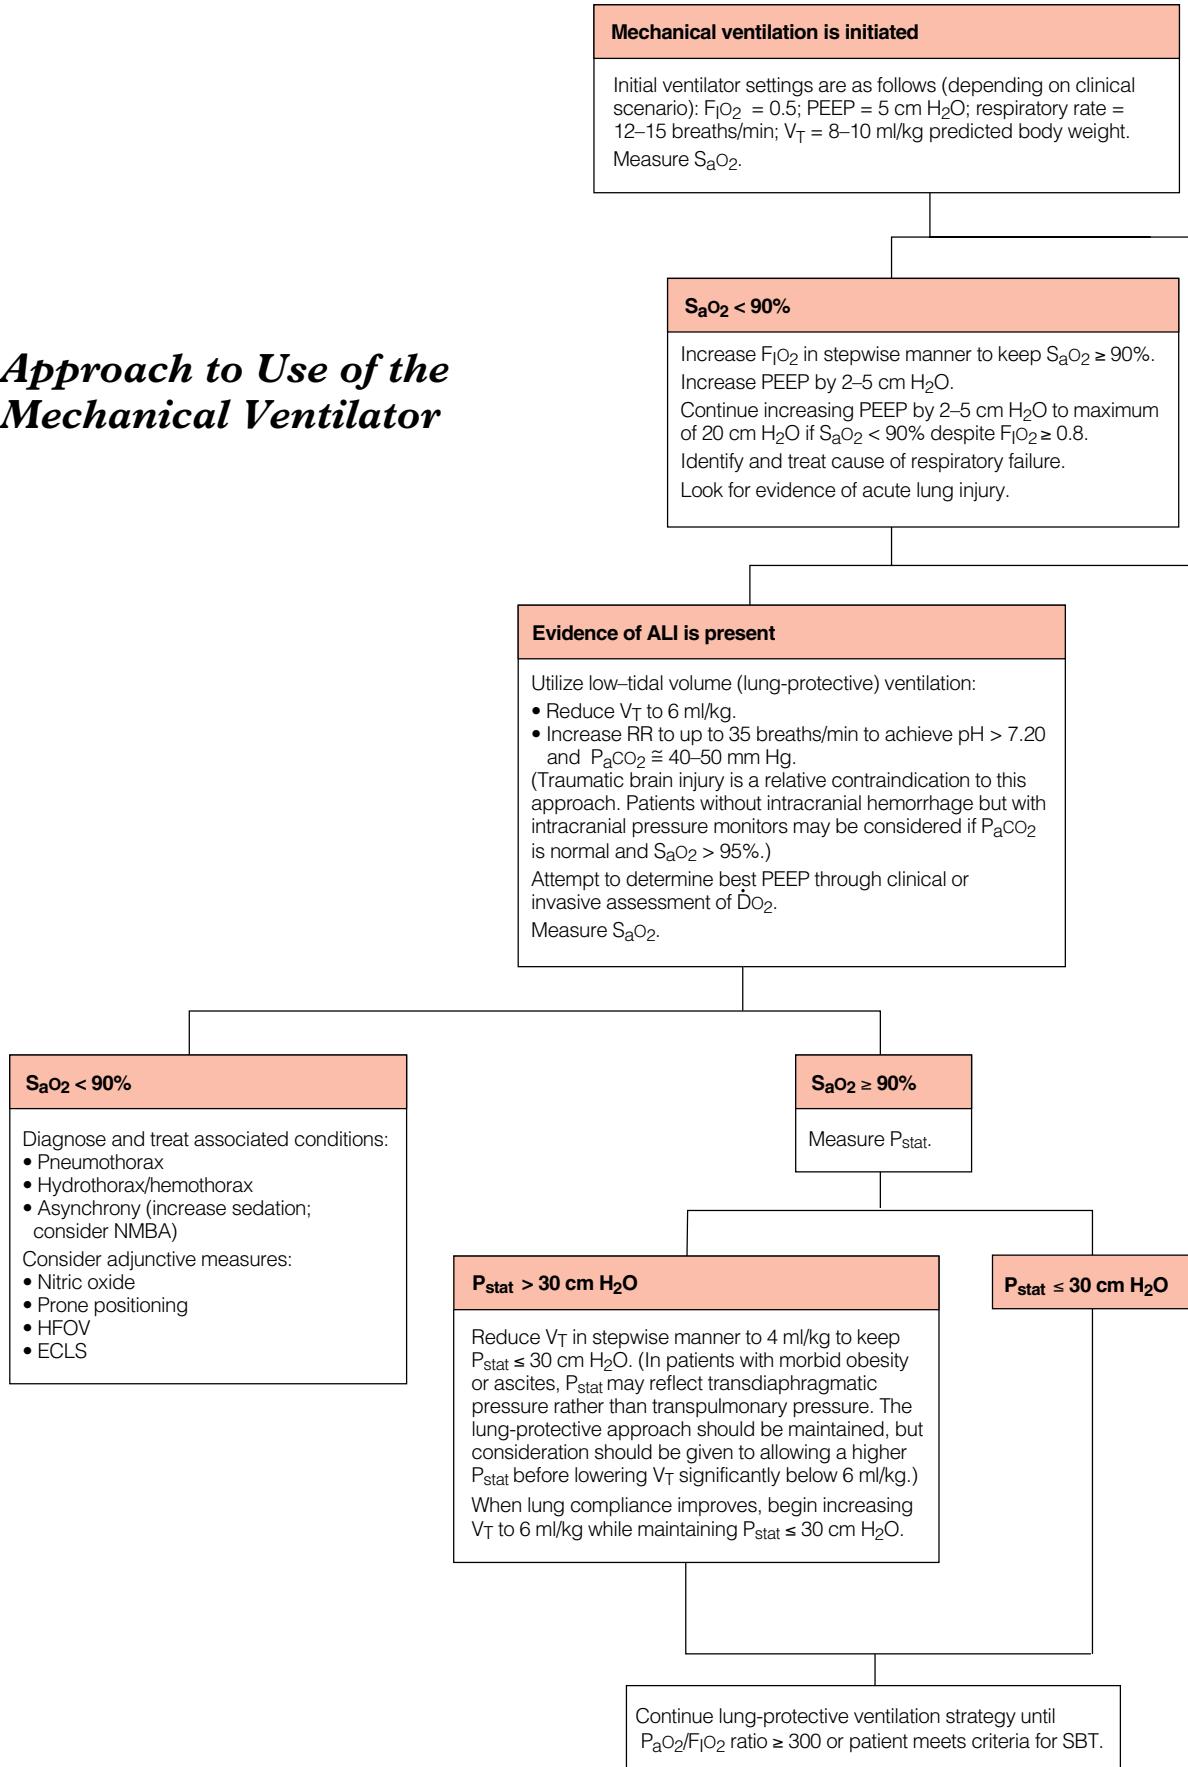

An essential concept in mechanical ventilation is the distinction between two key processes, ventilation and oxygenation. The primary purpose of ventilation is to excrete carbon dioxide. The minute ventilation (\dot{V}_E) is the total amount of gas exhaled per minute, computed as the product of the rate and the tidal volume (V_T). Minute ventilation has two components, alveolar ventilation (\dot{V}_A) and dead space ventilation (\dot{V}_D). Under normal conditions, approximately two thirds of \dot{V}_E reaches the alveoli and takes part in gas exchange (\dot{V}_A); the remaining third moves in and out of the conducting airways and nonperfused alveoli (\dot{V}_D). Thus, the ratio of dead space to tidal volume (V_D/V_T) is normally 0.33. The amount of CO_2 excreted is directly related to the amount of alveolar ventilation and inversely proportional to the partial pressure of CO_2 in the alveoli (P_{ACO_2}). During spontaneous breathing, \dot{V}_E is regulated by the brain stem respiratory center. The brain stem respiratory center responds primarily to changes in plasma pH and in the partial pressure of CO_2 in arterial blood (P_{aCO_2}). In the face of normal CO_2 production (~ 200 ml/min) and normal minute ventilation (6 L/min), alveolar ventilation amounts to approximately 4 L/min and corresponds to a P_{aCO_2} of 40 mm Hg.

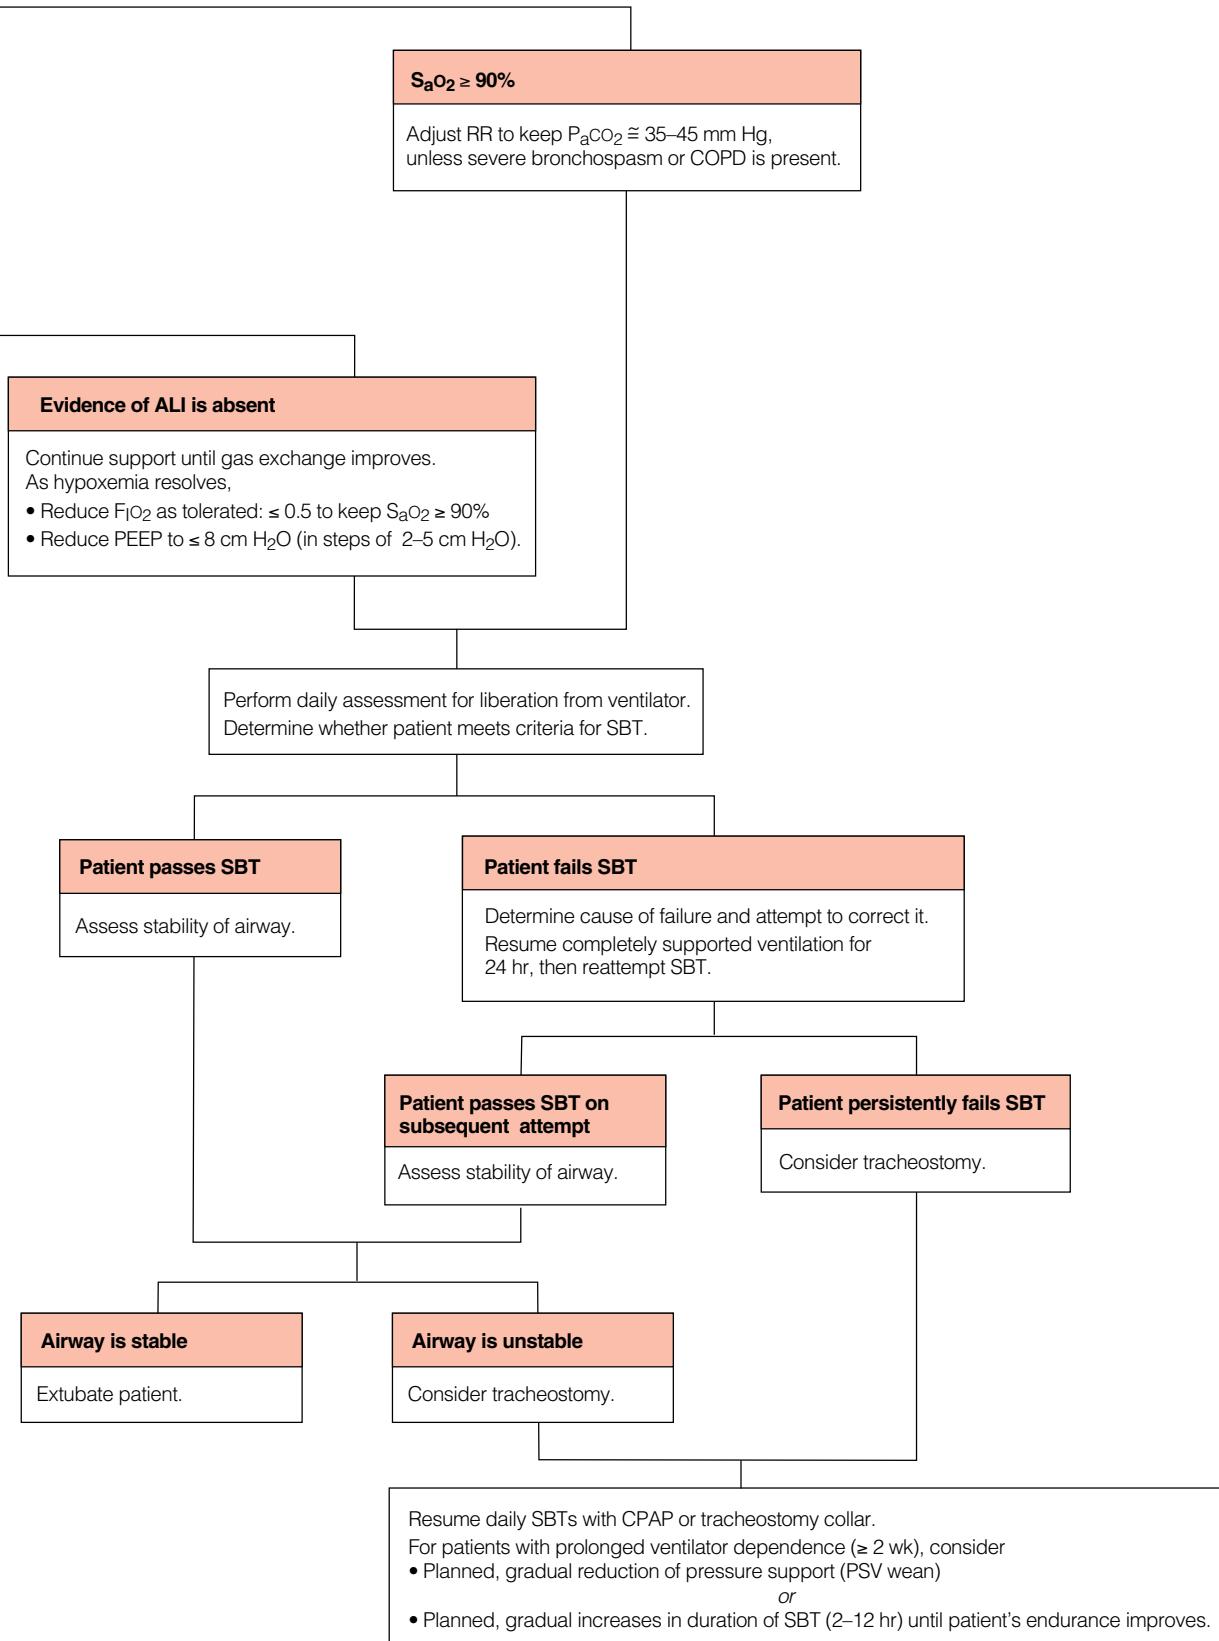

In a patient requiring mechanical ventilation, \dot{V}_E is at least partially determined by the mode and settings of the ventilator. Respiratory rate and tidal volume can be set independently, and the mode of ventilation can be set to allow additional spontaneous breathing if necessary. In most cases, the primary goal is maintenance of a near-normal P_{aCO_2} . The physician must be cognizant of factors that might increase CO_2 production (e.g., fever, sepsis, injury, and overfeeding) or \dot{V}_D (e.g., lung injury, ARDS, and massive pulmonary embolism), any of which would increase the \dot{V}_E requirements in a ventilated patient.

Oxygenation refers to the equilibrium between oxygen in the pulmonary capillary blood and oxygen in inflated alveoli. The oxygen tension gradient between the alveoli and the capillaries favors the transfer of oxygen into the blood. Although the partial pressure of oxygen in arterial blood (P_{aO_2}) is partially dependent on ventilation, it depends less on adequate alveolar ventilation than on the appropriate matching of pulmonary blood flow to well-inflated alveoli, a process referred to as ventilation-perfusion (\dot{V}/\dot{Q}) matching. \dot{V}/\dot{Q} matching can be affected by many factors, including patient position, airway pressure, pulmonary parenchymal disease, and small-airway disease. The efficiency of \dot{V}/\dot{Q} matching, and thus of oxygenation, can be evaluated by measuring the P_{aO_2} at a known value of the fraction (concentration) of inspired oxygen (F_{IO_2}). Under normal circumstances, oxygenation is very efficient, with P_{aO_2} values approaching 90% of P_{AO_2} . Its efficiency can be assessed by calculating the alveolar-arterial oxygen gradient (i.e., $P_{\text{AO}_2} - P_{\text{aO}_2}$).

Under normal conditions, P_{aO_2} is approximately 90 mm Hg. To determine P_{AO_2} , the following formula is employed:

Approach to Use of the Mechanical Ventilator

$$P_{AO_2} = [F_{I O_2}(\text{barometric pressure} - P_{H_2O}) - P_a CO_2 / RQ]$$

where RQ represents the respiratory quotient and P_{H_2O} represents the partial pressure of water vapor at sea level. Normally, at sea level, barometric pressure is approximately 760 mm Hg, $F_{I O_2}$ is 0.21, P_{H_2O} is 47 mm Hg, $P_a CO_2$ is 40 mm Hg, and RQ is 0.8. Accordingly,

$$P_{AO_2} = [0.21(760 - 47) - 40/0.8]$$

$$P_{AO_2} \approx 150 - 50$$

$$P_{AO_2} \approx 100$$

$$P_{AO_2} - P_a O_2 \approx 100 - 90 \approx 10$$

Thus, the alveolar-arterial gradient under these conditions is approximately 10 mm Hg, which falls within the standard range of 8 to 12 mm Hg.

A shorthand method of quantifying the degree of hypoxemia is to calculate the $P_a O_2/F_{I O_2}$ ratio (also referred to as the P/F ratio), which is simply an assessment of the efficiency of gas exchange. At sea level, with the patient breathing room air, $P/F \approx 100/0.21 \approx 500$.

Unlike regulation of \dot{V}_E , adjustment of the rate or V_T generally has little effect on $P_a O_2$, except at extremely low levels of ventilation. Greater effects on arterial oxygenation are achieved through adjustment of either $F_{I O_2}$ or mean airway pressure (P_{aw}), both of which can be readily manipulated with a mechanical ventilator.

Ventilator Modes

Current mechanical ventilators possess a wide, and potentially confusing, array of modes, settings, and capabilities. All of them, however, control three variables: trigger, limit, and cycle.

The trigger variable is the signal that serves to initiate the inspiratory phase. This signal occurs as a result of patient effort that leads to a change in either flow or pressure within the ventilator circuit. Flow-triggered ventilators deliver a continuous flow of gas across the inspiratory and expiratory limbs of the ventilator circuit and initiate the inspiratory phase when patient effort results in a change in this flow. The required change can be as little as 0.1 L/min; the sensitivity of the trigger is decreased by increasing the required flow change and therefore increasing the patient effort necessary to begin inspiration. Pressure-triggered ventilators initiate the inspiratory phase when a patient's spontaneous effort results in a change in pressure. At the most sensitive setting, a pressure change of approximately $-1 \text{ cm H}_2\text{O}$ is required; at the least sensitive setting, a change of $-15 \text{ cm H}_2\text{O}$ is required. Finally, a time trigger is used to start the inspiratory phase in mandatory ventilation modes, as well as in assisted modes.

The limit variable is the maximal set inspiratory pressure or flow. Pressure-controlled ventilation (PCV) and pressure-support ventilation (PSV) are both modes of pressure-limited ventilation. Because volume is the product of flow and time, volume-controlled ventilation is actually flow-limited ventilation during the inspiratory phase with the inspiratory time set independently.

The cycling variable is the factor that terminates the inspiratory cycle (i.e., time, flow, pressure, or volume). To add more confusion, each breath can be considered as a mandatory breath (which is time triggered), a spontaneous breath (which is patient initiated), or a combination of the two.

PRESSURE-LIMITED VERSUS VOLUME-LIMITED VENTILATION

Pressure-support ventilation is the simplest form of pressure-limited ventilation and, by definition, is a purely spontaneous mode of ventilatory support. In PSV, the patient triggers a breath

through an inspiratory effort, which leads to the delivery of a breath at a variable flow rate to meet a preset pressure. As the lung inflates, compliance decreases and flow decreases to maintain a constant inspiratory pressure. The result is a descending flow curve that is similar to air flow in unassisted breathing. Cycling in this mode occurs when flow declines to a specified percentage of the maximal flow rate (approximately 5% of the peak flow rate in some ventilator models) [see Figure 1]. When inspiratory flow ceases, the patient exhales passively.

Pressure-controlled ventilation is related to PSV in that flow descends in amplitude during the inspiratory cycle. It differs from PSV primarily in that the inspiratory time is set by the ventilator, not by the patient. PCV is generally used in the assist-control mode, which allows full support of patient-initiated breaths in addition to ventilator-initiated breaths (which are time triggered). It can also be used in conjunction with the intermittent mandatory ventilation (IMV) mode in newer ventilator models. The largest drawback of PCV is that V_T can change as lung compliance changes, necessitating frequent adjustments to ensure adequate \dot{V}_E . For example, as the lung becomes less compliant with increasing pulmonary edema, V_T will decrease, as will \dot{V}_E . This problem can be addressed by using another form of pressure-limited ventilation, known as pressure-regulated volume control (PRVC) [see Combined Modes of Ventilation, below].

Volume-controlled ventilation (VCV) is delivered at a set frequency (in the IMV or the assist-control mode) or may be patient initiated (in the assist-control mode). After the ventilator is triggered, a fixed flow of gas is generated for a specific time, thus providing a preset inspiratory volume (volume = flow \times time). Volume-limited ventilation is generally easier to regulate than pressure-limited ventilation, but it may be less comfortable for awake patients, because the flow curve is a square wave, which is markedly different from the normal inspiratory flow pattern in nonventilated patients.

MANDATORY VERSUS SPONTANEOUS VENTILATION

There are several modes of ventilation that provide mandatory ventilator support with or without patient-triggered ventilation. For example, assist-control ventilation ensures delivery of a minimum (mandatory) set \dot{V}_E but also allows additional patient-triggered (spontaneous) breaths. Each breath, regardless of the trigger, is completely supported, so that either a fixed volume (with VCV) or a fixed pressure (with PCV) is provided for a preset inspiratory time. Full support can be provided by increasing the mandatory rate. If the patient has respiratory drive, \dot{V}_E might be increased by adding spontaneous breaths. The major drawback of this approach is that agitated patients may become hyperventilated and may manifest respiratory alkalosis if not sedated.

The IMV mode allows only the preset number of breaths to be supported. In most cases, breaths are synchronized with the patient's effort (so-called synchronized IMV [SIMV]) if spontaneous respiration is occurring. Patient efforts at inspiration above the preset frequency are not supported with gas flow from the ventilator unless pressure support is added. In the past, IMV was frequently used as a weaning mode: by gradually decreasing the set frequency, patients gradually assumed a greater role in their own respirations. Today, however, it is not frequently employed for this purpose and plays only a limited role in weaning patients from the ventilator.

INSPIRATORY TIME, FLOW, RESPIRATORY RATE, AND INSPIRATORY-EXPIRATORY RATIO

Inspiratory time, flow, respiratory rate, and inspiratory-expira-

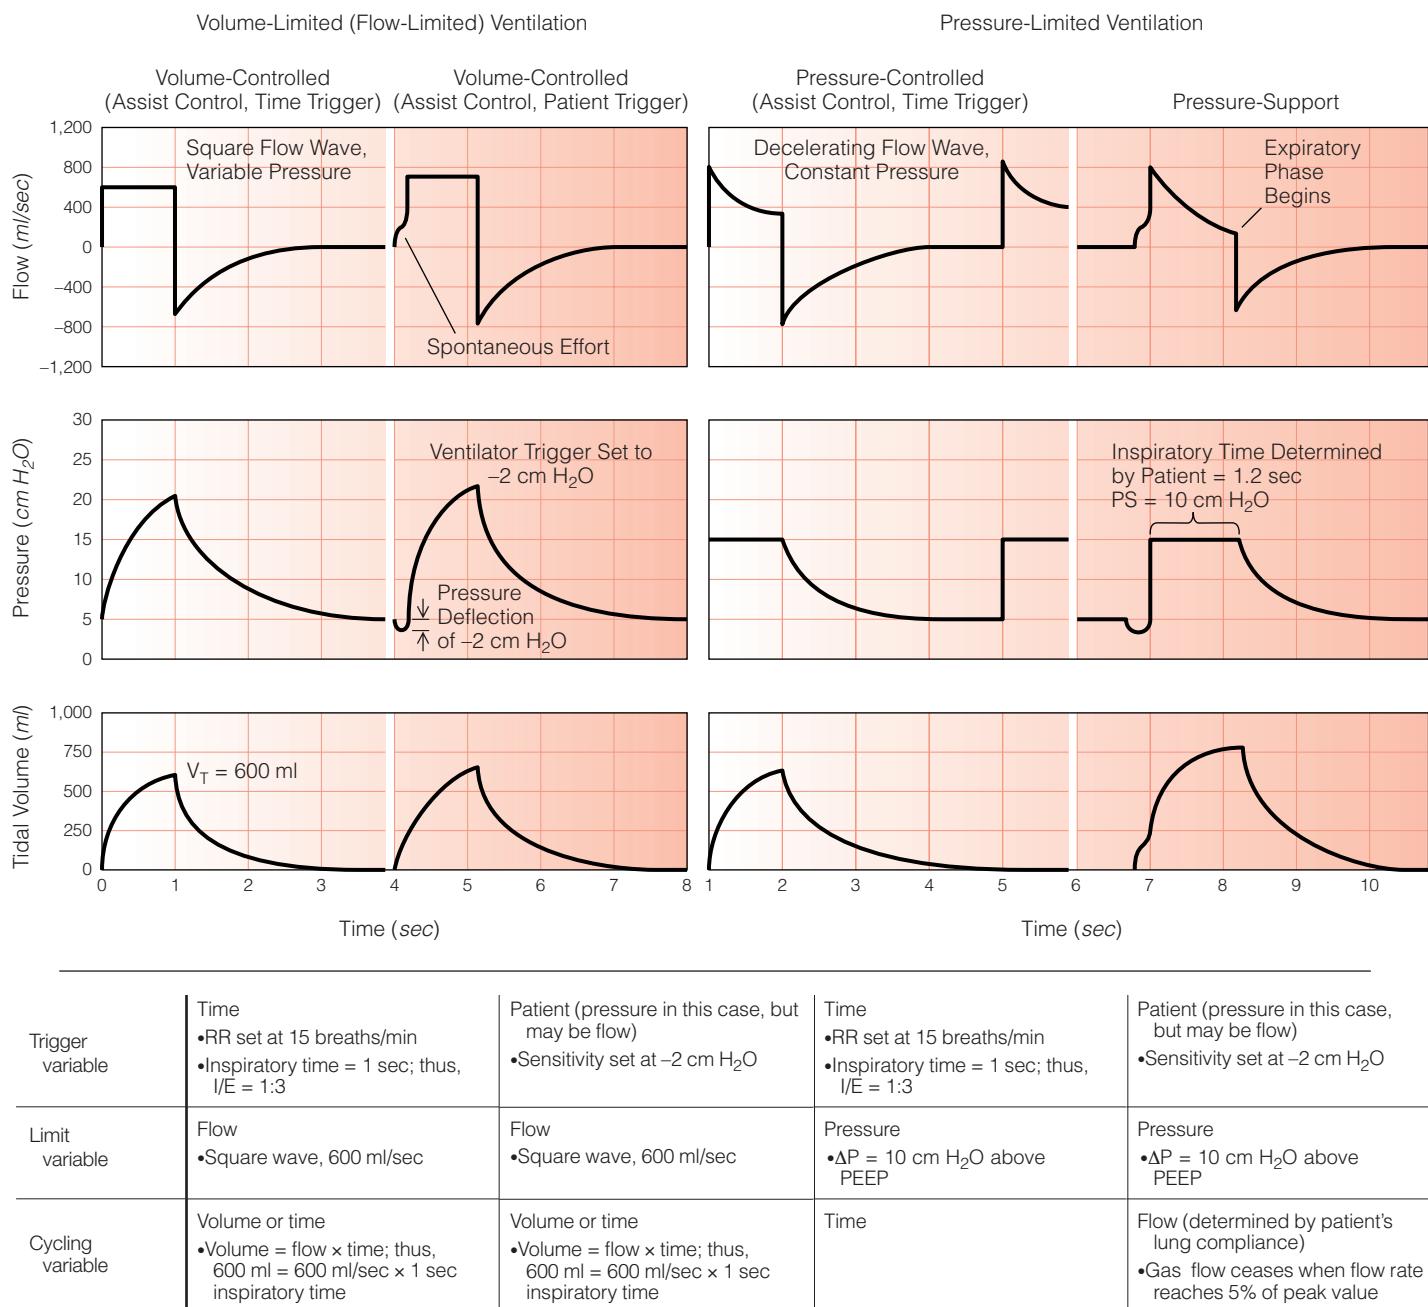

Figure 1 Shown are flow, pressure, and volume profiles in volume-limited and pressure-limited ventilation modes.

tory (I/E) ratio are all closely related. In most patients, they can be preset to mimic the normal respiratory cycle. The normal I/E ratio is approximately 1:3. With the respiratory rate set at 15 breaths/min, the inspiratory time is 1 second, with 3 seconds of expiratory time. The flow rate can then be manipulated so as to achieve a desired tidal volume (in VCV) or can be adjusted automatically by the ventilator so as to achieve a certain pressure (in PCV). Manipulation of these variables can be useful in certain conditions, such as a high level of intrinsic positive end-expiratory pressure (PEEP) [see Discussion, Special Problems in Ventilator Management, Chronic Obstructive Pulmonary Disease, below]. In the past, manipulation of the I/E ratio has been used to treat severe hypoxemia [see Alternative Modes of Ventilation and Adjunctive Therapies, Inverse-Ratio Ventilation, below].

AIRWAY PRESSURES, LUNG INJURY, AND OXYGENATION

The flow of gas through the ventilator circuit produces pressure both at the level of the endotracheal tube and across the alveolar surface. These pressures, though related, have different implications for the assessment and treatment of pulmonary dysfunction [see Figure 2]. Peak inspiratory pressure (PIP) is the pressure measured in the ventilator circuit during maximal gas flow; it primarily represents the interaction between the inspiratory flow rate and airway resistance. Mean airway pressure is the area under the pressure-time curve divided by the time required for a complete respiratory cycle. Because the normal respiratory cycle is dominated by the expiratory phase, P_{aw} is determined primarily by PEEP. P_{aw} is important in that it has a direct effect on alveolar recruitment and gas exchange; it also is the major determinant of

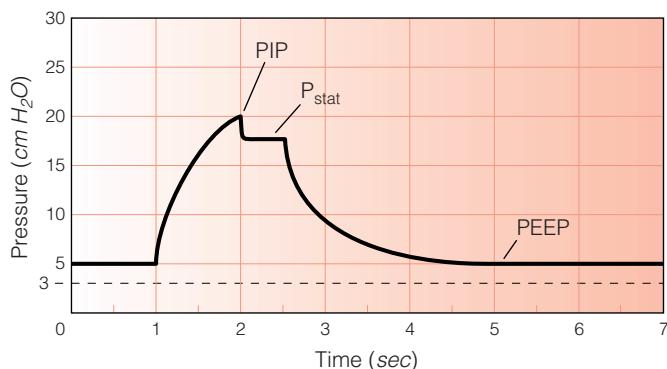

Figure 2 Shown are measured ventilator pressures during a single machine-triggered volume breath during VCV. (PEEP—positive end-expiratory pressure; PIP—peak inspiratory pressure; P_{stat} —static pressure measured during a 0.5 sec inspiratory pause)

intrathoracic pressure and thus is the parameter to follow when there is concern about the cardiovascular sequelae of higher ventilatory pressures. Static pressure (P_{stat}) is measured in the ventilator circuit during a 1-second pause at the end of inspiration. P_{stat} is generally considered to be the pressure distending the alveoli, on the assumption that intrathoracic pressure is equivalent to atmospheric pressure; this distending pressure is also referred to as transpulmonary pressure. Limitation of P_{stat} plays an important role in minimizing ventilator-induced lung injury [see Discussion, Special Problems in Ventilator Management, Acute Lung Injury and Acute Respiratory Distress Syndrome, below].

COMBINED MODES OF VENTILATION

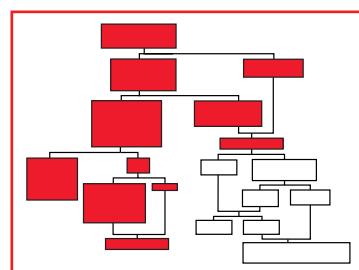

Many newer modes of ventilation are hybrids, incorporating combinations of pressure control and volume control and combinations of spontaneous and mandatory breathing. One such mode is pressure-regulated volume control. PRVC is a variant of PCV but has the ability to prevent significant changes in V_T if lung compliance changes. The ventilator accomplishes this by continuously evaluating changes in delivered V_T at a given pressure over several respiratory cycles and adjusting the pressure accordingly. The operator can preset the inspiratory pressure limit to prevent barotrauma.

Another hybrid mode is mandatory minute ventilation, which is a form of assisted VCV. In the assist mode, the patient may trigger a complete volume-cycled breath. The operator sets a specific V_E , rather than a specific rate and V_T . In this way, the operator can ensure adequate CO_2 removal in patients with variable respiratory drive.

In general, these combined modes are of limited utility in ventilator management. The overwhelming majority of patients can be managed with simple PCV or VCV or, if they have adequate respiratory drive, with PSV.

Use of the Mechanical Ventilator in Respiratory Failure

After endotracheal intubation, the initial ventilator settings should be determined by assessing the cause and severity of the patient's respiratory failure. After an initial stabilization period of approximately 30 minutes, blood gas values should be obtained and the ventilator

adjusted accordingly. Certain patients—specifically, those with profound hypoxemia—may require an immediate increase in $F_{\text{I}}\text{O}_2$, PEEP, or both; such increases should not be postponed to await blood gas results. $F_{\text{I}}\text{O}_2$ and PEEP can be manipulated on the basis of information from pulse oximetry, so that there is less need for frequent arterial blood gas assessment. Further treatment should be prioritized on the basis of the underlying problem of oxygenation or ventilation.

OXYGENATION

The purpose of ensuring adequate arterial oxygenation is ultimately to maintain adequate delivery of oxygen to the tissues. A $P_{\text{a}}\text{O}_2$ higher than 60 mm Hg generally results in an arterial hemoglobin saturation ($S_{\text{a}}\text{O}_2$) of 90% or greater and is sufficient for most patients, provided that the other components of oxygen delivery are normal or nearly so. An adequate $P_{\text{a}}\text{O}_2$ can be obtained by altering either $F_{\text{I}}\text{O}_2$ or P_{aw} . Increasing the $F_{\text{I}}\text{O}_2$ is the simplest maneuver, but it is not necessarily the correct adjustment in patients with pulmonary dysfunction. Nonetheless, it should be tried first, while other options are being considered. Generally, a moderate increase in $F_{\text{I}}\text{O}_2$ (to ≤ 0.6) has minimal adverse consequences. The desired and immediate effect is to increase the gradient for oxygen diffusion across the alveolar and pulmonary capillary membranes. In normal lungs, this increased gradient results in a proportional increase in $P_{\text{a}}\text{O}_2$. If an intrapulmonary shunt is present, however, increasing $F_{\text{I}}\text{O}_2$ has little effect on $P_{\text{a}}\text{O}_2$.

Often, an effort to increase $F_{\text{I}}\text{O}_2$ is combined with some measure aimed at increasing P_{aw} , the idea being that a smaller increase in $F_{\text{I}}\text{O}_2$ will then be required to produce the desired effect. Although a high $F_{\text{I}}\text{O}_2$ (> 0.6) has few negative consequences in the short term, prolonged maintenance of $F_{\text{I}}\text{O}_2$ at this level can

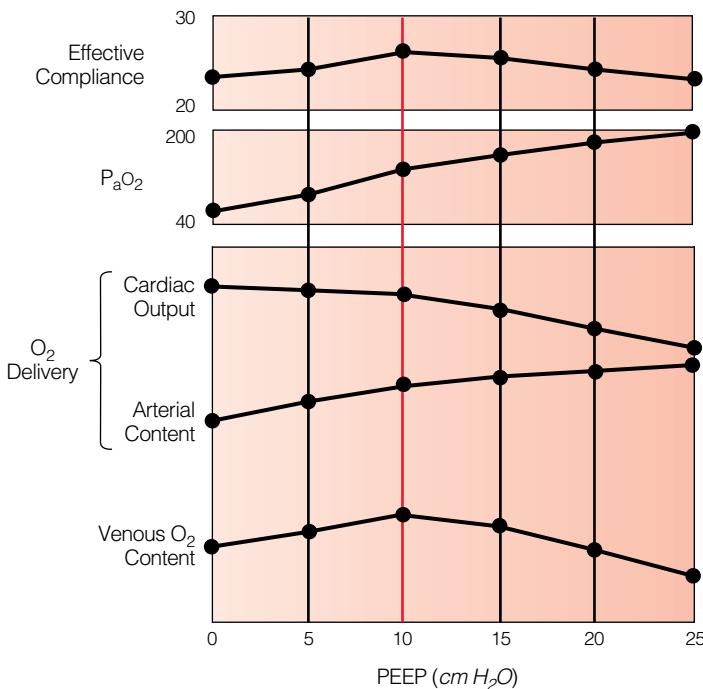

Figure 3 Shown are measurements for determining the optimal PEEP. The objective is to maximize the ratio of oxygen delivery to oxygen consumption, which is determined by measuring mixed venous saturation. Here, the best PEEP is 10 cm H₂O, even though the $P_{\text{a}}\text{O}_2$ and the arterial oxygen content are higher at higher levels of PEEP.

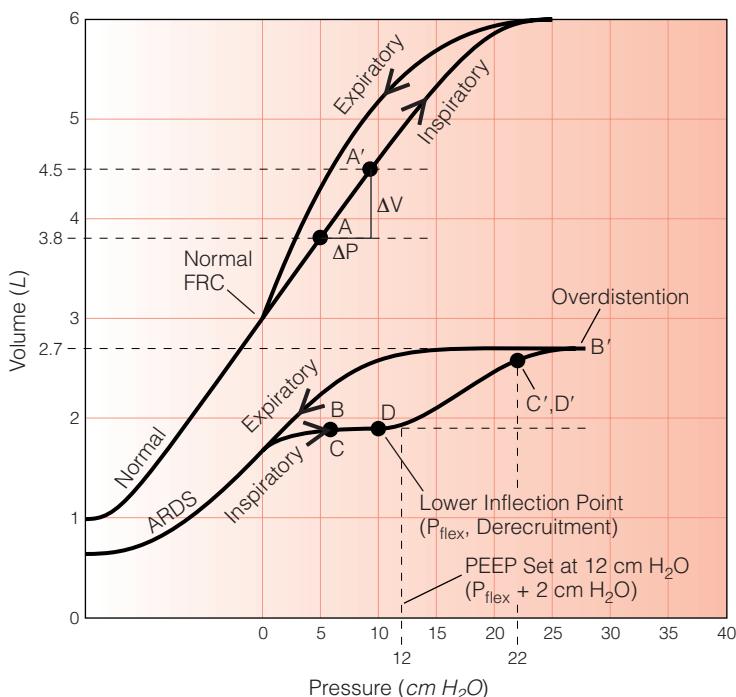

Figure 4 Depicted is a static volume-pressure curve. A → A' represents normal tidal ventilation in a normal lung, with a PEEP of 5 cm H₂O and a tidal volume of 10 ml/kg × 70 kg = 700 mL. C_{stat} = ΔV/ΔP = 700 mL / 5 cm H₂O/kg = 2 mL/cm H₂O + 70 kg. B → B' represents normal tidal ventilation in a lung from an ARDS patient, with a PEEP of 5 cm H₂O and a tidal volume of 10 ml/kg × 70 kg = 700 mL. C_{stat} = 700 / 22 cm H₂O + 70 kg = 0.45 mL/cm H₂O/kg. C → C' represents a low-tidal volume, lung-protective ventilation strategy, with a PEEP of 5 cm H₂O and a tidal volume of 6 mL/kg × 70 kg = 420 mL. C_{stat} = 420 / 17 cm H₂O + 70 kg = 0.35 mL/cm H₂O/kg. D → D' represents a low-tidal volume, lung-protective ventilation strategy, with a PEEP of 12 cm H₂O (best PEEP), which is above P_{flex}. The tidal volume is 6 mL/kg × 70 kg = 420 mL. C_{stat} = 420 / 10 cm H₂O + 70 kg = 0.60 mL/cm H₂O/kg. The low-tidal volume strategy prevents the overdistension that occurs at higher tidal volumes, whereas the higher PEEP level prevents the derecruitment that can occur at lower volumes. Although low-tidal volume ventilation strategies have been demonstrated to improve outcome in ARDS, higher PEEP levels, though theoretically attractive, have not been shown to be efficacious.

result in nitrogen washout, resorption atelectasis, and an increased pulmonary shunt fraction, with consequent exacerbation of hypoxemia.

The simplest way of increasing P_{aw} is to increase PEEP. The purpose of PEEP is to prevent loss of functional residual capacity (FRC), defined as the volume maintained in the lungs at the end of expiration. In normal persons, FRC is maintained by a balance between the negative intrapleural pressure and the elastic recoil of the lung. Negative intrapleural pressure is affected by patient position. The upright position yields a greater negative intrapleural pressure than the supine position, because of the weight of the abdominal viscera, which literally pull down on the diaphragm. In the supine position, this pull is absent, and FRC may be as much as 25% lower in normal persons in the supine position.^{2,3} This decrease is even more pronounced in patients with ascites or abdominal distention and especially in patients with intra-abdominal hypertension.⁴ In a normal alert patient, the loss of FRC can be reversed with changes in position or intermittent sigh breaths throughout the respiratory cycle, and there will be minimal net impact on pulmonary physiology. In a supine ventilated patient, the loss of FRC results in progressive atelectasis, intrapulmonary shunting, and hypoxemia. Accordingly, small amounts of PEEP (5–10 cm H₂O) should be delivered to help restore FRC to levels adequate for maintaining normal gas exchange and preventing hypoxemia in patients without significant pulmonary dysfunction.

In patients with pulmonary dysfunction, FRC is lost through alveolar collapse. This collapse occurs by several means—for example, through extrinsic pressure (see above) or through some combination of blood, pus, or secretions that results in occlusion of small airways. In these settings, increasing PEEP improves V/Q matching by “recruiting” these collapsed alveoli and thereby bringing about improved gas exchange and P_aO₂. Unfortunately, the increased intrathoracic pressure that may develop when PEEP is increased can have detrimental effects on cardiac output. Because the overall goal is to improve tissue oxygen delivery (not just P_aO₂), assessment of the net effect of an increase in PEEP should take into consideration the effect on oxygen delivery (D_O₂). The amount of PEEP necessary to maximize D_O₂ in a given patient is

referred to as best PEEP and generally corresponds to the PEEP setting that results in maximal static lung compliance.⁵ PEEP levels above this point may increase arterial oxygen content (C_aO₂) but typically impair cardiac output and result in decreased D_O₂ [see Figure 3].

The improvement in lung compliance achieved by increasing PEEP levels in patients with pulmonary dysfunction can be demonstrated by using a static or low-flow volume-pressure curve to determine the lower inflection point (P_{flex}) [see Figure 4]. P_{flex} corresponds to the point at which recruitable alveoli open and become available for tidal ventilation and gas exchange. Setting PEEP slightly higher (+2 cm H₂O) allows tidal ventilation over the range of maximal lung compliance and prevents the repetitive end-expiratory derecruitment that may be associated with ventilator-induced lung injury.⁶ Although this approach is theoretically attractive, determining P_{flex} is technically cumbersome and may not be tolerated by the sickest patients.

In practice, F_iO₂ and PEEP are manipulated simultaneously, with the specifics depending on the cause of arterial hypoxemia and on an empirical determination of best PEEP. Best PEEP is determined by means of stepwise increases in PEEP coupled with serial assessments of arterial oxygenation and cardiovascular function. At high levels of PEEP (> 15 cm H₂O), consideration should be given to using a pulmonary arterial catheter for assessment of D_O₂ and mixed venous oxygen saturation (S_vO₂). If an increase in PEEP results in a drop in either S_vO₂ or D_O₂, then the increase was detrimental to the goal of improving tissue oxygenation. As a rule, the maximal PEEP level that may provide benefit rarely exceeds 20 cm H₂O.⁷ Above this level, it is fairly common for detrimental effects on cardiovascular function to predominate and D_O₂ to decline.⁸

The initial settings for F_iO₂ and PEEP depend on the clinical scenario. Patients intubated for postoperative airway protection may require an F_iO₂ of 0.3 and a PEEP of 5 cm H₂O. In contrast, multiply injured patients who have been resuscitated may require an F_iO₂ of 1.0 and a PEEP of 15 cm H₂O. In either case, early evaluation of arterial blood gas concentrations can guide further manipulations. Alternatively, oxygen saturation and end-tidal CO₂

values may be followed noninvasively with pulse oximetry and capnography. Sudden decreases in $P_{a}O_2$ (or $S_{a}O_2$) should be treated by first increasing $F_{i}O_2$ and then increasing PEEP. These measures should be followed by attempts to ascertain the cause of the acute change. A first assessment—including suctioning, arterial blood gas measurements, and a chest radiograph—should be carried out immediately, with particular attention to rapidly reversible causes (e.g., mucous plugging, pneumothorax, a large hemothorax or hydrothorax, and cardiogenic pulmonary edema). A more detailed assessment should then follow to look for other possible causes (e.g., pulmonary embolism, worsening ARDS, aspiration pneumonitis, and pneumonia).

It must be kept in mind that in many cases, the etiology is multifactorial, and that in the treatment of profound hypoxemia, it is important to address any and all correctable abnormalities, even when the potential gain is small. For example, in a patient with no pulmonary reserve, drainage of a large hydrothorax may yield a significant improvement in oxygenation, whereas in a patient with near-normal pulmonary function, this measure would have little, if any, effect.

In a minority of cases, a mismatch between patient effort and ventilatory support can result in increased work of breathing, progressive respiratory muscle fatigue, and, on rare occasions, arterial desaturation. This situation, referred to as patient-ventilator asynchrony, occurs as a consequence of the ventilator's failure to match the patient's respiratory drive and pulmonary mechanics. It only occurs during spontaneous breathing modes and may be secondary to a problem in the inspiratory trigger (inspiratory asynchrony), the expiratory trigger (expiratory asynchrony), or the flow rate (flow asynchrony).⁹ In these cases, direct patient observation often suffices to establish the diagnosis. Therapy is aimed at improving the patient-ventilator interaction and may involve changing the mode of ventilation (e.g., from VCV or PCV to PSV), the trigger setting (e.g., from pressure to flow), the inspiratory gas flow (either the rate or the waveform), or the cycling variable (time, flow, or pressure). Alternatively, in severe cases that result in hypoxemia, it may be necessary to increase sedation to the point where spontaneous respiratory efforts are eliminated. Neuromuscular blocking agents should only be considered if other measures have failed and hypoxemia is worsening. Generally, use of these agents should be avoided in critically ill patients when possible, because their administration has been associated with significant complications.¹⁰

VENTILATION

Adequate CO_2 elimination can be achieved with either PCV or VCV; the two methods can be used to achieve the same end points, and neither has any overwhelming advantage over the other. Accordingly, it is reasonable to choose between them on the basis of individual or institutional experience, simply for ease of management. The initial settings should include a V_T of 8 to 10 ml/kg predicted body weight¹¹ and a set respiratory rate of 12 to 15 breaths/min. In general, the assist mode is preferable, because it allows the patient to regulate $P_{a}CO_2$ while still receiving completely supported ventilation. If PCV is preferred, the inspiratory pressure can be adjusted at the bedside to achieve a V_T of 8 to 10 ml/kg. In either case, if the V_D/V_T ratio is nearly normal, the resultant alveolar ventilation should be sufficient to eliminate all of the metabolically produced CO_2 and maintain a $P_{a}CO_2$ of 40 mm Hg. After approximately 30 minutes, blood gases should be measured and the respiratory rate adjusted accordingly.

In a patient with adequate respiratory drive, PSV is a reasonable choice. In the past, it was largely considered a weaning mode.

Table 1 Criteria for Liberation from Mechanical Ventilation

Patient criteria for spontaneous breathing trial (SBT) to assess readiness for liberation from mechanical ventilator

Resolution or stabilization of underlying disease process
No evidence of residual pharmacologic neuromuscular blockade
Spontaneous respiratory efforts
Hemodynamic stability (no recent increase in pressor or inotropic requirements)
Ventilator settings as follows:
 $F_{i}O_2 \leq 0.5$
 $PEEP \leq 8 \text{ cm H}_2\text{O}$
 $P_{a}O_2 > 75 \text{ mm Hg}$
Minute ventilation < 15 L/min
 $pH 7.30 - 7.50$

Patient criteria to assess readiness for extubation

Suctioning required less often than every 4 hr
Good spontaneous cough
Endotracheal tube cuff leak^{*}
No recent upper airway obstruction or stridor[†]
No recent reintubation for bronchial hygiene

Criteria for a failed SBT[‡]

Respiratory rate > 35 breaths/min for ≥ 5 min
 $S_{a}O_2 < 90\%$ for ≥ 30 sec
 $HR > 140$ beats/min, or 20% increase or decrease from baseline
 $Systolic BP > 180 \text{ mm Hg}$ or < 90 mm Hg
Sustained evidence of increased work of breathing (e.g., retractions, accessory muscle use)
Cardiac instability or dysrhythmias
 $pH \leq 7.32$

^{*}Absence of a cuff leak is not an absolute contraindication to extubation. Each patient's risk for postextubation upper airway obstruction should be assessed individually.

[†]If extubation has recently failed because of airway obstruction, patient should be assessed and the underlying cause addressed (if possible) before extubation is reattempted. Appropriate adjunctive measures (e.g., racemic epinephrine or helium-oxygen) should be available before patient is extubated.

[‡]If any of these criteria are met, SBT should be terminated and the patient placed back on previous ventilator settings for 24 hr.

Currently, however, it is considered to be best suited for patients in whom the acute physiologic derangements leading to respiratory failure are resolving but who are not ready to be liberated from the ventilator. The main difference from past applications of PSV is that in current practice, pressure support is not intentionally decreased over time [see Liberation from Mechanical Ventilation, below]; instead, the patient is completely supported while daily assessments of the patient's readiness for extubation are made. A potential advantage of PSV is enhanced patient comfort. This is a particularly important consideration when the patient's overall condition is improving and minimization of sedation may allow earlier extubation.

In the pressure-support mode, the patient determines the respiratory rate, inspiratory time, and \dot{V}_E . In a patient with normal lung compliance, pressure support of between 5 and 10 cm H_2O is usually sufficient and should result in a V_T of at least 600 ml. Pressure support may be increased as needed for patient comfort and should be titrated to keep the respiratory rate below 25 breaths/min. When pressures higher than 20 cm H_2O are required, most physicians elect to support the patient in the assist mode until pulmonary compliance improves.

If $P_{a}CO_2$ is elevated despite a \dot{V}_E of $100 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ (6–7 L/min), then the metabolic production of CO_2 is excessively high,

alveolar ventilation is an inappropriately low percentage of V_T (increased V_D/V_T), or both. To increase ventilation, the first step should be to increase the respiratory rate in a stepwise fashion to 20 to 25 breaths/min. In addition, the use of low-compliance ventilator tubing should be considered to minimize dead space in the ventilator circuit. If the P_aCO_2 is still elevated, V_D and total CO_2 production can be measured directly by using a metabolic cart. If CO_2 production is higher than normal ($130 \text{ ml} \cdot \text{m}^{-2} \cdot \text{min}^{-1}$), it can be decreased by reducing muscular activity or seizures, controlling hypermetabolic states (if possible), and minimizing the exogenous carbohydrate load.

If the P_aCO_2 is still elevated after all of these measures have been taken, the respiratory rate may be increased to 30 breaths/min or higher. It should be kept in mind, however, that the efficiency of ventilation decreases as the respiratory rate increases. This loss of efficiency occurs because the percentage of V_E used for gas exchange decreases as the respiratory rate increases because in the face of a fixed volume of dead space, there may be inadequate time for alveolar emptying during expiration. In addition, steps may be taken to increase V_T , though significant increases may worsen ventilator-induced lung injury through either barotrauma or volutrauma [see Discussion, Special Problems in Ventilator Management, Acute Lung Injury and Acute Respiratory Distress Syndrome, below].

The importance of maintaining a normal P_aCO_2 is often overstated. Allowing P_aCO_2 to climb above 40 mm Hg has no intrinsic detrimental effects in the absence of increased intracranial pressure, and it is not uncommon to permit the P_aCO_2 to rise to avert the adverse consequences of high tidal volumes and the ventilatory pressures required to generate these volumes. This approach, referred to as permissive hypercapnia, is safe as long as pH remains above 7.15. Over time, pH will increase with compensatory increases in renal bicarbonate preservation, provided that renal function is normal.

Liberation from Mechanical Ventilation

As the patient's condition improves, it is useful to distinguish between the need for continued endotracheal intubation and the ongoing requirement for mechanical ventilation. The need for endotracheal intubation requires an assessment of airway stability and is relatively straightforward (see below). Deciding when pulmonary function and respiratory muscle reserve are adequate for unassisted breathing is considerably more complex. The latter is what has traditionally been referred to as weaning from mechanical ventilation.

The term weaning implies a planned, gradual reduction in ventilator support whereby the patient assumes more and more of the work of breathing that had been performed by the ventilator. This is an inaccurate description of the actual process, which essentially involves assessment of a patient's ability to sustain independent ventilation and adequate gas exchange. Although the amount of support provided does decline as the patient improves, this decline is patient driven and is different from the physician-driven reduction of support historically used to wean the patient from the ventilator gradually.¹² Multiple indices have been devised for determining a patient's readiness for unassisted breathing, with variable degrees of success. Perhaps the optimal method might involve an

algorithm that incorporates clinical data, ventilator-derived data, and laboratory data to determine the timing and likelihood of successful liberation from the ventilator.

A randomized trial from 1995 compared four different weaning methods: (1) daily 2-hour SBTs, (2) twice-daily 2-hour SBTs, (3) gradual reduction of pressure support, and (4) gradual reduction of the IMV rate. The two SBT methods were superior in predicting successful extubation.¹³ In a follow-up study, the investigators reported that a 30-minute SBT was as effective as a 2-hour SBT, and the shorter duration is now preferred for most patients.¹⁴ Other traditional parameters used to predict the end of the need for mechanical ventilation are respiratory rate, rapid-shallow breathing index (RSBI; calculated as frequency divided by V_T), V_T , vital capacity, pressure-time product, and negative inspiratory force. These variables are useful adjuncts in the assessment of a patient's readiness to undergo an SBT, but they are not highly accurate in predicting the likelihood of successful extubation when used alone.¹⁵

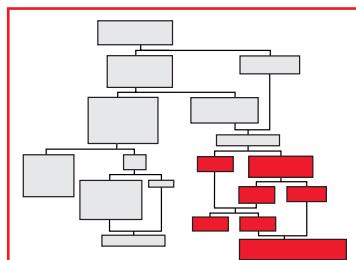

It is not necessary for the acute process to have resolved completely before an SBT can be performed, provided that other predetermined criteria are met [see Table 1]. To await normalization of the P/F ratio or resolution of the chest x-ray abnormality would result in a needless delay in extubation should the patient successfully complete the SBT. Unnecessary prolongation of mechanical ventilation heightens the risk of ventilator-associated pneumonia [see 8:17 Postoperative and Ventilator-Associated Pneumonia], increases sedation requirements, postpones mobilization, and delays discharge from the ICU.¹⁶

SPONTANEOUS BREATHING TRIAL

SBTs should be performed on a daily basis once the acute respiratory process has resolved and the patient is hemodynamically normal [see Table 1]. PEEP should be set at 5 cm H₂O, with or without an additional 5 cm H₂O of pressure support (if the endotracheal tube is less than 7.0 mm in diameter). The F_iO₂ should be set to a value approximately 10% greater than required while the patient is fully supported, and the patient should be allowed to breathe spontaneously for 30 to 120 minutes. At the conclusion of the SBT, blood gas values should be obtained, and the patient should be placed back on the ventilator at the previous settings. At all times, the patient's vital signs should be monitored for evidence of increased work of breathing. Criteria for a failed SBT include (1) significant changes in the respiratory rate, (2) evidence of increased work of breathing, (3) significant dysrhythmia, and (4) hemodynamic instability [see Table 1]. In addition, the arterial blood gas values should be evaluated for evidence of worsening hypoxemia or hypercarbia, though it should be kept in mind that a normal P_aCO_2 is less important if the pH is within the normal range.

If the patient successfully completes the SBT, extubation should be attempted. There are few reasons to continue mechanical ventilation in this situation. If it is suggested that the patient remain intubated, one should ask whether a further delay in extubation would improve the chances of success, and if so, how. Among the reasons frequently cited for continuing intubation are altered mental status and inability to protect the airway, a potentially technically difficult reintubation, the presence of an unstable injury to the cervical spine, the likelihood of return trips to the operating room, and the need for frequent suctioning. Each of these reasons must be balanced against the inherent risks of continued intubation, and a clear plan should be developed outlining how postponing extubation will alter the situation for the better.

The patient with traumatic brain injury (TBI) presents a unique problem, for two reasons. First, the patient is often unable

to maintain an adequate airway. Second, the patient is often unable to clear upper and lower airway secretions adequately and thus is at risk for continued aspiration and pneumonia. In patients whose mental status is altered but who are expected to recover quickly, the risk imposed by 1 or 2 additional days of intubation is relatively small, and delaying extubation to wait for mental status to clear can be justified. In TBI patients whose recovery is anticipated to take months (if it happens at all), the options are early tracheostomy [*see Tracheostomy, below*] and attempted extubation. Ultimately, the choice between these two options should be made on a case-by-case basis. Although tracheostomy is often preferred, these patients can frequently be extubated without significant sequelae.¹⁷

Failed SBT

When a patient fails an SBT, the first priority is to determine the reason for the failure. Initially, it is important to distinguish between patients who fail to meet the extubation criteria for unrelated reasons (e.g., agitation or cerebral storming in a TBI patient) and those who truly are not ready to be liberated from the ventilator. Direct observation of the patient during the SBT, if feasible, may provide insight into the failed attempt. The next step is to attempt to identify the specific cause of the failure. In these situations, a thorough knowledge of the patient's history is important, with special attention paid to age, comorbid conditions, reasons for and duration of mechanical ventilation, other indices of critical illness, and nutritional status [*see Table 2*]. Failure is frequently multifactorial, and actions to improve one or more of these factors should be undertaken to alter the outcome of the next SBT. After a failed attempt, it is best to provide a stable, nonfatiguing form of respiratory support (e.g., PSV) until the following day, thus allowing the patient a period of rest.

Patients who persistently fail SBTs are typically classified as exhibiting failure to wean. Comorbid conditions, including congestive heart failure, chronic lung disease, and renal or hepatic insufficiency, should be treated medically to the extent possible before further trials are attempted. The excess sodium and water frequently administered to critically ill patients can have negative effects on pulmonary mechanics, making liberation from the ventilator more difficult. Hydrostatic pulmonary edema, chest wall or visceral edema, and pleural effusions can have a greater impact on patients recovering from critical illness, who may be malnourished and deconditioned.

General measures to facilitate weaning include judicious use of diuretics, upright positioning, correction of electrolyte abnormalities (in particular, low serum potassium or phosphate levels), and, in some cases, drainage of hydrothoraces. In addition, attention should be given to providing appropriate nutritional support while avoiding excessive carbohydrate administration (which can increase CO₂ production). Physical therapy should begin as soon as possible to prevent further muscle atrophy. In addition to these general measures, consideration should be given to performing a tracheostomy. Although there is disagreement about the optimal timing and method of tracheostomy in this setting (see below), it is obvious that this measure can greatly facilitate attempts to discontinue mechanical ventilation by eliminating the risks associated with extubation. When the tracheostomy is in place and all general measures have been considered, SBTs should resume.

A very small percentage of patients are unable to tolerate the sudden reduction in support that occurs when they are treated with continuous positive airway pressure (CPAP) or a tracheostomy collar. These patients, who are often severely deconditioned after having been mechanically ventilated for several

Table 2 Causes of Failed Spontaneous Breathing Trials

Cause of Failure	Treatment
Anxiety/agitation	Judicious use of benzodiazepines ± haloperidol
Infection (pulmonary or extrapulmonary)	Diagnosis and treatment of causative infection
Electrolyte abnormalities (low K ⁺ , low PO ₄ ⁻)	Correction of electrolyte concentrations
Pulmonary edema/cardiac ischemia	Administration of diuretics ± nitrates
Deconditioning/malnutrition	Aggressive nutritional support (via enteral route whenever possible) Physical therapy
Neuromuscular disease (critical illness polyneuropathy, myasthenia gravis)	Aggressive bronchopulmonary hygiene Specific treatment of myasthenia gravis (pyridostigmine, steroids, plasmapheresis) Early consideration of tracheostomy
Increased intra-abdominal pressure (obesity, abdominal distention)	Semirecumbent positioning Nasogastric decompression
Hypothyroidism	Thyroid replacement
Large hydrothoraces (rarely primary cause but may increase work of breathing in patients with marginal reserve)	Initiation of diuresis ± thoracentesis
Excessive auto-PEEP (COPD, asthma)	Bronchodilator therapy I.V. sedation to prevent agitation and air trapping
Excessive minute ventilation requirements: ↑ CO ₂ production Metabolic acidosis	Reduction of carbohydrate intake Treatment of underlying cause (e.g., lactate production or renal failure) Consideration of HCO ₃ ⁻ replacement if wasting is present (e.g., with renal tubular acidosis or pancreatic fistula)

weeks or longer, may benefit from a more gradual reduction in ventilatory support. In these cases, the term weaning is probably an accurate description of the process. A planned gradual reduction in support may be better tolerated with scheduled decreases in pressure support or, alternatively, with gradual increases in the duration of periods of unassisted breathing. In the setting of chronic ventilator dependence, neither method is necessarily superior to the other. What is important is that the patient should never be allowed to continue until exhaustion during the weaning process. Formulating a well-defined plan for weaning is more important than choosing a particular weaning method. One approach is to use a daily workout calendar similar to those used for athletic training, so that the details of the plan are clear and easily understandable by the patient, the family, the nursing staff, the respiratory staff, and the ICU team. Finally, both patients and families should be counseled to expect weaning to last a long time.

PROTOCOL-BASED VENTILATOR MANAGEMENT

Once respiratory failure has resolved, the patient's readiness for extubation is assessed. Traditionally, this assessment has been made by the physician. Unfortunately, both physician factors and

patient factors can result in unnecessary delays that prolong the duration of mechanical ventilation. As a result, many institutions have developed respiratory therapist-driven and nurse-driven protocols that allow SBTs to occur without physician input. Implementation of these protocols has been shown to shorten ventilator time, reduce the incidence of ventilator-associated pneumonia, and lower costs.¹⁸⁻²⁰

Although respiratory therapist-driven or nurse-driven protocols improve outcome when applied to a population of ventilated patients, individual patient characteristics should still be a consideration when deciding on extubation in a given case. Successful completion of an SBT simply implies that the patient has the ventilatory capacity to breathe spontaneously; it does not guarantee that the airway is stable or that the patient can adequately clear tracheobronchial secretions. The decision to end ventilatory support must rest on a careful assessment of the risks of continued intubation and mechanical ventilation against those of failed extubation.

AIRWAY ASSESSMENT

Once a patient has successfully completed an SBT, a second assessment should be made to determine the need for continued airway support with the endotracheal tube. In patients who were initially intubated for a condition necessitating airway protection (e.g., altered level of consciousness or angioedema), the condition should be resolved before extubation. Alternatively, patients who have been ventilated for long periods may have secondary airway edema related to fluid resuscitation or vocal cord damage secondary to the use of the translaryngeal tube.²¹

One way of determining whether the patient will have significant airway compromise is to perform the so-called cuff leak test. In this test, the patient is placed on VCV, and the volume of air lost during a single respiratory cycle when the cuff is deflated is measured. Although the cuff leak test was originally described as a qualitative test in children with croup, it has since proved to have some value as a quantitative test, affording a degree of improvement in the ability to predict which patients will have significant postextubation upper airway edema.²²⁻²⁴ Leak values below 9% to 15% of the inspired volume have been associated with increased rates of postextubation stridor and the need for reintubation.²⁴⁻²⁶ Unfortunately, the cuff leak test is an imperfect predictor. In one study, a cutoff value of 15% had a positive predictive value of only 25% for reintubation.²⁴ With this cutoff value, a patient would have a 75% chance of successful extubation in the absence of an air leak. Results such as these suggest that the cuff leak test is best used as a tool for assessing risk and that failure on this test should not be an absolute contraindication to extubation. Patients who fail the test may be candidates for postextubation adjunctive measures, such as racemic epinephrine (to enlarge the upper airway aperture, helium-oxygen mixtures (to decrease airflow resistance), or both. Although evidence supporting the use of such measures in adults is lacking, there are some data to support their use in children to treat upper airway obstruction and postextubation stridor.²⁷⁻³⁰ Parenterally administered steroids have been employed to prevent postextubation stridor in children, with some success, but there is no evidence that they reduce the rate of reintubation in adults.³¹ Finally, patients who require prolonged intubation because of airway instability should be considered for tracheostomy (see below).

TRACHEOSTOMY

The decision as to when a patient can be liberated from the mechanical ventilator is often complicated by concerns about the risks associated with failure and reintubation. Prolonged endotracheal intubation can injure the airway and result in airway edema, making reintubation difficult. In addition, the possibility that reintubation may be required at night or at other times when qualified personnel may not be readily available contributes to delays in extubation. The main theoretical advantage of tracheostomy in this context is that the issue of airway stability can be separated from the issue of readiness for extubation, and this separation may hasten the physician's decision to discontinue mechanical ventilation. Tracheostomy has other potential advantages as well, including decreased work of breathing, avoidance of continued vocal cord injury, improved bronchopulmonary hygiene, patient comfort, and improved patient communication.³²⁻³⁴ On the other hand, it has several disadvantages, including the long-term risk of tracheal stenosis and the significant procedure-related complication rate (reported to be between 4% and 36%).³⁵⁻³⁷ Despite the potential risks, it is generally believed that in properly selected patients, tracheostomy placement may assist in liberation from the mechanical ventilator, though the evidence supporting this belief is inconsistent.³⁸⁻⁴¹

A relatively new technique that is rapidly gaining acceptance is the use of a percutaneous dilational approach to tracheostomy placement at the bedside. Several commercially available kits are available, and the long-term complication rate is similar to that seen with open tracheostomy.^{36,37,42} Percutaneous access is obtained with a needle, followed by serial dilation of the tracheotomy over a guide wire. Many advocate doing this procedure under bronchoscopic guidance, which may be associated with a lower periprocedural complication rate.⁴³ The main advantage of the percutaneous dilational approach is that it avoids the delays associated with obtaining OR time and obviates the risks associated with patient transport.⁴⁴

The main controversy surrounding tracheostomy in this setting is whether there is any benefit to performing the procedure early in the course of critical illness. To answer this question, several authors compared early tracheostomy (generally < 1 week) to prolonged translaryngeal intubation or, alternatively, to late tracheostomy (> 1 week).^{38,40,41,45-47} Outcome measures included duration of mechanical ventilation, number of episodes of ventilator-associated pneumonia, length of ICU stay, and mortality. Unfortunately, many of these reports were limited by their observational design, their small sample size, or their inclusion of only certain specific patient subgroups (e.g., medical or neurosurgical patients). Furthermore, surgeons have traditionally held very strong biases with regard to the use and timing of tracheostomy, and these biases tend to impede the conduct of randomized, controlled trials. One group carried out a multicenter randomized trial evaluating the use of tracheostomy in trauma and nontrauma patients who were expected to need mechanical ventilation for more than 7 days. In this trial, early tracheostomy offered no overall benefit; however, these results may be of limited applicability, in that the authors reported experiencing significant difficulty in obtaining the participation of physicians and institutions, mostly because of strong physician bias.⁴⁰ As a result, no clear consensus has yet been reached regarding the optimal use, timing, and method of tracheostomy in the ICU setting.

Discussion

Special Problems in Ventilator Management

ACUTE LUNG INJURY AND ACUTE RESPIRATORY DISTRESS SYNDROME

ALI and ARDS are common problems in the ICU and carry a high mortality [see 8:4 *Pulmonary Insufficiency*].⁴⁸ Over the past decade, an improved understanding of the pathophysiology of ventilator-induced lung injury has resulted in significant changes in ventilator management in patients with ARDS. It is now clear that the volume and pressure associated with mechanical ventilation can induce and perpetuate lung injury and the systemic inflammatory response syndrome (SIRS). As a result, the primary goals of ventilator management in ALI and ARDS patients are (1) to avoid repetitive expansion and collapse of recruitable alveolar units and (2) to avoid overdistention of functioning alveoli (volutrauma).

Several prospective trials have employed a low- V_T ventilation strategy to prevent ventilator-induced lung injury.^{49–53} The largest of these trials compared a lung-protective approach that used a V_T of 6 ml/kg of predicted body weight with a more traditional approach that used a V_T of 12 ml/kg. Mortality was reduced by 22% in the patients treated with lower tidal volumes, and both SIRS and the alveolar inflammatory response were attenuated. Accordingly, a low- V_T , lung-protective strategy is now standard for treatment of patients with ALI and ARDS.⁴⁹

High versus Low PEEP in ARDS

ARDS is characterized by a heterogeneously distributed loss of functioning alveoli, with normally compliant, open alveoli mixing with collapsed, nonrecruited alveoli.⁵⁴ In the setting of inadequate PEEP, a lung-protective ventilation strategy may contribute to further alveolar collapse and may perpetuate lung injury secondary to repetitive opening and closing of alveolar units.⁵⁵ It follows that higher levels of PEEP may prevent the injury associated with this phenomenon and perhaps improve patient outcome. Additionally, a frequent point of controversy in managing the hypoxicemic patient is whether it is preferable to employ higher levels of PEEP with lower levels of $F_I O_2$ or lower levels of PEEP with higher levels of $F_I O_2$. Many intensivists prefer to use higher levels of PEEP to keep $F_I O_2$ below 0.6, believing that higher oxygen levels may induce hyperoxic lung injury. However, a randomized, controlled trial that compared a high-PEEP strategy with a high- $F_I O_2$ strategy found the outcomes to be similar.⁵⁶ Thus, it is not currently possible to determine the optimal PEEP for ALI or ARDS patients with any certainty; the values chosen should be based on individual patient response.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

COPD is an uncommon indication for the initiation of mechanical ventilation in surgical patients; however, COPD may be present in varying degrees as a comorbid condition in ventilated patients and may thereby complicate ventilator management. Ventilated patients with COPD may be oxygen or steroid dependent and typically are in a tenuous state even in the absence of a surgical insult. The basic principles of management are (1) to treat the underlying cause of respiratory failure (e.g., sepsis or trauma), (2) to minimize airway hyperreactivity through generous use of bronchodilators and steroids when necessary, (3) to manage tracheobronchial secretions aggressively, and (4) to minimize the work of breathing.⁵⁷

The expiratory flow limitation observed in patients with COPD can result in incomplete expiration, air trapping, and intrinsic positive end-expiratory pressure (PEEPi, also referred to as auto-PEEP). These results can further impair respiration by decreasing the effective contribution of diaphragmatic contraction. Although reducing PEEPi can be difficult, there are several maneuvers that should be attempted initially to decrease air trapping and the resulting PEEPi. The first is to maximize the expiratory time by increasing the inspiratory flow rate or decreasing the respiratory rate. A reduction in tidal volume is also effective, in that less time is required for complete expiration of a smaller volume. Another maneuver is to administer bronchodilators liberally so as to minimize airflow limitation. If this measure is ineffective, adjusting the ventilator's PEEP setting to match the PEEPi should be considered for patients who are using a spontaneous mode of ventilation. This will minimize the increased work necessary to trigger the ventilator [see Figure 5]. Extubation can generally be accomplished once the acute episode resolves; it should be kept in mind that blood gas parameters were unlikely to have been normal at baseline. It is also reasonable to attempt a short period of bilevel positive-pressure ventilation immediately after extubation in patients with severe COPD in an effort to avoid having to reintubate these patients.

BRONCHOPLEURAL FISTULAS

Bronchopleural (or parenchymal pleural) fistulas (BPFs) are an infrequent but severe complication of thoracic trauma or pulmonary resection. The incidence ranges from 2% to 12%, and the condition is associated with a high mortality.^{58–60} Ventilator management of BPF patients is difficult because large air leaks through the fistula, which may represent the path of least resistance to airflow, limit adequate alveolar ventilation. Care is complicated by the need for a higher P_{aw} to maintain oxygenation, which may only increase flow through the fistula.

The determinants of flow through a BPF have important implications for ventilator management and have been investigated in animal models and in several small case series.^{61–64} Transpulmonary pressure and fistula resistance are the main factors influencing the size of the air leak. Specifically, P_{aw} appears to have the greatest impact on flow through the fistula; there is little or no change when peak inspiratory pressure is varied.^{62,65} Intrapleural pressure plays a role as well. Conventional chest tube management involves the use of -10 or -20 cm H₂O suction to evacuate the pleural space and promote pleural apposition. In the setting of a significant BPF, this measure increases the pressure gradient and may increase the size of the air leak.^{62,64}

There is no clearly beneficial method of ventilator management in BPF patients, but most would agree that limitation of P_{aw} should be the first step and that early extubation is indicated whenever possible. Various techniques for managing respiratory failure associated with large BPFs have been described in single case reports or small case series.^{65–75} High-frequency jet ventilation (HFJV) to support patients with BPF has been advocated on the basis of the low P_{aw} generated with this ventilatory mode. Several case reports have described a decrease in fistula airflow with subsequent closure of the BPF after the institution of HFJV.^{66,69,74–76} Unfortunately, although this technique may be useful in cases of isolated BPF, most of the reports do not involve patients with simultaneous lung parenchymal disease. The elevated P_{aw} required to treat the profound hypoxemia associated with ALI and ARDS

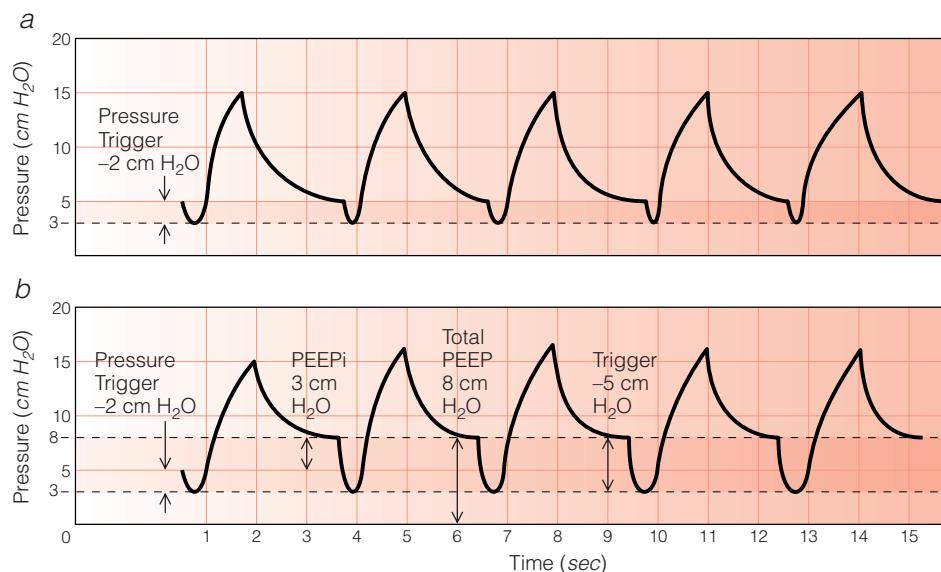

Figure 5 Illustrated is intrinsic PEEP during assisted spontaneous ventilation. In *a*, the patient is breathing spontaneously on VCV in the assist-control mode. The respiratory rate is 20 breaths/min, and the effective I/E ratio is 1:2 (inspiration, 1 sec; expiration, 2 sec). Expiratory time is adequate; therefore, no intrinsic PEEP (PEEPI) develops, and total PEEP is equal to the set PEEP (5 cm H₂O). In *b*, a patient who is breathing spontaneously on identical ventilator settings requires a longer expiratory phase to prevent air trapping and auto-PEEP. Incomplete expiration results in an auto-PEEP equivalent to 3 cm H₂O and a new total PEEP of 8 cm H₂O. This results in increased P_{aw}, but more important, the patient must now generate 5 cm H₂O of negative pressure during inspiration to trigger the ventilator.

may negate any potential benefit associated with HFJV.^{61,63}

Besides HFJV, a number of other unconventional modes of ventilation have been used to manage BPF patients, including the use of a double-lumen tube with a variable flow resistor,⁷¹ airway pressure-release ventilation (APRV),⁷² high-frequency conventional ventilation,⁷⁰ and differential lung ventilation using any combination of these modalities.^{66,70,75,77} Intermittent occlusion of the chest tube during inspiration in an effort to lower transpulmonary pressure has also been reported to assist ventilation in certain cases.⁶⁵ Bronchial blockade⁷⁸ and other newer therapies (e.g., bronchial stenting^{79,80} and endobronchial application of fibrin or other tissue sealants^{81,82}) may be useful in refractory cases. Ideally, large BPFs should undergo early operative revision if the injury and the patient's condition permit.

Alternative Modes of Ventilation and Adjunctive Therapies

INVERSE-RATIO VENTILATION

Inverse-ratio pressure control ventilation (PC-IRV) has been used to treat patients with ARDS and severe hypoxemia for several decades.^{83,84} This mode makes use of a prolonged inspiratory time to deliver a pressure-limited breath that results in an inverted I/E ratio (e.g., 2:1, 3:1, or 4:1 rather than the normal 1:3). The rationale for PC-IRV is based on two principles. The first principle is that a prolonged inspiratory time results in better gas distribution with a lower peak inspiratory pressure; the second is that the elevated P_{aw} improves alveolar recruitment, resulting in improved oxygenation. The theoretical advantages notwithstanding, both animal models of ALI and several observation studies in humans that compared normal-ratio ventilation with PC-IRV have failed to find any significant advantages to the latter when patients are ventilated with appropriate levels of PEEP.⁸⁵⁻⁸⁷ As

noted (see above), PEEP prevents derecruitment. This not only improves oxygenation but also has the theoretical advantage of preventing the repetitive collapse and reinflation of lung units associated with ventilator-induced lung injury. To date, there have been no randomized trials assessing outcome after PC-IRV, but the available data suggest that this mode is unlikely to improve patient outcomes in the setting of adequate PEEP.

PRONE VENTILATION

The finding of dependent atelectasis in patients with ARDS makes prone positioning an attractive therapeutic option.⁵⁴ Advocates cite several theoretical benefits, including recruitment of previously collapsed alveoli, relief of diaphragmatic pressure secondary to the abdominal viscera, and improved drainage of tracheobronchial secretions.⁸⁸ Several prospective randomized trials have evaluated the use of prone positioning in adults and children with ARDS.⁸⁹⁻⁹¹ Despite consistent improvements in oxygenation, no significant benefit in terms of mortality has yet been demonstrated.

In practice, prone positioning is performed intermittently throughout the day for periods ranging from 4 to 12 hours, with the remaining time spent in the supine position. The primary risk associated with prone positioning is accidental removal of the endotracheal tube, a chest tube, or an intravenous line. It is possible to place patients with an open abdomen prone in some cases; however, this remains technically challenging. Newer patient beds designed specifically for prone positioning (e.g., Rotoprone; KCI, San Antonio, Texas) facilitate prone ventilation, but they remain costly and are not universally available.

Multiply injured patients with increased intracranial pressure can pose a difficult challenge. Hypoxemia is associated with a worse neurologic outcome in this population, but because of the increased intracranial pressure that may occur, prone positioning is contraindicated. In this situation, limited axial rotation (i.e.,

continuous partial axial rotation to varying degrees, depending on patient tolerance) is an option that may yield similar improvements in oxygenation.⁹²

Other injuries (e.g., unstable spinal fractures or pelvic or long-bone fractures that call for traction) can be significant problems and are relative contraindications to prone positioning. In patients with ARDS and profound hypoxemia, they are generally secondary concerns and should not prevent the use of prone positioning as an adjunctive therapy.

HIGH-FREQUENCY OSCILLATORY VENTILATION

For several decades, high-frequency oscillatory ventilation (HFOV) has been used to treat respiratory failure in premature infants.⁹³ More recently, it has been used in adults with ARDS, both as primary treatment and as rescue therapy for severe hypoxemia.⁹⁴⁻⁹⁶ HFOV differs from HFJV in that it employs an oscillating piston or diaphragm that provides high-frequency, low-amplitude ventilation superimposed on an elevated P_{aw} . Its primary theoretical rationale is based on the so-called open lung approach to limiting ventilator-induced lung injury: it avoids the repetitive alveolar opening and closing that can occur at low airway pressures while also avoiding the overdistention that occurs at higher airway pressures.

P_{aw} is determined by the operator and is maintained by continuous gas flow from the ventilator through a resistance valve at the end of the circuit. The oscillating piston or diaphragm lies perpendicular to the gas flow. The oscillating frequency is set by the clinician and generally ranges from 3 to 6 Hz (180 to 360 breaths/min). As in conventional ventilation, oxygenation is achieved by adjusting P_{aw} , as well as F_{iO_2} . Ventilation is altered by changing both the frequency and the amplitude of the piston's oscillation. HFOV differs from conventional ventilation in that increases in ventilation are achieved by reducing the frequency of oscillation and increasing the amplitude, which allow more time for the expiratory phase of piston displacement. It also differs in that the expiratory phase is assisted by the backward piston movement.

The primary side effect of HFOV is potential hemodynamic compromise secondary to the elevated P_{aw} . Pneumothorax has also been associated with HFOV, but it may be a marker of the severity of lung injury rather than a consequence of the mode of ventilation.⁹⁴⁻⁹⁶ In addition, most patients require neuromuscular blocking agents to prevent spontaneous respiratory effort while being maintained on the oscillating ventilator. The requirement for a specialized adult oscillating ventilator and the general lack of familiarity with HFOV has hindered broad application of this technique.

Despite these limitations, several studies have shown HFOV to be well tolerated by patients with severe ARDS. In addition, consistent improvements in oxygenation have been documented when patients are converted from conventional ventilation to HFOV.⁹⁵⁻⁹⁸ As a result, HFOV is a potential option for patients with profound hypoxemia, either alone (as rescue therapy) or in combination with other adjunctive measures (e.g., nitric oxide [NO] inhalation and prone ventilation). Improved oxygenation, however, is not necessarily correlated with improved mortality. The role of HFOV in primary treatment of early ARDS remains to be determined.⁹⁹

AIRWAY PRESSURE-RELEASE VENTILATION

APRV is a relatively new mode of ventilation that, like HFOV, is based on the open lung approach to limiting ventilator-induced lung injury. APRV employs a high CPAP, which is intermittently released for short periods to allow lung emptying.¹⁰⁰ The primary rationale is based on the idea that optimal alveolar recruitment depends both on differential alveolar opening pressures and on

variations in regional alveolar time constants.¹⁰¹ Elevation of transpulmonary pressure above the upper inflection point is avoided because the sustained P_{aw} is generally below the peak or plateau pressures observed in conventional PCV or VCV. Compared with modes that induce a high P_{aw} (e.g., HFOV and PC-IRV), APRV has the advantage of allowing spontaneous respiration, thereby eliminating the need for neuromuscular blocking agents.

APRV has been studied extensively in animal models of ALI,¹⁰¹⁻¹⁰⁴ but human data are limited to case series and a few observational studies that reported primarily on application and safety.¹⁰⁵⁻¹⁰⁹ In practice, three variables are manipulated: the high continuous pressure (P_{high}), which ranges from 20 to 30 cm H₂O; the release period, which generally lasts no longer than 1 second; and the low release pressure (P_{low}), which is between 0 and 5 cm H₂O. The P_{high} and P_{low} settings can be manipulated along with the F_{iO_2} to achieve adequate arterial oxygenation [see Figure 6]. The release phase can be changed with respect to both duration and frequency to ensure adequate ventilation. Spontaneous respirations occur and are superimposed on the high CPAP.

No significant complications have been associated with APRV. There is a theoretical potential for hemodynamic compromise; however, because of the high levels of PEEP and the high plateau pressures already observed in patients with severe ARDS, P_{aw} is generally lower with APRV, and as a result, cardiovascular function may actually improve.¹⁰⁸ The theoretical benefits of APRV make it an attractive alternative to conventional ventilation. Unfortunately, this mode of ventilation has not been directly compared with low-tidal volume, lung-protective ventilation. APRV probably will not be widely used until it is shown to have a beneficial effect on outcome.

NONINVASIVE POSITIVE-PRESSURE VENTILATION

Noninvasive positive-pressure ventilation (NPPV) is positive-pressure ventilation administered through either a nasal or a full-face mask in the form of either CPAP or bilevel positive airway pressure (BiPAP). PEEP is generally set at 5 to 10 cm H₂O (CPAP), with or without additional pressure support at levels ranging from 5 to 20 cm H₂O (BiPAP), and titrated to keep the respiratory rate under 25 breaths/min. In comparison with medical therapy alone, NPPV has been demonstrated to reduce both the need for intubation and mortality in patients with exacerbated COPD.⁵⁷ Patients in whom medical therapy fails—as signaled by worsening tachypnea, hypoxemia, and respiratory acidosis—are candidates for NPPV. This mode should be used in conjunction with other measures, such as inhaled bronchodilators, inhaled steroids, and oral or parenteral steroids and antibiotics when appropriate.⁵⁷

NPPV has sometimes been used to treat respiratory failure associated with cardiogenic pulmonary edema.¹¹⁰⁻¹¹³ In this setting, NPPV has certain theoretical benefits, including decreased work of breathing, decreased left ventricular afterload,¹¹⁴ and, possibly, decreased preload as a result of the positive intrathoracic pressure. Nevertheless, the available data are inconclusive. One randomized trial was stopped early because a higher rate of myocardial ischemia was recorded in the BiPAP group than in the CPAP group.¹¹⁰ Another study reported no significant cardiac events in either group.¹¹¹ Both modes of NPPV, however, were superior to standard oxygen therapy in preventing the need for intubation.¹¹¹ These studies are limited by their sample sizes, and as a result, it is difficult to draw definitive conclusions. It is possible that NPPV may have a beneficial effect on outcome in patients with cardiogenic pulmonary edema, but whether CPAP or BiPAP is therapeutically optimal has yet to be determined.

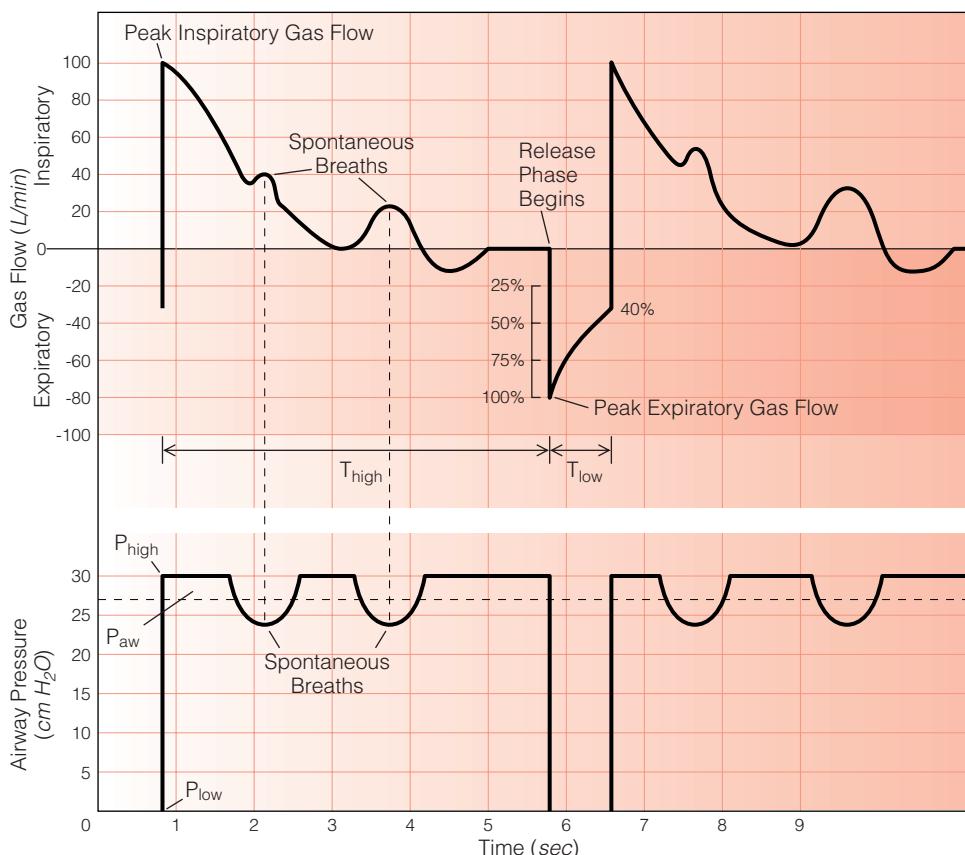

Figure 6 Illustrated is airway pressure-release ventilation, a ventilation mode that maintains a high CPAP with intermittent release periods. The operator sets the high and low pressure settings (P_{high} , P_{low}) and the release time (T_{low}). The mode has several theoretical advantages over conventional ventilation, including lower alveolar distending pressures (in patients with ARDS), avoidance of alveolar derecruitment, and the ability for the patient to breathe spontaneously.

The use of NPPV to treat hypoxic respiratory failure that is not due to cardiogenic pulmonary edema (e.g., respiratory failure resulting from pneumonia, thoracic trauma, ALI, or ARDS) has also been addressed in several small randomized trials and a systematic review.¹¹⁵ The results of the individual studies vary somewhat, but the overall indication is that there may be some benefit to be derived from reducing the need for mechanical ventilation, the duration of the ICU stay, and mortality in certain patient populations—particularly those in whom intubation portends a particularly poor prognosis (e.g., immunocompromised patients and recent lung transplant recipients).¹¹⁵

There are several relative contraindications to NPPV, including severe facial deformity or trauma (either of which can prevent sealing around the edges of the mask), a decreased level of consciousness that is not expected to improve with improved ventilation, hemodynamic instability, a need for endotracheal intubation for other reasons (e.g., airway protection or surgery), and a recent upper GI operation. In addition, NPPV should not be performed by physicians, therapists, or nurses unfamiliar with its use or in situations where patient monitoring is inadequate. Inappropriate performance of NPPV may lead to unrecognized patient intolerance, worsening respiratory status, and delays in endotracheal intubation.¹¹⁶

Complications of NPPV include skin breakdown over the mask pressure areas, gastric distention, ventilator asynchrony, and treatment failure (associated with worsening mental status, aspiration, and delayed endotracheal intubation). In addition, NPPV should generally be avoided as a method of preventing reintubation in the ICU, because it has been associated with a worse outcome.¹¹⁷ Despite these limitations, NPPV is generally well tolerated and should be considered as a treatment option in certain patient populations with acute respiratory failure.

NITRIC OXIDE INHALATION

NO is a potent vasodilator that is administered as an inhaled gas. The delivery mode allows NO to exert its vasodilatory effect on pulmonary arterioles supplying ventilated (and only ventilated) alveoli, thereby improving \dot{V}/Q matching, reducing intrapulmonary shunting, and increasing oxygenation.^{118,119} Because of its short half-life in the circulation (100 milliseconds), inhaled NO is not associated with systemic vasodilation and hypotension.¹²⁰

NO is administered through a specialized delivery system in doses of 5 to 40 parts per million. Several randomized trials have shown it to yield modest improvements in oxygenation in adults and children with ARDS.¹²¹⁻¹²⁴ There are also numerous reports of NO administration in conjunction with prone positioning,¹²⁵ HFOV,^{126,127} and HFJV,⁷⁶ as well as in patients with BPFs.⁷⁶ Unfortunately, the use of NO has not been demonstrated to improve mortality. On the other hand, there have been no reports of significant adverse effects. The high cost of NO administration has kept it from being routinely used in ARDS patients.

SURFACTANT REPLACEMENT

Surfactant production in adult patients with ARDS is both diminished and abnormal.^{128,129} The loss of surfactant may contribute to the alveolar collapse, intrapulmonary shunting, and hypoxemia seen in ARDS. Theoretically, surfactant replacement would prevent derecruitment and improve lung compliance and oxygenation. In addition, prevention of alveolar collapse is important in limiting ventilator-induced lung injury. As a result, surfactant replacement is an attractive therapeutic option for patients with ARDS.

Several methods of surfactant replacement in adults have been assessed in randomized, multicenter placebo-controlled trials. In an early trial of aerosolized surfactant given to patients with sep-

sis-induced ARDS, no benefit was observed with respect to either oxygenation indices or mortality.¹³⁰ This trial was limited both by the particular surfactant formulation used and by the failure to employ a low-tidal volume, lung-protective ventilation strategy. A subsequent report, summarizing data from two large trials of a protein C-based surfactant formulation given for 24 hours, documented modest improvements in oxygenation during surfactant administration. Neither trial, however, demonstrated any significant impact on mortality.¹³¹ In view of the lack of mortality benefit, it is probably best to limit the use of surfactant in adults with ARDS to the setting of clinical trials.

EXTRACORPOREAL LIFE SUPPORT

Extracorporeal life support (ECLS) is the use of a modified heart-lung machine to support gas exchange while allowing the diseased lung to rest. The theoretical advantage of this technique is that it should avoid the oxygen toxicity and the volutrauma or barotrauma that may accompany mechanical ventilation in patients experiencing severe respiratory failure. ECLS has become the standard treatment of severe respiratory failure in neonates¹³² and has also been used in the pediatric population.¹³³ In adult patients with severe respiratory failure, it has been employed mainly in specialized centers, with reported survival rates of

approximately 50%.^{134,135} Vascular access may be obtained via either a venoarterial or a venovenous circuit. The latter is typically used in adult patients; the former is preferred in patients with marginal cardiovascular function.

In some centers, ECLS is employed when the risk of death with continuing conventional ventilation is more than 90% and the primary process is reversible. In 2004, one group reported on their use of ECLS to treat 255 patients with severe ARDS (defined as a P/F ratio lower than 100 when F_{1O_2} was 1.0, an alveolar-arterial gradient higher than 600 mm Hg, or a transpulmonary shunt fraction greater than 30% despite maximal ventilatory support). More than half (53%) of the patients survived to hospital discharge.¹³⁶ Although these results are difficult to interpret in the absence of a control group, the mortality appears to be lower than would be expected with traditional ventilator management.

The main contraindications to the use of ECLS are advanced age, malignancy, severe neurologic injury, and mechanical ventilation lasting longer than 5 to 7 days. Complications include bleeding (heparinization is required), hemolysis, cerebral infarction, renal failure, infection, and venous thrombosis. In view of the risks, ECLS should be reserved for patients at specialized centers who have profound hypoxemia that is refractory to other, less invasive measures.

6 ACUTE RENAL FAILURE

Sean M. Bagshaw, M.D., M.Sc., F.R.C.P.C., and Rinaldo Bellomo, M.D., F.R.A.C.P., F.J.F.I.C.M.

Acute renal failure (ARF) remains one of the major therapeutic challenges facing the modern physician. The term describes a syndrome characterized by a rapid decrease (occurring within hours to days) in the kidney's ability to eliminate waste products, regulate extracellular volume, and maintain electrolyte and acid-base homeostasis. This loss of excretory function is manifested clinically by the accumulation of end products of nitrogen metabolism (e.g., urea and creatinine). Other typical clinical manifestations include decreased urine output (which is not always present), the accumulation of nonvolatile acids, and an increased serum potassium concentration.

In the literature, the incidence of ARF has been variable, depending on the criteria used to define the condition. ARF has been reported to occur in approximately 5% to 8% of hospitalized patients and 15% to 30% of patients admitted to an intensive care unit. Despite the advances that have been made in understanding the pathophysiology of ARF and developing extracorporeal therapies, the mortality associated with this condition continues to be alarmingly high. Moreover, there is evidence to suggest that the mortality is even higher in patients with ARF that is severe enough to warrant initiation of renal replacement therapy (RRT).

The term acute tubular necrosis (ATN) has frequently been used in the context of ARF, but current evidence suggests that this term has limited clinical relevance, in that it describes only the histopathology and is not reliably linked with differences in patient management. The concept of ATN comes from animal models that do not accurately reflect clinical situations and from old biopsy data. Even in cases where the term seems appropriate, the so-called necrosis is frequently patchy and mostly isolated to the thick ascending loop of Henle. Furthermore, cells found in the urinary tubular casts of such patients are viable on staining studies, a finding that partly invalidates the use of the term necrosis.

General Principles

DEFINITION OF ACUTE RENAL FAILURE

A logical approach to organ failure might reasonably begin by defining what a particular organ does. In the case of the kidney, the list of functions is long. Many of these functions, however, are either shared with other organs (e.g., acid-base control, which is shared with the lung) or require complex neurohormonal interactions that involve other organs (e.g., the renin-angiotensin-aldosterone axis). Other renal functions are not routinely measured (e.g., small peptide excretion, tubular metabolism, and hormonal production).

There are only two functions that are routinely and easily measured in patients and are unique to the kidney: (1) production of urine and (2) excretion of waste products of nitrogen metabolism. Accordingly, clinicians have focused on these two functions in their efforts to define the presence of so-called ARF.

The two waste products whose levels are routinely measured in patients are urea and creatinine. The urea level is the one that is affected more by extrarenal factors (e.g., gastrointestinal blood,

changes in nitrogen intake, and changes in protein catabolic rate) and that varies more rapidly. The creatinine level is a more reliable marker of the glomerular filtration rate (GFR) and is commonly used to define the presence or absence of ARF; however, it does not change in direct proportion to the loss of nephron mass and is not a real-time descriptor of the GFR. Nonetheless, using urea and creatinine levels to define ARF seems a practical and reasonable approach to the biochemical definition of this condition. The problem, however, is that in current practice, there are too many essentially arbitrary biochemical cutoff values for the definition of ARF. This point was highlighted by a review of 28 studies of post-operative ARF, in which each study used a different definition of this condition.¹ The lack of agreement on the operative definition of ARF has significantly hindered research in this field, especially with regard to the design and execution of randomized, controlled trials. In 2004, however, the work of the Acute Dialysis Quality Initiative (ADQI) (<http://www.ADQI.net>) led to the development and publication of a consensus definition of ARF. It is hoped that acceptance and use of this definition will lead to more consistent, reproducible, and generalizable results from epidemiologic and interventional studies of ARF [see Figure 1].²

ASSESSMENT OF RENAL FUNCTION

Waste Product Levels

As noted (see above), to establish that ARF is present, one must be able to measure renal function and detect that it has been altered; however, the complexity of renal function can make this a difficult undertaking. Accordingly, in the clinical context, monitoring of renal function is limited to indirect assessment of the GFR through measurement of urea and creatinine levels in blood. These levels are relatively inaccurate markers of GFR and are heavily influenced by patient age, patient sex, nutritional status, steroid use, and the presence of GI bleeding or muscle injury. Furthermore, they generally only become abnormal once the GFR has fallen by 50% or more; they do not reflect real-time dynamic changes in the GFR and can be grossly modified by aggressive fluid resuscitation. Determining creatinine clearance by means of 2-hour or 4-hour collections or calculating clearance by means of formulas adjusted for body weight, sex, or age may increase the accuracy of the results, but it rarely, if ever, changes clinical management. Sophisticated radionuclide-based tests are available, but they are cumbersome and are useful only for research purposes.

Urine Output

Urine output is a commonly measured parameter of renal function and often is more sensitive to changes in renal hemodynamics than biochemical markers of solute clearance are. However, urine output is also of limited sensitivity and specificity; some patients have severe ARF, as indicated by a markedly elevated serum creatinine level, while maintaining normal urine output (so-called nonoliguric ARF). Because nonoliguric ARF has a lower

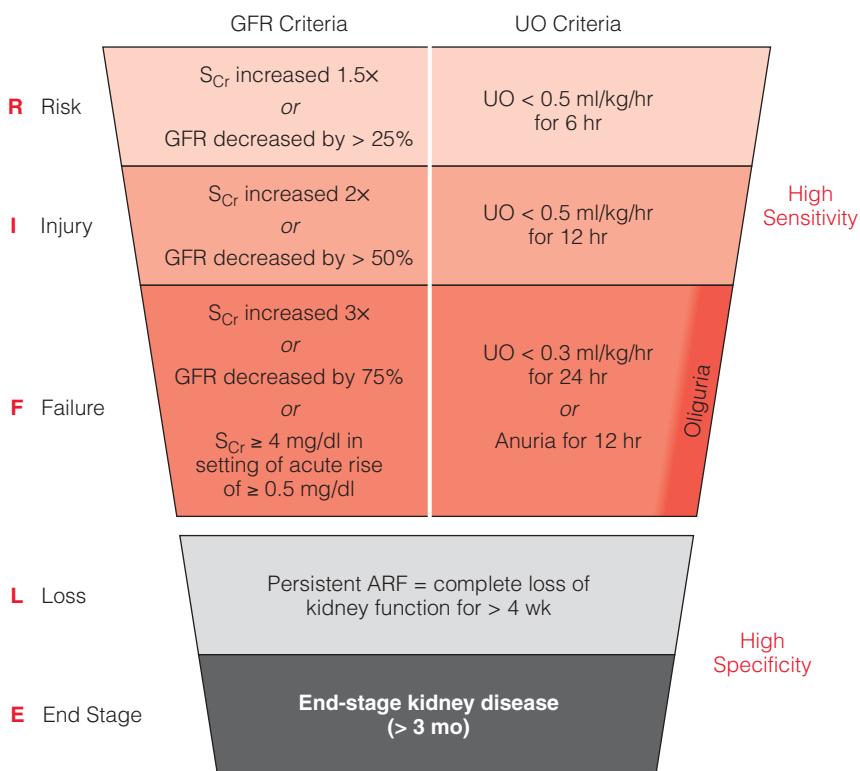

Figure 1 Depicted is the RIFLE (Risk, Injury, Failure, Loss, End stage) classification scheme for ARF.² The classification system includes separate criteria for GFR and urine output (UO). Those criteria that lead to the worst possible classification of renal failure should be used. The designation RIFLE-F (for failure) is appropriate even if there is a less than threefold increase in the serum creatinine concentration (S_{Cr}), provided that the new S_{Cr} is higher than 4.0 mg/dl (350 μ mol/L) in the setting of an acute increase of at least 0.5 mg/dl (44 μ mol/L). In this case, the designation RIFLE-FC should be used to denote acute-on-chronic disease. Similarly, when the presence of renal failure (RIFLE-F) is determined on the basis of urine output criteria only, the designation RIFLE-FO should be used to denote oliguria. The shape of the figure illustrates the point that more patients are included in the mild category (top), including some who do not have renal failure (higher sensitivity, lower specificity). In the severe category (bottom), the criteria are strict and therefore specific, but some patients with renal dysfunction may be missed (higher specificity, lower sensitivity).

mortality than oliguric ARF, urine output is frequently used as a means of distinguishing varieties of ARF.³ Classically, oliguria has been defined (approximately) as a urine output of less than 5 to 6 ml/kg/day or less than 0.5 ml/kg/hr. Often, changes in urine output can develop before biochemical changes in renal function become apparent.

Serum and Urine Biomarkers

Overall, it would be highly desirable to have markers of renal function that would enable physicians to diagnose true reductions in function associated with renal injury; the ability to diagnose such functional impairments would allow the identification of those patients in whom early intervention might be justified.

In the past few years, several serum and urine biomarkers have been developed for use in the detection of early renal dysfunction or injury. One such biomarker is cystatin C, a cysteine proteinase inhibitor of low molecular weight. This substance has many features that would make it an ideal tool for the assessment of renal function, especially its constant rate of production (which appears to be independent of any pathologic states), its exclusively renal excretion, and the good inverse correlation of its blood levels with radionuclide-derived measurements of the GFR.^{4,5} Another biomarker is kidney injury molecule-1 (KIM-1), a transmembrane protein that is present in the proximal renal tubule and is markedly upregulated and excreted in the urine in response to injury.⁶ Several other urinary biomarkers have been described that also appear to have potential for the detection of renal injury, including interleukin-18 (IL-18), Na^+/H^+ exchanger isoform 3 (NHE3), and neutrophil gelatinase-associated lipocalin (NGAL).⁷⁻⁹

These biomarkers are all promising; however, they are still relatively new, and thus, their roles in the diagnosis and management of ARF have not yet been assessed in large multicenter studies. At present, therefore, clinicians continue to rely on serum creatinine levels, plasma urea levels, and urine output as the three clinical pil-

lars of the diagnosis of ARF. They accept and understand the inaccuracy of these tests because they recognize that in this setting, obtaining absolute values is less important than detecting change and identifying the direction of change.

CLASSIFICATION OF ACUTE RENAL FAILURE

The classification of ARF into clinically useful etiologic categories remains challenging and problematic, for several reasons. First, several of the test results that are time-honored and commonly cited classifiers of ARF—such as a relatively high fractional excretion of sodium (FE_{Na}), a high urinary sodium level, a low specific gravity, the presence of casts, and a relatively low urinary osmolality—have yet to be validated against a widely accepted definition of ARF or a gold-standard test. Second, these test results have not been characterized in blinded, controlled, or standardized studies. Third, classification of ARF on the basis of these test results has not been shown to alter either patient management or outcome. Nevertheless, despite their limitations, these test results are widely used in the literature to classify and define ARF.

Unfortunately, there is no easy solution to the problems associated with classification of ARF. Clearly, more research is necessary before our understanding of ARF reaches the point where more reliable and objective subdivisions can be created (as has been done with pneumonia). The comprehensive process initiated by the ADQI (see above) should facilitate such research.²

These classification difficulties notwithstanding, there does exist a practical and useful approach to stratifying patients presenting with ARF. Traditionally, ARF is classified according to the probable source of renal injury: prerenal, renal (parenchymal), or postrenal (obstructive) [see Table 1].

Prerenal

Prerenal ARF is by far the most common type of ARF. The term prerenal typically indicates that the kidney is malfunctioning

predominantly as a result not of reasons intrinsic to the kidney but of systemic factors, which, through variable mechanisms, can alter renal blood flow (RBF) or intraglomerular hemodynamics and result in a decrease in GFR.

Clinicians frequently use terms such as prerenal azotemia or prerenal ARF to indicate not only that the cause or trigger of ARF is external to the renal parenchyma but also that a given patient has functional loss of GFR (i.e., loss of GFR without structural cell injury) as opposed to structural loss. In cases of suspected structural injury to the kidney, they typically use the term ATN instead. This clinical distinction probably does not reflect a true difference between two separate pathophysiologic states; more likely, these states simply represent two different points on a continuum of renal injury. Furthermore, no biopsy studies of ARF in patients treated in the ICU have been conducted to demonstrate that so-called ATN is the histopathologic basis of prolonged renal dysfunction.¹⁰

Common systemic causes of ARF include a low cardiac output state (e.g., myocardial infarction, tamponade, or valvular disease), cardiac surgery, major vascular surgery, trauma with hypovolemia, shock of any type (anaphylactic, hemorrhagic, or hypovolemic), hemodynamic instability associated with surgery, hepatic failure, increased intra-abdominal pressure, intra-abdominal hypertension, and rhabdomyolysis.^{3,11} The mechanisms by which these events induce ARF vary according to the causative trigger and are poorly understood; however, they are likely to be complex and to involve multiple pathways of renal injury. By far the most significant systemic factors contributing to ARF in developed countries

Table 1 Differential Diagnosis of Acute Renal Failure

Probable Source of Renal Injury	Differential Diagnosis
Prerenal	States of low cardiac output (myocardial, valvular, pericardial, or arrhythmic disease; pulmonary hypertension; pulmonary embolism; mechanical ventilation) States of decreased intravascular volume (dehydration; hemorrhage; burns; GI losses from vomiting, diarrhea, or surgery; renal losses from diuretics, osmotic diuresis, or diabetes insipidus) States of low systemic vasodilation (sepsis or septic shock; anaphylaxis; drugs; HRS) States of altered renal hemodynamics (from antiprostaglandin agents, ACE inhibitors, or exogenous vasopressors)
Renal (parenchymal)	Glomerulonephritis or vasculitis Renovascular disease (renal artery or vein occlusion; malignant hypertension) Exposure to toxins, either endogenous (myoglobin; hemoglobin; uric acid) or exogenous (radiocontrast media; antimicrobials; chemotherapeutic agents; immunosuppressive agents; ethylene glycol) Interstitial nephritis (from antimicrobials, diuretics, malignancy, or infection) Tubular deposition or obstruction (from bilateral cortical necrosis, multiple myeloma, or amyloidosis) Renal allograft rejection Trauma
Postrenal (obstructive)	Obstruction of ureter (from compression or kinking of ureters or pelviccaliceal area, calculi, malignancy, or external compression [e.g., retroperitoneal fibrosis]) Obstruction of bladder (from prostatic hypertrophy, calculi, malignancy, blood clot, or neurogenic bladder) Obstruction of urethra (from stricture, phimosis, or trauma)

ACE—angiotensin-converting enzyme HRS—hepatorenal syndrome

Table 2 Drugs Capable of Precipitating Acute Renal Failure

Radiocontrast media	ACE inhibitors
Aminoglycosides	Methotrexate
β-Lactam antibiotics	Cisplatin
Trimethoprim-sulfamethoxazole	Cyclosporine
Amphotericin	FK-506 (tacrolimus)
NSAIDs	

ACE—angiotensin-converting enzyme NSAIDs—nonsteroidal anti-inflammatory drugs

(especially in critically ill patients) are sepsis and septic shock, which account for more than 50% of all cases of ARF.¹²⁻¹⁴

If the systemic cause of prerenal ARF is rapidly removed or corrected, renal function usually improves, returning to near-normal or baseline levels over a period of days. If intervention is delayed or unsuccessful, however, renal injury can become established, and RRT may have to be initiated. In these circumstances, if the patient survives, it frequently takes several days or weeks to achieve renal recovery with independence from RRT.^{13,15-17}

Parenchymal

Parenchymal ARF is generally less common than prerenal ARF. The term parenchymal ARF is used to define a syndrome in which the principal source of damage is within the kidney and in which typical structural changes can be seen on microscopy. This syndrome can result from any of a number of disorders that affect the microvasculature, the glomerulus, the tubules, or the interstitium [see Table 1].

Nephrotoxic drugs are a particularly important cause of parenchymal ARF, especially in hospitalized patients.^{3,11} Many patients with drug-induced ARF show rapid improvement once the offending agent is removed. The drugs most commonly implicated in the development of ARF are aminoglycosides, penicillin or penicillin derivatives, nonsteroidal anti-inflammatory drugs (NSAIDs), trimethoprim-sulfamethoxazole, amphotericin B, cyclosporine, chemotherapeutic agents, and angiotensin-converting enzyme (ACE) inhibitors [see Table 2].¹¹ Not uncommonly, patients may be receiving several potentially nephrotoxic drugs concurrently. Accordingly, in all patients with ARF, a thorough history of drug administration is mandatory.

Other conditions that can cause parenchymal ARF include glomerulonephritis, vasculitis, interstitial nephropathy, malignant hypertension, pelviccaliceal infection, bilateral cortical necrosis, amyloidosis, and trauma.

Postrenal

Obstruction to urine outflow gives rise to postrenal ARF, which is the most common cause of functional renal impairment in the community (i.e., in nonhospitalized patients) and is usually secondary to prostatic hypertrophy. Obstructive ARF is also seen in hospitalized patients, albeit less commonly; typical causes in this population include prostatic hypertrophy, pelvic tumors, retroperitoneal fibrosis, papillary necrosis, and large calculi [see Table 1].

The clinical presentation of obstruction may be acute or acute-on-chronic in patients with long-standing renal calculi; oliguria is not always present. If obstruction is suspected, ultrasonography can be easily performed at the bedside. However, in some cases of acute obstruction, the ultrasonogram is abnormal, and in many cases, the obstruction occurs in conjunction with other renal

insults (e.g., staghorn calculi and severe sepsis of renal origin), so that the renal dysfunction is actually caused by a combination of factors.

Specific Syndromes

Hepatorenal syndrome Hepatorenal syndrome (HRS) is a form of ARF that typically occurs in the setting of advanced cirrhosis but can also occur in the setting of severe liver dysfunction caused by alcoholic hepatitis or in association with other forms of acute hepatic failure.¹⁸

The pathophysiologic hallmark of HRS is profound renal vasoconstriction in the setting of systemic and splanchnic vasodilation. The pathogenesis of HRS is incompletely understood; however, there are several mechanisms that may contribute to its development, including (1) activation of the renin-angiotensin system in response to systemic hypotension; (2) activation of the sympathetic nervous system in response to systemic hypotension and increased intrahepatic sinusoidal pressure; (3) increased release of arginine vasopressin in response to systemic hypotension; and (4) reduced hepatic clearance of various vascular mediators (e.g., endothelin, prostaglandins, and endotoxin).^{18,19}

HRS can occur spontaneously in patients with advanced cirrhosis. Much more frequently, however, it is caused by other precipitating conditions, including sepsis (specifically, spontaneous bacterial peritonitis), paracentesis-induced hypovolemia, elevated intra-abdominal pressure (from tense ascites), GI bleeding, diuretic-induced or lactulose-induced hypovolemia, and various combinations of these. Other contributing factors to ARF should be routinely sought, including cardiomyopathy related to alcoholism, nutritional deficiencies, viral infection, and exposure to nephrotoxins.

Typically, HRS patients have advanced cirrhosis and show evidence of portal hypertension with ascites in the absence of other apparent causes of ARF. They generally are oligoanuric, with progressive increases in serum creatinine or blood urea nitrogen levels and bland urinary sediment. These patients experience profound sodium and water retention, with significant hyponatremia, a urine osmolality higher than the plasma osmolality, and a very low urinary sodium concentration (< 10 mEq/L).

Rhabdomyolysis-associated ARF Rhabdomyolysis-induced ARF is estimated to occur in about 1% of hospitalized patients; however, it may account for close to 5% to 7% of cases of ARF in critically ill patients, depending on the setting.^{11,14,20} The pathogenesis of this condition involves the interplay of prerenal, parenchymal, and postrenal factors, including concurrent hypovolemia, renal ischemia, direct tubular toxicity mediated by the heme pigment in myoglobin, and intratubular obstruction.^{21,22}

The causes of muscle injury that can result in rhabdomyolysis include major trauma or compression, a drug overdose, vascular embolism, prolonged seizures, malignant hyperthermia, neuroleptic malignant syndrome, various infections (e.g., pyomyositis, necrotizing fasciitis, influenza, and HIV infection), severe exertion, alcoholism, and certain drug interactions (e.g., the combination of a macrolide antibiotic or cyclosporine with a statin).

Clinically, rhabdomyolysis is variably manifested by an elevated serum creatine kinase level, pigmented granular urinary casts, and a red-to-brown color in the urine. Various electrolyte disorders may also develop as a result of muscle breakdown, including hyperphosphatemia, hyperkalemia, hypocalcemia, and hyperuricemia.

Contrast-induced nephropathy Contrast-induced nephropathy (CIN) is currently the third most frequent cause of ARF in hospitalized patients, and its incidence is likely to increase further

with the broader utilization of radiocontrast media for diagnostic and interventional procedures.^{3,11} CIN results in prolonged hospitalization, higher mortality, excessive health care costs, and, possibly, long-term kidney impairment.^{23–25} In addition, CIN (or concerns regarding the risk of CIN) may result in delay or cancellation of important diagnostic or therapeutic procedures.

Experimental studies suggest that the pathophysiologic basis of CIN is the interplay among direct tubular epithelial cell toxicity, alterations in renal hemodynamics with ensuing ischemia, and concomitant atheroembolic showers of the renovasculature after procedures involving exposure to radiocontrast media.

Several different definitions of CIN appear in the literature. Generally, however, CIN is defined as an acute decline in kidney function occurring after the administration of intravascular radiocontrast media in the absence of other precipitants of renal dysfunction. Although it may seem obvious that CIN is the cause of the renal dysfunction, other important possible causes (e.g., atheroembolic disease, renal ischemia, and other nephrotoxic agents) should be considered before the diagnosis is made.²⁶ For research purposes and for better generalizability of results and outcomes across clinical studies, CIN has traditionally been defined as a 25% or greater (or $\geq 0.5 \text{ mg/dL}$ [$44 \mu\text{mol/L}$]) increase in the serum creatinine level from the baseline value.^{27,28}

Patients with CIN typically present with an acute rise in the serum creatinine level within 24 to 48 hours after injection of a radiocontrast agent. Oliguria is usually absent, and FE_{Na} may be low initially.²⁹ Urine studies may reveal granular brown casts, tubular epithelial cells, and minimal proteinuria ($< 300 \text{ mg/day}$). The presentation may vary, however. In some cases, there is no significant increase in the serum creatinine level, but urinalysis yields abnormal results or markers of renal tubular injury are present. In other cases, there is a clear increase in the serum creatinine level, but results of urinalysis are bland and nondiagnostic. As a rule, the serum creatinine level peaks within 3 to 5 days after radiocontrast injection and returns to baseline within 7 to 10 days. In some patients, however, kidney function does not return to baseline, and a degree of renal impairment persists.

Although transient declines in renal function have been reported after administration of radiocontrast media in almost all patients, clinically important declines are exceedingly uncommon in patients with normal baseline kidney function. In general, clinically important declines in renal function are associated with the presence of preexisting risk factors. In several epidemiologic studies, multivariate analyses suggested that the presence of preexisting chronic kidney disease ($\text{GFR} < 60 \text{ mL/min/1.73 m}^2$), a diagnosis of diabetes mellitus, the administration of a substantial quantity of radiocontrast media, the presence of hypotension or hypertension, increased age, anemia, a recent acute myocardial infarction, a history of congestive heart failure, the use of an intra-aortic balloon pump, and the presence of shock were independently associated with a risk of the development of CIN.^{30–34}

Clinical Evaluation

In all patients presenting with renal failure, it is important to determine whether the reduction in kidney function is truly acute or whether chronic kidney disease was already present. In this context, it is worth noting that more than one third of patients in whom ARF develops have some degree of preexisting chronic kidney disease with chronic parenchymal changes (e.g., as a result of aging, long-standing hypertension, diabetes, or atherosomatous disease of the renal vessels). Such patients may also have preexisting elevations of the serum creatinine concentration; however, this is

Table 3 Laboratory Tests Used to Help Diagnose Established Acute Renal Failure

Test	Result in Prerenal ARF	Result in Established ARF
Urine sediment	Normal	Epithelial casts
Specific gravity	> 1.020	< 1.020
U_{Na}	< 10 mEq/L	> 20 mEq/L
FE_{Na}	< 1%	> 1%
Urinary osmolality	> 500 mOsm/kg H ₂ O	< 300 mOsm/kg H ₂ O
U_{Cr}/P_{Cr} ratio	> 40	< 10
Plasma urea/creatinine ratio	High	Normal

ARF—acute renal failure FE_{Na} —fractional excretion of sodium P_{Cr} —plasma creatinine concentration U_{Cr} —urinary creatinine concentration U_{Na} —urinary sodium concentration

not always the case. Often, an insult that would be considered relatively trivial and incapable of fully explaining the onset of ARF in a normal patient is in fact sufficient to unmask a lack of renal functional reserve in another patient.

In general, diagnosis and management of ARF should always be based on four principles: (1) confirmation of the probable cause, (2) elimination of potential contributing factors, (3) institution of disease-specific therapy if appropriate, and (4) prevention and management of the complications of ARF.

In most cases, important clues to the cause of ARF in a given patient and an accurate working diagnosis can be obtained from a careful review of the medical record (with particular attention to medications administered, exposure to potential nephrotoxins, and recent events in the hospital, including any operative or other procedures undergone), in conjunction with physical examination and selected radiologic and laboratory investigations [see Investigative Studies, below]. In these cases, one can proceed to a therapeutic trial without having to resort to renal biopsy.

An important caveat in the workup of a patient with ARF is that one should not assume that ARF can always be correctly or simply attributed to a single mechanism. As an example, patients with postrenal obstruction frequently have some degree of sepsis, often are hypotensive, and sometimes are hypovolemic and underresuscitated. As another example, patients with crescentic glomerulonephritis are often systemically unwell and may have pulmonary disease with hypoxemia or hypotension (from volume depletion caused by inadequate oral intake or from the vasodilatory effect of inflammation). The possibility that several mechanisms can contribute to ARF in a single patient underscores the importance of careful clinical assessment in the approach to the patient with ARF of recent onset.

ARF patients frequently are critically ill and require admission to an ICU. Such patients often have sustained a major systemic insult. Upon transfer and admission to the ICU, fluid resuscitation either is well under way or has already been completed. Despite such efforts, patients often are profoundly oliguric or anuric, with a rising serum creatinine level and developing metabolic acidosis. Potassium and phosphate levels may be rising as well. Concomitant multiple organ dysfunction (signaled by the need for mechanical ventilation and vasoactive drugs) is common in ARF patients. Fluid resuscitation is typically continued or reinstated under the guidance of invasive hemodynamic monitoring. Vasoactive drugs

are often used to restore mean arterial pressure (MAP) to acceptable levels (typically, 70 to 75 mm Hg or higher). Improvement may be noted over time, and urine output may return, with or without the assistance of diuretic agents. If urine output does not return, however, early implementation of RRT should be considered. If the cause of ARF has been removed or resolved and the patient has become physiologically stable, renal recovery may occur slowly, over a period as short as 4 to 5 days or as long as 3 or 4 weeks. In some cases, even after renal recovery occurs, urine output continues to be higher than normal for several days. If the cause of ARF has not been adequately remedied, the patient remains gravely ill, the kidneys do not recover, and death from multiple organ dysfunction syndrome (MODS) commonly ensues.

Investigative Studies

As noted (see above), it is vital to identify the underlying condition or conditions responsible for ARF. The diagnosis may be obvious from the results of the clinical assessment; however, in many patients, it is best to consider all possibilities and to exclude common treatable causes by performing some simple investigative studies.

LABORATORY TESTS

A key study is microscopic examination of the urinary sediment. Urinalysis is an essential and simple noninvasive test that can yield important diagnostic information and highlight patterns suggestive of specific syndromes. For example, the finding of dysmorphic red blood cells (RBCs) or RBC casts is virtually diagnostic of active glomerulonephritis or vasculitis. Similarly, the finding of heavy proteinuria suggests some form of glomerular disease. The finding of white blood cell (WBC) casts can suggest either interstitial nephropathy or infection. A urinalysis that yields no abnormal findings can also provide important diagnostic information, suggesting that ARF is prerenal or obstructive. Finally, examination of the urine helps the clinician determine whether a urinary tract infection is present.

Several measures of urine and blood biochemistry have traditionally been used to help clinicians distinguish between prerenal ARF and so-called ATN or established ARF [see Table 3]. One such measure is the FE_{Na} .^{35,36} In the setting of prerenal ARF, filtered sodium is avidly reabsorbed from glomerular filtrate in the renal tubules, resulting in an FE_{Na} lower than 1%, whereas in the setting of renal tubular injury in established ARF, the resulting FE_{Na} is higher than 1%. However, the diagnostic utility of FE_{Na} has been questioned, and several reports have concluded that FE_{Na} must be interpreted with caution.^{37,38} For example, FE_{Na} is often higher than 1% in patients who have received diuretic therapy, regardless of the effective circulating volume (ECV).^{39,40} Furthermore, FE_{Na} may be lower than 1% in patients with conditions associated with parenchymal ARF (e.g., sepsis, rhabdomyolysis, and exposure to radiocontrast media), perhaps reflecting nonhomogeneous injury to the renal parenchyma and preservation of tubular function in some regions.⁴¹⁻⁴³

Overall, the clinical utility of these tests in hospitalized and critically ill patients who receive fluids in massive amounts, loop diuretics, or vasopressors is untested and questionable. Furthermore, it is important to keep in mind that, as noted [see Classification of Renal Failure, above], prerenal ARF and established ARF are part of a continuum of disease and that separating the two conditions, though conceptually valid, is of only limited clinical relevance. In general terms, therapy is the same for prerenal ARF as for established ARF: one treats the underlying cause while

promptly resuscitating the patient, using hemodynamic monitoring to guide therapy.

In certain circumstances, other laboratory investigations may be necessary to establish the diagnosis. Marked anemia in the absence of blood loss may suggest acute hemolysis, thrombotic microangiopathy, or paraproteinemia related to malignancy. If thrombotic-thrombocytopenic purpura or another cause of microangiopathic hemolytic anemia is suspected, a peripheral blood smear should be obtained and examined for evidence of hemolysis or schistocytes, and levels of lactic dehydrogenase, haptoglobin, unconjugated bilirubin, and free hemoglobin should be measured. If paraproteinemia from multiple myeloma or lymphoma is suspected, serum and urine protein electrophoresis should be done and the serum calcium concentration measured. A history of cancer or chemotherapy should prompt measurement of uric acid to detect possible tumor lysis syndrome.

In patients with a potential mechanism of muscle injury, creatine kinase and free myoglobin levels should be determined. If an elevated-anion gap metabolic acidosis is present and there is evidence that a toxin may have been ingested, ethylene glycol or methanol levels should be measured.

Systemic eosinophilia suggests the possibility of systemic vasculitis, allergic interstitial nephritis, or atheroembolic disease. Measurements of levels of specific antibodies (e.g., anti-glomerular basement membrane [GBM] antibodies, antineutrophil cytoplasmic antibodies [ANCA], antinuclear antibodies [ANAs], anti-DNA antibodies, or anti-smooth muscle antibodies) or cryoglobulins are extremely useful screening tests to support the diagnosis of vasculitis, certain types of collagen vascular diseases, or glomerulonephritis.

IMAGING

Renal ultrasonography is a rapid, noninvasive imaging modality that is designed primarily to look for evidence of obstruction, stones, cysts, masses, or overt renovascular disease. Doppler ultrasonography or magnetic resonance imaging can be useful in screening for renovascular occlusion. A chest x-ray may be indicated, either to assess possible pulmonary complications of ARF or to help confirm or rule out a diagnosis of systemic vasculitis.

BIOPSY

On rare occasions, percutaneous renal biopsy is necessary to confirm the diagnosis, determine the severity of renal injury, guide therapy, and estimate the potential for renal recovery.^{44,45} Renal biopsy is indicated when a thorough noninvasive investigation has failed to yield the diagnosis, after prerenal and postrenal causes have been excluded, and before aggressive immunosuppressive therapy is initiated. The biopsy is generally performed under ultrasonographic guidance, using local anesthesia. As a rule, the risk associated with performing a renal biopsy in a critically ill patient undergoing mechanical ventilation is comparable to that associated with performing a biopsy under standard conditions.⁴⁶

Prevention

GENERAL MEASURES

The fundamental principle of ARF prevention is to eliminate and treat precipitating causes of renal dysfunction. If prerenal factors are contributing to the problem, they must be identified, and hemodynamic resuscitation must be quickly instituted. Intravascular volume must be maintained or rapidly restored; this is often best done with the help of invasive hemodynamic monitoring. Oxygenation must be maintained. An adequate hemoglobin con-

centration (≥ 8 g/dL) must be maintained or immediately restored during the acute phase of resuscitation. Some patients remain hypotensive ($MAP < 75$ mm Hg) even after intravascular volume has been restored. In these patients, autoregulation of RBF may be impaired or lost. Restoration of MAP to near-normal levels is likely to improve RBF and increase GFR. Such restoration requires the administration of vasopressor drugs. In patients with hypertension or renovascular disease, a MAP of 75 to 80 mm Hg may still be inadequate.

Despite these measures, progressive ARF may still develop in patients whose cardiac output is inadequate. To improve cardiac output may require a variety of interventions, such as the addition of inotropic drugs or the application of ventricular assist devices. Whether additional fluid therapy in a patient with normal or increased cardiac output and adequate blood pressure provides any significant renal protection is questionable; such therapy may in fact contribute to excess accumulation of extravascular fluid, resulting in pulmonary edema.

Once hemodynamic resuscitation has been accomplished and nephrotoxins removed, it is unclear whether additional pharmacologic measures provide any further benefit to the kidneys. So-called renal-dose (or low-dose) dopamine therapy is still frequently used. There is little evidence that this regimen is effective in critically ill patients⁴⁷⁻⁴⁹; however, dopamine is a tubular diuretic that occasionally increases urine output,⁵⁰ and the increased output may be incorrectly interpreted as an increase in GFR.⁵¹ A large phase III trial that examined the use of low-dose dopamine in critically ill patients showed it to be no better than placebo for prevention of renal dysfunction.⁵² In patients with low cardiac output, however, higher-dose dopamine may increase cardiac output, RBF, and GFR (as might dobutamine or milrinone).

Fenoldopam is a selective D₁ dopamine receptor agonist with no affinity for adrenergic D₂, α , or β receptors. It has been shown to reduce systemic vascular resistance while increasing RBF through reversal of the vasoconstrictive effects of angiotensin II and endothelin.⁵³ Fenoldopam improves both renal cortical and renal medullary blood flow and decreases sodium reabsorption in the proximal tubule.⁵⁴ In a randomized, controlled trial of prophylactic continuous infusion of fenoldopam in critically ill patients with sepsis, this measure led to a reduction in the incidence of ARF; however, it had no impact on the need for RRT or on mortality.⁵⁵ At present, the clinical implications of this study are uncertain; a clearer understanding of the role of fenoldopam prophylaxis will have to await the results of a larger clinical trial.

There is a biologic rationale for the use of mannitol in this setting, as there is for the use of dopamine. Whereas animal experiments have yielded some encouraging findings, there are as yet no data from controlled human studies to support the clinical application of mannitol.⁵⁶ The value of mannitol as a renal-protective agent remains questionable.

Loop diuretics may protect the loop of Henle from ischemia by reducing its transport-related workload through inhibition of the Na⁺/K⁺/2 Cl⁻ pump.⁵⁷ The results of animal studies have been encouraging, as have those of ex vivo experiments.⁵⁸ To date, however, no double-blind, randomized, controlled studies of suitable size have definitively shown that these agents reduce the incidence of ARF in humans.⁵⁹⁻⁶² A few studies, however, have suggested that loop diuretics can induce polyuria, which may translate into prevention or easier control of volume overload, metabolic acidosis, and hyperkalemia—the three major triggers of RRT.^{59,60} When RRT can be avoided, treatment is simpler and less costly. Thus, loop diuretics may be useful for the purposes of prophylaxis, especially if given via continuous infusion.^{63,64}

Other agents, such as adenosine antagonists (e.g., theophylline) and atrial natriuretic peptides (e.g., urodilatin and anaritide), have also been suggested for prevention of ARF.⁶⁵⁻⁶⁸ In a randomized, controlled trial that included 504 critically ill patients with ARF, administration of atrial natriuretic peptide did not yield any overall improvement in dialysis-free survival.⁶⁶ Subgroup analysis suggested that this measure was of some benefit in patients with oliguric ARF; however, a follow-up study of 222 critically ill patients with oliguric ARF found no differences in dialysis-free survival or overall mortality between those who received atrial natriuretic peptide and those who received placebo.⁶⁷

SPECIFIC SYNDROMES

Rhabdomyolysis-Associated ARF

The principles of prevention of rhabdomyolysis-associated ARF are based primarily on animal studies, retrospective data, small case series, and multivariate logistic regression analyses; to date, no randomized, controlled trials have been conducted. These principles include (1) identification and elimination of potential causative agents or correction of underlying compartment syndromes; (2) prompt and aggressive fluid resuscitation to restore vascular volume and maintenance of polyuria (> 300 ml/hr) to flush obstructing cellular casts (if present); and (3) alkalinization of the urine (to a pH > 6.5) to reduce renal toxicity from myoglobin-induced lipid peroxidation and improve the solubility of myoglobin.²² Experimental studies suggest that mannitol may act as a scavenger of free radicals and thereby reduce cellular toxicity; however, the role of forced diuresis with mannitol remains controversial.

Contrast-Induced Nephropathy

Measures aimed at preventing CIN have been studied in several randomized trials; to date, however, few prophylactic or therapeutic interventions have conclusively been shown to reduce the incidence of CIN, and no therapeutic intervention has been found to be efficacious once CIN is established. The most prudent method of preventing CIN is to identify patients with risk factors before radiocontrast media are administered, then to consider either delaying the diagnostic or interventional procedure until kidney function can be optimized or switching to an alternative imaging modality. At the same time, every effort should be made to identify and correct underlying volume depletion and discontinue potential nephrotoxins. If the procedure is performed, the volume of radiocontrast media employed should be kept to a minimum.

The adoption of periprocedural hydration protocols and the use of nonionic iso-osmolar radiocontrast media (e.g., iodixanol) have reduced the incidence and severity of radiocontrast-associated renal injury.⁶⁹⁻⁷² In the first few years of the 21st century, randomized trials assessed the efficacy of *N*-acetylcysteine for the prevention of CIN, with highly variable results.⁷³⁻⁸² These results were further analyzed in several meta-analyses, which concluded that there appears to be a potential reduction in renal injury with *N*-acetylcysteine (though this conclusion remains controversial).⁸³⁻⁸⁷ It is reasonable to use *N*-acetylcysteine for prevention of CIN in routine care, in view of its relative ease of use, its low cost, and its good safety profile, especially in patients at high risk for CIN. There is also some evidence to suggest that adenosine antagonists may confer some protection against CIN; however, further evidence is required to confirm that the benefit is real.^{88,89}

Management

The fundamental principles of the management of ARF are (1) to identify, treat, and remove any precipitating factors and (2) to maintain physiologic homeostasis while renal recovery takes place.

PREVENTION OR TREATMENT OF COMPLICATIONS

Complications of ARF such as encephalopathy, pericarditis, severe electrolyte disturbances (e.g., hyperkalemia), serious metabolic disturbances (e.g., severe metabolic acidosis), myopathy, neuropathy, or major fluid derangements should never be permitted to occur in a modern hospital setting. Prevention of these complications may entail several different measures, which may vary in complexity from fluid restriction to the initiation of extracorporeal RRT.

Extracellular fluid expansion is a common complication in patients with ARF, particularly in those who have a diminished capacity for sodium and water excretion as a consequence of oliguria. Accumulation of extracellular fluid is manifested by weight gain, dependent interstitial edema, elevated central venous pressure, pleural effusion and ascites, and pulmonary interstitial and alveolar edema. Extracellular fluid overload can be further exacerbated in patients who require large volumes of parenteral medications or nutritional formulas. If a patient is nonoliguric, fluid overload can generally be prevented through judicious use of loop diuretics. If a patient is oliguric, however, the only way of averting dangerous fluid overload is to institute RRT at an early stage.

Marked azotemia (urea concentration > 112 mg/dl [40 mmol/L] or serum creatinine concentration > 4.5 mg/dl [400 µmol/L]) is undesirable and should probably be treated with RRT unless (1) recovery is imminent or already under way and (2) a return toward baseline or normal values is expected within 24 hours. It should be recognized, however, that to date, no randomized, controlled trials have defined the ideal time at which intervention with artificial renal support should be initiated.

Hyperkalemia (potassium concentration > 6 mEq/L) is another frequent complication of ARF. Obviously, patients with ARF and oliguria should never receive any potassium-containing solution, either orally or via continuous infusion. Spurious hyperkalemia secondary to hemolysis, thrombocytosis, and a very high WBC count may occur and must be excluded. Genuine hyperkalemia must be promptly treated to prevent the development of a life-threatening cardiac dysrhythmia. Patients should receive insulin with dextrose, bicarbonate (if acidosis is present), nebulized salbutamol, or all three together. If the serum potassium level exceeds 7 mEq/L or there are electrocardiographic signs of hyperkalemia, calcium gluconate (10 ml of a 10% solution I.V.) should also be immediately administered. These measures are temporizing actions only; urgent RRT should be arranged.

Metabolic acidosis is almost always present as a consequence of reduced excretion of nonvolatile acids produced through metabolism of dietary protein. In itself, the metabolic acidosis is rarely severe enough to necessitate treatment, but it can be greatly exacerbated by a host of concomitant processes when the kidney's capacity for generation of bicarbonate is diminished. Increased endogenous production of acid can occur in all types of shock, with elevated lactate production, severe sepsis, diabetic or starvation ketoacidosis, and liver disease. In addition, various exogenous sources can worsen metabolic acidosis, including toxins (e.g., ethylene glycol and salicylates) and solutions containing large amounts of chloride. When refractory severe metabolic acidosis (pH < 7.1) is present, early initiation of RRT should be considered.

ARF can also result in the development of anemia via any of several mechanisms, including bleeding, hemodilution, hemolysis, decreased RBC lifespan, and reduced erythropoiesis. One large randomized study suggested that a restrictive transfusion protocol for correction of hemoglobin levels higher than 7 g/dl in critically ill patients with anemia is adequate.⁹⁰ However, more liberal and aggressive transfusion may be necessary, depending on the results of individual patient assessments.

Nutritional support must be started early and must contain an adequate amount of calories (30 to 35 kcal/kg/day) in a mixture of carbohydrates and lipids. Sufficient protein (about 1 to 2 g/kg/day) must be administered. There is no evidence that specific renal nutritional solutions are useful. Vitamins and trace elements should be administered in amounts that at least match the recommended dietary allowance. The role of the newer immunonutritional solutions remains controversial. The enteral route is generally preferred to the parenteral route.

All drug regimens must be adjusted to take into account the effect of the decreased clearances associated with impaired renal function. Finally, assiduous attention should be paid to the prevention of infection.

MANAGEMENT OF HEPATORENAL SYNDROME

Management of HRS remains challenging. In general, it should include systematic identification and prompt treatment of any potentially reversible precipitating factors (especially infections and volume depletion). Prevention of hypovolemia by administering albumin to patients with spontaneous bacterial peritonitis has been shown to decrease the incidence of HRS and improve outcome.⁹¹

One small nonrandomized study found that treating HRS patients with a combination of midodrine and octreotide resulted in improved kidney function and outcome.⁹² Another small uncontrolled study suggested that I.V. N-acetylcysteine might improve GFR in patients with HRS through reductions in splanchnic vaso-dilatation achieved by decreasing the formation of nitric oxide and oxygen free radicals.⁹³

There is some evidence to suggest that vasopressin derivatives (ornipressin and terlipressin) may improve GFR in patients with HRS. In a small uncontrolled trial, administration of ornipressin, in conjunction with volume expansion, reduced plasma renin and norepinephrine levels and improved RBF, GFR, and urinary sodium excretion.⁹⁴ In other small studies, the combination of terlipressin and volume expansion led to similar improvements in systemic hemodynamics and kidney function, with a suggestion of improved short-term outcome.^{95,96} At present, however, the precise role of these agents in the management of HRS remains unclear.

Transjugular intrahepatic portosystemic shunting (TIPS) [see 5:10 *Portal Hypertension*] has been associated with modest improvements in kidney function in HRS patients, may improve outcome, and thus may be an option for patients who are not candidates for transplantation or are awaiting transplantation.⁹⁷⁻⁹⁹ In general, however, the ideal solution for reversal of ARF in HRS patients is to improve hepatic function by treating the underlying primary liver disease, to refer patients for orthotopic liver transplantation, or both.

RENAL REPLACEMENT THERAPY

When ARF is severe, resolution can take days to weeks. In these situations, extracorporeal techniques of blood purification often must be applied to prevent complications [see Prevention or Treatment of Complications, *above*]. Such techniques, collectively referred to as renal replacement therapy, include continuous renal replacement therapy (CRRT), intermittent hemo-

Table 4 Modern Criteria for Initiation of Renal Replacement Therapy*

Anuria (no urine output for ≥ 6 hr)
Oliguria (urine output < 200 ml/12 hr)
Serum urea concentration > 28 mmol/L or BUN > 80 mg/dl
Serum creatinine concentration > 3 mg/dl (265 μmol/L)
Serum potassium concentration ≥ 6.5 mEq/L or rapidly rising
Pulmonary edema unresponsive to diuretics
Uncompensated refractory metabolic acidosis (pH < 7.1)
Any uremic complication (encephalopathy, myopathy, neuropathy, or pericarditis)
Temperature ≥ 40° C (104° F)
Overdose with a dialyzable toxin (e.g., lithium or salicylates)

* If one criterion is met, RRT should be considered. If two criteria are met simultaneously, RRT is strongly recommended.

BUN—blood urea nitrogen

dialysis (IHD), and peritoneal dialysis (PD). The basis of all of these RRT techniques is the removal of unwanted solutes and water through a semipermeable membrane. Such a membrane may be either biologic (i.e., the peritoneum) or artificial (i.e., hemodialysis or hemofiltration membranes); each type has its advantages, disadvantages, and limitations.

In general, RRT for ARF should be initiated early, before complications develop. The commonly expressed concerns regarding early RRT stem from the adverse effects of conventional IHD with cuprophane membranes (in particular, hemodynamic instability) and from the risks and limitations associated with CRRT or PD. In the past few years, however, improved use of CRRT and the development of new hybrid techniques adapted from conventional IHD (e.g., sustained low-efficacy dialysis [SLED] and extended daily dialysis [EDD]) have reduced the incidence of these adverse effects.¹⁰⁰⁻¹⁰²

The criteria governing the initiation of RRT in patients with chronic renal failure may be inappropriate for patients with ARF, particularly if they are critically ill. Accordingly, a set of modern criteria for the initiation of RRT has been developed [see Table 4].

With either CRRT or IHD, the available data are insufficient to establish precisely what constitutes adequate intensity of dialysis; however, there is some evidence that a higher prescribed dose of RRT may improve survival.^{103,104} At a minimum, RRT should be of sufficient intensity to maintain homeostasis at all levels. An appropriate target urea level is 42 to 70 mg/dl (15 to 25 mmol/L), with a protein intake of about 1.5 g/kg/day. This target level can easily be achieved by using CRRT at urea clearances of 30 to 40 L/day (depending on patient size and catabolic rate).¹⁰⁴ If IHD is employed, daily treatment and extended treatment become desirable.¹⁰³

There remains considerable controversy regarding which modality of RRT is ideal for reducing mortality and enhancing renal recovery, in particular for patients who are hemodynamically unstable or critically ill. A major reason for the controversy is the difficulty of comparing the results of various small randomized, controlled trials that made use of different techniques.^{13,105-107} Large trials of sufficient statistical power would be hard to conduct and may never be performed. In the absence of such trials, RRT techniques should be judged on the basis of the following criteria: (1) biocompatibility, (2) hemodynamic side effects, (3) uremic control, (4) ability to control fluid status, (5) ability to control acidosis, (6) ability to allow full nutritional support, (7) risk of infection, (8) absence of specific side effects, and (9) cost.

CRRT and SLED may offer many advantages over conventional IHD and PD; however, the necessary technology and expertise are not available everywhere, and practice preferences vary widely from one country to another.¹⁰⁸ Therefore, it will be worthwhile to review certain salient features of CRRT and IHD.

Continuous Renal Replacement Therapy

CRRT was initially performed as an arteriovenous procedure (i.e., continuous arteriovenous hemofiltration [CAVH]), in which blood flow through the hemofilter was driven by the patient's blood pressure. A drawback of this approach was that the cannulation of an artery was associated with a morbidity of 15% to 20%. Accordingly, CRRT is now more commonly performed as a venovenous procedure using double-lumen catheters and peristaltic blood pumps (continuous venovenous hemofiltration [CVVH]), with or without control of the ultrafiltration rate. In a venovenous system, dialysate can also be delivered against the direction of blood flow (a technique known as continuous venovenous hemodiafiltration [CVVHDF]) to achieve either almost pure diffusive clearance or a mixture of diffusive and convective clearance. No matter which CRRT technique is used, the following outcomes are predictable: (1) a high level of biocompatibility, (2) hemodynamic stability, (3) continuous control of fluid balance, (4) control of acid-base status, (5) control of electrolytes (including phosphate and calcium), (6) the ability to provide protein-rich nutrition while achieving uremic control, (7) a minimal risk of infection, and (8) prevention of dangerous swings in intracerebral water balance.

Generally, performance of CRRT is restricted to ICUs and requires that specifically trained nursing and medical staff members be available 24 hours a day. Many small ICUs cannot provide this level of support. If CRRT is only performed five to 10 times a year, the cost of training may not be economically justifiable, and expertise may be hard to maintain. Furthermore, depending on how patient care is organized at a particular institution, CRRT may be more expensive than IHD.¹⁰⁹ In addition, the need for continuous anticoagulation of the extracorporeal circuit during CRRT raises the issues of possible hemorrhage, immune thrombotic thrombocytopenia, and increased transfusion requirements.¹¹⁰⁻¹¹² In view of these concerns, it is essential to consider the risks and benefits of more or less intensive anticoagulation and of alternative strategies.

In the vast majority of patients, low-dose heparin (< 500 IU/hr) is sufficient to achieve an adequate filter lifespan, is relatively easy and cheap to administer, and has almost no effect on coagulation test results. In some patients, a higher dose is necessary. In others (e.g., those with pulmonary embolism or myocardial ischemia), full heparinization may be indicated. Regional citrate anticoagulation is highly effective but somewhat complex, in that it requires a special dialysate or replacement fluid.¹¹³ Regional heparin or protamine anticoagulation is also somewhat complex, but it may be helpful if frequent filter clotting occurs and further anticoagulation of the patient is considered dangerous. Low-molecular-weight heparin (LMWH) is easy to administer but is more expensive than standard heparin.¹¹⁴ The LMWH dose must be adjusted for the loss of renal function, which is difficult to monitor. Heparinoids and prostacyclin may be useful if the patient has heparin-induced thrombocytopenia and thrombosis.¹¹⁵ Finally, in perhaps 10% to 20% of patients, anticoagulation is contraindicated because of endogenous coagulopathy or recent surgery. In such patients, mean filter lives longer than 24 hours can be achieved, provided that blood flow is kept at about 200 ml/min and reliable vascular access is maintained.¹¹⁶

Particular attention must be paid to the adequacy and ease of flow through the double-lumen catheter.¹¹⁷ Smaller (11.5 French)

catheters in the subclavian position pose particular problems; larger (13.5 French) catheters in the femoral position appear to function more reliably.¹¹⁸ The choice of membrane is a matter of some debate. There are several biosynthetic membranes on the market (e.g., those made of AN69, polyamide, polysulfone, or cellulose triacetate) that have excellent biocompatibility. To date, however, no controlled studies have shown any of them to possess a clinical advantage over any of the others.

Intermittent Hemodialysis

In IHD, as in CRRT, vascular access is typically obtained via a double-lumen catheter. Also as in CRRT, the circuit consists of venovenous blood flow driven by a peristaltic pump. As in CVVH, countercurrent dialysate flow is employed; however, standard IHD differs from CVVH in that it uses high dialysate flows (300 to 400 ml/min), generates dialysate by using purified water and concentrate, and is applied for short periods (3 to 4 hours). These differences have important implications. First, volume removal must be completed within a short time, and this process may be poorly tolerated by patients who are hemodynamically unstable or critically ill. There is a high incidence of hypotension in such patients, and repeated hypotensive episodes may contribute to delayed renal recovery.¹¹⁹ Second, solute removal is episodic, resulting in inferior uremic and acid-base control, decreased therapeutic efficacy, and a lower delivered dose of RRT. Suboptimal fluid and uremic control imposes unnecessary limitations on nutritional support. Furthermore, rapid solute shifts increase brain water content and raise intracranial pressure.¹²⁰

The issue of membrane bioincompatibility has given rise to a great deal of controversy. In comparison with high-flux synthetic membranes (also used for CVVH), standard low-flux dialyzing membranes made of cuprophane have been found to trigger the activation of several inflammatory pathways. It is possible that this proinflammatory effect contributes to further renal damage and delays recovery or even affects mortality. The controversy has not yet been resolved.

The limitations of conventional IHD in the setting of ARF led to the development of the new hybrid techniques SLED and EDD,^{100,101} which adapt IHD to specific clinical circumstances so as to make it easier to tolerate and more effective. At present, PD is rarely used in the treatment of adult ARF in developed countries; however, it may be a reasonable option in developing countries or in the treatment of children when alternatives are unavailable or are considered too expensive or invasive.¹⁰⁸

BLOOD PURIFICATION FOR INDICATIONS OTHER THAN ACUTE RENAL FAILURE

There is growing interest in the possibility that blood purification, by removing circulating mediators, may provide a clinically significant benefit for patients who are in a severe septic state.¹²¹⁻¹²³ Various techniques, including plasmapheresis, high-volume hemofiltration, very-high-volume hemofiltration, and coupled plasma filtration adsorption, are currently being assessed in animal studies and in phase I and II human studies.^{124,125} Initial findings suggest that continued exploration of this therapeutic option is worthwhile¹²⁶; however, randomized, controlled trials of sufficient statistical power have not yet been performed. Blood purification technology, in combination with the use of bioreactors containing either human or porcine liver cells, is also under active investigation as a form of artificial liver support for patients with fulminant or acute-on-chronic liver failure.¹²⁷ Some promising results have been reported.

Discussion

Pathogenesis of Acute Renal Failure

The pathogenesis of ARF varies, depending on the primary mechanism and contributing factors underlying the acute decline in kidney function.

For postrenal or obstructive ARF, the pathogenesis typically involves several humoral responses, as well as a host of mechanical factors. As a rule, a single functioning kidney has adequate capacity for clearance of daily nitrogenous waste and maintenance of water and acid-base homeostasis. Therefore, for postrenal ARF to develop, urinary flow must be obstructed in the urethra, in the bladder, or in both ureters (one ureter if the patient has only a single kidney). These mechanical factors can arise from within the genitourinary system (e.g., stones or strictures) or from extrinsic causes (e.g., ureteral compression or kinking) [see Table 1]. When urinary flow is obstructed, glomerular filtration initially continues, gradually elevating the intraluminal pressures proximal to the site of obstruction. Over time, the elevated pressures result in progressive distention and dilation of the proximal ureter, the renal pelvis, and the calyx and directly cause GFR to decline.

The pathogenesis of parenchymal ARF is typically immunologic. It is a complicated process that includes a wide variety of possible causative conditions (including glomerulonephritis, vasculitis, and interstitial nephropathy) and involves an extraordinary array of cell-mediated and humoral mechanisms, discussion of which exceeds the scope of this chapter.

The pathogenesis of prerenal ARF is of greater direct relevance to the surgeon. Traditionally, prerenal ARF is, by definition, the result of a reduction in ECV and a concomitant reduction in renal perfusion. A reduction in ECV is frequently accompanied by a reduction in MAP, which can stimulate several humoral and neural processes by activating arterial and cardiac baroreceptors. Increased activity in these baroreceptors stimulates the sympathetic nervous system and the renin-angiotensin-aldosterone system and triggers the release of arginine vasoressin from the posterior pituitary in an attempt to compensate for any reduction in GFR.

At the level of the kidney, there are several mechanisms that may play a major role in the development of prerenal injury, including (1) ischemia of the outer medulla, (2) activation of the tubuloglomerular feedback system (afferent arteriolar constriction), (3) tubular obstruction from cell casts, (4) interstitial edema secondary to back-diffusion of fluid, (5) inflammatory response to cell injury and local release of mediators, (6) disruption of normal cellular adhesion to the basement membrane, (7) oxygen free radical-induced apoptosis, and (8) phospholipase A₂-induced cell membrane injury. It must be kept in mind, however, that to date, most of these mechanisms have been demonstrated to be operative only in animal models. Because such models bear limited resemblance to the clinical scenarios in which ARF develops in humans, the relevance of these findings to human disease remains highly speculative. Even if these experimentally proven mechanisms are operative in humans, their hierarchy and their time sequence remain unknown, which makes the development of specific therapeutic targets for prevention and management a difficult task.

Epidemiology of Acute Renal Failure

As noted [see General Principles, Definition of Acute Renal Failure, above], defining ARF can be problematic. Even so, sever-

al useful observations can be made about the epidemiology of this condition.

First, some degree of acute renal injury (manifested by albuminuria; the loss of small tubular proteins; the inability to excrete a water, sodium, or amino acid load; or any combination of these) can be demonstrated in most ICU patients. The manifestations of renal injury may be seen in patients who are undergoing simple and successful cardiac surgery with cardiopulmonary bypass, as well as in patients who have severe sepsis but a normal serum creatinine concentration. Their significance is unclear, beyond the observation that some of them (e.g., albuminuria) have been associated with increased mortality.

Second, ARF is common in hospitalized patients, affecting between 5% and 8% (depending on the specific population being assessed and the criteria being used to define ARF).^{3,11} In a report from the Madrid ARF Study Group, the overall annual incidence of ARF was 209 cases/million, with ARF defined as either (1) a sudden increase in the serum creatinine concentration to 2.0 mg/dl (177 µmol/L) or higher in a patient with normal preexisting renal function or (2) a 50% or greater increase in the serum creatinine concentration in a patient with chronic kidney disease.¹²⁸ In several other population-based epidemiologic studies, the annual incidence of ARF ranged from 20 to 187 cases/million (again, depending on the operative definition of ARF used).^{15,129-131} If these general observations are applied to the more economically developed countries, which have a total population of approximately 1 billion people, it may be estimated that about 200,000 cases of ARF occur in this population each year. Unfortunately, little information is available on the incidence of ARF in the less developed countries.

Third, current trends suggest that the incidence of and mortality attributable to ARF may actually be increasing, particularly in critically ill patients, despite advances in the understanding of the pathophysiology of ARF and the development of new and improved methods for its treatment. One explanation for this increase may be that ARF as a manifestation of single-organ dysfunction is becoming less common, whereas MODS with associated ARF is becoming more common.¹³² In a multinational, multicenter study carried out by the Beginning and Ending Supportive Therapy for the Kidney (BEST Kidney) Investigators, it was estimated that ARF associated with admission to an ICU develops in approximately 6% of critically ill patients worldwide.¹² ARF was severe enough to warrant initiation of RRT in approximately 70% of the patients studied.¹² In other studies, the annual incidence of ARF severe enough to necessitate RRT has been estimated to range from 40 to 130 cases/million.^{12-14,132,133}

Fourth, large epidemiologic studies have identified a number of risk factors for the development of ARF, including greater age, male sex, preexisting illness, severe sepsis or septic shock, major surgery (in particular, cardiac surgery), cardiogenic shock, hypovolemia, and exposure to various nephrotoxic drugs.^{12,13} Smaller cohort studies have shown that ARF is common in the setting of MODS, specifically when there is concomitant acute circulatory, pulmonary, and hepatic organ dysfunction.¹³⁴⁻¹³⁷

Fifth, although the studies cited above suggest that ARF may in part be an expression of overall illness severity, there is evidence that ARF, in and of itself, significantly and independently increases mortality.¹³⁸ The overall hospital mortality for patients with ARF is estimated to be about 20%; however, the hospital mortality for

patients with more severe increasing renal injury (serum creatinine concentration ≥ 3.0 mg/dl [265 μ mol/L]) ranges from 40% to 60%.^{3,11} There is also evidence that the short- and long-term prognosis is worse for patients who are critically ill and patients who require RRT. In these patients, the hospital mortality is 45% to 60%, and the long-term mortality is 60% to 70%.^{12-14,20,132,138-140}

Sixth, independence from RRT is associated with enhanced overall quality of life and improved functional status and probably has important health economic implications^{133,141}; thus, renal recovery after ARF or an episode of critical illness is an important

outcome to consider. Estimates of dependence on RRT at hospital discharge for survivors of ARF vary, ranging from 5% to 33%.^{12-14,16,20,109,133} Several factors may be associated with a higher likelihood of renal recovery with independence from RRT, including male sex, little or no preexisting comorbid illness, no evidence of preexisting chronic kidney disease, the use of CRRT rather than IHD, and earlier initiation of RRT.¹³ Despite the high overall mortality for survivors of ARF, there is evidence that the majority (70% to 80%) recover renal function and gain independence from RRT within 90 days to 1 year.¹³

7 DISORDERS OF WATER AND SODIUM BALANCE

Richard H. Sterns, M.D.

Overview of Body Fluid Homeostasis

Life takes place in an aqueous solution. Cells, the blood bringing nutrients and oxygen to them, and the interstitial fluid bathing them are all mostly water. Each day, water and salt are lost and replaced. To maintain stability of the internal milieu, body fluids are processed by the kidney, guided by intricate physiologic control systems that regulate fluid volume and composition.

DISTRIBUTION AND COMPOSITION OF BODY WATER

Water accounts for approximately half of an adult human's body weight. Because fat contains little water, individuals with more body fat have less body water. On average, total body water constitutes 60% of lean body weight in young men, 50% in young women and older men, and 45% in older women. Two thirds of body water is intracellular and the remainder is contained in the extracellular fluid compartment, which includes intravascular (plasma) and interstitial fluid. Small amounts of water are also contained in bone, dense connective tissue, digestive secretions, and cerebrospinal fluid.¹

Extracellular solutes are predominantly sodium salts (primarily a mixture of NaCl and NaHCO₃). Thus, extracellular fluid can be thought of as saltwater. Except for protein (present at a higher concentration in plasma [approximately 1 mmol/L] than in interstitial fluid), the compositions of the intravascular and interstitial subdivisions of the extracellular fluid compartment are similar.

The sodium-potassium adenosine triphosphatase (Na⁺,K⁺-ATPase) pump on cell membranes keeps intracellular sodium at low levels. Potassium, the dominant intracellular cation, is electrically balanced, in large part, by anionic charges on impermeant macromolecules. Stability in the number of intracellular anionic charges makes the total solute content of cells much less variable than that of the extracellular fluid.

Osmolality

Extracellular and intracellular fluids contain different types of solutes, but the concentrations of solutes inside and outside of cells are equal. Concentration differences exist only transiently because they create an extremely strong force for water movement across cell membranes. Osmotic pressure moves water rapidly to the fluid compartment with the higher solute concentration until concentrations once again become equal. The osmotic pressure responsible for water movement across cell membranes depends on the total number of solute particles (osmoles) dissolved in solution, a property known as osmolality.² Osmolality is usually expressed as milliosmoles of solute per kilogram of solvent (mOsm/kg), but it can be thought of more simply as the number of millimoles of solute particles per liter of solution. A solute particle's contribution to osmolality is independent of its charge and molecular size. Ionic substances such as sodium chloride that dissociate in solution contribute more than one osmotically active particle. Sodium salts, glucose, and urea, commonly measured as blood urea nitrogen (BUN), are responsible for most of the solute particles normally present in extracellular fluid. Plasma osmolality can be measured directly with an osmometer or can be esti-

mated with reasonable accuracy from the concentrations of the major extracellular solutes, as follows:

$$P_{\text{osm}} \approx 2 \times \text{plasma } [\text{Na}^+] + \frac{[\text{Glucose}]}{18} + \frac{\text{BUN}}{2.8}$$

The multiple of 2 reflects the anions accompanying sodium ions, and 18 and 2.8 are the corrections required to convert glucose and urea nitrogen concentration from mg/dl (the units used by most laboratories in the United States) to mmol/L. Exogenous solutes (e.g., ethanol, methanol, ethylene glycol, glycine, mannitol) are measured by osmometers but are not included in the formula shown above. A discrepancy between the measured and the calculated plasma osmolality values (an osmolar gap) is useful clinically as a way to recognize the presence of an exogenous solute.²

Fluid Movement between Body Fluid Compartments

The intravascular and interstitial subdivisions of the extracellular fluid compartment are separated by capillary walls that are freely permeable to small extracellular solutes but relatively impermeable to plasma proteins. Protein-free saltwater continuously moves across the capillary endothelial barrier by filtration, driven by a hydrostatic pressure gradient (generated by contractions of the heart), which forces fluid from the capillary into the interstitium, and an oncotic pressure gradient (the consequence of the osmotic force created by intravascular protein), which draws interstitial fluid into capillaries [*see Figure 1*]. These so-called Starling forces, which regulate the disposition of fluid within the extracellular compartment, determine how much extracellular saltwater is contained in intravascular plasma and how much is in interstitial fluid [*see Disorder of Saltwater Excess: Edematous States, below*]. Sodium salts, urea, glucose, and other small extracellular solutes freely cross the capillary wall, achieving similar concentrations in the interstitial fluid and plasma. Thus, changes in plasma osmolality do not influence water movement between the intravascular and interstitial fluid compartments.

Fluid movement between the extracellular and the intracellular fluid compartments is unaffected by Starling forces. Rather, transcellular water movement is driven by osmotic forces, a function of the concentration of solutes in the extracellular fluid. A decrease in extracellular solute concentration (hypotonicity) drives water into cells, causing cell swelling; an increase in the concentration of exclusively extracellular solutes (hypertonicity) draws fluid out of cells, dehydrating them.

Not all solutes contribute to the tonicity of extracellular fluid.² Permeant solutes such as urea and ethanol readily cross cell membranes, achieving equal concentrations in the extracellular and intracellular fluid compartments without driving transcellular water movement and without affecting cell volume. Such solutes, which increase plasma osmolality without altering plasma tonicity, are sometimes called ineffective osmoles. Impermeant solutes are excluded from cell water either by active transport (e.g., sodium ions) or because the cell membrane is impermeable to them (e.g., mannitol).

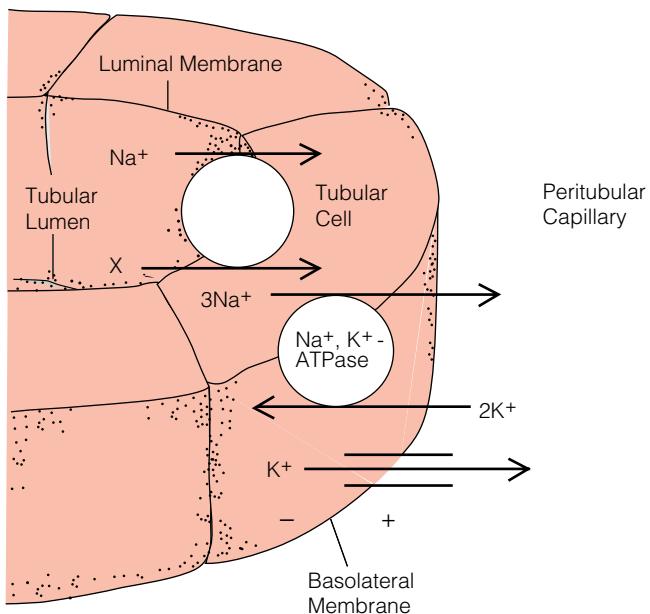

Figure 1 Sodium reabsorption by the renal tubules is driven by the Na^+, K^+ -ATPase pump in the basolateral (blood side) membrane, which maintains a low sodium concentration within the tubular cell. Filtered sodium in the tubular lumen enters the cell down its concentration gradient via a transmembrane carrier (which may also transport another solute, X) or via a channel in the luminal membrane [see Figure 2].

Such solutes, which cause both hyperosmolality and hypertonicity, are sometimes called effective osmoles.

Body Fluid Tonicity and the Plasma Sodium Concentration

Normally, sodium salts are the major effective osmoles in extracellular fluid, and potassium salts are the major effective osmoles in cells. Given that effective osmolality is equal in all fluid compartments, body fluid tonicity can be described by the following equation:

$$\text{Tonicity} \approx 2 \times \text{Plasma } [\text{Na}^+] \approx \frac{2 (\text{Exchangeable } \text{Na}^+ + \text{Exchangeable } \text{K}^+)}{\text{Total body water}}$$

therefore,

$$\text{Plasma } [\text{Na}^+] \approx \frac{\text{Exchangeable } \text{Na}^+ + \text{Exchangeable } \text{K}^+}{\text{Total body water}}$$

(Only the exchangeable fractions of sodium and potassium are included in the equation, because one third of overall body sodi-

um is bound to bone and is therefore osmotically inactive.)

Thus, the plasma sodium concentration is, in effect, a measure of the concentration of tonicity of all body fluids.³ In the absence of an osmolar gap, the plasma sodium concentration is a more valid measure of body fluid tonicity than plasma osmolality (which includes the ineffective osmole, urea). With a few exceptions, most notably hyperglycemia, a low plasma sodium concentration indicates hypotonicity and cell swelling, whereas a high plasma sodium concentration indicates hypertonicity and cellular dehydration.

RENAL PROCESSING OF BODY FLUIDS

Glomerular Filtration

Approximately 170 L of extracellular saltwater containing over 25,000 mmol of sodium are filtered by the glomerulus each day. Although glomerular hydrostatic pressure is considerably higher than the pressure of other capillary beds, the Starling forces that control fluid movement between intravascular and interstitial fluid also drive glomerular filtration. The glomerular filtrate contains the same concentrations of sodium and other solutes as interstitial fluid and is nearly protein free.

Tubular Reabsorption

On a conventional diet, all but 2 L of filtered fluid and all but 175 mmol of filtered sodium is reabsorbed by the renal tubules. Regulation of tubular reabsorption of salt and water is the key to renal regulation of body fluid balance.⁴

At the end of the proximal tubule, the remaining filtrate has the same sodium concentration as plasma has; as the filtrate passes through downstream tubular segments, it undergoes major changes in composition. In these more distal segments, sodium and water reabsorption are uncoupled; salt can be reabsorbed without water, and water can be reabsorbed without salt. Thus, depending on conditions, the sodium concentration of the final urine can vary from less than 1 mEq/L to nearly 300 mEq/L, and urine osmolality can vary from one sixth (50 mOsm/kg) to four times (1,200 mOsm/kg) that of plasma.

The process of sodium reabsorption is mediated by carriers or channels embedded in the tubular cell's luminal and basolateral (blood side) membranes. In each nephron segment, sodium reabsorption is powered by the so-called sodium pump, Na^+, K^+ -ATPase, which is located on the blood side of the tubular cell [see Figure 1]. This sodium pump exports sodium from the cell, lowering the intracellular sodium concentration. The lowered concentration of cellular sodium creates an electrochemical gradient driving sodium from the tubular lumen into the cell. Tubular segments at various regions of the nephron utilize different luminal mechanisms for sodium reabsorption [see Table 1 and Figure 2]. Luminal ex-

Table 1 Sodium Transport in Different Nephron Segments

Nephron Segment	Glomerular Filtrate Reabsorbed	Mechanism of Luminal Sodium Entry	Physiologic Regulation	Diuretic Site of Action
Proximal tubule	60%–70%	$\text{Na}^+ - \text{H}^+$ exchange; cotransport with glucose and other organic solutes	Angiotensin II; renal nerves; peritubular Starling forces	Carbonic anhydrase inhibitors (e.g., acetazolamide)
Loop of Henle	20%–25%	$\text{Na}^+ - \text{K}^+ - 2\text{Cl}^-$ cotransport	Flow dependent; peritubular Starling forces	Loop diuretics (e.g., furosemide, bumetanide, ethacrynic acid)
Distal tubule	5%	$\text{Na}^+ - \text{Cl}^-$ cotransport	Flow dependent	Thiazide diuretics
Collecting tubule	4%	Na^+ channels	Aldosterone; atrial natriuretic factor	Potassium-sparing diuretics (e.g., amiloride, triamterene, spironolactone)

changers, cotransporters, and ion channels along the nephron are subject to physiologic control, and they can be inhibited pharmacologically by specific diuretic agents.⁵ Mutations in these transport proteins are responsible for well-defined clinical disorders.⁶

The luminal membrane of the collecting duct is impermeable to water in the absence of arginine vasopressin, an antidiuretic hormone (ADH). Thus, when plasma ADH levels are low, this segment progressively reduces the osmolality and sodium concentration of the final urine and permits the excretion of large volumes (as much as 20 L daily) of dilute urine. In the presence of ADH, water chan-

nels—called aquaporins—are inserted in the luminal membrane of the distal tubule and collecting duct.^{7,8} When plasma levels of ADH are high, water is attracted osmotically from the tubular lumen to the hypertonic medullary interstitium, permitting excretion of a small volume (as little as 0.5 L daily) of concentrated urine.

REGULATION OF BODY FLUID VOLUMES

Saltwater (isotonic saline) is confined to the extracellular space. Accumulation of saltwater expands extracellular volume; loss of saltwater causes volume depletion. In either case, changes in saltwater balance do not alter the plasma sodium concentration or cell volume. By contrast, so-called electrolyte-free water, or pure water, is distributed throughout body fluids, affecting both extracellular and intracellular fluid compartments. Because only one third of body water is extracellular, electrolyte-free water has only one third the impact on extracellular volume that saltwater has; however, unlike saltwater balance, electrolyte-free water balance has a major impact on the plasma sodium concentration, body fluid tonicity, and cell volume.

Extracellular and intracellular fluid volumes are maintained by separate but interacting control systems [see Table 2]; the extracellular system primarily regulates urinary sodium excretion, whereas the intracellular system regulates the intake and excretion of water. Extracellular fluid volume maintains a proper degree of vascular fullness, a variable that is sensed by atrial stretch receptors and arterial baroreceptors. Intracellular volume is regulated by hypothalamic osmoreceptor cells that swell or shrink in response to changes in plasma tonicity.

Control of Extracellular Fluid Volume

In a healthy person, the amount of sodium in the extracellular space can vary considerably, depending on dietary salt intake. On the other hand, under normal conditions, the extracellular sodium concentration remains almost constant because of physiologic control systems that tightly regulate water intake and excretion. In healthy persons, more salt in the extracellular space means an expanded extracellular fluid volume; less salt means a smaller extracellular volume. In either case, the extracellular sodium concentration does not change.

Sodium balance and intravascular volume are affected by numerous hormonal and nonhormonal mediators; in addition to aldosterone and angiotensin—the best known mediators of sodium excretion—the sympathetic nervous system, natriuretic peptides, and changes in the renal circulation all play important regulatory roles [see Table 2].⁹ Because of redundancy and overlap in the control system, failure of a single factor does not cause major, sustained abnormalities in intravascular volume. The relative importance of the various mediators that affect urinary sodium excretion are incompletely understood, and it is likely that some sodium regulatory factors remain undiscovered.

Control of Intracellular Fluid Volume

Water balance and cell volume are controlled by a single hormonal mediator, arginine vasopressin [see Tubular Reabsorption, above], which is released into the systemic circulation by the neurohypophysis [see Table 2 and Figure 3]. The hormone activates V₂ receptors on the basolateral membrane of principal cells in the renal collecting duct, initiating a cyclic adenosine monophosphate-dependent (cAMP-dependent) process that culminates in the insertion of water channels (aquaporins) into the cells' luminal membranes.^{7,8} Modulation of the number of water channels controls urine osmolality and the rate of water excretion by the kidney. Vasopressin's short half-life in the circulation and continuous shuttling of

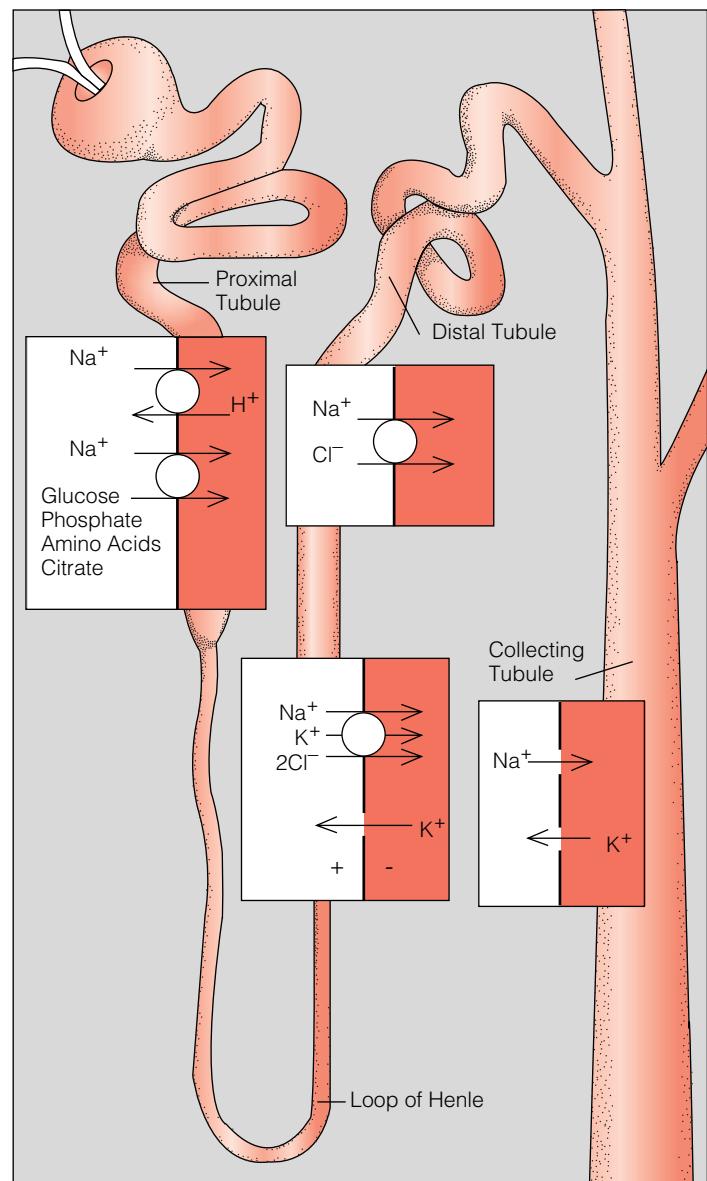

Figure 2 In each tubular segment, sodium enters the tubular cell passively, down the favorable electrochemical gradient created by the Na⁺, K⁺-ATPase pump. Luminal sodium enters by a different mechanism in each of the nephron segments. The proximal tubule reabsorbs filtered bicarbonate and other solutes, such as glucose, phosphate, amino acids, and citrate. An Na⁺, K⁺, 2Cl⁻ transporter mediates Na⁺ entry into the ascending limb of the loop of Henle. The distal tubule has an Na⁺, Cl⁻ cotransporter. Na⁺ enters the principal cells of the cortical collecting tubules through Na⁺ channels in the luminal membrane.

Table 2 Control of Body Fluid Volumes

	Saltwater Balance	Electrolyte-Free Water Balance	
		Day to Day	Emergency Backup
Regulated variable	Extracellular volume Vascular fullness	Cell volume	Arterial filling
Clinical indicator	Blood pressure Edema	Plasma sodium concentration	Blood pressure Edema
Sensors	Baroreceptors, atrial volume receptors	Hypothalamic osmoreceptors	Baroreceptors, atrial volume receptors
Mediators	Renin-angiotensin-aldosterone system Sympathetic nervous system Atrial natriuretic peptide Starling forces in peritubular capillaries	Antidiuretic hormone (arginine vasopressin) Thirst	Antidiuretic hormone (arginine vasopressin) Thirst
Affected variable	Urinary sodium excretion	Urine osmolality Water intake	Urine osmolality Water intake

aquaporins between the collecting duct's cell membrane and cytosol ensure that urinary water excretion responds rapidly to changes in body fluid tonicity.

Vasopressin levels are normally unmeasurable when the plasma sodium concentration falls to 135 mEq/L or lower [see Figure 3]. Low levels of the hormone result in the excretion of large volumes of a maximally dilute urine (50 mOsm/kg). Above a sodium level of 135 mEq/L, plasma vasopressin levels are linearly related to the plasma sodium concentration and increase measurably in response to changes in the plasma sodium concentration of as little as 1 mEq/L. Once the plasma sodium concentration reaches approximately 142 mEq/L, plasma vasopressin levels are high enough to promote the excretion of maximally concentrated urine (1,200 mOsm/kg). A rising plasma sodium concentration also causes hypothalamic cell volume receptors to relay signals to nearby thirst centers. Mediated by thirst and changes in vasopressin secretion, the plasma sodium concentration is normally prevented from rising above 142 mEq/L or falling below 135 mEq/L.

Under day-to-day conditions, water intake, vasopressin secretion, and urinary free water excretion primarily respond to changes in the plasma sodium concentration created by variations in electrolyte-free water balance. Unlike sodium excretion, which is affected only by changes in intravascular volume, free water excretion can be affected by two types of stimuli—intravascular volume and tonicity. Under pathologic conditions, osmotic control of vasopressin secretion and thirst can be overridden by hemodynamic stimuli. The hypothalamic neurons that secrete vasopressin receive neural input from baroreceptors in the great vessels and volume receptors in the atria. When these receptors are stimulated by hypotension or by a major reduction in plasma volume, impulses are carried via cranial nerves IX and X.⁸ Vasopressin and thirst responses to hypovolemia and hypotension can be regarded as back-up systems that serve to maintain arterial blood volume under emergency conditions, sacrificing tonicity to tissue perfusion.

CELL VOLUME REGULATION IN HYPOTONICITY AND HYPERTONICITY

Cell volume is determined by the amount and concentration of intracellular solute. Because intracellular and extracellular solute concentrations must be equal, the relation between cell water and extracellular osmolality can be described by the following equation:

$$\text{Cell volume} = \frac{\text{Cell water}}{\text{Extracellular osmolality}}$$

Normally, water intake and excretion are modulated to maintain body fluid tonicity within a narrow physiologic range. However, under pathologic conditions, body cells can be exposed to a hypotonic or hypertonic milieu.¹⁰ The first response to osmotic stress is a compensatory adjustment to intracellular electrolytes: loss of potassium in hypotonicity and accumulation of sodium and potassium in hypertonicity. With time, changes in organic solutes dominate the response.

Most cells maintain relatively high concentrations of small, osmotically active organic molecules known as organic osmolytes. Or-

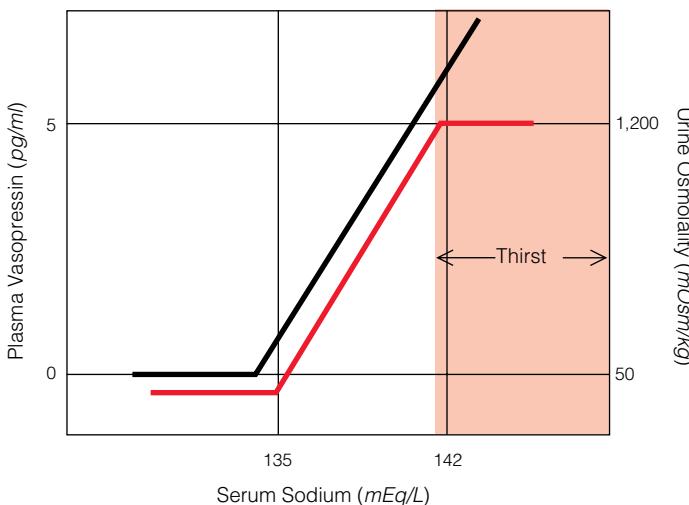

Figure 3 Graph depicts the normal relation between plasma vasopressin levels and urine osmolality (black line) and the plasma sodium concentration (red line). Plasma vasopressin levels change within minutes in response to changes in plasma sodium, and urine osmolality changes within minutes in response to changes in vasopressin levels. When hydration reduces the plasma sodium level below 135 mEq/L, plasma vasopressin becomes undetectable and the urine becomes maximally dilute (osmolality, 50 mOsm/kg). Between sodium concentrations of 135 and 142 mEq/L, vasopressin levels are linearly related to the plasma sodium, causing nearly a 100 mOsm/kg increase in urine osmolality for every 0.5 mEq/L increase in sodium concentration. Above a plasma sodium concentration of 142 mEq/L, the urine is maximally concentrated; increased water intake, mediated by thirst, then becomes the major defense against progressive hypernatremia.

ganic osmolytes are nonperturbing solutes; unlike sodium and potassium, their intracellular concentrations may vary widely without affecting tertiary protein structure. Cells accumulate organic osmolytes under hypertonic conditions and lose them when confronted with hypotonicity.

The need for cell volume regulation is most imperative in the brain, where the rigid calvaria places sharp limits on the degree of tissue expansion or contraction that can be tolerated.¹⁰⁻¹³ An increase in brain water content of more than about 5% to 10% is incompatible with life. Variations in the intracellular concentration of organic osmolytes provide the brain with an astonishing ability to adapt to chronic osmotic disturbances. However, because changes in the osmolyte content of brain cells require a few days to develop fully, the brain is imperiled by rapid osmotic changes. Thus, acute hyponatremia or hypernatremia may be fatal at plasma sodium concentrations that are well tolerated chronically.

With sustained osmotic disturbances, adaptations that protect against brain swelling and shrinkage also predispose to injury when the osmotic disturbance is suddenly corrected. In chronic hyponatremia, cellular solutes lost in the adaptive phase must be recovered when the plasma sodium concentration returns to normal—a process that may require several days. Unless solute recovery keeps pace with the rising extracellular osmolality, brain cells will become dehydrated.^{11,12} This phenomenon may cause clinical complications [*see* Disorder of Water Excess: Hyponatremia, Chronic Hyponatremia, Complications of Therapy: Myelinolysis and Osmotic Demyelination Syndrome, *below*]. Similarly, in chronic hypernatremia, accumulated solutes must be shed during correction of the electrolyte disturbance.^{10,13} Cells that have become acclimated to a hypertonic environment lose organic osmolytes slowly because of slow turnover of the efflux mechanism, slow downregulation of hypertonically stimulated uptake pathways, or both. Thus, when chronic hypernatremia is corrected rapidly, brain cells swell to a greater than normal volume.

Disorder of Water Excess: Hyponatremia

Hyponatremia simply means a low plasma sodium concentration. In most cases, hyponatremia is associated with a low plasma osmolality level and body fluids that are too dilute (hypotonic hyponatremia). However, there are exceptions to this rule [*see* Differential Diagnosis for Hyponatremia, *below*].

PATHOGENESIS OF HYPONATREMIA

Hypotonic hyponatremia results from two basic mechanisms individually or together: (1) massive water intake, exceeding the capacity to excrete electrolyte-free water, or (2) impaired water excretion. Normally, the capacity for water excretion is rather large. In the absence of vasopressin, urine osmolality falls to approximately 50 mOsm/kg. A typical American diet provides 600 to 900 mOsm of electrolytes and urea that must be excreted each day. At this rate of solute excretion, the volume of maximally dilute urine equals 12 to 18 L. Water intake can occasionally exceed the normal excretory capacity, primarily in psychotic patients who frantically ingest gallons of water over a few hours¹⁴ and in very heavy beer drinkers who ingest large volumes of fluid but take in small amounts of salt and protein.¹⁵ More commonly, hyponatremia occurs in patients with a diminished ability to excrete free water.^{8,12}

Impaired Water Excretion

Water excretion is obviously compromised in severe renal failure; oliguric patients become hyponatremic if they are given too much water. However, most cases of hyponatremia occur in patients

whose normal kidneys are unable to excrete maximally dilute urine. A pathologically low plasma sodium concentration occurs when water is taken in at a time when renal diluting mechanisms are not functioning maximally because either (1) diuretics or tubular transport defects are blocking sodium reabsorption in the renal diluting segments or (2) antidiuretic hormone levels are elevated.

Nonosmotic Release of Vasopressin

Vasopressin is a water-retaining hormone that is released when water is needed. Because hypotonic hyponatremia normally inhibits vasopressin secretion, detectable vasopressin in a patient who is hyponatremic indicates that a nonosmotic stimulus for vasopressin release must be present. Vasopressin action increases the urine osmolality, which can be thought of as a bioassay for the hormone.

Hemodynamic stimuli for vasopressin Hypovolemia, heart failure, and cirrhosis are the most common nonosmotic stimuli for antidiuretic hormone secretion.¹⁶⁻¹⁸ The hemodynamic abnormalities that stimulate vasopressin release also promote sodium reabsorption by the renal tubules; thus, these conditions result in both sodium and water retention.

Inappropriate antidiuretic hormone secretion Nonosmotic release of vasopressin without a hemodynamic stimulus to account for it is considered "inappropriate." Patients with the syndrome of inappropriate antidiuretic hormone secretion (SIADH) retain water because of nonosmotic release of vasopressin but have no abnormality in sodium balance, evidence of volume depletion, or tendency to form edema; in the steady state, sodium excretion matches intake.^{8,12,19} Because of water retention, SIADH causes mild, subclinical volume expansion. Any additional volume expansion is met by a brisk increase in urinary sodium excretion.

Reset osmostat Reset osmostat is a variant of SIADH, commonly seen in patients with chronic, debilitating illness; it is also a characteristic of normal pregnancy. Patients with this condition are able to dilute their urine normally but at a lower set-point than in normal individuals. Such patients are thus mildly hyponatremic, but unlike other patients with SIADH, they are not predisposed to progressive water retention and do not require dietary water restriction or other measures used to treat chronic hyponatremia.¹¹ Reset osmostat can, however, be seen in malignancies, and like other causes of SIADH, it requires a diagnostic evaluation to determine its cause.

Urinary Electrolyte Losses: Desalination and Hyponatremia

If the urine is concentrated, urinary sodium and potassium losses can contribute to the pathogenesis of hyponatremia. The plasma sodium concentration can be reduced either by loss of sodium or potassium or by water gain. However, to lower the plasma sodium concentration, electrolytes must be lost in urine that has a higher electrolyte concentration than plasma. The combination of high vasopressin levels (which concentrate the urine) and a high rate of sodium and potassium excretion can yield hypertonic urine capable of generating free water, which in essence desalinates the plasma.²⁰

DIFFERENTIAL DIAGNOSIS FOR HYPONATREMIA

Several conditions can lower the plasma sodium concentration without causing hypotonicity and are referred to as nonhypotonic hyponatremia [*see* Table 3]. The diagnostic and therapeutic approach to these conditions differs fundamentally from the approach to hypotonic hyponatremia. Thus, it is important that nonhypotonic hyponatremia be excluded whenever a low plasma sodium concentration is encountered.

Table 3 Causes of Nonhypotonic Hyponatremia

Condition	Plasma Osmolality	Pathogenesis	Therapeutic Implications
Hyperglycemia	High	Extracellular glucose osmotically draws water into the ECF, diluting extracellular sodium	During treatment of hyperglycemia, anticipate 3 mEq/L increase in serum sodium for every 200 mg/dL reduction in blood sugar
Intravenous hypertonic mannitol therapy	High	Water shift from ICF to ECF as with hyperglycemia	Mannitol is rapidly excreted when renal function is normal
Intravenous γ -globulin therapy	High	Maltose present in solution acts like mannitol	Measure plasma osmolality when hyponatremia is suspected
Irrigant absorption (prostatectomy or intrauterine surgery)	Normal or low (when hyposmolar irrigants are used)	Absorbed solute—mannitol, sorbitol, or glycine (most common)—initially confined to ECF, causing severe hyponatremia but little change in plasma osmolality	Mannitol is rapidly excreted; sorbitol is metabolized, causing late-onset hyponatremia; glycine is neurotoxic and causes transient blindness and is metabolized to ammonia, causing encephalopathy; consider hemodialysis
Pseudohyponatremia (severe hyperlipidemia, multiple myeloma, macroglobulinemia)	Normal	Laboratory artifact; plasma water constitutes a smaller fraction of the plasma sample, causing a more serious underestimate of the true sodium concentration	Suspect when serum is lactescent; compare measured plasma osmolality with calculated osmolality or measure plasma sodium with direct-reading sodium electrode

ECF—extracellular fluid ICF—intracellular fluid

Hyperglycemic Hyponatremia

Hyperglycemia lowers the plasma sodium concentration; in the absence of insulin, glucose is an effective osmole that attracts water from cells and thereby dilutes extracellular sodium. Therefore, the blood glucose level should always be examined when a low plasma sodium concentration is being evaluated. The plasma sodium concentration falls by approximately 3 mEq for every 200 mg/dL (10 mmol) increase in blood glucose and will increase by this amount when hyperglycemia is corrected with insulin. To evaluate hyponatremia in the presence of hyperglycemia, the serum sodium concentration must be “corrected” for the osmotic effect of glucose. In effect, the clinician must ask the question, What would the serum sodium concentration be if the excess glucose were no longer present? The correction factor most commonly used today is a 1.6 mEq/L decrease in serum sodium concentration for every 100 mg/dL increase in blood glucose. A small study has suggested that the true correction factor is approximately 2.4 mEq/L for every 100 mg/dL increase in blood glucose.²¹ A precise correction factor is probably unobtainable because in practice, hyperglycemia develops, in part, from the ingestion of glucose with water and resolves, in part, from the urinary excretion of glucose with water.²²

Exogenous solutes such as mannitol and maltose (a sugar contained in intravenous immunoglobulin preparations) are confined to the extracellular space and have an effect on the plasma sodium concentration similar to that of hyperglycemia. When the clinical setting suggests that these solutes might be responsible for hyponatremia, their presence can be confirmed by measuring the plasma osmolality and comparing it with the calculated value to identify an osmolar gap [see Overview of Body Fluid Homeostasis, Distribution and Composition of Body Water, Osmolality, above].^{2,11}

Postprostatectomy Syndrome and Hysteroscopic Hyponatremia

Irrigants containing mannitol, sorbitol, or glycine are used for endoscopic transurethral and intrauterine procedures [see Table 3].^{2,23} Occasionally, several liters of irrigant may be absorbed systemically, reducing the plasma sodium in a matter of minutes. Immediately after surgery, the serum sodium concentration is much lower than would be anticipated, because the electrolyte-free solution is initially confined to the extracellular space. Glycine, the most commonly used irrigant in the United States, is metabolized to ammonia and

eventually to urea and glucose. Hyperammonemia may be responsible for most of the symptomatology, and glycine itself has direct neuroinhibitory effects and may cause hypotension, bradycardia, and visual disturbances.

Pseudohyponatremia

High plasma concentrations of lipid or protein cause mild non-hypotonic hyponatremia because of an artifact of laboratory measurement [see Table 3].^{2,11} With extremely high concentrations of lipid (enough to cause lactescent serum) or protein (from multiple myeloma or Waldenstrom macroglobulinemia), plasma water may constitute a smaller fraction of the plasma sample than normal, which can result in an underestimate of the “true” sodium concentration. The plasma osmolality and the sodium concentration in plasma water (as measured by a sodium-sensitive electrode) are unaffected. There are no symptoms, and no therapy is required.

ACUTE HYponATREMIA (WATER INTOXICATION)

The term water intoxication was coined in the early 1920s to describe a neurologic syndrome that develops when large volumes of water are retained within a relatively short period of time (< 48 hours). The syndrome is often called acute hyponatremia.^{12,24}

Etiology

Acute hyponatremia develops when water intake is large and electrolyte-free water excretion is impaired. Potentially, hyponatremia can develop rapidly in any patient predisposed to water retention who takes in a large volume of water in a short period of time. However, this is likely to occur in a limited number of settings [see Table 4], and such instances account for most cases of severe symptomatic hyponatremia and for most of the recorded fatalities.

Postoperative hyponatremia Vasopressin is released immediately after surgical procedures in what appears to be a stress response [see Table 4].^{20,25} Particularly during the first 24 hours, the concentration of urinary cations (sodium plus potassium) may greatly exceed the plasma sodium concentration. As a result, even isotonic fluids may be “desalinated” and can lower the plasma sodium concentration.²⁰ Thus, all hypotonic fluids and excessive amounts of isotonic fluids should be avoided after surgery. As discussed earlier, endoscopic prostatectomy and intrauterine proce-

Table 4 Causes and Treatment of Acute Hyponatremia

Causes	Pathogenesis	Effect of Treatment	Recommendations
Postoperative stress*	Vasopressin is secreted in response to surgical stress for 2 or more days; free water from hypotonic I.V. fluids is retained and sodium and potassium are excreted in urine at high concentrations	Normal saline ineffective for correction—administered sodium excreted in concentrated urine, “desalinating” isotonic fluid and causing water retention	Avoid hypotonic fluid (e.g., D5W, 0.45% saline) and excessive volumes of isotonic fluid (lactated Ringer solution or 0.9% saline) after surgery; treat symptomatic hyponatremia with 3% saline and furosemide
Oxytocin	Used in obstetrics to induce labor; direct antidiuretic effect of drug mimics SIADH; free water from I.V. fluids retained	Urine becomes dilute when oxytocin is discontinued	Avoid administration of oxytocin in or with hypotonic fluids; treat hyponatremia by discontinuing drug
Cyclophosphamide	Drug has antidiuretic effect that persists for as long as 12 hours; patients are encouraged to drink large volumes of water to prevent chemically induced cystitis	Normal saline ineffective for correction as in other causes of persistent SIADH	Treat symptomatic hyponatremia with 3% saline and furosemide
Psychotic self-induced water intoxication	Extreme polydipsia (> 1 L/hr) common among patients with severe psychosis; retained water causes hyponatremia by late afternoon or evening, and water diuresis restores normonatremia by morning	Normal ability to dilute urine in most patients so hyponatremia self-corrects when water intake stops; some patients have vasopressin release (often transient) from stress, smoking, or medications (e.g., carbamazepine)	Monitor diurnal weight in institutionalized patients for early detection; avoid antidiuretic medications; treat hyponatremia with water restriction; use hypertonic saline and furosemide for occasional patient with SIADH
Marathon running	Extracellular volume depletion caused by saltwater losses from sweating and possibly stress are nonosmotic stimuli for vasopressin secretion; large volumes of sugar water consumed during race are retained	Isotonic saline restores ability to dilute urine	3% saline without furosemide for seizures; isotonic saline and water restriction for more moderate symptoms
Ecstasy (MDMA) use	Excessive fluid intake and inappropriate antidiuretic hormone secretion, induced by MDMA, is implicated	Isotonic saline ineffective; self-correction typical but may be delayed	Hypertonic saline for severe symptoms

*Excluding irrigant absorption syndromes [see Table 3].

D5W—5% dextrose in water MDMA—methylenedioxymethamphetamine SIADH—syndrome of inappropriate antidiuretic hormone

dures can cause hyponatremia if irrigant used in the procedures is absorbed systemically. The management of irrigant absorption syndromes differs from that of other causes of postoperative hyponatremia [see Postprostatectomy Syndrome and Hysteroscopic Hyponatremia, above].²⁵

Oxytocin infusions Oxytocin, which is used in obstetrics to induce labor, has a direct antidiuretic effect. If the drug is administered in 5% dextrose in water (formerly a common practice), symptomatic hyponatremia may emerge after the infusion of less than 3 L of fluid [see Table 4].¹¹ Termination of the infusion permits a water diuresis and correction of hyponatremia; however, the syndrome is best avoided by using isotonic saline as a vehicle for the drug.

Cyclophosphamide infusion Intravenous cyclophosphamide impairs water excretion by an unknown mechanism.²⁶ The antidiuretic effect of the drug begins 4 to 12 hours after injection and persists for as long as 12 hours. Patients receiving cyclophosphamide are particularly susceptible to hyponatremia, because they are encouraged to drink large volumes of water to prevent chemically induced cystitis [see Table 4].

Psychotic self-induced water intoxication Extreme polydipsia is relatively common in patients with psychiatric illnesses, particularly schizophrenia, and it may lead to symptomatic hyponatremia [see Table 4].¹⁴ Daily intake of 10 to 15 L has been documented, and much of the intake may take place over a few hours. Many patients become hyponatremic in the late afternoon and

evening; however, water diuresis typically restores normonatremia by the following morning. Occasionally, individuals drink enough water to produce seizures. By monitoring diurnal changes in body weight, water intoxication can be recognized before the onset of severe neurologic symptoms. Transient release of vasopressin (most commonly provoked by nausea and vomiting) may contribute to water retention. There is little evidence that any of the major tranquilizers has a significant antidiuretic effect; however, carbamazepine, an anticonvulsant, enhances sensitivity to vasopressin.

Water intoxication during exercise During a race, runners sweat profusely, losing large volumes of saltwater. Extracellular volume contraction and possibly the stress of exertion cause the release of vasopressin. When saltwater losses are replaced by the intake of sugar water, water retention and symptomatic hyponatremia may occur.^{27,28} Most severe cases have been reported after marathons or ultramarathons. However, symptomatic hyponatremia may occur after recreational running and military fitness training.

Water intoxication from “ecstasy” During the 1990s, 3,4-methylenedioxymethamphetamine (MDMA, or ecstasy) gained widespread popularity as a recreational drug taken at dances.²⁹ When malignant hyperthermia was recognized as a complication associated with this drug, MDMA users were advised in underground magazines and the lay press to drink plenty of fluids. Subsequently, acute water intoxication emerged as a potentially lethal complication of the drug [see Table 4]. Excessive fluid intake and inappropriate ADH secretion, induced by MDMA, have been implicated.

Diagnosis

Symptoms of water intoxication include headaches, weakness, nervousness, and vomiting, progressing to disorientation, delirium, tremulousness, and ultimately convulsions and coma.^{12,24} The pupils are often dilated, and bilateral Babinski signs may be present. On occasion, patients may present with hemiparesis, mimicking a cerebrovascular accident. The syndrome reflects cerebral edema, which can lead to herniation of the brain and death. Clinical findings may emerge explosively. Complaints of headache and mild confusion may be followed within hours by respiratory arrest and, in some cases, neurogenic pulmonary edema. For reasons that remain obscure, almost all reported fatalities from acute postoperative hyponatremia have been in women (usually of childbearing age) and young children. Fatal cases of acute hyponatremia from other etiologies have been recorded in men and women.

Acute hyponatremia should be suspected in any patient who has unexplained neurologic symptoms, especially in psychiatric patients, marathon runners, users of ecstasy, and patients receiving hypotonic fluids intravenously (e.g., after surgery). Serum electrolytes should be obtained immediately. In the proper setting, a tentative diagnosis of water intoxication is advisable when symptoms develop in a patient whose serum sodium concentration is lower than 130 mEq/L (provided that causes of nonhypotonic hyponatremia have been excluded). Although severe neurologic symptoms do not usually appear until the sodium level has fallen below 120 mEq/L, some patients may be unusually susceptible to brain edema when they become acutely hyponatremic; rare fatalities have been reported at plasma sodium concentrations between 120 and 128 mEq/L.^{20,25}

Computed axial tomography demonstrates cerebral edema in severe cases of water intoxication, and it rules out other potential explanations for neurologic findings. However, when symptoms are severe, therapy should not be delayed while imaging studies are being obtained.

Treatment

Free-water intake should be stopped immediately whenever water intoxication is suspected. Hypertonic saline is the treatment of choice for water-intoxicated patients who cannot autocorrect their electrolyte disturbance.^{24,25} Each 1 ml of 3% saline contains 0.5 mEq of sodium. Because there are approximately 0.5 L of body water for every 1 kg of body weight, 1 ml of 3% saline per 1 kg of body weight can be expected to increase the plasma sodium concentration by 1 mEq/L. For patients with severe neurologic symptoms, an infusion of 3% saline at 1 to 2 ml/kg/hr will increase the plasma sodium concentration by approximately 1 to 2 mEq/L/hr, a rate that is considered appropriate for initial therapy. Hypertonic saline is best infused in 100 ml containers to avoid inadvertently giving an excessive dose. Except when volume depletion is suspected (as in marathon runners), concurrent administration of a loop diuretic (furosemide, bumetanide, or torsemide) is advisable. The diuretic prevents volume overload and, by blocking sodium reabsorption in the loop of Henle, impedes the formation of concentrated urine.

The goal of therapy in acute hyponatremia is to decrease the severity of cerebral edema and to stop seizures. A 4 to 6 mEq/L increase in plasma sodium concentration is usually sufficient to accomplish these goals. Thus, the plasma sodium concentration should be monitored frequently during therapy and emergency treatment with hypertonic saline should be stopped after 2 to 3 hours. Once initial therapy with high-dose hypertonic saline has been completed, more conservative measures should be substituted

Table 5 Causes of the Syndrome of Inappropriate Antidiuretic Hormone

Tumors	Bronchogenic (small cell) Pancreatic Duodenal Urethral Nasopharyngeal Leukemia Hodgkin disease Thymoma
Neurologic disorders	Psychosis Trauma Neoplasms (primary and metastatic) Vascular (hemorrhage, infarction, and vasculitis) Infection (meningitis, brain abscess, and encephalitis) Miscellaneous (Guillain-Barré syndrome, multiple sclerosis, hydrocephalus, Shy-Drager syndrome)
Pulmonary disorders	Infectious (bacterial, viral, and fungal pneumonia and tuberculosis) Functional (asthma, acute respiratory failure, and mechanical ventilation)
Endocrine diseases	Glucocorticoid deficiency (hypopituitarism) Hypothyroidism
Drugs	Antidiuretic hormones (vasopressin, DDAVP, and oxytocin) Psychotropic agents (tricyclic antidepressants, serotonin reuptake inhibitors, monoamine oxidase inhibitors, and carbamazepine) Ecstasy (MDMA) Antineoplastic agents (cyclophosphamide, vincristine, and vinblastine) Nonsteroidal anti-inflammatory drugs Diabetic agents (chlorpropamide and tolbutamide) Miscellaneous (bromocriptine and nicotine)
Other causes	Postoperative stress Alcohol withdrawal AIDS Nausea

DDAVP—1-desamino-8-D-arginine vasopressin MDMA—methylenedioxymethamphetamine

to gradually return the plasma sodium concentration to normal. To avoid complications from excessive correction of hyponatremia, the plasma sodium concentration should not be intentionally increased by more than 12 mEq/L during the first day of therapy or by more than 6 mEq/L/day thereafter.

CHRONIC HYponATREMIA

The distinction between acute and chronic hyponatremia is somewhat arbitrary. We consider hyponatremia to be chronic when it has evolved over the course of 48 hours or more.^{11,12,24} Although the precise duration of an electrolyte disturbance cannot be known when it develops outside the hospital (except for psychotic water drinkers, marathon runners, and users of ecstasy) outpatients can be assumed to have chronic hyponatremia.³⁰ Prolonged hyponatremia cannot occur unless there is a sustained defect in water excretion. Except for patients with renal failure, virtually all chronically hyponatremic patients have some abnormality in vasopressin secretion.

Etiology

Advanced renal failure A low glomerular filtration rate limits the ability to excrete electrolyte-free water. Many patients with advanced renal failure excrete urine that has the same osmolality as plasma regardless of physiologic conditions (fixed isosthenuria). In

acute oliguric renal failure, the ability to excrete free water is virtually nil; administration of hypotonic fluids must be scrupulously avoided to avoid hyponatremia.

Diuretics Thiazide diuretics are commonly the sole cause or a major contributing factor of hyponatremia requiring hospital admission.^{30,31} For unknown reasons, severe hyponatremia caused by thiazides affects elderly women much more often than other groups. By blocking the reabsorption of sodium and chloride in the distal tubule, thiazides and metolazone prevent the generation of maximally dilute urine.³² Because sodium reabsorption in the ascending limb of the loop of Henle is left unaffected by these agents, they permit excretion of maximally concentrated, hypertonic urine and can lead to simultaneous retention of water and depletion of sodium and potassium. Extraordinarily severe hyponatremia can result from thiazides, with plasma sodium levels as low as 100 mEq/L. Vasopressin levels are usually elevated in patients who present with thiazide-induced hyponatremia, sometimes because of diuretic-induced volume depletion but more often because of the stress of minor intercurrent illnesses. Patients with thiazide-induced hyponatremia do not usually appear clinically volume depleted, presumably because retained water partially sustains extracellular fluid volume. Patients who have become hyponatremic on thiazides should not be given these agents again; recurrent episodes of severe hyponatremia are common.

Hypovolemia Hypovolemic hyponatremia is most often associated with gastrointestinal fluid losses caused by vomiting, diarrhea, or laxative abuse. Surprisingly, particularly in alcoholics, patients who continue to drink while vomiting repeatedly can still absorb enough ingested water to become hyponatremic. Electrolyte losses in the vomitus, combined with urinary sodium and potassium losses that result from metabolic alkalosis, lower the plasma sodium concentration.

Beer potomania Patients who subsist on beer (a practice known as beer potomania) are susceptible to hyponatremia because of their low rates of solute excretion (beer contains little protein or electrolyte). Nonosmotic stimuli to vasopressin secretion caused by nausea or gastrointestinal fluid losses or by treatment with thiazide diuretics are often contributing factors.¹⁵

Edeematous conditions Any disease that can cause edema also predisposes to water retention and hyponatremia. The same hemodynamic factors that promote sodium retention are nonosmotic stimuli for vasopressin release.^{8,16-18} Elevated vasopressin levels have been reported in hyponatremic patients with congestive heart failure, cirrhosis, and nephrotic syndrome. In heart failure, hyponatremia is associated with a low cardiac output and a poor prognosis.

SIADH Nonosmotic release of vasopressin that has no hemodynamic explanation is termed inappropriate [see Table 5].^{12,19} A number of tumors (most commonly small cell carcinoma of the lung) ectopically synthesize and secrete vasopressin.³³ Unexplained, persistent hyponatremia should be considered a marker for an underlying malignancy.

SIADH may also complicate the course of a wide variety of conditions in which there is damage to or inflammation of the central nervous system.^{8,12} In patients with subarachnoid hemorrhage, natriuretic peptides released by the brain may directly promote urinary sodium loss, regardless of extracellular volume (cerebral salt wasting).^{34,35} Urinary salt losses combined with vasopressin-induced water retention are responsible for hyponatremia. SIADH is

a common complication of chest infection. Antidiuretic activity has been demonstrated by bioassay in patients with tuberculous lung tissue, and tuberculosis causes SIADH.¹¹ In pneumonia, vasopressin levels are increased during the acute phase of the disease and return to baseline within a few days. Isolated glucocorticoid deficiency caused by anterior pituitary dysfunction also causes hyponatremia; patients with hypopituitarism develop inappropriate ADH secretion, but unlike patients with Addison disease, they have normal levels of mineralocorticoid and do not become hypovolemic or hyperkalemic. Hyponatremia caused by glucocorticoid deficiency promptly resolves when cortisol is replaced. Hypothyroidism also causes inappropriate ADH secretion; hyponatremia gradually resolves when thyroid hormone is replaced.³⁶ A number of therapeutic agents can induce SIADH.^{12,37} Nonsteroidal anti-inflammatory drugs (NSAIDs) decrease water excretion because they inhibit formation of prostaglandin E₂, which modulates vasopressin action.⁸ Rare cases of hyponatremia solely attributable to NSAIDs have been reported, but these commonly used agents may exacerbate other causes of hyponatremia.

Hyponatremia in AIDS Hyponatremia is an extremely common finding in AIDS.³⁸ Many AIDS patients have features of SIADH associated with opportunistic infections that cause pneumonia and meningitis. Others have clinical signs of volume depletion without low urine sodium values, a finding that may indicate coexistent renal disease or adrenal insufficiency.³⁹ Hyponatremia often occurs when antibiotics are administered in hypotonic intravenous solutions.

Diagnosis

Hyponatremia should be approached in a systematic fashion. First, the various disorders that can lower the plasma sodium concentration without causing hypotonicity should be excluded [see Differential Diagnosis for Hyponatremia, above]. Once it has been established that hypotonic hyponatremia is present, the mechanism for impaired water excretion is identified (hypovolemia versus an edematous condition versus SIADH), and the differential diagnosis that applies to that mechanism is considered. The most challenging goals of the diagnostic process are to determine whether chronic SIADH is present and, if it is, to define the specific disease responsible for the syndrome.

Clinical manifestations Because cerebral edema is usually not severe, the symptoms of chronic hyponatremia are much more subtle, vague, and nonspecific than those of acute water intoxication.^{12,24} The electrolyte disturbance is often asymptomatic at sodium levels that may be lethal to a patient with acute water intoxication. As the plasma sodium concentration falls below 115 to 120 mEq/L, patients often experience anorexia, nausea, vomiting, muscle weakness, and muscle cramps. They may be irritable and show personality changes, becoming uncooperative, confused, hostile, or simply slow to respond. At plasma sodium concentrations below 110 mEq/L, gait disturbances, falling, stupor, tremulousness, and, more rarely, seizures may occur.

Chronic hyponatremia itself is rarely, if ever, fatal. However, because hyponatremia can be a marker for severe underlying illness, hospitalized patients with hyponatremia often have a high mortality rate, dying with but not of chronic hyponatremia. There is little evidence that chronic hyponatremia itself leads to permanent sequelae, even when the plasma sodium concentration falls below 105 mEq/L.^{30,40} However, patients with prolonged severe hyponatremia are susceptible to iatrogenic injury if their electrolyte disturbance is corrected too rapidly [see Treatment, below].

History and physical examination The history of patients with chronic hyponatremia should include information about diet, fluid intake, gastrointestinal fluid losses, and use of diuretics, antidepressants, or other antidiuretic drugs. During the physical examination, physicians should look for clinical signs of volume depletion or an edematous condition. Evidence of volume depletion may not always be definitive, however. For example, vomiting may be a symptom rather than the cause of hyponatremia; extreme hyponatremia may occasionally impair baroreceptor reflexes causing postural hypotension and a false impression of volume depletion; and retained water may mask underlying volume depletion. When the distinction between hyponatremia caused by hypovolemia and hyponatremia caused by inappropriate antidiuretic hormone secretion is not obvious, laboratory clues may be helpful.

Laboratory tests Measurement of the urinary sodium, chloride concentration, or both is often the most helpful test.⁴¹ Water retention caused by hypovolemia or by an edematous condition is usually associated with a urinary sodium concentration lower than 20 mEq/L. Hypovolemia caused by upper gastrointestinal fluid losses is an important exception. Loss of gastric fluid causes a metabolic alkalosis that may increase urinary sodium excretion despite volume depletion; the diagnosis can be made by measuring the urine chloride concentration, which is reduced in this condition. In SIADH, urinary sodium matches intake; as the urine is usually concentrated, the urinary sodium concentration exceeds 40 mEq/L unless dietary sodium intake is very low. Measurements of the BUN and serum uric acid complement these measurements. When a hemodynamic abnormality is responsible for hyponatremia, the kidney is underperfused, urea and uric acid clearances are diminished, and the BUN and serum uric acid levels are usually elevated. Conversely, SIADH is a volume-expanded state, and BUN and uric acid levels are usually low. Uric acid is a more reliable indicator of volume status than the BUN, because the latter value is affected by dietary protein intake as well as renal clearance. Assessment of acid-base and potassium balance may provide helpful clues to the diagnosis. The serum potassium and bicarbonate levels are normal in SIADH. Hypokalemia and metabolic alkalosis suggest diuretic therapy or vomiting, which can be surreptitious. Hyperkalemia and metabolic acidosis suggest the possibility of adrenal insufficiency. Hypokalemia and acidosis are found in diarrhea and raise the possibility of surreptitious laxative abuse.

Withdrawal of hyponatremic drugs When a patient is taking a drug that can cause hyponatremia, it is important to exclude another underlying cause for hyponatremia before attributing the electrolyte disturbance to the medication. For example, thiazide diuretics can exacerbate hyponatremia caused by SIADH. The best way to make a diagnosis of drug-induced hyponatremia is to eliminate the offending agent and be sure that water excretion returns to normal when the patient is off the drug. Full resolution of hyponatremia and full recovery of diluting function may be delayed for a week or two in patients with thiazide-induced hyponatremia. During repair of sodium and potassium deficits, transient resetting of the osmostat is common and should not necessarily prompt an extensive search for an underlying cause.

Response to therapy On occasion, evidence regarding the cause of hyponatremia can be equivocal. In such cases, the patient's response to isotonic saline (or a generous oral salt intake and the passage of time) is the best clue to the diagnosis. Patients with subclinical edematous conditions will retain the administered sodium,

developing clinically obvious edema. Volume-depleted patients initially retain the administered sodium, but as soon as hypovolemia is corrected, the urine becomes dilute, the rate of urinary sodium excretion increases to match intake, and hyponatremia improves as water is excreted in the urine. Urinary sodium excretion promptly increases in patients with SIADH, but the urine remains concentrated and hyponatremia persists. Isotonic saline should be given with extreme caution to patients with very low plasma sodium concentrations; in SIADH, saline can exacerbate hyponatremia, whereas in volume depletion, hyponatremia may correct too rapidly.

Identifying a specific cause for SIADH SIADH is a mechanism for developing hyponatremia, not a diagnosis. In all patients with SIADH, a specific etiology for inappropriate vasopressin secretion should be sought. When hyponatremia develops in the hospital, the cause is sometimes obvious (e.g., pneumonia, meningitis, acute respiratory failure) and no further testing is indicated. In a patient with clinical features of SIADH but no obvious cause for it, a more extensive evaluation is indicated. The workup should include a careful search for malignancy and central nervous system pathology and an endocrine evaluation to exclude hypothyroidism and hypocortisolism. Sometimes, no cause for SIADH is found, especially in elderly patients and patients with psychiatric disorders, mental retardation, or alcoholism.⁴² Careful follow-up is important, because malignancies may become clinically apparent after several years in so-called idiopathic SIADH.

Treatment

Patients with very low plasma sodium concentrations usually have some neurologic symptoms, and they are at risk of injuries from falls. However, unlike acute water intoxication, there is little risk of an explosive onset of seizures or a fatal outcome in chronic hyponatremia. On the other hand, patients with chronic hyponatremia are at considerable risk of neurologic injury caused by over-aggressive correction. Thus, there are four major goals in managing chronic hyponatremia: (1) prevention of a progressive decrease in plasma sodium concentration; (2) amelioration of symptoms caused by hyponatremia; (3) avoidance of excessive correction; and (4) gradual restoration and maintenance of a normal plasma sodium concentration.

Free-water restriction should be instituted in all patients until the plasma sodium concentration has begun to increase. Intravenous fluids should be at least isotonic, and oral fluid intake should be limited to 500 to 1,000 mL/day, depending on the severity of the electrolyte disturbance. In patients with reversible defects in water excretion, limitations on free-water intake should be lifted once the plasma sodium concentration has begun to increase.

Attempts to calculate the dose of sodium chloride needed to correct hyponatremia are doomed to failure. The increase in plasma sodium concentration depends on the amounts of administered sodium and potassium that have been retained without being excreted, as well as on the amount of electrolyte-free water that is eliminated in the urine. Indeed, in some cases, the plasma sodium concentration will return to normal solely because of a water diuresis, with no sodium given. The measures required to increase the plasma sodium concentration, along with the likelihood of inadvertent rapid correction, vary depending on the cause of hyponatremia. For therapeutic purposes, the causes can be divided into reversible and persistent defects in water excretion.

Reversible defects in water excretion Hyponatremia corrects easily when the cause for defective water excretion can be

eliminated by volume expansion, by withdrawal of a therapeutic agent, or by treatment of an underlying illness [see *Table 4*]. In patients with reversible defects in water excretion, prevention of excessive correction may become a major challenge.

Hypovolemic hyponatremia responds readily to 0.9% sodium chloride because the sodium concentration of isotonic saline is higher than the cation concentration of the excreted urine. Once the volume deficit is repaired and the hemodynamic stimulus to vasopressin secretion is removed, the urine becomes dilute and a water diuresis may rapidly return the plasma sodium concentration to normal. Similarly, patients with diuretic-induced hyponatremia are extremely susceptible to rapid correction; restoration of the renal diluting mechanism when the diuretic is discontinued and replacement of sodium and potassium deficits contribute to the increase in plasma sodium concentration.

Intravenous saline should be discontinued once clinically apparent hypovolemia has been corrected and the plasma sodium concentration has begun to increase. Saline should be given cautiously, if at all, to hypokalemic patients who require potassium replacement. During repair of a potassium deficit, potassium enters cells, displacing sodium, which then returns to the extracellular fluid; administered potassium is therefore as effective as sodium in raising the plasma sodium concentration. Diuretic-induced hyponatremia does not usually necessitate use of intravenous saline; for most patients, an adequate diet, replacement of potassium deficits, and discontinuance of thiazide diuretics are sufficient. In severely hyponatremic patients, the plasma sodium concentration should be monitored every 6 to 8 hours for the first 2 to 3 days of therapy. If it appears that a water diuresis is going to increase the plasma sodium by more than the desired amount, replacement of fluid losses with oral water or 5% dextrose in water may become necessary.

Persistent defects in water excretion: SIADH Patients with SIADH tend to be resistant to rapid changes in plasma sodium concentration (unless the cause of SIADH is short-lived). Water restriction is the cornerstone of therapy, but if used alone, water restriction often leads to an extremely slow resolution of hyponatremia. Isotonic saline is ineffective and may even be counterproductive. Furosemide and loop diuretics are often useful therapeutic adjuncts because by blocking sodium reabsorption in the ascending limb of the loop of Henle, they interfere with the renal-concentrating mechanism, partially blocking the effect of vasopressin. Loop diuretics can be combined with oral salt or a slow infusion (approximately 15 ml/hr) of 3% saline. Oral and intravenous urea have been used extensively to treat SIADH in some parts of Europe, but experience with this agent in the United States is very limited. Demeclocycline, a tetracycline that blocks the effect of vasopressin on the collecting duct, is another therapeutic option in chronic SIADH; however, its expense and long duration of action limit its effectiveness. Several orally active vasopressin receptor blockers have been developed and are currently in clinical trials.^{43,44}

Persistent defects in water excretion: edematous conditions and renal failure Saline should rarely, if ever, be given to correct hyponatremia in edematous patients or patients with renal failure (except for those with prerenal azotemia). Because it has no effect on water excretion, 1 L of 0.9% saline will increase the plasma sodium concentration by only 1 mEq/L.¹² In addition, saline exacerbates edema and ascites in patients with cirrhosis and may cause pulmonary edema in patients with congestive heart failure or renal failure.

Although thiazide diuretics are contraindicated, loop diuretics

are the mainstay of treatment of hyponatremia for patients with edematous conditions because they increase free-water excretion and improve hyponatremia, particularly when dietary salt intake is increased. There is a natural inclination to discontinue loop diuretics when severely edematous patients develop hyponatremia. The usual problem, however, is oliguria and diuretic resistance rather than overdiuresis; the proper response is to increase the dose of loop diuretics and restrict water intake. The combination of a loop diuretic and an angiotensin converting enzyme (ACE) inhibitor is particularly effective in patients with congestive heart failure. The beneficial effect of an ACE inhibitor can be explained by reduced thirst and vasopressin secretion attributable to angiotensin II and by a direct effect on the hydro-osmotic effect of vasopressin, mediated by prostaglandins.¹¹

Hyponatremia in edematous conditions is mediated by vasopressin. Clinical trials have shown that vasopressin receptor antagonists can be effective in managing patients with hyponatremia and edema.^{43,44}

Treatment of hyponatremic seizures A small percentage of chronically hyponatremic patients with very low plasma sodium concentrations present with seizures. Regardless of the suspected duration or cause of the electrolyte disturbance, active seizures may be resistant to anticonvulsants alone and should be treated with hypertonic saline. The therapeutic approach is similar to that used for patients with acute water intoxication, except that even more vigilance is required to prevent an excessive increase in plasma sodium concentration once emergency measures have been discontinued.^{12,24}

Complications of Therapy: Myelinolysis and Osmotic Demyelination Syndrome

Excessive correction of chronic hyponatremia may be complicated by neurologic injury.^{40,45} Typically, the patient's hyponatremic symptoms improve as the plasma sodium concentration increases, but after a delay of one to several days, new findings emerge. The patient may become confused and may exhibit psychotic or catatonic behavior, pathologic crying, or a movement disorder. Swallowing dysfunction, progressive unresponsiveness, and a spastic quadripareisis may develop. In severe cases, locked-in syndrome occurs—that is, the patient is awake but unable to move or respond. The stereotypical pattern of delayed neurologic deterioration after rapid correction of hyponatremia has been named the osmotic demyelination syndrome,⁴⁵ because these clinical features are associated with brain lesions (myelinolysis) characterized by disruption of myelin and sparing of neurons and axons.^{46,47} Lesions, which are best identified by magnetic resonance imaging, are typically found in the center of the basal pons (central pontine myelinolysis [CPM]), but histologically similar lesions may also occur in a symmetrical distribution in extrapontine areas of the brain where there is a close admixture of gray and white matter. The osmotic demyelination syndrome has been reproduced in animal studies⁴⁶; these experiments have shown that the disorder is a complication of rapid correction of hyponatremia rather than the electrolyte disturbance itself. Observational studies in severely hyponatremic patients suggest that this therapeutic complication can be avoided if rates of correction are maintained below 10 to 12 mEq/L/day and 18 mEq/L/48 hr. Because large increases in the serum sodium concentration are seldom required to relieve hyponatremic symptoms and because unintentional excessive correction is common, the goal of therapy should be to increase serum sodium concentration by 8 mEq/L/day or less.¹²

Disorder of Water Deficiency: Hypernatremia**PATHOGENESIS**

Persistent hypernatremia results from one of two basic mechanisms: water is lost and not adequately replaced or, less commonly, too much salt is taken in without enough water [see Table 6].^{13,48-50} In either case, electrolyte-free water is needed to return the plasma sodium concentration to normal. Because thirst is the primary defense against hypertonicity, persistent hypernatremia means there is a defect in water intake. A maximally concentrated urine minimizes but does not prevent water losses. Insensible water losses from the skin and lungs are unavoidable and urea excretion obligates some urinary losses. Maintenance of a normal serum sodium concentration (135 to 142 mEq/L) requires that daily water losses be replaced.

Most hypernatremic patients are too sick, too young, or too old to obtain water themselves or ask for it.^{13,48} Sometimes, the thirst sensation itself is impaired, so that the patient has no desire to drink when the plasma sodium concentration increases above the normal range. Inadequate water intake by itself will lead to hypernatremia. When impaired intake is coupled with excessive water losses, severe hypernatremia results.

ETIOLOGY

Electrolyte-free water can be lost as pure water, with no accompanying electrolyte, or it can be lost in hypotonic fluids, which have lower electrolyte concentrations than plasma. Hypotonic losses can be thought of as mixtures of isotonic fluid and free water. Pure-water and hypotonic fluid losses, the most common causes of hypernatremia, are typically associated with a contracted extracellular fluid volume.¹³ However, this is not always the case. When hypernatremia is caused by a rapid intake of salt (acute salt poisoning), the extracellular volume expands because of water drawn from the intracellular space.⁴⁸ In critically ill patients, extracellular volume expansion with edema often coexists with hypernatremia^{49,51}; the finding reflects free-water losses in patients who become edematous after fluid resuscitation for shock or underlying conditions such as congestive heart failure, renal disease, and hepatic cirrhosis.

Pure-Water Losses

If pure-water losses are responsible for hypernatremia, each body-fluid compartment loses an equal percentage of its volume.^{13,48} Plasma constitutes only one twelfth of total body water (one quarter of extracellular fluid volume), and plasma volume is defended by oncotic pressure, which increases with water loss. Thus, plasma volume contracts by less than 83 ml for each 1 L of water lost; clinical signs of hypovolemia are unusual unless the water deficit is extremely large.

Insensible water losses Water is constantly lost by evaporation from the skin and lungs and must be replaced to avoid dehydration. Daily insensible water losses, normally about 0.5 L, can be increased severalfold by high environmental temperature, fever, or hypermetabolic states such as thyrotoxicosis.

Increased urea excretion Although urea is an ineffective osmole that freely crosses most cell membranes, urinary urea excretion can play an important role in water balance. High rates of urea excretion caused by protein-rich diets, catabolism, or recovery from renal failure obligate increased rates of water loss. When the urine solute is composed almost exclusively of urea, the urine becomes an electrolyte-free water solution, regardless of its osmolality.

Table 6 Causes of Hypernatremia

Electrolyte-free water losses	Extrarenal
	Insensible loss (skin and lungs)
	Renal
	Neurogenic (central) diabetes insipidus
	Nephrogenic diabetes insipidus
Hypotonic losses	Congenital
	X-linked (V_2 vasopressin receptor defect)
	Recessive (aquaporin defects)
	Acquired
	Electrolyte abnormalities: hypokalemia, hypercalcemia
Salt poisoning	Drugs: lithium, demeclocycline, methoxyflurane
	Pregnancy (vasopressinase)
	Excess urea excretion
	Extrarenal
	Sweat
Salt poisoning	Upper GI tract
	Osmotic cathartics
	Renal
	Glycosuria, mannitol, glycerol, diuretics
	Oral
Salt poisoning	Parenteral
	NaHCO ₃ , 3% or 5% I.V. saline, therapeutic abortion (inadvertent 29% I.V. saline)
	Hemodialysis with hypertonic dialysate

Diabetes insipidus Because sodium excretion is unaffected in diabetes insipidus (see below), the excess fluid lost in the urine is pure water. As long as water is available and the patient is able to drink, hypernatremia does not occur. Without water replacement, however, hypernatremia develops within a few hours.

Hypotonic Losses

Hypernatremia caused by hypotonic fluid loss is associated with extracellular volume depletion.

Sweat Sweat is a hypotonic solution containing water, sodium, potassium, and chloride. Sweat glands respond to aldosterone by lowering the sodium concentration and increasing the potassium concentration of their secretions.

Gastric fluid losses Fluid lost by vomiting or nasogastric suction is hypotonic to plasma. Without adequate water replacement, large gastric fluid losses can cause hypernatremia.

Osmotic cathartics Fecal losses of water contain electrolytes at a concentration comparable to that of plasma, except when osmotic cathartics such as sorbitol or lactulose are given. These cathartic agents osmotically attract electrolyte-free water to the intestinal lumen, leading to hypotonic fluid losses. Oral sorbitol is a nonabsorbable solute, given with sodium polystyrene sulfonate (Kayexalate) to treat hyperkalemia or with charcoal to treat poisoning; the sugar osmotically attracts electrolyte-free water into the intestinal lumen, where it is eliminated in the stool. Similarly, lactulose, which is used to treat hepatic encephalopathy, can promote large electrolyte-free water losses, causing a high incidence of hypernatremia unless the lost water is replaced.

Osmotic diuretics and glycosuria Glucose in the extracellular fluid acts as an effective osmole that attracts water to the extracellular fluid, dehydrating cells and lowering the plasma sodium

concentration.^{22,48} Excretion of glucose in the urine acts as an osmotic diuretic that can provoke the loss of several liters of hypotonic fluid. Electrolyte-free water losses induced by glycosuria raise the plasma sodium concentration, offsetting the hyponatremic effect of the high blood glucose levels. Intravenous hypertonic mannitol has a similar effect on body fluids.

Acute Salt Poisoning

Water losses increase the serum sodium concentration over hours or days. The oral ingestion of large amounts of salt without water—1 tbsp of salt contains nearly 350 mEq of NaCl, enough to increase the plasma sodium concentration by 8 mEq/L—or the intravenous infusion of hypertonic salt solutions can increase the plasma sodium concentration much more rapidly (i.e., cause acute salt poisoning).^{13,48}

DIAGNOSIS

Clinical Manifestations

An acute onset of hypernatremia (seen virtually exclusively in acute salt poisoning) causes the brain to shrink, leading to vascular injury and intracranial bleeding. Patients present with seizures, coma, hyperventilation, hyperreflexia, hypertonia, and high fever. Acutely hypernatremic patients with plasma sodium levels above 170 mEq/L often die.^{13,48}

Given time to adapt, brain cells protect their volume by accumulating organic osmolytes, preventing the hemorrhages caused by acute hypernatremia. Thus, the clinical manifestations of chronic hypernatremia are less dramatic than those seen in acute salt poisoning, ranging from lethargy to coma, depending on the severity of the electrolyte disturbance.^{13,48,50}

The clinical signs of pure-water loss and acute salt poisoning are primarily neurologic. Hypotonic fluid losses may be associated with signs and symptoms of extracellular fluid volume depletion in addition to symptoms related to hypernatremia.

Recognition of Water Deficit

The plasma or serum sodium concentration can be used to determine how much water is needed to restore normotonicity; it seriously underestimates the magnitude of the water deficit in diabetic patients with hyperglycemic dehydration [see Treatment, Diabetic Dehydration, below]. In patients without severe hyperglycemia, the percentage increase in the serum sodium concentration approximates the percentage decrease in total body water, as stated more precisely in the following:

$$\text{Water deficit} = \text{Normal body water} (1 - \text{serum } [\text{Na}^+]/140)$$

The value for body water is based on the patient's usual body weight (often an estimate), age, and sex.

The calculated water deficit is the amount of water that will return the serum sodium concentration to normal. It reveals nothing about the volume status of the extracellular fluid. Extracellular fluid volume deficits (or surfeits) must be estimated from the history and physical examination, not from the serum sodium concentration.

TREATMENT

Correction of severe extracellular volume depletion takes precedence over correction of hypernatremia. When the patient is hypotensive, initial therapy should include a rapid infusion of isotonic saline to quickly achieve hemodynamic stability. In hemodynamically stable patients, pure-water losses should be replaced with pure water, and isotonic saline is not required. Edematous patients with hy-

pernatremia can be given diuretics along with electrolyte-free water to replace urinary electrolyte-free water losses; the net effect is reduction of the extracellular volume surfeit and restoration of normotonicity and cell volume.

Electrolyte-free water can be given intravenously in a 5% dextrose solution (D5W) to patients who are unable to drink. Dextrose solutions cannot be infused more rapidly than approximately 500 ml/hr. More-rapid infusions provide more glucose than can be metabolized and therefore cause hyperglycemia, glycosuria, and urinary water losses, which are counterproductive to the correction of hypertonicity. Water replacement should not be based on formulas alone; the serum sodium concentration and urine output should be monitored frequently so that the fluid prescription can be adjusted appropriately.

Rate of Correction

In the vast majority of cases, the onset of hypertonicity is slow enough for brain adaptations to minimize cerebral dehydration. Organic osmolytes that accumulate in the adaptation to hypernatremia are slow to leave the cell during rehydration. If hypernatremia is corrected too rapidly, cerebral edema results.^{13,48} To be safe, the serum sodium concentration should be reduced by no more than 10 to 12 mEq/L/day. To achieve the desired rate of correction, electrolyte-free water intake should exceed free-water losses by no more than 2 L daily.

Acute salt poisoning causes devastating brain injury that is largely irreversible. In rare cases when acute salt poisoning can be rapidly diagnosed (e.g., in a case of inadvertent intravenous infusion of hypertonic saline during therapeutic abortion), an effort to prevent a neurologic catastrophe can be made with rapid infusions of electrolyte-free water along with a loop diuretic before the results of the serum electrolyte measurements are known.

Diabetic Dehydration

Hypertonicity associated with diabetes mellitus is a complex disorder.²² The osmotic diuresis induced by glycosuria results in both saltwater and electrolyte-free water losses; the accumulation of glucose in the extracellular fluid adds impermeant solute, which contributes to hypertonicity and neurologic symptoms. Severely dehydrated hyperglycemic patients may not appear hypovolemic at first, because the high glucose concentration in the extracellular fluid osmotically attracts water from cells, masking the loss of saltwater. With correction of hyperglycemia, marked hypovolemia may emerge. Initial treatment should include 1 to 2 L of isotonic saline in anticipation of this complication, even in patients who are initially normotensive. With volume expansion, excess glucose will be excreted in the urine, creating an ongoing requirement for both saline and electrolyte-free water. An infusion of 0.45% saline at a rate that exceeds urine output by approximately 250 ml/hr will serve to replace the electrolyte-free water deficit and remaining saltwater deficits. The serum sodium concentration, blood glucose level, and urine output should be monitored carefully so that fluid replacement can be tailored to the patient's needs. Rapid correction of hypertonicity should be avoided because of the risk of cerebral edema.

Patients with oliguric renal failure do not become dehydrated when they become severely hyperglycemic. Such patients often experience hypertension or congestive heart failure because of fluid shifts from cells to the extracellular fluid. Even after adjusting for the effect of hyperglycemia, the serum sodium concentration is often low. Insulin is the only required treatment; neither isotonic saline nor 0.45% saline is indicated.

Disorder of Water Conservation: Diabetes Insipidus

PATHOGENESIS

Neurogenic diabetes insipidus (DI) is caused by deficient secretion of vasopressin^{8,52,53}; nephrogenic DI results from the kidney's unresponsiveness to normally secreted hormone.⁵⁴ Both disorders present with polyuria (loosely defined as the passage of excessive volumes of urine—generally more than 3 to 4 L daily) and polydipsia (excessive thirst). Most patients with polyuria do not become hyponatremic, because thirst maintains electrolyte-free water balance.

Defective responsiveness to vasopressin (nephrogenic DI) may be inherited as an X-linked trait, caused by a mutation in the gene encoding for the V₂ vasopressin receptor or as an autosomal recessive trait caused by a mutation in the gene encoding for the vasopressin-responsive water channel (aquaporin 2). Acquired nephrogenic DI may be caused by lithium or demeclocycline therapy, hypokalemia, or hypercalcemia; or it may complicate a number of renal diseases [see Table 6]. Vasopressin-resistant DI may emerge during the late stage of pregnancy as a result of vasopressinase released by the placenta; many affected patients have underlying, sub-clinical partial neurogenic or nephrogenic DI that has been exacerbated by increased catabolism of circulating vasopressin.

DIAGNOSIS

Clinical Manifestations

Patients with DI complain of polyuria, nocturia (the need to urinate during the night), and polydipsia. The only significant physical findings or laboratory abnormalities are those of the underlying cause.

Laboratory Tests

A diagnosis of DI can be made if the urine osmolality is less than 250 mOsm/kg despite hyponatremia.⁸ When the disease is suspected in a polyuric patient whose serum sodium concentration is normal or borderline, the urine osmolality level can be monitored while the patient is deprived of water, allowing the serum sodium level to increase to higher than 143 mEq/L. Exogenous vasopressin increases urine osmolality by more than 150 mOsm/kg in patients with neurogenic, but not nephrogenic, DI. It is possible to misdiagnose DI in patients who actually have a primary thirst disorder. Excessive water intake suppresses vasopressin secretion and causes polyuria with dilute urine. Because patients with primary polydipsia secrete vasopressin normally, they do not become hyponatremic during diagnostic water deprivation. Correlation with plasma vasopressin levels is often necessary in borderline cases. Polyuric patients whose urine osmolality equals or exceeds plasma osmolality should be distinguished from patients with DI; polyuria in such cases is usually caused by excessive excretion of salt, urea, or glucose or by an osmotic diuretic (solute diuresis).

Magnetic resonance imaging of the brain can be helpful in the evaluation of patients with suspected DI.^{8,55} In 85% to 90% of healthy adults and children, the posterior pituitary emits a hyperintense signal, or so-called bright spot, on T₁-weighted magnetic resonance images, apparently related to the vasopressin release of the gland. This bright spot is also normal in 85% to 90% of patients with primary polydipsia, but it is almost always absent or greatly diminished in patients with pituitary DI.

TREATMENT

When access to water is limited, patients with DI are more susceptible to dehydration than normal persons. Thus, water losses must be carefully replaced during superimposed illnesses. Neuro-

genic DI is best treated with a synthetic antidiuretic hormone, 1-desamino-8-D-arginine vasopressin (DDAVP), which can be given parenterally or intranasally.^{8,53} Chlorpropamide or carbamazepine, both of which enhance vasopressin action, or thiazide diuretics, which limit the ability to maximally dilute the urine, can be used in patients with mild disease. Limiting dietary salt and protein intake is also helpful. Nephrogenic diabetes can also be treated with dietary measures or with thiazides and indomethacin (which helps concentrate the urine by inhibiting prostaglandin synthesis). Lithium-induced nephrogenic DI may be improved by amiloride, which blocks lithium entry into the collecting duct cell.

Disorder of Saltwater Excess: Edematous States

Edema, a swelling of the soft tissues that can be indented or pitted by the examiner's fingers, is the clinical manifestation of an expanded interstitial fluid volume. To be detected clinically, interstitial volume must increase by at least 2.5 to 3 L, nearly equaling the total amount of fluid in the intravascular space. Thus, generalized edema requires an increase in the total amount of saltwater in the extracellular space, and it implies retention of dietary or infused sodium, with an impaired ability to excrete saltwater.

PATHOGENESIS

Excess fluid collects in the interstitial space in response to Starling forces, which govern the movement of extracellular fluid into and out of the vasculature. Edema occurs when there is increased capillary blood pressure, decreased plasma oncotic pressure, increased capillary permeability to protein, or obstruction to lymph flow.

When fluid overflows from an overfilled vascular space into the interstitium, impaired sodium excretion is clearly implicated. However, even when edema formation results from decreased oncotic pressure or increased capillary permeability, renal sodium retention is required to replace the saltwater that has been lost from the vasculature.

ETIOLOGY

Primary Renal Sodium Retention: Edema Caused by Renal Disease

Nephrotic syndrome The nephrotic syndrome is characterized by heavy urinary protein losses (in excess of 3 g/day), hypoalbuminemia, and edema.⁵⁵ The syndrome, which can be seen in a variety of glomerular diseases, is caused by increased permeability of the glomerular capillary to protein. Traditionally, edema in the nephrotic syndrome has been ascribed to decreased plasma oncotic pressure. This no longer appears to be the sole explanation. Correction of hypoalbuminemia by infusing albumin does not consistently improve the edema, and resolution of edema in steroid-responsive cases may precede improvement of hypoalbuminemia. Thus, in most patients, primary sodium retention by the kidney, independent of an underfilled vasculature, plays a major contributing role.

Nephritic edema Glomerular diseases characterized by proliferation of mesangial cells (e.g., diffuse proliferative glomerulonephritis and membranoproliferative glomerulonephritis) often cause primary sodium retention that is not associated with heavy proteinuria or hypoalbuminemia (the nephritic syndrome). Patients with nephritic edema are typically hypertensive and may present with congestive heart failure because of an overexpanded vascular volume.

Secondary Renal Sodium Retention: Edema Caused by Extrarenal Disease

In congestive heart failure and hepatic cirrhosis, the body responds as if it were volume depleted. Despite an expanded interstitial fluid volume, as well as increased total body sodium content, the kidney avidly retains salt and water. The normal renal response to a high salt intake is lost, and progressive salt retention occurs. In these conditions, volume regulatory mechanisms are responding to reduced fullness of the arterial portion of the vascular system, which normally contains about 15% of the total blood volume.

Congestive heart failure Advanced stages of the many disorders that affect the pericardium, myocardium, or heart valves can produce congestive heart failure, a disorder characterized by renal sodium retention and interstitial edema in systemic or pulmonary capillary beds.^{16,17} Arterial receptors are activated when cardiac output falls (low-output congestive failure) or when cardiac output is not high enough to compensate for decreased peripheral resistance (high-output failure).

Cirrhosis Patients with severe liver disease may exhibit profound salt retention, often excreting less than 10 mEq of sodium in the urine each day. Scarring of the hepatic parenchyma increases resistance to blood flow in the postsinusoidal venules, resulting in high sinusoidal pressures and venous hypertension throughout the portal system. Portal hypertension and hypoalbuminemia promote the formation of ascites. In addition, the cirrhotic patient is vasodilated because of endotoxins, vasodilatory prostaglandins, nitric oxide, various gut hormones, and other mediators. The combined effects of blood pooling in the splanchnic circulation (caused by portal hypertension) and systemic vasodilatation lead to underfilling of the arterial circulation and subsequent activation of sodium-retaining factors.⁵⁶

Idiopathic edema Idiopathic edema is a benign disorder of young, menstruating women who have no cardiac, hepatic, or renal disease.⁵⁷ Fluid retention often begins premenstrually and then becomes persistent. Depression and neurotic symptoms are commonly present, and affected patients are often weight conscious and markedly concerned about even minor degrees of edema. Some patients episodically fast for days at a time and then accumulate edema on refeeding. In many others, diuretics play an important role in the pathogenesis of idiopathic edema. Long-term diuretic or cathartic use leads to persistent hypovolemia and chronic activation of sodium-retaining mechanisms, which include hypertrophy of the nephron segments distal to the site of action of the diuretic. When the diuretic is stopped, marked sodium retention occurs because the sodium-retaining forces cannot be shut off rapidly. The patient thus becomes convinced of the need for diuretics, and the cycle continues.

DIAGNOSIS

The symptoms and laboratory findings associated with edematous conditions depend on the underlying cause. Dyspnea on exertion and orthopnea provoked by pulmonary interstitial edema are prominent features in patients with left ventricular failure or nephritic edema, but these symptoms are usually absent when edema is caused by right heart failure, nephrotic syndrome, or cirrhosis. Mild peripheral edema collects in the dependent portions of the anatomy and is usually asymptomatic. Although more severe edema, which can extend to the thighs and buttocks, may be uncomfortable, it is usually harmless. A large volume of ascites not only causes discomfort but also may elevate the diaphragm, causing shortness of breath; promote reflux of gastric fluid, causing bleeding from esophageal varices; or become infected spontaneously.

The diagnosis of edema should be approached systematically, looking for evidence of heart, renal, or liver disease. A diagnosis can usually be made from the history and physical examination, urinalysis, liver function tests, and chest x-ray. More puzzling cases may require echocardiography or, rarely, right heart catheterization. Plasma levels of B-type natriuretic peptide (BNP) are increased in patients with heart failure. Used in conjunction with other clinical information, rapid-measurement BNP is useful in establishing or excluding the diagnosis of congestive heart failure in patients who present with acute dyspnea.⁵⁸

TREATMENT

Dietary salt restriction is important for patients with edema, but this measure alone is impractical or insufficient when urinary sodium excretion is reduced to very low levels. Thus, most edematous patients whose underlying condition cannot be reversed require treatment with diuretics.^{5,59} Salt restriction and diuretics are adjunctive treatments for heart failure. Therapy is also directed at improving cardiac performance by using digoxin and vasodilators to reduce afterload. Recombinant human BNP (nesiritide) has become available for the treatment of acute decompensated heart failure. The agent reduces pulmonary capillary wedge pressure and systemic vascular resistance, improves cardiac performance, and has a diuretic effect, in part because of its effect on sodium reabsorption in the distal nephron.⁶⁰

Ascitic fluid is a separate compartment of the extracellular fluid compartment that is much more difficult to mobilize than peripheral edema. Thus, cirrhotic patients who have ascites but no peripheral edema are susceptible to intravascular volume depletion when they are treated with diuretics; weight loss should thus be limited to 0.5 kg daily. Repeated large-volume paracenteses combined with intravenous albumin is a safe and effective alternative to diuretics that avoids intravascular volume depletion.⁶¹ The subsequent administration of diuretics prevents reaccumulation of ascitic fluid.

Use of Diuretics

Diuretics increase saltwater excretion by impairing tubular reabsorption of the sodium filtered by the glomerulus. The diuretic effect is dose-dependent; the maximum response is determined by the diuretic's site of action within the nephron, the filtered load of sodium, and the amount of sodium reabsorbed by nephron segments unaffected by the diuretic.

Mechanism of action All diuretics except spironolactone are specific inhibitors of luminal transporters and must gain access to the tubular fluid to block sodium reabsorption.^{5,59} Because diuretic agents are highly protein bound, they are not readily filtered at the glomerulus; instead, they are actively transported into the urine by the organic acid (e.g., acetazolamide, thiazide, and loop diuretic) or organic base (e.g., amiloride and triamterene) secretory pumps in the proximal tubule. A dose-response curve links the amount of drug reaching the urine to the amount of sodium excretion that is elicited [see Figure 4]. Spironolactone binds to the cytosolic receptor for aldosterone, and its diuretic action, unlike that of other diuretics, does not depend on secretion into the tubular lumen.

The most potent agents are those that block sodium transport in the loop of Henle. At high doses, loop diuretics almost totally block sodium reabsorption in this nephron segment, causing about 20% of the filtered load of sodium to be excreted in the urine; at low glomerular filtration rates, the same percentage of filtered sodium is excreted, but the total amount is reduced. Conditions such as volume depletion, heart failure, and cirrhosis, which cause avid sodium reabsorption in the proximal and distal tubules, blunt the maximum response to the diuretic.

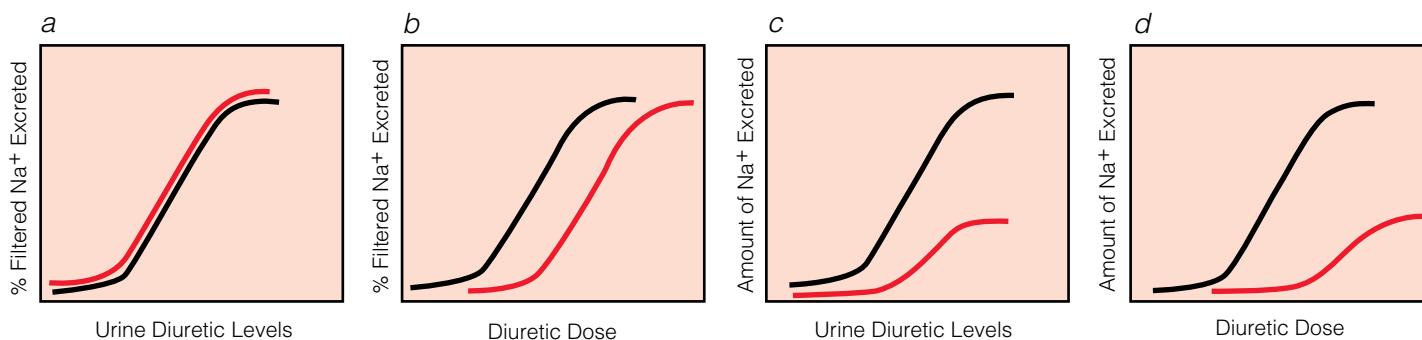

Figure 4 Dose-response curves for a loop diuretic in patients with normal (black line) and reduced (red line) renal function. Urinary sodium excretion responds to diuretic levels in the tubular lumen (as reflected by urinary drug levels). The diuretic effect reaches a maximum at approximately 20% of the filtered load of sodium regardless of renal function (a). Secretion of the diuretic into the tubular lumen is reduced in renal failure; thus, higher doses are required in azotemic patients to achieve the same urinary drug levels found in patients with normal renal function (b). Because the filtered load of sodium is reduced in patients with renal failure, absolute sodium excretion is also reduced, even at high doses (c and d).

Because gastrointestinal absorption of diuretics is often delayed in edematous conditions (presumably because of bowel edema), higher oral doses must be used to achieve adequate blood levels. In renal disease and cirrhosis, organic anions such as hippurate and bile acids compete with the diuretic for secretion into the proximal tubule; thus, higher plasma levels may be required to achieve adequate drug levels in the urine. Similarly, severe hypoalbuminemia can diminish drug secretion into the tubular lumen, because albumin binding of most diuretics maximizes the rate of diuretic delivery to the organic anion secretory pump in the proximal tubule. Reduced renal blood flow also limits delivery of drug to the tubular lumen. Some patients with advanced cirrhosis who are resistant to furosemide respond to spironolactone, a generally weak diuretic whose effectiveness does not depend on tubular secretion.

Agents that act in the proximal tubule, loop of Henle, or distal tubule cause potassium wasting and hypokalemia because they increase delivery of tubular fluid to the cortical collecting tubule, where potassium secretion is flow dependent. Potassium-sparing diuretics, which act in the cortical collecting tubule, cause hyperkalemia because sodium reabsorption at this site favors potassium secretion. The carbonic anhydrase inhibitor, acetazolamide, causes metabolic acidosis, as do the potassium-sparing diuretics. Thiazides and loop diuretics cause metabolic alkalosis because of increased distal delivery of sodium to sites where sodium reabsorption stimulates hydrogen ion secretion.

Clinical use Diuretic doses should be adjusted to achieve explicit therapeutic goals. Outpatient therapy is usually designed to produce a gradual loss of fluid, increasing the dose until a desired target weight is reached. The patient should be instructed to keep a daily log that records weight and diuretic dose. Patients are instructed to stop the diuretic if their weight falls too low, resuming at a lower dose when enough saltwater has been retained to restore the target weight.

Inpatient diuretic management should also employ the target-weight concept, but dose adjustments can be made more often and more aggressively, particularly at the start of therapy. It is important to rapidly define the dose that can deliver enough drug to the tubular lumen to reach the steep portion of the dose-response curve. Once an effective dose is defined, larger doses of diuretic provide little benefit. If a greater response is needed, the effective dose should be repeated several times during the day, or alternatively, a continuous infusion can be given to maintain effective urinary drug levels. Continuous infusion of loop diuretics induces a slightly larger natri-

uretic response than does bolus administration and is associated with a shorter hospital stay in patients with advanced heart failure.⁶²

Diuretic resistance Resistance to high doses of loop diuretics may be overcome by administering loop diuretics in combination with thiazide or metolazone. Acetazolamide may be used along with or in place of a thiazide or metolazone. This strategy blocks sodium reabsorption at several sites along the nephron, avoiding resistance caused by increased sodium reabsorption proximal or distal to the loop of Henle. Careful monitoring is extremely important, because these combinations can be extremely potent, causing large potassium and sodium losses.

Diuretic complications All diuretic agents may cause volume depletion and azotemia, but these complications are most likely to occur with loop diuretics.⁴ Hypokalemic alkalosis, hyperglycemia, and hyperuricemia (sometimes with clinical gout) are common dose-dependent complications of both thiazides and loop diuretics. Thiazides decrease calcium excretion and may cause hypercalcemia in patients with underlying conditions that increase gastrointestinal calcium absorption (e.g., sarcoidosis) or bone reabsorption (e.g., hyperparathyroidism). Thiazides are also much more likely to cause hyponatremia than other agents and should be avoided in patients who habitually drink large amounts of fluid. Potassium-sparing agents (e.g., triamterene, amiloride, and spironolactone) may cause hyperkalemia; these agents should generally not be given with potassium supplements, and they should be used with caution in patients with renal insufficiency (particularly diabetic nephropathy) and patients receiving ACE inhibitors or angiotensin II blocking agents. Loop diuretics can predispose to hearing loss, particularly when high doses are administered by bolus injection to patients receiving other ototoxic drugs.³² Hearing loss from ethacrynic acid is more likely to be permanent.

Disorder of Saltwater Deficiency: Volume Depletion

PATHOGENESIS OF VOLUME DEPLETION

Volume depletion occurs when saltwater is lost from the extracellular fluid at a rate that exceeds intake. Saltwater can be lost from the gastrointestinal tract, kidney, or skin, or it can result from extravascular sequestration (third-space losses) in the abdominal cavity or in traumatized tissues.

Underfilling of the arterial circulation triggers a cascade of physiologic responses that preserve blood flow to vital organs. Volume receptors and baroreceptors activate the sympathetic nervous system and the renin-angiotensin-aldosterone system. Except when renal salt wasting is the cause, these responses reduce urinary sodium excretion so that nearly all ingested salt is retained. Volume-depleted persons also become thirsty; ingested water is retained because vasopressin, released in response to volume depletion, concentrates the urine, decreasing water excretion. The plasma sodium concentration can be high, normal, or low in volume-depleted persons, depending on electrolyte-free water intake and excretion. Vasoconstriction maintains the systemic blood pressure and also reduces renal blood flow. Initially, efferent arteriolar resistance, mediated by angiotensin II, predominates, sustaining intraglomerular pressure and the glomerular filtration rate; in more severe hypovolemia, renal blood flow is further reduced and glomerular filtration falls.

ETIOLOGY

Because renal sodium conservation can reduce urinary sodium losses to less than 10 mmol/day, volume depletion is unlikely to occur from decreased intake alone. The small bowel and colon are the most common sources of isotonic fluid loss. Spectacular amounts of isotonic saltwater can be lost in diarrhea. For example, rice-water stool losses in cholera can reach 20 L/day, causing death within a few hours without fluid replacement. Small bowel obstruction causes pooling of several liters of saltwater within the bowel lumen. Fluid may also be sequestered in the abdominal cavity in patients with pancreatitis or peritonitis. Sequestration of fluid in the soft tissues may also complicate crush injuries with rhabdomyolysis or burns.

Renal salt wasting can cause volume depletion, but only a few disorders can cause enough renal salt loss to be clinically apparent. Diuretics and osmotic diuresis caused by glycosuria are the most frequent causes of renal salt wasting. Transient renal salt wasting may occur in the recovery phases of acute tubular necrosis or obstructive uropathy, and it can also occur in toxic nephropathies. Renal salt wasting also occurs in adrenal insufficiency.

DIAGNOSIS

Clinical Manifestations

Minor degrees of volume depletion (less than 10% of plasma volume, equivalent to the loss of one unit of blood) cause an increase in heart rate and may also be associated with complaints of fatigue, thirst, or muscle cramps. With modest hypovolemia, arteriolar vasoconstriction is sufficient to maintain the blood pressure when the patient is recumbent. However, dizziness and hypotension emerge on standing or during physical exertion. Severe fluid losses cause hypotension in recumbency and, ultimately, signs of tissue ischemia and shock (e.g., cool, clammy extremities, decreased urine output, lethargy, and confusion). Irreversible tissue injury may occur if this

condition is allowed to continue.

Loss of weight within a short period is the most reliable sign of volume depletion. Physical findings include a low jugular venous pulse rate and orthostatic changes in blood pressure and heart rate.^{63,64} However, because postural hypotension can occur in up to 30% of normovolemic persons older than 65 years, these changes must be interpreted with caution. Decreased skin turgor and dry mucous membranes are generally unreliable findings in volume-depleted adults; these signs can be absent in severe hypovolemia, and they can be present (particularly in mouth breathers and the elderly) when the patient is actually volume overloaded. The presence of edema makes true volume depletion unlikely.

Laboratory Tests

Laboratory findings are related to the decreased volume of intravascular saltwater and to decreased renal perfusion. Hematocrit increases in proportion to the contraction of plasma volume, and the serum albumin may be increased as well. Urinary sodium is usually less than 20 mEq/L except in metabolic alkalosis (in which the urine chloride is low) or when renal sodium wasting is the cause of the condition.^{41,65} Renal blood flow is reduced, but unless the patient is frankly hypotensive, the glomerular filtration rate is maintained by vasoconstriction of the efferent glomerular arteriole. Thus, except in severe volume depletion, the serum creatinine changes very little. Unlike creatinine, urea is reabsorbed from the glomerular filtrate. Thus, in volume depletion (prerenal azotemia), the BUN is increased disproportionately to the increase in creatinine.⁶⁵ Azotemia may be blunted in patients with a poor dietary-protein intake and may be exacerbated in patients who are catabolic, bleeding, or receiving steroid therapy.

TREATMENT

Patients with mild volume depletion can be treated by increasing their dietary intake of salt, relying on normal thirst mechanisms to provide the appropriate amount of water. For most patients, the familiar (but misguided) order to drink fluids should be replaced with an order to salt one's food. Even severe volume depletion can be treated with oral solutions containing electrolytes, sugar, and amino acids.⁶⁶ Glucose and amino acids promote intestinal absorption of sodium through cotransport mechanisms similar to those found in the proximal tubule of the kidney. Rice-based oral replacement solutions have been a major advance in the treatment of diarrhea in developing countries.

Intravenous fluids are necessary when fluids cannot be taken orally. If the patient is hypotensive, isotonic saline should be given as rapidly as possible until tissue perfusion is adequate. Colloid-containing solutions have no proven advantage over crystalloids.⁶⁷ There is no accurate way to estimate the total fluid deficit in hypovolemia other than continued clinical observation of the patient's response to therapy.

8 ACID-BASE DISORDERS

John A. Kellum, M.D., and Juan Carlos Puyana, M.D., F.A.C.S.

Anticipation and early identification of conditions that alter the body's ability to compensate for acid-base disorders are vital in the management of surgical and critically ill patients. A clear understanding of metabolic-respiratory interactions and a systematic approach aimed at identifying the separate components of acid-base disorders not only serves as a diagnostic tool but also helps in formulating therapeutic interventions. For example, abnormal acid-base balance may be harmful in part because of the patient's response to the abnormality, as when a spontaneously breathing patient with metabolic acidosis attempts to compensate by increasing minute ventilation. Such a response may lead to respiratory muscle fatigue with respiratory failure or diversion of blood flow from vital organs to the respiratory muscles, eventually resulting in organ injury. The increased catecholamine levels associated with acidemia may provoke cardiac dysrhythmias in critically ill patients or increase myocardial oxygen demand in patients with myocardial ischemia. In such cases, it may be prudent not only to treat the underlying disorder but also to provide symptomatic treatment for the acid-base disorder itself. Accordingly, it is important to understand both the causes of acid-base disorders and the limitations of various treatment strategies.

To treat acid-base disorders, it is not sufficient simply to return one or two laboratory parameters to normal values; one must understand the overall course of the disorder, as well as the specific forces involved at any particular time. For example, in a patient with acute lung injury and moderate hypercapnia, allowing mild acidemia may be preferable to forcing the lung to achieve a normal carbon dioxide tension (PCO_2). Similarly, prescribing bicarbonate therapy without anticipating the effects on the body's own compensatory efforts may induce an unwanted rebound alkalemia. A comprehensive understanding of the pathophysiology and a practical approach to bedside evaluation are complementary components of care and are equally necessary in the management of an acid-base disorder.

General Principles

DESCRIPTION AND CLASSIFICATION OF ACID-BASE DISORDERS

There are three widely accepted methods of describing and classifying acid-base abnormalities. Essentially, they differ from one another only with respect to assessment of the metabolic component of the abnormality; all three treat PCO_2 as an independent variable. The first method quantifies the metabolic component by using the bicarbonate ion (HCO_3^-) concentration (in the context of PCO_2); the second, by using the standard base excess (SBE); and the third, by using the strong ion difference (SID). In practice, these three methods yield virtually identical results when employed to quantify the acid-base status of a given blood sample.¹⁻⁴ Thus, the only significant distinctions between the methods are conceptual ones, related to how each one approaches the understanding of the mechanism of the disorder.⁵⁻⁷ In this chapter, we emphasize the physicochemical determinants of pH in the blood and the tissues; however, it is a simple matter to convert from one approach to the other if desired.

There are three mathematically independent determinants of blood pH: (1) the SID, defined as the difference in concentration between strong cations (e.g., sodium [Na^+] and potassium [K^+]) and strong anions (e.g., chloride [Cl^-] and lactate); (2) the total concentration of weak acids (A_{tot}), mainly consisting of albumin and phosphate; and (3) PCO_2 . These three variables, and only these three, can independently affect plasma pH. The H^+ and HCO_3^- concentrations are dependent variables whose values in plasma are determined by the SID, A_{tot} , and PCO_2 . Changes in the plasma H^+ concentration occur as a result of changes in the dissociation of water and A_{tot} brought about by the electrochemical forces generated by changes in the SID and PCO_2 . The SBE is mathematically equivalent to the difference between the current SID and the SID required to restore the pH to 7.4, given a PCO_2 of 40 mm Hg and the prevailing A_{tot} . Thus, an SBE of -10 mEq/L means that the SID is 10 mEq less than the value required to achieve a pH of 7.4.

The essential element of this physicochemical approach is the emphasis on independent and dependent variables. Only changes in the independent variables can bring about changes in the dependent variables. That is, movement of H^+ or HCO_3^- cannot affect plasma H^+ or HCO_3^- concentrations unless changes in the SID, A_{tot} , or PCO_2 also occur. Several reviews of this approach are available in the literature.³⁻⁹ In what follows, we discuss the clinical application of this approach to the diagnosis and treatment of individual acid-base disorders.

ASSESSMENT OF ACID-BASE BALANCE

Acid-base homeostasis is defined by the plasma pH and by the conditions of the acid-base pairs that determine it. Normally, arterial plasma pH is maintained between 7.35 and 7.45. Because blood plasma is an aqueous solution containing both volatile acids (e.g., CO_2) and fixed acids, its pH is determined by the net effects of all these components on the dissociation of water. The determinants of blood pH can be grouped into two broad categories, respiratory and metabolic. Respiratory acid-base disorders are disorders of PCO_2 ; metabolic acid-base disorders comprise all other conditions affecting pH, including disorders of both weak acids (often referred to as buffers, though the term is imprecise) and strong acids (organic and inorganic) and bases. Any of the following indicators serves to identify an acid-base disorder:

1. An abnormal arterial blood pH ($\text{pH} < 7.35$ signifies acidemia; $\text{pH} > 7.45$ signifies alkalemia).
2. An arterial PCO_2 ($P_a\text{CO}_2$) that is outside the normal range (35 to 45 mm Hg).
3. A plasma HCO_3^- concentration that is outside the normal range (22 to 26 mEq/L).
4. An arterial SBE that is either abnormally high (≥ 3 mEq/L) or abnormally low (≤ -3 mEq/L).

Once identified, an acid-base disorder can be classified according to a simple set of rules [see Table 1]. A disorder that does not fit well into the broad categories established by these rules can be considered a mixed (or complex) disorder. Some of the basic categories can be further divided into various subcategories (see

Table 1 Differentiation of Acid-Base Disorders⁶

Disorder	Physicochemical Parameter		
	HCO ₃ ⁻ Concentration (mEq/L)	Pco ₂ (mm Hg)	SBE (mEq/L)
Metabolic acidosis	< 22	= (1.5 × HCO ₃ ⁻) + 8 = 40 + SBE	< -5
Metabolic alkalosis	> 26	= (0.7 × HCO ₃ ⁻) + 21 = 40 + (0.6 × SBE)	> +5
Acute respiratory acidosis	= [(Pco ₂ - 40)/10] + 24	> 45	= 0
Chronic respiratory acidosis	= [(Pco ₂ - 40)/3] + 24	> 45	= 0.4 × (Pco ₂ - 40)
Acute respiratory alkalosis	= 24 - [(40 - Pco ₂)/5]	< 35	= 0
Chronic respiratory alkalosis	= 24 - [(40 - Pco ₂)/2]	< 35	= 0.4 × (Pco ₂ - 40)

SBE—standard base excess

below), but before the issue of classification is addressed in detail, three general caveats must be considered.

First, interpretation of arterial blood gas values and blood chemistries depends on the reliability of the data. Advances in clinical chemistry have improved the sensitivity of instruments used to measure electrolyte concentrations (e.g. ion-specific electrodes) and have greatly enhanced the speed and ease of analysis. Inevitably, however, prolonged exposure to the atmosphere results in a lowering of the Pco₂, and over time, there may be ongoing cellular metabolism. Accordingly, prompt measurement is always advisable. Even with prompt measurement, laboratory errors may occur, and information may be incorrectly reported. Samples drawn from indwelling lines may be diluted by fluid or drug infusions (a notorious source of error). When the situation is confusing, it is usually best to repeat the measurement.

Second, interpretation of arterial blood gas values may be problematic in patients with severe hypothermia (e.g., trauma patients undergoing damage-control interventions, who often are severely hypothermic and sometimes experience severe acidosis), in that the findings may not reflect the actual blood gas values present. Because blood samples are “normalized” to a temperature of 37° C before undergoing analysis, the results obtained in samples from a patient whose body temperature is significantly lower than 37° C may not be sufficiently accurate. To obviate this potential problem, the results may have to be adjusted to take the patient’s actual temperature into account. At present, however, such temperature correction is not routinely done, and there has been some controversy regarding whether it has real clinical value.^{10,11}

Third, whereas the aforementioned four indicators are useful for identifying an acid-base disorder, the absence of all four does not suffice to exclude a mixed acid-base disorder (i.e., alkalosis plus acidosis) in which the two components are completely matched. Fortunately, such conditions are rare. In addition, apart from distinguishing a respiratory acid-base disorder from a metabolic acid-base disorder, the four indicators and the rules previously mentioned [see Table 1] provide no information on the mechanism of an acid-base disorder.

Metabolic Acid-Base Disorders

Metabolic acid-base derangements are produced by a significantly greater number of underlying disorders than respiratory disorders are, and they are almost always more difficult to treat. Traditionally, metabolic acidoses and alkaloses are categorized

according to the ions that are responsible (e.g., lactic acidosis and chloride-responsive alkalosis).

It is important to recognize that metabolic acidosis is caused by a decrease in the SID, which produces an electrochemical force that acts to increase the free H⁺ concentration. A decrease in the SID may be brought about by the generation of organic anions (e.g., lactate and ketones), by the loss of cations (as with diarrhea), by the mishandling of ions (as with renal tubular acidosis), or by the addition of exogenous anions (as with iatrogenic acidosis or poisoning). By contrast, metabolic alkalosis is caused by an inappropriately large SID (though it may be possible for the SID to be inappropriately large without exceeding the normal range of 40 to 42 mEq/L). An increase in the SID may be brought about by the loss of more strong anions than strong cations (as with vomiting or diuretic therapy) or, in rare instances, by the administration of more strong cations than strong anions (as with transfusion of large volumes of banked blood containing sodium citrate).

Because metabolic acid-base disorders are caused by changes in the SID, their treatment necessarily involves normalization of the SID. Metabolic acidoses are corrected by increasing the plasma Na⁺ concentration more than the plasma Cl⁻ concentration (e.g., by administering NaHCO₃), and metabolic alkaloses are corrected by replacing lost Cl⁻ (e.g., by giving sodium chloride [NaCl], potassium chloride [KCl], or even hydrochloric acid [HCl]). So-called chloride-resistant metabolic alkaloses [see Metabolic Alkalosis, Chloride-Resistant Alkalosis, below] are resistant to chloride administration only because of ongoing renal Cl⁻ loss that increases in response to increased Cl⁻ replacement (as with hyperaldosteronism).

PATHOPHYSIOLOGY

Disorders of metabolic acid-base balance occur in one of three ways: (1) as a result of dysfunction of the primary regulating organs, (2) as a result of exogenous administration of drugs or fluids that alter the body’s ability to maintain normal acid-base balance, or (3) as a result of abnormal metabolism that overwhelms the normal defense mechanisms. The organ systems responsible for regulating the SID in both health and disease are the renal system and, to a lesser extent, the gastrointestinal tract.

Renal System

Plasma flows to the kidneys at a rate of approximately 600 ml/min. The glomeruli filter the plasma, producing filtrate at a rate of 120 ml/min. The filtrate, in turn, is processed by reabsorp-

tion and secretion mechanisms in the tubular cells along which it passes on its way to the ureters. Normally, more than 99% of the filtrate is reabsorbed and returned to the plasma. Thus, the kidney can excrete only a very small amount of strong ion into the urine each minute, which means that several minutes to hours are required to make a significant impact on the SID.

The handling of strong ions by the kidney is extremely important because every chloride ion that is filtered but not reabsorbed reduces the SID. Most of the human diet contains similar ratios of strong cations to strong anions, and thus, there is usually sufficient Cl^- available for renal Cl^- handling to be the primary regulating mechanism. Given that renal Na^+ and K^+ handling is influenced by other priorities (e.g., intravascular volume and plasma K^+ homeostasis), it is logical that so-called acid handling by the kidney is generally mediated through management of the Cl^- balance.

Traditional approaches to the question of renal acid handling have focused on H^+ excretion, emphasizing the importance of ammonia (NH_3) and its add-on cation, ammonium (NH_4^+). However, H^+ excretion per se is irrelevant, in that water provides an essentially infinite source of free H^+ . Indeed, the kidney does not excrete H^+ to any greater degree in the form of NH_4^+ than in the form of H_2O . The purpose of renal ammoniogenesis is to allow the excretion of Cl^- without Na^+ or K^+ . This purpose is achieved by supplying a weak cation (NH_4^+) that is "coexcreted" with Cl^- . The mechanisms of renal tubular acidosis are currently being reinterpreted by some authors in the light of a growing body of evidence showing that abnormal chloride conductance, rather than H^+ or HCO_3^- handling per se, is responsible for these disorders.³

Kidney-Liver Interaction

The importance of NH_4^+ to systemic acid-base balance, then, rests not on its carriage of H^+ or its direct action in the plasma (normal plasma NH_4^+ concentration < 0.01 mEq/L) but on its coexcretion with Cl^- . Of course, production of NH_4^+ is not restricted to the kidney. Hepatic ammoniogenesis (as well as glutaminogenesis) is also important for systemic acid-base balance, and as expected, it is tightly controlled by mechanisms sensitive to plasma pH.¹² Indeed, this reinterpretation of the role of NH_4^+ in acid-base balance is supported by the evidence that hepatic glutaminogenesis is stimulated by acidosis.¹³ Metabolism of nitrogen by the liver can yield urea, glutamine, or NH_4^+ . Normally, the liver releases only a very small amount of NH_4^+ , incorporating most of its nitrogen into either urea or glutamine. Hepatocytes have enzymes to enable them to produce either of these end products, and both allow regulation of plasma NH_4^+ at suitably low levels. At the level of the kidneys, however, the production of urea or glutamine has significantly different effects, in that the kidneys use glutamine to generate NH_4^+ and facilitate the excretion of Cl^- . Thus, production of glutamine by the liver can be seen as having an alkalinizing effect on plasma pH because of the way in which the kidneys use this substance.

Further support for this scenario comes from the discovery that hepatocytes are anatomically organized according to their enzymatic content.¹⁴ Hepatocytes with a propensity to produce urea are positioned closer to the portal venule; those with a propensity to produce glutamine are positioned farther downstream. The upstream (urea-producing) hepatocytes have the first chance at the NH_4^+ delivered. However, acidosis inhibits ureagenesis, thereby leaving more NH_4^+ available for the downstream (glutamine-producing) hepatocytes. The leftover NH_4^+ is thus, in a sense, packaged as glutamine for export to the kidney, where it is used to facilitate Cl^- excretion.

Gastrointestinal Tract

The GI tract is an underappreciated component of acid-base balance. In different regions along its length, the GI tract handles strong ions quite differently. In the stomach, Cl^- is pumped out of the plasma and into the lumen, thereby reducing the SID of the gastric juice and thus the pH as well. On the plasma side, the SID is increased by the loss of Cl^- , and the pH rises, producing the so-called alkaline tide that occurs at the beginning of a meal, when gastric acid secretion is maximal.¹⁵

In the duodenum, Cl^- is reabsorbed and the plasma pH restored. Normally, only slight changes in plasma pH are evident because Cl^- is returned to the circulation almost as soon as it is removed. If, however, gastric secretions are removed from the patient, whether by catheter suctioning or vomiting, Cl^- will be progressively lost and the SID will steadily increase. It is important to remember that it is the loss of Cl^- , not of H^+ , that determines the plasma pH. Although H^+ is lost as HCl , it is also lost with every molecule of water removed from the body. When Cl^- , a strong anion, is lost without the corresponding loss of a strong cation, the SID is increased, and therefore, the plasma H^+ concentration is decreased. When H^+ is lost as water rather than as HCl , the SID does not change, and thus, the plasma H^+ concentration does not change either.

The pancreas secretes fluid into the small intestine that possesses an SID much higher than the plasma SID and is very low in Cl^- . Thus, the plasma perfusing the pancreas has its SID decreased, a phenomenon that peaks about 1 hour after a meal and helps counteract the alkaline tide. If large amounts of pancreatic fluid are lost (e.g., as a consequence of surgical drainage), the resulting decrease in the plasma SID will lead to acidosis.

In the large intestine, the fluid also has a high SID, because most of the Cl^- was removed in the small intestine and the remaining electrolytes consist mostly of Na^+ and K^+ . Normally, the body reabsorbs much of the water and electrolytes from this fluid, but when severe diarrhea occurs, large amounts of cations may be lost. If this cation loss persists, the plasma SID will decrease and acidosis will result.

In addition to the acid-base effects of abnormal loss of strong ions from the GI lumen, the small intestine, in particular, may contribute strong ions to the plasma. This contribution is most apparent when mesenteric blood flow is compromised and lactate is produced, sometimes in large quantities. Although global hypoperfusion may compromise the mesentery, the intestine does not appear to be a source of lactic acid in patients resuscitated from a septic state [see Metabolic Acidosis, Positive-Anion Gap Acidosis, Lactic Acidosis, below].¹⁶ Moreover, whether the GI tract is capable of regulating strong ion uptake in a compensatory fashion has not been well studied. There is some evidence that the gut may modulate systemic acidosis in experimental endotoxemia by removing anions from the plasma¹⁷; however, the full capacity of the gut to affect acid-base balance remains to be determined.

METABOLIC ACIDOSIS

Traditionally, metabolic acidoses are categorized according to the presence or absence of unmeasured anions. These unmeasured anions are routinely detected by examining the plasma electrolytes and calculating the anion gap (AG) (see below). The differential diagnosis for a positive-AG acidosis includes various common and rare causes [see Table 2]. Generally speaking, non-AG acidoses can be divided into three types: renal, gastrointestinal, and iatrogenic [see Table 3]. In the ICU, the most common types of metabolic acidosis are lactic acidosis, ketoacidosis, iatrogenic acidosis, and acidosis secondary to toxins.

Table 2 Causes of Positive–Anion Gap Acidosis

Common causes	Renal failure
	Elevated ketone levels (ketoacidosis)
	Elevated lactate levels (lactic acidosis)
	Toxins (methanol, ethylene glycol, salicylate, paraldehyde, toluene)
Rare causes	Sepsis
	Dehydration
	Alkalemia
	Decreased concentrations of unmeasured cations (Mg^{2+} , K^+ , Ca^{2+})
	Sodium salts (lactate, citrate, acetate, penicillin, carbenicillin)
	Rhabdomyolysis

Even extreme acidosis appears to be well tolerated by healthy persons, particularly when the duration of the acidosis is short. For example, healthy individuals may achieve an arterial pH lower than 7.15 and a lactate concentration higher than 20 mEq/L during maximal exercise, with no lasting effects.¹⁸ Over the long term, however, even mild acidemia (pH < 7.35) may lead to metabolic bone disease and protein catabolism. Furthermore, critically ill patients may not be able to tolerate even brief episodes of acidemia.¹⁹ There do appear to be significant differences between metabolic and respiratory acidosis with respect to patient outcome, and these differences suggest that the underlying disorder may be more important than the absolute degree of acidemia.²⁰

If prudence dictates that symptomatic therapy is to be provided, the likely duration of the disorder should be taken into account. When the disorder is expected to be a short-lived one (e.g., diabetic ketoacidosis), maximizing respiratory compensation is usually the safest approach. Once the disorder resolves, ventilation can be quickly reduced to normal levels, and there will be no lingering effects from therapy. If the SID is increased (e.g., by administering $NaHCO_3$), there is a risk of alkalosis when the underlying disorder resolves. When the disorder is likely to be a more chronic one (e.g., renal failure), therapy aimed at restoring the SID to normal is indicated. In all cases, the therapeutic target can be accurately determined from the SBE. As noted (see above), the SBE corresponds to the amount by which the current SID differs from the SID necessary to restore the pH to 7.4, given a PCO_2 of 40 mm Hg. Thus, if the SID is 30 mEq/L and the SBE is -10 mEq/L, the target SID is 40 mEq/L. Accordingly, the plasma Na^+ concentration would have to increase by 10 mEq/L for $NaHCO_3$ administration to correct the acidosis completely.

It should be noted that the target SID is the SID at the equilibrium point between the SID, PCO_2 , and A_{tot} and that it may not be equal to 40 mEq/L, as in the example given. By convention, PCO_2

is set at 40 mm Hg, but the SBE is not corrected for abnormalities in A_{tot} . In many hypoalbuminemic patients, A_{tot} is lower than normal, and thus, the SID at the equilibrium point will be less than 40 mEq/L. Also, it is rare that the choice would be made to correct the acid-base abnormality completely. Therefore, the target SID should be used as a reference value, but in most cases, partial correction is all that is required.

If increasing the plasma Na^+ concentration is inadvisable for other reasons (e.g., hypernatremia), $NaHCO_3$ administration is inadvisable. It is noteworthy that $NaHCO_3$ administration has not been shown to improve outcome in patients with lactic acidosis.²¹ In addition, $NaHCO_3$ administration is associated with certain disadvantages. Large (hypertonic) doses, if given rapidly, may actually reduce blood pressure²² and may cause sudden, severe increases in P_aCO_2 .²³ Accordingly, it is important to assess the patient's ventilatory status before $NaHCO_3$ is administered, particularly if the patient is not on a ventilator. $NaHCO_3$ infusion also affects serum K^+ and Ca^{2+} concentrations, which must be monitored closely.

To avoid some of the disadvantages of $NaHCO_3$ therapy, alternative therapies for metabolic acidosis have been developed. Carbicarb is an equimolar mixture of sodium carbonate (Na_2CO_3) and $NaHCO_3$.²⁴ Like $NaHCO_3$, carbicarb works by increasing the plasma Na^+ concentration, except that it does not raise the PCO_2 . Results with carbicarb in animal studies have been mixed,²⁵ and experience in humans is extremely limited.

THAM (*tri*-hydroxymethyl aminomethane) is a synthetic buffer that consumes CO_2 and readily penetrates cells.²⁶ It is a weak base ($pK = 7.9$) and, as such, is unlike other plasma constituents. The major advantage of THAM is that it does not alter the SID, which means that there is no need to be concerned about having to increase the plasma Na^+ concentration to achieve a therapeutic effect. Accordingly, THAM is often used in situations where $NaHCO_3$ cannot be used because of hypernatremia. Although THAM has been available since the 1960s, there is surprisingly little information available regarding its efficacy in humans with acid-base disorders. In small uncontrolled studies, THAM appears to be capable of reversing metabolic acidosis secondary to ketoacidosis or renal failure without causing obvious toxicity²⁷; however, adverse reactions have been reported, including hypoglycemia, respiratory depression, and even fatal hepatic necrosis, when concentrations exceeding 0.3 mol/L are used. In Europe, a mixture of THAM, acetate, $NaHCO_3$, and disodium phosphate is available. This mixture, known as tribonate (Tribonat; Pharmacia & Upjohn, Solna, Sweden), seems to have fewer side effects than THAM alone does, but as with THAM, experience with its use in humans is still quite limited.

Anion Gap

Determination of anion gap The AG has been used by clinicians for more than 30 years and has evolved into a major tool for evaluating acid-base disorders.²⁸ It is calculated—or, rather, estimated—from the difference between the routinely measured concentrations of serum cations (Na^+ and K^+) and the routinely measured concentrations of anions (Cl^- and HCO_3^-). Normally, albumin accounts for the bulk of this difference, with phosphate playing a lesser role. Sulfate and lactate also contribute a small amount to the gap (normally, < 2 mEq/L); however, there are also unmeasured cations (e.g., Ca^{2+} and Mg^{2+}), which tend to offset the effects of sulfate and lactate except when the concentration of either one is abnormally increased. Plasma proteins other than albumin can be either positively or negatively charged, but in the

Table 3 Differential Diagnosis for Normal–Anion Gap Metabolic Acidosis

Urine SID > 0 mEq/L	Renal tubular acidosis
Urine SID < 0 mEq/L	GI condition Diarrhea Pancreatic or small bowel drainage Iatrogenesis Parenteral nutrition Saline

SID—strong ion difference

aggregate, they tend to be electrically neutral,²⁹ except in rare cases of abnormal paraproteins (as in multiple myeloma). In practice, the AG is calculated as follows:

$$\text{AG} = (\text{Na}^+ + \text{K}^+) - (\text{Cl}^- + \text{HCO}_3^-)$$

Because of its low extracellular concentration, K^+ is often omitted from the calculation. In most laboratories, normal values fall into the range of 12 ± 4 mEq/L (if K^+ is considered) or 8 ± 4 mEq/L (if K^+ is not considered). In the past few years, the introduction of more accurate methods of measuring Cl^- concentration has led to a general lowering of the normal AG range.^{30,31} Because of the various measurement techniques employed at various institutions, however, each institution is expected to report its own normal AG values.

Clinical utility of anion gap The primary value of the AG is that it quickly and easily limits the differential diagnosis in a patient with metabolic acidosis. When the AG is increased, the explanation is almost invariably one of the following five disorders: ketosis, lactic acidosis, poisoning, renal failure, and sepsis.³²

In addition to these disorders, however, there are several conditions that can alter the accuracy of AG estimation and are particularly frequent in critical illness.^{33,34} Dehydration increases the concentrations of all of the ions. Severe hypoalbuminemia lowers the AG, with each 1 g/dl decline in the serum albumin reducing the apparent AG by 2.5 to 3 mEq/L; accordingly, some recommend adjusting the AG for the prevailing albumin concentration.³⁵ Alkalosis (respiratory or metabolic) is associated with an increase of as much as 3 to 10 mEq/L in the apparent AG as a consequence of enhanced lactate production (from stimulated phosphofructokinase enzymatic activity), reduction in the concentration of ionized weak acids (A^-) (as opposed to A_{tot} , the total concentration of weak acids), and, possibly, the additional effect of dehydration (which, as noted, has its own impact on AG calculation). A low Mg^{2+} concentration with associated low K^+ and Ca^{2+} concentrations is a known cause of an increased AG, as is the administration of sodium salts of poorly reabsorbable anions (e.g., β -lactam antibiotics).³⁶ Certain parenteral nutrition formulations (e.g., those containing acetate) may increase the AG. In rare cases, citrate may have the same effect in the setting of multiple blood transfusions, particularly if massive doses of banked blood are used (as during liver transplantation).³⁷ None of these rare causes, however, will increase the AG significantly,³⁸ and they usually are easily identified.

In the past few years, some additional causes of an increased AG have been reported. The nonketotic hyperosmolar state of diabetes has been associated with an increased AG that remains unexplained.³⁹ Unmeasured anions have been reported in the blood of patients with sepsis,^{40,41} patients with liver disease,^{42,43} and experimental animals that received endotoxin.⁴⁴ These anions may be the source of much of the unexplained acidosis seen in patients with critical illness.⁴⁵

The accepted clinical utility of the AG notwithstanding, doubt has been cast on its diagnostic value in certain situations.^{33,41} Some investigators have found routine reliance on the AG to be "fraught with numerous pitfalls."³³ The primary problem with the AG is its reliance on the use of a supposedly normal range produced by albumin and, to a lesser extent, phosphate. Concentrations of albumin and phosphate may be grossly abnormal in patients with critical illness, and these abnormalities may change the normal AG range in this setting. Moreover, because these anions are not strong anions, their charge is altered by changes in

pH. These concerns have led some authors to advocate adjusting the normal AG range on the basis of the patient's albumin³⁵ or even phosphate⁶ concentration. Each 1 g/dl of albumin carries a charge of 2.8 mEq/L at a pH of 7.4 (2.3 mEq/L, pH = 7.0; 3.0 mEq/L, pH = 7.6), and each 1 mg/dl of phosphate carries a charge of 0.59 mEq/L at a pH of 7.4 (0.55 mEq/L, pH = 7.0; 0.61 mEq/L, pH = 7.6). Thus, the normal AG for a given patient can be conveniently estimated as follows⁶:

$$\text{Normal AG} = 2(\text{albumin [g/dl]}) + 0.5(\text{phosphate [mg/dl]})$$

or, in international units,

$$\text{Normal AG} = 0.2(\text{albumin [g/L]}) + 1.5(\text{phosphate [mmol/L]})$$

In one study, when this formula for calculating a patient-specific normal AG range was used to determine the presence of unmeasured anions in the blood of critically ill patients, its accuracy was 96%, compared with an accuracy of 33% with the routine AG (normal range = 12 mEq/L).⁶ This technique should be employed only when the pH is less than 7.35; even in this situation, it is only accurate within 5 mEq/L. When more accuracy is needed, a slightly more complicated method of estimating unmeasured anions is required.^{42,46}

Strong anion gap Another alternative to relying on the traditional AG is to use a parameter derived from the SID. By definition, the SID must be equal and opposite to the sum of the negative charges contributed by A^- and total CO_2 . This latter value ($\text{A}^- + \text{total CO}_2$) has been termed the effective SID (SIDe).²⁹ The apparent SID (SIDa) is obtained by measuring concentrations of each individual ion. The SIDa and the SIDe should both equal the true SID. If the SIDa differs from the SIDe, unmeasured ions must be present. If the SIDa is greater than the SIDe, these unmeasured ions are anions; if the SIDa is less than the SIDe, they are cations. The difference between the SIDa and the SIDe has been termed the strong ion gap (SIG) to distinguish it from the AG.⁴² Unlike the AG, the SIG is normally 0 and is not affected by changes in the pH or the albumin concentration.

Positive-Anion Gap Acidosis

Lactic acidosis In many forms of critical illness, lactate is the most important cause of metabolic acidosis.⁴⁷ Lactate concentrations have been shown to correlate with outcomes in patients with hemorrhagic⁴⁸ and septic shock.⁴⁹ Traditionally, lactic acid has been viewed as the predominant source of the metabolic acidosis that occurs in sepsis.⁵⁰ In this view, lactic acid is released primarily from the musculature and the gut as a consequence of tissue hypoxia, and the amount of lactate produced is believed to correlate with the total oxygen debt, the magnitude of hypoperfusion, and the severity of shock.⁴⁷ This view has been challenged by the observation that during sepsis, even in profound shock, resting muscle does not produce lactate. Indeed, various studies have shown that the musculature may actually consume lactate during endotoxemia.^{16,51,52}

The data on lactate release by the gut are less clear. There is little question that the gut can release lactate if it is underperfused. It appears, however, that if the gut is adequately perfused, it does not release lactate during sepsis. Under such conditions, the mesentery either is neutral with respect to lactate release or takes up lactate.^{16,51} Perfusion is likely to be a major determinant of mesenteric lactate metabolism. In a canine model of sepsis

induced by infusion of endotoxin, production of lactate by the gut could not be demonstrated when flow was maintained with dopexamine.⁵²

Both animal studies and human studies have shown that the lung may be a prominent source of lactate in the setting of acute lung injury.^{16,53,54} These studies do not address the underlying pathophysiologic mechanisms of hyperlactatemia in sepsis, but they do suggest that the conventional wisdom regarding lactate as evidence of tissue dysoxia is, at best, an oversimplification. Indeed, many investigators have begun to offer alternative explanations for the development of hyperlactatemia in this setting [see Table 4].⁵⁴⁻⁵⁸ One proposed mechanism is metabolic dysfunction from mitochondrial enzymatic derangements, which can and do lead to lactic acidosis. In particular, pyruvate dehydrogenase (PDH), the enzyme responsible for moving pyruvate into the Krebs cycle, is inhibited by endotoxin.⁵⁹ Current data, however, suggest that increased aerobic metabolism may be more important than metabolic defects or anaerobic metabolism. In a 1996 study, production of glucose and pyruvate and oxidation were increased in patients with sepsis.⁶⁰ Furthermore, when PDH was stimulated by dichloroacetate, there was an additional increase in oxygen consumption but a decrease in glucose and pyruvate production. These results suggest that hyperlactatemia in sepsis occurs as a consequence of increased aerobic metabolism rather than of tissue hypoxia or PDH inhibition.

Such findings are consistent with the known metabolic effects of lactate production on cellular bioenergetics.⁶¹ Lactate production alters cytosolic, and hence mitochondrial, redox states, so that the increased ratio of reduced nicotinamide adenine dinucleotide to nicotinamide adenine dinucleotide (NADH/NAD) supports oxidative phosphorylation as the dominant source of ATP production. Finally, the use of catecholamines, especially epinephrine, also results in lactic acidosis, presumably by stimulating cellular metabolism (e.g., increasing hepatic glycolysis), and may be a common source of lactic acidosis in the ICU.^{62,63} It is noteworthy that this phenomenon does not appear to occur with either dobutamine or norepinephrine⁶⁴ and does not appear to be related to decreased tissue perfusion.

Although the source and interpretation of lactic acidosis in critically ill patients remain controversial, there is no question about the ability of lactate accumulation to produce acidemia. Lactate is a strong ion because at a pH within the physiologic range, it is almost completely dissociated. (The pK of lactate is 3.9; at a pH of 7.4, 3,162 ions are dissociated for every one ion that is not.) Because lactate is rapidly produced and disposed of by the body, it functions as one of the most dynamic components of the SID. Therefore, a rise in the concentration of lactic acid can produce significant acidemia. Just as often, however, critically ill patients have a degree of hyperlactatemia that far exceeds the degree of acidosis observed. In fact, hyperlactatemia may exist without any metabolic acidosis at all. This is not because acid generation is separate from lactate production (e.g., through “unreversed ATP hydrolysis”), as some have suggested.⁶⁴ Phosphate is a weak acid and does not contribute substantially to metabolic acidosis, even under extreme circumstances. Furthermore, the H⁺ concentration is determined not by how much H⁺ is produced or removed from the plasma but by changes in the dissociation of water and weak acids. Virtually anywhere in the body, the pH is higher than 6.0, and lactate behaves as a strong ion. Generation of lactate reduces the SID and results in an increased H⁺ concentration; however, the plasma lactate concentration may also be increased without an accompanying increase in the H⁺ concentration.

Table 4 Mechanisms Associated with Increased Serum Lactate Concentration

Tissue hypoxia	Hypodynamic shock Organ ischemia
Hypermetabolism	Increased aerobic glycolysis Increased protein catabolism Hematologic malignancies
Decreased clearance of lactate	Hepatic failure Shock
Inhibition of pyruvate dehydrogenase	Thiamine deficiency ?Endotoxin
?Activation of inflammatory cells	

There are two possible explanations for these observations. First, if lactate is added to the plasma, not as lactic acid but rather as the salt of a strong acid (e.g., sodium lactate), the SID will not change significantly, because a strong cation (Na⁺) is being added along with a strong anion. Indeed, as lactate is metabolized and removed, the remaining Na⁺ will increase the SID, resulting in metabolic alkalosis. Hence, it would be possible to give enough lactate to increase the plasma lactate concentration without increasing the H⁺ concentration. However, given that normal metabolism results in the turnover of approximately 1,500 to 4,500 mmol of lactic acid each day, rapid infusion of a very large amount of lactate would be required to bring about an appreciable increase in the plasma lactate concentration. For example, the use of lactate-based hemofiltration fluid may result in hyperlactatemia with an increased plasma HCO₃⁻ concentration and an elevated pH.

A more important mechanism whereby hyperlactatemia can exist without acidemia (or with less acidemia than expected) involves correction of the SID by the elimination of another strong anion from the plasma. In a study of sustained lactic acidosis induced by lactic acid infusion, Cl⁻ was found to move out of the plasma space, thereby normalizing the pH.⁶⁵ Under these conditions, hyperlactatemia may persist, but compensatory mechanisms may normalize the base excess and thus restore the SID.

Traditionally, lactic acidosis has been subdivided into type A, in which the mechanism is tissue hypoxia, and type B, in which there is no hypoxia.⁶⁶ This distinction may, however, be an artificial one. Disorders such as sepsis may be associated with lactic acidosis through a variety of mechanisms [see Table 4], some conventionally labeled type A and others type B. A potentially useful method of distinguishing between anaerobically produced lactate and lactate from other sources is to measure the serum pyruvate concentration. The normal lactate-to-pyruvate ratio is 10:1,⁶⁷ with ratios greater than 25:1 considered to be evidence of anaerobic metabolism.⁵⁸ This approach makes biochemical sense because pyruvate is shunted into lactate during anaerobic metabolism, dramatically increasing the lactate-to-pyruvate ratio. However, the precise test characteristics, including normal ranges and sensitivity and specificity data, have not yet been defined for patients. Accordingly, this method remains investigational.

Treatment of lactic acidosis continues to be subject to debate. At present, the only noncontroversial approach is to treat the underlying cause; however, this approach assumes that the underlying cause can be identified with a significant degree of certainty, which is not always the case. The assumption that hypoperfusion is always the most likely cause has been seriously challenged, especially in well-resuscitated patients (see above). Thus, therapy

aimed at increasing oxygen delivery may not be effective. Indeed, if epinephrine is used, lactic acidosis may worsen.

Administration of NaHCO_3 to treat lactic acidosis remains unproven.²¹ In perhaps the most widely quoted study on this topic, hypoxic lactic acidosis was induced in anesthetized dogs by ventilating them with gas containing very little oxygen.⁶⁸ These animals were then assigned to treatment with NaHCO_3 or placebo, and surprisingly, the group receiving NaHCO_3 actually had higher plasma concentrations of both lactate and H^+ than the control group did. Furthermore, the NaHCO_3 -treated animals exhibited decreases in cardiac output and blood pressure that were not seen in the control group. One possible explanation for these findings is that the HCO_3^- was converted to CO_2 , and this conversion raised the PCO_2 not only in the blood but also inside the cells of these animals with a fixed minute ventilation; the resulting intracellular acidosis might have been detrimental to myocardial function. This hypothesis has not, however, been supported by subsequent experimental studies, which have not documented paradoxical intracellular acidosis or even detrimental hemodynamic effects after NaHCO_3 treatment of hypoxic lactic acidosis.⁶⁹ Furthermore, it is not clear how this type of hypoxic lactic acidosis, induced in well-perfused animals, relates to the clinical conditions in which lactic acidosis occurs. The results of clinical studies have been mixed, but overall, they do not support the use of NaHCO_3 therapy for lactic acidosis.²¹

Ketoacidosis Another common cause of a metabolic acidosis with a positive AG is excessive production of ketone bodies, including acetone, acetoacetate, and β -hydroxybutyrate. Both acetoacetate and β -hydroxybutyrate are strong anions (pK 3.8 and 4.8, respectively).⁷⁰ Thus, their presence, like the presence of lactate, decreases the SID and increases the H^+ concentration.

Ketones are formed through beta oxidation of fatty acids, a process that is inhibited by insulin. In insulin-deficient states (e.g., diabetes), ketone formation may quickly get out of control. The reason is that severely elevated blood glucose concentrations produce an osmotic diuresis that may lead to volume contraction. This state is associated with elevated cortisol and catecholamine secretion, which further stimulates free fatty acid production.⁷¹ In addition, an increased glucagon level relative to the insulin level leads to a decreased malonyl coenzyme A level and an increased carnitine palmitoyl acyl transferase level—a combination that increases ketogenesis.

Ketoacidosis may be classified as either diabetic ketoacidosis (DKA) or alcoholic ketoacidosis (AKA). The diagnosis is established by measuring serum ketone levels. It must be kept in mind, however, that the nitroprusside reaction measures only acetone and acetoacetate, not β -hydroxybutyrate. Thus, the measured ketosis is dependent on the ratio of acetoacetate to β -hydroxybutyrate. This ratio is low when lactic acidosis coexists with ketoacidosis because the reduced redox state characteristic of lactic acidosis favors production of β -hydroxybutyrate.⁷² In such circumstances, therefore, the apparent degree of ketosis is small relative to the degree of acidosis and the elevation of the AG. There is also a risk of confusion during treatment of ketoacidosis, in that ketone levels, as measured by the nitroprusside reaction, sometimes rise even though the acidosis is resolving. This occurs because the nitroprusside reaction does not detect β -hydroxybutyrate, and as β -hydroxybutyrate is cleared, ketosis persists despite improvement in acid-base balance. Furthermore, conversion of β -hydroxybutyrate to acetoacetate may cause an apparent increase in ketone levels—again, because the nitroprusside reaction detects the rising levels of acetoacetate but misses the falling levels of β -hydroxybutyrate.

Hence, it is better to monitor the success of therapy by measuring the pH and the AG than by assaying serum ketones.

Treatment of DKA includes administration of insulin and large amounts of fluid (0.9% saline is usually recommended); potassium replacement is often required as well. Fluid resuscitation reverses the hormonal stimuli for ketone body formation, and insulin allows the metabolism of ketones and glucose. Administration of NaHCO_3 may produce a more rapid rise in the pH by increasing the SID, but there is little evidence that this result is desirable. Furthermore, to the extent that the SID is increased by increasing the plasma Na^+ concentration, the SID will be too high once the ketosis is cleared, thus resulting in a so-called overshoot alkalosis. In any case, such measures are rarely necessary and should probably be avoided except in extreme cases.⁷³

A more common problem in the treatment of DKA is the persistence of acidemia after the ketosis has resolved. This hyperchloremic metabolic acidosis occurs as Cl^- replaces ketoacids, thus maintaining a decreased SID and pH. There appear to be two reasons for this phenomenon. First, exogenous Cl^- is often provided in the form of 0.9% saline, which, if given in large enough quantities, will result in a so-called dilutional acidosis (see below). Second, some degree of increased Cl^- reabsorption apparently occurs as ketones are excreted in the urine. It has also been suggested that the increased tubular Na^+ load produces electrical-chemical forces that favor Cl^- reabsorption.⁷⁴

AKA is usually less severe than DKA. Treatment consists of administration of fluids and (in contrast to treatment of DKA) glucose rather than insulin.⁷⁵ Insulin is contraindicated in AKA patients because it may cause precipitous hypoglycemia.⁷⁶ Thiamine must also be given to keep from precipitating Wernicke encephalopathy.

Acidosis secondary to renal failure Although renal failure may produce a hyperchloremic metabolic acidosis, especially when it is chronic, the buildup of sulfates and other acids frequently increases the AG; however, the increase usually is not large.⁷⁷ Similarly, uncomplicated renal failure rarely produces severe acidosis, except when it is accompanied by high rates of acid generation (e.g., from hypermetabolism).⁷⁸ In all cases, the SID is decreased and is expected to remain so unless some therapy is provided. Hemodialysis permits the removal of sulfate and other ions and allows the restoration of normal Na^+ and Cl^- balance, thus returning the SID to a normal (or near-normal) value. However, those patients who do not yet require dialysis and those who are between treatments often require some other therapy aimed at increasing the SID. NaHCO_3 may be used for this purpose, provided that the plasma Na^+ concentration is not already elevated.

Acidosis secondary to toxin ingestion Metabolic acidosis with an increased AG is a major feature of various types of intoxication [see Table 2]. Generally, it is more important to recognize these conditions and provide specific therapy for them than it is to treat the acid-base imbalances that they produce.

Acidosis secondary to rhabdomyolysis The extensive muscle tissue breakdown associated with myonecrosis may also be a source of positive-AG metabolic acidosis. In this situation, the acidosis results from accumulation of organic acids. The myoglobinuria associated with the disorder may also induce renal failure. In most cases, the diagnosis is a clinical one and can be facilitated by measuring creatinine kinase or aldolase levels. Early identification and aggressive resuscitation may prevent the onset of renal failure and improve the prognosis.⁷⁹

Acidosis of unknown origin Several causes of an increased AG have been reported that have yet to be elucidated. An unexplained AG in the nonketotic hyperosmolar state of diabetes has been reported.³⁹ In addition, even when very careful measurement techniques have been employed, unmeasured anions have been reported in the blood of patients with sepsis,^{40,41} patients with liver disease,⁴² and animals to which endotoxin had been administered.⁴³ Furthermore, unknown cations also appear in the blood of some critically ill patients.⁴¹ The significance of these findings remains to be determined.

Prognostic significance of positive-AG metabolic acidosis

Several studies have examined whether the presence of unmeasured anions in the blood is associated with particular outcomes in critically ill patients. Two such studies focused on trauma patients. In one, the investigators examined 2,152 sets of laboratory data from 427 trauma patients and found that the SIG altered the acid-base disorder diagnosis in 28% of the datasets.⁸⁰ Simultaneous measurements of blood gas, serum electrolyte, albumin, and lactate values were used to calculate the base deficit, the AG, and the SIG. Unmeasured anions (defined by the presence of an elevated SIG) were present in 92% of patients (mean SIG, 5.9 ± 3.3); hyperlactatemia and hyperchloremia occurred in only 18% and 21% of patients, respectively. The arterial SBE at ICU admission was poorly predictive of hospital survival, and its predictive ability was only slightly improved by controlling for unmeasured ions. In this dataset, survivors could not be differentiated from nonsurvivors in the group as a whole on the basis of the SIG. However, in the subgroup of patients whose lactate level was normal at admission, there was a significant difference in the SIG between survivors and nonsurvivors, though no such differences were noted in the conventional measures (i.e., SBE and AG).

The poor predictive ability of the SBE, the AG, and even the SIG has been confirmed by studies of general ICU patients. In one study, analysis of data from 300 adult ICU patients demonstrated statistically significant but weak correlations between these measures and hospital mortality.⁸¹ In another study, however, pre-treatment SIG was found to be a very strong predictor of outcome in 282 patients who had sustained major vascular injury.⁸² All but one of the nonsurvivors had an initial emergency department (ED) pH of 7.26 or lower, an SBE of -7.3 mEq/L or lower, a lactate concentration of 5 mmol/L or higher, and an SIG of 5 mEq/L or higher. All of the acid-base descriptors were strongly associated with outcome, but the SIG was the one that discriminated most strongly. The investigators concluded that initial ED acid-base variables, especially SIG, could distinguish survivors of major vascular injury from nonsurvivors.

Even though the uncorrected AG and the SBE correlate poorly with the arterial lactate concentration in trauma patients,⁸³ several investigators have proposed that these parameters be used as surrogate measures of the severity of shock or lack of resuscitation. Various studies have shown that the SBE is a poor predictor of lactic acidosis and mortality both in medical patients and in surgical or trauma patients and that it cannot be substituted for direct measurement of the serum lactate concentration.^{33,84,85} Some investigators, however, have found that the SBE can be used as a marker of injury severity and mortality and as a predictor of transfusion requirements.⁸⁶⁻⁸⁸ Unfortunately, the SBE can determine only the degree of acid-base derangement, never the cause. In many critically injured patients, abnormalities in body water content, electrolyte levels, and albumin concentration limit any potential correlation between SBE and lactate concentration, even when other sources of acid are absent.

Several reports in the trauma literature have focused on the prognostic value of persistently elevated lactic acid levels during the first 24 to 48 hours after injury. In one study, involving 76 patients with multiple injuries who were admitted directly to the ICU from the operating room or the ED, serum lactate levels and oxygen transport were measured at ICU admission and at 8, 16, 24, 36, and 48 hours.⁸⁹ In those patients whose lactate levels returned to normal within 24 hours, the survival rate was 100%, and in those whose lactate levels returned to normal between 24 and 48 hours, the survival rate was 75%. However, in those whose lactate levels did not return to normal by 48 hours, the survival rate was only 14%. Thus, the rate of normalization of the serum lactate level is an important prognostic factor for survival in a severely injured patient.

Non-Anion Gap (Hyperchloremic) Acidoses

Hyperchloremic metabolic acidosis occurs as a result of either an increase in the level of Cl^- relative to the levels of strong cations (especially Na^+) or a loss of cations with retention of Cl^- . The various causes of such an acidosis [see Table 3] can be distinguished on the basis of the history and the measured Cl^- concentration in the urine. When acidosis occurs, the kidney normally responds by increasing Cl^- excretion; the absence of this response identifies the kidney as the source of the problem. Extrarenal hyperchloremic acidoses occur because of exogenous Cl^- loads (iatrogenic acidosis) or because of loss of cations from the lower GI tract without proportional loss of Cl^- (gastrointestinal acidosis).

Renal tubular acidosis Most cases of renal tubular acidosis (RTA) can be correctly diagnosed by determining urine and plasma electrolyte levels and pH and calculating the SID_a in the urine [see Table 3].⁹⁰ However, caution must be exercised when the plasma pH is greater than 7.35, because urine Cl^- excretion may be turned off. In such circumstances, it may be necessary to infuse sodium sulfate or furosemide. These agents stimulate excretion of Cl^- and K^+ and may be used to unmask the defect and to probe K^+ secretory capacity.

Establishing the mechanisms of RTA has proved difficult. It is likely that much of the difficulty results from the attempt to understand the physiology from the perspective of regulation of H^+ and HCO_3^- concentrations. As noted, however (see above), this approach is simply inconsistent with the principles of physical chemistry. The kidney does not excrete H^+ to any greater extent as NH_4^+ than it does as H_2O . The purpose of renal ammoniogenesis is to allow the excretion of Cl^- , which balances the charge of NH_4^+ . In all types of RTA, the defect is the inability to excrete Cl^- in proportion to excretion of Na^+ , though the precise reasons for this inability vary by RTA type. Treatment is largely dependent on whether the kidney will respond to mineralocorticoid replacement or whether there is Na^+ loss that can be counteracted by administering NaHCO_3 .

Classic distal (type I) RTA responds to NaHCO_3 replacement; generally, the required dosage is in the range of 50 to 100 mEq/day. K^+ defects are also common in this type of RTA, and thus, K^+ replacement is also required. A variant of the classic distal RTA is a hyperkalemic form, which is actually more common than the classic type. The central defect in this variant form appears to be impaired Na^+ transport in the cortical collecting duct. Patients with this condition also respond to NaHCO_3 replacement.

Proximal (type II) RTA is characterized by defects in the reabsorption of both Na^+ and K^+ . It is an uncommon disorder and usually occurs as part of Fanconi syndrome, in which reabsorption

of glucose, phosphate, urate, and amino acids is also impaired. Treatment of type II RTA with NaHCO_3 is ineffective; increased ion delivery merely results in increased excretion. Thiazide diuretics have been used to treat this disorder, with varying degrees of success.

Type IV RTA is caused by aldosterone deficiency or resistance. It is diagnosed on the basis of the high serum K^+ and the low urine pH (< 5.5). The most effective treatment usually involves removal of the cause (most commonly a drug, such as a nonsteroidal anti-inflammatory agent, heparin, or a potassium-sparing diuretic). Occasionally, mineralocorticoid replacement is required.

Gastrointestinal acidosis Fluid secreted into the gut lumen contains more Na^+ than Cl^- ; the proportions are similar to those seen in plasma. Massive loss of this fluid, particularly if lost volume is replaced with fluid containing equal amounts of Na^+ and Cl^- , will result in a decreased plasma Na^+ concentration relative to the Cl^- concentration and a reduced SID. Such a scenario can be prevented by using solutions such as lactated Ringer solution (LRS) instead of water or saline. LRS has a more physiologic SID than water or saline and therefore does not produce acidosis except in rare circumstances [see Positive-Anion Gap Acidosis, Lactic Acidosis, *above*].

Iatrogenic acidosis Two of the most common causes of a hyperchloremic metabolic acidosis are iatrogenic, and both involve administration of Cl^- . One of these potential causes is parenteral nutrition. Modern parenteral nutrition formulas contain weak anions (e.g., acetate) in addition to Cl^- , and the proportions of these anions can be adjusted according to the acid-base status of the patient. If sufficient amounts of weak anions are not provided, the plasma Cl^- concentration will increase, reducing the SID and causing acidosis.

The other potential cause is fluid resuscitation with saline, which can give rise to a so-called dilutional acidosis (a problem first described more than 40 years ago).^{91,92} Some authors have argued that dilutional acidosis is, at most, a minor issue.⁹³ This argument is based on studies showing that in healthy animals, large doses of NaCl produce only a minor hyperchloremic acidosis.⁹⁴ These studies have been interpreted as indicating that dilutional acidosis occurs only in extreme cases and even then is mild. However, this line of reasoning cannot be applied to critically ill patients, for two reasons. First, it is common for patients with sepsis or trauma to require large-volume resuscitation; sometimes, such patients receive crystalloid infusions equivalent to 5 to 10 times their plasma volumes in a single day. Second, critically ill patients frequently are not in a state of normal acid-base balance to begin with. Often, they have lactic acidosis or renal insufficiency. Furthermore, critically ill patients may not be able to compensate for acid-base imbalance normally (e.g., by increasing ventilation), and they may have abnormal buffer capacity as a result of hypoalbuminemia. In ICU and surgical patients,⁹⁵⁻⁹⁷ as well as in animals with experimentally induced sepsis,⁹⁸ saline-induced acidosis does occur and can produce significant acidemia.

The reason why administration of saline causes acidosis is that solutions containing equal amounts of Na^+ and Cl^- affect plasma concentrations of Na^+ and Cl^- differently. The normal Na^+ concentration is 35 to 45 mEq/L higher than the normal Cl^- concentration. Thus, adding (for example) 154 mEq/L of each ion in 0.9% saline will result in a greater relative increase in the Cl^- concentration than in the Na^+ concentration. So much is clear; what may be less clear is why critically ill patients are more susceptible to this disorder than healthy persons are.

It appears that many critically ill patients have a significantly lower SID than healthy persons do, even when these patients have no evidence of a metabolic acid-base derangement.⁹⁹ This finding is not surprising, in that the positive charge of the SID is balanced by the negative charges of A^- and total CO_2 . Because many critically ill patients are hypoalbuminemic, A^- tends to be reduced. Because the body maintains PCO_2 for other reasons, a reduction in A^- leads to a reduction in SID so that a normal pH can be maintained. Thus, a typical ICU patient may have an SID of 30 mEq/L, rather than 40 to 42 mEq/L. If a metabolic acidosis (e.g., lactic acidosis) then develops in this patient, the SID will decrease further. If this patient is subsequently resuscitated with large volumes of 0.9% saline, a significant metabolic acidosis will result.

The clinical implication for management of ICU patients is that if large volumes of fluid are to be given for resuscitation, fluids that are more physiologic than saline should be used. One alternative is LRS, which has a more physiologic ratio of Na^+ content to Cl^- content and thus has an SID that is closer to normal (roughly 28 mEq/L, compared with an SID of 0 mEq/L for saline). Of course, the assumption here is that the lactate in LRS is metabolized, which, as noted (see above), is almost always the case. Volume resuscitation also reduces the weak acid concentration, thereby moderating the acidosis. One *ex vivo* study concluded that administration of a solution with an SID of approximately 24 mEq/L will have a neutral effect on the pH as blood is progressively diluted.¹⁰⁰

Unexplained hyperchloremic acidosis Critically ill patients sometimes manifest hyperchloremic metabolic acidosis for reasons that cannot be determined. Often, other coexisting types of metabolic acidosis are present, making the precise diagnosis difficult. For example, some patients with lactic acidosis have a greater degree of acidosis than can be explained by the increase in the lactate concentration,⁴⁰ and some patients with sepsis and acidosis have normal lactate levels.¹⁰¹ In many instances, the presence of unexplained anions is the cause,⁴⁰⁻⁴² but in other cases, there is a hyperchloremic acidosis. Saline resuscitation may be responsible for much of this acidosis (see above), but experimental evidence from endotoxemic animals suggests that as much as a third of the acidosis cannot be explained in terms of current knowledge.⁹⁸

One potential explanation for unexplained hyperchloremic acidosis is partial loss of the Donnan equilibrium between plasma and interstitial fluid. The severe capillary leakage that accompanies this loss of equilibrium results in loss of albumin from the vascular space, which means that another ion must move into this space to maintain the charge balance between the two compartments. If Cl^- moves into the plasma space to restore the charge balance, a strong anion is replacing a weak anion, and a hyperchloremic metabolic acidosis results. This hypothesis appears reasonable but, at present, remains unproven.

METABOLIC ALKALOSIS

Metabolic alkalosis occurs as a result of an increased SID or a decreased A_{tot} , secondary either to loss of anions (e.g., Cl^- from the stomach and albumin from the plasma) or increases in cations (rare). Metabolic alkalooses can be divided into those in which Cl^- losses are temporary and can be effectively replaced (chloride-responsive alkalooses) and those in which hormonal mechanisms produce ongoing losses that, at best, can be only temporarily offset by Cl^- administration (chloride-resistant alkalooses) [see Table 5]. Like hyperchloremic acidosis, metabolic alkalosis can be confirmed by measuring the urine Cl^- concentration.

Table 5 Differential Diagnosis for Metabolic Alkalosis

	Chloride-responsive alkalosis (urine Cl ⁻ concentration < 10 mmol/L)
	GI loss
	Vomiting
	Gastric drainage
	Chloride-wasting diarrhea (villous adenoma)
	Diuretic use
	Hypercapnia
	Chloride-resistant alkalosis (urine Cl ⁻ concentration > 20 mmol/L)
	Mineralocorticoid excess
	Primary hyperaldosteronism (Conn syndrome)
	Secondary hyperaldosteronism
	Cushing syndrome
	Liddle syndrome
	Bartter syndrome
	Exogenous corticoids
	Excessive licorice intake
	Ongoing diuretic use
Chloride loss (Cl ⁻ < Na ⁺)	Sodium salt administration (acetate, citrate)
	Massive blood transfusions
	Parenteral nutrition
	Plasma volume expanders
	Sodium lactate (Ringer solution)
Other	Severe deficiency of intracellular cations (Mg ²⁺ , K ⁺)

Chloride-Responsive Alkalosis

Chloride-responsive metabolic alkalosis usually occurs as a result of loss of Cl⁻ from the stomach (e.g., through vomiting or gastric drainage). Treatment consists of replacing the lost Cl⁻, either slowly (with NaCl) or relatively rapidly (with KCl or even HCl). Because chloride-responsive alkalosis is usually accompanied by volume depletion, the most common therapeutic choice is to give saline along with KCl. Dehydration stimulates aldosterone secretion, which results in reabsorption of Na⁺ and loss of K⁺. Saline is effective even though it contains Na⁺ because the administration of equal amounts of Na⁺ and Cl⁻ yields a larger relative increase in the Cl⁻ concentration than in the Na⁺ concentration (see above). In rare circumstances, when neither K⁺ loss nor volume depletion is a problem, it may be desirable to replace Cl⁻ by giving HCl.

Diuresis and other forms of volume contraction cause metabolic alkalosis mainly by stimulating aldosterone secretion; however, diuretics also directly stimulate excretion of K⁺ and Cl⁻, further complicating the problem and inducing metabolic alkalosis more rapidly.

Chloride-Resistant Alkalosis

Chloride-resistant alkalosis [see Table 5] is characterized by an increased urine Cl⁻ concentration (> 20 mmol/L) and ongoing Cl⁻ loss that cannot be abolished by Cl⁻ replacement. Most commonly, the proximate cause is increased mineralocorticoid activity. Treatment involves identification and correction of the underlying disorder.

Alkalosis from Other Causes

In rare situations, an increased SID—and therefore metabolic alkalosis—occurs secondary to cation administration rather than to anion depletion. Examples include milk-alkali syndrome and

intravenous administration of strong cations without strong anions. The latter occurs with massive blood transfusion because Na⁺ is given with citrate (a weak anion) rather than with Cl⁻. Similar results ensue when parenteral nutrition formulations contain too much acetate and not enough Cl⁻ to balance the Na⁺ load.

Respiratory Acid-Base Disorders

Respiratory disorders are far easier to diagnose and treat than metabolic disorders are because the mechanism is always the same, even though the underlying disease process may vary. CO₂ is produced by cellular metabolism or by the titration of HCO₃⁻ by metabolic acids. Normally, alveolar ventilation is adjusted to maintain the P_aCO₂ between 35 and 45 mm Hg. When alveolar ventilation is increased or decreased out of proportion to the P_aCO₂, a respiratory acid-base disorder exists.

PATHOPHYSIOLOGY

CO₂ is produced by the body at a rate of 220 ml/min, which equates to production of 15 mol/L of carbonic acid each day.¹⁰² By way of comparison, total daily production of all the nonrespiratory acids managed by the kidney and the gut amounts to less than 500 mmol/L. Pulmonary ventilation is adjusted by the respiratory center in response to P_aCO₂, pH, and PO₂, as well as in response to exercise, anxiety, wakefulness, and other signals. Normal P_aCO₂ (40 mm Hg) is attained by precisely matching alveolar ventilation to metabolic CO₂ production. P_aCO₂ changes in predictable ways as a compensatory ventilatory response to the altered arterial pH produced by metabolic acidosis or alkalosis [see Table 1].

RESPIRATORY ACIDOSIS

Mechanism

When the rate of CO₂ elimination is inadequate relative to the rate of tissue CO₂ production, the P_aCO₂ rises to a new steady state, determined by the new relation between alveolar ventilation and CO₂ production. In the short term, this rise in the P_aCO₂ increases the concentrations of both H⁺ and HCO₃⁻ according to the carbonic acid equilibrium equation. Thus, the change in the HCO₃⁻ concentration is mediated not by any systemic adaptation but by chemical equilibrium. The higher HCO₃⁻ concentration does not buffer the H⁺ concentration. The SID does not change, nor does the SBE. Tissue acidosis always occurs in respiratory acidosis because CO₂ inevitably builds up in the tissue.

If the P_aCO₂ remains elevated, a compensatory response will occur, and the SID will increase to return the H⁺ concentration to the normal range. The increase in the SID is accomplished primarily by removing Cl⁻ from the plasma space. If Cl⁻ moves into tissues or red blood cells, it will result in intracellular acidosis (complicated by the elevated tissue PCO₂); thus, to exert a lasting effect on the SID, Cl⁻ must be removed from the body. The kidney is designed to do this, whereas the GI tract is not (though the adaptive capacity of the GI tract as a route of Cl⁻ elimination has not been fully explored). Accordingly, patients with renal disease have a very difficult time adapting to chronic respiratory acidosis.

Patients whose renal function is intact can eliminate Cl⁻ in the urine; after a few days, the SID rises to the level required to restore the pH to a value of 7.35. It is unclear whether this amount of time is necessary because of the physiologic constraints of the system or because the body benefits from not being overly sensitive to transient changes in alveolar ventilation. In any case, this response yields an increased pH for any degree of hypercapnia. According to

the Henderson-Hasselbalch equation, the increased pH results in an increased HCO_3^- concentration for a given PCO_2 . Thus, the “adaptive” increase in the HCO_3^- concentration is actually the consequence, not the cause, of the increased pH. Although the HCO_3^- concentration is a convenient and reliable marker of metabolic compensation, it is not the mechanism of the compensatory response. This point is not merely a semantic one: as noted (see above), only changes in the independent variables of acid-base balance (PCO_2 , A_{tot} , and SID) can affect the plasma H^+ concentration, and HCO_3^- concentration is not an independent variable.

Management

Treatment of underlying ventilatory impairment As with virtually all acid-base disorders, treatment begins by addressing the underlying disorder. Acute respiratory acidosis may be caused by CNS suppression; neuromuscular diseases or conditions that impair neuromuscular functions (e.g., myasthenia gravis, hypophosphatemia, and hypokalemia); or diseases affecting the airway or the lung parenchyma (e.g., asthma and acute respiratory dysfunction syndrome [ARDS]). The last category of conditions produces not only alveolar hypoventilation but also primary hypoxia. The two can be distinguished by means of the alveolar gas equation:

$$\text{P}_{\text{AO}_2} = \text{P}_{\text{I}\text{O}_2} - \text{P}_{\text{a}\text{CO}_2}/R$$

where R is the respiratory exchange coefficient (generally taken to be 0.8), and $\text{P}_{\text{I}\text{O}_2}$ is the inspired oxygen tension (approximately 150 mm Hg in room air). Thus, as the $\text{P}_{\text{a}\text{CO}_2}$ increases, the P_{AO_2} should also decrease in a predictable fashion. If the P_{AO_2} falls by more than the predicted amount, there is a defect in gas exchange.

In most cases, chronic respiratory acidosis is caused by either chronic lung disease (e.g., chronic obstructive pulmonary disease [COPD]) or chest wall disease (e.g., kyphoscoliosis). In rare cases, it is caused by central hypoventilation or chronic neuromuscular disease.

Control of hypoxemia Another aspect of respiratory acidosis that is illustrated by the alveolar gas equation is that the primary threat to life comes not from acidosis but from hypoxemia. In patients breathing room air, the $\text{P}_{\text{a}\text{CO}_2}$ cannot exceed 80 mm Hg before life-threatening hypoxemia results. Accordingly, supplemental oxygen is required in the treatment of these patients. Unfortunately, oxygen administration is almost never sufficient treatment by itself, and it generally proves necessary to address the ventilatory defect. When the underlying cause can be addressed quickly (as when the effects of narcotics are reversed with naloxone), endotracheal intubation may be avoidable. In the majority of patients, however, this is not the case, and mechanical ventilation must be initiated. Mechanical support is indicated for patients who are unstable or at risk for instability and patients whose CNS function is deteriorating. Furthermore, in patients who exhibit signs of respiratory muscle fatigue, mechanical ventilation should be instituted before respiratory failure occurs. Thus, it is not the absolute $\text{P}_{\text{a}\text{CO}_2}$ value that is the most important consideration in this situation but, rather, the clinical condition of the patient.

Chronic hypercapnia must be treated if the patient’s clinical condition is deteriorating acutely. In this setting, it is important not to try to restore the $\text{P}_{\text{a}\text{CO}_2}$ to the normal range of 35 to 45 mm Hg. Instead, the patient’s baseline $\text{P}_{\text{a}\text{CO}_2}$, if known, should be the therapeutic target; if the baseline $\text{P}_{\text{a}\text{CO}_2}$ is not known, a target $\text{P}_{\text{a}\text{CO}_2}$ of 60 mm Hg is perhaps a reasonable choice. Overventilation can have two undesirable consequences. First, if the $\text{P}_{\text{a}\text{CO}_2}$

is rapidly normalized in a patient with chronic respiratory acidosis and an appropriately large SID, life-threatening alkalemia may ensue. Second, even if the $\text{P}_{\text{a}\text{CO}_2}$ is corrected slowly, the plasma SID may decrease over time, making it impossible to wean the patient from mechanical ventilation.

One option for treatment of hypercapnia is noninvasive ventilation with a bilevel positive airway pressure (BiPAP) system. This technique may be useful in the management of some patients, particularly those whose sensorium is not impaired.¹⁰³ Rapid infusion of NaHCO_3 in patients with respiratory acidosis may induce acute respiratory failure if alveolar ventilation is not increased to account for the increased CO_2 . Thus, if NaHCO_3 is to be given, it must be administered slowly, with alveolar ventilation adjusted appropriately. Furthermore, it must be remembered that NaHCO_3 works by increasing the plasma Na^+ concentration; if this effect is not possible or not desirable, NaHCO_3 should not be given.

Occasionally, it is useful to reduce CO_2 production. This can be accomplished by reducing the amount of carbohydrates supplied in feedings (in patients requiring nutritional support), controlling body temperature (in febrile patients), or providing sedation (in anxious or combative patients). In addition, treatment of shivering in the postoperative period can reduce CO_2 production. Rarely, however, can hypercapnia be controlled with these CO_2 -reducing techniques alone.

Permissive hypercapnia. In the past few years, there has been considerable interest in ventilator-associated lung injury. Overdistention of alveoli can result in tissue injury and microvascular permeability, which lead to interstitial and alveolar edema. In animal studies, prolonged use of elevated airway pressures and increased lung volumes resulted in increased pathologic pulmonary changes and decreased survival when compared with ventilatory strategies employing lower pressures and volumes.^{104,105} In a large multicenter clinical trial, simply lowering the tidal volume on the ventilator from 12 ml/kg to 6 ml/kg in patients with acute lung injury resulted in a 9% absolute reduction in mortality risk.¹⁰⁶ Although the protocol followed in this trial did not advocate a reduced minute ventilation and hence an elevated $\text{P}_{\text{a}\text{CO}_2}$, this approach, often referred to as permissive hypercapnia or controlled hypoventilation, has become increasingly popular. Uncontrolled studies suggest that permissive hypercapnia may reduce mortality in patients with severe ARDS.²⁰ This strategy is not, however, without risks. Sedation is mandatory, and neuromuscular blocking agents are frequently required. Intracranial pressure rises, as does transpulmonary pressure; consequently, this technique is unusable in patients with brain injury or right ventricular dysfunction. There is controversy regarding how low the pH can be allowed to fall. Some authors have reported good results with pH values of 7.0 or even lower,²⁰ but most have advocated more modest pH reductions (i.e., ≥ 7.25).

RESPIRATORY ALKALOSIS

Respiratory alkalosis may be the most frequently encountered acid-base disorder. It occurs in residents of high-altitude locales and in persons with any of a wide range of pathologic conditions, the most important of which are salicylate intoxication, early sepsis, hepatic failure, and hypoxic respiratory disorders. Respiratory alkalosis also occurs in association with pregnancy and with pain or anxiety. Hypocapnia appears to be a particularly strong negative prognostic indicator in patients with critical illness.¹⁰⁷ Like acute respiratory acidosis, acute respiratory alkalosis results in a small change in the HCO_3^- concentration, as dictated by the Henderson-Hasselbalch equation. If hypocapnia persists, the SID begins to

decrease as a consequence of renal Cl^- reabsorption. After 2 to 3 days, the SID assumes a new and lower steady state.¹⁰⁸

Severe alkalemia is unusual in respiratory alkalosis. Management therefore is typically directed toward the underlying cause. In general, these mild acid-base changes are clinically important more for what they can alert the clinician to, in terms of underlying disease, than for any direct threat they pose to the patient. In rare cases, respiratory depression with narcotics is necessary.

Pseudorespiratory Alkalosis

The presence of arterial hypocapnia in patients experiencing profound circulatory shock has been termed pseudorespiratory

alkalosis.¹⁰⁹ This condition occurs when alveolar ventilation is supported but the circulation is grossly inadequate. In such circumstances, the mixed venous PCO_2 is significantly elevated, but the $\text{P}_\text{a}\text{CO}_2$ is normal or even decreased as a consequence of reduced CO_2 delivery to the lung and increased pulmonary transit time. Overall CO_2 clearance is therefore markedly decreased, and profound tissue acidosis—usually both metabolic and respiratory—ensues. The metabolic component of the acidosis comes from tissue hypoperfusion and hyperlactatemia. Arterial oxygen saturation may also appear adequate despite tissue hypoxemia. Pseudorespiratory alkalemia is rapidly fatal unless the patient's systemic hemodynamic status can be normalized.

9 HEPATIC FAILURE

Juan R. Sanabria, M.D., M.Sc., F.A.C.S., and Achilles A. Demetriou, M.D., Ph.D., F.A.C.S.

Approach to the Patient with Liver Failure

Hepatic failure continues to be a frequent and major cause of morbidity and mortality in critically ill patients. In the past decade, new approaches to hepatic failure have been developed. Advances in critical care, the increasing use of sophisticated diagnostic modalities, and the adoption of a team approach to patient care (with active collaboration among intensivists, hepatologists, anesthesiologists, transplant surgeons, and other specialists) have resulted in improved overall outcomes.

Hepatic failure may be encountered as an instance of primary organ failure caused by a liver-specific disease process or as part of the multiple organ dysfunction syndrome (MODS). Typically, patients with secondary liver failure have no preexisting liver disease: their liver dysfunction is simply a reflection of their overall critical condition, and management usually involves treatment of underlying nonhepatic disorders. In what follows, we outline general management guidelines for primary hepatic failure and its complications.

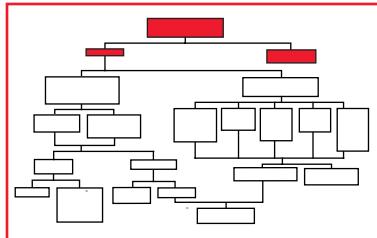

Clinical Evaluation and Investigative Studies

Evaluation of patients with suspected liver disease is often complex and typically requires extensive patient workup—including a detailed history and physical examination, as well as various diagnostic studies—to establish the diagnosis and confirm the underlying cause of the disease. Common risk factors include a history of alcohol or I.V. drug abuse, previous transfusion of blood or blood products,¹ the use of certain medications, tattoos, sexual promiscuity, and incarceration. Less common risk factors include a family history of liver disease and exposure to various toxins and chemicals.

CHARACTERISTIC FINDINGS

Liver disease gives rise to several easily recognizable manifestations. Jaundice and encephalopathy are common symptoms. In the early stages of liver disease, increasing fatigue, changes in sleep patterns, loss of short-term memory, inability to concentrate, and reduced libido may be noted. In the later stages, portal hypertension (PHT) is signaled by the development of ascites and upper or lower gastrointestinal bleeding. In addition, hypersplenism and abdominal wall collateral vessels may be detected on physical examination. Changes that occur primarily as a consequence of altered liver metabolism include palmar erythema, spider angiomas, gynecomastia, testicular atrophy, and encephalopathy. Many patients exhibit a degree of protein-calorie malnutrition, with muscle wasting and reduced physical activity.

Initial laboratory evaluation should include a complete blood count, a platelet count, liver function tests, a coagulation profile,

and assessment of renal function. In addition, a toxicology screen should be ordered and a sepsis workup initiated. Detection of one or more drugs in the urine or blood may help establish the diagnosis and direct treatment. Specific tests to detect other conditions (e.g., metabolic or autoimmune disorders) are ordered as needed. Blood and urine cultures are done to look for a concomitant or causative infectious agent; if ascites is present, analysis of the ascitic fluid (including a cell count with differential, Gram staining, and culture) is recommended. Serologic testing for hepatitis viruses and other viruses (e.g., herpesvirus, cytomegalovirus [CMV], and Epstein-Barr virus [EBV]) is indicated. In addition, a chest x-ray must be obtained, and additional imaging studies should be performed as indicated. At times, a liver biopsy is required to establish or confirm the diagnosis of liver disease.

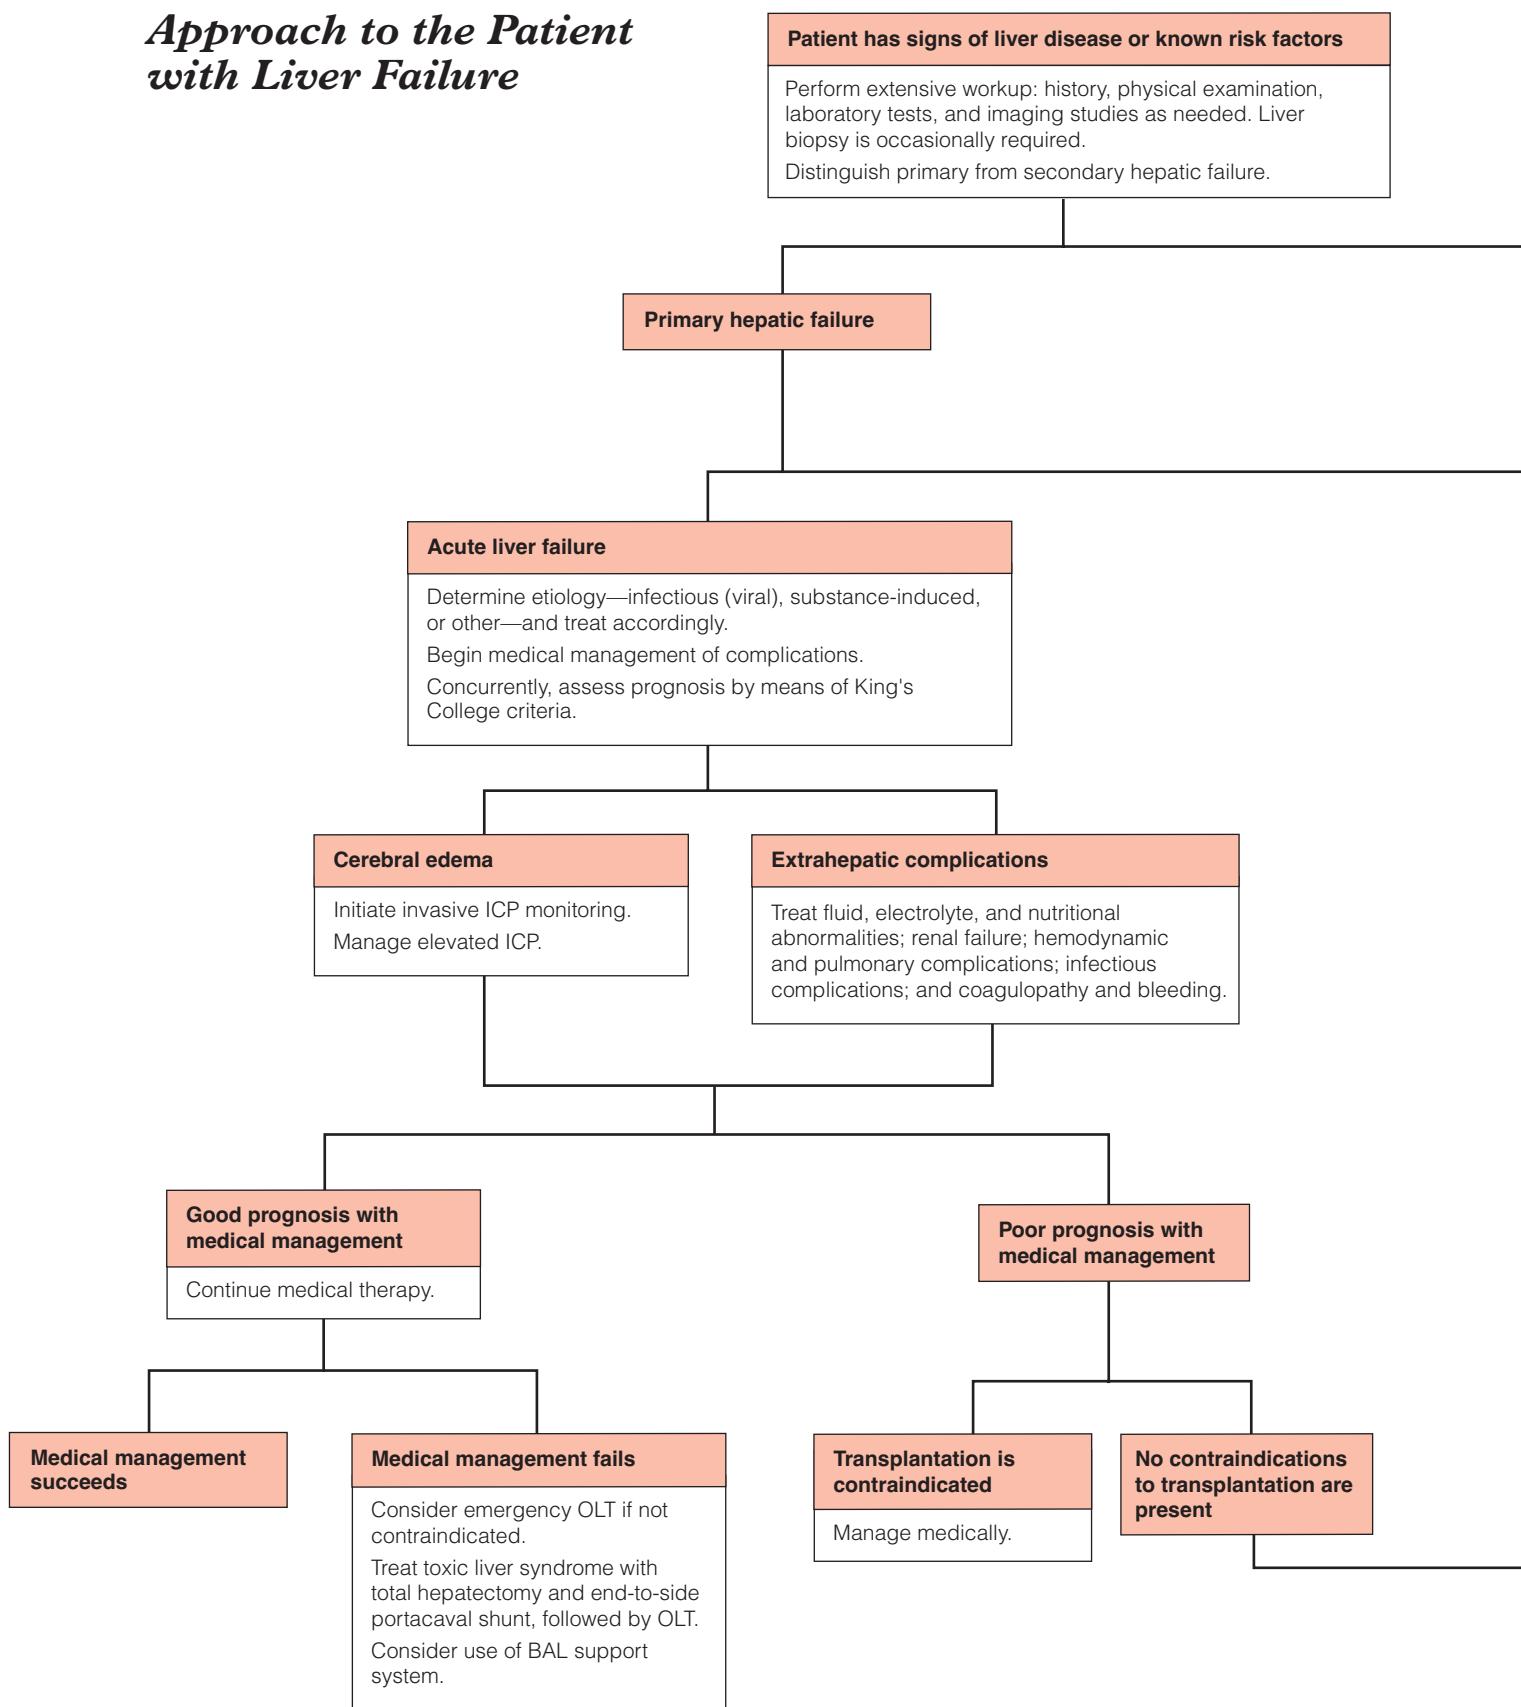

Most patients with primary hepatic failure have a history of preexisting liver disease and possibly of cirrhosis, generally presenting with one or more complications of chronic liver disease (e.g., GI bleeding, hepatic encephalopathy, spontaneous bacterial peritonitis [SBP], or renal failure). In one subgroup of patients, hepatic failure occurs as a result of an acute exacerbation of preexisting liver disease (e.g., acute reactivation of hepatitis B, acute decompensated Wilson disease, or autoimmune hepatitis). In another subgroup, primary hepatic failure develops acutely in the absence of any preexisting liver disease or known risk factors; this condition is known as fulminant hepatic failure (FHF). These patients present with massive liver necrosis, jaundice, and profound coagulopathy and often go on to experience deep coma and cerebral edema, which may lead to irreversible brain damage and death.

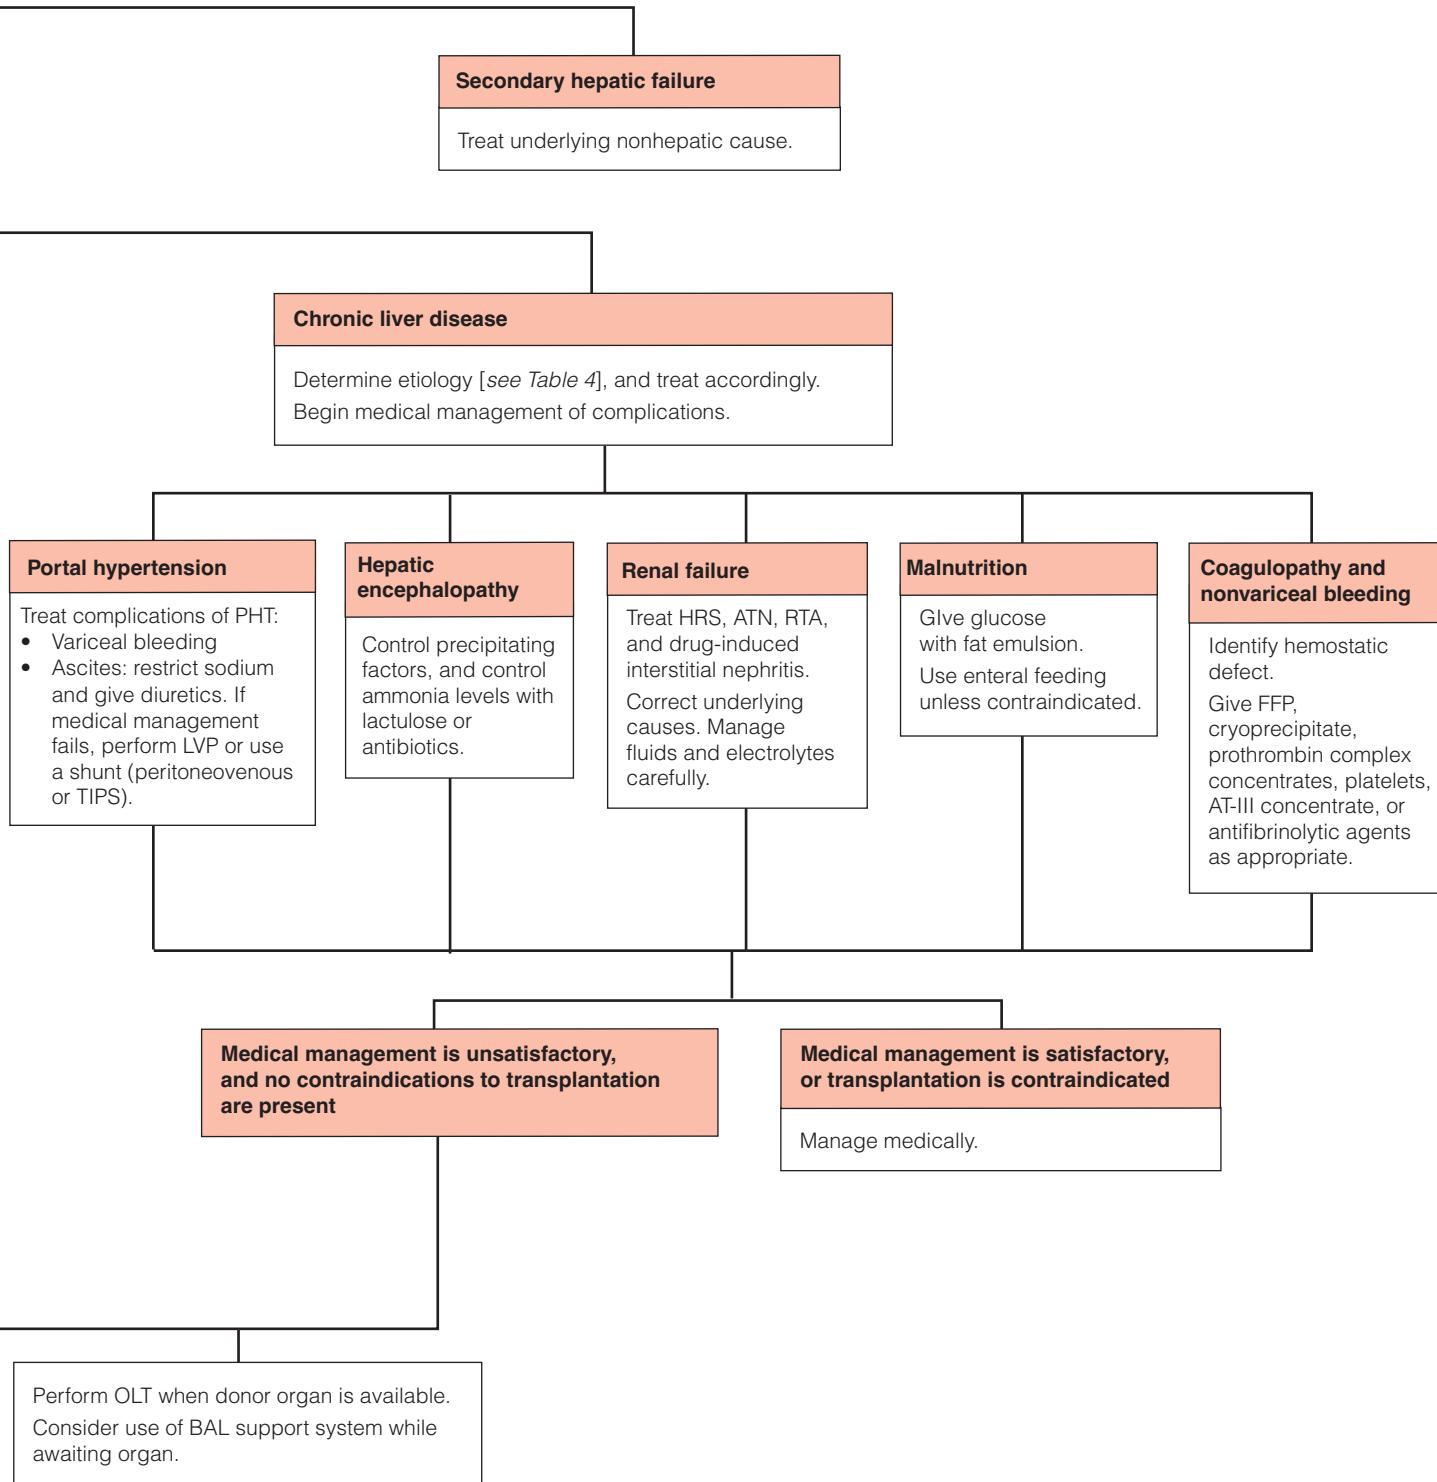

The distinction between an acute liver process and a chronic one is important. Acute liver failure (ALF) may be associated with severe multisystem organ involvement, as in the acute respiratory distress syndrome (ARDS) or MODS. The etiology of ALF includes the use of medications (in particular, acetaminophen), infection (specifically, viral hepatitis), miscellaneous conditions, and indeterminate causes. ALF may also develop after liver transplantation secondary to primary graft nonfunction (PNF) or hepatic artery thrombosis (HAT). It is manifested mainly by encephalopathy, progressive coagulopathy, poor urinary output, and elevated liver enzyme levels. Cerebral edema is uncommon in patients with PNF.

PROGNOSTIC FACTORS

A thorough initial physical examination is important for establishing a baseline for comparison, so that trends toward improvement or deterioration can be detected during clinical evaluations subsequently conducted at 4- to 6-hour intervals. Worsening encephalopathy with rapidly deteriorating mental status is an indication for early endotracheal intubation. Reduced urine output in a euvolemic patient is a sign of impending renal failure. Elevated liver enzyme concentrations and an elevated international normalized ratio (INR) suggest that spontaneous liver recovery is unlike-

Approach to the Patient with Liver Failure

ly. The development of hypoglycemia is a sign that only a limited amount of functional liver tissue remains. Metabolic acidosis may also reflect lack of functional liver reserve in a euvolemic patient setting. In addition, factor V levels and the degree of hepatocyte necrosis observed at liver biopsy may help guide further therapy. Increasing levels of α -fetoprotein (AFP) have been associated with liver regeneration and liver recovery. Finally, the patient's overall medical status (e.g., the presence of severe coronary artery disease or a history of recent myocardial infarction) may determine the final outcome.

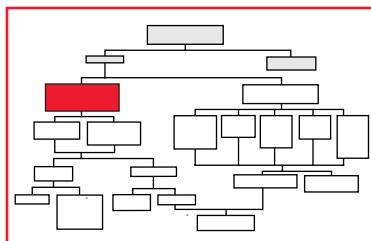

Initial Management

Initial management of a patient with hepatic failure includes the following components:

1. Airway protection. Airway management and maintenance should be established early in the course of the disease to prevent hypoxia with worsening brain edema or bronchial aspiration with pneumonitis, decreased gas exchange, and sepsis. Patients with cerebral edema require hyperventilation to lower the carbon dioxide tension (PCO_2) and reduce cerebral vasodilatation; however, the effect on PCO_2 is transient.
2. Monitoring of serum glucose levels. In patients who have experienced an acute loss of functional liver tissue, the lack of gluconeogenic pathways leads to decreased metabolism of lactic acid. The result is a high-anion gap metabolic acidosis with hypoglycemia, a state that is exaggerated in cases of sepsis with poor tissue perfusion.
3. Monitoring of cerebral perfusion pressure (CPP). The mental status of a patient with ALF should be followed by means of serial neurologic examinations, serial computed tomograms of the brain as indicated, and monitoring of intracranial pressure (ICP) and CPP. The signs detected by physical examination are not reliable, and changes in cerebral CT scans may develop late after the establishment of cerebral edema. Measuring CPP is the most reliable means of monitoring the degree of cerebral edema and can help guide early therapy.
4. Hemodynamic monitoring. Continuous assessment of central venous pressure is desirable in ALF patients to optimize fluid administration. Every effort should be made to establish adequate perfusion pressure without significantly increasing right-side cardiac pressures, diminishing venous return from the brain, and subsequently aggravating cerebral edema. Placement of a pulmonary artery catheter may be indicated in severely ill patients who may be hemodynamically unstable.
5. Correction of coagulopathy. The platelet count and the INR are the main variables monitored for assessment of coagulation. Because ALF patients typically are subjected to multiple interventions, invasive monitoring, and other procedures, fresh frozen plasma (FFP) and platelets are frequently administered.
6. Diagnostic workup. A rapid diagnostic workup is undertaken to allow appropriate disease management. Specific treatment should be instituted promptly to enhance liver recovery (e.g., administration of *N*-acetylcysteine to treat acetaminophen toxicity). It is of particular importance to identify any conditions that may rule out liver transplantation as a therapeutic option; such conditions include active infection, cancer, irreversible brain damage, and MODS. Evaluation of the patient for potential liver transplantation should begin early. To this end, it is important that the liver transplant team take part in the initial assessment and management of ALF patients.

Management of Acute Liver Failure

In the United States, ALF affects 2,300 to 2,800 patients each year.² How liver failure is defined depends largely on the temporal relation between the onset of illness and the appearance of jaundice, encephalopathy, and coagulopathy. For example, some define FHF as ALF in which the interval between disease onset and the appearance of major symptoms is 8 weeks or less.³ In most cases, however, it is difficult to establish the precise time of onset of the disease process and thus hard to determine precisely how much time elapsed before hepatic failure developed. Recognizing that clinical findings and prognosis vary depending on the interval between the onset of jaundice and the appearance of encephalopathy, some authorities distinguish between FHF and subfulminant hepatic failure (SHF). Bernau and coworkers defined FHF as an episode of ALF that was complicated by encephalopathy developing within 2 weeks of the onset of jaundice and defined SHF as ALF that was complicated by encephalopathy developing 2 to 12 weeks after the onset of jaundice.⁴ We use the term ALF for cases in which there is no evidence of chronic liver disease and in which liver disease develops within 8 weeks after the initial onset of illness.

CLASSIFICATION

ALF may be classified into three major categories on the basis of the underlying cause of the disease: infectious, substance-induced, and miscellaneous. In two multicenter studies, acetaminophen-induced toxicity was found to be the most common cause (20% and 39%) of ALF, followed by cryptogenic or indeterminate causes (15%).^{5,6}

Infectious (Viral Hepatitis)

Infectious ALF can be caused by several different viruses. Most cases are attributable to hepatitis viruses (types A through G), though herpesviruses (e.g., herpes simplex virus, varicella-zoster virus, CMV, and EBV), coxsackieviruses, echoviruses, adenoviruses, and parvovirus B19 are also capable of causing ALF.

Hepatitis A The incidence of FHF and SHF in patients with hepatitis A virus (HAV) infection is very low (< 0.01%).⁴ The virus is transmitted orally. HAV infection usually occurs in children and typically gives rise to minimal manifestations that resolve uneventfully, resulting in detectable levels of antibodies. About 10% of patients experience a relapse, usually within 2 to 3 months after an initial clinical improvement. Relapse is signaled by increased serum transaminase and bilirubin levels and the reappearance of the virus in the stool. If encephalopathy develops during this period, the prognosis is poor.⁷ The clinical course of the disease tends to be more severe in older patients. Immunoglobulin therapy may reduce infection rates among young family members and HAV-naïve health care workers.

Hepatitis B ALF related to hepatitis B virus (HBV) occurs in fewer than 1% of HBV infections but is the most common form of virus-induced FHF.^{4,5,8} Like HAV infection, HBV infection leads to FHF more often than to SHF. HBV is transmitted by contact with blood or body fluids and by intercourse. Detection of hepatitis B surface antigen (HBsAg) and a quantitative polymerase chain reaction (PCR) for HBV DNA establish the diagnosis. In

some cases of FHF secondary to HBV infection, however, these markers may be absent,⁹ which indicates that in certain FHF patients, an enhanced immune response prevents further HBV replication and results in more rapid clearance of HBsAg. The survival rate is much lower for patients who are HBsAg-positive on presentation (17%) than for patients who are HBsAg-negative (47%).⁴ Clearance of HBsAg and HBV DNA results in better survival, as well as lower recurrence rates after emergency liver transplantation.¹⁰ Protocols based on antiviral therapy with lamivudine and anti-HBV immunoglobulin yield low rates of HBV recurrence after successful liver transplantation.

Hepatitis D Hepatitis D virus (HDV, also referred to as the delta agent) is a defective virus that uses HBsAg as its envelope protein. HDV RNA is detected in only 10% of patients with fulminant hepatitis D.¹¹ HDV infection can be either a coinfection (in conjunction with HBV infection) or a superinfection (in patients with previous HBV infection).¹² In FHF patients, HDV coinfection is more common than HDV superinfection; however, the latter is associated with a higher mortality than the former (72% versus 52%), as well as a stronger predisposition to subsequent chronic liver disease (54% versus 31%).¹³

Hepatitis C and indeterminate hepatitis Previously, FHF of indeterminate etiology was attributed to non-A, non-B viral hepatitis. It is now clear that some such cases are caused by hepatitis C virus (HCV) infection, though the precise extent to which HCV infection contributes to this indeterminate group is unclear. Unlike HAV and HBV infection, HCV infection is more likely to cause SHF than FHF. Despite the availability of advanced serologic testing, there are still many cases of FHF and SHF whose cause cannot be determined.^{14,15} These cases may be attributable to other, more recently described types of hepatitis viruses (e.g., hepatitis E virus [HEV], hepatitis F virus [HFV], and hepatitis G virus [HGV]). ALF caused by HEV infection, though rare in Western countries, is the most common form of FHF in India.¹⁶

Substance-Induced

Drugs Drug toxicity accounts for 35% of all cases of FHF and SHF and usually runs a subfulminant course.⁵ Drug ingestion causes hepatic injury in fewer than 1% of patients, about 20% of whom manifest FHF or SHF. In most cases of drug-induced hepatotoxicity, the degree of the toxicity correlates with the dose ingested and the serum drug level, but in others (e.g., certain cases of valproic acid-induced toxicity), patients manifest an idiosyncratic reaction with massive liver necrosis after exposure to the drug. As a general rule, however, increasing the total drug dose, simultaneously ingesting other drugs that induce or inhibit hepatic enzymes (synergistic toxicity), and continuing drug administration after the onset of liver disease all increase the risk of hepatic failure.⁴

Acetaminophen toxicity is the most common cause of drug-induced hepatic failure. The prognosis for patients with FHF caused by acetaminophen is usually better than that for patients with FHF caused by other drugs (e.g., isoniazid, psychotropic drugs, antihistamines, and nonsteroidal anti-inflammatory drugs).¹⁷ Halothane-induced FHF occurs within 2 weeks after general anesthesia and carries a high mortality.¹⁸

Toxins Most cases of toxin-induced FHF involve mushroom poisoning or exposure to industrial hydrocarbons. In mushroom poisoning, the active agents are heat-stable and are not destroyed

by cooking.¹⁹ Liver damage from mushroom toxins is delayed and is usually preceded by several days of vomiting and diarrhea. Mortality is high: up to 22% in one series. Emergency liver transplantation is sometimes successful.²⁰ Industrial hydrocarbons (e.g., carbon tetrachloride, trichloroethylene) are rare causes of FHF. In developing nations, aflatoxin and herbal medicines have been implicated as causes of FHF.

Acute, severe ethanol intoxication may result in the development of acute alcoholic hepatitis (AAH), a condition associated with high mortality. Treatment with steroids improves survival in AAH patients; other measures are instituted to treat complications and associated conditions (e.g., withdrawal syndrome and malnutrition). Liver transplantation has not been advocated for treatment of acute AAH.

Miscellaneous

ALF may be caused by any of a number of miscellaneous processes, including metabolic, vascular, and autoimmune conditions. The most frequent metabolic cause of ALF is Wilson disease, which may present as FHF or SHF with intravascular hemolysis and renal failure.^{21,22} A family history of hepatic and neurologic disease, the presence of Kayser-Fleischer rings, and low serum ceruloplasmin levels help establish the diagnosis. Acute decompensated Wilson disease carries a high mortality and is an indication for emergency liver transplantation.²³

Acute fatty liver of pregnancy is a rare cause of FHF associated with high mortality for both mother and infant. Delivery of the fetus results in regression of the microvesicular steatosis and improvement in liver function for the mother. The risk of FHF is increased with misdiagnosis and continuation of pregnancy. Liver transplantation has been successfully performed to treat this condition.²⁴

An unusual cause of ALF is the Budd-Chiari syndrome (acute hepatic vein thrombosis). The typical patient is a young woman who presents with right upper quadrant pain of acute onset, hepatomegaly, and ascites. The clinical course is usually benign, and liver enzyme levels normalize promptly. Occasionally, however, the syndrome progresses to FHF. Portal decompression sometimes treats this type of ALF successfully if done before massive hepatic necrosis occurs; once FHF develops, liver transplantation is the only option.

Acute autoimmune hepatitis can cause FHF. It is typically seen in female patients and may occur either with or without known autoimmune disorders. A panel of reactive antibodies confirms the diagnosis. High-dose steroid therapy usually arrests the process, resulting in rapid normalization of liver enzyme levels. In 10% to 20% of cases, urgent liver transplantation is necessary.

Several other conditions and disease processes are also known to cause ALF in both adults and children [see Table 1].

ASSESSMENT OF PROGNOSIS

Several prognostic criteria and indicators have been developed for predicting outcome after optimal medical management of FHF. The two main factors determining likelihood of survival are (1) the extent of liver necrosis and (2) the potential for hepatocyte regeneration. In a 1989 study, investigators at King's College Hospital in London compiled a set of indicators for predicting a poor outcome after medical therapy and hence the need for emergency liver transplantation.²⁵ The underlying cause of FHF was the single most important predictive variable. Accordingly, patients were divided into two groups, one comprising all cases of acetaminophen-induced FHF and the other all cases of FHF from other causes. Age, degree of encephalopathy, serum pH, prothrombin time (PT),

tive of survival when measured within 6 hours after admission.²⁷ Assessment of the residual functional reserve of the liver has been studied as an indicator of prognosis. The ratio of acetoacetate to β -hydroxybutyrate in an arterial blood sample (also known as the arterial ketone body ratio [AKBR]) is thought to reflect hepatic energy status.²⁸ Galactose clearance reflects both residual liver mass and hepatic blood flow.²⁹ This test has long been considered a standard test of hepatic functional reserve, and newer tests are routinely compared to it. At present, functional assessment tools are not widely used.

At our center, we apply the King's College criteria on admission to predict the likely outcome with medical therapy. Once the initial assessment is completed, the decision to proceed with emergency evaluation for liver transplantation is made. Evaluation, if indicated, is usually completed within 12 to 24 hours. The evaluation is similar to that of patients with chronic liver disease [see Chronic Liver Disease, below], with a few exceptions. Patients with FHF usually do not have preexisting liver disease; thus, it is vital that the evaluation [see Table 3] reveal the probable cause of liver failure. Unlike chronic liver disease, FHF is associated with cerebral edema and elevated ICP, which is the leading cause of death in these patients. Therefore, an extensive neurologic evaluation should be completed before a patient is listed for transplantation. Serial neurologic assessment is necessary to rule out irreversible brain damage and brain-stem herniation; use of short-acting sedatives make this evaluation less difficult.

TREATMENT OF COMPLICATIONS**Cerebral Edema**

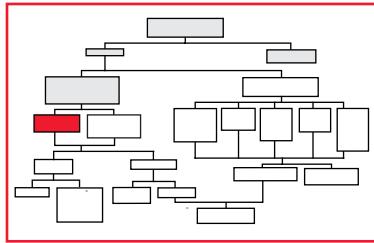

Cerebral edema develops in most patients with FHF, and its presence significantly influences management and outcome. Autopsy studies indicate that cerebral edema is present in 80% of patients who die of FHF.^{30,31} It occurs in advanced stages of FHF and can be recognized by clinical, radiologic, or invasive means. Clinical findings include decerebrate posturing, myoclonus, spastic rigidity, seizure activity, systemic hypertension, bradycardia, hyperventilation, and mydriasis with diminished pupillary response. These findings initially are paroxysmal but later become persistent. Papilledema is a late finding and often does not occur at all, even in advanced stages of the disease.³² Noninvasive diagnostic modalities (e.g., CT scanning, electroencephalographic monitoring, and transcranial Doppler flow measurement) have not proved helpful for early detection and management of cerebral edema.^{33,34} CT scanning of the brain is not a sensitive test for detecting early cerebral edema: 25% to 30% of patients with elevated ICP exhibit no radiographic changes.³⁵ It is, however, useful for ruling out intracranial bleeding.

Currently, ICP monitoring is the best means of monitoring intracranial hypertension and is recommended for guiding treatment in patients with stage III or IV encephalopathy. ICP can be measured by using epidural, subdural, or intraventricular catheters. Although epidural catheters are slightly less sensitive to ICP changes, they have the lowest complication rate (3.8%) and the lowest rate of fatal hemorrhage (1%).³⁶ Despite a slightly higher complication rate, we prefer subdural catheters: in our view, they offer more reliable ICP monitoring. Institution of ICP monitoring is followed by aggressive treatment of any concomitant coagulopathy. FFP infusions are given to bring the PT below 25 seconds,

time of onset of encephalopathy, and admission serum creatinine and bilirubin levels also proved to be significant variables [see Table 2]. Patients who met the criteria in either group had a 95% chance of dying with medical therapy alone and were identified as candidates for emergency liver transplantation. The major strength of the King's College study is that it based patient assessment on parameters that are easily obtained within a few hours of admission to the emergency department. This approach to assessment facilitates early transfer of patients with a poor prognosis to a specialized liver unit for evaluation for transplantation.

In another study, plasma factor V level and age were found to be independent predictors of survival.²⁶ The criteria for liver transplantation were the presence of hepatic encephalopathy (stage III or IV) and a factor V level either less than 20% of normal in patients younger than 30 years or less than 30% of normal in patients older than 30 years.

Other predictive models have been developed. A study of 59 patients with non-acetaminophen-induced FHF showed that plasma levels of albumin, lactate, valine, and pyruvate were predic-

and platelet transfusions are given if the patient has severe thrombocytopenia (platelet count < 50,000/mm³). Once ICP monitoring is established, bolus administration of FFP is repeated as needed to keep the INR below 5 so as to reduce the risk of intracranial bleeding. To minimize the need for ICP monitoring, it has been suggested that patient selection should be based on reverse jugular oxygen saturation; saturations lower than 65% or higher than 80% are associated with a high likelihood of elevated ICP.³⁷

The goal of invasive monitoring is to keep the ICP below 15 mm Hg while keeping CPP, which is a better predictor of outcome, above 50 mm Hg. CPP is calculated by subtracting the ICP from the mean arterial pressure (MAP). ICP monitoring allows early detection of cerebral edema and hence earlier introduction of aggressive management. To date, no randomized, controlled trials have addressed the effect of high ICP and low CPP on outcome after liver transplantation; however, it appears that persistence of either an ICP higher than 25 mm Hg or a CPP lower than 40 mm Hg for more than 2 hours is associated with an increased risk of irreversible brain damage and a poor outcome.^{38,39}

Management of elevated ICP involves hyperventilation, minimization of external stimuli, deep sedation, elevation of the head, maintenance of hemodynamic stability, and infusion of mannitol. Patients are usually sedated with a short-acting agent (e.g., propofol) in small boluses before a procedure, nasotracheal suction, venipuncture, or line placement. Mechanical hyperventilation reduces ICP by lowering arterial carbon dioxide tension ($P_a\text{CO}_2$) to 25 to 30 mm Hg, thereby maximizing cerebral vascular constriction and reducing blood flow. This vascular effect diminishes progressively after 6 hours of therapy, though a clinical response is apparent for days. As many as 80% of patients without renal failure respond to mannitol infusions.⁴⁰ Serum osmolality should be measured frequently and maintained at 300 to 320 mOsm/L. Mannitol should be withheld if osmolality reaches or exceeds 320 mOsm/L, if renal failure occurs, or if oliguria and rising serum osmolality develop simultaneously. Repeated administration of mannitol may reverse the osmotic gradient. Mannitol should be discontinued if the ICP does not respond after the first few boluses.

Table 2 King's College Hospital Prognostic Criteria Predicting Poor Outcome for Patients with FHF

Acetaminophen-induced FHF	pH < 7.30 (irrespective of grade of encephalopathy) <i>or</i> All of the following: PT > 100 sec (INR > 6.5) Serum creatinine > 3.4 g/dl Stage III or IV hepatic encephalopathy
Non-acetaminophen-induced FHF	PT > 100 sec (INR > 6.5) (irrespective of grade of encephalopathy) <i>or</i> Any three of the following (irrespective of grade of encephalopathy): Age < 10 or > 40 yr Etiology: non-A, non-B hepatitis, halothane hepatitis, drug toxicity Duration of jaundice to encephalopathy > 7 days PT 50 sec (INR > 3.5) Serum bilirubin > 17.5 g/dl

Acute renal failure is a frequent complication. Fluid management is very difficult in this setting. Continuous hemofiltration or continuous venovenous hemodialysis (CVVHD) can be beneficial. Continuous hemofiltration is less deleterious than intermittent therapy in the management of patients with brain edema and renal dysfunction,¹⁶ probably because it does not cause the large fluid shifts that can occur with the intermittent technique.

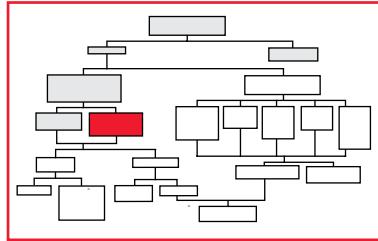

Patients who do not respond to conventional therapy may be placed in a barbiturate coma. Thiopental infusion decreases cerebral metabolic activity, lowers CNS oxygen demand, and protects the brain from ischemic injury secondary to decreased cerebral blood flow. In a retrospective, nonrandomized study, it lowered ICP and reduced mortality from FHF.⁴¹ In our experience, however, the effect of thiopental infusion on ICP is transient and unpredictable. Subclinical seizure activity has been detected in as many as 24% of ALF patients, but in a 2004 study, administration of phenytoin with control of the abnormal electrical activity did not affect overall outcome in ALF patients with seizures.⁴² In a study of 30 patients with ALF, the use of hypertonic saline led to significantly decreased ICP levels.⁴³ Administration of indomethacin or dexamethasone has led to modest reductions of ICP.

Studies evaluating the use of mild hypothermia (32° to 33° C [89.6° to 91.4° F]) in managing ALF reported significant decreases in ICP in all patients, some of whom were cooled for as long as 5 days.^{44,45} Bleeding and other coagulation disorders were not

observed; however, upon rewarming, a rebound effect was noted with an increase in ICP. In view of these findings, the authors suggested caution and recommended gradual, gentle rewarming. In addition, they found that liver implantation could be successfully performed under hypothermic conditions. Moderate hypothermia appears to be a promising experimental technique in ALF patients, but its utility in clinical practice remains to be determined.

Other Complications

In addition to cerebral edema and increased ICP, MODS and a variety of life-threatening complications are associated with FHF. Most of these complications are similar to those seen in chronic liver disease [see Chronic Liver Disease, Treatment of Complications, *below*]; however, the following complications are seen with particular frequency in FHF.

Fluid, electrolyte, and nutritional abnormalities Euvoolemia must be maintained to prevent fluid overload, pulmonary edema, and dehydration; extreme fluid shifts should be avoided. The presence of cerebral edema and intracranial hypertension calls for careful fluid administration so as not to expand the intravascular space or exacerbate the edema. Electrolyte and acid-base imbalances are frequent in FHF patients and should be managed appropriately. Hyperkalemia may be multifactorial; usually it is secondary to liver necrosis, massive transfusion, acid-base imbalance, and renal failure. Acidosis results from increased lactic acid production and decreased handling of lactate by the failing liver. Compensatory respiratory alkalosis develops initially, but if encephalopathy progresses, respiratory acidosis may result. Sodium or potassium bicarbonate infusions should be administered in cases of severe acidosis. Acetate provides twice the bicarbonate load and is metabolized outside the liver; thus, if sodium and potassium intake is severely restricted, continuous infusion of acetate salts may be useful.

Initially, amino acids should be withheld to prevent excessive nitrogen loading; later, limited nitrogen supplementation (70 to 80 g protein/day) may be provided. Most patients present with severe hypoglycemia that can be fatal and warrants aggressive therapy. Hypoglycemia should be corrected rapidly by infusion of 50% dextrose, followed by continuous infusion of a more dilute solution at a rate of 4 mg/kg/min. A 10% solution is usually adequate; however, higher concentrations should be considered in patients whose hypoglycemia persists or whose fluid intake is restricted. Caloric supplementation has not been extensively studied in FHF.

Renal failure Renal failure occurs in as many as 55% of FHF patients. Functional renal failure is a common cause of renal failure in this population. However, acute tubular necrosis (ATN) is more common in these patients than in those with chronic liver disease and cirrhosis.⁴⁶ This is especially true in patients who have not been resuscitated adequately, who have experienced prolonged hypotension, or who have ingested hepatotoxins that are also nephrotoxic (e.g., acetaminophen).

Adequate urine volume can be maintained by judicious volume expansion, administration of loop diuretics, or both, along with infusion of low doses of dopamine. Depleted intravascular volume may be managed by giving blood products, volume expanders, or both. Because plasma albumin levels are invariably low, salt-poor

albumin solutions may be preferable to carbohydrate-based volume expanders. If oliguria is present, especially if mannitol is administered to treat ICP, hemodialysis or hemofiltration may be needed to maintain optimal fluid volume.

Hemodynamic and pulmonary complications Circulatory disturbances tend to occur at an early stage of ALF and to worsen over the course of the illness; they are characterized by generalized vasodilatation, resulting in increased cardiac output and reduced systemic vascular resistance and MAP.⁴⁷⁻⁴⁹ The mechanisms of these hemodynamic disturbances are unclear, but increased levels of nitric oxide and cyclic guanosine monophosphate (cGMP) have been demonstrated during the later stages of the disease.⁵⁰ Fluids are managed so as to achieve euvoolemia (see above). A particular problem in managing hypotension related to ALF is that autoregulation of cerebral blood flow is typically lost.⁵¹ Terlipressin (a vasopressin analogue) is widely used in patients with end-stage liver disease (ESLD) and hepatorenal syndrome (HRS). This agent acts through both V1 receptors, which are distributed in the systemic circulation and mediate vasoconstriction, and V2 receptors, which are distributed in the cerebral vasculature and mediate cerebral vasodilatation. The role of terlipressin in the hemodynamic management of patients with ALF remains unclear.

Pulmonary complications, especially pulmonary edema, aspiration pneumonia, and ARDS, are common in FHF patients.⁵² Pulmonary edema is seen in as many as 40% of patients. Supplemental oxygen and mechanical ventilation are indicated. Sedative and paralytic agents may be required to ensure tolerance of ventilation; however, they should be used sparingly because they may hinder neurologic evaluation. Aspiration pneumonia is a potential contraindication to transplantation and should therefore be treated aggressively.

Infectious complications Infection poses a serious threat to FHF patients both by placing them at risk for sepsis and by being a contraindication to liver transplantation. Immunologic defects observed in this setting include impaired opsonization, impaired chemotaxis, impaired neutrophil and Kupffer cell function, and complement deficiency.^{53,54} Bacterial translocation through a failed mucosal barrier has been implicated as one of the factors responsible for a high incidence of septic episodes in this population. Gram-negative organisms and the lipopolysaccharide derived from their cell walls promote a systemic inflammatory response that aggravates the patient's overall condition.⁵⁵ To lower the risk of infectious complications, some groups advocate selective gut decontamination. This practice appears to have no significant advantages over systemic antibiotic prophylaxis alone.⁵⁶

Bacterial infection, usually originating from the respiratory or the urinary tract or from a central venous catheter, occurs in more than 80% of cases. In one study, bacteremia was documented in 25% of patients, with staphylococci, streptococci, and gram-negative rods the most common pathogens.⁵⁷ Because most FHF patients have percutaneous lines and indwelling catheters in place, iatrogenic sources must always be considered. Fungal infection is less common than bacterial infection in this setting; however, one series found a significant incidence of fungal infections, with *Candida albicans* cultured in 33% of the patients studied.⁵⁸ The majority of the patients had renal failure and had been treated with antibiotics for longer than 5 days.

The high prevalence of infection notwithstanding, we do not advocate antibiotic prophylaxis in this population unless either there is strong suspicion of active infection or an ICP monitor is in place. However, our decision threshold for initiating antibiotic

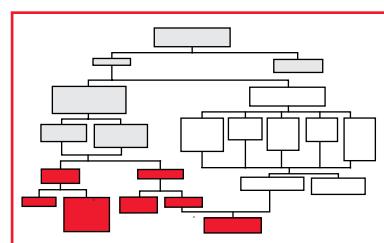

therapy is low, given that the usual clinical presentation (fever and leukocytosis) may be absent in as many as 30% of FHF patients.⁵⁷ Surveillance cultures for bacteria and fungi must be obtained at frequent intervals from blood (peripheral and central lines), urine, sputum, and open wounds. If ascites is present, the ascitic fluid should be cultured. In addition, chest radiographs should be obtained to identify developing infiltrates. Administration of broad-spectrum antibiotics should be initiated at the first sign of infection; as soon as an organism is identified, specific treatment may be focused more narrowly. Initiation of antifungal therapy with either fluconazole or another agent should be considered if a fungal culture is positive and if fever persists beyond 5 days while the patient is on antibiotics, especially if renal failure is present. The duration of antimicrobial therapy should be individualized for each patient. Follow-up cultures are recommended if a specific organism is isolated.

Coagulopathy and bleeding Bleeding is a frequent complication of FHF, typically resulting from massive liver necrosis, impaired hepatic synthesis of clotting factors, and platelet dysfunction. All clotting factors synthesized by the liver (i.e., factors II, V, VII, IX, and X) exhibit depressed plasma activity in FHF. Factor II, with a half-life of 2 hours, is the first to be depleted with hepatocellular dysfunction and also the first to be repleted during hepatocellular recovery. PT is invariably prolonged, reflecting a generalized clotting factor deficiency; it is used as one of the criteria for determining the likelihood of spontaneous recovery. At some centers, FFP transfusion is withheld and PT is followed carefully to determine upward or downward trends in the course of the disease and hence the likelihood of either spontaneous recovery or need for transplantation (unless the PT is greater than 25 seconds or the INR is greater than 5, especially if an ICP monitor is in place). Intracranial bleeding is the most devastating complication of coagulopathy in FHF patients with ICP monitors in place. In a 2003 study, administration of recombinant factor VIIa showed promising results in a group of patients with refractory coagulopathy.⁵⁹

Thrombocytopenia and abnormalities of platelet function are also common in FHF. Acute splenomegaly, consumptive coagulopathy, and bone marrow suppression all contribute to the development of thrombocytopenia. Conversely, clearance of older platelets from the blood by the reticuloendothelial system is hindered, resulting in an older, less effective platelet pool. In one study, a mean platelet count of 50,000/mm³ was associated with a higher incidence of GI hemorrhage.⁶⁰ Our current practice is to give platelets to patients who either are thrombocytopenic (platelet count < 50,000/mm³) or are actively bleeding.

MULTIDISCIPLINARY MEDICAL THERAPY AND INDICATIONS FOR LIVER TRANSPLANTATION

Because of the complexity of the underlying disease, medical management of FHF requires a multidisciplinary approach. Hemodynamic and respiratory support and prevention and treatment of cerebral edema are major goals. Complications of hepatic failure must be treated aggressively to prevent sepsis, ARDS, and MODS, which is the second most common cause of death in these patients if they survive the first few days. As noted [see Assessment of Prognosis, above], liver transplant evaluation must be carried out simultaneously with aggressive ICU care, and the patient's chances of spontaneous

taneous recovery must be assessed. In addition to determining the King's College prognostic score on admission, we follow the general trend in clinical course with respect to the development of encephalopathy, ICP elevation, coagulopathy, metabolic acidosis, and renal failure. The decision whether to continue with medical therapy or to perform liver transplantation must be made whenever a donor liver becomes available. In general, patients who appear to be deteriorating rapidly and who have no contraindications to liver transplantation should undergo emergency liver transplantation. Similarly, patients whose synthetic function does not improve within the first 48 to 72 hours should be considered for liver transplantation: the risk of complications and death from MODS if transplantation is not performed outweighs the risk of the procedure.

Toxic Liver Syndrome

Even with a multidisciplinary, comprehensive approach to therapy, a few patients with FHF go on to manifest the so-called toxic liver syndrome, characterized by severe intracranial hypertension, profound lactic acidosis, hemodynamic instability, and MODS. It has been suggested that removal of the necrotic liver may improve the hemodynamic status of these patients and lower their ICP. In such extreme cases, a two-stage procedure has been performed: total hepatectomy with an end-to-side portacaval shunt, followed by liver transplantation when an allograft becomes available. In one large series,^{61,62} 32 adult patients with toxic liver syndrome underwent total hepatectomy with a portacaval shunt. The patients were anhepatic for 6.5 to 41.4 hours. Whereas 13 patients showed no signs of improvement after hepatectomy and soon died of MODS, 19 became more stable and underwent the full procedure. Only seven patients were alive at 46 months.

In the early 1990s, we used this approach to treat an 18-year-old female patient with uncontrollable cerebral edema secondary to FHF; she underwent total hepatectomy with a portacaval shunt, followed by orthotopic liver transplantation (OLT) 14 hours later.⁶³ During the anhepatic period, she was supported with the help of a bioartificial liver (BAL) [see Discussion, Bioartificial Liver Support System, below]. With artificial liver support, the severe neurologic dysfunction was reversed, ICP was normalized, and the serum ammonia level was reduced. The patient recovered completely, with no neurologic deficits. We subsequently used the same approach with another FHF patient, also successfully (unpublished data). It appears that for highly selected patients exhibiting severe toxic metabolic derangement and uncontrollable intracranial hypertension, total hepatectomy with a portacaval shunt—preferably accompanied by some form of artificial liver support—followed by OLT may be considered as a desperate salvage measure.

LIVER TRANSPLANTATION

With the introduction of orthotopic OLT as a treatment modality for FHF patients, overall patient survival improved from less than 20% to greater than 60%.^{64,65} As more experience was gained with OLT, it became apparent that optimal patient selection is essential for a successful outcome. FHF patients must be considered for OLT before irreversible brain injury, MODS, and sepsis develop. Patient selection should be based on a clear understanding of the natural history of the disease, the underlying cause, and the likelihood of spontaneous recovery without transplantation.

One of the most difficult aspects of managing FHF patients is the lack of reliable prognostic criteria predicting outcome. In our experience, the King's College criteria are less sensitive and specific in determining prognosis for patients with acetaminophen-induced FHF than for patients with FHF from other causes. As

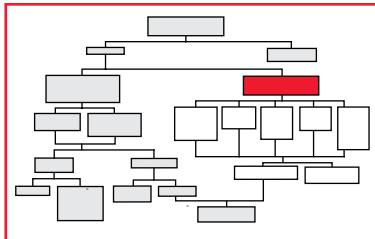

a result, a small number of patients who either might have recovered spontaneously or might have sustained irreversible brain damage undergo unnecessary or unwarranted liver transplantation. Given the severe shortage of organ donors, as well as the cost and morbidity of liver transplantation and a commitment to lifelong immunosuppression, this is a significant problem.

Two interacting factors tend to influence the outcome of transplantation in the setting of ALF: (1) the severity of the illness before transplantation and (2) the condition of the graft used. The importance of the second factor was illustrated by the early experience with liver transplantation in France. Initially, French surgeons used the first available graft for ALF patients, regardless of its size, quality, or blood group compatibility. Subsequently, a study of 116 patients demonstrated that outcomes were significantly worse when adverse graft conditions (i.e., marginal quality, reduced size, and ABO incompatibility) were present.⁶⁶

Some centers have successfully performed living donor liver transplantation in ALF patients.⁶⁷ This approach has been more commonly employed in pediatric patients.⁶⁸ Wider application has been limited by the risks this procedure poses to the donor in a setting where, because of the rapid progression of the disease, there is rarely enough time to evaluate potential donors appropriately and to eliminate the elements of pressure and coercion.⁶⁹ The potential for not just one but possibly two tragic outcomes must be emphasized.

Management of Chronic Liver Disease

Chronic liver disease usually develops as a result of long-standing, ongoing liver injury. The repeated injury and the ensuing repair usually result in deposition of an excessive amount of extracellular matrix (ECM), with or without accompanying inflammation. As the disease process progresses, excess ECM forms connective tissue bridges linking portal and central areas (so-called bridging fibrosis), eventually leading to cirrhosis. Cirrhosis is an irreversible state that gives rise to significant physiologic impairment, including poor exchange of nutrients and metabolites between sinusoidal blood and hepatocytes. Eventually, the lobular architecture becomes distorted and blood flow altered, leading to PHT and its numerous complications. In addition to PHT, repeated parenchymal injury results in the loss of a large number of functioning hepatocytes and subsequently leads to hepatic failure.

CLASSIFICATION

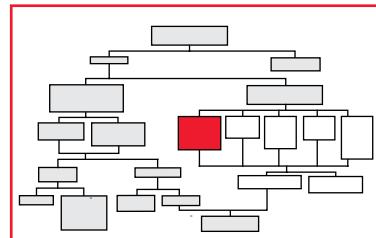

Like ALF, chronic liver disease is usually classified on the basis of the underlying cause [see Table 4]. According to the United Network for Organ Sharing (UNOS), the most common indication for liver transplantation in North America is chronic liver disease resulting from HCV infection. Other common indications are alcohol-induced liver disease, cholestatic liver disease (primary sclerosing cholangitis, primary biliary cirrhosis, autoimmune liver disease), and cryptogenic cirrhosis. The occurrence of the metabolic syndrome (obesity, diabetes, and hypertension) is the most important risk factor for the development of nonalcoholic steatohepatitis (NASH), which is the most common cause of cryptogenic cirrhosis.

TREATMENT OF COMPLICATIONS

Chronic liver disease may be associated with a variety of complications, depending on the nature and extent of hepatocyte injury and regeneration. Most patients with chronic liver disease and possible cirrhosis are well compensated, maintain a relatively normal functional status, and remain essentially undiagnosed; however, a small percentage of patients become symptomatic. Hepatic failure secondary to cirrhosis is not an all-or-none process: patients may lose one or more specific liver functions while retaining the remainder. In addition to hepatic effects, cirrhosis and hepatic failure can exert a wide range of extrahepatic effects that involve virtually every organ system, leading to MODS and death in most cases if appropriate therapy is not instituted promptly. Consequently, treatment of cirrhosis and chronic hepatic failure must focus on treating both the underlying primary disease and all of its extrahepatic manifestations and complications.

Portal Hypertension

In most patients with chronic liver disease and cirrhosis, PHT develops as a result of increased resistance to portal venous blood flow within the liver. PHT is defined as a portal venous pressure higher than

12 mm Hg or a hepatic wedge venous pressure that exceeds the inferior vena cava pressure by more than 5 mm Hg. It is classified as prehepatic, hepatic, or posthepatic according to the anatomic site of increased portal venous resistance. Hepatic PHT is further classified according to the functional relationship to the hepatic sinusoids [see 5:10 Portal Hypertension]. Sinusoidal obstruction is more frequently seen with postnecrotic cirrhosis (e.g., cirrhosis resulting from HCV and HBV infection), whereas postsinusoidal obstruction is more common with alcoholic cirrhosis. Prehepatic and posthepatic causes of PHT are less often encountered in

patients with cirrhosis; however, efforts should always be made to rule out such causes, because these conditions all require different therapeutic approaches.

PHT is associated with numerous complications, most of which are life-threatening if not diagnosed and treated promptly. The most dramatic and catastrophic complication of PHT is bleeding from esophageal and gastric varices. Prompt diagnosis and management are vital. Since the early 1990s, management of variceal bleeding has evolved significantly, thanks to the advent of novel endoscopic therapies and nonoperative portosystemic shunt procedures. Although the esophagus and the stomach are the most common sites of bleeding varices, other sites within the GI tract may be involved as well, including the duodenum, the jejunum, the rectum, and ileostomy and colostomy sites.

One of the principal clinical manifestations of cirrhosis and PHT is ascites (i.e., leakage of lymph fluid into the peritoneal cavity). The appearance of ascites is indicative of advanced liver disease and is associated with a poor prognosis.⁷⁰ It is believed that increased hepatic sinusoidal pressure results in increased formation of lymph and causes hepatic lymph to weep from Glisson's capsule into the peritoneal cavity. As ascitic fluid accumulates, patients exhibit increasing abdominal distention, which in turn causes abdominal pain, decreased appetite, dyspnea, and, occasionally, pleural effusion (so-called hepatic hydrothorax).

An elevated WBC count in the ascitic fluid provides immediate information about possible bacterial infection. Cell counts higher than 500/mm³ suggest bacterial peritonitis, especially when the absolute neutrophil count exceeds 250/mm³.⁷¹ More than 20% of cirrhotic patients with ascites eventually manifest SBP. Patients with a low total protein level in their ascitic fluid (< 1.5 g/dl) appear to be at highest risk as a result of the reduced complement level and opsonic activity in the fluid. The diagnosis of SBP should be considered in any cirrhotic patient with fever, abdominal pain, worsening encephalopathy, or deteriorating renal function. Ascitic fluid analysis [see Table 5] distinguishes SBP from secondary bacterial peritonitis that develops as a consequence of an intra-abdominal abscess or a perforated viscus. Like ascites, SBP carries a grave prognosis: the estimated 1-year survival is less than 50% without liver transplantation.^{72,73}

Evaluation and management of PHT and its associated complications are addressed further elsewhere [see 5:10 Portal Hypertension].

Hepatic Encephalopathy

Hepatic encephalopathy is a complex neuropsychiatric syndrome that is seen in patients with severe hepatic insufficiency and cirrhosis. It is characterized by progressive alteration of cognitive function and coordination and depression of consciousness, leading to deep coma. Hepatic encephalopathy takes two main forms: (1) acute encephalopathy associated with FHF and (2) portosystemic encephalopathy (PSE) associated with cirrhosis and portosystemic shunts. It is classified into four stages according to the severity and extent of CNS impairment [see Table 6].

For accurate diagnosis of hepatic encephalopathy, it is necessary to recognize and correct all other disorders that affect cerebral function, including fluid and electrolyte abnormalities, hypoglycemia, azotemia, metabolic acidosis or alkalosis, hypoxia, and plasma hyperosmolality. Sedatives and paralytic agents should be

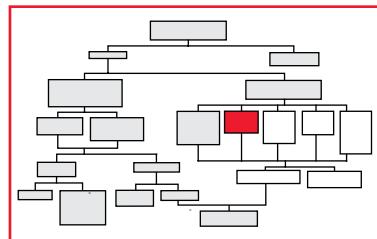

Table 5 Differentiation of Spontaneous Bacterial Peritonitis from Secondary Bacterial Peritonitis through Analysis of Ascitic Fluid

Fluid Assay	Spontaneous Bacterial Peritonitis	Secondary Bacterial Peritonitis
WBC (cells/mm ³)	> 500	> 500
Total protein (g/dl)	< 1.0	> 1.0
Glucose (mg/dl)	> 50	< 50
Lactic dehydrogenase (U/L)	< 225	> 225
Gram stain	Monomicrobial	Polymicrobial

avoided during the initial assessment period if possible; if sedation or paralysis is required, the combination of poor hepatic function with the shunting of blood away from the liver may greatly lengthen drug elimination, thereby complicating patient assessment. Frequently, patients with PSE carry out normal activities while the disorder goes unrecognized, and PSE is diagnosed only when its presentation is exaggerated by infection or GI bleeding. PSE is also exacerbated by constipation, the onset of portal vein thrombosis, and the development of a liver malignancy.

Management of PSE begins with treatment of all potential precipitating factors: sedatives and other drugs with CNS effects should be discontinued, fluid and electrolyte abnormalities should be corrected, GI bleeding should be controlled, and underlying infections (especially SBP) should be treated. Early endotracheal intubation for airway protection may be needed in patients with stage III or IV encephalopathy because of the high risk of aspiration and subsequent pneumonia.

The therapeutic objectives in the management of hepatic encephalopathy are (1) to minimize ammonia formation and (2) to augment ammonia elimination [see Discussion, Mechanism of Hepatic Encephalopathy, below]. Lactulose and certain antibiotics are commonly employed to achieve these ends. Lactulose is a synthetic disaccharide cathartic that can be delivered orally, through a nasogastric tube, or via a high enema and can be administered early in the course of the disease. The dosage should begin at 25 g/day and then be titrated to a level at which the patient can produce three or four loose bowel movements daily. Lactulose is nei-

Table 6 Grading of Hepatic Encephalopathy

Encephalopathy Stage	Neurologic Changes
Stage I	Mild confusion, euphoria or depression, decreased attention span, slowing of ability to perform mental tasks, irritability, disorder of sleep pattern
Stage II	Drowsiness, lethargy, gross deficit in ability to perform mental tasks, obvious personality changes, inappropriate behavior, intermittent and short-lived disorientation
Stage III	Somnolent but arousable, unable to perform mental tasks, disorientation with respect to time or place, marked confusion, amnesia, occasional fits of rage, speech present but incomprehensible
Stage IV	Coma

ther absorbed nor metabolized in the upper GI tract. When it reaches the colon, the ensuing bacterial degradation acidifies the luminal contents and causes an intraluminal osmotic shift. The more acidic environment inhibits coliform bacterial growth, thereby reducing ammonia production. Additionally, the low intraluminal gut pH causes ammonia to be converted to ammonium ions, which do not enter the bloodstream easily. Finally, the cathartic action of lactulose clears ammonium ions from the bowel. Aggressive lactulose therapy may induce volume depletion and electrolyte imbalance; metabolic acidosis is a rare occurrence.

Neomycin, an agent commonly used for bowel preparation, alters gut flora, especially *Escherichia coli* and other urease-producing organisms, and reduces the production of ammonia. About 1% of neomycin is absorbed systemically; because of possible ototoxicity and nephrotoxicity, special care should be taken if it is administered on a continuous basis.⁷⁴ Other oral antibiotics used to treat hepatic encephalopathy are polymyxin B, metronidazole, and vancomycin, which affect gut flora in much the same fashion as neomycin.

Aromatic amino acids (AAAs) are known neurotransmitter precursors. It has been suggested that their products interfere with the activity of true neurotransmitters. It has also been shown that the ratio of branched-chain amino acids (BCAAs) to AAAs in plasma decreases steeply with worsening encephalopathy. Because AAAs and BCAAs compete for the same blood-brain barrier carrier transport sites, the relative paucity of BCAAs leads to increased cerebral uptake of AAAs, which in turn promotes synthesis of false neurotransmitters that then compete with the endogenous transmitters dopamine and norepinephrine.⁷⁵ Parenteral administration of BCAA-enriched formulas to patients with hepatic encephalopathy has been advocated, but it has not proved beneficial when compared with administration of conventional amino acid solutions.⁷⁶

Renal Failure

Liver disease and cirrhosis are commonly associated with functional renal failure—that is, impaired renal function in the absence of significant underlying renal pathology. The most common functional renal abnormality in cirrhotic patients is HRS, which is defined as a reversible state of renal failure characterized by azotemia, oliguria (< 10 mEq/L), and an increased urine-plasma osmolality ratio (U/P > 1.0) in the absence of urinary sedimentation. HRS occurs in 18% to 55% of cirrhotic patients with ascites and is typified by intense renal vasoconstriction, a decreased glomerular filtration rate (GFR), preserved tubular function, and normal renal histology.^{46,77} Although the exact cause of HRS is not known, current evidence suggests that it is multifactorial, involving systemic vasodilatation and reduced effective plasma volume, along with increased activity of the renin-angiotensin-aldosterone system, which causes further reduction of the GFR. HRS is classified as either type 1 or type 2. In type 1 HRS, renal failure is rapidly progressive, as defined by a doubling of the initial serum creatinine level to a value higher than 2.5 mg/dL or a 50% reduction in the initial creatinine clearance to a value lower than 20 mL/min in less than 2 weeks. In type 2 HRS, renal failure takes a slower, more gradual course.

The prognosis for patients with HRS is poor: to date, all therapeutic approaches have proved unsuccessful. Pharmacologic therapy has consisted of correcting effective volume status and attempt-

ing to reverse renal vasoconstriction through I.V. administration of vasodilators (e.g., dopamine, misoprostol, and aminophylline) or drugs that inhibit the synthesis or the effects of endogenous vasoconstrictors (e.g., captopril and thromboxane inhibitors). These approaches have not yielded effective and reproducible improvements in renal hemodynamics and renal function. Several investigators have reported improved renal function after OLT.^{46,77}

An approach to the management of HRS has been introduced that is aimed at correcting the primary underlying defect (i.e., systemic vasodilatation) instead of the secondary renal vasoconstriction. Two classes of drugs have been investigated: (1) agents that inhibit the effects of endogenous systemic vasodilators (e.g., prostacyclin, nitric oxide, and glucagon) and (2) agents that cause systemic vasoconstriction (e.g., ornipressin and terlipressin). In one small series of patients with type 1 HRS, a combination of an oral beta-adrenergic drug with midodrine and octreotide led to improved renal function and better long-term outcome.⁷⁸

Besides functional renal failure, various types of nonfunctional (i.e., organic) renal failure may occur in patients with cirrhosis (e.g., ATN, renal tubular acidosis [RTA], and drug-induced interstitial nephritis). ATN is especially common in patients with chronic liver disease or FHF and is usually seen in patients who are poorly resuscitated, have experienced prolonged hypotension, have undergone severe septic episodes, or have ingested hepatotoxins that are also nephrotoxic (e.g., acetaminophen). ATN is characterized by an abrupt rise in blood urea nitrogen (BUN) and serum creatinine levels, accompanied by oliguria or anuria. Unlike HRS, ATN leads to impairment of the concentrating ability of the tubular system and to excessive urinary sodium excretion; accordingly, a urine sodium concentration greater than 10 mEq/L is considered diagnostic for ATN in cirrhotic patients [see Table 7]. RTA is commonly seen in patients with primary biliary cirrhosis, autoimmune liver disease, and alcoholic cirrhosis. It is characterized by the inability of the renal tubules to acidify the urine in the presence of a normal GFR.

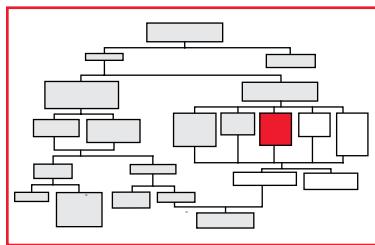

Table 7 Differentiation of Hepatorenal Syndrome from Acute Tubular Necrosis

Criteria	Hepatorenal Syndrome	Acute Tubular Necrosis
Underlying liver disease	Advanced liver damage with jaundice and impaired synthetic function	Mild or severe liver disease
Precipitant	GI bleeding, diuretics, paracentesis, sepsis, or none	Shock, nephrotoxins, sepsis
Onset	Days to weeks	Hours to days
Urinalysis	Renal epithelial cells with or without pigmented granular cells	Pigmented granular casts with or without RBCs, WBCs
Urinary sodium concentration	< 10 mEq/L	> 10 mEq/L
Urinary osmolarity	> Serum osmolarity	Isotonic
Urinary volume	Oliguric	Variable
Course	Progressive, unremitting	Deterioration followed by improved renal function

Management of renal failure is usually aimed at correcting the underlying precipitating causes. In patients with ascites, who experience ongoing loss of fluid and protein into the peritoneum, it is important to maintain an adequate intravascular volume. If intravascular volume is depleted, blood components, volume expanders, or both should be given. Given that the plasma albumin level is invariably low in these patients, salt-poor albumin solutions may be preferable to carbohydrate-based volume expanders. Albumin replacement has been effectively used for volume expansion after LVP.⁷⁹

Because of the complex physiologic liver-kidney interaction, fluid and electrolyte management often proves challenging. It is difficult to estimate the actual intravascular volume, which is depleted in most cirrhotic patients even though total body fluid volume is greater than normal. Sodium retention and free water retention are the two most common abnormalities of renal function that lead to ascites and dilutional hyponatremia. Typically, sodium retention is an early manifestation, whereas water retention and renal failure are late findings. Nephrotoxic drugs and I.V. contrast agents should be avoided, and dosages of antibiotics and other medications should be adjusted appropriately.

Hypernatremia and metabolic acidosis can develop secondary to excessive lactulose therapy and dehydration and result in renal function deterioration. Hypokalemia is also common; it develops secondary to increased serum aldosterone concentration, which leads to excessive excretion of potassium in exchange for sodium. Once renal failure develops, hyperkalemia, hypercalcemia, and hyperphosphatemia become significant problems, often necessitating dialysis.

Malnutrition

Most cirrhotic patients present with depleted glycogen stores, severe protein-calorie malnutrition, and wasting. Impaired hepatic synthetic activity, causing a deficiency of both visceral and structural proteins, is one of the hallmarks of advanced liver disease. In addition, poor appetite, tense ascites, abdominal pain, and excessive loss of protein through repeated LVP and overall increased energy expenditure tend to exacerbate malnutrition.

Excessive protein administration can induce hepatic encephalopathy; accordingly, protein intake should be limited to 1 to 1.2 g/kg/day. Glucose is the main energy source given to malnourished cirrhotic patients; however, its use is not without complications, in that these patients typically exhibit glucose intolerance. Lipid emulsion can be safely administered to most patients with hepatic failure and should be withheld only from patients with overt coma.⁸⁰ It is generally agreed that the ideal energy source should consist of a mixture of glucose and fat emulsion. Approximately 30% to 40% of all nonprotein calories can be provided in the form of fat. The total energy requirement should be 25 to 35 kcal/kg/day.

As noted [see Hepatic Encephalopathy, *above*], although AAAs have been implicated in the pathogenesis of hepatic encephalopathy, administration of BCAA solutions has not proved helpful, and current evidence does not support their routine use.^{76,81}

In general, the potential risks and complications associated with total parenteral nutrition (TPN) outweigh the benefits in patients with a functioning GI tract. When properly administered, enteral nutrition is safer, more physiologically appropriate, and significantly more cost-effective than TPN. It should therefore be considered the first choice for nutritional support in most patients with chronic liver disease unless a contraindication to enteral feeding is present.

Coagulopathy and Nonvariceal Bleeding

The spectrum of coagulation disorders in patients with liver disease ranges from minor localized bleeding to massive life-threatening hemorrhage. Abnormal bleeding may be spontaneous in some patients, but it is more often the result of a hemostatic challenge (e.g., surgical wounds or procedures, gastritis, portal hypertensive gastropathy, gastric or duodenal ulcers, or ruptured varices). The underlying anatomic lesion is believed to be as responsible for bleeding as the hemostatic defect; accordingly, therapy should be directed at correcting both. In addition, general physiologic monitoring is maintained. A physiologic pH and a normal core temperature optimize coagulation factors and platelet function. Poor nutrition and cholestatic diseases are associated with depleted levels of vitamin K. I.V. administration of vitamin K₁ can be accomplished with minor complications.

Although most bleeding episodes are secondary to decreased synthesis of clotting factors, other causes of bleeding (e.g., defective or dysfunctional factor synthesis and increased consumption of clotting components) must be ruled out. In most patients, the decreased levels of clotting factors parallel the progressive loss of parenchymal cell function. Usually, the levels of the vitamin K-dependent factors (i.e., prothrombin, factor VII, factor IX, factor X, protein S, and protein C) fall first, followed by the levels of other factors as cirrhosis progresses. Factor V is synthesized independently of vitamin K availability, and its concentration is of special interest because the plasma factor V level seems to be a predictor of the extent of liver cell damage. Impaired synthesis of coagulation proteins also has an impact on antithrombin III (AT-III), protein C inhibitor, plasminogen, and α_2 -antiplasmin, as well as on several other inhibitors and activators of both the extrinsic coagulation pathway and the intrinsic pathway. The combination of decreased factor levels and impaired synthesis of coagulation proteins explains the prolongation of the PT, the activated partial thromboplastin time (aPTT), and the thrombin clotting time (TCT) in these patients.^{82,83}

Given the complexity of hemostasis in cirrhotic patients, accurate diagnosis of a bleeding disorder is often hard to achieve. Several disorders and abnormalities may be present simultaneously, and one or more parameters of hemostasis and coagulation may be impaired. Therefore, any effective treatment approach should be broad-based and aimed at correcting several deficiencies or abnormalities at once. FFP contains all of the components of the clotting and fibrinolytic systems but lacks platelets. In most cases, transfusion of 6 to 8 units of FFP corrects severe clotting factor defects; however, the excess volume may not be well tolerated. Cryoprecipitate, the precipitate formed when FFP is thawed at 4° C, is rich in factor VIII, von Willebrand factor, and fibrinogen but lacks the vitamin K-dependent factors. Therefore, it should be given only when the fibrinogen level is lower than 100 mg/dL. Prothrombin complex concentrates contain only the vitamin K-dependent factors and proteins, and their use can provoke serious thromboembolic complications, including DIC. Therefore, their potential utility must be weighed carefully against the risk that thrombotic events may develop.⁸⁴

Other major disorders of hemostasis in patients with chronic liver disease and cirrhosis involve platelets and are manifested as thrombocytopenia, abnormal platelet function (thrombocytopathy), or both. In most cases, thrombocytopenia is related to sple-

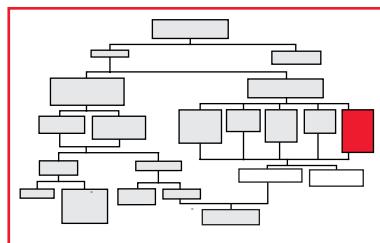

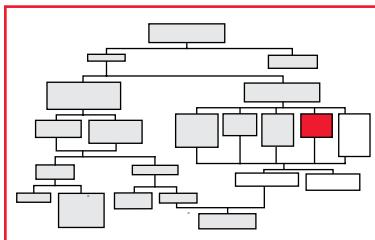

Table 8 Contraindications to Liver Transplantation

Absolute contraindications	Severe, irreversible brain damage
	HIV infection
	Extrahepatic malignancy
	Uncontrolled sepsis
	Severe pulmonary hypertension and advanced cardiopulmonary disease
	Active substance abuse or major psychosocial problems
	Extrahepatic portal vein thrombosis in patients with hepatocellular carcinoma
Relative contraindications	Elevated ICP or reduced CPP (in patients with FHF)
	Multiple organ dysfunction syndrome
	Hemodynamic instability
	Advanced age
	Portal vein thrombosis (except when secondary to hepatocellular carcinoma)

CPP—cerebral perfusion pressure ICP—intracranial pressure

omegaly and hypersplenism (a common feature of PHT). Abnormal platelet function is attributed to many causes, including intrinsic platelet defects and abnormal interaction among platelets, endothelial surfaces, and clotting factors. It is manifested by a prolonged bleeding time, impaired platelet aggregation, and reduced adhesiveness. Some authorities attribute the inhibition of platelet aggregation to fibrin degradation products (FDPs); however, the FDP levels noted in the plasma of cirrhotic patients are not sufficient to impair platelet aggregation, nor do they correlate with the observed reductions in platelet aggregation.⁸⁵

Platelets should be transfused whenever a patient with either a quantitative or a qualitative defect experiences active bleeding. A normal response is a rise of 10,000/mm³ with each unit transfused; however, in cases of hypersplenism and accelerated consumption, such a response is rare. Transfusion should be continued until all serious bleeding has ceased, with the therapeutic goal being the maintenance of a platelet count near 50,000/mm³. Platelet transfusion is also indicated before any surgical or invasive procedure (e.g., paracentesis or liver biopsy). Indications for prophylactic platelet transfusion are less clear, and any potential gains must be balanced against potential side effects and development of antibodies. Most patients with advanced cirrhosis and liver failure have platelet counts lower than 100,000/mm³; however, prophylactic platelet transfusion is usually not recommended until the count falls below 15,000 to 20,000/mm³, at which point the risk of spontaneous bleeding is considerably increased.

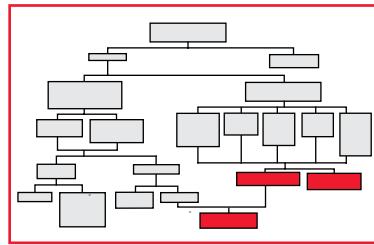

Another feature of severe liver disease is increased fibrinolytic activity, which may be either primary or secondary to DIC.⁸⁶ The precise causes of primary fibrinolysis and DIC remain unclear. Primary fibrinolysis appears to be a result of increased activity of tissue plasminogen activator and decreased levels of α_2 -antiplasmin.⁸⁷ DIC is believed to be triggered by the release of thrombo-elastic substances into the circulation as a consequence of liver cell damage or necrosis and by poor clearance of circulating activated tissue and clotting factors and FDPs by a defective reticuloendothelial system. Accelerated fibrinolysis is manifested by reductions in the whole blood clot lysis time and the euglobulin clot lysis time, as well as by elevated levels of fibrinolysis products (e.g., FDPs and D-dimer). Although enhanced fibrinolysis is relatively common in patients with cirrhosis, most of the characteristic abnormalities can occur after many types of physiologic stress and are not necessarily accompanied by a bleeding tendency.

At present, no satisfactory method of managing DIC is available. An extensive workup must be completed to rule out underlying causes (e.g., sepsis, ARDS, and MODS). FFP, platelet concentrates, and low-dose heparin (200 to 800 U/hr) may be given. AT-III concentrate has been used in an attempt to inhibit the action of thrombin, thereby decreasing procoagulant consumption, restoring normal levels of factors, and improving hemostasis. Clinical experience with AT-III therapy in this setting has been limited; however, there is evidence suggesting that AT-III may reduce hemostatic abnormalities and help control bleeding.⁸⁸

Antifibrinolytic agents (e.g., ϵ -aminocaproic acid and tranexamic acid) impede fibrinolysis and may be useful in treating bleeding in patients who have liver disease and show evidence of fibrinolysis.⁸⁹ In patients with DIC, administration of antifibrinolytic agents is contraindicated because of the potential for thrombotic complications. D-dimer levels should be determined to rule out DIC before use of these medications is considered. Because it is difficult to rule out DIC in patients with liver disease, the use of antifibrinolytic agents in liver disease is limited. Other antifibrinolytic compounds have been tested for use in liver transplantation. Of these, apronitin has been shown to reduce the number of packed red blood cells given during liver implantation in selected patients.

LIVER TRANSPLANTATION

In 2005, 6,444 liver transplants were performed in the United States in 2004. The 1-year survival rates for patients and grafts have improved to greater than 90% and 85%, respectively. At present, the main limiting factor for the continued growth of liver transplantation is the scarcity of donors. Living related donor liver transplants account for approximately 5% of the total number of transplants.

End-Stage Liver Disease

Liver transplantation is an accepted therapy for ESLD. The standard indications for liver transplantation are well documented⁹⁰; they include PHT, poor hepatic synthetic function, hepatic encephalopathy, progressing jaundice, severe malnutrition, and excessive fatigue. PHT is manifested by variceal bleeding, hypersplenism, thrombocytopenia, ascites, hepatic hydrothorax, and SBP. Poor synthetic function is usually manifested by an elevated INR and low serum albumin and cholesterol levels. In general,

Table 9 Child-Turcotte-Pugh Scoring System

Points	1	2	3
Encephalopathy	None	Stage I or II	Stage III or IV
Ascites	Absent	Slight (or controlled by diuretics)	Moderate despite diuretic treatment
Bilirubin (mg/dl) Patients with PBC or PSC	< 2 < 4	2–3 4–6	> 3 > 6
Albumin (g/L)	> 3.5	2.8–3.5	< 2.8

PBC—primary biliary cirrhosis PSC—primary sclerosing cholangitis

any concurrent medical or psychosocial condition that prohibits a major surgical procedure or subsequent immunosuppression constitutes a contraindication to liver transplantation [see Table 8].

UNOS currently regulates organ allocation to transplant candidates. In January 1988, minimal listing criteria for liver transplantation were implemented.⁹¹ These criteria were based on the Child-Turcotte-Pugh (CTP) scoring system [see Table 9], which includes five parameters: serum albumin and bilirubin levels, PT, ascites, and hepatic encephalopathy. Graft allocation had a subjective component, taking into account the time spent on the waiting list. The criteria currently used were implemented in February 2002 and are based on the Modeling for End-Stage Liver Disease (MELD) scoring system, which predicts patient survival without a liver transplant at 90 days.^{92,93} This scoring system was developed to predict survival in patients with cirrhosis after TIPS, and it has been shown also to predict patient survival after liver trans-

plantation.⁹⁴ The MELD score is calculated from three laboratory values that feed into a logistic regression formula: INR, serum creatinine level, and total bilirubin concentration. Modifications have been implemented to improve allocation, and exception policies are evolving. A similar scoring system, the Pediatric End-Stage Liver Disease (PELD) system, has been developed for pediatric patients, incorporating information on serum albumin levels and growth failure. A patient who has FHF is listed as status 1, and no MELD score is assigned.

Liver Cancer

Hepatocellular carcinoma (HCC) [see 5:9 *Tumors of the Pancreas, Biliary Tract, and Liver*] is 30 times more common in cirrhotic patients than in noncirrhotic patients. Its high growth rate and high mortality have prompted the development of exception points that favor HCC patients for rapid graft allocation.

Discussion

Mechanism of Hepatic Encephalopathy

The association between liver disease and altered mental status and consciousness has been recognized for centuries, but the exact underlying mechanism remains unknown. It appears that this syndrome has a multifactorial etiology and is associated with a number of complex changes, which are manifested collectively as hepatic encephalopathy. It is generally believed that hepatocerebral dysfunction is caused by an accumulation of cerebral toxins as a result of low hepatic clearance.⁹⁵

Of all the physiologic factors thought to contribute to the development of encephalopathy, the best known is ammonia. Arterial ammonia levels are frequently elevated in patients with hepatic encephalopathy; however, the clinical severity of hepatic encephalopathy correlates poorly with the ammonia level.⁹⁶ The precise contribution of ammonia to hepatic encephalopathy remains unclear; however, ammonia is known to inhibit the uptake of glutamate into astrocytes, thereby causing a rise in the extracellular glutamate level that appears to downregulate the postsynaptic glutamate receptors, resulting in decreased neuronal excitation.⁹⁷

Endogenous or exogenously ingested benzodiazepines may also play a role in the etiology of acute and chronic hepatic encephalopathy by interacting with the high-affinity γ -aminobutyric acid (GABA)-benzodiazepine receptor complexes. These substances are known to enhance inhibitory GABAergic tone. Animal studies suggest that gut flora may contribute benzodiazepine ligand activity,⁹⁸ as well as increased benzodiazepine receptor agonist activity.⁹⁹ Studies of FHF patients show increased benzodiazepine receptor ligands with enhanced GABAergic tone in all stages of encephalopathy.¹⁰⁰ Ammonia-induced activation of peripheral-type benzodiazepine receptors on astrocytes may cause the release of neurosteroids that enhance GABAergic neurotransmission. Hence, neurosteroids may potentiate the inhibitory actions of GABA at the receptor level, as well as lengthen the period during which the GABA ligand remains in the synaptic cleft. Ammonia also acts directly to potentiate GABAergic tone by enhancing the affinity of GABA for GABA-A receptors.¹⁰¹

These findings notwithstanding, there is no apparent correlation between benzodiazepine ligand activity and clinical stage of encephalopathy, nor is ligand elevation a consistent finding in all

patients. Furthermore, clinical and animal studies in which a benzodiazepine receptor antagonist has been administered have not shown consistent effects. The anecdotal success of flumazenil, the principal benzodiazepine antagonist, has been ascribed to the antagonism of benzodiazepines ingested by patients. Support for the concept of so-called endogenous benzodiazepines arising from the intestine can be found in a number of sources, including studies of dogs with congenital portacaval shunts, which document ligand activity in stool samples.¹⁰² Whether there is a causal relation to hepatic encephalopathy or whether this is merely a case of associated phenomena remains to be determined. Whatever the contribution of benzodiazepines to the pathophysiology of acute hepatic encephalopathy and cerebral edema, it appears likely that other mechanisms are involved.

Bioartificial Liver Support System

Despite the best management efforts, the morbidity and mortality associated with ALF remain exceptionally high. For most severe cases, liver transplantation is still the only effective therapeutic modality. Unfortunately, because of the severe organ donor shortage, the waiting period for transplantation is long, and patients consequently are at risk for the development of irreversible complications or contraindications to liver transplantation while awaiting a donor. In an effort to mitigate this problem, investigators have studied various artificial liver support systems designed to provide full metabolic, hemodynamic, and physiologic support until either the native liver regenerates or a liver becomes available for transplantation. From the 1970s to the 1990s, most therapeutic attempts focused primarily on detoxifying plasma. All such attempts either failed or had no significant impact on survival.¹⁰³

The ongoing severe organ shortage led several investigators to develop and test xenogeneic-based liver support systems employing whole-organ perfusion or isolated hepatocytes. We developed and tested a hybrid bioartificial liver (BAL) support system employing isolated porcine hepatocytes in an extracorporeal perfusion circuit. We subsequently initiated a clinical trial addressing the use of this system in patients with severe ALF as a bridge to either transplantation or spontaneous recovery.¹⁰⁴⁻¹⁰⁷

In 1997, the BAL our group developed (HepatAssist; Circe Biomedical, Inc., Lexington, Massachusetts) was tested in a phase I clinical trial.¹⁰¹ Patients were admitted to a dedicated liver support unit. Invasive hemodynamic monitoring (via peripheral arterial catheter and pulmonary artery catheter) was instituted after blood product administration for partial correction of coagulopathy. All patients received standard medical care, along with one to five BAL treatments (each lasting 6 to 7 hours). If signs of intracranial hypertension were observed, an ICP monitor was placed at the bedside for ICP and CPP monitoring. Patients were intubated endotracheally when in stage 4 encephalopathy and were placed on ventilatory support. The BAL treatments were well tolerated, and no technical problems were identified during BAL therapy. A total of 32 patients were treated with the BAL (29 patients with FHF and three with PNF after transplantation), of whom 84% survived with or without transplantation (unpublished data). Patients experienced remarkable neurologic improvement, with reversal of the decerebrate state after BAL treatments. Posturing, anisocoria, and sluggish pupil reactivity were reduced, and patients became more responsive to external stimuli. Brain-stem function improved, and there was a significant reduction in ICP, with a concomitant increase in CPP. Other effects of BAL

treatment included a decrease in ammonia, transaminase, and bilirubin levels and a significant increase in the BCAA-AAA ratio.

Subsequently, the safety and efficacy of the BAL were evaluated in a prospective, randomized, controlled, multicenter trial that included 171 patients with severe ALF (86 in the control group and 85 in the BAL group).¹⁰⁷ Both patients with FHF or SHF and patients with PNF after liver transplantation were enrolled in this trial. Data were analyzed with and without consideration of the following confounding factors: liver transplantation, time to transplant, disease etiology, disease severity, and treatment site. In the study population as a whole, 30-day survival was 71% for the BAL group and 62% for the control group. In the FHF/SHF subpopulation (with PNF patients excluded), 30-day survival was 73% for the BAL group and 59% for the control group. When survival was analyzed so as to take into account the aforementioned confounding factors, there was no difference in survival between the BAL group and the control group in the study population as whole, but in the FHF/SHF subpopulation, survival was significantly higher in the BAL group than in the control group. This was the first prospective, randomized, controlled trial of an extracorporeal liver support system to demonstrate a significant survival advantage in patients treated with such a system.

10 ENDOCRINE PROBLEMS

Robert H. Bartlett, M.D., and Preston B. Rich, M.D.

Patients scheduled for operation may be receiving treatment with insulin, oral hypoglycemics, corticosteroids, thyroid hormone, or estrogen. The presence of any state calling for such treatment must be taken into consideration in planning operative management and perioperative care. In addition, glucose intolerance may develop in otherwise normal patients after operation, and this possibility must be taken into account as well. In what follows, we describe an approach to preventing and managing common endocrine conditions that occur as complicating factors in the perioperative period. We do not, however, address perioperative problems related to operations for primary endocrine disease.

Diabetes Mellitus

Diabetics have a 50% chance of undergoing a surgical procedure during their lifetime.¹ In the past, operation in these patients was associated with a mortality of 4% to 13%,² usually attributed to cardiovascular complications—clearly a significant operative risk. Any subsequent improvement in diabetes-related operative mortality has probably been offset by the increasing age of patients with diabetes and the larger variety of procedures they undergo.

Perioperative management of diabetic patients [see *Figure 1*] is complicated both by the metabolic abnormalities of the disease and by the effects of any diabetic complications that may be present. There is also an increased risk of postoperative surgical site infection (SSI).

EVALUATION OF THE DIABETIC PATIENT

History and Physical Examination

In taking a preoperative history from a diabetic patient, attention should be directed to any recent fluctuation in blood glucose level as well as to the type of therapy used to control the condition. The timing and dosage of medication should be considered, especially if the patient is taking long-acting insulin or an oral hypoglycemic. The extent to which diabetes is controlled in the perioperative period, which has a significant impact on postoperative recovery, may be affected by certain medications (e.g., antihypertensive agents). The presence of diabetic complications (e.g., atherosclerotic disease, diabetic nephropathy, and autonomic neuropathy) should be documented because these conditions may have serious effects during and after operation.

Medications used to control diabetes include the various forms of insulin as well as oral hypoglycemic agents. The most commonly used oral hypoglycemics are sulfonylurea, which acts by stimulating insulin secretion, and metformin, which acts by decreasing intestinal absorption. Patients should stop taking oral hypoglycemics before major operations, and their blood glucose should be controlled with insulin if necessary. Because sudden discontinuance of sulfonylurea can lead to hypoglycemia, blood

glucose levels should be carefully monitored in patients taking this medication who have experienced injury or undergone operation.

Laboratory Studies

The degree of control of diabetes can be assessed by recording blood glucose measurements at frequent intervals during fasting and at other times during the day and by determining what percentage of total hemoglobin is combined with carbohydrate (i.e., glycosylated). Normally, glycosylated hemoglobin (commonly called HbA_{1c}) accounts for 4% to 7% of total hemoglobin. HbA_{1c} levels increase when hyperglycemia occurs, and the increases are cumulative over time. The value of measuring HbA_{1c} in a preoperative patient known to be diabetic is that it gives the attending physicians some idea of how well hyperglycemic episodes are being controlled by insulin or oral hypoglycemics. Monthly measurements yield a good picture of the adequacy of glucose control over extended periods. HbA_{1c} percentages higher than 10% to 20% indicate that the hyperglycemic aspect of diabetes has been poorly controlled. Chronic diabetic complications are reduced when good control of blood glucose is maintained; diabetic patients are advised to measure their blood glucose levels frequently, which should result in normal HbA_{1c} levels. HbA_{1c} percentages higher than 15% suggest that the diabetes is quite brittle and that more frequent monitoring of blood glucose levels and closer control of insulin administration are indicated during and after operation. As long as the patient is carefully monitored, there is no evidence that high levels of HbA_{1c} are associated with any increased risk of impaired glucose control or complications after operation.

The other important laboratory study in diabetic patients is measurement of serum creatinine levels (or, perhaps, creatinine clearance) as an indicator of renal function. Renal insufficiency is a common complication of diabetes that may not be recognized during normal preoperative testing.

PREOPERATIVE MANAGEMENT

Metabolic Monitoring and Medications

All diabetic patients who are candidates for elective surgical procedures should undergo careful preoperative assessment, including metabolic monitoring. Ideally, glycemic control is achieved before a diabetic patient is admitted to the hospital. More realistically, however, admission may have to be scheduled for the day before the operation to allow time for optimizing metabolic control in all insulin-dependent patients as well as in non-insulin-dependent patients who have inadequate metabolic control. As a rule, target blood glucose levels before operation should be less than 125 mg/dL (6.9 mmol/L) during fasting and less than 180 mg/dL (10.0 mmol/L) postprandially. If emergency operation is required in patients with severe metabolic derangements (e.g., diabetic ketoacidosis or hyperosmolar nonketotic states), 6 to 8 hours of intensive treatment with insulin infusion

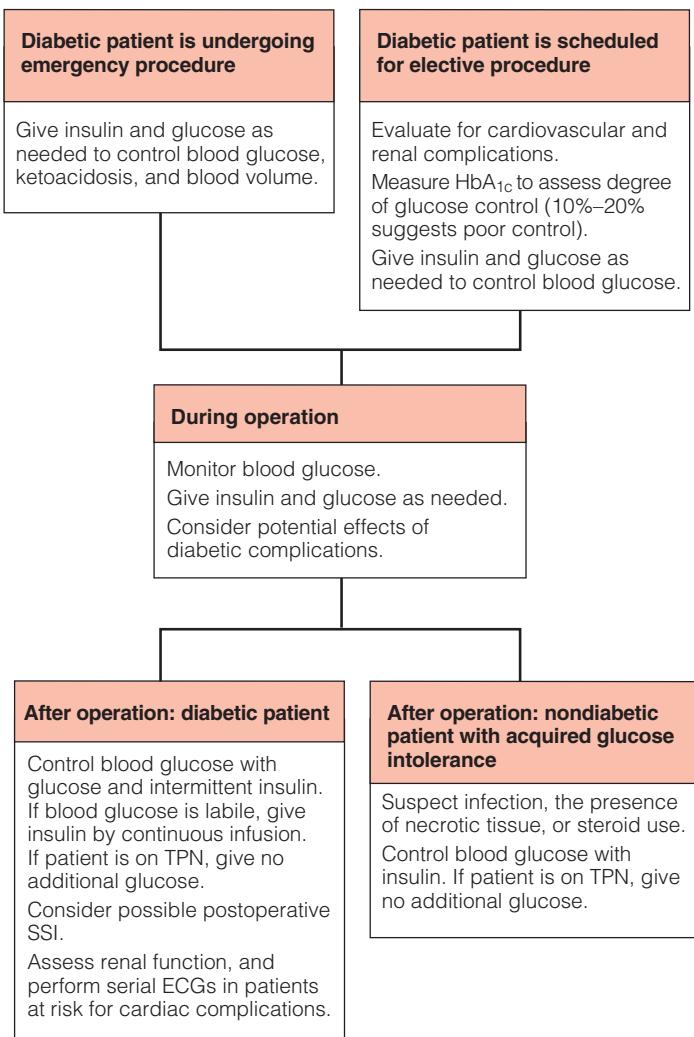

Figure 1 Shown is an algorithm outlining preoperative and postoperative management of the diabetic surgical patient.

and volume restoration usually improves their general condition. This brief period permits clarification of the diagnosis in patients with acute abdominal pain, which may be the consequence of diabetic ketoacidosis rather than a so-called surgical abdomen.

In preparing diabetic patients for operation, all long-acting insulins (i.e., Ultralente preparations) should be replaced with intermediate-acting insulins (i.e., neutral protamine Hagedorn [NPH] or Lente preparations). If the patient has type 2 (non-insulin-dependent) diabetes mellitus, use of long-acting sulfonylureas (e.g., chlorpropamide and glyburide) should be stopped because of the risk of hypoglycemia; a short-acting preparation should be substituted. Use of metformin should be stopped because of the risk of lactic acidosis when renal function is impaired, as it may be during any procedure requiring anesthesia. Chronically hyperglycemic patients are frequently dehydrated, and this condition should be corrected before operation.

INTRAOOPERATIVE MANAGEMENT

Metabolic Effects of Operation and Anesthesia

During anesthesia and operation, endogenous insulin secretion is suppressed, but the plasma levels of counterregulatory hormones (glucagon, epinephrine, cortisol, and growth hor-

mone) increase in nondiabetic as well as diabetic patients. Increased secretion of these hormones in the setting of low insulin levels stimulates hepatic production of glucose. In non-diabetic persons, major procedures are frequently associated with blood glucose levels of 150 to 200 mg/dl (8.3 to 11.1 mmol/L). In diabetic persons, the metabolic abnormality varies according to the extent and duration of the surgical procedure and the degree to which insulin secretion is impaired.

A study in patients with stable type 1 (insulin-dependent) diabetes mellitus showed that blood glucose levels rose from about 180 mg/dl (10.0 mmol/L) to about 270 mg/dl (15.0 mmol/L) postoperatively.³ Ketone body levels increased by about 100%, as compared with levels in nondiabetic control subjects. Similar metabolic findings were reported even in patients with type 2 diabetes mellitus who underwent minor procedures that generated relatively little stress: blood glucose levels rose to 180 mg/dl (10.0 mmol/L), with higher than normal levels of ketone bodies and free fatty acids.⁴

Autonomic neuropathy can cause severe hypotension during induction of anesthesia. Diabetic nephropathy complicates fluid management and usually results in electrolyte abnormalities. All diabetic patients are at high risk for postoperative myocardial infarction, which is often asymptomatic. Poor nutrition and impaired phagocytosis make diabetic patients more susceptible to infection and slower to heal.

Insulin and Glucose Administration

Emergency procedures Diabetic patients may be more likely than nondiabetic patients to undergo emergency operation, which can cause rapid metabolic decompensation with dehydration, hyperglycemia, and ketoacidosis. In addition, a surgical emergency can precipitate uncontrolled diabetes in patients with no history of diabetes. Appropriate management depends, to a large extent, on the patient's metabolic condition. When one is faced with a so-called surgical abdomen, it is crucial to determine whether there is a metabolic abnormality that may be causing the condition. Given this possibility, it is sensible to manage the patient conservatively at first, with an emphasis on metabolic correction. If the underlying problem is in fact metabolic, it should resolve or improve in 3 to 4 hours; if the problem is surgical, it should remain the same or worsen over this period.

Elective major procedures In a patient undergoing general anesthesia, regardless of the duration of the operation, infusion of insulin and glucose is recommended if the patient is taking insulin for diabetes or is using drugs or diet therapy (or both) without achieving satisfactory control of type 2 diabetes mellitus.

Several methods of insulin administration may be used during the perioperative period. Most of the protocols include I.V. administration of short-acting insulin and 5% to 10% glucose. In some, glucose and insulin are administered together in a single infusion. The advantage of this approach is that if the glucose infusion is accidentally disconnected or obstructed, the insulin infusion is disconnected or obstructed as well, so that the risk of hypoglycemia is eliminated. The disadvantage of this method is that it is impossible to change the delivery rate of one agent without changing the delivery rate of the other. Administration of insulin and glucose in separate bags allows either infusion rate to be adjusted without the other being affected. The insulin infusion rate is progressively increased and the glucose infusion rate progressively decreased in accordance with the capillary blood glucose levels, measured hourly [see Table 1]. With this protocol,

Table 1 Representative Protocol for Insulin-Glucose Infusion during the Perioperative Period

1. Infuse 5% dextrose in water (D5W) I.V. via pump.
2. Make insulin solution with 0.5 U/ml of short-acting insulin (i.e., 250 U of regular insulin in 500 ml of normal saline). Administer in piggyback fashion via infusion pump into D5W infusion or through a separate I.V. site.
3. After initiating glucose-insulin infusion, stop all subcutaneous insulin therapy.
4. Measure capillary blood glucose levels every hour.
5. On the basis of hourly blood glucose levels, adjust each infusion according to the following schedule:

Blood Glucose (mg/dl)	Insulin Infusion		D5W Infusion (ml/hr)
	(ml/hr)	(U/hr)	
< 70*	1.0	0.5	150
71–100	2.0	1.0	125
101–150	3.0	1.5	100
151–200	4.0	2.0	100
201–250	6.0	3.0	100
251–300	8.0	4.0	75
> 300	12.0	6.0	50

*Give 10 ml D5W I.V. and repeat blood glucose measurement 15 min later.

a blood glucose level in the range of 125 to 200 mg/dl (6.9 to 11.1 mmol/L) can easily be maintained throughout the perioperative period. Close observation of blood glucose levels and prompt adjustment of insulin and glucose delivery are mandatory for achieving a stable blood glucose level. Electrolyte supplementation is administered via a separate infusion.

Minor procedures Diabetic patients who fast before minor operations (e.g., endoscopic procedures and operations performed with the patient under local anesthesia) should omit the morning dose of insulin or oral hypoglycemic agent, and their capillary blood glucose level should be measured every 2 to 4 hours. Supplemental subcutaneous short-acting insulin can be administered according to a variable insulin schedule, and the usual insulin or oral agent can be taken after the procedure [see Table 2]. This method of administration, which is associated with unpredictable absorption and variable plasma insulin levels, is restricted to surgical patients undergoing minor procedures and should not be used in those undergoing major operations.

POSTOPERATIVE MANAGEMENT

Insulin and Glucose Administration

After minor procedures, diabetic patients should receive I.V. glucose and insulin until their metabolic condition is stable and oral feeding can be tolerated. To prevent ketosis, the insulin and glucose infusions should be continued for at least 1 hour after the administration of subcutaneous short-acting insulin. After major procedures, patients should receive I.V. glucose and insulin until they are able to take solid food without difficulty. A regimen consisting of multiple subcutaneous injections of short-acting insulin before meals and intermediate-acting insulin twice

daily is recommended during the first 24 to 48 hours after cessation of the insulin and glucose infusions and before resumption of the patient's usual insulin regimen.

Total parenteral nutrition (TPN) [see 8:23 *Nutritional Support*], often required during the postoperative period, can cause serious metabolic derangements in diabetic patients. For a diabetic patient receiving TPN, a variable insulin infusion schedule [see Table 2] is recommended, with hourly determinations of blood glucose; however, additional glucose is not needed, because it is included in the TPN solution. Initially, the insulin should be given as a continuous infusion separate from the TPN solution. Once a stable dose of insulin is reached (usually within 24 to 48 hours), the total amount of insulin required over a 24-hour period can be added to the TPN bag. This amount may be high—often more than 100 units. At this point, capillary blood glucose levels can be measured every 2 to 4 hours.

Hypoglycemia can be difficult to detect in critically ill patients, in whom blood glucose levels are often elevated for any of a number of reasons. Accordingly, it has been common practice to accept blood glucose levels ranging from 150 to 200 mg/dl in these patients. This practice, however, was called into question by a 2001 randomized study of 1,548 ICU patients in which liberal glucose control (blood glucose level, 180 to 200 mg/dl) was compared with tight control (blood glucose level, 80 to 110 mg/dl).⁵ ICU survival was significantly better in the tight control group (95.4%) than in the liberal control group (92%). In addition, the tight control group had a lower incidence of systemic infection, had less need of antibiotic therapy, required fewer transfusions, and were less subject to hypobilirubinemia. These findings support the view that tight regulation of glucose and insulin to maintain normal blood glucose levels is desirable in critically ill patients.

Cardiovascular and Renal Assessment

Serial postoperative electrocardiograms are recommended for older diabetic patients, those with long-standing type 1 diabetes mellitus, and those with known heart disease. Postoperative myocardial infarction, which may be silent, is associated with a high mortality. Careful monitoring of blood urea nitrogen and serum creatinine levels facilitates the detection of acute renal

Table 2 Management of Diabetes in Patients Undergoing Minor Surgical Procedures³⁰

If patient fasted

1. Withhold morning dose of insulin or oral agent.
2. Measure capillary blood glucose level before procedure and every 2–4 hr thereafter.
3. Give short-acting insulin every 2–4 hr, as follows:

Blood Glucose (mg/dl)	Short-Acting Insulin (U)
< 150	0
151–200	2
201–250	3
251–300	5
> 300	6

4. After procedure, give usual dose of insulin or oral agent.

failure [see 8:6 *Renal Failure*]. If a contrast agent is used, the patient should be well hydrated before and after the procedure.

Infection

SSI is common in diabetic patients with poor metabolic control. Impaired granulocyte function resulting from hyperglycemia may predispose to bacterial infections. Autonomic neuropathy, if present, may lead to difficulty in postoperative voiding, which increases the risk of urinary tract infection. Poor circulation as a result of macroangiopathy or microangiopathy can also contribute to the likelihood of postoperative infection.

Tight metabolic control during the perioperative period can decrease the risk of postoperative infection. When SSIs do occur in the diabetic population, they are usually caused by mixed flora, including aerobic and anaerobic organisms such as *Escherichia coli*, Enterobacteriaceae, various streptococci, *Staphylococcus aureus*, and *Bacteroides fragilis*. Necrotizing infections (e.g., fasciitis, gangrene, and Fournier gangrene) are more common and spread more readily in diabetic patients.

Surgical debridement and drainage, if needed, should be performed early. Cultures should be obtained during drainage procedures. Ideally, antibiotic therapy awaits and is based on culture results; however, in practice, it is often preferable to initiate empirical therapy for the most likely organisms before the results are available. Swarming of *Proteus* organisms may obscure other pathogens on culture plates. Unless the patient is clearly manifesting a septic response, aminoglycosides should be avoided because of their nephrotoxicity and the likelihood that diabetic patients may have underlying renal disease. If severe infections do not respond to antibiotic therapy, the presence of *Candida* or other fungal species should be suspected.

Many factors play a role in the increased susceptibility of diabetics to infection, including macroangiopathy, microangiopathy, neuropathy, impaired neutrophil and lymphocyte function, increased capillary permeability, and impaired granulation and healing.⁶ An obvious example of this interaction of multiple contributing factors is a chronically infected nonhealing ulcer on a neuropathic foot. A less obvious but more serious example is the failure of host defenses against peritonitis, soft tissue infection, and bacteremia that develops in diabetic patients. Chemotaxis, adherence, phagocytosis,⁷ bacterial killing, and production of cytokines and complement are all impaired in patients with type 1 diabetes mellitus. The greater prominence of such abnormalities in patients with type 1 diabetes mellitus suggests that the most likely cause is related to chronic and irreversible glycosylation of many proteins, which limits the function of intracellular and intercellular messengers. The implication of this theory is that tight short- and long-term control of blood glucose should allow better control of infection.⁵

The impaired wound healing seen in diabetic patients clearly is related in part to increased susceptibility to infection; however, it is also observed with sterile wounds. Many animal studies have corroborated the clinical observation that skin, fascia, and bone all heal more slowly and with less strength in diabetic patients. Such studies have generally found that this impaired healing is partially mitigated by insulin control, which suggests that glycosylation of proteins is an important factor. A 1999 study indicated that the impaired healing is significantly mediated by endogenous corticosteroids.⁸ Local application of inflammatory substances or growth factors (e.g., platelet-derived growth factor, tissue growth factor, bacterial by-products, growth hormone, and hyperosmotic sugar) has been shown to stimulate healing in diabetic animals.^{6,9}

Adrenal Insufficiency

The anti-inflammatory properties of the glucocorticoid steroids [see Table 3] are commonly exploited to treat disease. Patients are often treated for long periods with large pharmacologic doses of steroids (commonly, prednisone by mouth) for inflammatory or autoimmune diseases such as arthritis, systemic lupus erythematosus, inflammatory bowel disease, and bronchial asthma. Primary failure of the hypothalamic-pituitary-adrenal (HPA) axis (as in Addison disease, Sheehan syndrome, and panhypopituitarism) is rare, but when it does occur, it must be treated with long-term administration of physiologic doses of corticosteroids. It is not uncommon for patients who are receiving such corticosteroid therapy to require operations, and this surgical population presents a unique perioperative management challenge [see Figure 2]. It is axiomatic that any patient treated with exogenous steroids may eventually manifest adrenal atrophy as a result of suppressed endogenous production of adrenocorticotrophic hormone (ACTH). Actual or relative adrenal insufficiency may occur during or after a major operation, resulting in a syndrome whose manifestations can range from nausea, vomiting, fever, abdominal pain, and electrolyte abnormalities to complete circulatory collapse.

The adrenal cortex is central to the maintenance of homeostasis both at rest and during stress.¹⁰ Cortisol, the predominant glucocorticoid hormone, is produced by the fascicular and reticular zones of the adrenal cortex. It is under the strict regulatory control of both the hypothalamus (via corticotropin-releasing hormone) and the anterior pituitary gland (via ACTH). Cortisol itself participates in its own regulation, imparting a potent negative feedback signal to both the hypothalamus and the ACTH-producing basophilic cells within the adenohypophysis of the pituitary. Together, these components, which constitute the HPA axis, form a finely regulated feedback loop for cortisol secretion.

Under unstressed physiologic conditions, the adrenal cortex constitutively produces approximately 20 to 25 mg of cortisol daily.¹¹ Cortisol secretion normally occurs in diurnal surges; consequently, simple measurements of serum cortisol levels in isolation generally do not suffice for accurate evaluation of the status of the HPA axis. Much of the daily variability in cortisol secretion can be tracked with 24-hour urinary measurements of the hydroxysteroid metabolites; however, there can be significant

Table 3 Selected Corticosteroid Preparations

Preparation	Equivalent Doses (mg)	Glucocorticoid Activity*	Mineralocorticoid Activity*
Short-acting (8–12 hr)			
Hydrocortisone	20	1	1
Cortisone	25	0.80	0.80
Intermediate-acting (12–36 hr)			
Prednisone	5	4	0.80
Prednisolone	5	4	0.80
Methylprednisolone	4	5	0
Triamcinolone	4	5	0
Long-acting (36–54 hr)			
Betamethasone	0.60	25	0
Dexamethasone	0.75	30	0
Mineralocorticoid	—		
Fludrocortisone	—	10	125

*Ranked on a scale rating hydrocortisone as 1.

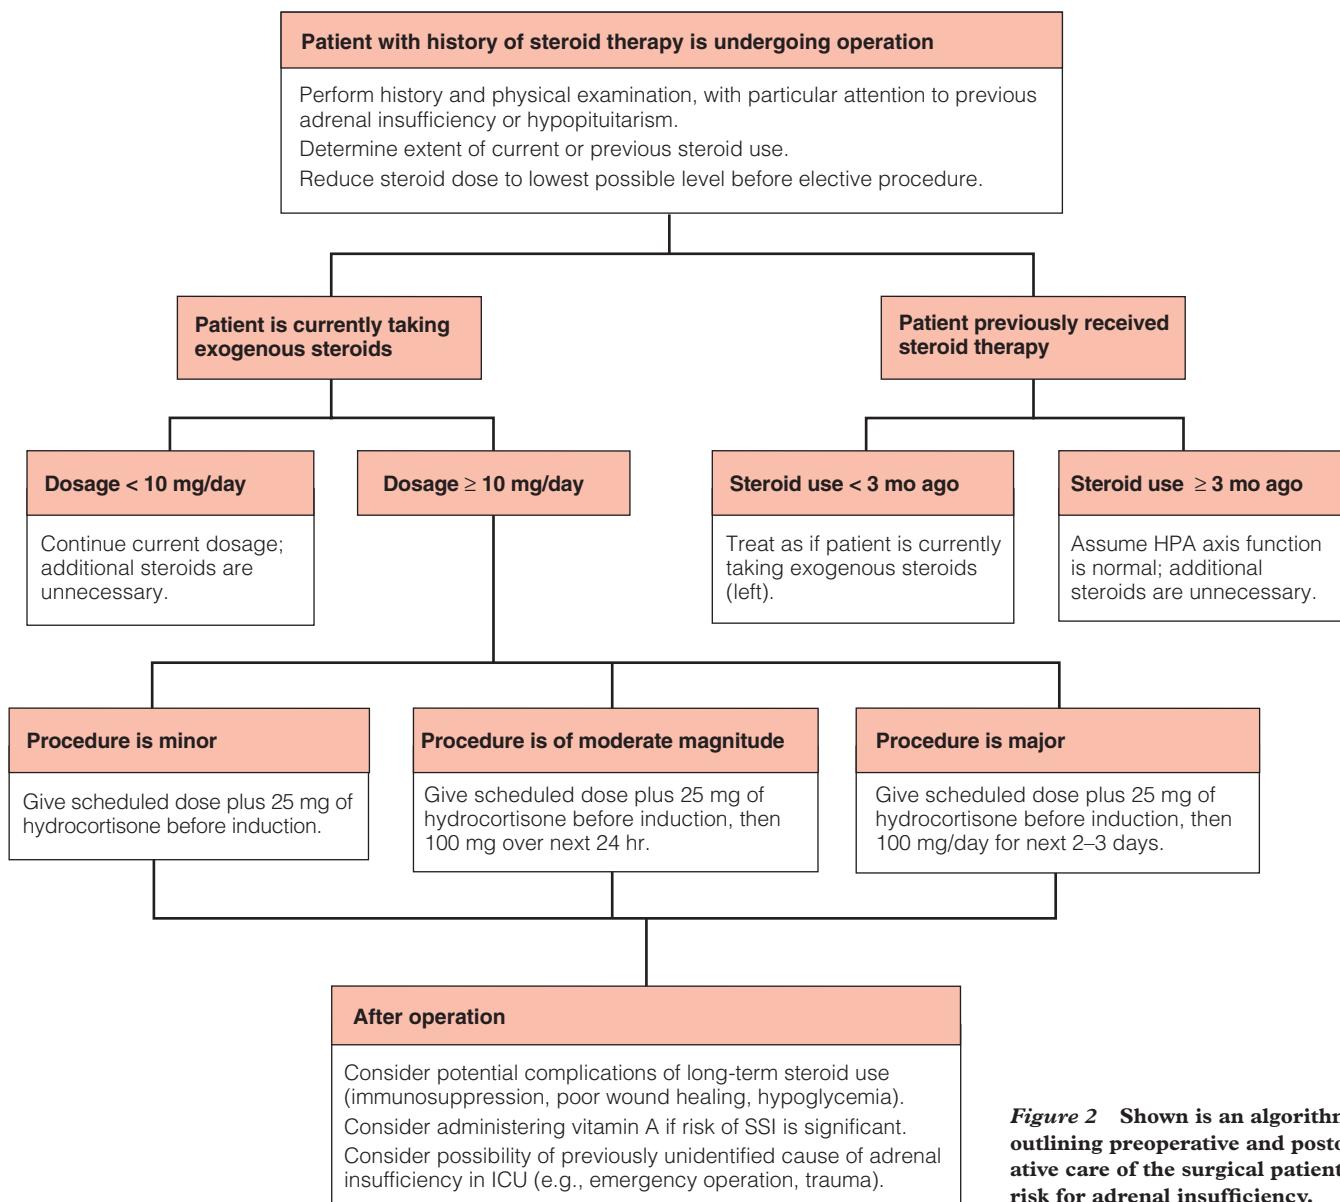

Figure 2 Shown is an algorithm outlining preoperative and postoperative care of the surgical patient at risk for adrenal insufficiency.

overlap between normal patients and those with clinical adrenal insufficiency.¹² Provocative testing of the HPA axis is based on the normal physiologic response of the adrenal gland to release cortisol in a receptor-mediated G-protein-coupled response to circulating ACTH.

Although there is some controversy regarding which laboratory evaluation is the best predictor of adequate adrenal response to a surgical stress, it is clear that ACTH stimulatory testing is more sensitive and specific than unprovoked steroid measurement alone. Hypoglycemia-induced release of ACTH in response to exogenous insulin infusion (the insulin tolerance test, or ITT) has long been considered the gold standard for determination of relative adrenal insufficiency, but various complications, including discomfort, seizures, and even death, limit its clinical usefulness as a routinely applied test.¹³ In several studies, strong correlations have been observed between the ITT and adrenal stimulation with a synthetic corticotropin construct.^{14,15} In this test, the plasma cortisol response is measured 0, 30, and 60 minutes after infusion of 250 µg of the ACTH analogue. Although there is no unanimously accepted cutoff value for stim-

ulated cortisol levels above which the HPA axis can be assumed to be intact, it has been suggested that a value higher than 600 mol/L at 30 minutes should be a sufficiently sensitive confirmation of an intact HPA axis.

Adrenal glucocorticoids are important modulators of the stress response: they play a complex role in the metabolic pathways for carbohydrates, fats, and proteins; modulate gluconeogenesis and lipolysis; mediate insulin resistance; and exert a host of well-documented effects on inflammation and wound healing. It is clear that physiologic stresses (e.g., burns, trauma, and iatrogenic tissue damage occurring during operations) result in an ACTH-induced surge in the adrenal steroid response.^{16,17} Serum measurements reveal that this response can produce cortisol elevations several times greater than those produced under basal conditions. It is becoming apparent that although this exaggerated adrenal stress response may have conferred a certain evolutionary benefit, prolonged exposure to high doses of steroids may nonetheless have deleterious consequences. The potential complications of long-term or high-dose administration of glucocorticoids are well described: they include hyper-

tension, cataracts, myopathy (especially when glucocorticoids are used in conjunction with nondepolarizing paralytic drugs), osteonecrosis (particularly on the femoral head), impaired wound healing, and immunosuppression.¹⁸

It was the observed (and presumably physiologic) magnitude of the cortisol response to stress that led to the long-held—albeit never corroborated—assumption that supraphysiologic levels of steroids were required to maintain homeostasis in the stressed environment. In the 1950s, two case reports were published that described perioperative deaths thought to result from untreated and unrecognized adrenal insufficiency.^{19,20} Thereafter, it became common practice to supply supraphysiologic doses of exogenous steroids (i.e., doses two to three times that expected under basal conditions) to patients believed to be at risk for adrenal suppression and therefore unable to mount the expected cortisol surge during operation. Subsequently, this practice came under scrutiny. Primary studies suggested that although HPA suppression could occur as a result of long-term steroid use, normal physiologic replacement doses were sufficient to maintain perioperative homeostasis; supraphysiologic doses were unnecessary.²¹ The concept that significantly lower doses of steroids are required to maintain homeostasis and normotension in the perioperative period than was once believed has been supported by prospective clinical studies in humans.²²

It is clear that ACTH is not only stimulatory but also trophic for the adrenal cortex. There is evidence that if the adrenal cortex is not exposed to ACTH, it is subject to hyposecretion and anatomic atrophy. It was once thought that exposure to even low doses of steroids (< 10 mg of prednisone equivalent) was sufficient to suppress the endogenous release of ACTH and thus to result in a state of adrenal insufficiency. This belief led to the common practice of administering so-called stress-dose steroids to surgical patients who had received exogenous steroids even in small doses or as long ago as 1 year before operation. Provocative studies on patients previously exposed to steroids demonstrated that the HPA axis usually remains intact despite either ongoing exposure to small doses of exogenous steroids (< 10 mg of prednisone equivalent daily) or earlier steroid use (if the time since discontinuance was longer than 2 to 3 months).²³⁻²⁶

In summary, the glucocorticoids are essential components of human homeostasis both at rest and under stressful conditions

such as occur during surgery. Complete or even relative adrenal insufficiency is preventable; when it does occur, it can have disastrous consequences if not recognized and appropriately treated. Exogenous administration of steroids in sufficient doses is generally adequate to prevent the syndrome of adrenal insufficiency. The decision to administer supplemental perioperative steroids should be based on the specific details of the history of steroid use as well as on the magnitude of the proposed operation.

Hormone Replacement

Many surgical patients are receiving thyroid or ovarian hormone replacement therapy. In addition, the use of growth hormone, growth hormone precursors, and anabolic steroids has become more common in general practice. The effects of these hormone medications must be taken into account in any patient undergoing an elective or emergency operation. Because all of these substances have long half-lives, replacement is not necessary for the first 2 weeks after operation; however, if the illness or the operation itself prevents oral intake for more than 2 weeks, the possibility of hypothyroidism or estrogen depletion should be considered. Postoperative weakness, lack of energy, depression, and sleeping disorders can all be caused by the lack of long-term hormone supplements.

Some patients exhibit decreased endogenous thyroid function after operation, either because their thyroid-stimulating hormone (TSH) levels are depressed as a consequence of long-term thyroid medication or because they experience complications and become critically ill. Critical illness typically leads to reduced blood levels of triiodothyronine (T_3) and thyroxine (T_4). In addition, glucocorticoids, radiopaque dyes, propranolol, and amiodarone all lower plasma T_4 levels,²⁷ and dopamine decreases TSH secretion directly.²⁸ Most critically ill patients, however, do not exhibit metabolic or hemodynamic changes indicative of hypothyroidism. Measurement of TSH is helpful for determining the significance of thyroid function in critically ill patients. If the serum TSH level is lower than 5 $\mu\text{U}/\text{ml}$ and the patient is not on high-dose dopamine therapy, thyroid function is considered adequate regardless of other plasma markers. If the TSH level is higher than 20 $\mu\text{U}/\text{ml}$, replacement with thyroxine is indicated.²⁹

11 COMA, COGNITIVE IMPAIRMENT, AND SEIZURES

Maxim D. Hammer, M.D.

Coma is the neurologist's favorite consultation: the history is usually straightforward, the neurologic examination is focused, and the differential diagnosis is limited. A good neurologic examination, in combination with a thoughtful battery of tests, will invariably achieve the correct diagnosis. It is vital for the intensivist to become equally comfortable with the rapid assessment of coma. Once initial stabilization of the patient has been achieved, management of coma is determined by the specific causative condition or conditions present. Rapid recognition of potentially reversible causes of coma (e.g., basilar artery occlusion [BAO], nonconvulsive status epilepticus, and herniation), followed by the appropriate emergency consultations, can often prevent or reduce morbidity and mortality.

This chapter is intended as a practical, rational, and efficient approach to the diagnosis and management of coma. To that end, an algorithmic approach to diagnosis is formulated, general treatment measures for comatose patients are outlined, specific causes of coma are reviewed, and prognostic issues are considered. Detailed discussions of neuroanatomy and cranial nerve pathways, which are readily available elsewhere,¹ are intentionally omitted, as are detailed descriptions of specific treatment of individual causes of coma (other than BAO, status epilepticus, cardiac arrest, increased intracranial pressure [IICP], and certain metabolic derangements).

Classification of Levels of Consciousness

AWAKENESS, ALERTNESS, AND AWARENESS

A patient's level of consciousness can usefully be described in terms of the three As of consciousness: awake, alert, and aware. To be awake means to be fully roused and thus not asleep. To be alert means to be able to pay attention to one's environment or to an examiner. Finally, to be aware means to have an understanding of oneself and one's environment. Being oriented is a manifestation of being aware of one's environment [see Figure 1].

A person who is awake, alert, and aware may be said to be fully conscious. One who is awake and alert but has lost awareness is severely demented. Someone who is merely awake and not alert or aware is delirious. A delirious patient's level of wakefulness may wax and wane. A person who is not awake, alert, or aware either is asleep (in which case he or she can be rendered awake—i.e., is arousable) or is somewhere along the so-called spectrum of coma (see below).

Admittedly, describing patients simply in terms of awakeness, alertness, and awareness omits many important nuances; nevertheless, it is an excellent and easily reproducible way of assessing level of consciousness.

UNRESPONSIVE PATIENT

The term unresponsive is used frequently, but often in a vague manner that does not yield a clear meaning. Fortunately, in the

setting of coma management, there are only three possible meanings that need be considered [see Figure 2].

First, the term unresponsive may be applied to a patient who is actually fully conscious but is unable or unwilling to respond verbally. For example, a patient with aphasia (a common manifestation of stroke) may be awake, alert, and aware, yet unable to speak. As another example, a patient who is in a locked-in state (either from a brain stem injury or from generalized muscle paralysis) is fully conscious but cannot speak and cannot communicate except through subtle eye movements. Finally, patients with a psychiatric disorder may present with a so-called functional coma while remaining fully conscious; simple examination techniques quickly reveal that they are completely awake.

Second, the term unresponsive may be applied to a patient who has a waxing-and-waning level of wakefulness. This fluctuation between wakefulness and coma is what defines delirium, and it is invariably caused by infection, metabolic disturbances, or alcohol withdrawal.

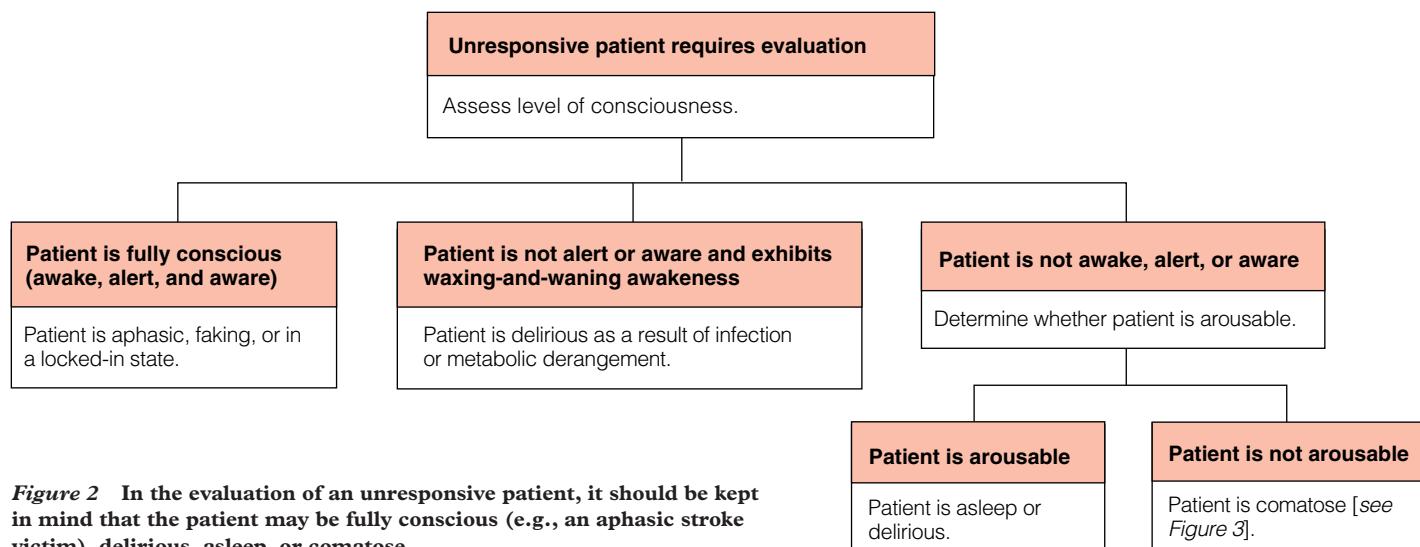

Third, the term unresponsive may be applied to a patient who truly is not even awake. In this sense, the term could of course be applied to a person who is simply asleep, but for the purposes of this chapter, it should be understood as referring to a patient who is comatose.

SPECTRUM OF COMA

Patients who are not aware, alert, or even awake (except for those who are simply asleep) fall somewhere along the spectrum of coma. This spectrum reflects varying levels of impairment of

			Aware
		Alert	
	Awake		
Sleep, Coma	Delirium	Dementia, Infant Consciousness	Normal Adult Consciousness

Figure 1 Awareness depends on alertness, which in turn depends on arousal (i.e., how awake one is). Normally cognizant adults are aware of themselves and their environment. Persons who have lost awareness but retain alertness and wakefulness may be characterized as severely demented. Persons who have lost alertness are delirious by definition, though their level of wakefulness may wax and wane. Finally, persons who are not aware, alert, or awake may be either asleep or in a coma.

the response to stimuli. On the high end of the spectrum, for example, is the patient who can be aroused (albeit perhaps only temporarily) by the sound of a voice. Somewhat farther down is the patient who can be temporarily aroused by a painful stimulus. Farther down still is the patient who cannot be aroused by a painful stimulus but at least exhibits some motor response to it. On the low end of the spectrum is the patient who has no motor response to a painful stimulus; this is the generally accepted definition of coma.

The terms lethargy, stupor, and obtundation, though widely used, have come to signify different things to different people. Accordingly, to ensure precise communication, it is perhaps advisable to employ clear clinical patient descriptions rather than rely on these particular terms.

Initial Stabilization

The first step in dealing with coma is to stabilize the patient by addressing the ABCs of resuscitation (*Airway, Breathing, and Circulation*). The patient's airway must be cleared of all foreign material, and the patency of the airway must be verified. The spontaneous rate and rhythm of respiration should be noted. Endotracheal intubation is indicated in patients who are dyspneic, hypoventilating, or vomiting uncontrollably. If a patient is to be intubated, however, it is extremely helpful first to obtain a focused neurologic examination (which can be done in 60 seconds) because the information that can be gained from this examination will be lost when the patient is paralyzed for the intubation. Hyperventilation with a bag and mask and 100% oxygen should be performed before intubation to ensure adequate oxygenation during the procedure. If there is any possibility of cervical spine injury, intubation should be delayed, if possible, until fracture can be ruled out radiographically.

Circulation must be vigorously supported, especially in the setting of brain injury or hypoxia. This is accomplished by inserting a large-bore I.V. or central venous catheter and infusing isotonic fluids or volume expanders. The use of solutions containing free water (e.g., 5% dextrose in water) should be avoided, especially in the setting of brain injury or stroke, because such solutions have the potential to increase cerebral edema.

Clinical Evaluation

As the patient is being stabilized, evaluation should be initiated. A witness or someone else capable of providing a history should be sought. The differential diagnosis of coma is wide but limited [*see Table 1*]. Clues from the history, the focused neurologic examination, and the general physical examination are often helpful and sometimes diagnostic [*see Figure 3*].

History

The ideal historian is a person who knows the patient well. Optimally, if the coma was of sudden onset, a witness was present who can describe what occurred. A history of trauma, drug use, medications, recent febrile illness, heart disease, organ failure, or seizures often rapidly leads to the correct diagnosis [*see Table 2*]. Typically, the most challenging cases are those patients who are “found down”; such cases necessitate a clear diagnostic approach that begins with the physical and neurologic examinations.

Focused Neurologic Examination

There are two good reasons for performing a neurologic examination on a coma patient. First, such an examination allows the physician to assign the patient a Glasgow Coma Scale (GCS) score [*see Table 3*], which may be used in making decisions about the necessity for intubation and which provides an objective means of following (at least superficially) the patient's neurologic status. Second, the neurologic examination may quickly yield important diagnostic information.

A complete and exhaustive neurologic examination is totally unnecessary. For the purposes of evaluating coma, a focused neurologic examination is preferable, being both valuable and rapid (~ 60 seconds). If intubation is indicated, the coma examination should be performed quickly before sedative and paralytic agents are given. This examination addresses a number of key findings [*see Table 4*], but in general, it may be thought of as assessing four neurologic variables: (1) spontaneous movements (~ 15 seconds), (2) papillary response (~ 15 seconds), (3) ocular motility (~ 15 seconds), and (4) motor response (~ 15 seconds). A reflex hammer is not needed.

Spontaneous movements should be observed over a period of 10 to 20 seconds. Generalized seizures may present as tonic or tonic-clonic movements of one or both sides. Tonic seizures are character-

ized by sustained contractions with upper-extremity flexion and lower-extremity extension. Tonic-clonic seizures are characterized by tonic contractures alternating with periods of muscle atonia, resulting in rhythmic contractions. Myoclonus consists of motor jerks that are sudden, brief, shocklike, and randomly distributed; it may be seen in patients with hypoxic-ischemic encephalopathy (e.g., after cardiac arrest) or other metabolic disturbances. Other findings (e.g., a flaccid arm that hangs down the side of the stretcher or a leg that is extorted) may be indicative of hemiparesis. The motor response to pain can be tested and assigned a GCS score. Asymmetry should be noted.

Pupillary responses are important in that their presence or absence distinguishes structural from metabolic coma (because the pupils are generally resistant to metabolic insult); they also indicate the integrity of the brain stem [see Table 5]. The origin of the reticular activating system (RAS), the so-called on switch of consciousness, may be physically located adjacent to the brain stem nuclei that control pupillary response.

The pathways that control ocular motility also lie adjacent to the RAS. Roving eye movements usually indicate that the brain stem is intact and that a metabolic problem is affecting the brain. Minimal or absent eye movement in conjunction with reactive pupils also typically signifies a metabolic process. Gaze deviation may indicate a stroke: a cortical stroke will cause the eyes to look toward the damaged side of the brain, whereas a pontine stroke will cause the eyes to look away from the damaged side of the pons. Gaze deviation may also signify an ongoing seizure: the eyes look away from the hemisphere in which the seizure is occurring or, after the seizure is over, toward the postictal hemisphere. Vertical disconjugation of the eyes (skew deviation) is indicative of brain stem disease and frequently occurs during basilar artery thrombosis. Ocular bobbing (rapid downward movements with a slow drift back to the original position) is occasionally seen in the setting of extensive pontine damage.

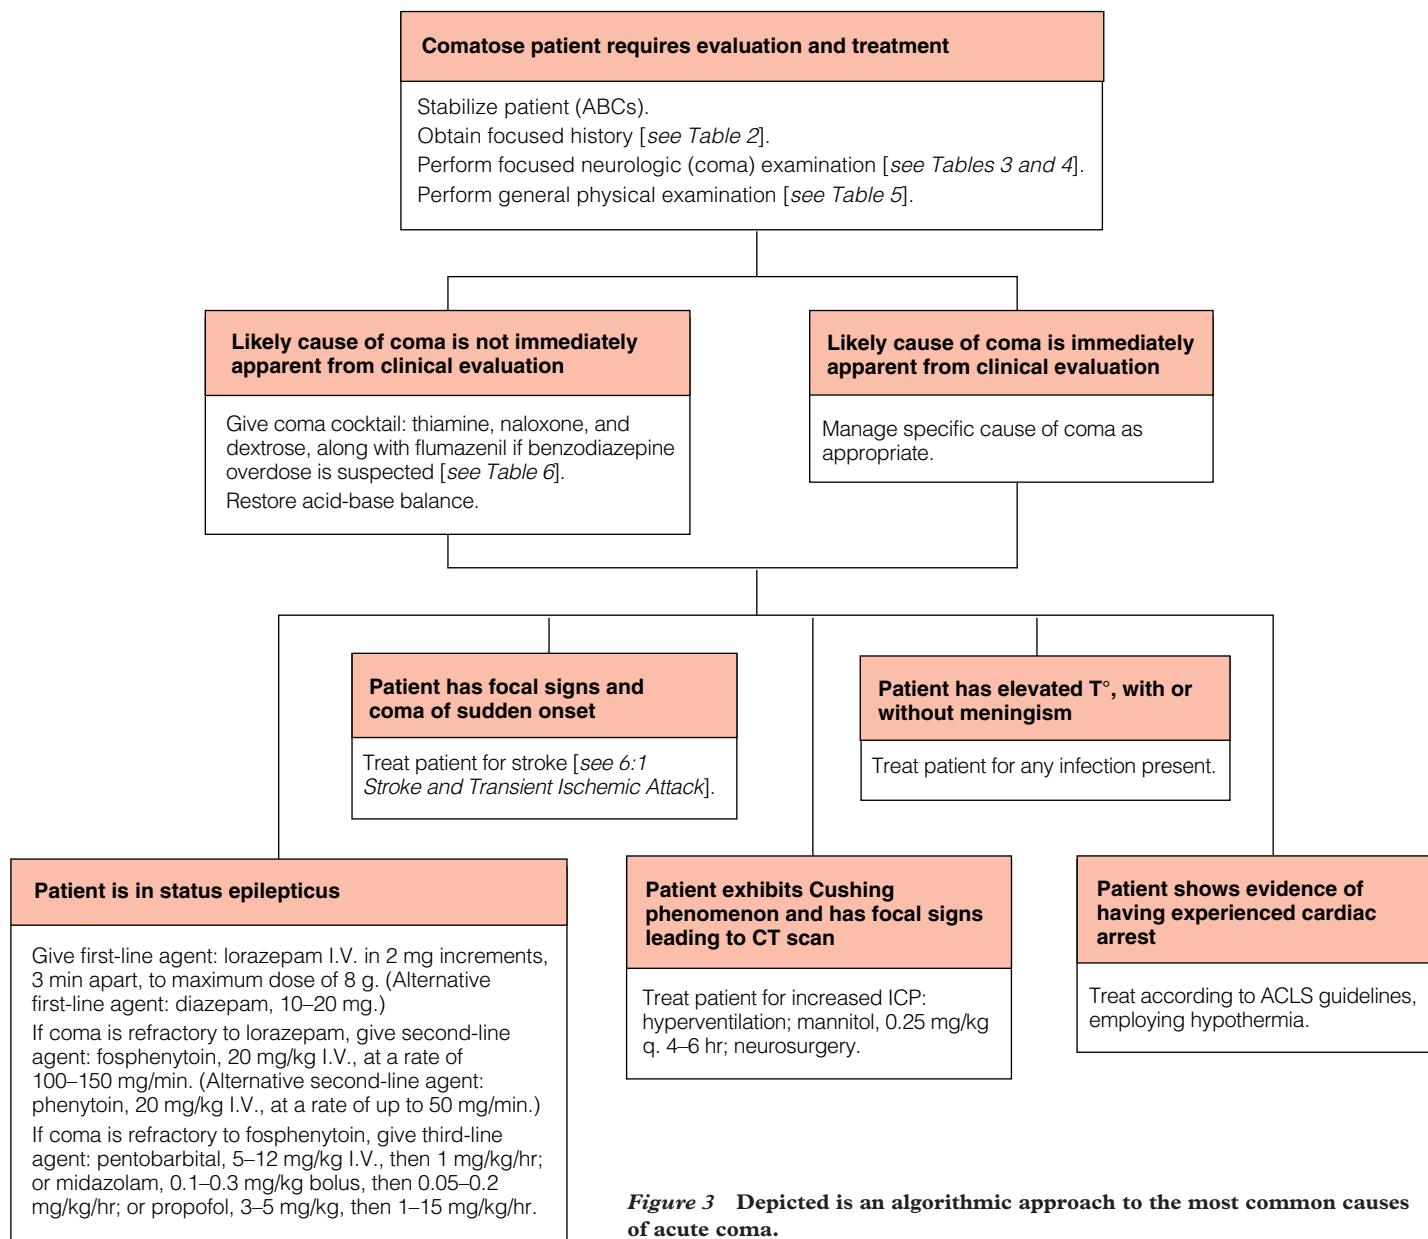

Figure 3 Depicted is an algorithmic approach to the most common causes of acute coma.

General Physical Examination

Blood pressure, heart rate, and cardiac rhythm are key to the diagnosis of the various cardiovascular and hemodynamic causes of coma [see *Table 1*]. Hypothermia is noted in cases of exposure,

Table 1 Differential Diagnosis of Coma

Potential Cause of Coma	Differential Diagnosis
Cerebrovascular	Large brain stem stroke (with or without basilar artery occlusion) Massive stroke or hemorrhage with mass effect Subarachnoid hemorrhage Subdural or epidural hematoma Hypoxic-ischemic encephalopathy after cardiac arrest Hypertensive encephalopathy
Cardiovascular	Cardiac arrest Cardiac arrhythmia Congestive heart failure Hypotension Myocardial infarction
Infectious	Bacteremia or sepsis Meningitis Encephalitis (e.g., herpesvirus, arbovirus)
Traumatic	Multiple severe concussions (diffuse axonal injury, second-hit syndrome) Subdural or epidural hematoma Multiple contusions Penetrating head injury
Toxic	Alcohol intoxication/withdrawal Opiate intoxication Anesthesia Overdose Antianxiety agents or antidepressants Anticholinergics Anticonvulsants Antihistamines Insulin Lithium Neuroleptics Opiates Salicylates Sedatives
Metabolic	Hyperglycemia or hypoglycemia Diabetic ketoacidosis Hyperosmolar nonketotic coma Hypernatremia or hyponatremia Osmotic demyelination syndrome: central pontine myelinolysis Hepatic failure Renal failure Hypoxia or hypercarbia Hypothermia
Epileptic	Grand mal status epilepticus Nonconvulsive status epilepticus Postictal state
Mass	Massive stroke or hemorrhage with mass effect Tumor or abscess with mass effect
Hematologic	Thrombotic thrombocytopenic purpura
Psychiatric	Conversion Malingering

Table 2 Coma History

Questions to Be Asked	Possible Causes to Be Considered
Is there a witness?	[If no, see <i>Table 4</i> .]
Was it sudden?	Stroke If stepwise deterioration, consider BAO Seizure Cardiac arrest
Was there trauma?	Traumatic brain injury Subarachnoid hemorrhage Subdural or epidural hematoma with mass effect and herniation
Has there been drug use? If so, which drugs?	Recreational drug overdose Opioids, alcohol Prescription drug overdose Opioids, benzodiazepines, barbiturates, anticholinergics
Was there a recent febrile illness?	Meningitis or encephalitis Bacteremia or sepsis
Is there a history of heart disease?	Cardiac arrest Myocardial infarction Congestive heart failure Cardiac arrhythmia Hypotension
Is there a history of organ failure?	Renal failure Hepatic failure
Is there a history of seizures?	Postictal from single seizure Convulsive status epilepticus Nonconvulsive status epilepticus

BAO—basilar artery occlusion

drowning, methanol poisoning, and septic shock. Hyperthermia is obviously suggestive of an ongoing infectious process. A stiff neck is often caused by meningeal irritability resulting from infection or inflammation; it may be indicative of meningitis, but it also may be the only physical sign of subarachnoid hemorrhage. Various other physical findings may be observed in comatose patients as well [see *Table 5*].

A rise in intracranial pressure (ICP) occurs with any space-occupying lesion in the calvaria. Signs of rising ICP include increasing blood pressure, decreasing heart rate, and slowing or periodic respiration (Cushing phenomenon). Papilledema caused by increased ICP usually takes weeks to develop and is seldom a presenting sign.

Management**GENERAL MEASURES, TRIAGE, AND TEST BATTERY**

As emergency management is being provided, laboratory studies should be obtained, including serum electrolyte, calcium, magnesium, phosphorus, blood urea nitrogen (BUN), and creatinine levels, as well as liver function tests. A complete blood count (CBC), a urinalysis, and a urine toxicity screen should also be obtained. A lumbar puncture should be performed only if meningitis is suspected on the basis of clinical examination.

The so-called coma cocktail—consisting of dextrose, naloxone, and thiamine—is administered if the cause of coma is not immediately apparent from the brief history and physical examination; the addition of flumazenil is considered if benzodiazepine over-

Table 3 Glasgow Coma Scale

Test	Response	Score
Eye opening (E)	Spontaneous	4
	To verbal command	3
	To pain	2
	None	1
Best motor response (arm) (M)	Obedience to verbal command	6
	Localization of painful stimulus	5
	Flexion withdrawal response to pain	4
	Abnormal flexion response to pain (decorticate rigidity)	3
	Extension response to pain (decerebrate rigidity)	2
	None	1
Best verbal response (V)	Oriented conversation	5
	Disoriented conversation	4
	Inappropriate words	3
	Incomprehensible sounds	2
	None	1
Total (E + M + V)		3–15

dose is suspected [see Table 6].^{2,3} It should be kept in mind that administering dextrose to a thiamine-depleted patient (especially one who is malnourished or alcoholic) may precipitate the Wernicke-Korsakoff syndrome. As a rule, therefore, thiamine should always be given before dextrose.

Any comatose patient with focal signs on the coma examination should undergo head CT scanning. Any patient with signs of meningitis on the physical examination should receive emergency antibiotic therapy. When drug overdose or toxin ingestion is suspected, activated charcoal, 50 to 100 mg (with or without gastric lavage), should be given to prevent systemic absorption. As noted, flumazenil may be given for suspected benzodiazepine overdose and may produce dramatic arousal; however, this agent is contraindicated in patients taking tricyclic antidepressants because of an increased risk of seizures.

Once the recommended general treatment measures have been carried out, the next step is to look for and address specific causes of coma.

MANAGEMENT OF SPECIFIC CAUSES OF COMA

Basilar Artery Occlusion

BAO is an uncommon cause of stroke but also an underrecognized one. Morbidity and mortality are high, with only about 15% to 45% of victims surviving.⁴ BAO may be caused by embolism (most often from the heart but sometimes from the vertebral arteries), by intrinsic atherothrombosis, or by vertebral dissection. It frequently presents with a stepwise accumulation of neurologic deficits that culminates in a coma.

A typical case scenario for BAO, occasionally heard by stroke neurologists, is as follows. A patient presents with double vision, followed hours later by ataxia. This may prompt an emergency department (ED) visit. The patient is admitted to the hospital but, on the nursing unit, becomes suddenly unresponsive and needs intubation for airway protection. In another typical scenario, a patient who has just undergone cardiac catheterization becomes suddenly unresponsive on the angiography table but is hemodynamically stable.

Table 4 Focused Neurologic Examination (Coma Examination)

Neurologic Variable Assessed	Findings	Likely Cause of Coma
Spontaneous movement (15 sec)	Rhythmic movements	Seizure
	Random jerks (myoclonus)	Hypoxic-ischemic encephalopathy
Pupillary response (15 sec)	Unilateral fixed and dilated pupil	Brain herniation (mass) Posterior communicating artery aneurysm
	Midposition unreactive pupils	Midbrain lesion
	Pinpoint unreactive pupils	Pontine lesion
	Small and sluggishly reactive pupils	Drug intoxication
	Large and unreactive pupils	Atropine
	Unreactive pupils	Barbiturates, paralytics, lidocaine, phenothiazines, methanol, aminoglycoside antibiotics, hypothermia
	Roving eye movements	Metabolic insult to brain; brain stem is intact
Ocular motility (15 sec)	Gaze deviation	Stroke (eyes look toward damaged side of brain) Seizure (eyes look away from side of brain producing seizure)
	Skew deviation	BAO
	Ocular bobbing	Extensive damage to pons
	Unilateral weakness	Structural injury (e.g., stroke)
	Motor response (15 sec)	Herniation (mass) Extensive cortical injury

Table 5 General Physical Examination

Physical Variable Assessed	Finding and Possible Causative Condition
Skin	Signs of trauma around head/neck Jaundice Hepatic failure Exanthema Viral infection Petechial rash Meningococcal infection
Head and neck	Brudzinski or Kernig sign Meningitis, meningoencephalitis Subarachnoid hemorrhage
Temperature	Fever Infection (meningitis, encephalitis, bacteremia, sepsis) Hypothermia Exposure Intoxication (alcohol, benzodiazepine, barbiturate) Myxedema coma Sepsis
Breath	Alcohol intoxication Fetor hepaticus Hepatic failure Uriniferous smell Uremia Ketoacidosis
Blood pressure	Hypotension Shock Sepsis Intoxication Myocardial infarction Addison disease Hypertension Hypertensive encephalopathy
Cardiac conduction and rhythm (ECG)	Arrhythmia Acute myocardial infarction
Abdomen	Hepatomegaly Splenomegaly

A comatose patient with BAO usually manifests obvious clinical signs of brain stem injury, such as quadripareisis, skew deviation, and diminished gag reflex (many physicians report that intubation is unexpectedly easy). On occasion, CT scanning may reveal an apparently hyperdense basilar artery [see *Figure 4*]; imaging of the posterior circulation invariably reveals the problem. Management of BAO should be aimed at immediate recanalization of the occluded artery. Thrombolysis, either intravenous (with tissue plasminogen activator) or intra-arterial (with urokinase or mechanical clot disruption), may be lifesaving.

As noted, patients with extensive brain stem injury resulting from BAO often die. Some enter what is known as the locked-in state, in which they remain conscious but are unable to move, breathe, or swallow. Occasionally, patients retain the capacity for subtle eye movements or eye blinking and thus are able to communicate through yes/no responses to questions. Most stroke neurologists consider the locked-in state a fate worse than death.

Seizures

A seizure disorder can cause coma in two different ways. First, the coma may be the initial manifestation of the immediate postictal state after a generalized seizure. In such cases, the coma resolves rapidly, and further management is unnecessary. The duration of the postictal coma may be directly correlated with patient age and inversely correlated with baseline functional status. Second, coma may develop when multiple generalized seizures occur in succession and there is not enough time between seizures to allow patients to recover. The resulting state is status epilepticus.

Generalized convulsive status epilepticus (GCSE) may be defined either as (1) continuous seizure activity lasting longer than 5 minutes or as (2) two or more discrete generalized seizures between which there is incomplete recovery of consciousness. GCSE is most frequently the result of noncompliance with an antiepileptic drug regimen, alcohol use or withdrawal, or drug toxicity. Less common causes include CNS infection, a cerebral tumor, trauma, refractory epilepsy, stroke, metabolic disorders, and cardiac arrest. If untreated, GCSE leads to cerebral edema, herniation, and death.

A tonic-clonic seizure begins with a tonic contraction that lasts as long as 30 seconds, followed by several minutes of repeated muscle contractions, loss of pupillary response to light, sweating, tachycardia, excessive bronchial secretion, and marked hypertension. Repeated seizures cause lactic and respiratory acidosis, rhabdomyolysis and myoglobinuria, aspiration and pulmonary edema, shoulder dislocations, rib fractures, and cardiac arrhythmias. The neuronal damage induces an inflammatory response, and if seizures continue, cerebral edema ensues.

In the treatment of GCSE, the aim is not to stop the body from convulsing but to stop the abnormal cerebral electrical activity immediately. The longer GCSE continues, the more refractory it will be to treatment. Paralytics mask (but do not prevent) the seizures; therefore, intubation and paralysis should be avoided if possible.

Like all other coma victims, patients with GCSE should first be stabilized [see Initial Stabilization, *above*]. I.V. access should then be obtained. Glucose should be given empirically, along with thiamine, and blood should be drawn and sent for laboratory tests (including anticonvulsant levels).

Anticonvulsant management of status epilepticus is discussed in detail elsewhere^{5,6} and so need only be summarized here. The first-line treatment for GCSE consists of administration of lorazepam [see *Figure 3*]. Although there is no significant difference between the benzodiazepines with respect to rapidity of seizure control, lorazepam is thought to bind more tightly to brain receptors and thus is believed to have a longer duration of action. Lorazepam is given in 2 mg increments 3 minutes apart to a maximum dose of 8 mg before another agent is tried [see *Table 7*]. Diazepam may be employed as an alternative. The second-line agent is fosphenytoin, 20 mg/kg at up to 150 mg/min I.V.; phenytoin may be given as an alternative. If the patient does not respond to either lorazepam or fosphenytoin, a third-line agent—pentobarbital, midazolam, or propofol—should be given in a continuous infusion. Of the three third-line choices, midazolam may be the most effective, and it certainly has the lowest side effect profile.

The goal of therapy is to achieve a burst-suppression pattern on electroencephalography for 12 to 24 hours before any attempt is made to taper medications.

Increased Intracranial Pressure

If IICP is suspected on the basis of clinical examination and herniation is identified, treatment must be initiated immediate-

Table 6 Coma Cocktail

Drug	Indications	Dosing (Adults)	Potential Adverse Effects
Thiamine	Wernicke-Korsakoff syndrome Ethylene glycol ingestion	100 mg I.V. over 5 min	Anaphylactoid reaction Hypotension Angioedema
Dextrose	Symptomatic hypoglycemia Altered mental status without ability to rapidly obtain serum glucose level	50–100 ml of 50% dextrose I.V. Alternatively, 250 ml of 10% dextrose (to prevent the phlebitis that frequently occurs with administration of 50% dextrose)	Phlebitis Cellulitis
Naloxone	Reversal of CNS depression and respiratory depression caused by overdose of opioid medication	0.1 mg I.V. initially (I.V. route is more effective than subcutaneous or endotracheal), aimed at producing subtle improvement in ventilation Repeat doses given in 2–3 min intervals, increased very slowly each time If no response after total dose of 10 mg, opioid toxicity ruled out	Hypersensitivity reaction Precipitation of sudden narcotic withdrawal syndrome (If heroin has been tainted with scopolamine, withdrawal of opioid can precipitate anticholinergic crisis) Lung injury, hypertension, and cardiac arrhythmias (rarely reported)
Flumazenil	Benzodiazepine overdose	0.2 mg I.V. over 30 sec If no response, 0.3 mg I.V. over 30 sec If still no response, 0.5 mg I.V. every 30 sec to maximum dose of 3 mg	Contraindicated in patient experiencing seizure Benzodiazepine withdrawal, which may cause seizures and autonomic dysfunction

ly.⁷ Medical management of IICP is a temporizing measure, aimed at slowing the process of herniation until the problem can be corrected neurosurgically.

The head of the patient's bed should be elevated to an angle of 30° to 45° to facilitate venous return from the head. If the patient is intubated, hyperventilation to bring the patient's carbon dioxide tension below 25 mm Hg will rapidly, but only transiently, lower

the ICP. Mannitol, 0.25 mg/kg every 4 to 6 hours, will also control IICP temporarily. Steroids may be used in the setting of tumors or abscesses of the brain. In most cases of IICP, the eventual treatment is neurosurgical decompression.

Cardiac Arrest

Cardiac arrest, if ongoing, is treated according to advanced cardiac life support (ACLS) guidelines. Several preliminary studies on the use of hypothermia for brain resuscitation after ventricular fibrillation (VF) cardiac arrest led to the publication of two randomized, controlled clinical trials in back-to-back issues of the *New England Journal of Medicine* in 2002.^{8,9} Both trials clearly demonstrated that hypothermia significantly improved survival and neurologic outcomes. As a result, the Advanced Life Support Task Force of the International Liaison Committee on Resuscitation issued a guideline statement containing the following recommendation: "Unconscious adult patients with spontaneous circulation after out-of-hospital cardiac arrest should be cooled to 32°C to 34°C for 12 to 24 hours when the initial rhythm was VF. Such cooling may also be beneficial for other rhythms or in-hospital cardiac arrest."¹⁰ This recommendation has spurred the implementation of hypothermia for resuscitation of cardiac arrest victims in many hospital centers.

Metabolic Derangements

Intoxication Many comatose patients who are seen in the ED are suffering from an overdose of alcohol, narcotics, sedatives, or some combination thereof. Most of these drugs induce depression of respiration and cardiovascular function, which is a major cause of mortality in comatose patients. Anticipation and early treatment of these complications may alleviate their effects. Early intubation, respiratory support, and maintenance of normal blood pressure are essential. Gastric lavage is effective when ingestion of a drug is discovered no more than 4 hours after the event (except in the case of salicylates, which may be removed in substantial amounts as long as 10 hours after ingestion). Accordingly, in most cases of drug overdose, little is gained by performing gastric lavage more than 4 hours after ingestion, unless the patient has been in shock and consequently manifests delayed gastric emptying and slowed absorption. When

Figure 4 In this noncontrast head CT scan, the basilar artery, which runs ventral to the pons and the lower midbrain, appears hyperdense. In the setting of acute coma, this finding suggests BAO.

Table 7 Drugs Used to Treat Status Epilepticus

Drug	Priority of Use	Dosing	Potential Adverse Effect
Lorazepam	First-line agent	2 mg increments I.V. 3 min apart to maximum of 8 mg	Respiratory depression Hypotension
Diazepam	Alternative first-line agent	10 mg I.V., 1 or 2 doses	Respiratory depression Hypotension
Fosphenytoin	Second-line agent	20 mg/kg, 150 mg/min	Arrhythmia Hypotension
Phenytoin	Alternative second-line agent	20 mg/kg, 50 mg/min	Arrhythmia Hypotension (Risk is lower than with fosphenytoin)
Pentobarbital	Third-line agent	5–12 mg/kg, 1–10 mg/kg/hr	Poor WBC chemotaxis Paralysis of respiratory cilia Poikilothermia
Midazolam	Third-line agent	0.1–0.3 mg/kg, 0.05–2.0 mg/kg/hr	Tachyphylaxis Death (mortality lower than with propofol)
Propofol	Third-line agent	3–5 mg/kg, 1–15 mg/kg/hr	Recurrent seizures after abrupt discontinuance Hypotension Hypertriglyceridemia Anemia Death (mortality higher than with midazolam)

WBC—white blood cell

a patient is comatose or uncooperative, however, the examiner is rarely able to determine the exact time of ingestion; thus, gastric lavage is almost always indicated in this situation.

Patients are intubated with a cuffed endotracheal tube (to protect the airway from aspirated gastric contents) and placed in the left lateral decubitus position (to allow pooling of the gastric contents) with the head down. Lavage is then performed with copious amounts of fluid until the returned fluid is clear. After evacuation, a slurry containing 10 g of activated charcoal in 30 to 50 ml is instilled into the stomach via a nasogastric tube. After lavage, cathartic agents may be used to shorten the transit time through the GI tract and thus to decrease absorption of the ingested material. Diuresis (saline, ionized, or osmotic), dialysis, and charcoal hemoperfusion all facilitate excretion of toxins. Specific antidotes exist for several common intoxicants; however, discussion of these antidotes is beyond the scope of this chapter.

Hypoglycemic coma Symptomatic hypoglycemia may occur when plasma glucose levels fall below 45 mg/dl. Symptoms may range from jitteriness with palpitations and diaphoresis to focal neurologic symptoms mimicking ischemic stroke to frank coma. The most common predisposing cause is diabetes; other common causes include alcoholism, hepatic failure, and renal failure.

If hypoglycemic coma is prolonged, it may result in permanent brain damage. Therefore, initial management involves urgent restoration of the patient to a euglycemic state. This may be accomplished through I.V. injection of glucose. Traditionally, injection of an ampule (50 ml) of a 50% solution is prescribed; however, this measure frequently results in loss of the peripheral I.V. site used. Alternatively, 250 ml of a 10% dextrose solution is rapidly injected; this measure provides the same amount of dextrose without causing any loss of venous access. If necessary, infusion of a 5% dextrose solution may be continued subsequently. As noted [see General Measures, Triage, and Test Battery, *above*], if the patient is thiamine depleted, 100 mg of thiamine should be given before dextrose so as not to precipitate Wernicke-Korsakoff syndrome.

Further treatment consists of prevention, in the form of educating patients in the use of insulin and encouraging them to carry glucose tablets or sweets with them at all times. A supply of glucagon (1 g I.M.) that can be administered by relatives may also be stored at home.

Diabetic ketotic coma Because patients who are comatose as a result of diabetic ketoacidosis often present in a profoundly dehydrated state, treatment must be initiated as soon as possible. The following are the key components of the management of diabetic ketoacidosis.

1. Replacement of fluid losses (the average fluid loss is approximately 7 L).
2. Normalization of electrolyte levels and careful monitoring of serum potassium.
3. Restoration of acid-base balance (bicarbonate infusion is reserved for severe cases).
4. Correction of insulin deficiency (4 to 6 U/hr).
5. Replenishment of energy stores (e.g., through dextrose infusion with insulin coverage until the patient can resume oral feeding).
6. Investigation to identify an underlying cause (infection is common).

Hyperglycemic hyperosmolar nonketotic coma Management of hyperosmolar nonketotic coma is essentially the same as that of diabetic ketotic coma. It is particularly important, however, that meticulous rehydration be performed, given that many patients with this condition are elderly.

Vegetative State

Approximately 10% to 12% of comatose patients eventually lapse into a vegetative state (VS). Whereas comatose patients have closed eyes and do not respond to pain, VS patients have spontaneous eye opening according to sleep-wake cycles and may have

minimal, purposeless movement. Specifically, the diagnosis of VS can be made if there is intermittent wakefulness (sleep-wake cycles); no evidence of awareness of self or environment or ability to interact with others; no evidence of sustained, reproducible, purposeful, or voluntary behavioral responses to external stimuli; no evidence of language comprehension or expression; and sufficiently preserved hypothalamic and brain stem autonomic function to permit survival with medical and nursing care. VS that persists for more than 1 month is referred to as a persistent vegetative state (PVS); PVS that lasts for 1 year or longer is considered permanent VS.^{11,12}

Prognosis

At least 50% of patients who are in traumatic VS will recover consciousness within 1 year, compared with only 15% of patients in nontraumatic VS. In one series, 69% of nontraumatic VS patients died, 20% survived with severe disability, and 8% survived without severe disability. Indicators of poor prognosis in nontraumatic VS patients include the absence of pupillary reflexes for 24 hours after the event; no withdrawal from painful stimuli after 72 hours; the absence of roving eye movements after 7 days; and the absence of motor response to noxious stimuli after 72 hours.¹³⁻¹⁵

12 BRAIN FAILURE AND BRAIN DEATH

David Crippen, M.D., F.C.C.M.

He seems to be completely unreceptive
 The tests I gave him show no sense at all
 His eyes react to light; the dials detect it
 He hears but cannot answer to your call
 "Go to the Mirror Boy" (from *Tommy*, The Who, 1969)

Brain Failure

BRAIN FAILURE AND IMPAIRMENT OF CONSCIOUSNESS

As a type of organ system failure, brain failure invariably affects consciousness. Consciousness is structurally produced in the cerebral hemispheres, including the pons and the medulla.¹ These structures are all interconnected by the reticular formation, which begins in the medulla and extends to the midbrain, where it forms the reticular activating system. This pathway modulates the perception of events and controls integrated responses.²

Clinical evaluation of consciousness states is heavily dependent on the findings from physical examination. When the physical examination yields visual and palpable clues to the integrity of consciousness, impairment thereof may be classified into one of the following categories³:

1. Cloudy consciousness. This state is defined as a mild deficit in the speed of information processing by the brain, resulting from disruption of cell-to-cell connectivity at the histologic level. Cloudy consciousness may be noted after mild to moderate head trauma and may persist for several months. Memory of recent events is often diminished, but long-term memory typically remains intact.
2. Lethargy. This state is defined as a decrease in alertness, resulting in impaired ability to perform tasks that are normally accomplished without effort. Patients rouse briefly in response to stimuli, then settle back into inactivity when left alone. They retain awareness of their immediate environment.
3. Obtundation. This state is defined as a decrease in awareness and alertness, in which patients rouse briefly in response to stimuli and follow simple commands but are unaware of their immediate surroundings. When stimulation ceases, they settle back into inactivity.
4. Stupor. In this state, patients cannot communicate clearly but can be aroused by continued painful stimulation. Arousal may be manifested only as withdrawal from painful stimuli. As soon as stimuli are removed, patients settle back into inactivity.
5. Coma. In this state, patients do not respond to even the most vigorous stimuli.
6. Brain death. This state is equivalent to functional decapitation and is characterized by irreversible cessation of whole brain function and function of the hemispheres and the brain stem.

It should be kept in mind that the efficacy of the physical examination in the evaluation of consciousness diminishes when visual clues disappear (e.g., during heavy sedation or therapeutic musculoskeletal paralysis). In such situations, monitoring of cerebral function is helpful in assessing the effect of therapy on neuronal function.

RELATION OF CARDIAC ARREST TO BRAIN FAILURE

In a substantial proportion of unconscious patients admitted to the intensive care unit, the brain failure resulted from metabolic and hemodynamic deteriorations that followed cardiac arrest.⁴ There is a great difference between surviving cardiopulmonary resuscitation (CPR) and walking out of the hospital unaided after such an event. It is relatively easy to restart the heart with traditional CPR; it is considerably harder to restart the brain.⁵ After several minutes of cardiac arrest, CPR will occasionally restore cardiac activity, but it will not necessarily restore useful brain function. Brain metabolism requires a constant high flow of oxygenated blood and nutrients. During cardiac resuscitation, cerebral perfusion decreases sufficiently to promote hypoxia and tissue edema. A number of mechanisms have been shown to underlie deteriorating and failed reflow. Hyperviscosity from hemoconcentration of plasma proteins and formed elements contributes to initial poor reperfusion at the capillary level. Endothelial cell swelling and edema of the pericapillary astrocytes also greatly inhibit reperfusion by reducing capillary diameter to less than 5 µm.

During reperfusion, abnormally high amounts of superoxide convert almost all available nitric oxide to peroxynitrite, which is regarded as the agent that causes most of the damage to brain capillary endothelial cells.⁶ As noted (see above), damage to the endothelium not only increases edema (tissue swelling resulting from leakiness) but also causes endothelial protrusions (blebs) that can block capillaries. Calcium-mediated vasospasm also plays a role. L-type calcium channel blockers, given before the insult, have been shown to prevent the no-reflow phenomenon in dogs and to result in an 80% survival rate (compared with an 86% mortality in the control group).⁷

During CPR, cerebral perfusion tends to decrease dramatically over time if adequate flow is not quickly reestablished.⁸ Maintaining a small amount of blood flow to the brain with CPR is not necessarily beneficial. Incomplete brain ischemia, which is created when only a small amount of blood is allowed into the brain after an anoxic insult (as in CPR), appears to result in more detrimental alterations in brain metabolism than does the complete anoxia resulting from the absence of any flow.⁹ When a small amount of blood is allowed to flow into an actively distorted and stressed metabolic system, the resulting cellular activity generates more toxic products of metabolism than complete anoxia would have produced.¹⁰ In other words, more brain damage seems to occur with prolonged CPR states than with no-flow states¹¹—especially if there is an increased level of glucose in the small quantities of blood supplied by CPR.¹² To date, this phenomenon has not been completely explained. Acidosis, in and of itself, is unlikely to be the only damaging factor, because severe respiratory acidosis does not damage the brain.¹³

PATHOPHYSIOLOGY OF BRAIN FAILURE

In vitro, central nervous system neurons can tolerate between 20 and 60 minutes of complete ischemic anoxia without irreversible injury.¹⁴ *In vivo*, however, injury occurs after a much shorter time

and is much more severe. Immediately after the cessation of circulation to the brain, the cerebral vessels dilate in response to the local environmental factors and to increased arterial carbon dioxide tension (P_aCO_2). Because the brain has no stores of glucose, cellular metabolism quickly ceases. Absence of nutrients and hypoxia cause the most sensitive structures to lose their cellular integrity. This loss results in capillary leakage, edema, and cellular disruption and leads to the release of proteases and other damaging compounds into the surrounding tissues.¹⁵

These events, in turn, result in clogged microcirculation, stasis, and a vicious circle of worsening damage that backs up into the macrocirculation. If this process is allowed to continue for a substantial period and blood flow is then reestablished, the increased pressure gradient in the damaged area tends to disrupt the fragile architecture, much as the sudden bursting of a dam might do to downstream communities. The result is a progressive postresuscitative hypoperfusion state in which blood flow falls to less than 20% of normal within 90 minutes after reperfusion and remains at this low level for as long as 18 hours.^{16,17}

Two explanations for these phenomena have been proposed. The first is that massive overloading of the cells with calcium ions (Ca^{2+}) may be the initial stage of irreversible damage.¹⁸ Normally, the extracellular level of Ca^{2+} is high and the intracellular level is low. The damage to the cell membrane caused by hypoxia and loss of nutrient flow alters the gradient and allows Ca^{2+} to enter the cell, causing interference with enzymes, DNA, RNA, mitochondria, and energy production cycles. Infusion of high levels of Ca^{2+} into precapillary arterioles causes vasospasm and a vicious circle characterized by decreased flow and further depletion of oxygen and nutrients. The second theory is that during ischemia, abnormal metabolism may result in the creation of reactive oxygen metabolites, which attack DNA, RNA, and mitochondria, causing irreversible damage.¹⁹

Brain Death

DIAGNOSIS OF BRAIN DEATH

Brain death protocols have evolved to become highly specific and sensitive.²⁰ Brain death is a diagnosis of what is, not what might be. Initially, for an accurate diagnosis of brain death, there must be clear evidence of an acute, catastrophic, irreversible brain injury, and any reversible conditions that may obfuscate the clinical assessment (e.g., drug intoxication, hypothermia, and metabolic abnormalities) must be excluded.²¹ Subsequently, the physical examination must show coma, absent motor responses, absent brain stem reflexes, and apnea. Some protocols call for a second examination, performed after a variable interval.²² Further confirmatory studies (e.g., electroencephalography [EEG] or cerebral blood flow studies) may be ordered if there is any ambiguity in the clinical evaluation.²³

A typical brain death protocol may be summarized as follows:

1. Confirm that the patient is in a coma.
2. Evaluate the patient for seizure activity and decerebrate or decorticate movements.
3. Test for motor response to painful stimulation.
4. Test for pupillary response to light.
5. Test for the corneal reflex.
6. Test for the oculocephalic reflex (the doll's head reflex).
7. Test for the vestibulo-ocular reflex (the caloric test).
8. Test for upper and lower airway stimulation (e.g., pharyngeal and endotracheal suction).

9. Test for the gag reflex.
10. Perform the apnea test. This test should be the last test and should be conducted after two clinical examinations (separated by the mandatory observation period) have confirmed the absence of brain stem functions. The patient is disconnected from the ventilator while oxygenation of the lungs is continued passively. On the basis of calculation (whereby P_aCO_2 is assumed to rise 4 mm Hg in the first minute and 3 mm Hg every minute thereafter), the patient is allowed to build up to a P_aCO_2 of 60 mm Hg or more without becoming hypoxic. If there is no respiratory effort, the apnea test is considered confirmatory.²⁴
11. Consider ordering an EEG. The EEG should show electrocerebral silence for at least 30 minutes and must conform to established criteria for brain death.²⁵
12. If the cause of death cannot be determined with absolute accuracy, consider cerebral angiography. The absence of intracranial arterial circulation, as demonstrated by four-vessel angiography, confirms brain death.²⁶

DEFINITION OF DEATH

In earlier times, it could be said that a person was dead when the heart and lungs ceased functioning. Today, however, this view no longer suffices, because with the advent of critical care techniques such as mechanical ventilation, selected organ systems can be artificially supported.^{27,28} In this era of critical care, death is more a process than an event. Lack of blood flow to the brain leads to loss of consciousness within seconds, but other functions of the brain may persist for much longer.²⁹ Other somatic organs may take hours to stop functioning, and connective tissues can take days to die.³⁰

The evolution of life support systems capable of prolonging death indefinitely necessitated a more eclectic definition of death, which arrived in 1968 with the formulation of the Harvard criteria.³¹ In essence, these criteria considered the irreversible loss of certain organ functions, rather than whole body metabolic cessation, to be indicative of death. When the Harvard criteria were met, death was inevitable, even with continuing treatment. A 1970 study found that a population of patients meeting the Harvard criteria all eventually died while undergoing continued medical treatment.³² The Harvard criteria objectified the progression of disease, thereby making it possible for clinicians to predict death.

These early studies only predicted with a reasonable certainty that patients meeting particular criteria would eventually die. A prognosis of death, however, cannot serve as a diagnosis. In 1981, the President's Commission broke with the past and established brain death as a criterion for determining death, not simply for predicting the inevitability of death.³³ The Uniform Determination of Death Act (UDDA) made brain death and cardiopulmonary collapse criteria for death in 44 states³⁴:

An individual who has sustained either: (1) irreversible cessation of circulatory and respiratory functions, or (2) irreversible cessation of all functions of the entire brain, including the brain stem, is dead.

Under the UDDA, death is pronounced at the time the criteria are met, and families may not demand continuing mechanical ventilation or other forms of ICU life support (except in the states of New York and New Jersey, both of which have conscience clauses).³⁵

Is Brain Death Equivalent to Death?

Physicians and ethicists continue to disagree on the question of whether whole brain death (WBD) is equivalent to death.³⁶ It

is generally asserted that there is only one real definition of death—irreversible cessation of the integrated functioning of the organism as a whole—but as noted (see above), the determination of death can have either a cardiovascular or a neurologic basis. The connections between cardiovascular and neurologic criteria are tenuous, and the criteria mean different things to different people at different times. For example, the criterion of irreversible cessation of all circulatory and respiratory function does not imply the cessation of brain function.³⁷ Conversely, the criterion of irreversible cessation of all brain function does not imply the cessation of circulation and respiration.³⁸ It appears, then, that the definition of death does not require the permanent cessation of the functioning of the organism as a whole but, rather, cessation of only certain functions.³⁹

Ethicists maintain that the criteria used to fulfill the definition of death should be both necessary and sufficient.³⁰ This is not an easy standard to meet. For example, loss of consciousness is necessary for death, but it is not sufficient. Although the UDDA endorses two criteria for death—cardiac death and WBD—only WBD is both a necessary and a sufficient criterion, because a declaration of death can be made without the heart having stopped beating. Therefore, the UDDA does not ensure that each of the two criteria is an instantiation of the other.⁴⁰ Loss of heartbeat and breathing is sufficient for death, but it is not necessary if WBD is present. Moreover, the UDDA does not require that every brain cell be dead for brain death to be declared—only those cells that contribute to the integration of the organism as a whole.⁴¹ Accordingly, the UDDA suggests that death occurs when “critical” parts of the brain responsible for integrated functioning of the rest of the body cease functioning, in that, according to this argument, it is the brain that integrates the entire organism.

It is commonly postulated that when the brain dies, the body must die with it. However, there is a problem with the idea of the brain as the fundamental orchestrator of all body functions. It has been pointed out that many organ functions are, for variable periods, not obligately linked to the brain as an integrating controller.³⁰ In fact, the rest of the body can be viably sustained for some time in the absence of brain function simply by maintaining protection, ventilation, circulation, and nutrition. Some WBD patients actual-

ly require less support than other patients who are clearly alive but gravely ill.⁴² It can easily be shown that the brain will continue to function for a time after cessation of cardiopulmonary function.

Brain Death and Artificial Organ Support

Acceptance of WBD as essentially defining death involves the assumption that artificially maintained respiration and circulation are irrelevant because they are controlled by mechanical intervention rather than by the brain.⁴³ This assumption is based on the further assumption that because body functions are being manipulated externally, they cannot be functioning in any integrated manner. However, death cannot be predicated on the use of life-sustaining treatment, for two reasons. First, the availability of life-sustaining treatment ought not to determine who is alive and who is dead. Second, if the definition of death were to be contingent on the need for an artificial intervention, patients who require life-sustaining treatment to recover from an illness would have to be considered resurrected from the dead.⁴⁴ Furthermore, the definition of death does not require irreversible cessation of “spontaneous” organism functions, because spontaneous function is not necessary for life, as evidenced by the many patients who require life-sustaining treatment but who are very much alive.⁴⁵

IMPLICATIONS FOR FUTURE DEFINITIONS OF DEATH

There are disturbing differences between a corpse in a morgue and a brain-dead patient. If the WBD patient is a corpse, he or she is certainly a corpse with some unusual properties—one that breathes, circulates blood, digests food, filters wastes, and is capable of carrying a pregnancy to term.⁴⁶ These considerations raise the issue of whether there is a practical or ethical difference between being dead, being almost dead, or being in the process of dying, and they show that the precise moment when death occurs cannot be accurately pinpointed. It is clear that a WBD patient can be maintained on life-sustaining treatment for much longer than was once thought and still retain definite characteristics of a living being. The organism as a whole, though disabled, is not yet dead and should not be represented as such—a fact that may have important consequences for our future conceptions of death and of life in death.

13 MULTIPLE ORGAN DYSFUNCTION SYNDROME

John C. Marshall M.D., F.A.C.S., F.R.C.S.C.

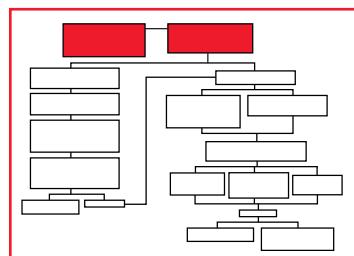

Approach to Multiple Organ Dysfunction Syndrome

The multiple organ dysfunction syndrome (MODS)—also known as progressive systems failure,¹ multiple organ failure,² and multiple system organ failure³—is characterized by progressive but potentially reversible physiologic dysfunction of two or more organ systems that arises after resuscitation from an acute life-threatening event. The term MODS was introduced by a 1991 consensus conference of the American College of Chest Physicians (ACCP) and the Society of Critical Care Medicine (SCCM).⁴ The designation of MODS as a syndrome emphasizes that dynamic alterations in physiologic function in critically ill patients may have common pathophysiologic underpinnings. However, MODS is as much a paradigm as a syndrome—that is, it represents an approach to the care of the critically ill patient that emphasizes intensive monitoring and support of organ system function over specific therapies for isolated disease processes and that focuses on preventing or minimizing iatrogenic injury resulting from ICU interventions.

MODS evolves in the wake of a profound disruption of systemic homeostasis.^{5,6} It was originally described in patients with overwhelming infection, multiple injuries, or tissue ischemia; however, it has many overlapping risk factors [see Table 1]. Preexisting illness—in particular, chronic alcohol abuse⁷—predisposes to the development of organ dysfunction in patients exposed to these risk factors.

Clinical Definitions of Organ Dysfunction

Although MODS is readily recognized by experienced clinicians, there is still no clear consensus on its description with respect to either the systems whose function is deranged, the descriptors that best measure that derangement, or the degree of derangement that constitutes organ dysfunction or failure.

A systematic review of 30 published clinical studies evaluated the organ systems and variables used to describe MODS.⁸ Seven organ systems—the respiratory system (all 30 reports), the renal system (29 reports), the hepatic system (27 reports), the cardiovascular system (25 reports), the hematologic system (23 reports), the GI system (22 reports), and the CNS (18 reports)—were included in at least half of the studies. Scoring systems from both North America^{9,10} and Europe^{11,12} define MODS using six of these seven organ systems, eliminating the GI system because of the declining prevalence of stress-related upper GI bleeding and the lack of satisfactory measures of GI dysfunction. These scoring systems have many similarities [see Table 2].

In general terms, the dysfunction of a given organ system can be described in one of three ways:

- As a physiologic derangement (e.g., an altered ratio of arterial oxygen tension [P_aO_2] to fractional inspiration of oxygen [F_iO_2] or an altered platelet count).
- As the clinical intervention used to correct that derangement (e.g., mechanical ventilation or blood component replacement therapy).
- As a discrete clinical syndrome incorporating several descriptive variables (e.g., acute respiratory distress syndrome [ARDS] or disseminated intravascular coagulation [DIC]).

Whichever of these three perspectives is adopted, common pathogenetic mechanisms underlie MODS, and common principles direct its prevention and management.

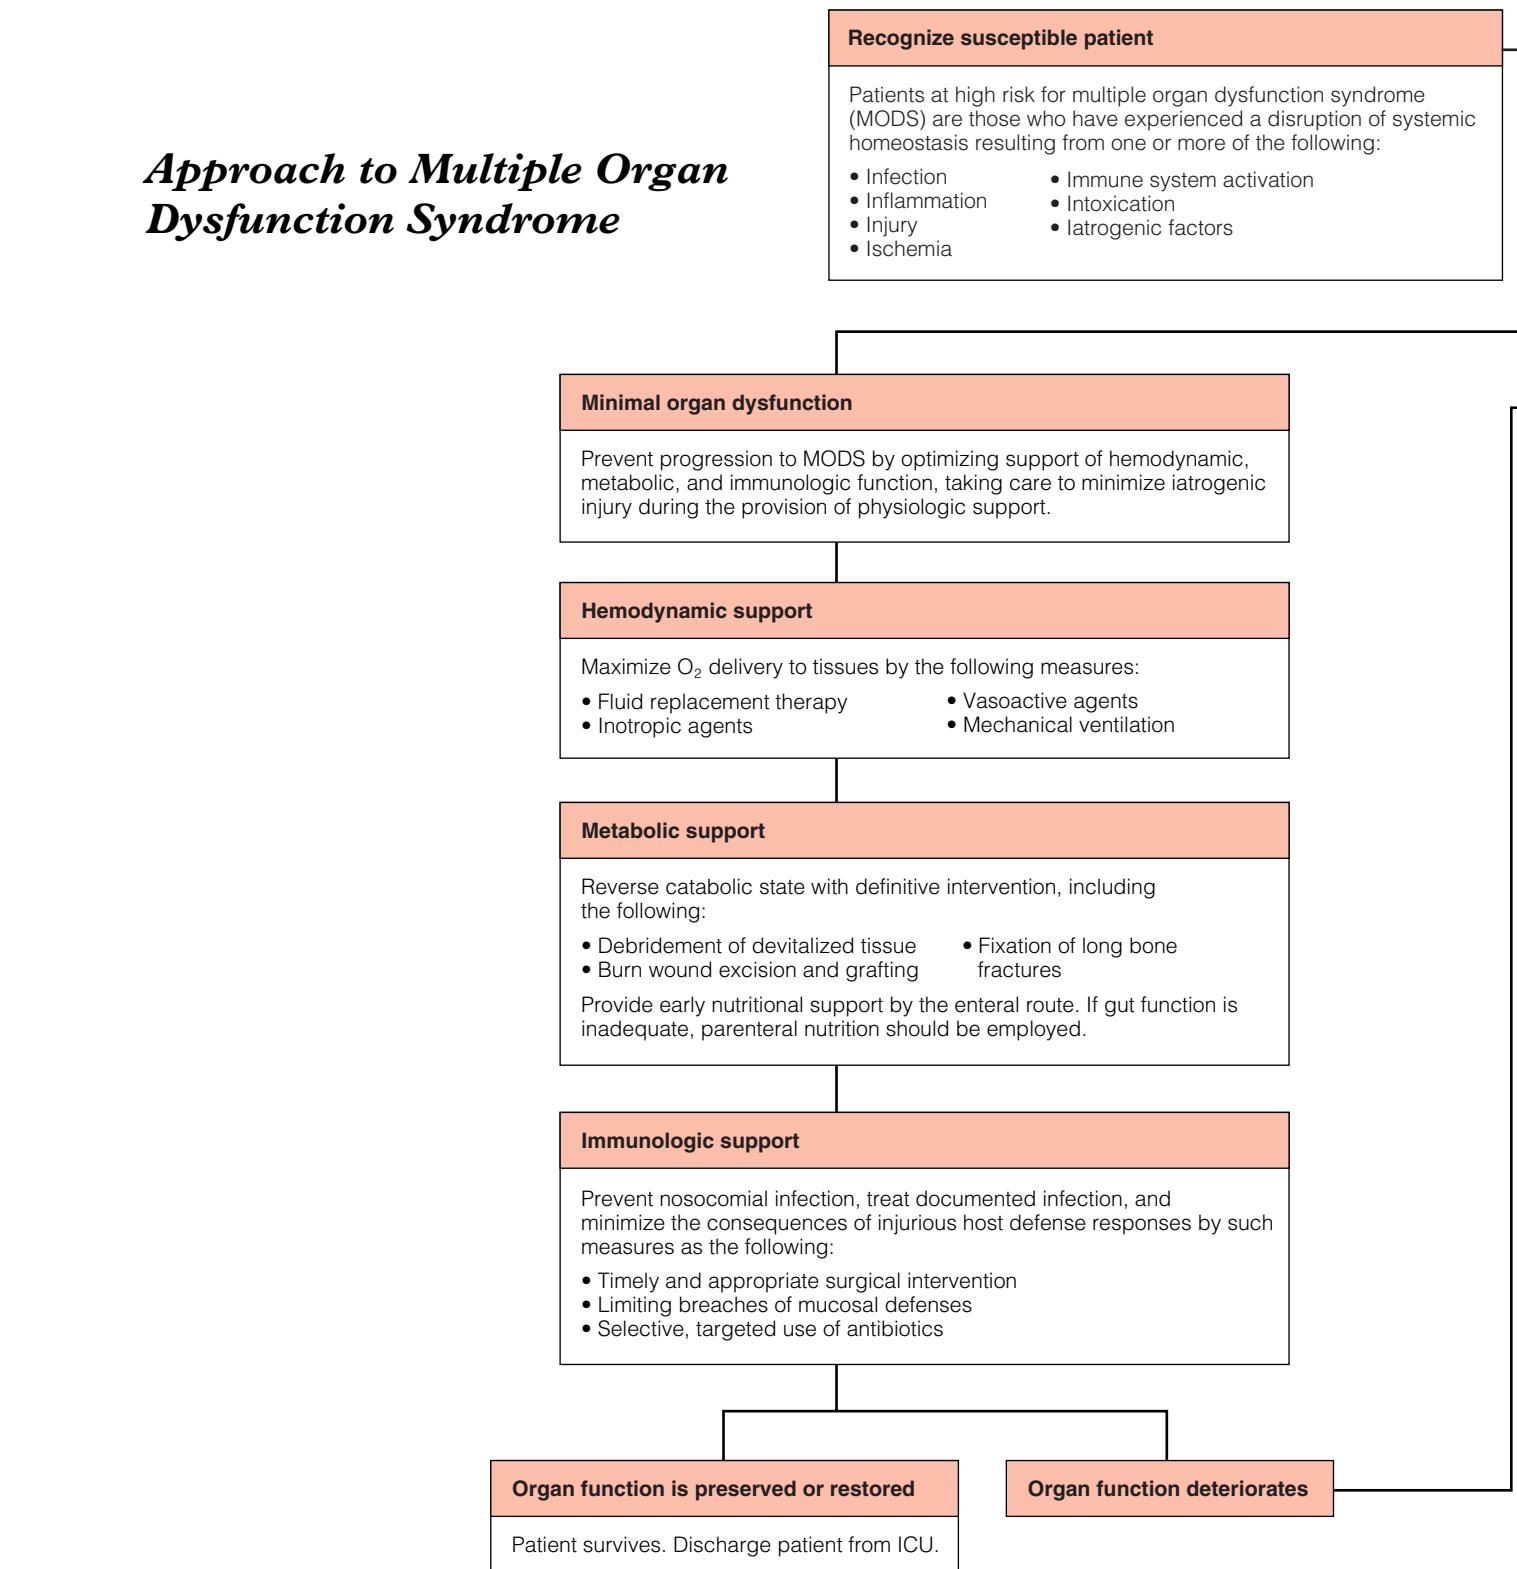

RESPIRATORY DYSFUNCTION

ARDS, initially described in the early 1960s,^{13,14} is the prototypical expression of respiratory dysfunction in MODS.¹⁵ In its

Table 1 Risk Factors for MODS

Infection	Peritonitis and intra-abdominal infections Pneumonia Necrotizing soft tissue infections
Inflammation	Pancreatitis
Injury	Multiple trauma Burn injury
Ischemia	Ruptured aneurysm Hypovolemic shock Mesenteric ischemia
Immune reactions	Autoimmune disease Transplant rejection Graft versus host disease
Iatrogenic factors	Delayed or missed injury Blood transfusion Injurious mechanical ventilation Total parenteral nutrition
Intoxication	Drug reactions Arsenic intoxication Drug overdose
Idiopathic factors	Thrombotic thrombocytopenic purpura Hypoadrenalinism Pheochromocytoma

Approach to Multiple Organ Dysfunction Syndrome

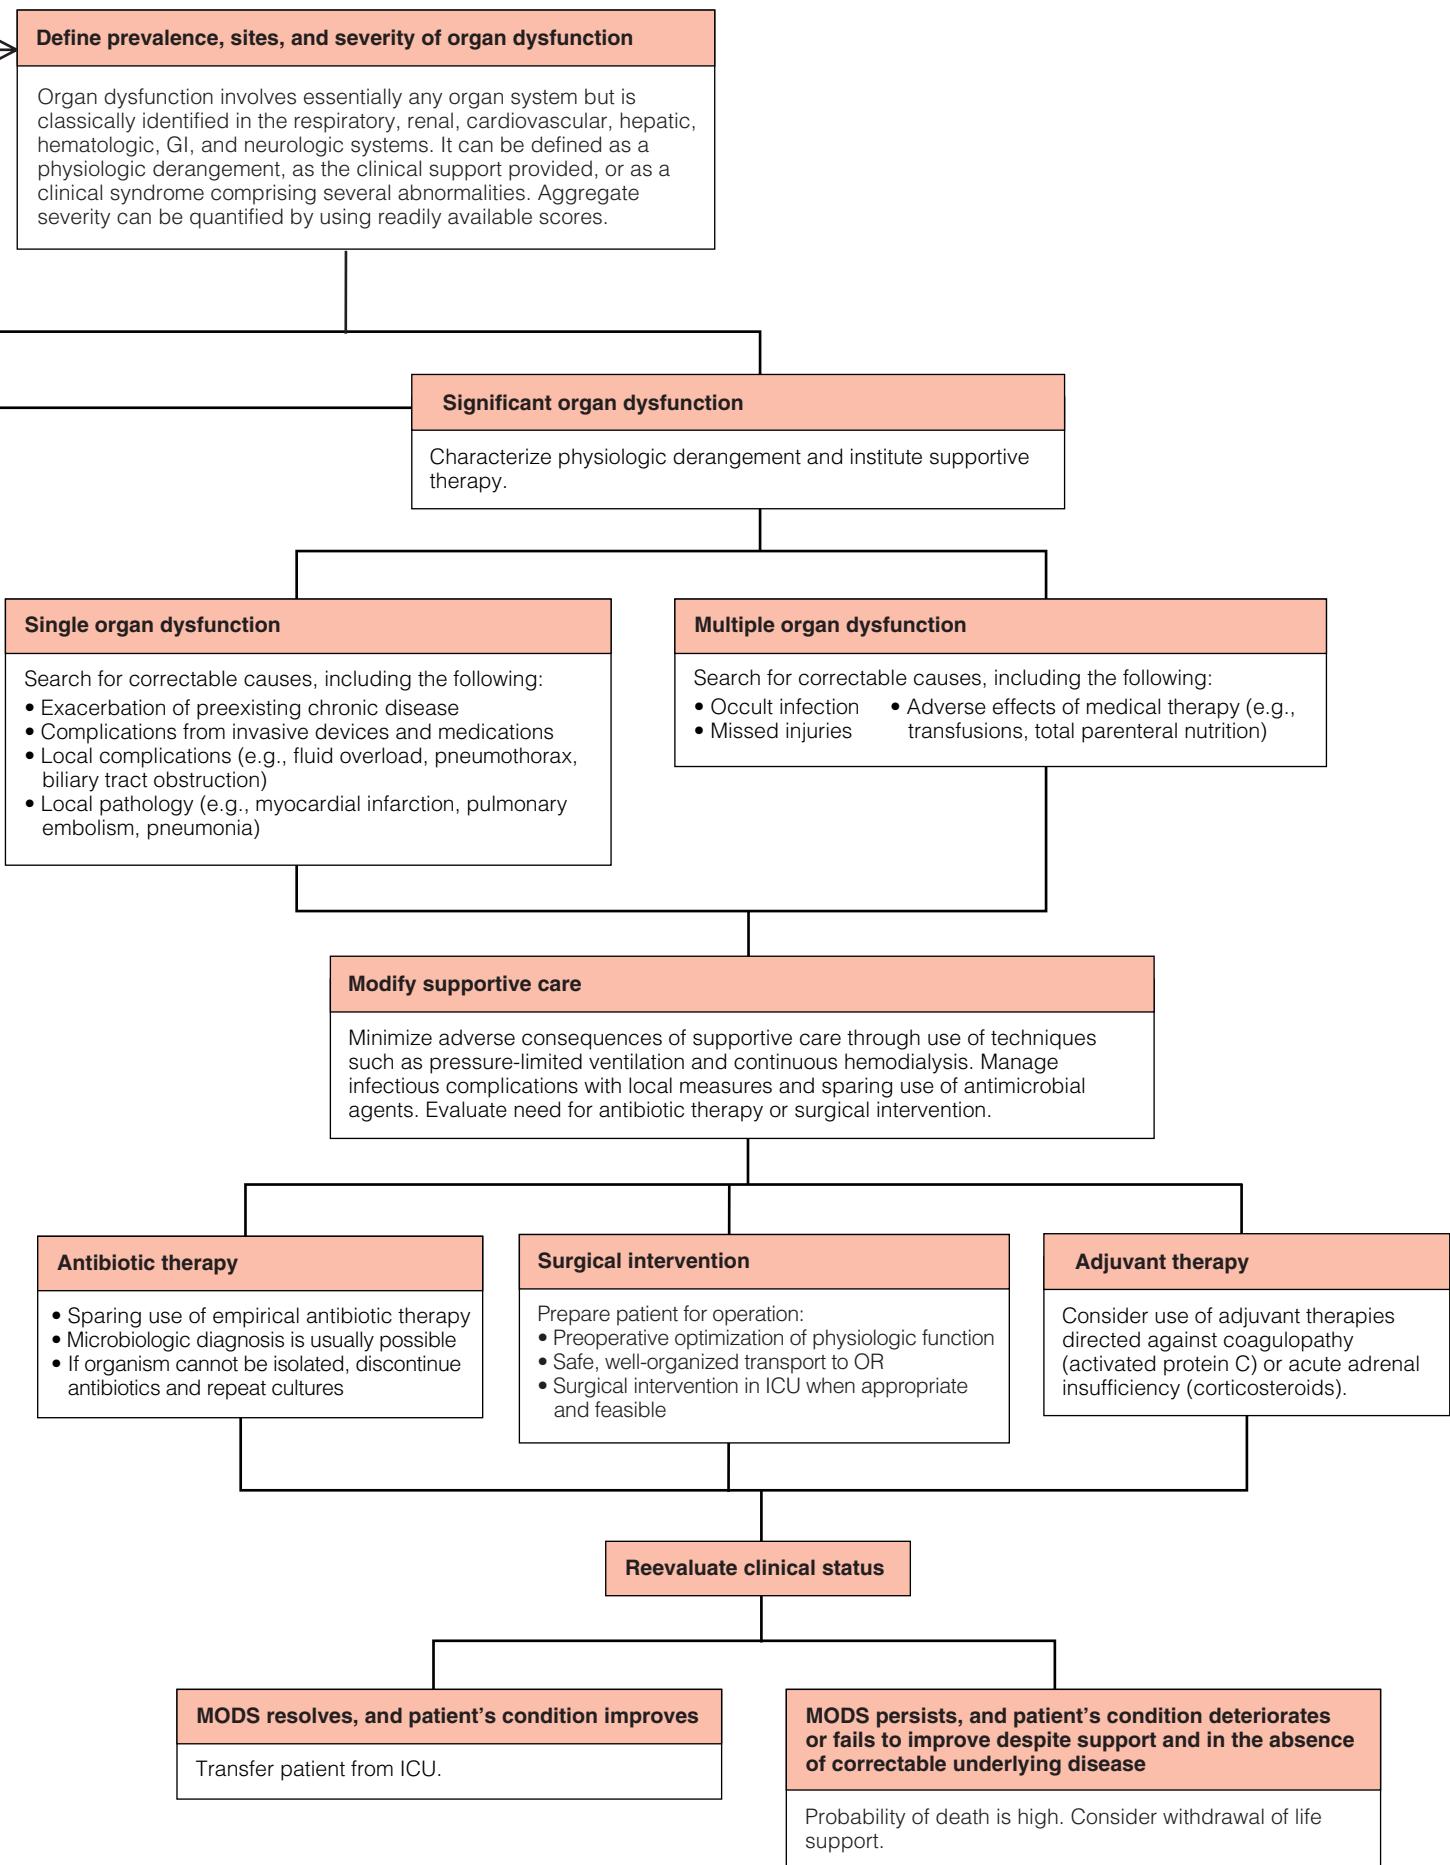

Table 2 Multiple Organ Dysfunction (MOD) Score⁹

Organ System	Indicator of Dysfunction	Degree of Dysfunction				
		None (0)	Minimal (1)	Mild (2)	Moderate (3)	Severe (4)
Respiratory	P _a O ₂ /F _i O ₂ ratio	> 300	226–300	151–225	76–150	≤ 75
Renal	Serum creatinine level	≤ 100 μmol/L	101–200 μmol/L	201–350 μmol/L	351–500 μmol/L	> 500 μmol/L
Hepatic	Serum bilirubin level	≤ 20 μmol/L	21–60 μmol/L	61–120 μmol/L	121–240 μmol/L	> 240 μmol/L
Cardiovascular	Pressure-adjusted HR*	< 10.0	10.1–15.0	15.1–20.0	20.1–30.0	> 30.0
Hematologic	Platelet count	> 120,000/mm ³	81,000–120,000/mm ³	51,000–80,000/mm ³	21,000–50,000/mm ³	≤ 20,000/mm ³
Neurologic	Glasgow Coma Scale score	15	13–14	10–12	7–9	≤ 6

*Calculated as the product of HR and central venous pressure (CVP), divided by mean arterial pressure (MAP): (HR · CVP)/MAP.

mildest form, respiratory dysfunction is characterized by tachypnea, hypocapnia, and hypoxemia. As lung injury evolves, a combination of worsening hypoxemia and increased work of breathing necessitates mechanical ventilatory support [see 8:5 Mechanical Ventilator].

Increased capillary permeability and neutrophil influx are the earliest pathologic events in ARDS. As the acute inflammatory process resolves, further lung injury results both from the process of repair, which involves fibrosis and the deposition of hyaline material, and from further lung trauma, resulting from positive pressure mechanical ventilation.¹⁶

Lung involvement in ARDS is inhomogeneous, with areas of functional and aerated alveoli interspersed with areas of non-functional alveoli.¹⁷ The distribution of injury reflects the sequelae of care in the intensive care unit: consolidation occurs in the posterior dependent regions of the lung, and cystic changes develop from overdistention by the ventilator in the antidependent regions.¹⁸

Impaired lung function is reflected in a reduced P_aO₂. To ensure adequate oxygen delivery to the tissues, mechanical ventilation must be instituted and F_iO₂ increased. The ratio of P_aO₂ to F_iO₂, therefore, provides a sensitive and objective measurement of the degree to which oxygenation is impaired and so is a reliable measure of physiologic respiratory dysfunction.¹⁹ Mechanical ventilation reflects the clinical intervention triggered by impaired oxygenation, and the additional criteria for ARDS—bilateral lung infiltrates and a normal pulmonary capillary wedge pressure—serve to exclude such primary causes of acute hypoxemia as pulmonary embolism, atelectasis, and congestive heart failure. By consensus, ARDS is defined as a P_aO₂/F_iO₂ ratio lower than 200 mm Hg in association with bilateral fluffy pulmonary infiltrates and a pulmonary capillary wedge pressure lower than 18 mm Hg.²⁰

ARDS is a robust model for the complex interactions that result in MODS. Lung injury in ARDS is the outcome of an interaction between an insult, a susceptible host, and the clinical therapeutic response, and its severity reflects not only the degree of the initial insult but also various poorly defined genetic influences in the host²¹ and the inadvertent adverse consequences of the mode of respiratory support employed.²²

RENAL DYSFUNCTION

Acute renal failure (ARF) [see 8:6 Renal Failure] was first described as a significant clinical problem during World War II,²³

but supportive care, in the form of dialysis, did not become available until the 1950s.

Clinical or subclinical renal dysfunction is common in MODS. Early-onset renal dysfunction typically results from hypotension and decreased renal blood flow. The etiology of late-onset renal failure is multifactorial and includes both pre-renal factors (e.g., decreased cardiac output and hypovolemia) and the cumulative renal effects of nephrotoxic agents (e.g., medications and radiocontrast material).²⁴ Intrarenal vasoconstriction results in a reduction in the glomerular filtration rate, hypoxic or oxidative injury to tubular epithelial cells, and desquamation of injured cells into the tubules, causing leakage of filtrate back into the renal interstitium and evoking neutrophil-mediated inflammation that causes further local tissue injury.²⁵ Intrarenal shunting of blood flow, coupled with occlusion of the renal microvasculature by thrombi or aggregated blood cells, further contributes to ischemia and physiologic dysfunction. The situation may be further aggravated by renal circulatory changes resulting from vasoactive agents administered to treat shock and by increased intra-abdominal pressure consequent to massive fluid resuscitation. Histologic studies show acute tubular necrosis with disruption of the basement membrane, patchy necrosis of the renal tubules, interstitial edema, and tubular casts; these microscopic changes correlate poorly with functional impairment.²⁶ Activated neutrophils have also been implicated in the pathogenesis of ARF,^{27,28} as has the induction of apoptosis in renal epithelial cells.²⁹

Renal dysfunction in MODS is reflected physiologically in a decreased urine output, biochemically in a rising serum creatinine level, and therapeutically as the introduction of exogenous renal replacement therapy or dialysis.

HEPATIC DYSFUNCTION

Hepatic dysfunction after trauma, like ARF, was first described during World War II [see 8:9 Hepatic Failure].³⁰ Two clinical syndromes have been described. The first, ischemic hepatitis, or shock liver, characteristically follows an episode of profound hypotension with splanchnic hypoperfusion. Early elevations of aminotransferase levels are striking and may be associated with an increased international normalized ratio and hypoglycemia; centrilobular necrosis is evident histologically. Successful resuscitation of the shock state results in rapid normalization of the biochemical abnormalities.³¹ The second syndrome, ICU jaundice, is much more common than ischemic

hepatitis and typically evolves many days after the inciting physiologic insult. Conjugated hyperbilirubinemia is a prominent feature, whereas elevation of aminotransferase levels and alterations of hepatic synthetic function are less pronounced.³² Histologic features include intrahepatic cholestasis, steatosis, and Kupffer cell hyperplasia. The pathogenesis is multifactorial and includes ongoing hepatic ischemia, total parenteral nutrition (TPN)-induced cholestasis, and drug toxicity.

An increased serum bilirubin level is the most commonly recognized feature of the hepatic dysfunction of MODS. Although extracorporeal support devices have been used for patients with end-stage liver disease, the hepatic dysfunction of critical illness is not considered to be life-threatening in itself, and no specific supportive therapy is indicated.

CARDIOVASCULAR DYSFUNCTION

Both peripheral vascular and myocardial function are altered in MODS. Characteristic changes in the peripheral vasculature include a reduction in vascular resistance and an increase in microvascular permeability, resulting in a hyperdynamic circulatory profile and peripheral edema. Both alterations jeopardize tissue oxygenation—reduced vascular resistance by facilitating shunting in the microvasculature and edema by increasing the distance across which oxygen carried in the blood must diffuse to reach the cell. Shunting also occurs as a result of occlusion of the microvasculature by thrombi and aggregates of nondeformable red cells³³; it is signaled by a reduction in arteriovenous oxygen extraction and an increase in mixed venous oxygen saturation ($S_{mv}O_2$). Biventricular dilatation with a reduction in the right and left ventricular ejection fractions has been described.³⁴ Right ventricular dysfunction is particularly prominent, perhaps as a consequence of increased pulmonary vascular resistance secondary to concomitant lung injury.³⁵ Finally, a loss of normal heart rate variability characterizes advanced cardiovascular dysfunction.³⁶

The cardiovascular dysfunction of MODS is apparent clinically as increased peripheral edema with hypotension that is refractory to volume challenge and therapeutically in the use of vasoactive agents to support the circulation. Nitric oxide (NO) has been implicated in both the peripheral vasodilatation³⁷ and the myocardial depression³⁸ associated with critical illness.

NEUROLOGIC DYSFUNCTION

Abnormalities of both central and peripheral nervous system function are common in critical illness. CNS dysfunction occurs in as many as 70% of critically ill patients, typically presenting as a reduced level of consciousness without localizing signs. Its pathophysiology is incompletely understood. Postulated mechanisms include the direct effects of proinflammatory mediators on cerebral function, the development of vasogenic cerebral edema, areas of cerebral infarction related to hypotension, and alterations in the blood-brain barrier resulting in changes in the composition of the interstitial fluid.³⁹ Electroencephalography typically shows one of four patterns indicating increasingly abnormal activity: diffuse theta wave rhythms, intermittent rhythmic delta waves, triphasic delta waves, and suppression or burst-suppression patterns.³⁹

Peripheral nervous system dysfunction, also known as critical illness polyneuropathy, is also common in MODS, though its clinical presentation tends to be more subtle than that of CNS dysfunction.⁴⁰⁻⁴² Peripheral nervous system dysfunction may present as failure of weaning from mechanical ventilation⁴³ or as limb weakness with relative sparing of the cranial nerves. Endoneurial edema and axonal hypoxia⁴⁴ contribute to its pathogenesis, as do the iatrogenic sequelae of neuromuscular blockade.⁴⁵

HEMATOLOGIC DYSFUNCTION

The most common hematologic abnormality of critical illness is thrombocytopenia, which occurs in approximately 20% of all ICU admissions.^{46,47} Causes include increased consumption, intravascular sequestration, and impaired thrombopoiesis secondary to suppression of bone marrow function. In addition, heparin-induced thrombocytopenia resulting from antibodies to complexes of heparin and platelet factor 4 develops in as many as 10% of patients receiving heparin.⁴⁸ The most fulminant expression of hematologic dysfunction in MODS is DIC, which is characterized by derangements in platelet numbers and clotting times and the presence of fibrin degradation products in plasma.⁴⁹ The coagulopathy of critical illness is complex, involving multiple alterations in the biochemical mediators of coagulation and resulting in a shift to a procoagulant state.⁵⁰

Mild anemia is common in critical illness, though the nature of abnormalities in red cell production and removal are less well characterized in this setting.⁵¹ Transient leukopenia may develop in response to an overwhelming inflammatory stimulus, but neutrophilia is much more commonly encountered; total lymphocyte counts are reduced. Abnormalities in white cell populations reflect, at least in part, altered expression of apoptosis, which is inhibited in the neutrophil⁵² but accelerated in lymphoid cells.⁵³

GASTROINTESTINAL DYSFUNCTION

Upper GI hemorrhage after burn injury was first described by Curling in 1842.⁵⁴ Stress bleeding was once a relatively common complication, but improved techniques of resuscitation and hemodynamic support, earlier diagnosis of infection, and the widespread use of stress ulcer prophylaxis have reduced the frequency of this event, to the point where it now is seen in fewer than 4% of ICU admissions.⁵⁵ Other manifestations of GI dysfunction in MODS include ileus and intolerance of enteral feeding,^{56,57} pancreatitis,⁵⁸ and acalculous cholecystitis.⁵⁹

OTHER ORGAN SYSTEM DYSFUNCTION

MODS is associated with functional abnormalities of virtually every organ system. Endocrine abnormalities include impaired glucose regulation with hyperglycemia and insulin resistance⁶⁰ and hypercortisolism with impaired responsiveness to adrenocorticotropic hormone (ACTH) stimulation.^{61,62} The sick euthyroid syndrome, characterized by reductions in serum T₃, with or without an increase in reverse T₃ levels and a normal T₄ level, is another manifestation of the endocrine dysfunction of MODS.⁶³

Numerous derangements of immune function have been described in MODS patients. Cell-mediated immunity is impaired, as reflected by anergy to delayed hypersensitivity recall skin testing⁶⁴ and impaired in vitro lymphocyte proliferative responses.⁶⁵ The development of ICU-acquired infections caused by organisms of low intrinsic virulence can also be considered a manifestation of impaired immunity in MODS.⁶⁶

Abnormal wound healing also occurs in MODS. Common manifestations of impaired wound healing are the failure of an open wound to develop satisfactory granulation tissue and the development of decubitus ulcers.⁶⁷

Quantification of Organ Dysfunction

Physiologic instability is the major indication for ICU admission, and support of failing organ function is the ICU's *raison d'être*. The degree of physiologic derangement present at the time of ICU admission is a potent determinant of ICU survival,^{68,69} and irreversible organ dysfunction is the preeminent

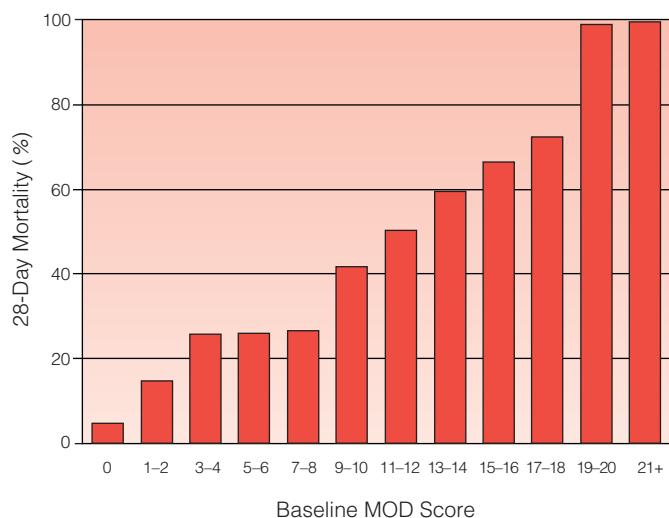

Figure 1 Increasing severity of organ dysfunction is directly correlated with increasing ICU mortality.

mode of ICU death.^{6,70} Formal quantification of the severity of physiologic derangement or of the evolution of organ dysfunction over time is not generally incorporated into individual patient care in the ICU. However, validated scoring systems have proved invaluable in describing patient populations, stratifying patients for entry into clinical trials, and assessing ICU morbidity in patient groups.

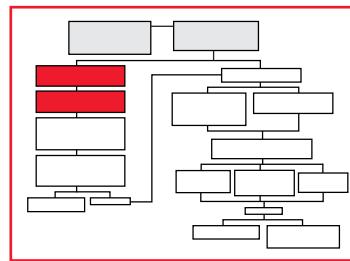

There are a number of published systems for quantifying the severity of organ dysfunction in the critically ill.^{9,10,12,66,71-74} These systems are all structurally similar, evaluating dysfunction in each of six or seven organ systems on a numerical scale in which more points are assigned for greater degrees of physiologic severity; they vary primarily with respect to the variables used to describe dysfunction. A representative example of such a scoring system is the Multiple Organ Dysfunction (MOD) score [see Table 2].⁹

The numerical scores can be obtained and applied in a variety of ways.⁷⁵ Scores can be calculated on the day of ICU admission or at the start of the institution of a novel therapy during the ICU stay; such scores provide a measure of baseline illness severity and correlate in a graded manner with the risk of ICU mortality [see Figure 1]. Scores can also be calculated daily, allowing the clinician to track net clinical improvement or deterioration over time⁷⁶ and to assess the progression or resolution of organ dysfunction (expressed as the area under the curve for the daily

scores).⁷⁷ Alternatively, the aggregate severity of organ dysfunction over time can be quantified by summing the worst values over time in each of the component systems. Such an approach permits quantitation of attributable ICU morbidity as the difference between the aggregate score and the score at baseline—thus identifying that component of ICU morbidity that can be prevented by an effective ICU intervention. Finally, morbidity and mortality can be combined into a single value by using a mortality-adjusted score that assigns a maximum number of points plus 1 to any patient who dies [see Table 3].

Prevention of Organ Dysfunction in Critically Ill Patients

Acute organ dysfunction is the most common indication for admission to an ICU, and any patient with significant physiologic instability is at risk for MODS. A number of risk factors for the development of organ dysfunction have been identified [see Table 1]: these reflect a common pathogenesis for the syndrome through the activation of an innate immune response to tissue injury.

The first priority for optimal ICU care is to halt the progression of existing organ dysfunction while preventing the development of new organ dysfunction. Prevention of organ dysfunction is perhaps best approached from the perspective of optimization of hemodynamic, metabolic, and immune homeostasis. There are a number of interventions for which level 1 evidence of efficacy in reducing mortality or preventing organ dysfunction exists [see Table 4].

OPTIMIZING HEMODYNAMIC HOMEOSTASIS

The ability of the heart to pump blood is determined by (1) the preload delivered to the right atrium, (2) the intrinsic contractility of the myocardium, and (3) the afterload against which the heart must work—all of which may be deranged in critical illness. First, reduction of intravascular volume as a consequence of hemorrhage, third-space loss, and increased microvascular permeability reduces preload. Second, circulating mediators and NO depress myocardial contractility and thus impair the heart's intrinsic pumping ability. Third, reduced vascular tone, mediated by NO, reduces afterload. The first two abnormalities reduce cardiac output; the third increases it but may, by altering resistance gradients

Table 3 Approaches to Measuring Severity of MODS⁷⁵

Objective	Approach	Uses
To quantify baseline severity of organ dysfunction	Calculate organ dysfunction score on day of admission (admission MODS)	To establish baseline severity (e.g., for entry criteria for a clinical trial) or to ensure comparability of study groups
To quantify severity of organ dysfunction at point in time	Calculate score on particular ICU day (daily MODS)	To determine intensity of resource utilization or evolution or resolution of organ dysfunction at discrete point in time
To measure aggregate severity of organ dysfunction over ICU stay	Sum individual worst scores for each organ system over defined time interval (aggregate MODS)	To determine severity of physiologic derangement over defined time interval (e.g., ICU stay)
To quantify new organ dysfunction arising after ICU admission	Calculate difference between aggregate and admission scores (delta MODS)	To measure organ dysfunction attributable to events occurring after ICU admission
To provide combined measure of morbidity and mortality	Adjust aggregate score so that all patients dying receive maximal number of points (mortality-adjusted MODS)	To create single measure that integrates impact of morbidity in survivors and mortality for nonsurvivors

Table 4 ICU Interventions That Reduce Mortality or Attenuate Organ Dysfunction

Objective	Intervention
Resuscitation	Early goal-directed resuscitation ²⁴³
Prophylaxis	Selective digestive tract decontamination ⁹⁰
ICU support	Restrictive transfusion strategy ¹⁰⁷ Low tidal volume ventilation ²² Daily wakening ¹⁴⁴ Tight glucose control ⁶⁰ Enteral feeding ⁸⁶
Mediator-targeted therapy	Activated protein C ¹⁴⁶ Corticosteroids ¹⁴⁸ Antibody to TNF ²⁴⁴

in the microvasculature, alter nutrient flow to the tissues.

The first priority in supporting cardiovascular homeostasis, therefore, is to restore intravascular volume by administering fluids. There is no convincing evidence that any particular resuscitation fluid is superior in all patients, though crystalloid is associated with a lower mortality in trauma patients.⁷⁸ Either normal saline or lactated Ringer solution is an appropriate choice. The volume of fluid needed to restore optimal preload may be significant, reflecting not only acute losses but also the effective expansion of the vascular compartment because of vasodilatation and the loss of fluids into the extravascular compartment because of increased capillary permeability. Blood loss should be corrected by transfusing red cells, preferably in fresh, leukocyte-depleted blood. When hypotension is refractory to fluid administration, vasoactive agents, including vasopressors (e.g., dopamine and norepinephrine) and inotropes (e.g., dobutamine, epinephrine, and amrinone) may help increase blood flow to the tissues.⁷⁹

Given that the goal of hemodynamic stabilization is to support organ function rather than to restore physiologic or biochemical normalcy, the best measures of the success of resuscitation are those that reflect either return of function (in particular, urine output) or adequate blood flow to the tissues (e.g., $S_{mv}O_2$ or lactate concentration). Each of these measures, however, has shortcomings of which the clinician must be aware. Urine output may be decreased because of intrinsic renal damage even in the face of adequate renal flow. $S_{mv}O_2$ may be artefactually high because of shunting and abnormalities of oxygen uptake in the microvasculature. Lactate concentration is relatively insensitive to mild degrees of inadequate oxygen delivery and may be elevated in patients with liver disease.

Gastric production of CO_2 as measured with a gastric tonometer has been proposed as a means of evaluating splanchnic blood flow, but the benefits of tonometry in improving outcome are unproven.⁸⁰ Microvascular flow can also be directly visualized in the tongue or another exposed mucosal surface by using orthogonal polarization spectral imaging.⁸¹ Neither of these approaches has been widely used to guide resuscitation.

Blood pressure is widely used as an index of the initial adequacy of resuscitation, but pressure measurements may not reliably reflect flow in the microvasculature, particularly when systemic vascular resistance is low. Measurement of central venous or pulmonary capillary wedge pressures provides an estimate of the preload to the heart, though factors such as positive pressure ventilation, the extent of capillary leakage in the lungs, and

intrinsic myocardial dysfunction can all alter the pressure at which optimal preload is obtained.

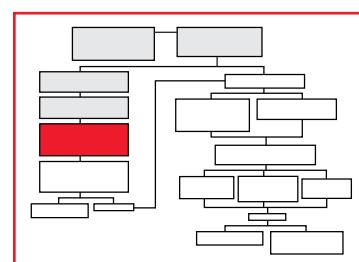

In practice, resuscitation should be titrated to optimize the balance between several parameters rather than targeting any one parameter. It is sobering to recognize that current sophisticated approaches to resuscitation using the pulmonary arterial catheter have not been shown to yield net clinical benefit and may, in fact, cause harm [see 8:26 *Cardiopulmonary Monitoring*.]⁸²

Hemodynamic resuscitation is most effective when it is early and rapid. A randomized trial of goal-directed therapy for sepsis, using a protocol comprising fluid administration, transfusion, and vasoactive support titrated to $S_{mv}O_2$ as measured from the superior vena cava through a central venous catheter, found that mortality was reduced from 46.5% to 30.5% when patients were resuscitated according to protocol in the emergency department within hours of their initial presentation. On the other hand, studies of goal-directed therapy initiated in the ICU have generally failed to demonstrate any evidence of benefit.^{83,84}

Optimization of oxygen delivery presupposes the ability to oxygenate blood adequately in the lungs. Increased pulmonary capillary permeability, atelectasis, altered consciousness, and intrinsic lung disease can all reduce oxygen uptake in acutely ill patients. Support can be provided through the administration of oxygen to the spontaneously breathing patient, through the use of positive pressure ventilation by mask, or through endotracheal intubation and mechanical ventilation. Positive pressure ventilation can cause further lung injury, however, particularly when the lung has been rendered vulnerable by early acute lung injury. Limiting tidal volume during mechanical ventilation to 6 ml/kg has been shown to improve survival in patients with early ARDS.²²

OPTIMIZING METABOLIC HOMEOSTASIS

The acute response to stress and injury is a complex, coordinated process characterized by increases in levels of catecholamines, glucocorticoids, antidiuretic hormone, and hormones that regulate intermediary metabolism, including insulin, glucagon, and growth hormone [see 8:22 *Metabolic Response to Critical Illness*.]⁶ The activation of this response results in a predictable series of metabolic alterations, including retention of salt and water, increased production of glucose, enhanced lipolysis, increased protein catabolism, and an altered pattern of hepatic protein synthesis known as the acute-phase response, characterized by increased synthesis of C-reactive protein, alpha₁-anti-trypsin, and fibrinogen and reduced synthesis of albumin.

Metabolic prophylaxis of MODS is directed toward reversal of the stimuli responsible for the catabolic hormonal milieu and toward the provision of adequate biochemical substrate at a time of increased metabolic demand. Early definitive surgical therapy in the form of debridement of devitalized tissue, burn wound excision and grafting, and rigid fixation of long bone fractures can attenuate the postinjury hypermetabolic state and minimize the subsequent development of MODS, though the benefits of early definitive therapy must be weighed against the additional stress of blood loss and hemodynamic instability. In the face of overwhelming injury, a policy of damage control to permit stabilization of the patient in the ICU is associated with an improved clinical outcome.⁸⁵

Nutritional support should be provided by the enteral route if possible [see 8:23 *Nutritional Support*]. Enteral nutrition is feasible in most patients, particularly if feedings are initiated early. The administration of even small quantities of enteral nutrition is considered advisable, even if it must be supplemented by some degree of parenteral nutrition. There is increasing evidence that immunologically enhanced enteral formulas can yield better clinical outcomes than standard enteral formulas.⁸⁶

Close regulation of glucose levels in accordance with an intensive policy of monitoring and insulin administration has been shown to improve clinical outcome.⁶⁰ On the other hand, there is no evidence that administration of growth hormone offers any significant benefit.⁸⁷

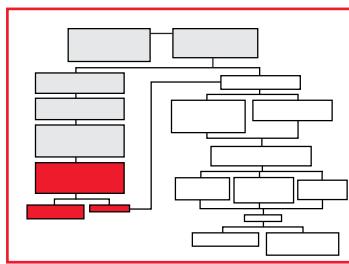

OPTIMIZING IMMUNOLOGIC HOMEOSTASIS

Infection is an important risk factor for MODS, but the converse is equally true: patients with MODS are at significantly increased risk for infection. This risk arises as a consequence both of impairment of normal host defense mechanisms and of colonization with potentially infectious nosocomial pathogens [see 8:16 *Nosocomial Infection*].

Of the numerous derangements of normal immune function with which critical illness is associated, impairment of mucosal defenses is probably the most important (and certainly the most preventable). Mucosal defenses are breached by surgical incisions and by invasive devices, including intravascular catheters, urinary catheters, and endotracheal and nasogastric tubes. Limiting the number of such devices in use and paying rigorous attention to their insertion and maintenance are important for minimizing nosocomial infection rates.⁸⁸ Gastric acid plays a primary role in maintaining the relative sterility of the stomach. Antacids ablate this defense and are a recognized risk factor for nosocomial pneumonia; they should not be used for stress ulcer prophylaxis. The declining incidence of clinically significant stress bleeding in the contemporary ICU suggests that prophylaxis should be limited to patients who are at increased risk for stress ulceration.⁵⁵ Cytoprotective agents (e.g., sucralfate) appear to have no significant advantages over H₂ receptor antagonists in reducing the risk of ventilator-associated pneumonia and are less efficacious in preventing bleeding⁸⁹; accordingly, H₂ receptor antagonists appear to be the prophylactic agents of choice.

An alternative strategy for preventing pathologic gut colonization and nosocomial infection involves prophylactic administration of a combination of systemic antibiotics (e.g., cefotaxime) and topical nonabsorbed antibiotics (e.g., tobramycin, polymyxin, and amphotericin B). This approach, known as selective decontamination of the digestive tract (SDD), has proved effective in reducing nosocomial infection rates and even ICU mortality⁹⁰; the effect is particularly evident in surgical patients who receive both systemic and topical therapy.⁹¹

Enteral feeding is beneficial in preventing nosocomial infection. Systemic antibiotics suppress the indigenous flora of mucosal surfaces, promoting pathologic colonization with resistant organisms.⁹² Therefore, use of antimicrobial agents in critically ill patients must be selective and targeted, and the use of broad-spectrum empirical therapy should be minimized by regular reviews of culture and sensitivity results and restrictions on antibiotic prescription practices.

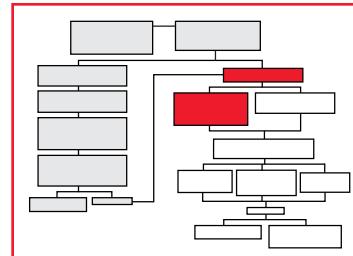

Although nosocomial infections in critically ill patients usually arise from endogenous reservoirs, pathogens may also spread from patient to patient and from environment to patient. Certain organisms—in particular, *Acinetobacter*, *Xanthomonas*, and *Legionella*—are transmitted through aqueous sources in the ICU, and the isolation of these organisms from a critically ill patient is evidence of a potential problem in environmental infection control. Hand washing is an important but underutilized mode of infection prevention in the ICU [see 1:2 *Prevention of Postoperative Infection*]. There is no clear evidence that protective isolation of critically ill patients warrants the increased costs and increased demands on nursing staff.

The role of immunomodulation in the prophylaxis of MODS remains undefined. At present, there is no defined role for chemoprophylaxis of MODS beyond the specific effects of drugs such as heparin (prevention of deep vein thrombosis [DVT]) and H₂ receptor antagonists (prevention of upper GI bleeding).

Evaluation of the Patient with Organ Dysfunction

SINGLE ORGAN DYSFUNCTION

Single organ dysfunction suggests local disease and should trigger a search for potentially correctable causes in the organ system involved. Isolated organ dysfunction may reflect preexisting chronic disease or a local problem such as fluid overload, atelectasis, biliary tract obstruction, or elevated intracranial pressure. Complications related to invasive devices or the adverse effects of medications are common causes of single organ dysfunction; the diagnosis is often presumptive, established on the basis of clinical improvement after discontinuance of the agent or removal of the device. Finally, single organ dysfunction may indicate acute disease in the involved organ, such as myocardial infarction, pulmonary embolism, or bone marrow suppression.

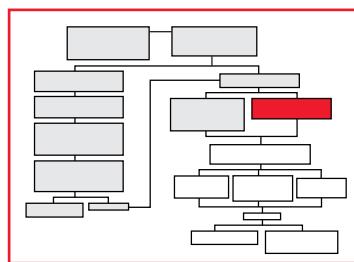

Acute respiratory dysfunction, for example, may be caused by pneumonia, atelectasis, pleural effusion, pneumothorax, or pulmonary embolism. Central venous and pulmonary arterial catheters may induce tachyarrhythmias as a result of mechanical irritation of the conducting system. Isolated renal dysfunction may be a consequence of abdominal compartment syndrome or of the nephrotoxic effects of medications (e.g., acute tubular necrosis caused by aminoglycosides and interstitial nephritis caused by penicillins and cephalosporins). Occasionally, renal dysfunction arises from a postrenal cause, such as blockage of a Foley catheter.

Medications are important causes of liver dysfunction in the critically ill patient. Erythromycin, ketoconazole, and haloperidol, for example, can induce cholestatic liver injury. Thrombocytopenia is an important adverse effect of a number of medications, including heparin flushes to maintain the patency of arterial lines. A decreased level of consciousness is usually the result of the poorly characterized metabolic encephalopathy of critical illness; however, it is necessary to rule out local causes such as meningitis, encephalitis, brain abscess, and subdural hematoma. Excessive or prolonged use of narcotics or sedative-hypnotics may lead to sustained alterations in level of consciousness, particularly when hepatic or renal function is impaired. Nondepolarizing muscle relaxants (e.g., vecuronium) may cause prolonged neuromuscular blockade and peripheral neuropathy.⁴⁵

MULTIPLE ORGAN DYSFUNCTION

Although it has been suggested that there is a characteristic temporal sequence in the development of MODS [see Table 5],^{3,9} the clinical course tends to be variable and depends in part on the criteria used to define organ system dysfunction (see above). The specific pattern of dysfunction is much less important than the course of the evolving syndrome. Resolution of dysfunction suggests an appropriate response to specific and supportive therapy. Worsening of dysfunction, on the other hand, should prompt a search for potentially correctable causes and a reevaluation of the methods of supportive care in use. Not infrequently, a treatable cause of evolving MODS is found; often, however, no cause is evident. When no specific cause of the deterioration can be identified, therapy should focus on optimizing supportive measures to limit iatrogenic injury either until the patient recovers or, alternatively, until a considered decision is made that continuing active care is futile.

Search for Correctable Causes

Occult infection Uncontrolled infection, particularly infection arising within the abdomen, is an important risk factor for MODS.^{2,3,93} The development of otherwise unexplained organ dysfunction should trigger a careful radiologic search for an occult intra-abdominal focus.⁹⁴ However, MODS also develops in patients with pneumonia⁵⁸ and other life-threatening infections, and it sometimes evolves in patients in whom no infectious focus can be identified.^{66,95}

When MODS develops in the postoperative period, a careful search for infection must be undertaken, concentrating in particular on the operative site and on any invasive devices used. With appropriate attention to the clinical possibilities, aided by ultrasonography and CT scanning, the presence or absence of significant intra-abdominal pathology can usually be established. Local wound exploration may suggest the possibility of occult intra-abdominal infection through the demonstration of impaired wound healing or fascial dehiscence or through the isolation of typical intestinal microflora from a wound infection. The diagnosis of pneumonia in intubated ICU patients is notoriously difficult; however, the use of quantitative techniques (e.g., protected specimen brush bronchoscopy and bronchoalveolar lavage) can

Table 5 Temporal Evolution of MODS^{3,9}

System	Time from ICU Admission to Onset of Significant Dysfunction (days)
Respiratory	1–2
Hematologic	3
Central nervous	4
Cardiovascular	4
Hepatic	5–6
Renal	4–11
Gastrointestinal	10–14

aid in establishing or excluding the diagnosis.^{96,97}

MODS is rarely caused by urinary tract infections or device-related bacteremias, though these conditions are common in patients with significant organ dysfunction. *Clostridium difficile* colitis or disseminated fungal infection may also present as deteriorating organ function in critically ill patients.⁹⁸

Iatrogenic factors MODS can be considered the quintessential iatrogenic disorder, reflecting both the successes and the failures of contemporary ICU practice. On one hand, the syndrome arose only because the supportive care available today permits the prolonged survival of critically ill patients who, in an earlier era, would have died rapidly; on the other hand, potentially avoidable iatrogenic factors contribute prominently to the evolution of MODS.

Technical or judgmental errors often set the stage for MODS.^{99–101} Whenever a patient manifests unexplained organ failure in the postoperative period, the surgeon must consider the possibility of an iatrogenic complication—for example, a missed intestinal perforation in a trauma victim, a leak from a tenuous anastomosis, or left colon ischemia after aneurysmectomy.

Many of the therapeutic interventions that are the mainstay of ICU care have the potential to cause local and remote organ injury. In the experimental setting, mechanical ventilation with high tidal volumes and low levels of positive end-expiratory pressure (PEEP) can induce both pulmonary and remote organ injury.^{102,103} A multicenter, randomized, controlled trial confirmed that mechanical ventilation of patients with acute lung injury in accordance with a lung-protective strategy (i.e., a tidal volume of 6 ml/kg) significantly improves survival²² and attenuates the local and systemic release of proinflammatory mediators [see 8:5 Mechanical Ventilator].¹⁶ Oxygen in high concentrations can produce pulmonary damage, probably as a result of the generation of toxic oxygen intermediates [see 8:24 Molecular and Cellular Mediators of the Inflammatory Response].¹⁰⁴

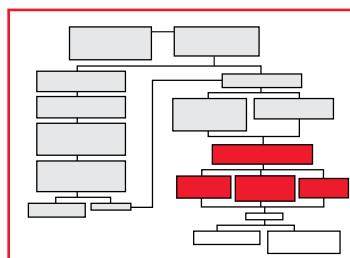

Blood transfusion has been implicated in the development of organ dysfunction, an effect that occurs independent of the effects of shock, blood loss, and fluid resuscitation.^{105,106} A multicenter, randomized, controlled trial demonstrated a significant reduction in the severity of new organ dysfunction in a heterogeneous population of critically ill patients when transfusion was withheld unless the hemoglobin concentration was less than 70 g/L (7 g/dl).¹⁰⁷ The age of the blood administered may be an underappreciated factor in defining optimal transfusion strategies. The effects of blood transfusion on splanchnic blood flow as measured with a gastric tonometer are significantly dependent on the age of the transfused blood. Transfusion of blood that is more than 12 days old can have an adverse impact on oxygen delivery.¹⁰⁸

TPN can also contribute to the de novo development of organ dysfunction. TPN-associated alterations in hepatic function with intrahepatic cholestasis and fatty infiltration are relatively common and are manifested by elevated aminotransferase and alkaline phosphatase levels.¹⁰⁹ TPN may also give rise to glucose intolerance and can aggravate ventilatory impairment through increased CO₂ production. In patients with borderline pulmonary function, this additional CO₂ production may prevent weaning from ventilatory support.¹¹⁰ Parenteral nutrition is also associated with higher rates of postoperative and nosocomial infections after multiple trauma.¹¹¹

Medications—in particular, analgesics, sedatives, and antibiotics—have also been associated with evolving organ dysfunction.

Support of Patients with Established Organ Dysfunction

The fundamental challenge in providing intensive supportive care to patients with established organ dysfunction is how to support physiologic function while minimizing new iatrogenic organ dysfunction. As more is understood about the consequences of various treatment strategies, it is increasingly apparent that optimizing function is not synonymous with maximizing function and that the clinician must be acutely aware of the potential for causing more harm than good.

VENTILATORY SUPPORT

Although ventilatory support is generally provided by endotracheal intubation and mechanical ventilation, noninvasive positive pressure ventilation may be appropriate for patients with milder degrees of respiratory failure. A small randomized trial of patients with cardiogenic pulmonary edema found that when compared with conventional administration of oxygen by mask, noninvasive positive pressure ventilation shortened the time to resolution of respiratory failure and reduced the need for subsequent endotracheal intubation.¹¹² Whether this approach is useful in patients with early ARDS is less clear, however; it may be associated with a higher risk of complications.¹¹³

Endotracheal intubation and positive pressure ventilation constitute the mainstay of support for critically ill patients with respiratory failure. In unstable patients, it is best to use a controlled ventilatory mode (e.g., pressure control ventilation) rather than a spontaneous breathing mode (e.g., pressure support ventilation). Oxygenation can be optimized through the use of PEEP, a maneuver that may also decrease the accumulation of interstitial fluid and minimize ventilator-associated lung injury.¹¹⁴ Ventilation with large tidal volumes and high peak inspiratory pressures contributes to lung injury, and it has been shown that the survival of ARDS patients can be improved by using low tidal volumes (~ 6 ml/kg).²² Pressure-controlled ventilatory techniques limit peak airway pressures to a maximum predetermined level, optimizing gas exchange by inverting the inspiration-to-expiration ratio (I/E) from its normal value of 1:2 to 1:1 or higher and by changing the shape of the inspiratory flow curve (normally square) to one in which flow initially is rapid, then decelerates [see 8:5 *Mechanical Ventilator*].¹¹⁵ Although oxygenation can be maintained with low tidal volumes, ventilation is jeopardized, with the result that CO₂ levels rise (so-called permissive hypercapnia).¹¹⁶ Hypercapnia per se does not appear to be deleterious¹¹⁷; indeed, animal studies suggest that increased levels of CO₂ may be independently beneficial to critically ill patients.¹¹⁸ For patients with refractory hypoxemia, high-frequency oscillation appears to be a promising ventilatory mode.^{119,120}

Inhaled NO is selectively delivered to ventilated lung segments and may effect early improvement of oxygenation in ARDS patients¹²¹; whether this early physiologic effect translates into an improved clinical outcome is unknown. Extracorporeal lung support by means of extracorporeal membrane oxygenation or extracorporeal CO₂ removal can be lifesaving in patients with isolated severe respiratory failure that is refractory to other forms of respiratory support.^{122,123} These techniques are resource intensive, however, and have not been convincingly shown to yield better outcomes than conventional mechanical ventilation.¹²⁴ If the patient remains hypoxic despite optimization of

ventilatory support, it may be necessary to accept an arterial oxygen saturation (S_aO₂) as low as 80%.

CARDIOVASCULAR SUPPORT

Tissue oxygen delivery ($\dot{D}O_2$) is a function of three variables—cardiac output, hemoglobin concentration, and S_aO₂ (oxygen dissolved in the plasma makes only a negligible contribution). Tissue oxygen consumption (VO₂) is a function of cardiac output and oxygen extraction (defined as the difference between arterial and venous oxygen content). In practice, multiple factors can impair oxygen delivery and consumption, and it is important that the clinician recognize these.

Oxygen uptake in the tissues is an entirely passive process, resulting from the diffusion of oxygen toward the relatively hypoxic extravascular space along an oxygen saturation gradient that is highest in the microvasculature and lowest at the cell. This passive diffusion can be reduced if there is interstitial edema, which makes the concentration gradient less steep, or if blood flow through the microvasculature is rapid. Alternatively, a reduction in the resistance of small arterioles may impede the diversion of blood into the microvasculature. Moreover, nutrient vessels in the microcirculation may be occluded by aggregates of neutrophils, platelets, and aged (and thus less deformable) red blood cells. The net result of these abnormalities is the shunting of oxygenated blood from the arterial side of the circulation to the venous side. This phenomenon is readily detected through measurement of S_{vo}O₂, which is about 70% in normal persons but typically is much higher in patients with sepsis and organ dysfunction.

Paradoxically, each of the interventions commonly used to increase tissue oxygen delivery can also decrease it. Fluid resuscitation can increase cardiac output by increasing preload, but in patients with altered capillary permeability, it can create edema, thereby lengthening the distance across which oxygen must diffuse. Vasopressors can raise cardiac output by increasing peripheral vascular resistance, but at the cost of reducing flow through nutrient vessels in the microcirculation. Inotropes, on the other hand, directly increase cardiac output, albeit at the cost of increased myocardial oxygen consumption, but agents such as dobutamine may lead to further shunting by decreasing peripheral vascular resistance.

Currently, intensive invasive monitoring of critically ill patients with organ dysfunction is employed less frequently than it once was. The benefits of such monitoring remain somewhat uncertain. For example, a 1996 study suggested that the use of a pulmonary arterial catheter was associated with a 24% increase in mortality—not, presumably, because of complications of the catheter itself but rather because the decisions made on the basis of the data provided led to greater harm than benefit.¹²⁵ Although this estimate of harm may be exaggerated, there is little countervailing evidence of benefit to justify routine use of pulmonary arterial catheters. A 2003 study of 1,994 high-risk patients undergoing major elective surgery found that Swan-Ganz catheterization and preoperative optimization did not reduce mortality but was associated with a significant increase in the risk of pulmonary embolism.⁸⁴

RENAL SUPPORT

Renal replacement therapy in critically ill patients with MODS serves three functions:

1. Regulation of fluid and electrolytes in patients in whom normal renal function is compromised and altered capillary permeability has led to total body fluid overload with edema.

2. Removal of products of metabolism, medications, and other toxins that the failing kidneys are unable to clear.
3. Removal of circulating mediators of inflammation.

The first two are classic indications for dialysis, though the therapeutic objectives may differ; the third lies more in the realm of promising experimental therapy.

Fluid overload is a common consequence of hemodynamic resuscitation during the early stages of acute illness. It results from increased capillary permeability, peripheral vasodilatation with expansion of the intravascular compartment, and impaired renal function. The use of continuous renal replacement therapies to titrate fluid balance and reduce uremia is conceptually appealing, but the benefits remain unproven. Both individual randomized trials^{126,127} and a systematic review¹²⁸ failed to show that early and aggressive continuous renal replacement improved clinical outcome. On the other hand, a multicenter randomized trial of more than 400 ICU patients with ARF showed that high-flow ultrafiltration (at a rate of 35 ml/kg/hr or higher) increased survival,¹²⁹ and a prospective study demonstrated that daily (as opposed to alternate-day) intermittent hemodialysis improved survival and hastened the resolution of ARF.¹³⁰ Another systematic review suggested that imbalances between study groups might have masked a potential benefit of therapy associated with early continuous hemodialysis.¹³¹

Whether it significantly improves outcome or not, early continuous renal replacement therapy does facilitate early management of the patient with MODS by permitting the removal of fluid, and it is generally better tolerated by hemodynamically unstable patients than is intermittent hemodialysis. Evidence that dialytic therapy can accelerate the clearance of circulating mediators of sepsis is scant.¹³²

SUPPORT OF OTHER ORGANS

Enteral nutritional support has been shown to reduce the rate of infectious complications in patients with multiple trauma^{111,133} and in those with pancreatitis.¹³⁴ A systematic review of 15 randomized trials found that early enteral feeding reduced the infectious complication rate and shortened the ICU stay without affecting mortality.¹³⁵ The use of immunologically enhanced enteral formulas appears to be associated with a further reduction in infectious complications, ventilator days, and length of hospital stay.¹³⁶ Paralytic ileus makes the provision of enteral feeding more difficult. Erythromycin, which is a motilin secretagogue, can facilitate bedside placement of enteral feeding tubes¹³⁷ and accelerate gastric emptying.¹³⁸

Techniques for extracorporeal support of the failing liver have been described, but their use is generally limited to a few centers with a particular interest in liver failure and organ transplantation.^{139,140} Unlike primary liver failure, the hepatic dysfunction of MODS does not lead to life-threatening organ system insufficiency and rarely calls for specific support. Hypoalbuminemia is common in MODS, occurring as a consequence of increased vascular permeability, loss through the GI tract, and reduced hepatic synthesis from the activation of an acute-phase response. Although hypoalbuminemia is associated with increased ICU morbidity and mortality, there is no convincing evidence that albumin supplementation improves clinical outcome.¹⁴¹

A randomized trial of transfusion strategies in the ICU demonstrated that organ function was improved by a restrictive transfusion policy that withheld transfusion unless the hemoglobin level dropped below 70 g/L,¹⁰⁷ a conclusion supported by a large European multicenter observational study.¹⁴² Benefit is also

seen in patients with underlying cardiovascular disease.¹⁴³ Thrombocytopenia is corrected by transfusion of platelet concentrates, but this generally is done only if the platelet count drops below 20,000/mm³. Coagulation factors can be replaced by giving fresh frozen plasma or cryoprecipitate.

Adequate analgesia and sedation are essential components of the care of MODS patients; however, the natural desire to alleviate pain and discomfort can lead to oversedation. A policy of daily awakening can reduce morbidity and shorten the ICU stay.¹⁴⁴

PHARMACOLOGIC THERAPY TARGETING HOST RESPONSE

Experimental studies implicate an activated inflammatory response in the pathogenesis of MODS. Despite extensive evaluation of a variety of novel strategies to target the host response in sepsis, to date, only two approaches have demonstrated an ability to improve survival.

Activated protein C is an endogenous anticoagulant molecule that inhibits factors V and VIII; in addition to its anticoagulant activities, it exerts significant anti-inflammatory activity [see 8:24 *Molecular and Cellular Mediators of the Inflammatory Response*.]¹⁴⁵ Activated protein C has been produced as a recombinant protein (drotrecogin alfa activated) and has been evaluated in a multicenter randomized trial involving 1,690 patients with severe sepsis. In this trial, treatment resulted in a 6.1% improvement in 28-day survival¹⁴⁶ and a more rapid resolution of cardiovascular, respiratory, and hematologic dysfunction.¹⁴⁷ The benefit appears to be greatest in patients who have more severe illness (reflected in an elevated APACHE II [Acute Physiology and Chronic Health Evaluation II] score or a greater number of dysfunctional organs), community-acquired infection, or coagulopathy.

Critical illness is associated with multiple abnormalities of endocrine function, including reduced responsiveness to endogenous glucocorticoids,⁶² a state that predicts an increased risk of ICU mortality.⁶¹ In a 2002 study, administration of pharmacologic doses of corticosteroids (50 mg of hydrocortisone every 6 hours and 50 µg of fludrocortisone) to patients with refractory septic shock and an impaired response to a short-course ACTH stimulation test reduced mortality by 10%.¹⁴⁸ In contrast, earlier studies of high-dose corticosteroids in more heterogeneous groups of patients with sepsis found no evidence of benefit.¹⁴⁹

Systematic reviews have suggested that neutralization of tumor necrosis factor (TNF) or interleukin-1 (IL-1) can improve outcome in sepsis,¹⁵⁰ but neither of these approaches is clinically available at present. Other anticoagulant or anti-inflammatory strategies have been suggested but remain unproven.

MODS AND ICU-ACQUIRED INFECTION

Infection is a risk factor for organ dysfunction, but the converse is equally true: organ dysfunction is a risk factor for nosocomial infection, with the risk increasing as the severity of organ dysfunction increases.⁶⁶ The typical isolates are microbes of low intrinsic pathogenicity, including coagulase-negative *Staphylococcus*, *Enterococcus*, and *Candida* species and gram-negative organisms such as *Pseudomonas* and *Enterobacter*.¹⁵¹ These organisms commonly colonize the upper GI tract of the critically ill patient,¹⁵² they emerge under antibiotic pressures, and they form colonies on invasive devices—all of which may explain why they emerge as predominant infecting species in this setting. Studies of SDD have demonstrated that preventing such infections reduces ICU morbidity and mortality,^{90,153} but there is scant evidence that aggressive antimicrobial therapy to treat suspected nosocomial infection improves outcome. In fact, two reports from 2000 suggested that a more restrictive approach to the pre-

scription of antimicrobial agents reduced mortality and morbidity.^{97,154} Worsening organ dysfunction should prompt a careful search for untreated foci of infection, but empirical therapy should be used cautiously; if such therapy is started, it should be discontinued promptly as culture data are obtained. Often, mere removal of a colonized device (e.g., a central line or a urinary catheter) amounts to definitive therapy for these infections.

The association of organ dysfunction with occult intra-abdominal infection^{3,94} stimulated a period of enthusiasm for the practice of so-called blind laparotomy—that is, laparotomy undertaken to identify and treat an intra-abdominal infectious focus without radiographic evidence that infection is present.^{155,156} The uniformly disappointing results of such intervention,¹⁵⁷ coupled with improvements in diagnostic imaging techniques, led to abandonment of this approach except in certain unusual circumstances (e.g., clinically compelling evidence of a surgically correctable problem, suspicion of visceral ischemia, or the absence of the appropriate imaging facilities). It goes without saying that the classic physical findings of peritonitis—particularly when no abdominal operation has been done—may be the sole indication for surgical exploration. Moreover, in a complicated postoperative patient transferred from another institution because of worsening organ dysfunction, repeat laparotomy may legitimately be considered a component of the admission physical examination.

Outcome

PROGNOSTIC INDICATORS

The prognosis of MODS is directly related to the severity of the underlying organ dysfunction, which can be expressed in terms of either the number of failing systems^{3,73,158} [see Table 6] or the global severity of dysfunction as determined by an organ dysfunction score [see Figure 1]. It must be emphasized, however, that prognostic indicators reflect the expected outcome of a group of patients and are of limited use in making decisions about the care of an individual patient. Moreover, the prognostic weight of these scales reflects standards of care prevalent at a particular time and in a particular clinical setting. For example, at the time when Ranson's criteria were developed,¹⁵⁹ patients with pancreatitis and six or more

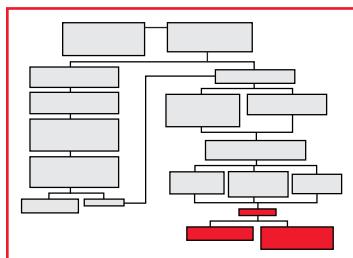

Table 6 Prognosis in MODS

Number of Failing Systems	Mortality (%)
0	3
1	15–30
2	50–60
3	60–100
4	70–100
5	100

positive indicators according to those criteria had a mortality of close to 100%; today, a majority of such patients survive.⁹³

Organ dysfunction is potentially recoverable when the factors responsible for the persistence or progression of MODS can be reversed. Identifying these factors, treating them appropriately, and providing optimal physiologic support can prove a daunting challenge, and it is often advisable to consider seeking independent advice or transporting the patient to a center with the clinical expertise and facilities to manage the multidisciplinary problems faced by MODS patients. Given that MODS often evolves as a consequence of medical misadventure, early consultation or referral may be a sound approach from a medicolegal perspective as well. On the other hand, it is a common contemporary ICU scenario that MODS evolves and worsens despite optimal care, necessitating a decision whether to continue or discontinue active care.

WITHDRAWAL OF LIFE SUPPORT

The most common mode of death for a patient with advanced MODS is limitation or withdrawal of life support in the face of a persistent failure to respond to full, aggressive ICU care.¹⁶⁰ The decision to withdraw or withhold life support is a complex one, and there are considerable differences of professional opinion and practice regarding how best to make it.¹⁶¹ Factors that must be taken into consideration include the nature of the underlying disease, the patient's premorbid health status, the wishes of the patient and the family regarding long-term ICU care, the patient's ultimate prospects for an independent existence, and the presence of active problems amenable to medical therapy. Although end-of-life deliberations may be difficult for medical staff and family alike, careful and realistic consideration of the expectations of all involved can facilitate a decision to discontinue active therapy in a manner that is dignified and humane rather than adversarial.

Discussion

MODS: Evolution of a Syndrome

The first ICU was established in Baltimore in the late 1950s.¹⁶² Its development marked much more than a simple advance in medical technology. The improvements in fluid resuscitation achieved during World War II, followed by the development of techniques of positive pressure mechanical ventilation, hemodialysis, and central venous catheterization over the subsequent decade, had set the stage for an entirely new disease paradigm—that of a disease that arose only in patients who would have died in the absence of resuscitation and exogenous support. The need for that support to sustain life became the metaphor that described this new disorder, originally described as sequential systems failure¹⁶³ and now generally known as

MODS.⁴ MODS is perhaps the classic instance of the new disease paradigm, in that it develops only in patients who would have died without medical intervention and evolves because of the inadvertent consequences of that intervention.

Earlier reports had described the physiologic failure of discrete organ systems after trauma or acute illness. Stress-related upper GI bleeding was described in 1842⁵⁴ and trauma-related renal²³ and hepatic³⁰ dysfunction during World War II. Description of respiratory failure awaited the widespread use of mechanical ventilators, but a process termed high-output respiratory failure was described in patients with peritonitis in 1963,¹³ anticipating the classic description of ARDS 4 years later.¹⁴ In each of these reports, however, the physiologic organ

abnormality was viewed as an isolated problem of a single organ, albeit one that could have broader secondary consequences. The suggestion by Baue¹ in 1975 that each organ abnormality was simply the local manifestation of a systemic process set the stage for attempts to identify common systemic pathologic processes and hence to develop therapies that were not merely supportive but also targeted fundamental mechanisms in the pathogenesis of MODS. The search for such therapies is, admittedly, still in its infancy. Not only is the disease process complex, but our ability to describe and characterize it is limited as well.

MODS is invariably preceded by evidence of systemic activation of an adaptive host stress response to infection or tissue injury. This response, which includes changes in cardiorespiratory function, increased microvascular permeability, evidence of activation of innate immune mechanisms, and alterations in intermediary metabolism, is termed sepsis when caused by infection and the systemic inflammatory response syndrome (SIRS) when considered independent of cause.^{4,164} SIRS is mediated through the release of a complicated network of host-derived mediator molecules (see below). The name notwithstanding, designation of SIRS as a syndrome may be somewhat presumptuous. There is no discrete or invariant pattern of clinical manifestations that identifies patients with activation of this complex response, nor is there convincing evidence that the response is common to all patients who meet the clinical criteria for SIRS.

It has been suggested that it is also possible to define a compensatory anti-inflammatory response syndrome (CARS) or a mixed acute response syndrome (MARS)¹⁶⁵; however, these "syndromes" are more conceptual entities than they are diseases that can be diagnosed and treated.¹⁶⁶

Theories of Pathogenesis

Organ dysfunction must ultimately be the consequence of the malfunctioning or death of cells in that organ. Although cellular derangements are readily documented under experimental conditions, it remains largely unknown how these derangements translate into the physiologic changes that define the clinical syndrome. Cellular dysfunction may reflect altered patterns of synthetic function, either because of activation of alternate patterns of gene expression or because of relative cellular oxygen deficiency from defective cellular respiration (so-called cytopathic hypoxia).¹⁶⁷ Mechanisms of fibrosis and repair may alter the normal cellular anatomic relationships and thereby impair function. Finally, cell death may result from mechanical or biochemical injury of sufficient severity to prevent oxidative metabolism and produce anatomic disruption of the cell or necrosis, but it may also occur through the activation of apoptosis (programmed cell death). Each of these abnormalities has been described in patients with sepsis, and each has multiple overlapping causes.

INFECTION AND HOST SEPTIC RESPONSE

The earliest descriptions of MODS emphasized its association with occult infection,^{58,94} prompting the hypothesis that organ dysfunction arises through the direct effects of one or more microbial toxins. However, the observations that MODS could also develop in patients with no identifiable focus of infection⁹⁵ and that treatment of infection did not necessarily reverse the syndrome¹⁶⁸ suggested that infection may be a cause of organ dysfunction in critical illness but is not necessarily the fundamental mechanism.

Microbial products, independent of bacterial viability, can evoke the clinical features of sepsis. Injection of endotoxin, or

lipopolysaccharide (LPS), derived from the cell wall of gram-negative bacteria reproduces the physiologic features of sepsis in human volunteers,¹⁶⁹ with larger doses producing life-threatening organ dysfunction.¹⁷⁰ Moreover, endotoxin can be detected in the circulation of patients at risk for MODS—not only patients with sepsis,^{171,172} but also those who have experienced traumatic¹⁷³ or thermal injury¹⁷⁴ and those who are undergoing cardiopulmonary bypass or repair of an abdominal aortic aneurysm.¹⁷⁵

Animal studies, however, have shown that the sequelae of endotoxemia are an indirect consequence of the activation of host innate immunity rather than a direct cytopathic effect of the endotoxin molecule. The C3h HeJ strain of mice arose through a spontaneous mutation of the parental C3h HeN strain, involving an alteration in a single gene product. This defect, later recognized as a point mutation in the gene encoding Toll-like receptor 4 (TLR4),¹⁷⁶ conferred complete resistance to endotoxin lethality in C3h HeJ mice. Studies involving bone marrow irradiation and crossover transplants of bone marrow cells between C3h HeN and C3h HeJ mice showed that endotoxin sensitivity was transferred with bone marrow cells¹⁷⁷ and confirmed that the sequelae of endotoxin challenge arose indirectly, through the activity of marrow-derived cells from the host. Microarray studies have demonstrated that literally hundreds of genes are expressed in macrophages, endothelial cells, and neutrophils after stimulation by LPS.^{178,179} The importance of this enormously complex response is underlined by the observation that the lethality of murine endotoxemia can be prevented by neutralizing any one of several dozen of these gene expressions before endotoxin challenge.¹⁴⁵

Endotoxin interacts with cells of the host innate immune system through TLR4. TLR4 is one of a family of 10 TLRs that have evolved to recognize danger signals in the extracellular environment and to activate cells to mount an appropriate response to a threat.¹⁸⁰ TLRs recognize not only microbial products (e.g., endotoxin) and components of the wall of gram-positive bacteria (e.g., lipoteichoic acid and peptidoglycan) (TLR2) but also bacterial DNA (TLR9) and even heat-shock proteins and structural components of damaged cells (TLR2) [see Table 7]. Thus, the response evoked appears not to be specific for the stimulus that elicited it, just as the clinical syndrome of systemic inflammation and organ dysfunction is not unique to patients with infection but can also be seen in association with other causes of tissue injury.^{164,181}

The binding of endotoxin to TLR4 triggers a cascade of intracellular signaling pathways leading to the expression of hundreds of genes whose products mediate innate immunity [see Figure 2]. The resulting alterations in normal patterns of cellular protein synthesis are profound: not only does the initial stimulus trigger a complex response, but the newly synthesized protein products of this response also, in turn, are capable of acting on the cell to induce a further cascade of mediator molecules. Any attempt to classify the mediators involved is inevitably arbitrary and simplistic. It is useful, however, to consider the response as involving (1) early inflammatory mediators (e.g., TNF and IL-1), (2) late inflammatory mediators (e.g., macrophage inhibitory factor and high-mobility group box [HMGB]-1), (3) counterinflammatory and tissue repair mediators (e.g., IL-10 and transforming growth factor [TGF]- β), (4) enzymes involved in the regulation of non-protein inflammatory mediators (e.g., inducible NO synthase, phospholipase A₂, and platelet-activating factor acetylhydrolase), (5) acute-phase reactants, and (6) cell surface adhesion or signaling molecules (e.g., intercellular adhesion molecule [ICAM]-1 and tissue factor).

Table 7 Toll-like Receptors and Their Ligands

Toll-like Receptor	Ligand(s)
TLR1	<i>Mycobacterium leprae</i> lipopeptide, <i>Borrelia</i> outer surface protein
TLR2	Peptidoglycan, lipoteichoic acid, bacterial lipoprotein, <i>Mycoplasma</i> lipopeptide, zymosan, CMV, <i>M. leprae</i> lipopeptide, lipoarabinomannans, injured cells
TLR3	Double-stranded RNA
TLR4	Endotoxin, HSP60, β -glucan, neutrophil elastase
TLR5	Flagellin
TLR6	<i>Mycoplasma</i> lipopeptide
TLR7	Imidazoquinolones, guanine ribonucleosides
TLR8	Unknown
TLR9	Bacterial CpG DNA
TLR10	Unknown

Blockade of any of these molecules prevents lethality in mice that are subsequently challenged with endotoxin. None of these mediators, however, is directly cytotoxic, which suggests that their role is to activate effector mechanisms of injury further downstream. The identity of those downstream mechanisms of cellular dysfunction or death is still speculative, though a number of attractive possibilities have been proposed.

GENETIC FACTORS IN HOST RESPONSE

A Scandinavian population-based study of causes of premature mortality in adoptees revealed that genetic factors play a significant role in the outcome of infection. When one of an adoptee's biologic parents died before the age of 50, the adoptee faced a six-fold increase in the risk of infectious mortality; this increased risk was substantially greater than that associated with premature death from cardiovascular disease or cancer.¹⁸² It is now known that polymorphisms in genes for TLRs and cytokines are common in the general population¹⁸³ and are associated with both altered expression of the gene product and enhanced susceptibility to sepsis and organ dysfunction. A mutation in the gene for TLR4 has been associated with a significantly increased risk of gram-negative infection in ICU patients.^{184,185} Polymorphisms in the genes for CD14,¹⁸⁶ TNF,^{187,188} heat shock protein 70,¹⁸⁹ IL-10,¹⁹⁰ and IL-1 receptor antagonist¹⁹¹ all have been associated with greater degrees of organ dysfunction and a worse clinical outcome in critical illness.

TISSUE INJURY MEDIATED BY PHAGOCYTIC CELLS OF INNATE IMMUNE SYSTEM

Polymorphonuclear neutrophils and monocytes form the first line of innate host defenses against invading microorganisms and injured tissue. Neutrophils are recruited to the site of tissue invasion or injury by locally released chemokines (e.g., IL-8). They adhere to the endothelium of the microvasculature through the interaction of the neutrophil adhesion molecule CD11b with ICAM-1 on the endothelial cell [see 8.24 Molecular and Cellular Mediators of the Inflammatory Response]. Adherent neutrophils are

then able to extravasate by degrading the tight junctions between endothelial cells, probably through the action of the neutrophil enzyme elastase; this process can cause injury to the cell as the neutrophil transits.¹⁹² Once localized to the site of challenge, the neutrophil releases a variety of molecules (e.g., proteases and reactive oxygen intermediates) that directly injure microorganisms and host tissue alike. Opsonization of bacteria by immunoglobulin or complement enables the neutrophil to phagocytose and kill invading pathogens. Activated neutrophils have been implicated in the pathogenesis of pulmonary,^{193,194} hepatic,¹⁹⁵ GI,¹⁹⁶ and renal²⁸ injury in experimental models of inflammation. Similarly, though ablation of fixed tissue macrophages increased the number of bacteria isolated from an animal model of peritonitis, it nonetheless reduced the severity of septic symptoms and improved survival.¹⁹⁷

Other studies have implicated natural killer (NK) cells^{198,199} and CD8-positive T cells²⁰⁰ in the lethality of experimental sepsis, though it is unclear whether lethality is a consequence of direct cellular cytotoxicity or of the activation of other biologic processes by secreted products of these cells.²⁰¹

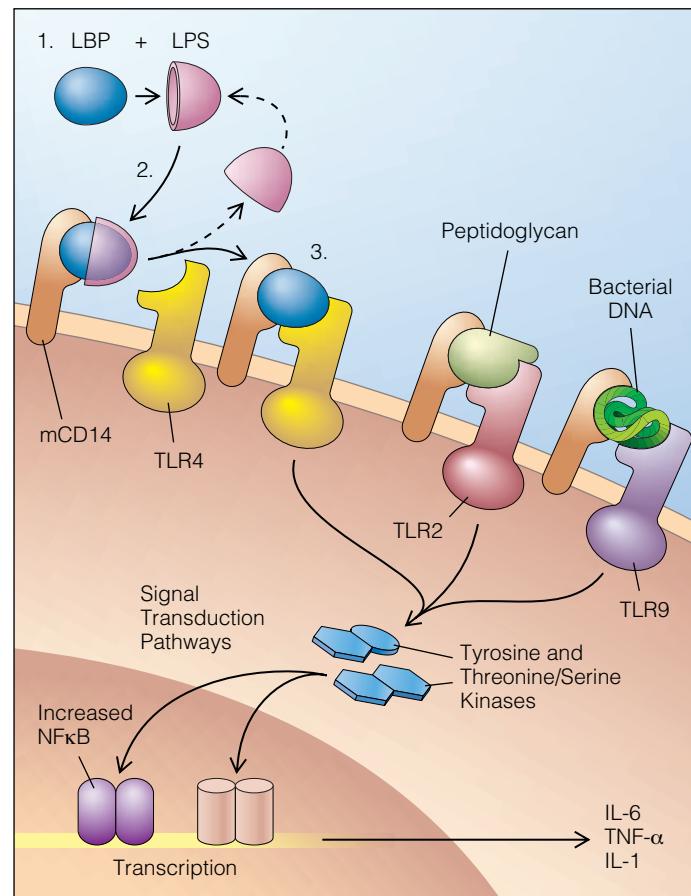

Figure 2 During lipopolysaccharide (LPS) signaling, (1) LPS binds to LPS-binding protein (LBP). (2) This complex is delivered to membrane-bound CD14 (mCD14). (3) The CD14-LPS complex interacts with Toll-like receptor 4 (TLR4), which initiates the intracellular signal transduction pathway. The signal transduction pathway leads to NF- κ B translocation into the nucleus, with increased transcription of proinflammatory cytokines. TLR2 is known to signal membrane compounds of gram-positive bacteria such as peptidoglycan. TLR9 recognizes bacterial DNA. (IL—interleukin; NF- κ B—nuclear factor κ B; TNF- α —tumor necrosis factor- α).

ENDOTHELIAL INJURY

The network of endothelial cells lining the large and small vessels of the vascular tree is enormous, encompassing an area 600 times larger than that of the skin.²⁰² Far from being a passive conduit for blood cells and plasma, the endothelium contributes actively to the initiation, localization, and resolution of inflammation.²⁰³ Circulating inflammatory mediators evoke an endothelial cell response characterized by upregulation of adhesion molecules such as ICAM-1 and vascular cell adhesion molecule (VCAM), expression of TLR2 and tissue factor, and shedding of endothelial cell thrombomodulin.^{203,204} These changes result in neutrophil localization and local activation of coagulation with secondary tissue injury. In addition, healthy endothelial cells appear to play a role in limiting host injury during inflammation, as indicated by the observation that mice with a genetic deletion of syndecan-4 (a proteoglycan involved in endothelial cell adhesion and signaling) exhibit increased mortality and exaggerated release of IL-1 after endotoxin challenge.²⁰⁵

Postmortem studies of patients with ARDS show that ICAM-1 is upregulated throughout the lung, whereas VCAM is expressed in larger vessels,²⁰⁶ and that circulating markers of endothelial activation are present in critically ill patients with organ failure.²⁰⁷ Moreover, diffuse endothelial injury is suggested by the presence of circulating endothelial cells in the blood of patients in septic shock.²⁰⁸ Therapeutic strategies that target the adhesive interactions of lymphocytes and endothelial cells have shown promise against inflammatory conditions such as psoriasis and Crohn disease; studies of agents targeting the interaction of neutrophils with endothelial cells have so far yielded disappointing results.²⁰⁹

INTRAVASCULAR COAGULATION

Although plasma contains all the factors necessary to induce coagulation and formation of a fibrin clot, intravascular coagulation is limited in healthy persons by the absence of a trigger and the presence of endogenous anticoagulant mechanisms. This balance is disrupted in persons experiencing systemic inflammation, resulting in microvascular coagulation and obstructing oxygen delivery to the cell. Injury and inflammation can upregulate endothelial cell tissue factor expression and activate the coagulation cascade by catalyzing the conversion of factor VII to factor VIIa. Sequential activation of circulating coagulation factors results in the conversion of prothrombin to thrombin and, in turn, the conversion of fibrinogen to fibrin. The activation of coagulation is inhibited by three important endogenous anticoagulant pathways: the protein C pathway, the antithrombin pathway, and the tissue factor pathway inhibitor (TFPI) pathway. Each of these is impaired in critical illness, leading to a net procoagulant state.

Protein C is synthesized in the liver and circulates as an inactive precursor. It is activated in the vascular tree through its interaction with thrombomodulin on the endothelial cell; activated protein C blocks thrombin generation through its inhibitory interactions with factors V and VIII.²¹⁰ Hepatic production of protein C is impaired in sepsis. Moreover, shedding of endothelial cell thrombomodulin results in a reduction in the activation of available protein C, whereas acute-phase reactants such as α_1 -antitrypsin accelerate its degradation. The importance of this anticoagulant mechanism is underlined by a 2001 study of recombinant activated protein C in patients with severe sepsis, in which treated patients experienced a significant improvement in 28-day survival and those with the greatest degrees of organ dysfunction benefited most.¹⁴⁷

Antithrombin is a serine protease inhibitor that binds to and

inactivates thrombin and inhibits factors IXa, XIa, and XIIa. Levels of circulating antithrombin are reduced in sepsis. Administration of recombinant antithrombin failed to improve survival in a large multicenter study of patients with severe sepsis, though interaction with heparin may have masked a therapeutic effect.²¹¹

TFPI is synthesized by endothelial cells in response to cytokines and shear stress. It too is a serine protease inhibitor whose target is the complex of tissue factor, factor VIIa, and factor Xa that initiates the coagulation cascade. Recombinant TFPI has been evaluated as a therapy for sepsis; however, a large multicenter trial failed to show any survival benefit from such therapy.²¹²

The interactions between coagulation and inflammation are complex. Protein C binds to a receptor expressed on endothelial cells and neutrophils, and prevention of this interaction results in a disseminated inflammatory process.¹⁴⁶ Binding of activated protein C to its receptor in brain endothelium inhibits endothelial cell apoptosis and is neuroprotective during cerebral ischemia.²¹³

APOPTOSIS

Apoptosis, or programmed cell death, is a process through which cellular structural elements and DNA are degraded and residual cellular constituents are converted into membrane-bound vesicles (apoptotic bodies) that are cleared by macrophages. Phagocytosis of apoptotic bodies prevents the uncontrolled release of cellular constituents and so prevents an inflammatory response to the injured cell.²¹⁴ Apoptosis is also an intrinsically anti-inflammatory process, however, in that phagocytosis of an apoptotic cell by the macrophage evokes the expression of anti-inflammatory genes such as those for TGF- β and IL-10.^{215,216} Apoptosis, like cell replication, is a physiologic process that is essential for normal growth and development; either excessive or inadequate apoptosis can produce disease.

Increased rates of apoptosis of colonic epithelial cells and splenic lymphocytes are seen in autopsy specimens from patients dying as a consequence of sepsis or multiple trauma.²¹⁷ Conversely, whereas circulating neutrophils survive less than a day *in vivo* in healthy persons, neutrophils isolated from the blood of patients with sepsis show both phenotypic features of activation and prolonged survival (a consequence of the inhibition of a constitutively expressed apoptotic program).⁵² Animal studies have shown that inhibition of lymphoid cell apoptosis improves survival after septic challenge.²¹⁸ Conversely, induction of neutrophil apoptosis improved survival in a rodent model of intestinal ischemia-reperfusion injury.²¹⁹ The potential role of apoptosis in the pathogenesis of MODS is further suggested by animal studies of ventilator-induced lung injury, which demonstrated that injurious mechanical ventilation strategies can induce renal epithelial cell apoptosis and biochemical evidence of renal dysfunction.²²⁰

GASTROINTESTINAL DYSHOMEOSTASIS

Because MODS not infrequently evolves despite apparently adequate control of infection or other inciting triggers, it has been suggested that the GI tract may serve as the unseen motor of the pathologic state,²²¹⁻²²⁴ both as a reservoir of microorganisms and their products and as a mechanism for the evolution of inflammation.

The GI tract of a healthy human being harbors upward of 600 different microbial species, and bacteria outnumber human cells 10 to 1.²²⁵ The composition of the GI flora is stable over a person's lifetime, but intercurrent disease can produce profound changes in bacterial numbers and patterns of colonization. In critically ill surgical patients, the normally sterile proximal GI tract

becomes heavily colonized with the same organisms that predominate in nosocomial ICU-acquired infection—*Staphylococcus epidermidis*, *Pseudomonas*, *Candida*, and *Enterococcus*. Colonization is significantly associated with the development of nosocomial infection with the same organism.¹⁵² Extensive studies in animal models have shown that acute insults (e.g., endotoxemia, peritonitis, pneumonia, trauma, burns, biliary tract obstruction, malnutrition, and lack of enteral feeding) can induce bacterial overgrowth in the gut and translocation of enteric bacteria to regional lymph nodes of the peritoneal cavity.²²⁶ Similar stimuli result in translocation in humans,^{227,228} and prevention of colonization with topical nonabsorbed antibiotics reduces the incidence of nosocomial infections, including bacteremias.¹⁵³ Detection of circulating endotoxin after burns¹⁷⁴ or major vascular surgery¹⁷⁵ suggests that endotoxin is also absorbed from the gut under conditions of altered gut barrier function.

The role of the gut in MODS is not limited to that of a microbial reservoir. The GI tract and adjacent structures constitute the largest aggregation of immune cells in the body. Normal interactions between the indigenous flora and the gut immune system serve to prevent the generation of immune responses to luminal antigens. Loss of these tonic inhibitory interactions may, in turn, contribute to a state of systemically activated inflammation. Accordingly, hemorrhagic shock results in significantly elevated levels of TNF and IL-6 in portal venous blood,²²⁹ and portal endotoxemia replicates systemic features of MODS, such as hypermetabolism,²³⁰ impairment of cell-mediated immunity,²³¹ and activation of coagulation.²³² Ablation of the hepatic Kupffer cell population has improved survival in animal models of peritonitis.¹⁹⁷ Mesenteric lymph has been shown to contain factors that can evoke inflammatory changes in organs remote from the gut.²³³ Thus, dysfunction of normal microbiologic and immunologic homeostasis in the GI tract and the liver results in the gut serving as a secondary source of the stimuli that induce and perpetuate MODS.

A clinically relevant role for the gut in the pathogenesis of MODS is supported by the results of randomized trials of SDD.¹⁵³

Table 8 Characteristics of Linear and Complex Systems²⁴¹

Assumptions of Linear Systems	Assumptions of Complex Systems
Mediators have unique, consistent biologic effects	Mediators have redundant, variable, and context-dependent effects
Antagonism of effect is mediated by specific inhibitor	Antagonism of effect is not attributable to single mediator or process
Biologic processes occur sequentially	Biologic processes occur concurrently
Biologic response is reliably predicted by measurement of responsible mediator	Biologic response is not consistently predicted by measure of single mediator
Modulation of biologic process occurs in dose-dependent fashion; small intervention has small effect	Modulation of process is not predictably dose-dependent; small perturbation may have large effect
Normal behavior of system results in physiologic stability	Normal integrated behavior of system results in physiologic variability or oscillations over time

TWO-HIT HYPOTHESIS

A complementary hypothesis of MODS pathogenesis suggests that an acute insult, such as infection or trauma, primes the host so that a subsequent, relatively trivial, insult produces a markedly exaggerated host response.²³⁴ Such a model would account for the severity of MODS developing late after multiple trauma¹⁸¹ as well as the substantial morbidity associated with nosocomial infection in the ICU.¹⁵¹ Studies in animal models have revealed that previous hemorrhagic shock leads to an exaggerated response to subsequent endotoxin challenge.²³⁵

MODS and Complexity Theory

None of the various theories of pathogenesis described so far is adequate to explain the evolution of the clinical syndrome of MODS. These models are not mutually exclusive; rather, they reflect differing perspectives on a profoundly deranged state of systemic homeostasis—one that has evolved only because the health care team has intervened to subvert an otherwise lethal process. The enormously complicated interactions among multiple predisposing patient factors, a series of physiologic insults, and an endogenous response effected via multiple cell types and many hundreds of biochemical mediators is best modeled by means of complexity theory.^{236,237}

According to the precepts of complexity theory, a complex system cannot be understood through isolated analysis of its component parts: it can be understood only through an appreciation of the various interactions of those parts. The result of these multiple interactions is neither a state of anarchy nor a limitless series of unpredictable outcomes but, rather, a series of stable responses known as an emergent order. This stable order is dependent on the interactions of all its parts but is much more than their simple sum. It is characterized both by a resilience to potentially disruptive external influences and by a degree of intrinsic variability. Loss of intrinsic variability is a marker of a failing or diseased system. The healthy human heart exhibits normal variability in rate and rhythm, which is lost in patients with significant congestive heart failure.²³⁸ Loss of intrinsic heart rate and blood pressure variability is also evident in patients with septic shock.^{239,240}

The idea that concepts inherent in complex nonlinear systems can be applied to the understanding of MODS is compelling.²⁴¹ Clinicians are most familiar with linear models of disease, and the assumptions on which these models are based generally lead to effective clinical responses. For example, diabetes results from the deficiency of a single protein and is treated effectively by replacing that protein; cholangitis is the consequence of obstruction of the bile duct and is treated by relieving that obstruction. For linear diseases such as these, a single abnormality produces the clinical phenotype, and definitive therapy involves correcting that abnormality. Disorders of biologic pathways such as the coagulation cascade represent a somewhat more elaborate variation on the same theme. For example, pathologic coagulation resulting in DVT can be treated by means of a variety of different strategies aimed at disrupting the clotting cascade. Similarly, hypertension can be managed by means of various pharmacologic strategies that modify different aspects of the regulation of vasomotor tone.

Complex disorders such as MODS, however, are not so predictable, and the therapeutic modulation required is much more difficult [see Table 8]. The consequences of manipulating a particular mediator may be highly context dependent, varying with the nature of the insult, the predisposition of the host,

and the timing of administration.¹⁴⁵ Moreover, intervention carries the potential cost of inadvertent iatrogenic harm. A sobering consequence of high-quality clinical trials performed in the ICU over the past decade has been the realization that

making a normal or supranormal physiologic state the therapeutic target in a critically ill patient whose homeostasis is profoundly disrupted may, on occasion, be detrimental rather than beneficial.^{22,107,242}

14 CLINICAL AND LABORATORY DIAGNOSIS OF INFECTION

David C. Evans, M.D. and Jonathan L. Meakins, M.D., D.Sc.

Approach to Diagnosis of Surgical Infection

Surgical infection is a term that, though frequently used, is not clearly defined. In the strictest sense, it implies infection amenable to operative management through surgical source control, as in the case of complicated diverticulitis or necrotizing soft tissue infection. More generally, however, the term can refer to any infection commonly seen in surgical patients (e.g., central line infection or postoperative pneumonia). Both definitions are pertinent, in that the same diagnostic principles apply in each situation.

The presence of surgical infectious disease is usually determined clinically and confirmed microbiologically. Identification of an infection is rarely incidental; most often it is sought in response to a clinical signal. This signal is frequently fever but may be one or more of a number of other symptoms and signs.

Most surgical infections are outpatient conditions that are easily diagnosed and treated. Infections in hospitalized patients, whether related to the primary surgical disease or resulting from surgical therapy, are less easily managed. The greatest challenges in diagnosis and treatment of surgical infections arise in the perioperative and postoperative periods.

Terminology

Traditionally, the terms infection, sepsis, septicemia, bacteremia, endotoxemia, and septic shock have borne similar connotations; this imprecision of terminology has led to considerable confusion about the specific role of microbial infection as a cause of the common clinical presentation of fever, tachycardia, and occasional hypotension. The traditional tendency to conflate these distinct concepts in this simplistic and unrefined manner has had major implications for how antibiotics are used—or, more to the point, misused—in surgical patients.

The human body's physiologic response to systemic infection is well characterized and is often referred to as sepsis. However, infection and sepsis are distinct entities. The normal septic response to infection may, in fact, be completely absent in immunosuppressed patients. Most surgeons, for example, have encountered a patient receiving high doses of steroids who has a perforated intra-abdominal viscus and fecal peritonitis but whose leukocyte count, temperature, and blood pressure are all normal. Conversely, a systemic inflammatory response mimicking sepsis may be present in noninfected patients.^{1,2} For example, patients with acute pancreatitis, tissue necrosis, or fractures may manifest physiologic and metabolic changes that are indistinguishable from those associated with bacteremia, even in the absence of infection. Animal studies have confirmed that a sepsislike syndrome can occur without microbial invasion of host tissues.³

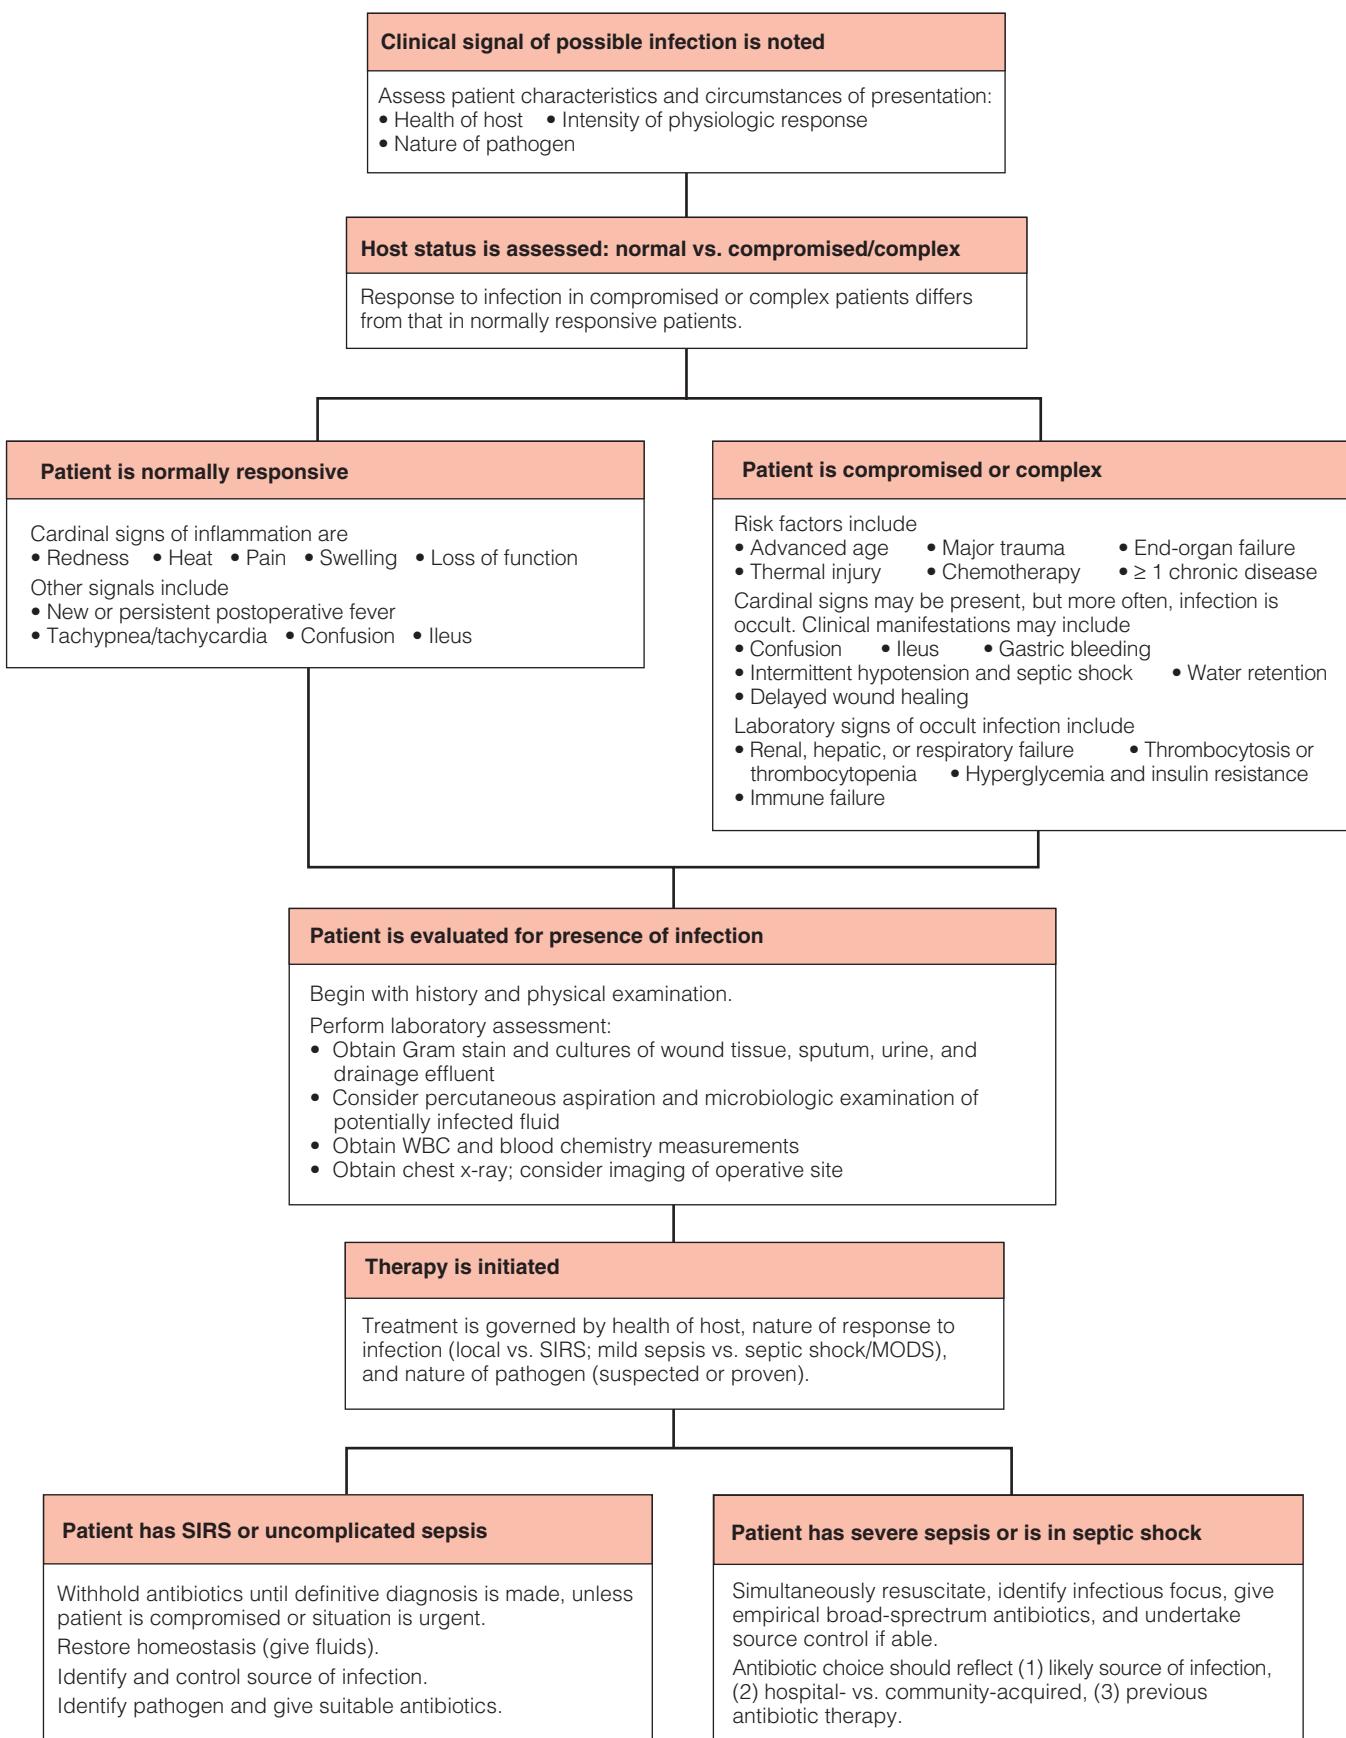

Accordingly, several clinicians have used the term sepsis syndrome to refer to the group of signs, symptoms, and physiologic changes that result from a variety of sterile inflammatory processes as well as from systemic infection.^{2,4} The problem with using the term in this way, however, is that it derives from a Greek word (*sepsis*, “decay”) that implies infection with microorganisms. It is therefore not surprising that application of the term sepsis syndrome to noninfectious settings has led to some confusion.^{5,6}

To clarify the relevant terminology and provide a common vernacular with which to discuss surgical infection, the American College of Chest Physicians and the Society of Critical Care Medicine held a joint consensus conference in 1991 that led to the publication in 1992 of the currently used terminology and definitions [see Sidebar Definitions of Key Concepts].⁷ A key outcome was the definition of the nonspecific clinical picture of temperature, heart rate, respiratory rate, and white blood cell (WBC) count abnormalities as the systemic inflammatory response syndrome (SIRS). SIRS may or may not be due to infection; when it is, it is referred to as sepsis. When sepsis results in organ dysfunction, the ensuing state is referred to as severe sepsis; when it results in persistent cardiovascular decompensation, the ensuing state is referred to as septic shock.

Definitions of Key Concepts

- *Systemic inflammatory response syndrome (SIRS)*: This response is manifested by the occurrence of two or more of the following conditions as a result of infection: (a) temperature higher than 38° C (100.4° F) or lower than 36° C (96.8° F), (b) heart rate greater than 90 beats/min, (c) respiratory rate greater than 20 breaths/min or arterial carbon dioxide tension less than 32 mm Hg, and (d) white blood cell count greater than 12,000/mm³ or less than 4,000/mm³, or immature (band) forms accounting for more than 10% of the neutrophils present.
- *Sepsis*: SIRS when specifically caused by infection.
- *Severe sepsis*: Sepsis associated with organ dysfunction, hypoperfusion, or hypotension. Hypoperfusion and perfusion abnormalities may include, but are not limited to, lactic acidosis, oliguria, or acute alteration of mental status.
- *Septic shock*: Sepsis with hypotension despite adequate fluid resuscitation, with persistent perfusion abnormalities that may include, but are not limited to, lactic acidosis, oliguria, or acute alteration of mental status. Patients receiving inotropes or vasoconstrictors may not be hypotensive at the time perfusion abnormalities are measured.
- *Multiple organ dysfunction syndrome (MODS)*: MODS is the presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention.

Approach to Diagnosis of Surgical Infection

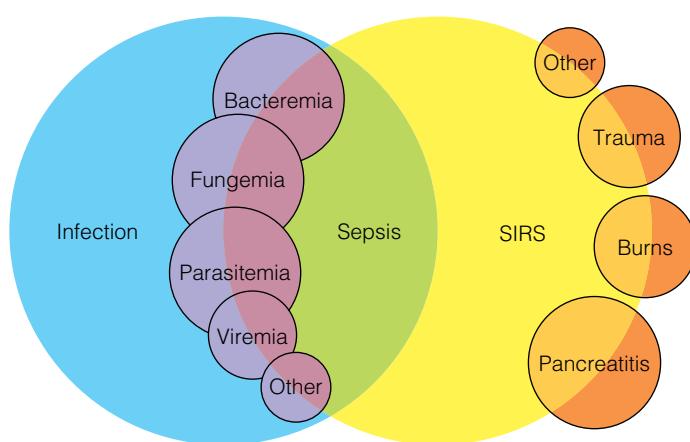

Figure 1 Depicted are the interrelationships among infection, sepsis, and the systemic inflammatory response syndrome (SIRS).

Clearly, SIRS includes all the signs, symptoms, and physiologic changes characteristic of the sepsis syndrome; however, use of the term SIRS avoids the idea that such manifestations are necessarily the product of infection. Sepsis may be thought of as a special case of SIRS—SIRS associated with infection [see Figure 1]. The term sepsis syndrome, although very useful in guiding clinical thinking, is insufficiently precise for our current needs and probably should no longer be used. The term septicemia should not be used either.

The crucial point is that infection and sepsis are conceptually distinct: infection is a process, and sepsis is the response to that process. The response provides the clinical signals that lead to diagnosis of the initiating process. As a rule, infection, once diagnosed, is easily treated with antibiotics and drainage. It is the management of sepsis that is difficult [see 8:13 *Multiple Organ Dysfunction Syndrome*].

General Approach to Diagnosis of Infection

The search for an infection is prompted by a clinical signal indicating a problem in need of resolution [see Table 1]. The signal denotes the response of a patient to an infectious stimulus and is a function of the patient's physiologic ability to react to the endogenous and exogenous mediators liberated through the infectious process. A thorough history and physical examination are imperative and should be followed by selected laboratory tests. Normally responsive patients tend to show the classic signals, whereas compromised or complex patients often show more subtle signs that may only be noted as abnormalities on routine bloodwork.

The diagnostic approach to suspected infection must be modified according to patient characteristics and the circumstances of presentation; for example, the specific differential diagnosis for infection appearing on postoperative day 1 will clearly be different from that for infection appearing after 1 week in the ICU. There are three important elements at play when a surgical patient experiences an infection: (1) the health of the host, (2) the intensity of the physiologic response to infection, and (3) the nature of the pathogen. All three factors must be considered carefully in the diagnosis of surgical infection.

Host Status: Normally Responsive versus Compromised or Complex

That signs and symptoms of infection in compromised or complex patients differ from those in normally responsive hosts has important diagnostic implications. Normally responsive patients, for whom the physician can obtain a history and perform a physical examination, respond to infection in the classic manner—typically, with fever, tachycardia, leukocytosis, malaise, and other appropriate symptoms. For many reasons—even simply if the infection is severe—normally responsive patients may become compromised. Compromised or complex patients are unable to meet inflammatory or infectious challenges in the normal manner.

Hence, the clinical signals of infection in such patients differ from those in normally responsive patients, often being absent or developing at a later stage of infection. Indeed, a multitude of clinical conditions or physiologic states define compromised or complex patients. These include the extremes of age, immunosuppression as a result of either disease (e.g., HIV infection or lymphoma) or medication (e.g., chemotherapy), thermal injury, major trauma, acute end-organ failure in the ICU, and the presence of more than one chronic disease. The prevalence of such patients in modern hospital surgical practice is increasing steadily.

It must be kept in mind, however, that the normally responsive patient and the compromised or complex patient are merely extreme points on the clinical spectrum rather than categorically distinct populations.

Physiologic Response to Infection

NORMALLY RESPONSIVE PATIENTS

Cardinal Signs of Inflammation

Rubor, calor, dolor, tumor, and functio laesa—that is, redness, heat, pain, swelling, and loss of function—have been considered the cardinal signs of localized inflammation since the times of Hippocrates and Galen. They remain the primary signals leading to medical consultation for outpatient surgical infections and for many of the infectious complications of operation. They are emblematic of the host's effort to contain infection locally and may signal the presence of infection even in cases where the primary site of infection is a deeply situated organ or tissue. Infections amenable to surgical intervention may present in this way; however, nosocomial infections complicating the course of surgical patients are generally signaled in more subtle ways.

Fever

Fever is perhaps the most common signal that an infectious process is present.

Postoperative fever is a normal part of the recovery process; understanding the typical febrile course is important in differentiating normal from pathologic fever. It is unusual for a sudden, very high fever to be the first signal of an infection. Infection usually begins to manifest itself with a prodrome, recognition of which speeds diagnosis and therapy. Investigation should be started when the patient's temperature reaches 38° C (100.4° F) rather than 40° C (104° F). Although this point may seem obvious, many of the cri-

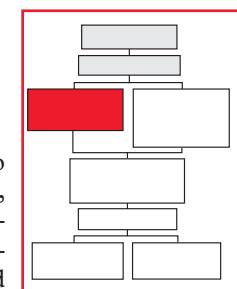

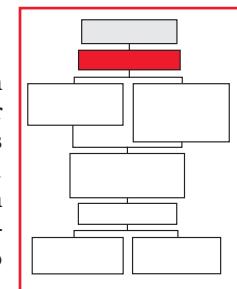

Table 1 Fundamental Approach to Diagnosis of Infection

Recognize clinical signal and observe its characteristics:

- Nature
- Intensity
- Rapidity of development

Make best guess as to source and likely pathogen on the basis of

- History of surgical disease
- Physical examination
- Microbiologic examination of stained specimens
- Radiologic findings

Confirm presence of infection by means of

- Laboratory results
- Observation of clinical course
- Invasive procedures (e.g., paracentesis, thoracentesis, interventional radiology, operation)

sis intervention measures required in managing fevers could be avoided if the significance of more modest temperature elevations were recognized more often.

A fever that appears after the normal postoperative temperature elevation has resolved must not be ignored. To simply wait for such a fever to dissipate is to court disaster. In the absence of a clear diagnosis, a thorough physical examination of the patient, directed by laboratory tests and followed by reexamination as necessary, is required to identify occult infection.

Miscellaneous Signals

It is common wisdom that the signals communicating underlying infection in the compromised or complex host may be subtle. The astute clinician will be in tune with these and, with experience, will recognize when to undertake a diligent search for infection.

Altered heart rate A heart rate that is either too high or too low may signal an infection. On rare occasions, a change in rhythm in the elderly (e.g., paroxysmal atrial tachycardia, flutter, or atrial fibrillation) indicates an infectious process. Gram-negative sepsis may produce a so-called relative bradycardia, meaning that the resulting tachycardia is not as pronounced as one might expect. An unexplained sustained increase in heart rate should not be ignored.

Tachypnea Whereas tachypnea occurs commonly after operation in response to pain or poor pulmonary toilet, it may also signal either the prodrome of infection or the onset of SIRS. Because tachypnea may herald not only infection but also other important diagnoses (e.g., pulmonary embolism), it must be thoughtfully and methodically evaluated.

Pain Pain that persists or is out of proportion to the expected response deserves attention. Whenever a surgical wound that was healing favorably for the first 5 to 7 days becomes more painful, a deep surgical site infection (SSI) must be suspected and ruled out, even if other signs are absent. Unexplained muscular pain is often the first harbinger of deadly necrotizing soft tissue infection caused by gram-positive bacteria (e.g., group A streptococci), the early recognition of which may be lifesaving and limb-preserving [see 3:2 *Soft Tissue Infection*]. Sometimes pain is re-

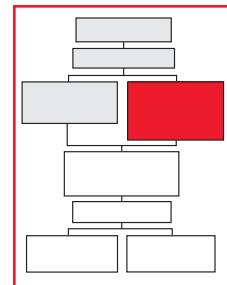

ferred, and the painful area appears normal on examination. Pneumonia that presents with abdominal findings is a classic example, as is the shoulder-tip pain with a normal range of motion seen in patients with a subphrenic abscess.

Confusion Confusion is a common symptom of infection in the elderly; it is also an important signal in patients who had been well and fit. The physician's first response to confusion in an elderly patient in the postoperative period must be to seek a cause, not to order sedation.

Ileus Ileus has many causes, some of which are not well understood. Prolonged ileus after abdominal operation—as well as almost any ileus after other operations—requires explanation. Infections at remote sites (e.g., SSI and pneumonia) can produce ileus, as if the bowel were a target organ such as the kidney, the liver, or the lung.

COMPROMISED OR COMPLEX PATIENTS

The presence of fever remains a common signal of infection in the compromised or complex patient; however, it may be absent, or the patient's temperature may already be elevated as a result of other causes. Cardinal signs of infection may be present. More often, however, the infection is occult, and classic signals are unrelated to the infectious focus. In some very ill immunocompromised patients, findings that usually signal an infection may already be present. Slight changes in clinical status (e.g., minor temperature elevations, increased fluid requirements, confusion, and ileus) or changes in laboratory findings (e.g., an elevated WBC count, glucosuria, and hyperglycemia) should trigger investigation.

Patients in whom the first signal of an infectious process is organ dysfunction or failure, rather than fever and tachycardia, are likely to be physiologically compromised and seriously ill; perhaps more important, however, is that they are a group whose diagnosis and management require expert clinical skills. Because the classic septic response may not be present, it is essential to be alert to the signs and symptoms of occult infection (see below). In these patients, the laboratory and the radiology suite become increasingly important in diagnosing and documenting the evolution of the infection.

Clinical Signs and Symptoms of Occult Infection

Subtle changes in temperature, mental status, pulse rate, or respiratory rate may signal occult infection, as may the development of pain or ileus.

Intermittent hypotension and septic shock Septic shock, an important manifestation of an unrecognized focus of infection, is the original expression of multisystem failure. Fortunately, it rarely occurs without warning. The prodrome often includes fever and sometimes other signals. Recurring hypotension is the most characteristic signal; it usually is not catastrophic and responds quickly to fluid resuscitation. Oliguria may accompany the hypotension. If this clinical state is allowed to progress, the hypotension will lead to renal failure (see below), with substantial water retention. Septic shock will result if the infection is not identified and treated with appropriate antibiotics and source control as necessary.

Both clinical assessment and laboratory studies are necessary to confirm the presence of septic shock, although florid septic shock is easily recognized on clinical examination alone [see 8:3

Shock. Any or all of the following findings may be present in varying degrees: tachycardia; tachypnea; hypotension; warm, dry extremities; generalized flushing; and other signs suggesting a hyperdynamic, hypermetabolic state. Swan-Ganz catheter measurements confirm high cardiac output and low peripheral vascular resistance.

Gastric hemorrhage Gastric hemorrhage may be the presenting symptom of serious infection even if prophylactic measures against such hemorrhage have been taken. It is particularly suggestive of perigastric abscess resulting from anastomotic leakage after upper abdominal surgery. Gastric hyperacidity and bleeding generally respond to drainage of an abscess. Hemorrhagic gastritis must always be considered a signal of occult infection, which demands prompt diagnosis and treatment.

Delayed wound healing The absence of wound healing can indicate the presence of a significant infection. Typically in such a case, wounds left for delayed primary closure or secondary closure do not exhibit the appropriate granulation tissue and appear pale, dry, and unhealthy. The development of good granulation tissue is a sign that infection is controlled.

Laboratory Signs of Occult Infection

Renal failure Renal failure [see 8:6 *Renal Failure*] is identified by elevations in serum creatinine and blood urea nitrogen (BUN) levels, which can be highly sensitive signals of developing infection. A still more sensitive indicator is an alteration in creatinine clearance, a laboratory test underutilized in the ICU. Such alterations are generally evident before changes in serum levels. Creatinine clearance should be measured at an early stage in high-risk patients. In the presence of shock, renal failure can develop suddenly. Otherwise, loss of renal function is insidious, but it can usually be identified if sought before oliguria or anuria develops. Resolution of infection is associated with return of function.

Hepatic and respiratory failure Hepatic failure [see 8:9 *Hepatic Failure*], primarily manifested as jaundice, and respiratory failure, initially presenting as a falling arterial oxygen tension and subsequently marked by a need for mechanical ventilation or by a change in the fraction of inspired oxygen (F_1O_2) requirement, can behave in the same way as renal failure (i.e., with drainage and control of infection leading to restoration of function).

Abnormal platelet count Thrombocytosis is often seen in association with infection, particularly with compromised hosts, in whom the infection may be occult. Thrombocytopenia may also indicate serious infection, though it is not a common signal. When this occurs in the context of sepsis, it is either because disseminated intravascular coagulation (DIC) has developed or because there is a diminution of all blood lines indicating marrow dysfunction. The cause of any abnormal platelet count should be identified promptly if possible.

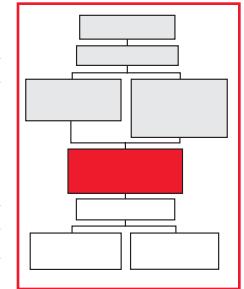

Hyperglycemia and insulin resistance Hyperglycemia and insulin resistance are often reliable signals of the presence of infection in diabetic patients as well as in nondiabetic patients. The degree of insulin resistance can reflect the severity of the infection as well as the effectiveness of infection control.

Immune failure Immune failure is discussed in detail elsewhere. Severe infection is

immunosuppressive. The most clinically applicable measure of immune failure at present is probably delayed wound healing.

Evaluation for Presence of Infection

Once the surgeon has evaluated in which ways the patient may be compromised or susceptible to infection and to which degree the physiologic response is inappropriate or harmful (i.e., provokes multiple organ dysfunction or shock), then it is important to consider which microorganisms might be responsible for the presenting clinical picture. This obviously varies with the clinical situation and requires knowledge of specific condition-associated pathogens, as well as the prevalence of certain pathogens in a particular hospital or ICU.

The prevalence of resistant bacterial strains should be monitored in clinical settings in order to guide empirical therapy. Methicillin-resistant *Staphylococcus aureus* (MRSA), once an occasional finding, has become so common in some ICUs and chronic wards that surveillance and isolation programs are no longer employed. It is now the rule for extensive invasive monitoring and access devices to be used in the care of critically ill patients, who thereby become particularly predisposed to gram-positive infection; accordingly, it is important to appreciate the likelihood that MRSA will be encountered. The same is true of *Pseudomonas aeruginosa*, a ubiquitous commensal and a common gram-negative pathogen in hospitals. In compromised patients exposed to multiple antibiotics, *P. aeruginosa* readily acquires antibiotic resistance that usually necessitates the use of double-agent or broad-spectrum coverage for effective management.

Recognizing the virulence of certain pathogens is as important as appreciating their antibiotic susceptibilities. Enteroinvasive *Escherichia coli* 0157-H7, for example, may cause a rapidly progressive hemorrhagic enteritis and provoke a fatal septic syndrome marked by acute renal failure, bleeding, and coma. Necrotizing soft tissue infections, particularly when caused by gram-positive organisms, may be precipitously fatal. Early Gram stain microscopy to identify the specific pathogen is a critical step in the management of this condition.

Essentially the same clinical and laboratory assessments are used to evaluate normally responsive and compromised or complex patients for the presence of infection. There is, however, a significant difference in emphasis. In normally responsive patients, the diagnosis of infection is usually made on clinical grounds with laboratory support, whereas in compromised or complex patients, the diagnosis is usually made on the basis of laboratory findings with clinical support.

The ICU patient presents a particular conundrum. Nosocomial infection is identified in an estimated 20% of such patients.⁸ Despite the frequency with which it is suspected and reported, it is difficult to prove unequivocally. The perceived prevalence of nosocomial infection has created a strong predisposition toward instituting empirical antibiotic therapy in ICU patients; however, the global value of this action in terms of both patient outcome and the impact on the ecology of the ICU is unconfirmed and requires validation. The enormous inconsistencies in how infections are diagnosed have a tremendous effect on our ability to assess the efficacy of therapy for infection. The current approach to diagnosing infection in surgical patients, particularly those who are critically ill or compromised, is still in great need of clarification and standardization.⁹ Until these issues are resolved, the clin-

ician must be familiar with the strengths and limitations of a variety of current diagnostic methodologies and then exercise thoughtfulness and disciplined diligence. The likelihood that a particular patient is infected (i.e., the pretest probability) is as important in the decision to treat as the fulfillment of any particular constellation of diagnostic criteria.

HISTORY AND PHYSICAL EXAMINATION

The history should include all comorbid conditions (e.g., diabetes, lung disease, cirrhosis, hepatitis, kidney disease necessitating dialysis, and previous important infections) as well as a hospitalization history that covers health status, surgical diagnosis and therapy, additional therapeutic interventions (including interventional radiology, monitoring devices, drains, and drugs), and other related variables.

In the early postoperative period (3 to 6 days after operation), the traditional causes of the signals of infection have their origin in the wound, intravascular lines, the urinary tract, and the lungs. Deep thrombophlebitis, with or without pulmonary embolism, may also initiate a systemic inflammatory response that mimics sepsis. The general physical examination is often unrewarding, but a number of specific examinations should be carefully performed, with emphasis given to (1) all wounds and surgical sites, (2) all invasive monitoring or therapeutic devices and surrounding areas (notably central and peripheral I.V. lines), (3) all drainage systems and surrounding tissue, with particular attention paid to the nature of the drainage and whether it has recently changed in character or volume (particularly if it has stopped), (4) the rectal examination (for pelvic or prostatic infection), (5) areas of potential decubitus ulcers, (6) the neck (for CNS infection), (7) intravascular lines, surrounding tissue, and proximal vessels, (8) the lungs, and (9) the legs. The physical examination is important as a guide for selecting specimens for microbiologic analysis, particularly when there have recently been significant changes in wounds or drainage. The decision to seek radiologic consultation may depend on the findings on physical examination.

DIAGNOSTIC TESTS

Hematologic and Biochemical Tests

After physical assessment, laboratory blood tests are routinely relied on to orient the surgeon toward or away from a clinical diagnosis of infection. Leukocytosis, particularly with an increase in band forms, is a usual but inconsistent marker for infection. The WBC count is widely used to follow the response of infection to therapy and thus has been adopted as a surrogate indicator of the success or failure of therapy. Surprisingly, however, the documentation supporting this ubiquitous practice is sparse.^{10,11} Not only is the daily series of complete blood counts often ordered in conjunction with the initiation of antibiotic therapy wasteful and unpleasant for the patient, but it also typically tells the clinician little about the clinical course that cannot be gleaned at the bedside.

In more complex surgical patients, other biochemical cues are used to varying degrees as means of assessing the likelihood of infection. In addition to thrombocytosis, thrombocytopenia, hyperglycemia, and metabolic acidosis, which commonly reflect the stress of severe infection, changes in the erythrocyte sedimentation rate (ESR) and in blood levels of C-reactive protein (CRP), procalcitonin (PCT), interleukin-6 (IL-6), and tumor necrosis factor (TNF) have a significant association with the presence of clinical infection. Plasma CRP concentration, which has been extensively used in some European countries to monitor the evolution of infection, has been

found to be significantly elevated in patients with pulmonary aspiration that has induced bacterial infection, compared with patients with sterile pneumonitis.¹² Some investigators have suggested that because CRP concentration appears to be particularly responsive to bacterial infection, it may be useful as a monitor of the efficacy of antibiotic use, thereby guiding discontinuance of treatment.¹³ A host of cytokines, cellular adhesion molecules, oxidants, and other biomolecules known to participate in systemic inflammation from numerous causes are being extensively investigated to establish both diagnostic and therapeutic functions [see **8:24 Molecular and Cellular Mediators of the Inflammatory Response**]. As yet, however, no single mediator of systemic inflammation has been validated as a reliable clinical tool for surveillance of the progression of infection or the response of infection to treatment.

Case Study: Clinical Picture of Sepsis without Infection

Infection is a process; sepsis is the response.

The difficulty of managing the patient who manifests the septic response in the absence of infection is illustrated by the following case.

A 55-year-old insulin-dependent man with peripheral vascular disease presented with evidence of infection in both feet. Hydration and antibiotic therapy did not prevent progression of the infection, and within 18 hours, it was apparent that amputation would be required for source control. In the course of the operation, gas gangrene, more extensive than had been clinically suspected, was discovered. The initial below-the-knee amputations were eventually followed by a hip disarticulation on one side and a high above-the-knee amputation on the other. Over the 36-hour period during which the infectious process was being controlled, classic septic shock, renal failure, coma, and respiratory failure developed. There was no change in the patient's hyperdynamic and hypermetabolic state after the amputations. During the next 3 weeks, he required ventilator support and daily hemodialysis or hemofiltration; became jaundiced and more deeply comatose; received fluids in amounts significantly in excess of output to maintain blood volume; was hyperglycemic despite receiving regular insulin in dosages of 3 to 5 U/hr; and remained in a hyperdynamic state. Shortly after the last operation, an ileus developed, accompanied by gross fluid retention, which further increased the patient's girth. This state of overt sepsis with hypermetabolism persisted while the wounds healed by primary closure, but no focus of infection could be found.

Antibiotic therapy was stopped for 10 days after operation; the patient's clinical status did not change. Frequent searches were made to ensure that no infection had been overlooked. Suggestions—seriously put forward—to explore the patient's abdomen because "there must be something there" were not heeded. At the end of the third week, for no obvious reason, the patient started to urinate, his ileus resolved, and he was gradually weaned from the ventilator. His level of consciousness improved, the massive edema cleared, and the high cardiac output and low peripheral resistance resolved over a period of 72 hours. He was discharged from the surgical ICU 1 day later and from the hospital in 3 weeks. Some noninfectious process that had maintained this patient's persistent septic response had disappeared or had been turned off, and the result was rapid resolution of the septic state and recovery of health.

As noted, initial control of infection, though difficult, was achieved relatively early. Subsequent therapeutic efforts involved providing hemodynamic, metabolic, and physiologic support of the patient's failing organs and organ systems while waiting for the septic response to resolve. The real problem in this case was not the infection but the patient's unremitting septic response, which was initiated by the infection but maintained in its absence.

Microbiologic Studies

As a rule, Gram stains and cultures of wound tissue, sputum, urine, and drainage effluent are useful studies. In some cases, a battery of cultures of potential sites of infection may be the only feasible approach. Culture techniques are discussed more thoroughly elsewhere [see **8:25 Blood Cultures and Infection in the Patient with the Septic Response** and **8:16 Nosocomial Infection**].

The use of polymerase chain reaction (PCR) technology to detect bacterial DNA is emerging as a useful alternative to microbiologic culture for determining the presence of infection. PCR identifies and amplifies a specific bacterial DNA sequence by means of a chemical proliferation process that may take no longer than a few hours. Unfortunately, the sensitivity and specificity of this powerful technique is highly variable. Although investigations have shown PCR to be a sensitive method of confirming the presence of bacteria in the blood of clinically septic ICU patients,¹⁴ comparison of PCR results with blood culture results is problematic in that nonviable bacteria or bacterial debris are likely to create false positive results, leaving the clinician uncertain as to whether treatment is indicated. The accuracy of PCR thus remains to be established, but the rapidity with which it yields results makes it highly promising as a potential guide to therapeutic intervention.

Radiology

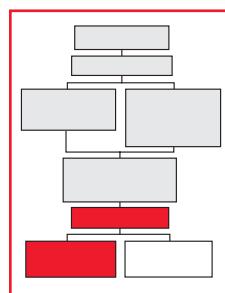

A chest x-ray is mandatory. Ultrasonographic examination of the operative site may be useful to evaluate the possibility of a deep abscess. Computed tomography of the operative site is often more useful than ultrasonography because the presence of wounds, dressings, and drainage tubes may obscure ultrasonographic findings. The possibility of acalculous cholecystitis must be kept in mind, though this is probably an overdiagnosed entity of unvalidated clinical significance.

In compromised or complex patients who have not recently undergone an operation, the medical and surgical history combined with the radiologic examination may be the only guide to the potential infectious focus (e.g., ulcer, diverticulitis, cholecystitis or cholangitis, or obstructed ureter). Percutaneous aspiration of potentially infected fluid should be considered, and this fluid should be microbiologically examined if possible.

Institution of Therapy

As noted, the response to infection occupies a continuum ranging from virtually no clinical expression in the immunosuppressed patient to full-blown septic shock. Sepsis, in its basic form, represents a mild to moderate response to infection that occurs in normally responsive patients as well as in many compromised or complex patients. On the basis of the results of clinical or laboratory tests, the clinician can evaluate the magnitude of the septic response and thus its clinical gravity.

It is therefore the magnitude of the host response, in combination with the health of the patient and the nature of the likely infecting organism, that directs the clinician's approach to therapy. The greater the degree of sepsis, the greater the clinical urgency of solving the two fundamental problems involved: resolution of the initiating process (i.e., treatment of the infection) and modulation of the response to that process (i.e., management of sepsis) [see **8:13 Multiple Organ Dysfunction Syndrome**]. The therapeutic approach to a given patient is based on the need for speed.

SIRS

As mentioned, SIRS was specifically defined in such a way as to emphasize that this common clinical syndrome frequently occurs without infection and does not routinely necessitate treatment, especially with empirical antibiotic therapy. As an illustration, simply climbing a set of stairs is often enough to enable a healthy individual to fulfill the diagnostic criteria for SIRS—albeit briefly.

The point that SIRS is not invariably associated with microbial invasion is especially relevant to critically ill and traumatized ICU patients, in whom it is not uncommon for clinical signs and symptoms indistinguishable from those of severe sepsis to arise or persist in the absence of any infection [see *Sidebar Case Study: Clinical Picture of Sepsis without Infection*]. Burn injury and pancreatitis are classic examples of conditions that can provoke such a response: both can give rise to a hyperdynamic, hypermetabolic clinical picture identical to that of sepsis or severe sepsis, even when no infection is present. Surgeons have learned not to give antibiotics unless there is evidence of infection. The instinctive reflex to do something must be held in check: “masterful inactivity” is the appropriate response until a specific source that can be controlled is identified.

UNCOMPLICATED SEPSIS

The approach to treatment of infection in both normally responsive and compromised patients with mild to moderate sepsis includes five steps: (1) resuscitation and reestablishment of homeostasis and organ function, if necessary; (2) identification of the focus of infection by clinical or radiologic examination; (3) source control, which implies removal, containment or control of the infectious focus (e.g., open drainage of an infected wound; resection of compromised bowel, as for appendicitis or advanced diverticulitis; or percutaneous drainage, as for pancreatic abscess); (4) microbiologic characterization of the offending pathogen by means of culture, Gram stain, or both; and (5) empirical or targeted treatment with antibiotics, depending on the clinical urgency.

In compromised patients, empirical antibiotic therapy is often started before diagnosis, and its efficacy gauged by the patient's subsequent clinical course [see *Discussion, below*]. In normal hosts with uncomplicated sepsis, many would consider it appropriate to withhold empirical therapy until source control has been effected and the pathogen or pathogens characterized. Adequate source control, when possible, is often all that is required for successful management of sepsis, particularly in healthy hosts. In such cases, antibiotic use for prophylaxis against complications such as SSIs is of proven benefit; however, there actually is little evidence to indicate that antibiotics are necessary to treat sepsis if mechanical source control has been definitively achieved.

Antibiotic Treatment

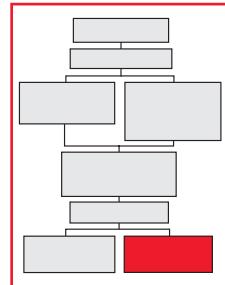

In the absence of convincing culture data, antibiotic treatment must be directed against a likely cause, as determined by recent history (particularly procedures), past history, and physical examination. Examples of likely causes are (1) urinary manipulation, which necessitates coverage against enterococci and gram-negative bacteria with ampicillin and an aminoglycoside; (2) colonic flora, which mandates wide coverage against anaerobes and aerobes; (3) infected vascular lines, which warrant coverage against gram-positive organisms; (4) cholangitis, which calls for coverage against aerobic gram-negative bacteria with ceftriaxone or an aminoglycoside; and (5) pneumonia, which necessitates coverage against gram-positive and gram-negative aerobes.

Drainage

The search for the focus of infection is important because drainage may resolve the entire problem. The clinical state can be changed dramatically by technical or mechanical management of pus behind an obstruction (e.g., in the biliary tree, the urinary tract, or the tracheobronchial tree) or pus under pressure (e.g., an abscess), by manipulation of a drain, or by removal of a foreign body (e.g., an intravascular line). Prompt elimination of all foci of infection that can be drained or are operable is critical. Needle aspiration of peritoneal or pleural fluid may be very helpful. Wounds must be reevaluated constantly and the presence of pressure sores ruled out. Drainage can often be performed either percutaneously (e.g., for pyelonephritis from ureteral obstruction or for subphrenic abscess) or endoscopically (e.g., for cholangitis). Antibiotics alone may suffice to treat small collections not accessible by means of percutaneous techniques.

SEVERE SEPSIS AND SEPTIC SHOCK

For assessment and management of severe sepsis and septic shock [see Sidebar Definitions of Key Concepts], the four steps in treatment—resuscitation, diagnosis of the infectious focus, antibiotic therapy, and drainage—must be performed concurrently. Specifically, I.V. administration of empirical antibiotics must be initiated promptly, before the diagnostic process is completed, and any potentially drainable focus must be identified via physical examination or radiologic imaging. The choice of antibiotic depends on (1) what the likely source of infection is (e.g., a lung, a perforated viscus, or the biliary tract), (2) whether the infection is hospital acquired (in which case antibiotic resistance must be considered), and (3) whether the patient has previously received antibiotic therapy.

Discussion

Approaches to Specific Infections in Complex Surgical Patients

The following infections may occur in all surgical patients. They are, however, much more difficult to identify in complex surgical patients, such as those admitted to the ICU. Because the signals of infection are less specific and extremely difficult to interpret after injury or operation, the approach to diagnosing and treating infection must be cautious and disciplined.

SURGICAL SITE INFECTION

SSIs include all infections occurring within the operative field, from the skin to the actual area of surgery [see 1.2 Prevention of Postoperative Infection].¹⁵ The patient history should address previous diseases as well as issues concerning the operation itself, such as wound risk classification, duration, difficulty, urgency, use of drains, other details of the procedure, time elapsed since the operation, and whether the patient was immunosuppressed, experienced trauma, or received chemotherapy. Physical examination should focus on the cardinal signs of infection and the absence or presence of a healing ridge.

Deeper infections tend to become apparent later in the postoperative course, often after a period in which the patient appears to be recovering, and are associated with a variety of signals, some of which can appear suddenly. The physical examination is often useless or misleading because of discomfort associated with the operation. Surgical site pain that increases or fails to resolve in the 7 to 10 days following surgery is an important yet subtle marker for occult infection that calls for investigation. Rectal examination is important because it may detect abscess formation or bleeding. Return of ileus after an abdominal operation is a significant clue to the presence of abdominal infection.

Culture is essential because use of the correct antibiotics is particularly vital in treatment of compromised or complex patients. Knowledge of the organism and its sensitivities is the key to identifying epidemic or multiresistant strains.

URINARY TRACT INFECTION

Nearly all patients admitted to the ICU have a urinary catheter in place; of these, it is estimated that about 20% progress to uri-

nary tract infection (UTI).⁸ Bacteria adhere to urinary catheter surfaces, where they promote growth of a so-called biofilm composed of microorganisms, bacterial glycocalices, Tamm-Horsfall protein, and urinary salts. Eradication of this infectious nidus is essentially impossible without catheter removal.¹⁶ The standard criterion for the diagnosis of UTI (10^5 bacteria/ml) is difficult to apply in catheterized patients because antibiotic therapy without removal of the catheter and the source of bacteriuria would be ineffective. Furthermore, it is well established that urine cultures demonstrating as few as 10^1 or 10^2 bacteria/ml increase 1,000-fold within 1 to 2 days¹⁷; effectively, therefore, any bacterial growth on a urine culture from a catheterized patient signals heavy colonization, if not infection.

More important than quantifying the degree of bacteriuria is determining whether there is any evidence of tissue invasion by urinary bacteria, which would present as pyelonephritis, cystitis, prostatitis, epididymitis, bacteremia, or sepsis. The patient history should determine whether a Foley catheter was used and for how long; how, when, and why it was inserted; instrumentation (e.g., a so-called in-and-out catheter, cystoscopy, or transurethral resection of the prostate); and whether the patient has had any previous UTIs. The physical examination should ascertain whether there is any costovertebral angle tenderness or evidence of prostatic or epididymal tenderness.

Laboratory tests should include gross and microscopic urinalysis, urine culture, and sensitivity tests. Blood culture is important because it may substantiate the diagnosis, identify the bacteria present, and determine the degree of invasiveness of the infectious process.

VASCULAR CATHETER INFECTION

The most frequent sites of infection postoperatively are I.V. catheters, particularly peripheral ones. Diagnosis of peripheral catheter infection is simple and is made on clinical grounds. Diagnosis of central venous catheter (CVC) infection is more difficult. Because hospitalized patients are increasingly being managed with monitoring or therapeutic modalities that depend on vascular access (e.g., total parenteral nutrition and dialysis), line infections have become more common, with an incidence ranging

from two to 30 infections per 1,000 CVC days.¹⁸ The combined pressures imposed by (1) the need to maintain vascular access in sicker and more complex patients and (2) the increasing predominance of gram-positive CVC infections observed since the late 1970s have led clinicians in many centers to administer empirical therapy without line removal to complex patients as a matter of course; some even advocate 10 to 21 days of vancomycin-based therapy. The problems associated with the latter approach—emerging vancomycin resistance, nephrotoxicity, and rash—are serious and relate specifically to the diagnostic strategy used to manage potential CVC infections. Distinguishing between contamination, colonization, and true infection is problematic; as a result, a number of diagnostic strategies have been advocated that are predicated more on practicality and cost-effectiveness than on microbiologic reality.

It is believed that CVC infection most commonly arises from invasion by skin microorganisms (*S. aureus* or *S. epidermidis* in about 80% of cases), which may manifest itself as exit-site purulence with or without local cellulitis, as a tunnel infection that may be clinically difficult to detect, or as catheter-related bloodstream infection (CR-BSI). Of these, CR-BSI, which complicates as many as 5% of line placements, is the most clinically important entity. It is strictly diagnosed by identification of the same microorganism (identical species and antibiogram) grown from both the catheter and a peripheral blood culture.

The catheter may be cultured in one of several ways, the most common of which is the roll-plate method [see 8:16 *Nosocomial Infection*]. Because it is theoretically possible that this technique may fail to detect bacteria harbored within the catheter lumen, some authorities advocate the more sensitive sonication method, in which the catheter segment is immersed and agitated in a medium to produce a broth that contains bacteria from both the internal and the external surfaces of the line. This technique is both more costly and more time consuming, in that it requires quantitative cultures that are deemed positive only when more than 10^3 colony-forming units are detected. More often, blood drawn through the CVC or cultured from an exit-site exudate is compared with peripheral cultures, and thus there is no need to remove the line. If quantitative cultures are done, a line blood culture showing five to 10 times more growth than the peripheral sample strongly suggests that the catheter is the source of the bacteremia. A less costly method that renders quantitative cultures unnecessary relies on the speed of bacterial growth: if growth in catheter-drawn blood is faster than that in peripherally drawn blood, a primary line infection is likely. On its own, a line blood culture is not sensitive or specific enough to be diagnostically useful.

PULMONARY INFECTION

Diagnosis and management of nosocomial pneumonia in surgical patients is addressed in detail elsewhere, The central issue is that there is no universal agreement as to how pneumonia—particularly ventilator-associated pneumonia—should be diagnosed. Of the innumerable diagnostic options, none can rely on demonstration of tissue invasion by microorganisms, as would be ideal: all are to some degree nonspecific, and any may be invoked to justify initiation of antibiotic therapy.¹⁹ Randomized trials linking mode of diagnosis to therapeutic strategy and then to outcome are yet to resolve this issue.²⁰

SINUSITIS

All patients undergoing prolonged nasogastric intubation are predisposed to sinus infection. Previous facial trauma and a history of sinusitis are potential contributing factors as well. (Otitis and pharyngitis, which are not often considered, occur in much the

same group of patients.) Because maxillary or frontal area tenderness is nonspecific in very ill surgical patients, the diagnosis is usually based on CT demonstration of sinus opacification or air-fluid levels. As a first step, sinus drainage should be reestablished by removal of an unnecessary nasogastric tube. Some authorities advocate sinus aspiration for culture before empirical antibiotic therapy is begun in urgent cases.

PAROTITIS

Parotitis is an increasingly common clinical diagnosis in elderly patients. It is usually caused by *S. aureus* and diagnosed on the basis of the presence of the classic local signs of inflammation. Culture of Stensen's duct and blood culture are useful.

PROSTATITIS

Prostatitis (diagnosed by rectal examination) and epididymitis are clinical expressions of Foley catheter-related infection. The aid of prostatic massage is important in obtaining specimens for culture. It should be remembered that a blocked Foley catheter is the most common cause of hospital anuria. This obstruction can lead to devastating purulent cystitis and upper UTI.

PSEUDOMEMBRANOUS ENTEROCOLITIS

Antibiotic-associated pseudomembranous enterocolitis is diagnosed by obtaining specimens for serology and culture and performing proctosigmoidoscopy. *Clostridium difficile* is frequently identified as the causative pathogen. Although pseudomembranous colitis is rarely clinically impressive and is easy to overlook, it can be rapidly fatal. Initial appropriate antibiotic therapy is not always successful; therefore, reevaluation at the end of the treatment course is required.

Problems with Empirical Treatment of Infection

The frequent presence of SIRS in complex or critically ill surgical patients usually prompts a reflexive response to “pan-culture” the patient if no credible source of infection is apparent. When permissive or loose diagnostic criteria for infection are invoked, the inevitable result is the commencement of empirical antibiotic therapy for suspected infection, which is often, by default, continued for days, if not weeks, pending definitive culture results or clinical improvement. This strategy may seem reasonable and is understandably difficult to resist, but it is potentially deleterious in many ways, and there are many sound objections to its reflexive use.²¹

Empirical antibiotic therapy can obfuscate future cultures, predispose to the emergence of resistant organisms (which are associated with increased attributable mortality), promote derepression of homeostasis-maintaining endogenous flora, cause toxic reactions and secondary effects, alter the ecology of the unit in which it is used (as shown by the rising prevalence of MRSA and vancomycin-resistant enterococci in both European and North American centers), and raise the cost of patient care. This widely used strategy is largely unvalidated.^{10,11} It must be emphasized that the paramount principle of therapy for infection is treatment focused on appropriate microbiologic cultures in the context of strict diagnostic criteria for infection.

Many authorities espouse streamlining of empirically begun broad-spectrum antibiotic therapy in response to microbiologic data once culture results are available; however, it is frequently difficult to discontinue antibiotics once they have been started. When strict diagnostic criteria for infection are not met or, more important, when antibiotic therapy based on nonmicrobiologic evidence of infection yields negligible results, strong consideration should be

given to stopping the antibiotics, and an exhaustive effort should be made to identify and control any occult persistent cause of the inflammatory state. Of course, this is easier said than done. Moreover, positive cultures do not automatically confirm infection, and great discretion must be exercised in determining how the microbiologic information obtained should be used. For example, tracheal aspirates from intubated patients routinely reveal gram-negative flora, but this finding in no way confirms pneumonia. A single blood culture growing *S. epidermidis* is similarly difficult to interpret.

Despite ubiquitous use in surgical patients, there is not a great deal of evidence in the clinical literature to substantiate the effectiveness of either empirical or streamlined antibiotic therapy. Further efforts must be made to find such evidence because this practice could theoretically exact a substantial cost from both the patient and the environment in which the patient is cared for. In the meantime, clinicians must approach the development of SIRS or other nonspecific signs of infection in their patients by predicated antimicrobial use on carefully formulated diagnostic criteria for the presence of infection; CDC consensus definitions of infection are a good starting point.

Source Control for Management of SIRS

In the past, because the term sepsis was loosely used to describe any general systemic inflammatory state and because such states often arose as a result of infection, it was assumed that antimicrobial therapy was generally appropriate in the management of "septic" patients. Now that sepsis has been redefined exclusively as SIRS in a patient in whom a causative source of infection has been identified, it is clear that the use of antibiotics in "septic" (i.e., SIRS) patients should be more discriminating.

In the same vein, so-called source control was developed as a strategy for managing "septic" patients. Like the term sepsis, the term source control traditionally connotes management of infection rather than, more generally, management of a cause of inflammation. Classically, source control consists of a three-pronged approach employing measures to (1) eradicate a focus of infection, (2) eliminate ongoing microbial contamination, and (3) render the local environment inhospitable to microbial growth and tissue invasion. Diligent source control has long been considered pivotal to successful management of sepsis. Although this traditional approach addresses the infectious causes of local or systemic inflammation very well in a great variety of clinical situations, good judgment must not yield to dogmatism in deciding which processes are required to control infection and inflammation. Challenging convention, a surprising number of investigators have successfully managed many supposedly surgical conditions (e.g., appendicitis²² and intra-abdominal abscess²³) without intervention or by using only prolonged antibiotic therapy. Seasoned general surgeons are well aware that if acute cholecystitis is not operated on urgently, it may certainly harm the patient or cause recurring discomfort, but

it may also resolve completely on its own. What actually constitutes adequate source control and how this can be measured are critical questions and remain the subject of debate. These questions become particularly problematic with respect to ICU patients, in whom SIRS is highly nonspecific.

It would seem rational to take our current understanding of SIRS as encompassing both infectious and noninfectious pathology and extrapolate it to the concept of source control. Indeed, as regards more complex surgical patients, it may be appropriate to broaden the definition of source control to include control of all causes of SIRS, not merely infectious ones. For example, debriding devitalized injured tissue, removing a rejected allograft, and resolving postoperative atelectasis are all important for successfully abating a systemic inflammatory state that might easily be mistaken for a manifestation of infection. Deemphasizing infection as the predominant cause of SIRS and withholding antibiotic therapy until stricter, more focused diagnostic criteria for infection are met should make treatment paradigms for managing difficult surgical patients, if not altogether more effective, at least more evaluable.

If one assumes that source control is in fact a therapeutic response to the presence of SIRS, one may then think of it as being either assisted or unassisted. The therapeutic response is initiated by the host, with either complete or partial success. Only in the latter instance should one assist the host's efforts at source control by providing antibiotics or taking surgical measures. This is by no means to suggest that one should not search diligently for a correctable cause of infection or inflammation but rather to suggest that when such an effort yields negligible results, one should consider the possibility that SIRS may be not only appropriate but desirable and may represent the patient's own adequate management of the underlying physiologic insult. Thus, in certain situations, source control may be best regarded as an endogenous or unassisted event. For instance, when fever, tachycardia, and leukocytosis are observed in a surgical patient who is coping well, antibiotics should not necessarily be given automatically. Indeed, such "default therapy" should be actively discouraged. One should also keep in mind that some forms of injury or insult (e.g., some viral infections) not only are very well managed without intervention but may not even prompt clinically evident SIRS.

The notion that no intervention may be required is understandably difficult for many surgeons to embrace at the bedside. Nonetheless, extensive ongoing research elucidating the complex dynamic of circulating proinflammatory and counterinflammatory mediators (e.g., TNF, the interleukins, and a host of other cytokines) suggests that a poorly understood but highly sophisticated biologic apparatus exists for responding to injury and insult. Indeed, it is widely hypothesized (though yet unproved) that this systemic response can be manipulated to restore health in stressed or deteriorating surgical patients. The prospect of untangling the complex biology of systemic inflammation through advances in this field is truly engaging.

15 ANTIBIOTICS

Nicolas V Christou, M.D.

Antibiotic Therapy in Surgical Patients

Several important advances in antimicrobial therapy have been made since the early 1980s. Among these advances are (1) improved understanding of the microbiologic spectrum of so-called optimal therapy, (2) better application of pharmacokinetic principles to drug administration, (3) the development of several new classes of antibiotics, and (4) greater insight into the interplay among host resistance factors, microorganisms, and chemotherapy.

General Principles of Antimicrobial Therapy

EMPIRICAL THERAPY

Even with the most rapid bacteriologic tests currently available, it may not be possible to identify a pathogen in less than 24 hours, and antimicrobial sensitivities can rarely be obtained in less than 48 to 72 hours. In seriously ill patients, treatment cannot be delayed for 2 to 3 days until these data become available. If therapy is to be successful, it must be started as soon as a life-threatening infection is diagnosed or, in some patients, as soon as such an infection is suspected. Which antimicrobial agents are to be used depends on the suspected site of infection and on the organisms that are commonly pathogenic at this site. Therapy is initiated with an agent or combination of agents whose action is broad enough to cover all the suspected microbial pathogens. The application of such broad-spectrum antibiotic therapy in the absence of microbiologic confirmation is termed empirical therapy.

To make a rational decision regarding empirical therapy, the surgeon must be familiar with the organisms that are likely to be encountered when a particular infection (e.g., an intra-abdominal abscess) is suspected. Selection of the agent or agents is based on the history, the physical examination, where the infection was likely to have been acquired, the host defense status, the overall clinical severity of the infection, and the response of the host. Definitive therapy is initiated after the host response to the infection and to the empirical treatment has been monitored and the results from the microbiology laboratory—specifically, identification of the isolated organisms and the minimal inhibitory concentrations (MICs) of various antimicrobial agents—have been assessed.

LABORATORY TESTS

Many laboratory tests, if used in the proper context, can guide selection of optimal antimicrobial therapy.

In vitro susceptibility tests are indicated when the susceptibility of an organism is not completely predictable or when certain other specific problems arise, such as the necessity of determining whether resistance has developed during the course of therapy. An organism is generally considered susceptible if the concentration of antimicrobial agent necessary to inhibit its growth is lower than that usually attainable in body fluids, particularly blood, cerebrospinal fluid, or urine.

The disk diffusion method has been standardized by the

National Committee for Clinical Laboratory Standards (NCCLS)¹ for in vitro susceptibility testing. Commercially available paper disks containing specific amounts of antimicrobial agents are placed on Mueller-Hinton agar plates that contain a standard bacterial inoculum. A zone of inhibition of bacterial growth develops around each active antibiotic after overnight incubation. The size of the zone determines the organism's susceptibility or resistance; prior studies have correlated zone sizes with MICs obtained through dilution tests. Arbitrary zone-size break points for susceptibility have been established by clinical and laboratory investigators on the basis of such additional factors as achievable serum levels, degree of protein binding, and toxicity.

The broth dilution method exposes an inoculum of bacteria to various concentrations of an antimicrobial agent during incubation. The MIC of an agent that inhibits growth can be determined, and this value can be correlated with blood, urine, or other body fluid levels of the antimicrobial agent. Moreover, those tubes that show inhibition of growth can be subcultured to an antimicrobial-free medium, and the minimal bactericidal concentration (MBC) can be determined. Unfortunately, this test is not well standardized at present, and its reproducibility is poor when it is subjected to intralaboratory and interlaboratory comparisons.²

The agar dilution method works in much the same way as the broth dilution method, except that the former employs agar plates that contain various dilutions of antimicrobial agents, and as many as 36 organisms can be efficiently inoculated on each plate by means of a replicator device. The MIC is determined by reading inhibition of colony growth on the agar surface. Agar dilution has the advantage of producing MIC data efficiently in a laboratory that performs large numbers of tests daily.

In the serum bactericidal test (SBT), samples of the serum of the treated patient are obtained and incubated with the infecting organism in doubling dilutions with broth to determine the highest dilution that is bactericidal. (Not all antimicrobial agents exhibit bactericidal activity; some exhibit only bacteriostatic activity [see Table 1].) The drawing of serum specimens can be timed to coincide with anticipated peak and trough antimicrobial levels. In effect, this test indirectly assesses both the susceptibility of the organism and the serum concentration of the antimicrobial agent, as well as the interactions between serum and organism and serum and drug. The NCCLS has developed proposed guidelines for the SBT.³ A comprehensive review of the technical and clinical considerations associated with the SBT has been published.⁴

Factors Influencing Application of Antimicrobial Therapy

ROUTE OF ADMINISTRATION

Many antibiotics are absorbed sufficiently well via the oral route to provide effective blood levels in patients with normal GI function.⁵ The enteral absorption of some antimicrobials is

impeded by food and some medications (e.g., antacids). Many antibiotics cannot be given intramuscularly because of local pain or necrosis at the injection site. Intravenous administration must be used in the treatment of major and life-threatening infections such as suppurative diffuse peritonitis. In many cases, patients are clinically stable during intravenous treatment, and it is often possible to discharge them and to administer parenteral antibiotics on an outpatient basis. Supervision by special teams of physicians, nurses, and pharmacists is required⁶; antibiotics can be administered either in the hospital outpatient department or at home if competent family members are available. New antibiotics with long half-lives can be used with improved intravenous catheters and delivery devices in simplified regimens; this leads to substantial economic benefits, enhanced patient comfort, and good therapeutic results with few complications.⁷

HOST FACTORS

Hypersensitivity to Antibiotics

Because of widespread exposure to antimicrobial agents, many patients develop allergies to them.⁸ A careful history of hypersensitivity should thus be obtained [see Hypersensitivity Reactions, below].

Concurrent Illnesses

Patients with immunosuppressive illnesses are vulnerable to opportunistic pathogens. These patients may require broader antimicrobial coverage as well as intense therapy for ordinary pathogens. The same is true to a lesser extent for patients with a chronic debilitating illness. Patients with renal insufficiency or liver disease may be unusually susceptible to direct drug toxicity.

Pregnancy

The administration of antimicrobial agents during pregnancy and in the postpartum period poses several problems. Foremost is the question of safety, both for the mother and the fetus or neonate. Although most antibiotics cross the placenta and enter maternal milk, the concentrations to which the fetus or neonate is exposed vary widely. Because the immature liver may lack the enzymes required to metabolize certain drugs, pharmacokinetics and toxicities in the fetus are often very different from those in older children and adults. Teratogenicity is a major concern when any drug is administered during pregnancy. Finally, it may be necessary to alter the dosage schedules of drugs that appear to be safe to use during pregnancy; increases in maternal blood vol-

ume, glomerular filtration rule (GFR), and hepatic metabolic activity often reduce the maternal serum levels of antimicrobials by 10% to 50%, especially late in pregnancy and in the early postpartum period. In some women, delayed gastric emptying may reduce the absorption of antibiotics that have been administered orally during pregnancy.

Even though 25% to 40% of women receive antibiotics during pregnancy, data regarding safety and efficacy in this setting are often scarce. Some general recommendations have been proposed, but they are intended only as a guide [see Table 2]; in all cases, therapy must be individualized, and both the indications for antibiotics and the possible risks to mother and fetus must be considered. Individual decisions are also required for lactating mothers; although most antimicrobials appear safe for breast-fed infants, chloramphenicol and the tetracyclines should be avoided.⁹

Advanced Age

Physiologic changes that occur with age can alter the pharmacokinetics of antimicrobial agents. For example, decreased gastric acidity and intestinal motility can impair drug absorption; increased body fat and decreased serum albumin levels can alter drug distribution; and decreased hepatic blood flow and enzymatic action can delay drug metabolism. Although these factors have not consistently affected antibiotic levels in the elderly, the decrease in GFR that occurs with age can lead to the accumulation of drugs excreted by the kidney. The high therapeutic index of the penicillins and cephalosporins obviates major changes in dosage schedules in elderly patients who have normal serum creatinine levels. However, in the case of aminoglycosides and vancomycin, decreased dosage schedules are often required; ideally, drug levels should be measured and renal function should be monitored when these agents are given. The dosage of amantadine and rimantadine should also be reduced in elderly patients.

Antibiotic Selection for Infections in Surgical Patients

The term surgical infection is difficult to define, but for the purposes of this chapter, it means infections that are related to surgical procedures or that require, in addition to antibiotic therapy, surgical debridement or control of the source of the infection. Such infections include infections of the soft tissues of the integument; muscles; bones; and body cavities (e.g., empyema, intra-abdominal infections, pyelonephritis, and infections of the retroperitoneum).

A framework for antibiotic selection for intra-abdominal infections is presented [see Table 3]; this framework can be modified for the selection of antibiotic for other types of surgical infection. A therapeutic regimen for the treatment of intra-abdominal infection should include agents that are active against *Staphylococcus aureus*, enteric gram-negative bacilli, and anaerobes, including *Bacteroides fragilis*. The regimen that has been regarded as the gold standard consists of an aminoglycoside, to cover the enteric gram-negative organisms, and clindamycin or metronidazole, to cover the anaerobes; other approaches, however, look promising.

A well-designed, controlled, prospective, randomized trial that compared imipenem therapy with acceptable aminoglycoside-based regimens supports the use of imipenem as monotherapy for intra-abdominal infections in which an enteric mixed flora is anticipated.¹⁰ When the analysis was restricted to the residual effect of treatment assignment, a significant improvement in outcome was found in the patients receiving imipenem ($P = 0.043$).

Table 1 Bactericidal and Bacteriostatic Agents¹⁵⁵

Bactericidal Agents	Bacteriostatic Agents
Aminoglycosides*	Chloramphenicol
Aztreonam	Clindamycin
Bacitracin	Erythromycin
Cephalosporins	Sulfonamides
Imipenem	Tetracyclines
Penicillins	Trimethoprim
Polymyxins [†]	
Quinolones [‡]	
Vancomycin	

*Including streptomycin, neomycin, kanamycin, gentamicin, tobramycin, amikacin, and netilmicin.

[†]Including polymyxin B and colistimethate.

[‡]Including norfloxacin and ciprofloxacin.

Table 2 Antibiotics in Pregnancy¹⁵⁵

Drug	Major Toxic Potential		Pharmacology	
	Maternal	Fetal	Maternal Serum Levels	Excreted in Mother's Milk
Considered safe				
Cephalosporins	Allergies	None known	Decreased	Trace
Erythromycin base	Allergies, GI intolerance	None known	Decreased	Yes
Penicillins	Allergies	None known	Decreased	Trace
Spectinomycin	?	None known	?	?
Use with caution				
Aminoglycosides	Ototoxicity, nephrotoxicity	Ototoxicity	Decreased	Yes
Clindamycin	Allergies, colitis	None known	Unchanged	Trace
Ethambutol	Optic neuritis	Probably safe	?	?
Isoniazid	Allergies, hepatotoxicity	Neuropathy, seizures	Unchanged	Yes
Rifampin	Hypersensitivity, hepatotoxicity	Probably safe	Unchanged	Yes
Sulfonamides (contraindicated at term)	Allergies, crystalluria	Kernicterus (at term), hemolysis (G6PD deficiency)	Unchanged	Yes
Avoid if possible				
Metronidazole	Hypersensitivity, alcohol intolerance, neuropathy	None known (teratogenic in animals)	Probably unchanged	Yes
Contraindicated				
Chloramphenicol	Blood dyscrasias	Gray syndrome	Unchanged	Yes
Erythromycin estolate	Hepatotoxicity	None known	Decreased	Yes
Nalidixic acid	GI intolerance	Increased intracranial pressure	?	?
Nitrofurantoin	Allergies, neuropathy, GI intolerance	Hemolysis (G6PD deficiency)	Decreased	Trace
Norfloxacin, ciprofloxacin, ofloxacin, lomefloxacin	GI intolerance	Arthropathies in immature animals	?	?
Tetracyclines	Hepatotoxicity, renal failure	Tooth discoloration and dysplasia, impaired bone growth	Probably unchanged	Yes
Trimethoprim	Hypersensitivity	Teratogenicity	Unchanged	Yes

Meropenem was found to be as effective as imipenem for the treatment of moderately severe intra-abdominal infections.¹¹

Ertapenem has a pharmacokinetic profile and an antimicrobial spectrum that support its use as a once-daily agent for the treatment of common mixed aerobic and anaerobic infections. A prospective, randomized, controlled, double-blind trial compared ertapenem with piperacillin-tazobactam as therapy following adequate surgical management of complicated intra-abdominal infections. The modified intent-to-treat population consisted of 633 patients, of whom 396 met all criteria for the evaluable population. Patients with a wide range of infections were enrolled. A prospective expert-panel review was conducted to assess the adequacy of surgical source control in patients in whom therapeutic failure was a component of evaluability. For the modified intent-to-treat groups, 245 of 311 patients treated with ertapenem (78.8%) were cured; 232 of 304 patients (76.3%) treated with piperacillin-tazobactam were cured. Of 203 microbiologically evaluable patients treated with ertapenem, 176 (86.7%) were cured; 157 of the 193 patients (81.3%) treated with piperacillin-tazobactam were cured. In this study, ertapenem, 1 g once a day, was equivalent to piperacillin-tazobactam, 3.375 g every 6 hours, in the treatment of a range of intra-abdominal infections. Ertapenem may be a useful option that could eliminate the need for combination therapy, multidose antibiotic regimens, or both for the empirical treatment of intra-abdominal infections.¹²

Appropriate surgical control of the source of the intra-abdominal infection is of utmost importance in determining outcome; antibiotics play a necessary but secondary role.^{13,14} The controversies regarding the pathogenicity of enterococci have been

addressed by guidelines published by members of the Surgical Infection Society.¹⁵ The third-generation cephalosporins have been proposed as candidates for single-agent therapy for infection in the abdominal cavity because their spectra of activity encompass both the aerobic gram-negative bacilli and some of the anaerobic isolates that cause infection in this region. No cephalosporin, of any generation, has been shown to have a clear advantage over an aminoglycoside-clindamycin combination in the treatment of intra-abdominal infections.

Interpretation of overall results in intra-abdominal infections is difficult because of the numerous variables involved, including the diversity of the possible infectious processes, the variable quality of the surgical technique employed, the variety of the patient characteristics observed, the possibility of one or more underlying diseases, and the differing doses of antibiotics used in individual studies.¹⁶ Most third-generation cephalosporins do not cover anaerobes well and should be used in conjunction with an antianaerobic agent, such as clindamycin or metronidazole, for empirical therapy for serious intra-abdominal infections. In a recent prospective, randomized, double-blind study, cefoxitin was found to be comparable to imipenem with regard to outcome (defined as survival); failure to cure infections was attributed to resistant organisms at the primary site in the cefoxitin arm of the trial.¹⁷

Adverse Reactions to Antimicrobial Agents

There are three general types of adverse reactions to antimicrobial agents: hypersensitivity reactions (which are not dose related), direct drug toxicity (which usually is dose related and

Third Pass 06/24/03

Table 3 Antibiotic Selection for Infections in Surgical Patients

Type of Infection	Expected Pathogen	First Choice I.V. Rx	Second Choice I.V. Rx	Switch to P.O. Choice
Brain infection (abscess, subdural empyema, intracranial suppurative thrombophlebitis)				
Traumatic brain injury	<i>Staphylococcus aureus</i> , Enterobacteriaceae, <i>Pseudomonas aeruginosa</i>	Cefepime, 2 g I.V. q. 8 hr	Meropenem, 1 g I.V. q. 8 hr	Not recommended
Postneurosurgical procedure	<i>S. aureus</i> , <i>S. epidermidis</i>	Nafcillin, 2 g I.V. q. 4 hr or Cefepime, 2 g I.V. q. 8 hr or If methicillin resistant: Linezolid, 600 mg I.V. q. 12 hr	Meropenem, 1 g I.V. q. 8 hr	Linezolid, 600 mg p.o., q. 12 hr
Vascular graft infection				
Arteriovenous graft/shunt	<i>S. aureus</i> , Enterobacteriaceae, enterococci	Vancomycin, 1 g I.V. plus Gentamicin, 240 mg I.V. and remove graft	Meropenem, 1 g I.V. q. 8 hr and remove graft	Moxifloxacin, 400 mg p.o. and remove graft
Aortic graft (treat with antibiotics until graft is replaced)	<i>S. aureus</i> , <i>S. epidermidis</i> , Enterobacteriaceae	Cefepime, 2 g I.V. q. 12 hr or Imipenem, 1 g I.V. q. 8 hr or Meropenem, 1 g I.V. q. 8 hr	Ceftizoxime, 2 g I.V. q. 8 hr or Cefotaxime, 2 g I.V. q. 6 hr	Levofloxacin, 500 mg p.o., q. 24 hr or Moxifloxacin, 400 mg p.o., q. 24 hr
Intra-abdominal infection (peritonitis, abscess)				
Gastric perforation (peptic ulcer disease)	<i>Candida</i> , oral anaerobes, <i>S. aureus</i>	Cefazolin, 1 g I.V. q. 8 hr	Ceftizoxime, 2 g I.V. q. 8 hr or Cefotaxime, 2 g I.V. q. 6 hr	Levofloxacin, 500 mg p.o., q. 24 hr or Moxifloxacin, 400 mg p.o., q. 24 hr
Gastric perforation (malignancy)	<i>S. aureus</i> , <i>S. epidermidis</i> , Enterobacteriaceae, <i>Candida</i>	Cefepime, 2 g I.V. q. 12 hr or Imipenem, 1 g I.V. q. 8 hr or Meropenem, 1 g I.V. q. 8 hr	Ceftizoxime, 2 g I.V. q. 8 hr or Cefotaxime, 2 g I.V. q. 6 hr	Levofloxacin, 500 mg p.o., q. 24 hr or Moxifloxacin, 400 mg p.o., q. 24 hr
Cholecystitis with gangrene/perforation	<i>Escherichia coli</i> , <i>Klebsiella</i> , enterococci	Piperacillin-tazobactam, 4.5 g I.V. q. 8 hr	Cefotaxime, 2 g I.V. q. 6 hr	Levofloxacin, 500 mg p.o., q. 24 hr or Moxifloxacin, 400 mg p.o., q. 24 hr
Emphysematous cholecystitis	<i>Clostridium perfringens</i>	Piperacillin-tazobactam, 4.5 g I.V. q. 8 hr	Ertapenem, 1 g I.V. q. 24 hr	Clindamycin, 300 mg p.o., q. 8 hr
Ascending cholangitis	<i>E. coli</i> , <i>Klebsiella</i> , enterococci	Imipenem, 1 g I.V. q. 8 hr or Meropenem, 1 g I.V. q. 8 hr	Cefoperazone, 2 g I.V. q. 12 hr	Levofloxacin, 500 mg p.o., q. 24 hr or Moxifloxacin, 400 mg p.o., q. 24 hr
Infected hemorrhagic/necrotizing pancreatitis	Enterobacteriaceae, <i>Bacteroides fragilis</i>	Imipenem, 1 g I.V. q. 8 hr or Meropenem, 1 g I.V. q. 8 hr or Ertapenem, 1 g I.V. q. 24 hr	Piperacillin-tazobactam, 4.5 g I.V. q. 8 hr or Ampicillin-sulbactam, 3 g I.V. q. 6 hr	Clindamycin, 300 mg p.o., q. 8 hr plus Levofloxacin, 500 mg p.o., q. 24 hr or Moxifloxacin, 400 mg p.o., q. 24 hr
Liver abscess (bacterial)	Enterobacteriaceae, <i>B. fragilis</i>	Imipenem, 1 g I.V. q. 8 hr or Meropenem, 1 g I.V. q. 8 hr or Ertapenem, 1 g I.V. q. 24 hr	Metronidazole, 1 g I.V. q. 24 hr plus Levofloxacin, 500 mg I.V. q. 24 hr or Moxifloxacin, 400 mg I.V. q. 24 hr	Metronidazole, 500 mg p.o., q. 12 hr plus Levofloxacin, 500 mg p.o., q. 24 hr or Moxifloxacin, 400 mg p.o., q. 24 hr
Liver abscess (amebiasis)	<i>Entamoeba histolytica</i>	Metronidazole, 750 mg p.o., q. 8 hr	Tinidazole, 2 g/day p.o. in three divided doses	Not applicable

Table 3 (continued)

Type of Infection	Expected Pathogen	First Choice I.V. Rx	Second Choice I.V. Rx	Switch to P.O. Choice
Intra-abdominal Infection (peritonitis, abscess) (continued)				
Distal small bowel, appendix, colon, rectum perforation in nonhospitalized patient (mild to moderate infection)	Enterobacteriaceae, enterococci, <i>B. fragilis</i>	Piperacillin-tazobactam, 4.5 g I.V. q. 8 hr or Ertapenem, 1 g I.V. q. 24 hr	Cefoxitin, 2 g I.V. q. 6 hr or Ampicillin-sulbactam, 3 g I.V. q. 6 hr	Ciprofloxacin, 250–750 mg p.o., q. 12 hr <i>plus</i> Metronidazole, 500 mg p.o., q. 12 hr
Distal small bowel, appendix, colon, rectum perforation in hospitalized patient (severe infection requiring ICU support)	Enterobacteriaceae, enterococci, <i>B. fragilis</i> , <i>P. aeruginosa</i> , <i>Acinetobacter</i>	Imipenem, 1 g I.V. q. 8 hr or Meropenem, 1 g I.V. q. 8 hr	Tobramycin, 5 mg/kg loading dose, then 3 mg/kg I.V. q. 8 hr <i>plus</i> Clindamycin, 900 mg I.V. q. 8 hr	Moxifloxacin, 400 mg p.o., q. 24 hr
Spontaneous bacterial peritonitis	Enterobacteriaceae	Ciprofloxacin, 400 mg I.V. q. 12 hr	Cefepime, 2 g I.V. q. 12 hr	Ciprofloxacin, 250–750 mg p.o., q. 12 hr <i>plus</i> Metronidazole, 500 mg p.o., q. 12 hr
Pelvic inflammatory disease (tubo-ovarian abscess, salpingitis, endometritis, infected abortion)				
Mild to moderate infection (outpatients)	Enterobacteriaceae, <i>B. fragilis</i> , <i>N. gonorrhoeae</i> , <i>Chlamydia trachomatis</i>	Moxifloxacin, 400 mg p.o., q. 24 hr	None	Ciprofloxacin, 250–750 mg p.o., q. 12 hr <i>plus</i> Doxycycline, 100 mg p.o., q. 12 hr
Severe infection (hospitalized patient)	Enterobacteriaceae, <i>B. fragilis</i> , <i>N. gonorrhoeae</i> , <i>C. trachomatis</i>	Doxycycline, 200 mg I.V. q. 12 hr <i>plus</i> Clindamycin, 600 mg I.V. q. 8 hr	Levofloxacin, 500 mg p.o., q. 24 hr <i>plus</i> Metronidazole, 1 g I.V. q. 24 hr	Moxifloxacin, 400 mg p.o., q. 24 hr

manifests in a single organ or, occasionally, in several organs), and microbial superinfection.

HYPERSensitivity REACTIONS

A history of allergies should be taken before antimicrobial therapy is initiated in any patient. More information is available regarding allergies to the penicillins than allergies to other agents, but skin eruptions, drug fever, and even anaphylaxis may be produced by many antibiotics. Allergic reactions occur in 1% to 10% of patients who receive penicillin. Fatal anaphylactic reactions are much less frequent.

DIRECT DRUG TOXICITY

Although antimicrobials can produce damage to virtually all human organ systems, the potential for toxicity varies widely from drug to drug.¹⁸ The principal antibiotics that are directly toxic to the kidney are aminoglycosides, polymyxins, and amphotericin B; azotemia and renal tubular damage may be caused by any of these drugs. Patients with preexisting renal insufficiency are at increased risk for toxic reactions to various antibiotics, including nephrotoxicity, coagulopathies and other hematologic toxicities, seizures, and ototoxicity and other neurotoxicities.

Penicillins, cephalosporins, tetracyclines, and rifampin can cause hemolytic anemia, thrombocytopenia, and leukopenia that involve an immune mechanism, but these reactions are uncommon. Macrolides and trimethoprim-sulfamethoxazole have been associated with agranulocytosis. Trimethoprim can produce anemia, leukopenia, and thrombocytopenia from folate deficiency; the effect is reversible with folic acid. Amphotericin B commonly produces a reversible normocytic normochromic anemia,

probably secondary to injury to the red cell membrane. Flucytosine causes bone marrow suppression (leukopenia or pancytopenia) when its excretion is reduced by renal failure. Linezolid can also produce myelosuppression; although experience is limited, bone marrow function usually recovers when the drug is discontinued. Neutropenia can occur during therapy with penicillins, cephalosporins, or vancomycin. It may be severe, but it is self-limited; recovery occurs 1 to 7 days after the antibiotic is withdrawn. Penicillins inhibit platelet aggregation by adenosine diphosphate, which may account for the bleeding that occurs in some patients receiving these antibiotics in high doses. Various cephalosporins may produce coagulopathies by prolonging the prothrombin time; the methylthiotetrazole side chain present in cephalosporins such as cefotetan appears to be responsible.

Antibiotics may produce a wide range of toxic effects on the central and peripheral nervous systems. Ototoxicity, either vestibular or auditory, can be produced by any of the aminoglycosides; neuromuscular blockade is much less common. Minocycline has occasionally been reported to produce significant vestibular reactions. Vancomycin can cause auditory neurotoxicity. Intravenous administration of large doses of penicillin and other β -lactams may produce seizures, especially when administered in very high doses or when given to azotemic patients or to patients with underlying epilepsy.

Metronidazole can sometimes cause ataxia, encephalopathy, seizures, or peripheral neuropathies. Ofloxacin has been reported to cause seizures; mania has been attributed to clarithromycin. Optic neuritis, usually manifested by decreased visual acuity and decreased perception of the color green, may occur as a side effect of ethambutol.

Table 4 Antimicrobial Drugs of Choice for Various Infections in Adults¹⁸

	Causative Organism	Drug of Choice	Alternative Drugs
Gram-Positive Cocci	<i>Staphylococcus aureus</i> Methicillin-sensitive Methicillin-resistant ¹	Vancomycin, ² with or without rifampin or gentamicin Penicillinase-resistant penicillin ⁵	Linezolid; quinupristin-dalfopristin Trimethoprim-sulfamethoxazole (TMP-SMX), ² with or without rifampin ² ; a fluoroquinolone ³ ; a tetracycline ⁴ A cephalosporin, ⁶ clindamycin, vancomycin, ⁷ meropenem or imipenem, ⁸ ticarcillin-clavulanic acid, ampicillin-sulbactam, amoxicillin-clavulanic acid, piperacillin-tazobactam, a fluoroquinolone ³
	Coagulase-negative staphylococci ⁹	Vancomycin, ⁷ with or without rifampin ² or gentamicin	Linezolid, quinupristin-dalfopristin, a cephalosporin, a penicillinase-resistant penicillin, meropenem or imipenem, ⁸ a fluoroquinolone ³
	Anaerobic streptococcus (<i>Peptostreptococcus</i>)	Penicillin G ¹⁰	Clindamycin, a cephalosporin, ⁶ vancomycin ⁷
	<i>Streptococcus bovis</i>	Penicillin G ^{10,11}	A cephalosporin, ⁶ vancomycin ⁷
	Groups A, G, and C streptococci	Penicillin G ^{10,12} or penicillin V	A cephalosporin, ⁶ vancomycin, ⁷ an erythromycin, ¹³ clindamycin, clarithromycin, azithromycin
	Group B streptococcus	Penicillin G ^{10,12} or ampicillin	A cephalosporin, ⁶ vancomycin, ⁷ an erythromycin
	<i>S. pneumoniae</i> (pneumococcus)	Penicillin G ^{10,12} or penicillin V, amoxicillin	An erythromycin, ^{12,13} a cephalosporin, ⁶ meropenem or imipenem, ⁸ vancomycin, ^{7,12} azithromycin, clarithromycin, a fluoroquinolone; a tetracycline ⁴
	Penicillin sensitive		—
	Non-penicillin sensitive	Vancomycin; ceftriaxone or cefotaxime ⁶ ; levofloxacin, moxifloxacin, or gatifloxacin ³ ; linezolid; quinupristin-dalfopristin; imipenem or meropenem	
Gram-Positive Bacilli	Viridans streptococcus	Penicillin G, ^{10,11} with or without gentamicin	A cephalosporin, ⁶ vancomycin ⁷
	Enterococcus	Penicillin or ampicillin, plus gentamicin ¹⁴ or streptomycin	Vancomycin, ⁷ with gentamicin or streptomycin; linezolid; quinupristin-dalfopristin
	Endocarditis or other serious infection	Ampicillin or amoxicillin	A fluoroquinolone, ³ nitrofurantoin, ¹⁵ fosfomycin
	Uncomplicated urinary tract infection		
	<i>Bacillus cereus</i> , <i>B. subtilis</i>	Vancomycin	Meropenem or imipenem, ⁸ clindamycin
	<i>Bacillus anthracis</i>	Penicillin G	Ciprofloxacin, ³ a tetracycline, ⁴ an erythromycin ²
	<i>Clostridium difficile</i>	Metronidazole ¹⁶	Vancomycin ¹⁶
Gram-Negative Cocci	<i>C. perfringens</i>	Penicillin G; clindamycin	Metronidazole, meropenem or imipenem, ⁸ chloramphenicol ⁷
	<i>C. tetani</i>	Metronidazole	Penicillin G, a tetracycline ⁴
	<i>Corynebacterium diphtheriae</i>	An erythromycin	Penicillin G
	<i>Corynebacterium</i> , JK group	Vancomycin	Penicillin G, with gentamicin; an erythromycin
	<i>Listeria monocytogenes</i>	Ampicillin, with or without gentamicin	TMP-SMX
Enteric Gram-Negative Bacilli	<i>Propionibacterium</i>	Penicillin G	Clindamycin, an erythromycin
	<i>Moraxella</i> (formerly <i>Branhamella</i>) <i>cataarrhalis</i>	Cefuroxime, ⁶ a fluoroquinolone ³	TMP-SMX, amoxicillin-clavulanic acid, an erythromycin, a tetracycline, third-generation cephalosporins, clarithromycin, azithromycin
	<i>Neisseria gonorrhoeae</i> ¹⁷	Ceftriaxone or cefixime, ⁶ ciprofloxacin, ofloxacin, or gatifloxacin ³	Cefotaxime, ¹⁰ penicillin or ampicillin
	<i>N. meningitidis</i>	Penicillin G	A third-generation cephalosporin, ⁶ TMP-SMX, a fluoroquinolone, ³ chloramphenicol ⁷
Enteric Gram-Negative Bacilli	Meningitis, bacteremia	Rifampin	Minocycline, ciprofloxacin
	Carrier state		
	<i>Bacteroides</i>	Metronidazole or clindamycin	Cefoxitin, cefotetan, ceftizoxime, or cefmetazole; chloramphenicol ¹⁸ ; imipenem or meropenem ⁸ ; ticarcillin-clavulanic acid; ampicillin-sulbactam, piperacillin-tazobactam
	GI tract strains (<i>B. fragilis</i>)		Metronidazole, cefoxitin, ⁶ cefotetan, ceftizoxime, cefmetazole, chloramphenicol ⁷
	Respiratory tract strains	Penicillin G or clindamycin	Gentamicin
	<i>Campylobacter fetus</i>	Imipenem or meropenem ⁸	A fluoroquinolone, ³ a tetracycline, ⁴ gentamicin ⁷
	<i>C. jejuni</i>	Azithromycin or an erythromycin	A fluoroquinolone, ³ amikacin; TMP-SMX; a tetracycline ⁴ ; a third-generation cephalosporin ⁶
	<i>Citrobacter</i>	Imipenem or meropenem ⁸	A third-generation cephalosporin ⁶ ; for serious infections, use with a fluoroquinolone ³ or gentamicin; gentamicin, tobramycin, amikacin, a fluoroquinolone, ³ a carboxypenicillin or acylaminopenicillin, ¹⁹ aztreonam ²⁰
	<i>Enterobacter</i>	Imipenem or meropenem ⁸	Gentamicin, ²¹ tobramycin, amikacin, imipenem or meropenem, ⁸ aztreonam ²⁰
	<i>Escherichia coli</i>	Ampicillin, a cephalosporin, ⁶ a fluoroquinolone, ³ TMP-SMX ²²

Table 4 (continued)

	Causative Organism	Drug of Choice	Alternative Drugs
Enteric Gram-Negative Bacilli (continued)	<i>Helicobacter pylori</i>	Tetracycline with metronidazole and bismuth subsalicylate or omeprazole with amoxicillin and clarithromycin	Amoxicillin with metronidazole and bismuth subsalicylate; tetracycline with clarithromycin and bismuth subsalicylate; clarithromycin with omeprazole; amoxicillin with clarithromycin
	<i>Klebsiella</i>	A cephalosporin ⁶	Imipenem or meropenem, ⁹ gentamicin, ²³ tobramycin, amikacin, TMP-SMX, ²¹ a carboxypenicillin or acylaminopenicillin, ²¹ amoxicillin-clavulanic acid, ampicillin-sulbactam, ticarcillin-clavulanic acid, piperacillin-tazobactam, aztreonam, ²⁰ a fluoroquinolone ³
	<i>Proteus mirabilis</i>	Ampicillin	A cephalosporin, gentamicin or tobramycin, chloramphenicol, ⁷ a carboxypenicillin or acylaminopenicillin, ¹⁹ imipenem or meropenem, ⁸ TMP-SMX, aztreonam, ²⁰ a fluoroquinolone ³
	non- <i>mirabilis</i> , including <i>P. vulgaris</i> , <i>Morganella morganii</i> , and <i>Providencia rettgeri</i>	A third-generation cephalosporin ⁶	Gentamicin, tobramycin, amikacin, a carboxypenicillin or acylaminopenicillin, ¹⁹ imipenem or meropenem, ⁸ aztreonam, ²⁰ ampicillin-sulbactam, ticarcillin-clavulanic acid, piperacillin-tazobactam, amoxicillin-clavulanic acid, a fluoroquinolone ³
	<i>Providencia stuartii</i>	A third-generation cephalosporin ⁶	An aminoglycoside, TMP-SMX, ²¹ imipenem or meropenem, ⁸ aztreonam, ²⁰ a carboxypenicillin or acylaminopenicillin, ¹⁹ a fluoroquinolone ³
	<i>Salmonella typhi</i> Other <i>Salmonella</i> species	Ceftriaxone or a fluoroquinolone ³ Ceftriaxone or cefotaxime or a fluoroquinolone ³	Chloramphenicol or ampicillin, ²² TMP-SMX Ampicillin or amoxicillin, TMP-SMX, chloramphenicol ⁷
	<i>Serratia</i>	Imipenem or meropenem	A third-generation cephalosporin, ⁶ gentamicin or amikacin, a carboxypenicillin or acylaminopenicillin, ¹⁹ chloramphenicol, ⁷ aztreonam, a fluoroquinolone ³
	<i>Shigella</i>	A fluoroquinolone ³	TMP-SMX, ampicillin, ceftriaxone, azithromycin
Other Gram-Negative Bacilli	<i>Acinetobacter (Herellea)</i>	Imipenem or meropenem ⁸	Tobramycin, gentamicin, amikacin, doxycycline, minocycline, a carboxypenicillin or acylaminopenicillin, ¹⁹ TMP-SMX, a fluoroquinolone, ³ ceftazidime
	<i>Aeromonas hydrophilia</i>	TMP-SMX ²	A fluoroquinolone, ³ gentamicin, tobramycin, imipenem or meropenem ⁸
	<i>Bartonella henselae</i> (cat-scratch disease)	Azithromycin	Ciprofloxacin, ³ TMP-SMX, gentamicin; rifampin, erythromycin
	<i>Bartonella henselae</i> (bacillary angiomatosis)	Erythromycin	Doxycycline, azithromycin
	<i>Bordetella pertussis</i> (whooping cough)	Erythromycin	TMP-SMX; azithromycin or clarithromycin
	<i>Brucella</i>	A tetracycline, with rifampin	A tetracycline with gentamicin or streptomycin; chloramphenicol, ⁷ with or without streptomycin; TMP-SMX ² with or without gentamicin; ciprofloxacin ³ with rifampin
	<i>Eikenella corrodens</i>	Ampicillin	An erythromycin, a tetracycline, ⁴ amoxicillin-clavulanic acid, ampicillin-sulbactam, ceftriaxone
	<i>Francisella tularensis</i> (tularemia)	Streptomycin	Gentamicin, a tetracycline, ⁴ chloramphenicol, ⁷ ciprofloxacin ³
	<i>Fusobacterium</i>	Penicillin	Clindamycin, metronidazole, chloramphenicol ⁷ ; cefoxitin
	<i>Gardnerella</i> (formerly <i>Haemophilus</i>) <i>vaginalis</i>	Metronidazole ² (oral)	Intravaginal metronidazole, intravaginal or oral clindamycin
	<i>Haemophilus influenzae</i> Bronchitis, otitis media	TMP-SMX	Ampicillin or amoxicillin; a tetracycline ⁴ ; amoxicillin-clavulanic acid, cefuroxime axetil, ceftizoxime, clarithromycin, azithromycin, a fluoroquinolone ³
	Meningitis, epiglottitis, life-threatening infections	Cefotaxime or ceftriaxone	Chloramphenicol, ²⁴ meropenem ⁹
	<i>Legionella</i> species	Azithromycin or a fluoroquinolone ³	Erythromycin, rifampin, ²⁵ TMP-SMX, ² doxycycline ⁴
	<i>Pasteurella multocida</i>	Penicillin G	A tetracycline, ⁴ a cephalosporin, ⁶ amoxicillin-clavulanic acid, ampicillin-sulbactam
	<i>Calymmatobacterium granulomatis</i> (granuloma inguinale)	TMP-SMX	A tetracycline ⁴ ; ciprofloxacin with or without rifampin
	<i>H. ducreyi</i> (chancroid)	Ceftriaxone or azithromycin	A fluoroquinolone ³
	<i>Pseudomonas aeruginosa</i> Urinary tract infections	Ciprofloxacin ³	Levofloxacin; gentamicin or tobramycin; amikacin; ceftazidime, ⁶ with or without gentamicin or tobramycin; imipenem or meropenem ⁸ ; aztreonam, ²⁰ a carboxypenicillin or acylaminopenicillin ¹⁹
	Other infections	Gentamicin or tobramycin, with or without a carboxypenicillin or acylaminopenicillin ¹⁹ ; ceftazidime or ceftipime; imipenem or meropenem ⁸ ; aztreonam, ²⁰ alone or with gentamicin or tobramycin	Amikacin, with or without a carboxypenicillin or acylaminopenicillin ¹⁹ ; ciprofloxacin ⁷
	<i>P. cepacia</i>	TMP-SMX	Chloramphenicol, ⁷ ceftazidime, ² imipenem ^{2,8} or meropenem ⁸
	<i>Streptobacillus moniliformis</i> (rat-bite fever)	Penicillin G	A tetracycline, ⁴ streptomycin

Note: all superscript numbers refer to footnotes that follow table.

Table 4 (continued)

	Causative Organism	Drug of Choice	Alternative Drugs
Other Gram-Negative Bacilli (continued)	<i>Vibrio cholerae</i>	A tetracycline ⁴	TMP-SMX, a fluoroquinolone ³
	<i>V. vulnificus</i>	A tetracycline ⁴	Cefotaxime
	Agents of Vincent stomatitis (trench mouth)	Penicillin G	A tetracycline, ⁴ an erythromycin
	<i>Stenotrophomonas</i> (formerly <i>Xanthomonas</i>) <i> maltophilia</i>	TMP-SMX	Minocycline, ceftazidime, ⁶ a fluoroquinolone ³
	<i>Yersinia enterocolitica</i>	TMP-SMX ²	A fluoroquinolone, gentamicin, ² tobramycin, ² amikacin, cefotaxime ^{2,6} or ceftizoxime ^{2,6}
Acid-Fast Bacilli	<i>Y. pestis</i> (plague)	Streptomycin with or without a tetracycline	A tetracycline, ⁴ chloramphenicol, ⁷ gentamicin, ² TMP-SMX
	<i>Mycobacterium avium</i> complex	Clarithromycin or azithromycin plus one or more of the following: ethambutol, rifabutin, ciprofloxacin	Rifampin, amikacin
	<i>M. fortuitum</i>	Amikacin ² with clarithromycin	Rifampin, ² cefotixin, a sulfonamide, doxycycline, ethambutol, linezolid
	<i>M. kansasi</i>	Isoniazid with rifampin, with or without ethambutol or streptomycin	Cycloserine, ethionamide, clarithromycin
	<i>M. leprae</i>	Dapsone ⁷ with rifampin, with or without clofazimine	Minocycline, ⁴ ofloxacin or sparfloxacin, ³ clarithromycin
	<i>M. marinum</i> (<i>balnei</i>) ²⁶ <i>M. tuberculosis</i> ²⁷	Minocycline Isoniazid with rifampin, and pyrazinamide with or without ethambutol or streptomycin	TMP-SMX, rifampin, clarithromycin, doxycycline Ciprofloxacin or ofloxacin; third-line agent
Actino-mycetes	<i>Actinomyces israelii</i>	Penicillin G	A tetracycline ⁴ ; an erythromycin; clindamycin
	<i>Nocardia</i>	TMP-SMX	Minocycline, sulfisoxazole, imipenem or meropenem, ⁸ amikacin, ² cycloserine, linezolid
Chlamydia	<i>Chlamydia psittaci</i> (psittacosis) <i>C. trachomatis</i>	A tetracycline ⁴	Chloramphenicol ⁷
	Inclusion conjunctivitis	An erythromycin (oral or I.V.)	A sulfonamide (topical plus oral)
	Lymphogranuloma venereum	A tetracycline ⁴	An erythromycin
	Pneumonia	An erythromycin	A sulfonamide
	Trachoma	Azithromycin	A tetracycline ⁴ (topical plus oral), a sulfonamide (topical plus oral)
	Urethritis or pelvic inflammatory disease	Doxycycline or azithromycin	Erythromycin, ofloxacin, amoxicillin
Mycoplasma	<i>C. pneumoniae</i>	An erythromycin or clarithromycin or azithromycin; a fluoroquinolone	A tetracycline
	<i>Mycoplasma pneumoniae</i>	An erythromycin, clarithromycin or azithromycin; a fluoroquinolone, ³ doxycycline ⁴	—
	<i>Ureaplasma urealyticum</i>	An erythromycin	A tetracycline, ⁴ clarithromycin, or azithromycin; ofloxacin ³
Rickettsia	Various rickettsial organisms Rocky Mountain spotted fever, epidemic and endemic (murine) typhus, rickettsial pox, Q fever, scrub typhus	Doxycycline ⁴	Chloramphenicol, ⁷ a fluoroquinolone, ³ rifampin
Spirochetes	<i>Borrelia burgdorferi</i> (Lyme disease) <i>B. recurrentis</i> (relapsing fever)	Doxycycline or amoxicillin or ceftriaxone	Penicillin, an erythromycin, clarithromycin, azithromycin, cefuroxime
	<i>Leptospira</i>	A tetracycline ⁴	Penicillin G
	<i>Treponema pallidum</i>	Penicillin G	A tetracycline, ⁴ an erythromycin
		Penicillin G	A tetracycline, ⁴ an erythromycin, ceftriaxone

1. Some strains of *S. aureus* and most strains of coagulase-negative staphylococci are resistant to penicillinase-resistant penicillins; these strains are also resistant to cephalosporins.

2. Not approved for this indication by the FDA.

3. None of these drugs is recommended for children. In 1999, the FDA limited trovafloxacin to inpatient use for limb- or life-threatening infections.

4. Doxycycline is the safest tetracycline for treatment of extrarenal infections in renal insufficiency. Tetracyclines should be avoided in pregnant women and in children younger than 8 yr.

5. For severe infections, I.V. nafcillin or oxacillin should be used. For mild infections, oral cloxacillin, dicloxacillin, or oxacillin may be employed. Between 1% and 2% of *S. aureus* strains are resistant to penicillinase-resistant penicillins (and usually to cephalosporins) but are susceptible to vancomycin. High doses of penicillin G, ampicillin, amoxicillin, carbenicillin, or ticarcillin do not overcome the clinical resistance of penicillinase-producing staphylococci to these drugs.

6. Cephalosporins are sometimes used as alternatives to penicillin in patients with sus-

pected penicillin allergy but not in patients with serious hypersensitivity (especially immediate anaphylactic or accelerated urticarial reactions). Patients allergic to penicillin may be hypersensitive to cephalosporins. Only third-generation cephalosporins are effective in bacterial meningitis.

7. In view of the occurrence of adverse reactions, this drug should be used only for serious infections and when less toxic drugs are ineffective.

8. Imipenem and meropenem are β -lactam antibiotics that should be used with caution in patients who are allergic to penicillins and cephalosporins.

9. In vitro sensitivity testing with cephalosporins or penicillins may be misleading because of heteroresistance and because these antibiotics may be bacteriostatic only. For serious infections, vancomycin is preferred (see text).

10. Crystalline penicillin G is administered parenterally for serious infections. For less severe infections caused by pneumococci, group A streptococci, gonococci, or *T. pallidum*, procaine penicillin is administered I.M. once or twice daily. For mild infections caused by streptococci and pneumococci, oral penicillin V is preferable to oral penicillin G. Benzathine penicillin G is given I.M. (once monthly) for the prophylaxis of rheumatic fever,

Table 4 (continued)

a single injection for the treatment of group A streptococcal pharyngitis) when patients' compliance for oral medication is questionable and for treatment of syphilis, in one to three doses at weekly intervals, depending on the stage of the disease.

11. The combination of penicillin G with streptomycin for the first 2 wk of treatment of endocarditis caused by viridans streptococci is preferred by some.
12. In patients with major allergy to penicillin, erythromycin is the alternative for respiratory tract infections; chloramphenicol is the preferred alternative for meningitis. Occasional strains of pneumococci have high-level resistance to penicillin and to most other antibiotics except vancomycin.
13. Some strains of pneumococci and group A streptococci are erythromycin resistant.
14. Various aminoglycosides have been used in synergistic combination with penicillin or vancomycin. Because of the appearance of enterococcal strains resistant to the synergistic action with streptomycin (but not gentamicin), gentamicin is preferred for use in the combination.
15. Contraindicated in pregnancy or in the presence of renal insufficiency.
16. Antibiotics may be administered orally for antibiotic-associated pseudomembranous enterocolitis. Vancomycin and metronidazole are equally effective but metronidazole is much less expensive.
17. Large doses of penicillin G or ampicillin (or amoxicillin) may be required because some strains are resistant to these drugs. Penicillinase-producing gonococci, which are more resistant to penicillin, have appeared in the United States; spectinomycin is the treatment of choice for infections with such strains.

Trovafloxacin was restricted for use in seriously ill patients because of hepatotoxicity, but other fluoroquinolones have not been implicated. The tetracyclines can occasionally cause fatty liver; hepatotoxicity is most likely to occur in patients receiving 2 g or more daily by the intravenous route. Patients receiving high-dose β -lactam antibiotics may develop hepatitis or cholestasis, presumably as a result of hypersensitivity reactions. Nitrofurantoin may cause chronic active hepatitis in some patients. Erythromycins and sulfonamides have been associated with acute hepatitis, and a case of fatal hepatic necrosis has been attributed to fluconazole.

GI reactions to antibiotics result either from direct irritation by the drug, the occurrence of which is usually dose related, or from bacterial overgrowth.¹⁹ Irritative GI side effects are usually produced when antibiotics are administered orally rather than parenterally. The predominant site of irritation varies from drug to drug; for example, erythromycin more commonly produces gastric irritation with epigastric distress and nausea, whereas tetracyclines may produce diarrhea as well as upper GI symptoms. Some qualitative and quantitative changes in the intestinal flora occur after antibiotic administration; they may contribute to flatulence and other lower GI symptoms, which are quite common when broad-spectrum antibiotics are administered orally. Selective overgrowth of *Clostridium difficile* can result in antibiotic-induced pseudomembranous enterocolitis.²⁰

Antibiotics may cause various other toxicities. Erythromycin and other macrolides can cause prolongation of the QT interval and polymorphic ventricular tachycardia; in rare instances, this toxicity occurs in the absence of predisposing factors, but it is more likely to occur in patients with significant heart disease and in patients taking terfenadine, astemizole, or cisapride. Several fluoroquinolones, such as moxifloxacin, gatifloxacin, and sparfloxacin, can have similar effects on cardiac conduction.^{21,22} All fluoroquinolones can cause tendinitis. Trimethoprim-sulfamethoxazole can cause hyperkalemia, particularly in azotemic patients. Sulfonamides, fluoroquinolones, and tetracyclines can produce photosensitivity.²³

MICROBIAL SUPERINFECTION

Antimicrobial therapy reduces susceptible organisms from the normal flora of the skin, oral and genitourinary mucosae, and GI tract and exerts selective pressures that favor survival of drug-resistant organisms. Such resistant organisms can occasionally establish a superinfection, either at the site of the original infection or at remote sites.

18. In CNS infection, metronidazole or chloramphenicol should be used.
19. The carboxypenicillins are carbenicillin and ticarcillin; the acylaminopenicillins are mezlocillin, azlocillin, and piperacillin. When one of these drugs is used for a severe infection, an aminoglycoside is often recommended as well.
20. Aztreonam is a β -lactam antibiotic; cross-sensitivity has not occurred, but use with caution in patients allergic to penicillins, cephalosporins, or imipenem.
21. Principally in treatment of uncomplicated urinary tract infections.
22. Ampicillin or amoxicillin may be effective in milder cases.
23. In severely ill patients, an aminoglycoside is combined with a cephalosporin.
24. Some encapsulated *H. influenzae* (type b) strains and some unencapsulated strains are resistant to ampicillin, and rare strains are resistant to chloramphenicol. Chloramphenicol plus ampicillin (or chloramphenicol alone) should be used for initial treatment of meningitis or epiglottitis in children until the organism is identified and its susceptibility is determined. For adults with meningitis of unknown etiology and an indeterminate Gram stain and in whom *H. influenzae* is suspected, chloramphenicol is added to ampicillin (or penicillin G) for the first 24 hr until the results of culture are available. Ampicillin is preferred when the infecting strain of *H. influenzae* is susceptible.
25. Not an FDA-approved use. Evidence for possible efficacy comes only from in vitro susceptibility testing and from treatment of infections in experimental animals. In both cases, *L. pneumophila* is highly susceptible to rifampin.
26. Most infections are self-limited without therapy.
27. Various combination treatments are available.

Public Health Considerations

ANTIMICROBIAL RESISTANCE

The extensive use of antimicrobial agents, especially in ICUs²⁴ and other health care facilities, strongly favors the selection of resistant microbial species, particularly bacterial strains harboring plasmids that confer transmissible resistance.^{25,26} Although antibiotics have played a major role in the treatment of such infections, the pathogens have responded to the antibiotic challenge, developing resistance to all available antimicrobial agents to a greater or lesser degree. Specific mechanisms of resistance are evident in the reduced permeability of cell wall membranes, changes in the target sites of antimicrobial agents, enzymatic inactivation of antibiotics, and the development of pathways bypassing antimicrobial targets.²⁷

The widespread use of antibiotics for animals compounds the problem; about 50% of the 25,000 tons of antibiotics that are sold annually in the United States are used in agriculture and aquaculture.²⁸ Infections from highly resistant strains of *Enterococcus*, *Pneumococcus*, *Staphylococcus aureus*, *Gonococcus*, *Salmonella*, *Serratia*, *Klebsiella*, *Acinetobacter*, *Enterobacter*, and *Mycobacterium* have become important problems. Infections from resistant strains can spread rapidly, first within an institution, then throughout a community, and eventually even globally.²⁹ Although antibiotic resistance is a worldwide problem, control depends on local measures, beginning with the judicious prescription of antibiotics by individual practitioners³⁰ and with formulary restrictions that reinforce prudence.³¹ Patients harboring resistant strains should be identified rapidly, treated appropriately, and isolated as needed to prevent the spread of infection.

The incidence of suprainfection with cephalosporin therapy is actually quite low (< 5%); however, the organisms encountered are often more virulent and difficult to eradicate than the original infecting pathogen.³² Commonly seen suprainfecting pathogens include *Enterobacter* species, *Pseudomonas aeruginosa*, *S. aureus*, *Acinetobacter* species, enterococci, and *Candida* species. Because these organisms are generally multiresistant, therapy with antibiotic combinations, including aminoglycosides, is usually necessary. There appear to be no significant differences among the cephalosporins with respect to the incidence of suprainfection or the types of suprainfecting pathogens found.

The most worrisome resistance is that of vancomycin-resistant enterococci (VRE). Risk factors for bloodstream infection with VRE are an increasing APACHE II (Acute Physiology and

Table 5 Antimicrobial Drug Dosages for Treatment of Bacterial Infections in Adults with Normal Renal Function¹⁵⁵

Class of Agent	Specific Agent	Trade Names	Modest Infections*			
			Oral		Intramuscular	
			Daily Dose	Interval	Daily Dose	Interval
Penicillinase-susceptible penicillins	Penicillin G	Pentids, Crystifor, Pfizerpen, etc.	0.8–3.2 million units	6 hr	1.2 million units	8 hr

Note: all superscript numbers refer to footnotes following table.

*Infections of the upper respiratory tract, soft tissues, etc.

¹Osteomyelitis, peritonitis, bacteraemia, meningitis, endocarditis, etc.

1. Benzathine penicillin G is used primarily in three circumstances. (1) Treatment of streptococcal pharyngitis in cases in which patient compliance is questionable (a single dose of 1.2 million units I.M.). (2) Prophylaxis of rheumatic fever recurrences (1.2–2.4 million units I.M. once monthly). (3) Treatment of syphilis: for primary, secondary, or early (< 1 yr) latent syphilis, a single dose of 2.4 million units I.M.; for late syphilis (late latent, cardiovascular, neurosyphilis, etc.), 2.4 million units I.M. weekly for three doses has been recommended, but many authorities now treat neurosyphilis with high-dose I.V. penicillin.

2. Each tablet of carbencillin indanyl sodium is equivalent to 382 mg of carbenicillin (usual dosage is one to two tablets p.o., q.i.d.).

3. Piperacillin is most often used in the treatment of serious infections caused by susceptible *Pseudomonas*, *Klebsiella*, *Enterobacter*, and non-*mirabilis* *Proteus* strains; the agent is given in maximal dosage (12–18 g I.V. daily). It is commonly used in synergistic combination with tobramycin or gentamicin for treatment of *Pseudomonas* infections. Occasionally, it is given in smaller dosages (1.0–1.5 g I.M. or I.V. q. 6 hr) to treat an uncomplicated urinary tract infection caused by the same organisms.

4. Ticarcillin, piperacillin, mezlocillin, and azlocillin are usually used in the treatment of serious infections caused by susceptible *Pseudomonas*, *Enterobacter*, and non-*mirabilis* *Proteus* strains and are given in maximal dosage (12–24 g I.V. daily). One of these agents is commonly used in synergistic combination with tobramycin or gentamicin for treatment of *Pseudomonas* infections. Occasionally, they are given in smaller dosages (1 g I.M. or I.V. q. 6 hr) to treat an uncomplicated urinary tract infection caused by the same organisms.

5. Naftcilin is not reliably absorbed by the oral route.

6. Cefazolin may be used in the treatment of acute uncomplicated urinary tract infections caused by susceptible gram-negative bacilli (*E. coli*, *P. mirabilis*, and *Klebsiella*). It is administered I.M. in a dosage of 2 g daily (given as aliquots q. 8 hr).

7. Although the second- and third-generation cephalosporins can be used for milder infections at the lower end of their recommended dosage range, these potent but expensive agents should generally be reserved for treatment of serious infections or for the treatment of resistant organisms when the alternative is a more toxic antimicrobial drug.

8. The I.M. route is acceptable for milder illnesses, but the I.V. route is recommended for serious infections, including bacteremias and meningitis. The range for the I.M. dosage is the same as that for the I.V. dosage.

9. Dosage must be reduced in the presence of renal insufficiency. The daily parenteral dose should not exceed 15 mg/kg, and the total daily amount administered should not exceed 1.5 g, regardless of the patient's weight.

10. The I.V. dose should be infused during a period of 30–60 min q. 8 hr.

11. For urinary tract infections caused by resistant organisms.

12. Dosage must be reduced in the presence of renal insufficiency. The I.V. dose should be administered for a period of 30–60 min q. 8 hr. In patients with meningitis caused by susceptible gram-negative bacilli, intrathecal gentamicin (5 mg for adults, 1–2 mg for infants) is often administered once daily along with parenteral gentamicin until CSF cultures are negative.

13. Dosage must be reduced in the presence of renal insufficiency. The daily parenteral dose should not exceed 15 mg/kg (daily dose should not exceed 1.5 g, regardless of the patient's weight); the total quantity administered in a therapeutic course should not exceed 15 g.

14. The I.V. route should be employed only when I.M. administration is not possible. The I.V.

dose should be administered during a period of at least 60 min q. 8 hr.

15. There are no clinical indications for the parenteral administration of neomycin in view of its marked toxicity and the availability of safer alternative drugs. The drug is given p.o. or by nasogastric tube (4–6 g daily in 4 divided doses) to reduce the number of ammonia-forming bacteria in the intestine in the short-term treatment of acute hepatic coma. It is also given in a total daily dose of 2–3 g in long-term therapy for chronic hepatic encephalopathy or episodic hepatic coma. Nephrotoxicity and ototoxicity have followed prolonged high-dose therapy in hepatic coma, particularly in patients with some renal impairment. Neomycin is also used along with vigorous mechanical cleansing of the large bowel as preoperative prophylaxis for bowel surgery. In this situation, it is administered for 1–3 days preoperatively (40 mg/kg p.o. daily in 6 divided doses).

16. Dosage must be reduced in the presence of renal insufficiency. The I.V. dose should be administered during a period of 30–60 min q. 8 hr.

17. Usually administered as 100 mg p.o. q. 12 hr on the first day of treatment, followed by 50 mg q. 12 hr. For more difficult infections, the dosage may be continued at 100 mg q. 12 hr.

18. Usually administered as 100 mg I.V. q. 12 hr on the first day of treatment. Thereafter, it may be given as 50–100 mg I.V. q. 12 hr. Each I.V. dose should be given during a period of 1–4 hr.

19. Usually administered initially as 200 mg p.o., followed by 100 mg q. 12 hr.

20. Usually given initially as 200 mg I.V., followed by 100 mg q. 12 hr. Maximum dose in any 24-hr period is 400 mg.

21. I.M. administration is generally unsatisfactory because of poor absorption and local irritation.

22. In special circumstances, it may be given in higher doses but not in excess of 500 mg q. 6 hr.

23. Cholestatic hepatitis may develop as a hypersensitivity response to erythromycin estolate but not to the other erythromycin preparations. For this reason, erythromycin base or erythromycin stearate is preferable.

24. A loading dose of one half the daily dose is given initially. In severe infections, the dosage of sulfonamide is adjusted to provide a blood level of 10–15 mg/dl. Sulfonamides must be used with caution in patients with renal insufficiency. Sulfoxazole is the preferred sulfonamide.

25. Each tablet contains 80 mg trimethoprim and 400 mg sulfamethoxazole. Double-strength tablets are also available (usual dosage is 1 tablet q. 12 hr). Pediatric suspensions contain 40 mg trimethoprim and 200 mg sulfamethoxazole/5 ml. Trimethoprim-sulfamethoxazole has also been used in the treatment of typhoid fever in the same dosage as recommended for urinary tract infections. It has been used in a dosage of 4–8 standard tablets daily in the treatment of brucellosis. For pneumonia caused by *Pneumocystis carinii*, the oral dosage is 20 mg/kg trimethoprim and 100 mg/kg sulfamethoxazole/24 hr (equally divided doses q. 6 hr). The I.V. dosage of trimethoprim-sulfamethoxazole ranges from 8 mg/kg trimethoprim and 40 mg/kg sulfamethoxazole/24 hr to 20 mg/kg trimethoprim and 100 mg/kg sulfamethoxazole/24 hr. The lower dosage range is used in the treatment of urinary tract infections that require parenteral antimicrobial therapy and in the treatment of shigellosis; the larger dosage is employed in the treatment of *P. carinii* pneumonia.

26. Chloramphenicol sodium succinate, the parenteral preparation, should only be used I.V. It is ineffective when administered I.M.

27. Chloramphenicol should not be used in the treatment of a urinary tract infection that could

(continued)

Chronic Health Evaluation II) score, treatment with vancomycin, and a diagnosis of hematologic malignancy. Thus, severe illness, underlying disease, and the use of vancomycin are major risk factors for infection of the bloodstream with VRE.³³ Fueling the excessive use of broad-spectrum antimicrobial drugs is the lack of reliable tests that would permit physicians to discern when antimicrobial drugs are not needed. When antimicrobial therapy is needed, improved diagnostic tests would permit better targeting and thereby reduce the widespread administration of broad-spectrum drugs. Selective pressure exerted by widespread antimicrobial use is the driving force in the development of antibiotic resistance. The association between increased rates of antimicro-

bial use and resistance has been documented for nosocomial infections³⁴ and community-acquired infections in studies associating resistance patterns with rates of drug use on a regional or national basis.³⁵

Resistance to antimicrobial drugs is a global problem. Multidrug-resistant pathogens travel not only locally but globally. Because of increased international travel and increased foreign trade in fresh-food products, the threat of global spread of antibiotic resistance is greater than ever. There is no national or global surveillance system for the monitoring of antibiotic resistance in animals or humans. New classes of antimicrobials are being developed to deal with drug resistance.

Table 5 (continued)

Uncomplicated Urinary Tract Infections		Major and Systemic Infections [†]			
Oral		Intramuscular		Intravenous	
Daily Dose	Interval	Daily Dose	Interval	Daily Dose	Interval
—	—	—	—	7.5 mg/kg	8 hr
—	—	—	—	600 mg (I.V. or p.o.)	12 hr

[†]Osteomyelitis, peritonitis, bacteremia, meningitis, endocarditis, etc.

be managed with another, safer, effective antimicrobial.

28. The only approved indication for the use of spectinomycin is in the treatment of anogenital and urethral gonorrhea in a penicillin-allergic patient or when the infecting organism is highly penicillin resistant. In geographic areas where antibiotic-resistant gonococci are prevalent, treatment with 4 g of spectinomycin (2 g in each gluteal region) may be indicated.

29. Vancomycin is not absorbed through the GI tract. Its use orally is for treatment of staphylococcal enterocolitis or antibiotic-associated enterocolitis.

30. The dry powder is reconstituted by addition of Sterile Water for Injection, USP, without a bacteriostatic agent. The solution is then added to a bottle of 5% Dextrose Injection, USP. The pH of the dextrose solution should first be checked to verify that it is above 4.2. If it is not, a buffer solution (as described in package insert) should be added. Amphotericin B solutions should be administered promptly after preparation and should be protected from light during administration. It is given once a day over 6 hr. (Later in the course of administration, double the daily dose is sometimes given on an alternate-day schedule.) Dosage is 1 mg on the first day and then increased in 5 mg increments each day until maintenance dosage is reached. The daily dose is determined by the susceptibility of the organism and the occurrence of toxic side effects. In some instances (e.g., cryptococcal meningitis), combination therapy with flucytosine p.o. may allow employment of smaller daily doses (0.3–0.4 mg/kg) of amphotericin B. In fungal meningitis, intrathecal administration may be necessary (0.1 mg initially, increased gradually to 0.5 mg q. 48–72 hr), depending on the evaluation of the patient's condition.

31. Fluconazole is very useful for the treatment of oropharyngeal, esophageal, and disseminated infections caused by *Candida* and for control of cryptococcus, especially chronic suppression of cryptococcal meningitis in patients with AIDS. To initiate therapy, a loading dose of twice the usual daily dose should be used. A daily dose of 400 mg can be used for cryptococcal meningitis, depending on the patient's response to therapy. The dose should be reduced in patients who have renal insufficiency.

32. Used in the treatment of urinary tract infections and visceral infections caused by *Candida*. Also used in cryptococcal infections in which amphotericin B is not tolerated. Resistance to flucytosine may develop during treatment of candidal and cryptococcal infections. Sometimes

used in combination with amphotericin B to treat systemic fungal infections.

33. Ketoconazole is indicated in the treatment of patients with susceptible fungal infections that have failed to respond to amphotericin B or in the treatment of patients unable to tolerate the toxic effects of amphotericin B. In either role, it is generally preferred to therapy with miconazole when the patients can take oral medications. It is also the drug of choice in the long-term treatment of chronic mucocutaneous candidiasis. It has been useful in the treatment of histoplasmosis, coccidioidomycosis, chromomycosis, and paracoccidioidomycosis. In view of its poor penetration of the CSF, it should not be used in the treatment of coccidioidal or cryptococcal meningitis. Ketoconazole requires gastric acidity for dissolution and absorption. Antacids and cimetidine, if needed, should be given at least 2 hr after a dose of ketoconazole. The most frequent side effects have been nausea and vomiting. Several cases of liver injury of varying severity, possibly the result of idiosyncratic reactions, have occurred during ketoconazole therapy. Liver function tests, therefore, should be evaluated before and periodically during treatment, especially in patients who are on prolonged therapy or who have preexisting hepatic disease. Ketoconazole, in daily dosages of 200–1,800 mg p.o., is used in major and systemic fungal infections for which the mycotic agent is susceptible and amphotericin B cannot be employed.

34. Miconazole is available for parenteral therapy for systemic mycoses. Experience is relatively limited, and it should probably be reserved for patients who cannot tolerate or who do not respond to amphotericin B and flucytosine. Miconazole is metabolized by extrarenal mechanisms, and patients with fungal bladder infections require supplementary bladder irrigation with the drug. Side effects of miconazole include phlebitis, fever, rash, nausea and vomiting, anemia, thrombocytopenia, and transient hyperlipidemia caused by the diluent used.

35. Not absorbed from the GI tract. Use only in treatment of intestinal tract colonization by *Candida* species and not for any systemic mycotic infection. Nystatin suspension (400,000–600,000 units q.i.d.) is used as a mouthwash in treatment of oral thrush. The suspension can also be swallowed for use in the treatment of candidal esophagitis.

36. None of these drugs is recommended for children. In 1999, the FDA limited trovafloxacin to inpatient use for limb- or life-threatening infections.

Discussion

The antimicrobial agents of choice for various infections (e.g., community-acquired pneumonia^{7–9}) in adults are well established [see Table 4], as are their dosages in patients with normal renal function [see Table 5]. Excellent reviews and practice guidelines have been published.^{18,19}

Penicillins

Although the original penicillins are still useful against specific bacteria, there are some infections in which both they and the penicillinase-resistant semisynthetic penicillins are ineffective because of the emergence of penicillinase-producing staphylococci and methicillin-resistant staphylococci. The penicillins can be classified by structure, β -lactamase susceptibility, and spectrum of action [see Figure 1].

The action of the penicillins depends on the presence of a bacterial cell wall containing peptidoglycans that are accessible to the agent. In actively growing bacteria, interference with biosynthesis of the peptidoglycan structure—specifically, of the cross-linkages between the peptide chains—prevents the bacterium from developing its normal structural firmness, and this lack of firmness leads to lysis.

NATURAL PENICILLIN

Aqueous Crystalline Penicillin G

Aqueous crystalline penicillin G is used when a high serum concentration of the agent is required.³⁶ Its half-life is normally 30 minutes but may be as long as 10 hours in patients with anuria. Approximately 50% of penicillin G is bound to plasma proteins.

Generic Name	Side-Chain Substituent (R)	Penicillin Structure
Penicillin G		
Oxacillin		
Nafcillin		
Ampicillin		
Carbenicillin		 The diagram shows the penicillin nucleus: R-C(=O)-HN-CH(C(=O)N-CH2-C(=O)OH)-CH2-S-C(CH3)(CH3)-C(=O)OH. A wavy arrow points to the four-membered beta-lactam ring (HN-C(=O)-CH2-N).

Figure 1 Various semisynthetic penicillins have been produced by modifying the structure of the side chain (R) attached to the penicillin nucleus (right). In this way, penicillins have been developed that lack some of the drawbacks of penicillin G, such as poor gastrointestinal absorption, limited spectrum of antibacterial activity, and inactivation by penicillinase-producing microorganisms; for example, oxacillin and nafcillin are resistant to inactivation by penicillinase. This bacterial enzyme (also termed β -lactamase) cleaves the β -lactam ring of penicillin to form an inactive product; the site of action of penicillinase is shown at right.

Penicillin G sodium contains approximately 2 mEq of sodium per one million units. Therefore, the potassium salt of penicillin G should be used except in patients with renal insufficiency, who may not be able to tolerate the 1.7 mEq of potassium contained in each one million units. This agent is destroyed by gastric acid when given orally.

Penicillin G Benzathine

Penicillin G benzathine, 1.2 to 2.4 million units I.M., is used in the definitive management of certain infections, such as streptococcal sore throat, and as prophylaxis for several conditions, such as rheumatic fever, in which reinfection by β -hemolytic streptococci is a constant threat.

Penicillin G Procaine

Penicillin G procaine is used intramuscularly when a long-acting preparation is preferred and high blood levels are not required. It is indicated for the treatment of pneumococcal pneumonia, uncomplicated cases of which are adequately treated by administration of one or two daily doses of 300,000 units, and for treatment of acute genitourinary gonorrhea, for which a dose of 4.8 million units is divided and injected at two sites and 1 g of probenecid is given orally before the injection.

Penicillin V

Phenoxyethyl penicillin, or penicillin V, is resistant to gastric acid and therefore reaches higher serum concentrations, when given orally, than penicillin G does at similar doses. Penicillin V should not be substituted for parenterally administered penicillin G when such therapy is needed, but it can be given orally to treat

mild infections of the throat, the respiratory tract, or soft tissue in doses of 125 to 500 mg given four to six times daily.

PENICILLINASE-RESISTANT PENICILLINS

Methicillin

Methicillin is the least protein-bound of this group (39%); nafcillin (90%), oxacillin (94%), cloxacillin (95%), and dicloxacillin (98%) all have higher rates of protein binding. Methicillin was the first of the semisynthetic penicillinase-resistant penicillins.³⁷ It must be administered parenterally and is usually given every 4 to 6 hours in a total daily dose of 100 to 300 mg/kg body weight.

Oxacillin and Nafcillin

Oxacillin seems to be as effective as methicillin against staphylococcal infections, and it causes interstitial nephritis less often. For parenteral use, oxacillin or nafcillin can be given in dosages of 100 to 300 mg/kg/day for children and up to 4 to 12 g/day for adults.

Cloxacillin and Dicloxacillin

If penicillinase-producing organisms are identified or suspected and oral therapy is desired, cloxacillin or dicloxacillin, 1 to 2 g/day, can be given.

AMINOPENICILLINS

Ampicillin

Ampicillin is active against a variety of bacteria, including many strains of *Escherichia coli*, *Proteus mirabilis*, *Salmonella*, *Shigella*,

Listeria, and *Haemophilus influenzae*. Most strains of *Klebsiella* and all strains of *P. aeruginosa* are resistant.

Because it is stable in gastric juices, ampicillin is suitable for oral as well as parenteral use. When it is given orally, peak serum levels are reached in about 2 hours, but they seldom exceed 0.3 µg/ml. When it is given intramuscularly, peak serum levels are achieved in 1 hour, and they are both higher and more prolonged than the peak levels achieved after oral administration. About 10% of ampicillin is bound to plasma proteins. The recommended daily dose is 1 to 4 g; parenteral administration of up to 12 g/day is recommended for major systemic infections.

Amoxicillin

Amoxicillin is closely related to ampicillin, both in chemical structure and in spectrum of antibacterial activity.³⁸ Amoxicillin, however, is more completely absorbed than ampicillin: approximately 70% of a dose of amoxicillin is absorbed, compared with approximately 50% of a dose of ampicillin. Consequently, the blood levels attainable with a given dose of amoxicillin are usually about twice those attainable with a comparable dose of ampicillin. Amoxicillin is at least as effective as ampicillin in the treatment of respiratory disorders that are caused by susceptible bacteria, including otitis media, sinusitis, and bronchitis.

CARBOXYOPENICILLINS

Carbenicillin

Carbenicillin has an antibacterial range similar to that of ampicillin, with the added benefit of activity against certain strains of *P. aeruginosa*,³⁹ indole-positive *Proteus* species, and *Enterobacter* species.⁴⁰ Because carbenicillin is inactivated by penicillinase, penicillinase-producing *S. aureus* is resistant to it. *Klebsiella* species are resistant to carbenicillin, as are many *Serratia* organisms. Carbenicillin is bactericidal and is recoverable from blood, urine, lymph, CSF, and most body tissues. About 50% of the drug is bound to serum proteins.⁴¹

Ticarcillin

The antibacterial spectrum of ticarcillin is similar to that of carbenicillin; however, it is two to four times more active against *P. aeruginosa*. It is frequently preferred to carbenicillin in the treatment of serious gram-negative infections because of its greater potency and the lower incidence of adverse effects.⁴² The primary use of ticarcillin is in the treatment of proven or suspected *Pseudomonas* infections. The recommended dosage is 16 to 24 g/day.

UREIDOPENICILLINS

Mezlocillin, Azlocillin, and Piperacillin

Mezlocillin, azlocillin, and piperacillin are semisynthetic penicillins derived from the ampicillin molecule with side-chain adaptations. The ureidopenicillins are generally bactericidal and act primarily by inhibiting cell wall synthesis in dividing bacteria. In comparison with the carboxyopenicillins carbenicillin and ticarcillin, the ureidopenicillins exhibit less pronounced plasma protein binding, a shorter serum half-life, and a greater volume of distribution.⁴³⁻⁴⁵ They are minimally metabolized (10%) and are primarily excreted in an active form by glomerular filtration and tubular secretion. Unlike carbenicillin and ticarcillin, the ureidopenicillins achieve high concentrations in bile because of increased biliary excretion.

In vitro, the ureidopenicillins are active against streptococci,

enterococci, most Enterobacteriaceae, *Pseudomonas*, β-lactamase-negative staphylococci, *Neisseria*, and *Haemophilus*.⁴⁶⁻⁴⁸ β-Lactamase-producing staphylococci and *H. influenzae* are resistant. The major advantage the ureidopenicillins have over other penicillins in clinical use is their increased activity against *P. aeruginosa* and *Klebsiella*.

The recommended dosages of the ureidopenicillins are 6 to 16 g/day for mild to moderate infections and 18 to 24 g/day for severe to life-threatening infections. Small doses may be given intramuscularly, but large doses must be given intravenously. The dosing interval is usually 4 to 6 hours.

Cephalosporins

Cephalosporium acremonium was discovered in 1948. This fungus was found to produce cephalosporin C, from which cephalothin, the first cephalosporin to be introduced, was in turn derived. The basic cephalosporin structure consists of a dihydronaphthazine ring fused to a β-lactam ring.

Substitutions at the acyl side chain have led to differences in antibacterial spectrum and β-lactamase stability. The side chains substituted at this position interfere with proper stereotactic binding of the molecule to the β-lactamase active site, thus preventing degradation of the cephalosporin. Some of the side effects involving platelet aggregation that have been observed with the use of moxalactam can be traced to substitutions at this position.

For convenience, cephalosporins are divided into four generations or groups according to the nature and extent of their antibacterial spectra. More specifically, the division into generations is based on the number of gram-negative bacterial species against which each cephalosporin demonstrates clinical activity. It must be remembered, however, that although the members of each generation are sufficiently similar to be grouped together, they also are different from one another in a number of ways [see Table 6].

FIRST-GENERATION CEPHALOSPORINS

First-generation cephalosporins have good activity against aerobic gram-positive cocci such as *S. aureus*, group B streptococci, and *Streptococcus pneumoniae*. In addition, they are effective against three aerobic gram-negative bacilli—*E. coli*, *K. pneumoniae*, and *P. mirabilis*—although even among these three, resistance is common, occurring in as many as 30% of cases. First-generation cephalosporins are also active against most anaerobic cocci and bacilli (other than *B. fragilis*). They have little or no activity against *Enterobacter*, *Serratia*, *Acinetobacter*, *Pseudomonas*, methicillin-resistant *S. aureus*, *S. epidermidis*, and enterococci. They are also inactive against *B. fragilis*, *Citrobacter*, *Listeria monocytogenes*, *Proteus* (except for *P. mirabilis*), and *Providencia*.

First-generation cephalosporins are used for infections caused by gram-positive cocci, such as skin infections and osteomyelitis, although penicillins are the agents of choice for all streptococcal infections and for infections proven by culture to be caused by susceptible staphylococci. The best use for first-generation cephalosporins is in surgical prophylaxis. For this application, cefazolin sodium is the preferred agent.

SECOND-GENERATION CEPHALOSPORINS

Second-generation cephalosporins possess the same spectrum of activity as the first-generation cephalosporins, with the addition of broader coverage of gram-negative organisms, including *H. influenzae*, *E. aerogenes*, and some *Neisseria* species. Fewer than

Table 6 Properties of Cephalosporins¹⁵⁵

	Specific Agent	Trade Names	Comment*
First Generation	Oral Cefadroxil Cephalexin Cephadrine Parenteral Cefazolin Cephapirin Cephadrine	Duricef, Ultracef Keflex Anspor, Velosef Ancef, Kefzol Cefadyl Anspor, Velosef	Longer half-life Most experience with this agent Properties are similar to those of cephalexin Longer half-life; well tolerated when given I.M. Properties are similar to those of other first-generation cephalosporins Properties are similar to those of other first-generation cephalosporins
Second Generation	Oral Cefaclor Cefprozil Cefuroxime axetil Loracarbef Parenteral Cefamandole Cefmetazole Cefonicid Ceforanide Cefotetan Cefoxitin Cefuroxime	Ceclor Cefzil Ceftin Lorabid Mandol Zefazone Moncid Precef Cefotan Mefoxin Zinacef, Kefurox	Moderately active against <i>Haemophilus influenzae</i> Active against <i>H. influenzae</i> Active against <i>H. influenzae</i> A carbacephem with properties and spectrum similar to those of cefuroxime Active against <i>H. influenzae</i> ; may cause bleeding Spectrum and half-life similar to cefoxitin; may cause bleeding Spectrum similar to that of cefamandole Spectrum similar to that of cefamandole Spectrum similar to that of cefoxitin; longer half-life than cefoxitin; may cause bleeding Active against <i>Bacteroides fragilis</i> , <i>Serratia</i> , <i>Neisseria gonorrhoeae</i> Active against <i>H. influenzae</i> ; only second-generation drug approved for meningitis (selected pathogens)
Third Generation	Oral Cefixime Cepodoxime Ceftibuten Parenteral Cefepime Cefoperazone Cefotaxime Ceftazidime Ceftizoxime Ceftriaxone	Suprax Vantin Cedax Maxipime Cefobid Claforan Fortaz, Tazidime, Tazicef Cefizox Rocephin	More active against gram-negative bacilli, gonococci, <i>Moraxella catarrhalis</i> , and <i>H. influenzae</i> than other oral cephalosporins but much less active against <i>Staphylococcus aureus</i> ; not active against <i>Pseudomonas</i> Similar to cefixime but more active against <i>S. aureus</i> Similar to cefixime but has poor activity against pneumococci and staphylococci Active against most gram-positive cocci (except enterococci and methicillin-resistant staphylococci), <i>Neisseria</i> , <i>Haemophilus</i> , enteric gram-negative bacilli, and <i>Pseudomonas</i> Increased activity against <i>Pseudomonas aeruginosa</i> but less against Enterobacteriaceae; may cause bleeding More active against gram-positive cocci Most active against <i>Pseudomonas</i> Properties are similar to those of cefotaxime Longer half-life; less active against <i>Pseudomonas</i> , <i>B. fragilis</i>

Note: detailed information about the various cephalosporins is covered in the text.

*Agents are being compared with other members of the same generation of cephalosporins.

5% of *E. coli* and *Proteus* strains are resistant to second-generation cephalosporins. The activity of second-generation agents against *S. pyogenes* and *S. pneumoniae* is equal to that of the first-generation agents, but their activity against staphylococci is variable: the MIC ranges from 0.20 to 25 µg/ml. Of the second-generation agents, the most active against staphylococci is cefamandole, which has an MIC of 0.6 µg/ml for *S. aureus*. Cefotetan and cefoxitin have significant activity against *B. fragilis*. Cefoxitin is less active against *H. influenzae* and *E. aerogenes* than other second-generation cephalosporins, but it is more active against *Serratia* species. Cefoxitin by itself is effective in patients with community-acquired peritonitis who are unlikely to be infected with *Enterobacter* or *P. aeruginosa*.⁴⁹ Cefuroxime and cefamandole have been used with some success in empirical therapy for community-acquired pneumonia.⁵⁰ Cefotetan, a cephemycin introduced in 1986, has a spectrum of activity very similar to that of cefoxitin.⁵¹ It is as active as cefoxitin against *B. fragilis* but is less active against other strains in the *B. fragilis* group. Unlike cefoxitin, cefotetan is active against *H. influenzae*. Cefotetan has proved effective and safe in a variety of clinical situations, including gynecologic infections and surgical prophylaxis.⁵²

Cefprozil is an oral agent whose spectrum of activity includes gram-positive and gram-negative pathogens. It has achieved good results in patients with pharyngitis or tonsillitis.⁵³

Loracarbef is an oral agent of the carbacephem class that is active in vitro against the common pathogens associated with skin infections, otitis media, sinusitis, bronchopulmonary infections, and urinary tract infections.⁵⁴

THIRD-GENERATION CEPHALOSPORINS

In the third-generation cephalosporins, activity against gram-positive cocci is replaced by broader gram-negative coverage. This development is illustrated by susceptibility testing done on *S. aureus*: the MIC of first-generation cephalosporins is 1 µg/ml, that of second-generation cephalosporins is 2 µg/ml, and that of third-generation cephalosporins is 3 µg/ml. Third-generation cephalosporins are more active against the enteric gram-negative bacilli covered by first- and second-generation cephalosporins. Their spectrum of activity includes *Serratia* and *Citrobacter*. They are also highly active against *H. influenzae* and *N. gonorrhoeae* and moderately active against *P. aeruginosa* and some anaerobes. At first, the third-generation cephalosporins seemed capable of providing the same spectrum of activity as the aminoglycosides but without their inherent toxicity; however, they have failed to gain wide popularity in the treatment of high-risk patients or patients with extensive infections. The reasons for this failure include their incomplete spectra of activity against the range of organisms likely to be encountered in polymicrobial infections, their unexpect-

ed agent-specific toxicity, their suboptimal pharmacokinetic properties, and their high propensity for inducing resistance.

Cefixime, an orally absorbed iminomethoxyaminothiazolyl cephalosporin, inhibits 90% of *S. pneumoniae*, *H. influenzae*, and *H. parainfluenzae* strains, whether they produce β -lactamase or not, at concentrations of less than 0.25 mg/L. It inhibits 90% of *Moraxella catarrhalis* strains at concentrations of less than 1 mg/L.

Ceftibuten is an orally active third-generation cephalosporin that possesses increased potency against members of the Enterobacteriaceae.⁵⁵ Generally, it is about 16 times more active than cefuroxime, cefaclor, cephalexin, or amoxicillin-clavulanate; its activity is comparable to that of cefixime. Ceftibuten is ineffective against staphylococci and only partially effective against *S. pneumoniae*. *H. influenzae* and *Neisseria* species, however, are highly susceptible to this agent.

Pharmacokinetics

After I.V. administration, third-generation cephalosporins conform to an open, two-compartment model, characterized by an initial rapid distribution phase followed by a slower terminal elimination phase. The relatively long elimination half-lives of many of the newer β -lactam antibiotics make less frequent dosing possible. Most third-generation cephalosporins are primarily eliminated renally, with two exceptions: cefoperazone and ceftriaxone. Cefoperazone is primarily eliminated unchanged in the bile, and only about 25% of an administered dose is recovered in the urine after 24 hours.⁵⁶ Peak biliary concentrations of cefoperazone approach or exceed 2,000 μ g/ml after a 2 g I.V. dose.⁵⁷ Fifty percent of an administered dose of ceftriaxone is eliminated in the bile; the rest is eliminated renally. Ceftriaxone elimination is decreased to a small extent in end-stage renal disease; however, because the drug is normally given every 12 to 24 hours, there is little accumulation and therefore no need to adjust the dose. In general, third-generation cephalosporins penetrate most tissue and fluid compartments in amounts that, though variable, usually exceed the MIC for most susceptible pathogens. Sputum concentrations in the range of 0.3 to 6.0 μ g/ml are attained with all the agents, and higher concentrations are found in purulent sputum. Ascitic fluid concentrations ranging from 2.4 μ g/ml with ceftizoxime to greater than 60 μ g/ml with cefoperazone are seen in patients with peritonitis.⁵⁸

Concentrations in excess of the MIC for susceptible aerobic and anaerobic organisms (except for *B. fragilis*) are achieved in female genital tissue with all these agents.⁵⁹ These compounds also appear to penetrate the prostate, the testes, the ureters, and renal tissue in significant amounts.⁶⁰

With each of these agents, therapeutic concentrations can be obtained in the gallbladder wall; these concentrations may be as high as 60 μ g/g with cefoperazone. Bone-penetration studies reveal penetration with each of these agents.⁶¹

Clinical Utility

Many studies have compared third-generation cephalosporins in an effort to establish a superior drug or drug combination for life-threatening infections; most have found no statistically significant differences. It is important to remember that even if there is a difference in efficacy between two or more antibiotics, that difference may not be apparent if the study group is not large enough. For example, if one agent fails in 10% of patients and another in only 5%, a study group of 250 to 500 patients would be required to show a statistical difference.^{62,63} Most comparative antibiotic trials, however, have reported on fewer than 60 patients and thus have not been able to pinpoint small differences in effi-

cacy between antibiotics.⁶⁴ Many studies that find no difference between two regimens are in fact subject to this type of error.

FOURTH-GENERATION CEPHALOSPORINS

Cefepime is an extended-spectrum parenteral cephalosporin that provides coverage against both gram-positive and gram-negative organisms, including *S. aureus* and *P. aeruginosa*. Cefepime, which is a zwitterion, has a net neutral charge that allows it to penetrate the outer membrane of gram-negative bacteria faster than third-generation cephalosporins. It is more stable against β -lactamases because of the lower affinity of the enzymes for cefepime when compared with third-generation cephalosporins. In comparison with third-generation cephalosporins, cefepime appears to be less likely to induce resistance, because of a lower rate of hydrolysis by β -lactamases, a low affinity for these enzymes, and more rapid permeation into the cell. It has been used to treat patients with pneumonia, with results comparable to those obtained with ceftazidime.⁶⁵ Because of its antibacterial coverage and proven tissue penetration in acute pancreatitis, cefepime should be studied in patients with severe acute pancreatitis.⁶⁶ However, it offers poor coverage against *Bacteroides* and must be combined with metronidazole or clindamycin. The combination of cefepime and metronidazole was found to be equivalent to imipenem in a prospective, randomized study of intra-abdominal infections.⁶⁷

ADVERSE EFFECTS

Cephalosporins are associated with a number of adverse side effects. The adverse reactions associated with their use are similar to those associated with use of other β -lactam compounds, such as local pain and irritation, hypersensitivity reactions, positive Coombs reaction, leukopenia, thrombocytopenia, transient abnormalities in liver function enzyme levels, and GI disturbances.^{68,69} These reactions are usually mild and reversible, except in those rare patients who manifest life-threatening hypersensitivity reactions. Cephalosporins may be administered to most patients who are allergic to penicillin, because only 5% to 15% of penicillin-allergic patients react adversely to cephalosporins.⁷⁰ An excellent review of cephalosporin allergy and its treatment has been published.⁷¹

Aminoglycosides

Aminoglycosides are composed of two or more amino sugars bound by glycosidic linkage to a central hexose (aminocyclitol) nucleus. Their highly polar, polycationic structure contributes to their poor GI absorption and their meager ability to penetrate the blood-brain barrier. They bind irreversibly to the 30S bacterial ribosome and interfere with protein synthesis. Aminoglycosides also disturb calcium homeostasis and induce cell death as a result of efflux of potassium, sodium, and other essential bacterial constituents. Unlike most other antimicrobial agents that inhibit protein synthesis, aminoglycosides are bactericidal.

All aminoglycosides share certain pharmacokinetic properties. Because they are poorly absorbed when given orally, adequate serum concentrations can be obtained only through parenteral administration. Protein binding is negligible,⁷² and the volume of distribution approximates the volume of the extracellular space.⁷³ In adults with normal renal function, the aminoglycosides have a half-life of about 2 hours, but there is considerable variation between individual patients.⁷⁴ In patients with deteriorating renal function, the half-life of an aminoglycoside increases, often exceeding 24 hours in patients with end-stage renal disease.⁷⁵

The prolonged half-lives of aminoglycosides are substantially shortened during hemodialysis⁷⁶; these agents are much less efficiently removed by peritoneal dialysis.⁷⁷ The aminoglycosides do not penetrate the blood-brain barrier well, even in patients with meningeal inflammation.^{78,79} Drug levels in pulmonary secretions are typically 20% to 40% of serum levels. Low concentrations of aminoglycosides in purulent fluids are probably related to local inactivation caused by DNA released from leukocytes⁸⁰ and by the low regional pH.

The aminoglycosides are rapidly excreted, primarily by glomerular filtration. Urine concentrations may be 100 times the serum level in patients with normal renal function. The aminoglycosides accumulate in the renal cortex; sensitive assay techniques can detect them in urine and serum for up to 10 days after cessation of therapy.

STREPTOMYCIN

Widespread resistance among Enterobacteriaceae has limited the usefulness of streptomycin. At present, streptomycin is almost always employed in combination with other antimicrobial agents. With penicillin or vancomycin, streptomycin is used to treat infective endocarditis caused by viridans streptococci or susceptible enterococcal streptococci. It may also be given in conjunction with other antituberculous drugs to treat mycobacterial diseases and in conjunction with tetracycline to treat brucellosis. Streptomycin is used alone in the treatment of tularemia and plague.

KANAMYCIN

Because of widespread resistance among Enterobacteriaceae and *P. aeruginosa*, kanamycin is rarely used today. It is occasionally used as a second-line agent in combination with other antibiotics in the treatment of tuberculosis.

GENTAMICIN

Gentamicin is used for serious hospital-acquired infections caused by Enterobacteriaceae and most strains of *P. aeruginosa* in institutions in which there is minimal background resistance to this agent (other *Pseudomonas* species are predictably resistant to aminoglycosides). Gentamicin is given with penicillin to treat enterococcal endocarditis and with vancomycin plus rifampin to treat prosthetic valve endocarditis caused by *S. epidermidis*.

TOBRAMYCIN

Tobramycin closely resembles gentamicin with respect to antimicrobial spectrum and pharmacokinetics. Tobramycin is more active against some strains of *A. calcoaceticus* but less active against *S. marcescens*. Although tobramycin has slightly greater intrinsic activity against *P. aeruginosa*, most gentamicin-resistant strains of this organism are also resistant to tobramycin. The difference in nephrotoxicity between gentamicin and tobramycin is clinically insignificant.⁸¹⁻⁸³

AMIKACIN

Amikacin is a semisynthetic derivative of kanamycin. Its major advantage is its resistance to aminoglycoside-modifying enzymes, the production of which is the principal mechanism of bacterial resistance to aminoglycosides. Amikacin may therefore be used against gentamicin-resistant organisms, and it is clearly the aminoglycoside of choice where gentamicin resistance is prevalent. Fortunately, no substantial increase in amikacin resistance has been noted, even in medical centers where it has been used extensively.⁸⁴

NETILMICIN AND SISOMICIN

Netilmicin, a semisynthetic derivative of sisomicin, is not metabolized by most of the aminoglycoside-modifying enzymes and therefore is active against some strains of Enterobacteriaceae that are resistant to gentamicin and tobramycin; however, it is less active against *P. aeruginosa*. Animal studies suggest that netilmicin may be less nephrotoxic than other aminoglycosides,^{82,85} and human studies suggest that it is somewhat less likely to exert toxic effects on cranial nerve VIII.⁸² Sisomicin is more active than gentamicin against Enterobacteriaceae and *P. aeruginosa*, but the nephrotoxicity it has exhibited in animal studies exceeds that of other aminoglycosides.⁸⁶

ADVERSE EFFECTS

Unlike β -lactam antibiotics, aminoglycosides, have a narrow range between therapeutic and toxic levels and are thus more likely to cause side effects. Their ototoxicity is potentially more significant than their nephrotoxicity because it is often irreversible. Cochlear toxicity has been reported in 8% to 10% of patients and has been clinically evident in as many as 4% of patients treated with aminoglycosides for various infections.⁸⁷ Vestibular toxicity, as manifested by electronystagmographic changes, has been found in 5% to 10% of patients and has been clinically significant in 1% to 5%.⁸² Vestibular toxicity is more frequently associated with streptomycin, gentamicin, and tobramycin, whereas auditory toxicity is more typical of kanamycin and amikacin. Ototoxicity and vestibular toxicity are difficult to monitor, particularly in hospitalized patients for whom formal audiometry and caloric testing may be cumbersome or uncomfortable. Because aminoglycoside-associated auditory toxicity generally affects the higher frequencies, early bedside detection is difficult. Toxic effects on cranial nerve VIII seem to be related to advanced age, previous aminoglycoside treatment, and excessive serum levels.

AMINOGLYCOSIDE PHARMACOKINETICS

Peak aminoglycoside concentrations higher than 5 $\mu\text{g}/\text{ml}$ are associated with improved survival in patients with gram-negative infections.^{88,89} With gram-negative pulmonary infections, peak concentrations of 8 to 10 $\mu\text{g}/\text{ml}$ are necessary because of poor penetration of aminoglycosides into the lungs.^{90,91} It has been shown that a loading dose of gentamicin or tobramycin of 2 mg/kg of lean body weight cannot guarantee adequate peak concentrations in acutely ill patients. The most likely explanation for the usually low peak serum concentrations of aminoglycosides in acutely ill patients is an expanded volume of distribution.⁹²⁻⁹⁶ Dosage adjustments based on blood levels should be made as soon as possible after the beginning of therapy and after the steady state has been reached.

Once-Daily Dosing of Aminoglycosides

Efforts to improve the toxic-to-therapeutic ratio of aminoglycosides include once-daily dosing schedules and reevaluations of the recommended therapeutic ranges. In conventional administration of aminoglycosides to patients with normal renal function, divided doses are administered at 8- to 12-hour intervals. In an effort to improve efficacy and decrease toxicity and cost, once-daily regimens have been compared with conventional regimens. In most protocols, the total doses were equivalent in the single and divided-dose regimens. Two meta-analyses of such trials have concluded that once-daily dosing is as effective as divided dosing and has a lower risk of toxicity in patients with normal renal function.^{97,98} Although most trials evaluated immunocompetent

adults, similar trends were noted for children and for patients with febrile neutropenia. In elderly patients, however, the high peak serum concentrations that occur with once-daily dosing may increase the risk of nephrotoxicity,⁹⁹ probably because of diminished renal clearance. There are several excellent reviews of the subject in the literature.^{100,101}

Tetracyclines

The tetracyclines act against microorganisms by inhibiting protein synthesis; their site of action is the bacterial ribosome. Resistance to the tetracyclines appears slowly and in a stepwise fashion and is mediated by plasmids. Plasmids impart resistance by coding for proteins that interfere with active transport of tetracycline through the cytoplasmic membrane. Microorganisms that acquire resistance to one tetracycline are usually resistant to the other tetracyclines as well.

At appropriate dosages, peak serum concentrations 1 hour after intravenous administration of tetracycline, doxycycline, or minocycline are typically 10 to 20 µg/ml. The newer semisynthetic tetracyclines—doxycycline, methacycline, and minocycline—have considerably longer serum half-lives than the older agents.

Tetracyclines are metabolized by the liver and concentrated in the bile. Biliary concentrations of these agents are, on average, five to 10 times higher than concurrent plasma concentrations. The tetracyclines penetrate body tissues well and are capable of entering the CSF even in the absence of inflammation of the meninges. They readily cross the placental barrier, and relatively high concentrations are found in human milk.

Tetracyclines are useful in the treatment of sexually transmitted diseases. Tetracyclines are also effective for the treatment of other chlamydial infections, such as lymphogranuloma venereum, psittacosis, inclusion conjunctivitis, and trachoma. A tetracycline may also be used in the treatment of gonococcal infections in patients who are unable to tolerate penicillin G. Other sexually transmitted diseases that may be treated with tetracyclines are chancroid and granuloma inguinale.

A tetracycline or erythromycin is the agent of choice for the treatment of *Mycoplasma pneumoniae* infection. Tetracyclines are also effective against rickettsial infections, tularemia, and cholera; in patients unable to tolerate penicillin, they may be used to treat actinomycosis. Doxycycline is useful as prophylaxis against traveler's diarrhea caused by toxicogenic strains of *E. coli*. Unfortunately, the widespread use of tetracyclines as additives to livestock feed has resulted in increasing bacterial resistance to these agents.

Macrolides

ERYTHROMYCIN

Erythromycin is a macrolide that contains a many-membered lactone ring to which one or more deoxy sugars are attached. Erythromycin and other macrolide antibiotics inhibit protein synthesis through reversible binding to the 50S ribosomal subunits of susceptible microorganisms.

Erythromycin is well absorbed from the GI tract. The presence of food in the stomach reduces absorption of the drug, except when it is in the estolate form.¹⁰² Erythromycin is excreted primarily in the bile; only 2% to 5% of a given dose is excreted in the urine. Concentrations in the bile may be more than 10 times those in plasma. Erythromycin diffuses readily into most tissues, except for the brain and the CSF.

Erythromycin is the agent of choice for the treatment of *M. pneumoniae* and *Legionella* infections. It is also effective against infections caused by group A β-hemolytic streptococci or *S. pneumoniae*. Accordingly, it is the agent of choice for the treatment of community-acquired pneumonia in nonimmunosuppressed patients who do not require hospitalization and who are allergic to penicillin.¹⁰³ In addition, erythromycin may be used to treat gonorrhea and syphilis in patients who are unable to tolerate penicillin G or tetracycline. The incidence of serious erythromycin-related adverse effects is low.

CLARITHROMYCIN AND AZITHROMYCIN

Clarithromycin and azithromycin are new semisynthetic macrolides that are structurally related to erythromycin. They inhibit protein synthesis in susceptible organisms by binding to the 50S ribosomal subunit. Clarithromycin and azithromycin are well absorbed and widely distributed, with excellent cellular and tissue penetration. Both agents have a broader spectrum of activity than erythromycin does; in addition, they have fewer GI side effects (a major obstacle to compliance with erythromycin therapy).

Clarithromycin is several times more active against gram-positive organisms in vitro than erythromycin, whereas azithromycin is two to four times less potent than erythromycin. Azithromycin has excellent in vitro activity against *H. influenzae*; clarithromycin, although less active against *H. influenzae* according to standard in vitro testing, is metabolized into an active compound with twice the in vitro activity of the parent drug. Azithromycin and clarithromycin also are active against some unexpected pathogens (e.g., *Borrelia burgdorferi*, *Toxoplasma gondii*, *M. avium* complex, and *M. leprae*). At present, clarithromycin appears to be the more active of the two against atypical mycobacteria, giving new hope to surgeons faced with what has become a difficult group of infections to treat.

Superior pharmacodynamic properties distinguish these new macrolides from the prototypical macrolide, erythromycin. Azithromycin has a large volume of distribution, and although serum concentrations remain low, it concentrates readily within tissues, demonstrating a tissue half-life of approximately 3 days; a 5-day course of therapy will provide therapeutic tissue concentrations for at least 10 days. These properties allow novel dosing schemes. For instance, azithromycin can be given once daily for 5 days to treat respiratory tract and soft tissue infections, and administration of a single 1 g dose of azithromycin can effectively treat *Chlamydia trachomatis* genital infections; these more convenient dosing schedules improve patient compliance.

DIRITHROMYCIN

Dirithromycin is an oral macrolide antibiotic with an antibacterial spectrum similar to that of erythromycin; it can be administered once daily but has no other advantages over erythromycin. The drugs produce similar GI side effects, and dirithromycin is substantially more expensive.

Clindamycin

Clindamycin is a 7-deoxy-7-chloro derivative of lincomycin that consists of an amino acid attached to a sulfur-containing octose. Clindamycin binds exclusively to the 50S subunit of bacterial ribosomes and suppresses the synthesis of protein. Clindamycin, erythromycin, and chloramphenicol all act at the same site, and the binding of one of these antibiotics to the ribosome may inhibit the binding of the others. Plasmid-mediated

resistance to clindamycin has been reported in *B. fragilis*; this may be caused by methylation of bacterial RNA found in the 50S ribosomal subunit.¹⁰⁴ Peak serum concentrations 1 hour after intravenous administration of a 600 mg dose are approximately 10 to 12 µg/ml. Clindamycin is metabolized by the liver and excreted in an inactive form in the urine. It readily penetrates most body tissues but not the CSF.¹⁰⁵

Clindamycin is active against *B. fragilis* and other anaerobic microorganisms and is useful in the treatment of patients with intra-abdominal, pelvic, and pulmonary infections. It is associated with a modest number of adverse effects.

Chloramphenicol

Chloramphenicol is unique among antibiotics in that it contains a nitrobenzene moiety and is a derivative of dichloroacetic acid. Like clindamycin, it inhibits bacterial protein synthesis by binding reversibly to the 50S ribosomal subunit, thus keeping the amino acid-containing end of aminoacyl-transfer RNA (tRNA) from binding to the ribosome. Chloramphenicol is rapidly and completely absorbed from the GI tract, and absorption is not impaired by concomitant ingestion of food or administration of antacids. It is inactivated in the liver by glucuronyl transferase. Chloramphenicol and its metabolites are excreted rapidly in the urine. About 80% to 90% of a dose is excreted in this way, about 5% to 10% of which is in the biologically active form. The drug penetrates well into all tissues, including the brain; it also penetrates well into the CSF and the aqueous humor.

Because of the risk of serious or fatal bone marrow toxicity, chloramphenicol should be used only against those infections for which the benefits of its use outweigh the risks of its potential toxicity. It still plays a major role in the treatment of typhoid fever, although plasmid-mediated resistance of *S. typhi* to chloramphenicol has been reported. Chloramphenicol is effective therapy for bacterial meningitis and brain abscesses caused by susceptible microorganisms; in conjunction with penicillin, it is effective empirical therapy for brain abscesses.

Vancomycin

Vancomycin is a narrow-spectrum antibiotic derived from *Nocardia orientalis*. Vancomycin exerts its bactericidal effect by inhibiting the biosynthesis of the major structural cell wall polymer, peptidoglycan.¹⁰⁶ Vancomycin is about 55% protein bound. Its activity is not significantly affected by pH values between 6.5 and 8.0. It is poorly absorbed from the GI tract. Because patients invariably experience pain after intramuscular injections, parenteral administration is limited to the intravenous route. Vancomycin is primarily excreted by the kidneys; about 80% to 90% of the dose is eliminated in a 24-hour period. Its half-life is approximately 6 hours in patients with normal renal function. In anuric patients, the half-life may be prolonged to approximately 7 days.¹⁰⁷ Vancomycin is not removed by hemodialysis or peritoneal dialysis.

Vancomycin is mainly effective against gram-positive organisms. No cross-resistance has been demonstrated between vancomycin and other antibiotics, and resistance is uncommon. Vancomycin, given alone, is the agent of choice in the treatment of methicillin-resistant *S. aureus* infections.^{108,109} Some strains of methicillin-resistant *S. aureus*, however, are resistant to vancomycin. If vancomycin therapy is ineffective against severe infections caused by such strains, the addition of either an aminoglycoside or rifampin, or both, should be considered. Several reports

have indicated that vancomycin is not bactericidal for enterococci.¹¹⁰ Vancomycin is indicated for other serious infections caused by organisms with multiple antibiotic resistance, such as CSF shunt infections and prosthetic valve infection caused by *S. epidermidis* or *Corynebacterium diphtheriae*.¹¹¹ It is the agent of choice for infections caused by penicillin-resistant group JK corynebacteria¹¹² and is uniformly active against rare, multiply resistant strains of *S. pneumoniae*.¹¹³ Given orally, vancomycin is also the agent of choice for *C. difficile*-associated enterocolitis,¹¹⁴ although less expensive agents, such as bacitracin¹¹⁵ and metronidazole,¹¹⁶ may be as effective.

Anaphylactoid reactions to vancomycin have been reported since the earliest clinical trials. Such reactions can occur with the first dose; signs and symptoms range from mild pruritus to dramatic hypotension and cardiovascular arrest. The rapid intravenous infusion of vancomycin can cause a peculiar reaction consisting of pruritus; an erythematous or maculopapular rash involving the face, neck, and upper torso; and possible hypotension.

Metronidazole

Metronidazole acts by disrupting bacterial DNA and inhibiting nucleic acid synthesis¹¹⁷; it is bactericidal against almost all anaerobic gram-negative bacilli, including *B. fragilis*, and against most *Clostridium* species. Although true anaerobic streptococci are generally susceptible to it, microaerophilic streptococci as well as *Actinomyces* and *Propionibacterium* species are often resistant.

Metronidazole is excellent for anaerobic infections of the abdomen and pelvis. For serious anaerobic infections, the drug is administered intravenously; a loading dose of 15 mg/kg is given, followed by 7.5 mg/kg every 6 hours until the patient is well enough to take an oral dosage of 7.5 mg/kg every 6 hours. The dosage need not be reduced in azotemic patients, but it should be reduced in patients with hepatic insufficiency. Because of its bactericidal action and excellent tissue penetration, intravenous metronidazole may be the treatment of choice for *B. fragilis* endocarditis and central nervous system infections, both of which are uncommon. When metronidazole is administered orally, it is well absorbed and is widely distributed in body tissues, including those of the CNS.

Side effects of metronidazole include dry mouth (associated with a metallic taste) and nausea. Concurrent use of alcohol may cause a reaction similar to that produced when alcohol is ingested after taking disulfiram. Neurologic symptoms, including peripheral neuropathy and encephalopathic reactions, and neutropenia are uncommon. Pancreatitis has been reported,¹¹⁸ but alternative drugs are available.

Carbapenems

Imipenem and meropenem were the first carbapenems available for clinical use in the United States; the third, ertapenem, was released in 2002. Like other β-lactam antibiotics, they are bactericidal and act by inhibiting bacterial cell wall synthesis.¹¹⁹ Three properties account for the extraordinarily broad antibacterial spectrum of the carbapenems: there is no permeability barrier excluding the drugs from bacteria; they have high affinity for penicillin-binding protein 2, which is a crucial component of cell wall structure; and they are extremely resistant to hydrolysis by β-lactamases.

Carbapenems are extraordinarily active against gram-negative bacteria. Whereas imipenem tends to be more active against gram-positive cocci, meropenem appears to be more active

against gram-negative bacilli. Virtually all Enterobacteriaceae are susceptible. *Haemophilus* and *Neisseria* species are also susceptible to carbapenems but at concentrations somewhat higher than those of third-generation cephalosporins. *Acinetobacter*, which is resistant to most other β -lactam antibiotics, is susceptible to imipenem and meropenem, as are *Serratia*, *Salmonella*, *Citrobacter*, *Yersinia*, and *Brucella* species. Gram-negative anaerobes, including *B. fragilis*, are susceptible. *P. aeruginosa* is also susceptible, but some resistant strains have emerged during therapy; as a result, imipenem or meropenem should probably be combined with a second antipseudomonal drug when they are used to treat serious pseudomonal infections. Certain nosocomial pathogens, such as *Stenotrophomonas maltophilia* and *P. cepacia*, are resistant, as are *Flavobacterium* species.

Imipenem is extensively degraded in the renal tubule, which results in low urinary levels of the drug. This drawback can be prevented by using cilastatin, an inhibitor of the brush-border enzyme dehydropeptidase-1. Cilastatin also appears to prevent the tubular damage that is occasionally observed in animals given imipenem alone in high doses. For clinical use, imipenem and cilastatin are administered simultaneously in equal doses.

Meropenem is pharmacologically similar to imipenem except that it is not susceptible to degradation by dehydropeptidase; as a result, it can be administered without cilastatin. About 70% of both meropenem and imipenem is excreted in the urine; the dosage should be reduced in azotemic patients. Like imipenem, meropenem is active against most clinically active gram-positive and gram-negative bacteria, including anaerobes; however, neither drug is active against methicillin-resistant staphylococci or *E. faecium*. Resistant strains of *P. aeruginosa* have emerged during therapy with each drug.

The clinical efficacy and toxicity of meropenem are similar to those of imipenem, except that meropenem appears more likely to be effective in meningitis and less likely to cause seizures.

Because the newest carbapenem, ertapenem, has a longer half-life than the other members of the group, it can be administered in a single daily intravenous dose.¹²⁰ Like the other carbapenems, ertapenem is excreted in the urine, and the dosage should be reduced in azotemic patients. The antibacterial spectrum of ertapenem is similar to that of meropenem, except that *Pseudomonas* and *Acinetobacter* strains are less susceptible, and *E. faecalis* is resistant.¹²¹ Ertapenem appears effective against community-acquired pneumonias, intra-abdominal infections, complicated skin and soft tissue infections, and complicated urinary tract infections, but experience is limited.

The carbapenems have broader antibacterial spectrums than any other β -lactam antibiotics. They are active against most gram-positive bacteria—both aerobes and anaerobes. Exceptions include some enterococci; many *E. faecalis* strains are sensitive to imipenem and meropenem but not ertapenem, and most *E. faecium* strains are resistant to all three drugs. Some diphtheroids are resistant. Although most *S. aureus* strains are very sensitive, the susceptibility of methicillin-resistant *S. aureus* and coagulase-negative staphylococci is highly variable. Methicillin-resistant *S. aureus* and *Listeria* exhibit carbapenem tolerance. Finally, some strains of *C. difficile* are resistant.

Ertapenem has a spectrum of activity similar to that of meropenem, except that *Pseudomonas* and *Acinetobacter* strains are much less susceptible, and *E. faecalis* is resistant.

The safety of carbapenems seems comparable to that of other β -lactam antibiotics. Nausea and vomiting, local pain at injection sites, and hypersensitivity are the most common reactions. Seizures, although unusual, are a potential concern with imipen-

em; they have been observed in 0.9% of patients who have received the drug; risk factors for seizure include excessive dosages of the drugs, preexisting CNS lesions, epilepsy, and renal insufficiency. Meropenem is less likely to provoke seizures.¹¹⁹ Transient elevations of liver enzymes and leukopenia can occur in patients who are given carbapenems. Antibiotic-associated pseudomembranous colitis has occurred.

Because the structure of the carbapenems resembles that of the penicillins and cephalosporins, there is potential for cross-reactivity in patients allergic to other β -lactam antibiotics. Clinical experience in this situation is limited, but it appears prudent to avoid carbapenems in patients with anaphylactic sensitivity to β -lactam drugs and to use them with caution in patients with milder allergies to penicillins or cephalosporins.¹²²

Carbapenems have been used successfully in patients with pneumonia, intra-abdominal infections, urinary tract infections, endocarditis, bacteremia, osteomyelitis, cellulitis, and febrile neutropenia. The broad spectrum and apparent low toxicity of carbapenems is impressive, but they should be used selectively and with restraint.

Monobactams

The monobactams are monocyclic β -lactam antibiotics that lack the thiazolidine ring found in penicillins and the dihydrothiazine ring found in cephalosporins. Although there are several monobactams under investigation, only aztreonam has been approved for clinical use in the United States. It has been evaluated in open and comparative studies against a number of agents currently used to treat infections.^{123,124} It inhibits only aerobic gram-negative species. It can be administered two or three times daily. It is a poor hapten and has been successfully administered to small numbers of patients with proven allergy to penicillins and cephalosporins.¹²⁵

Aztreonam has been shown to be effective against bacteremia caused by *E. coli*, *K. pneumoniae*, *P. mirabilis*, *S. marcescens*, *P. aeruginosa*, *Enterobacter* species, *Proteus* species, and *Providencia* species.^{126,127} It has also been used, alone or in combination with clindamycin, to treat gram-negative aspiration pneumonia, with results comparable or superior to those obtained with an aminoglycoside-clindamycin combination.^{128,129}

Aztreonam has been advocated as directed therapy to obviate more toxic drugs. It seems possible that aztreonam could replace aminoglycosides in many situations in which they are combined with other agents.

β -Lactamase Inhibitors

A novel approach to antibacterial chemotherapy is the use of β -lactamase inhibitors with β -lactam agents. Clavulanate has been combined with both amoxicillin and ticarcillin. Because neither clavulanate nor sulbactam inhibits the β -lactamases that function primarily as cephalosporinases in *Enterobacter*, *Serratia*, and *P. aeruginosa* infections, the addition of clavulanate or sulbactam does not enhance ticarcillin's activity against *Pseudomonas*. The principal use of amoxicillin-clavulanate has been in the treatment of upper respiratory tract infections caused by β -lactamase-producing *H. influenzae* or *M. catarrhalis*. Ticarcillin-clavulanate has been used to treat pneumonia caused by *P. aeruginosa* and mixed β -lactamase-producing flora as well as intra-abdominal infections and gynecologic infections in which the infecting organisms often possess β -lactamases. In febrile neutropenic patients, its efficacy is comparable to that of other agents, but superinfections may be

a problem.^{130,131} Because some strains of *K. pneumoniae* are not adequately inhibited by ticarcillin-clavulanate, addition of an aminoglycoside would be appropriate in neutropenic patients. Sulbactam has also been combined with ampicillin.

Clavulanate, sulbactam, and tazobactam have all been combined with piperacillin in an attempt to enhance the agent's activity against β -lactamase-producing bacteria.^{132,133} Tazobactam enhances the spectrum of action and potency of piperacillin to a greater extent than sulbactam does. Although piperacillin-clavulanate is more potent than piperacillin-tazobactam, the two combinations are effective against virtually the same spectrum of resistant β -lactamase-producing gram-negative organisms. Piperacillintazobactam is more potent than ticarcillin-clavulanate and is effective against a wider range of gram-negative enteric organisms. Combinations of piperacillin with tazobactam or clavulanate have a broader spectrum of activity than combinations of piperacillin with sulbactam against bacteria that produce characterized plasmid-mediated enzymes of clinical significance. In particular, piperacillin-tazobactam and piperacillin-clavulanate inhibit TEM-1, TEM-2, and SHV-1 β -lactamases, but piperacillin-sulbactam does not. In mice infected with β -lactamase-producing *E. coli*, *K. pneumoniae*, *P. mirabilis*, and *S. aureus*, both tazobactam and clavulanate have provided greater enhancement of the therapeutic efficacy of piperacillin than sulbactam has. Reviews of the TEM-type β -lactamases¹³⁴ and the piperacillin-tazobactam combinations¹³⁵ have been published.

Quinolones

The addition of a fluorine group and a piperazine substituent to the first quinolones has greatly improved the antibacterial spectrum of this class of drugs; the addition of a methyl group on the piperazine ring appears to further enhance the bioavailability of these compounds.

The fluoroquinolones are bactericidal compounds that act by inhibiting DNA gyrase, the bacterial enzyme responsible for maintaining the supertwisted helical structure of DNA; DNA topoisomerase IV is a secondary target.¹³⁶ The fluoroquinolones rapidly kill bacteria, probably by impairing DNA synthesis and possibly by mechanisms involving the cleaving of bacterial chromosomal DNA. Bacterial resistance to the fluoroquinolones depends on a change in their DNA gyrase. Bacterial strains that are resistant to one fluoroquinolone tend to be cross-resistant to related compounds; such resistance is usually mediated by chromosomes, but plasmid-mediated resistance raises the possibility of transferable resistance.

The fluoroquinolones are broad-spectrum antimicrobials. Most enteric gram-negative bacilli, including *E. coli*, *Proteus*, *Klebsiella*, and *Enterobacter*, are highly susceptible; common GI pathogens, such as *Salmonella*, *Shigella*, and *Campylobacter* species, are also very sensitive. Other gram-negative organisms that are killed by low concentrations of the fluoroquinolones are *N. gonorrhoeae* and *N. meningitidis*, *H. influenzae*, *P. multocida*, *M. catarrhalis*, and *Y. enterocolitica*. *Acinetobacter* and *Serratia* are somewhat less susceptible. *P. aeruginosa* is susceptible to ciprofloxacin and trovafloxacin; ofloxacin and levofloxacin are moderately active, but the other quinolones are not effective. *P. cepacia* and *S. maltophilia* are quinolone-resistant. Ciprofloxacin is the drug of choice for *Bacillus anthracis*; ofloxacin and levofloxacin are also active in vitro.¹³⁷ Among gram-positive cocci, methicillin-sensitive strains of *S. aureus* and coagulase-negative staphylococci are usually susceptible to quinolones, but methicillin-resistant *S. aureus* and enterococci are not. Lomefloxacin is not active against pneumococci and

other streptococci; ciprofloxacin and ofloxacin are moderately active; and levofloxacin, sparfloxacin, gatifloxacin, moxifloxacin, and trovafloxacin are highly effective, even against non-penicillin-sensitive pneumococci. Even fastidious intracellular pathogens can be inhibited by the quinolones; *Chlamydia*, *Mycoplasma*, *Listeria*, *Legionella*, and *M. tuberculosis* are in this category. Only trovafloxacin is highly active against anaerobes. Levofloxacin, gatifloxacin, moxifloxacin, and sparfloxacin demonstrate some activity against anaerobes, but the other quinolones do not. *C. difficile* is resistant to quinolones.

The fluoroquinolones are rapidly absorbed from the GI tract. Penetration into body fluids and tissues is generally excellent; therapeutic concentrations are readily achieved in blister fluid, bile, urine, saliva and sputum, bone, and muscle. Excellent concentrations of these drugs are achieved in the prostate, and stool levels are extraordinarily high. The fluoroquinolones appear to penetrate the CSF in the presence of meningeal inflammation,¹³⁸ but experience in treating meningitis is scant.

Although serum protein binding is modest, the fluoroquinolones have long serum half-lives, which range from 3 to 4 hours for ciprofloxacin to 12 hours for moxifloxacin. Most fluoroquinolones are eliminated by glomerular filtration and tubular secretion, and their dosages should be reduced in the presence of moderately severe renal failure. Trovafloxacin and moxifloxacin, however, are excreted chiefly by the liver.

The fluoroquinolones appear to be very well tolerated, with mild GI side effects (nausea, vomiting, or anorexia), CNS side effects (light-headedness, dizziness, somnolence, or insomnia), or rash occurring in fewer than 10% of treated patients. Lomefloxacin and sparfloxacin can cause phototoxicity. Less common side effects include allergic intestinal nephritis, pseudomembranous colitis, and neutropenia. Sparfloxacin and moxifloxacin may cause QT interval prolongation and should not be used by patients who have conditions or are using drugs known to prolong the QT interval or predispose to arrhythmias.¹³⁹ Tendinitis has been reported; in severe cases, it has resulted in rupture of the tendons of the shoulder and hand and the Achilles tendon. Crystalluria has been reported after the use of very large doses. Because fluoroquinolones have caused arthropathy in young animals, these drugs should be avoided in children and in women who are pregnant or nursing. Ciprofloxacin is safe in long-term use; there is less long-term experience with the other fluoroquinolones.

The fluoroquinolones have been useful clinically in a variety of infections, including urinary tract, genital, prostatic, GI, respiratory tract, soft tissue, and bone infections. Because of its excellent activity against anaerobes, trovafloxacin was considered useful in intra-abdominal and pelvic infections, but concerns about serious hepatotoxicity have restricted its use to infections deemed life- or limb-threatening and for patients in whom the benefit of trovafloxacin outweighs its potential risks. If it must be used, liver function must be monitored carefully.

The fluoroquinolones, administered in various regimens ranging from a single dose to 5 days of therapy, are effective in preventing and treating traveler's diarrhea and shigellosis. They have been highly effective in the treatment of typhoid fever. However, prolongation of the carrier state limits their role in nontyphoidal *Salmonella* enteritis, and the development of resistance limits their role in *Campylobacter* enteritis. The fluoroquinolones may be useful in the empirical treatment of severe community-acquired gastroenteritis, particularly if treatment is started early.

Because of their extraordinarily broad antimicrobial activity, their favorable pharmacokinetics, and their low toxicity,¹⁴⁰ the

fluoroquinolones are extremely valuable new drugs. Like all antimicrobials, however, fluoroquinolones should be used judiciously, especially in view of new concerns about resistance^{141,142} and toxicity and practical considerations about expense.

ADVERSE EFFECTS

Adverse reactions to the quinolones are estimated to occur in 4% to 8% of cases.¹⁴³ Most such reactions are not severe: cessation of therapy has been necessary in only about 1% to 2% of patients, and in all cases, the reactions have been reversible. The most common adverse effects are gastrointestinal—namely, nausea, vomiting, and diarrhea. The next most common are CNS effects, which include dizziness, headache, insomnia, hallucinations, agitation, and seizures. (The last three have been attributed to coadministration of enoxacin and theophylline.) Other effects include skin rash, pruritus, photosensitivity (with ofloxacin and pefloxacin), and mild alterations in hematologic and biochemical laboratory values.

Streptogramins

Quinupristin and dalfopristin are two structurally distinct streptogramins that bind to separate sites on the bacterial 50S ribosomal subunit; they thus act synergistically to inhibit protein synthesis. The drugs are marketed together in a 30:70 ratio as Synercid.¹⁴⁴

Although quinupristin-dalfopristin is active against a variety of bacteria, its major use is in the treatment of serious infections caused by vancomycin-resistant strains of *E. faecium*. The drugs may also be useful in occasional vancomycin-intolerant patients with severe infections caused by methicillin-resistant *S. aureus* or coagulase-negative staphylococci. Resistance to quinupristin-dalfopristin is emerging.¹⁴⁵

Quinupristin-dalfopristin is administered intravenously; because of a high incidence of phlebitis, a central line should be used. Other adverse effects include arthralgias and myalgias, which may be severe, and elevated bilirubin levels. The antibiotic may elevate levels of drugs that are metabolized by the hepatic enzyme CYP3A4; nifedipine and cyclosporine are examples.

The usual dose of quinupristin-dalfopristin is 7.5 mg/kg given intravenously over 1 hour every 8 hours. The drug is metabolized by the liver, so no dose reduction is required in azotemic patients. Quinupristin-dalfopristin is extremely expensive.

Oxazolidinones

In 2000, linezolid became the first member of the oxazolidinone class to be approved for clinical use in the United States.¹⁴⁶ Linezolid is a synthetic antibiotic that inhibits protein synthesis by binding to a site on the bacterial 23S ribosomal RNA of the 50S subunit, thus preventing function of the initiation complex that is required for ribosomal function.¹⁴⁷ Because no other antibiotic acts in this way, bacteria that have developed resistance to other ribosomally active antimicrobials do not display cross-resistance to linezolid.

Linezolid is active against nearly all aerobic gram-positive cocci at concentrations of 4 mg/ml or less,¹⁴⁸ including penicillin-resistant pneumococci, methicillin-resistant staphylococci, and vancomycin-resistant enterococci; however, resistant strains have been isolated.¹⁴⁹ The drug is bacteriostatic against staphylococci and enterococci, but it is bactericidal against most streptococcal strains. Linezolid is also active against *L. monocytogenes*, *M. catarrhalis*, *H. influenzae*, *N. gonorrhoeae*, *Bordetella pertussis*, *Pasteurella*

multocida, and *Nocardia* species. *C. difficile*, *C. perfringens*, and *Bacteroides* species are susceptible, but enteric gram-negative bacilli and *Pseudomonas* species are not.¹⁵⁰

Intravenous and oral preparations of linezolid are available; the oral form is absorbed rapidly and completely with 100% bioavailability that is not affected by meals. Linezolid is widely distributed in well-perfused tissues. Nonrenal mechanisms account for 65% of the drug's clearance. Patients with mild to moderate renal or hepatic insufficiency do not appear to require reduced doses; linezolid is removed by hemodialysis.

Linezolid is well tolerated. Adverse effects have been reported in about 2.8% of all patients¹⁵⁰; nausea, vomiting, and headaches are the most common side effects, but reversible marrow suppression, including thrombocytopenia, leukopenia, and anemia, can also occur. Because linezolid is a reversible inhibitor of monoamine oxidase, patients taking linezolid may experience an exaggerated hypertensive response to sympathomimetic agents. In addition to avoiding decongestants, patients taking linezolid should avoid foods or beverages with a high tyramine content; aged cheeses, air-dried meats, tap beer, red wine, soy sauce, and sauerkraut are examples. Monoamine oxidase inhibitors and other antidepressants should not be administered during linezolid therapy.

Linezolid has been used successfully in the therapy of multidrug-resistant gram-positive bacterial infections.^{146,147,151} The drug is approved for vancomycin-resistant enterococcal infections and for pneumonias and skin and soft tissue infections. The usual dosage is 600 mg every 12 hours (p.o. or I.V.); uncomplicated skin and soft tissue infections may be treated with 400 mg every 12 hours.

Linezolid is a very promising new antimicrobial agent, but clinical experience is still limited. Although resistance is uncommon, it can develop during therapy. As a result, it may be wise to reserve this unique antibiotic for serious infections in hospitalized patients; in particular, linezolid should be useful for infections caused by methicillin-resistant *S. aureus* or coagulase-negative staphylococci that do not respond to vancomycin, for penicillin-resistant pneumococcal infections that do not respond to other agents, and for vancomycin-resistant enterococcal infection. An excellent general review of the use of linezolid in serious gram-positive infections has been published.¹⁵²

Fosfomycin

Fosfomycin is a broad-spectrum antibiotic that inhibits cell wall synthesis in infections caused by *E. coli*, *S. saprophyticus*, and many other common urinary tract pathogens.¹⁵³ Although it has been used parenterally in Europe for many years, the drug is approved in the United States only for the single-dose treatment of uncomplicated urinary tract infections in women. A 3 g dose is generally effective and well tolerated; diarrhea is the most common side effect. Because of its activity against vancomycin-resistant enterococci (VRE), fosfomycin may be a useful alternative to linezolid and quinupristin-dalfopristin in the treatment of VRE infections in certain clinical situations (e.g., uncomplicated urinary tract infections). In addition, the use of fosfomycin could limit the use of newer agents, thus reducing the chance of development of further resistance in the enterococci.¹⁵⁴

Concerns for the Future

Despite a century of often-successful prevention and control efforts, infectious diseases remain an important global problem in

public health, causing over 13 million deaths each year. Changes in society, technology, and the microorganisms themselves are contributing to the emergence of new diseases, the reemergence of diseases once controlled, and the development of antimicrobial resistance. Two areas of special concern in the 21st century are food-borne disease and antimicrobial resistance. The effective control of infectious diseases in the new millennium will require effective public health infrastructures that will rapidly recognize and respond to outbreaks and will prevent emerging problems.

Over the past 40 years, the search for new antibiotics has been largely restricted to well-known classes of compounds that are

active against a standard set of drug targets. Although many effective compounds have been discovered, insufficient chemical variability has been generated to prevent a serious escalation in clinical resistance. Recent advances in genomics have provided an opportunity to expand the range of potential drug targets and have facilitated a fundamental shift from direct antimicrobial screening programs toward rational target-based strategies. The application of genome-based technologies such as expression profiling and proteomics will lead to further changes in the drug discovery paradigm by combining the strengths and advantages of both screening strategies in a single program.

16 NOSOCOMIAL INFECTION

E. Patchen Dellinger, M.D.

Approach to Postoperative Symptoms of Infection

Nosocomial infections are a potential threat to all hospitalized patients. They increase morbidity and mortality, prolong hospital stay, increase patient care costs,¹⁻⁵ and occur in almost every body site.

At any time during hospitalization, but especially postoperatively, the onset of fever or an elevated white blood cell count may signal an infectious process. Fever that begins or persists after postoperative day 4 is more likely to represent true infection. Although an infection will not develop in many febrile postoperative patients [see Discussion, below], a careful, directed examination of the patient, guided by history and operative procedure, should be undertaken, including inspection of the ears and the pharynx. Laboratory tests and x-rays are complementary. The use of empirical antibiotics or the prolonged administration of perioperative prophylactic antibiotics in the absence of a specific diagnosis is rarely efficacious. In fact, either may confuse the clinical picture and may lead to separate toxic or allergic complications. Antibiotics alone rarely constitute an adequate response to infectious complications, especially in the early postoperative period.

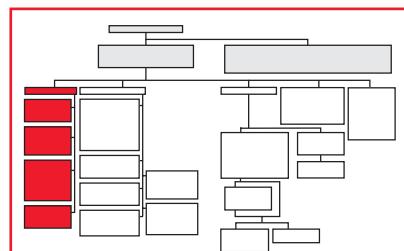

Respiratory infections are the most common early infection, with most wound infections presenting between postoperative days 4 and 7 and urinary tract infections (UTIs) occurring throughout hospitalization. However, if a high fever (temperature $> 38.9^{\circ}\text{C}$ [102°F]) develops in a patient within 48 hours of an operation, three diagnoses are most likely: atelectasis [see 8:4 *Pulmonary Insufficiency*], peritonitis caused by a leaking viscus after intra-abdominal operation [see 8:18 *Intra-abdominal Infection*], and invasive wound infection. Of these, atelectasis is most often diagnosed. It is not serious if recognized and treated. It can be diagnosed on the basis of decreased breath sounds, rales, or both on physical examination and on the basis of platelike densities or volume loss on chest x-ray. Atelectasis may be accompanied by hypoxemia and usually responds to standard physical measures. However, many patients with x-ray evidence of atelectasis are not febrile, and more than one third of patients with fever and no other apparent cause have no evidence of atelectasis.^{6,7}

Clues to the diagnosis of peritonitis caused by a leaking viscus are knowledge of problems in the conduct of the operative procedure, evidence of the hemodynamic and fluid balance changes that usually accompany a leaking viscus, and suggestive findings

on abdominal examination. Technical difficulties with anastomoses, excessive operative blood loss, and multiple bowel injuries can all increase the risk of leakage. Diffuse abdominal tenderness away from the incision, excessive fluid requirements in the early postoperative interval, and tachycardia all suggest iatrogenic peritonitis. Treatment always involves operative intervention and antibiotics. The least common cause of early high postoperative fever is an invasive wound infection, either with β -hemolytic streptococci or with clostridia. Diagnosis is made by local inspection of the wound and by a Gram stain of the wound's contents; treatment requires operative intervention in addition to antibiotics [see Infection Related to Operative Site or Injury, below].

Respiratory Infection

Pneumonia is the third most common nosocomial infection on surgical services and is the one most commonly associated with death

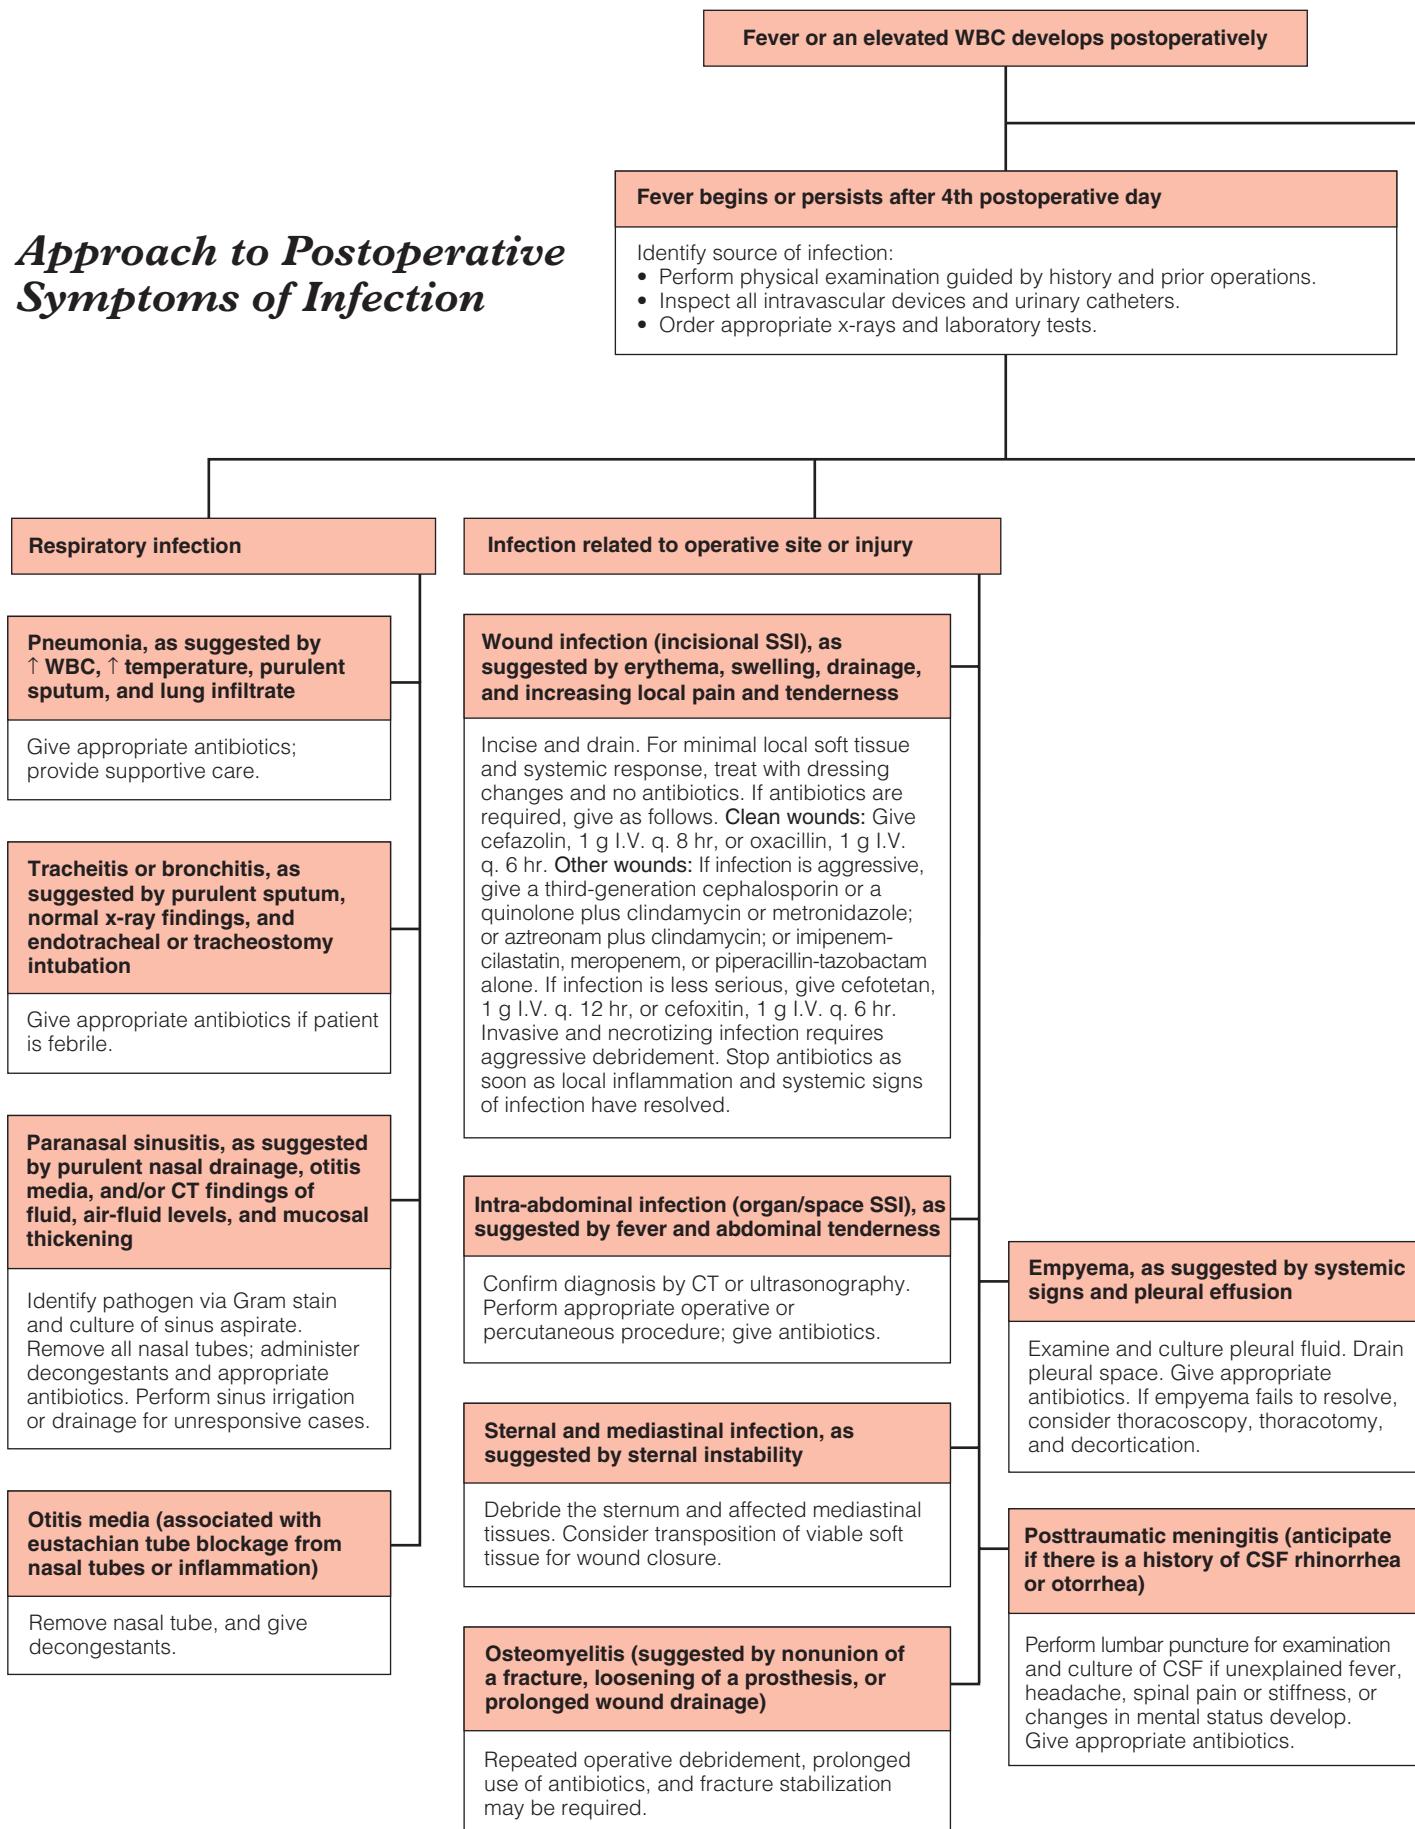

.⁸ Diagnosis

is not usually difficult in a patient without respiratory failure who is breathing spontaneously. In a patient with acute respiratory distress syndrome (ARDS) who is intubated and being ventilated, however, the diagnosis may be extremely difficult.⁹ This is because ARDS is associated with markedly abnormal chest x-ray findings and gas exchange abnormalities and may also include an elevated temperature without infection. A number of techniques for diagnosis, including bronchoalveolar lavage both with and without a bronchoscope and protected specimen brush cultures, have been reported to increase the sensitivity and specificity of diagnosis of pneumonia in this setting but have not been widely adopted.^{10,11}

The prevention of pneumonia in ventilated patients would be the best alternative, but there is not widespread agreement about the best means of prevention. Recommendations include standard infection control measures, elevation of the head of the bed, and possibly the use of endotracheal tubes that permit the aspiration of subglottic secretions.^{10,12-14}

The diagnosis of pneumonitis or atelectasis (see above) is frequently entertained during the workup of postoperative fever. It is important to remember that a common cause of basilar atelectasis and pleural effusion in the postlaparotomy patient is an inflammatory process below the diaphragm. Tracheitis or bronchitis, as indicated by purulent sputum in the absence of pul-

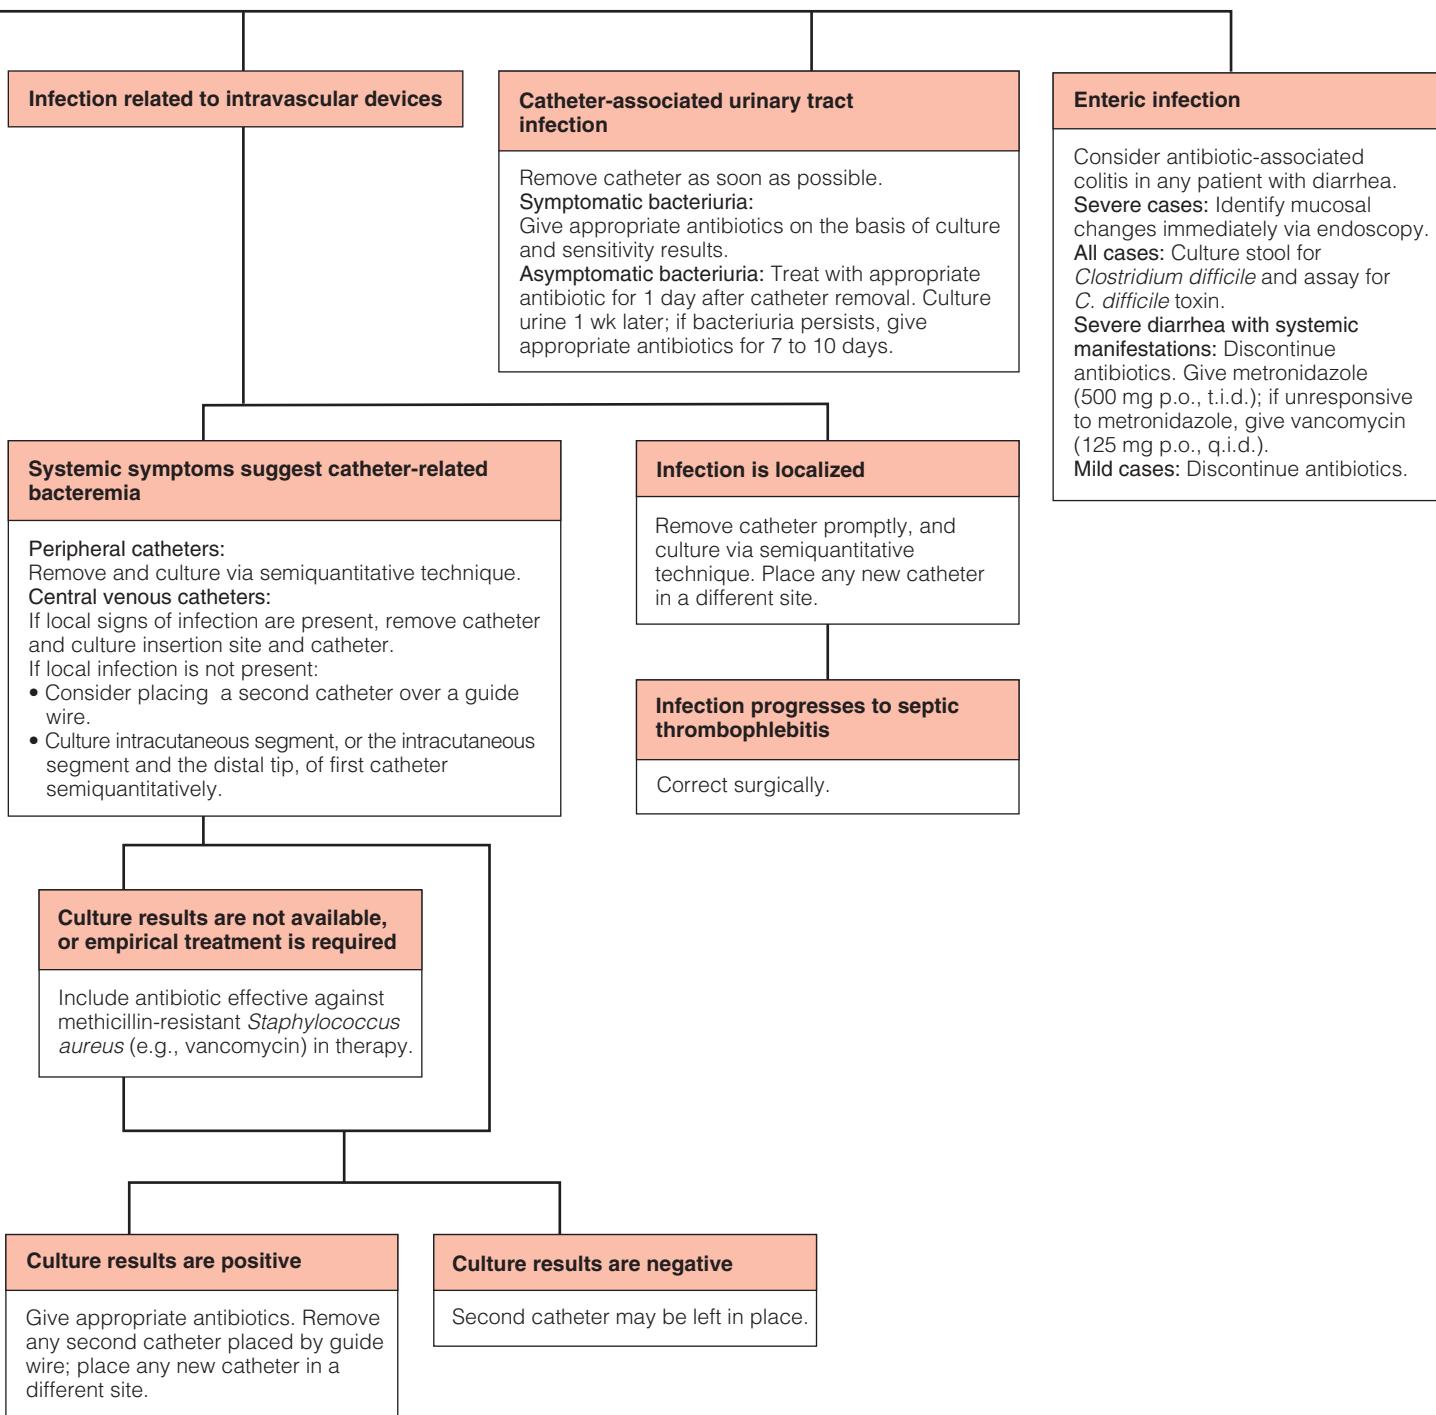

Approach to Postoperative Symptoms of Infection

High fever (> 38.9° C [102° F]) develops within 48 hr of operation

Consider:

- Atelectasis (suggested by decreased breath sounds or rales, or both, and by platelike densities or volume loss on x-ray): Manage via standard physical measures.
- Peritonitis from a leaking viscus (suggested by hemodynamic changes, diffuse abdominal tenderness, excessive early fluid requirements, and tachycardia): Treat with operative intervention and antibiotics.
- Invasive wound infection: Inspect wound and obtain Gram stain of wound contents; treat with operative intervention and antibiotics.

monary infiltrate, is often seen in modern ICUs, most commonly in association with an endotracheal or tracheostomy tube. Pneumonia may or may not follow. There is often a febrile response, in which case antibiotics may be appropriate on the basis of culture and sensitivity information. Sorting out the cause of purulent secretions in intubated patients is not easy but is important. Other causes of fever should be sought and an overall judgment rendered regarding the probable cause. If tracheitis or bronchitis is suspected, it can be treated with a brief course of antibiotics. A 2000 report described empirical treatment of patients for suspected pneumonia, followed by reevaluation at 3 days.¹⁵ By stopping antibiotic treatment at 3 days for patients without a confirmed diagnosis, the investigators were able to reduce antibiotic use threefold in that group, lower costs by more than half, and decrease the frequency with which resistant bacteria were isolated by more than half.

Paranasal sinusitis is a potentially lethal nosocomial infection, especially in ICU patients with nasogastric or nasotracheal tubes in place.¹⁶⁻¹⁸ In one report, it accounted for 5% of all nosocomial infections.¹⁶ The diagnosis of paranasal sinusitis should be considered in any febrile postoperative patient with nasal tubes or with facial fractures. Purulent nasal drainage is an important clue but may not be present. Plain films can be diagnostic but are often difficult to interpret in these patients because of superimposition of tubes, preexisting injuries, and suboptimal portable films. Fluid, air-fluid levels, and mucosal thickening are more easily detected by computed tomography. Diagnosis ultimately requires demonstration of white blood cells and bacteria on a Gram stain of sinus aspirate as well as culture for identification and sensitivity testing.

In one study of 67 patients with craniofacial injuries who underwent prospective otoscopy three times a week, 11 patients experienced either serous or purulent otitis media and were all found to have purulent paranasal sinusitis.¹⁹ Eleven of 12 patients who were ultimately diagnosed as having purulent paranasal sinusitis had coexistent otitis media.

The spectrum of causative bacteria of paranasal sinusitis is similar to that of nosocomial pneumonia. Treatment includes removal of all nasal tubes and administration of decongestants and antibiotics. Occasionally, sinus irrigation, drainage, or both may be required. If empirical therapy must be initiated before specific culture results are known, the agents chosen should be effective against bacteria known to be present in sputum. The best method of prevention is to limit the number and the duration of use of nasal tubes.

Inflammation and infection of the nasopharyngeal mucosa can be significant in an ICU patient, though it is not often identified. Eustachian tube blockage, either from tubes or from inflammation, can be associated with either serous or infective otitis media. Prudent use of tubes is the most effective preventive measure. If clinical infection is recognized, tube removal and decongestants will usually provide adequate treatment.

Infection Related to Operative Site or Injury

SURGICAL SITE INFECTION

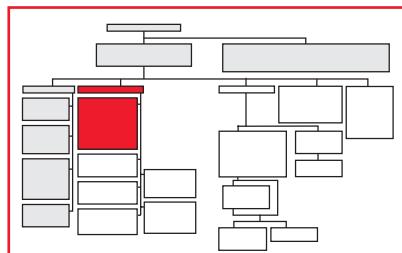

An infection of a surgical wound—that is, an incisional surgical site

infection (SSI)—traditionally reflects on a surgeon's care and skill and is the classic surgical nosocomial infection [see 1.2 *Prevention of Postoperative Infection*] Such infections are diagnosed primarily on the basis of local findings. Erythema, swelling, and drainage, as well as increasing local pain and tenderness in a site at which pain should be decreasing, all suggest infection. Fever and an elevated white blood cell count may or may not be present. An incisional SSI develops most commonly in the subcutaneous layer, though animal studies fail to explain this observation.²⁰ In an obese patient, however, a thick, overlying layer of uninfected tissue may obscure evidence of infection and thus delay diagnosis. Presentation may also be delayed if the infection begins in anatomic layers below fascial and muscular barriers, as may be the case after a thoracotomy or an operation on the femur.

Whether an infection will occur in a wound is probably determined within the first few hours of wounding^{21,22}; efforts to prevent wound infection are probably ineffective after this period.²³⁻²⁷ The incidence of SSI is reduced with appropriate use of perioperative antibiotics.^{28,29} However, there is no advantage to continuing prophylactic antibiotics beyond the perioperative period in response to fever or local wound erythema in the hope of preventing an overt SSI.³⁰⁻³²

The risk that an SSI will develop in an individual patient is best described by an index defined by the Centers for Disease Control and Prevention (CDC) in its National Nosocomial Infections Surveillance (NNIS) System. The index awards one point each for an American Society of Anesthesiologists (ASA) preoperative assessment score of III, IV, or V; an operation classified as either contaminated or dirty-infected; and an operation duration exceeding the 75th percentile for that procedure.^{33,34} Examination of the NNIS data demonstrates that in patients undergoing procedures commonly performed laparoscopically, SSI rates are decreased to levels comparable to those reported in patients with a one point lower risk index who undergo equivalent open procedures.³⁵ The CDC definitions for SSI were agreed to by a consensus panel representing the CDC, the Society for Hospital Epidemiology of America, the Association for Practitioners in Infection Control, and the Surgical Infection Society.^{34,36} In addition to appropriate use of prophylactic antibiotics, proper management of intraoperative temperature, oxygen concentrations, and blood glucose levels exerts a powerful influence on the risk of SSI and of other nosocomial infections.³⁷⁻⁴¹

Primary treatment of an SSI consists of opening the wound. When an SSI is suspected, the patient should not be given antibiotics without the wound having been opened. In most cases, the infection is confined to the incision. If the infection is of a superficial wound and if no major systemic manifestations are present, antibiotic therapy is unnecessary. If the local reaction around an infected wound is severe or extensive, administration of antibiotics is advisable until the reaction subsides (which usually takes no more than 3 days). In clean wounds that are away from the perineum and that are not associated with an operation that entered the bowel, the likely pathogens are *Staphylococcus aureus*, streptococci, or both. In such cases, treatment with cefazolin, 1 g I.V. every 8 hours, or oxacillin, 1 g I.V. every 6 hours, is satisfactory. By contrast, SSIs in the perineum and those that occur after bowel operations often involve mixed aerobic and anaerobic bacterial flora. If the infection is not very serious, it can be treated with cefoxitin, 1 g I.V. every 6 hours, or with cefotetan, 1 g I.V. every 12 hours. For more aggressive infections accompanied by evidence of tissue invasion or necrosis beyond the immediate

wound or by a severe systemic reaction, more comprehensive antibiotic treatment is indicated—that is, a third-generation cephalosporin or a quinolone combined with clindamycin or metronidazole; aztreonam combined with clindamycin; or imipenem-cilastatin, meropenem, or piperacillin-tazobactam alone. Infection of an abdominal incision may be a superficial manifestation of an underlying intra-abdominal abscess or of peritonitis.

Occasionally, infection is invasive and necrotizing. In surgical wounds, such an infection is most common after a GI procedure in which the wound was exposed to colonic microflora and in which wound closure was difficult. Necrotizing infection is also more likely in a patient who is seriously ill or who has evidence of multiple organ failure. Such infection should be suspected if there is undermining of the wound edges, extensive fascial necrosis, distant signs of infection, or a marked systemic response. It requires aggressive operative debridement and administration of antibiotics [see 3:2 Soft Tissue Infection].

Clostridium species, which can cause life-threatening postoperative necrotizing SSI, can also cause routine postoperative incisional infection limited to the wound and without myonecrosis.⁴² Such infection is marked by the absence of the systemic symptoms associated with clostridial myonecrosis and by the presence of intact white blood cells on a Gram stain of the wound contents. (Clostridial myonecrosis, on the other hand, is characterized by a Gram stain that shows gram-positive rods but few or no white blood cells [see 3:2 Soft Tissue Infection].)

INTRA-ABDOMINAL INFECTION

Intra-abdominal infections—that is, organ/space SSIs—are a major cause of postoperative morbidity and mortality, particularly when diagnosis is delayed.^{43,44}

Suspected intra-abdominal organ/space SSI in a patient with fever or abdominal tenderness, or both, after an abdominal procedure or injury should not be treated with antibiotics alone; after a specific diagnosis, the appropriate operative or percutaneous procedure must be performed [see 8:18 Intra-abdominal Infection].

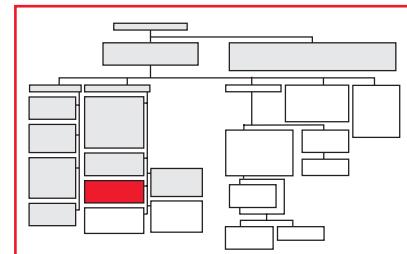

EMPYEMA

Empyema, which may follow thoracotomy or chest trauma necessitating tube thoracostomy, is a significant cause of posttraumatic infection.⁴⁵ Less commonly, empyema develops as a complication of pneumonia. Empyema should be suspected in any patient with systemic signs of infection, a pleural effusion, and no other obvious source of infection. Diagnosis requires thoracentesis of pleural fluid for a Gram stain and culture. The most common pathogen is *S. aureus*, though many other pathogens may be found as well. Initial treatment is by drainage with a chest tube and by administration of appropriate antibiotics based on the results of the Gram stain and culture. Because treatment is invasive, it should not be instituted until the diagnosis is confirmed.

Cases that do not resolve promptly and completely may ultimately require thoracoscopy or thoracotomy and decortication. Empyema after pulmonary resection or esophageal operation raises the possibility of a leaking bronchial closure or esophageal anastomosis. A leak is almost certain if an air-fluid level is present on chest x-ray. An esophageal leak is treated with repair or diversion.

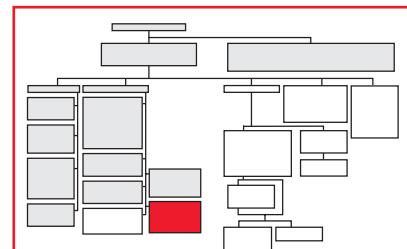

STERNAL AND MEDIASTINAL INFECTION

Sternal and mediastinal infections are the most serious infectious complications of operations that involve a median sternotomy.⁴⁶ The risk that a superficial infection will spread to involve the sternum and mediastinum is high because there is little soft tissue between the skin and the sternum. Infection may also start deep to the sternum without early superficial evidence. Sternal instability is an important indication of sternal infection. Computed tomography of the chest is sensitive and specific for the diagnosis of sternal osteomyelitis and mediastinitis.⁴⁷ All such infections require operative debridement of the sternum and of affected mediastinal tissues. Some wounds can then be closed. Many wounds require closure of the mediastinal space by transposition of viable soft tissue. Pectoralis or rectus muscle flaps, omental flaps, or both are commonly used.⁴⁸

POSTTRAUMATIC MENINGITIS

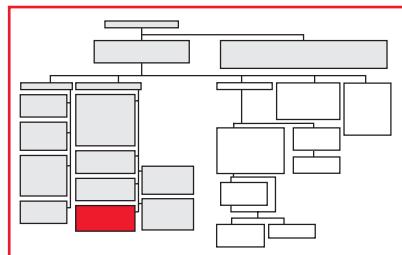

A basilar skull fracture with a cerebrospinal leak increases the risk of posttraumatic meningitis.⁴⁹ The most common pathogens are *Streptococcus pneumoniae*, *S. aureus*, other streptococcal species, and *Haemophilus influenzae*, but any oropharyngeal organism can be responsible.⁵⁰ Since the association between trauma and meningitis was first reported in 1970,⁴⁹ the appropriate use of antibiotics in these patients has been debated. Some researchers advocate prophylactic administration of antibiotics until any CSF leakage ceases,⁵¹ whereas others advocate them for an arbitrary period after injury (usually 5 days); however, controlled studies have failed to support a specific protocol.⁵⁰ Furthermore, experience in other clinical settings suggests that prophylactic antibiotics would be as likely to promote the development of resistant oropharyngeal flora and subsequent meningitis as they are to prevent it.^{52,53}

The ideal approach to patients with CSF rhinorrhea or otorrhea is to maintain a high index of suspicion for the development of meningitis. Fever not clearly attributable to another source or not immediately responsive to specific treatment for its presumed cause should prompt a lumbar puncture for examination and culture of spinal fluid. Lumbar puncture should also be performed to investigate headache, spinal pain or stiffness, or unexplained changes in mental status. Such an approach should result in a prompt diagnosis and permit early specific treatment of the responsible pathogen if meningitis is diagnosed.

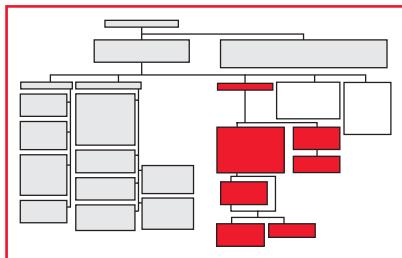

OSTEOMYELITIS

Osteomyelitis is a relatively rare complication after elective orthopedic procedures. Its diagnosis and management are similar to those of infections involving other operative sites, but because the infection is deep and covered by muscular and fascial planes, diagnosis may be delayed. Nonunion of a fracture or loosening of a prosthesis may be the first sign of infection. Infection after open fractures is common; rates range from 5% to 50%.⁵⁴⁻⁵⁶ The primary determinants of infection after open fracture are the degree of soft tissue damage surrounding the fracture and the surgeon's ability to stabilize the fracture fragments.⁵⁵ Other important factors include the patient's age and overall condition, the severity of other injuries, the interval between injury and definitive management, and the use of prophylactic antibiotics. A brief course of perioperative antibiotics may prevent subsequent infection as effectively as a more prolonged course.^{30,57}

Treatment of osteomyelitis may require repeated operative debridement, prolonged use of specific antibiotics, and fracture stabilization. Pathogens include *S. aureus* for all grades of open fracture and, increasingly, gram-negative bacteria (e.g., *Pseudomonas aeruginosa* and *Klebsiella* and *Enterobacter* species) for grade III fractures.⁵⁷

Infection Associated with Intravascular Devices

Every type and location of intravascular device has been associated with clinically significant nosocomial bloodstream infection. The incidence of infection is highest with central venous catheters used for monitoring purposes.^{58,59}

It is important to specify the different definitions of catheter infection and catheter-related bloodstream infection (CRBSI). Infection at the catheter site is commonly defined as the presence of lymphangitis, purulence, or at least two of the following: erythema, tenderness, increased warmth, and a palpable thrombosed vein. However, many cases of phlebitis with no evidence of bacterial infection present with erythema and with tenderness, a palpable thrombosed vein, or both.⁶⁰ Few or no premonitory signs occur before phlebitis is obvious, and the first evidence of as many as 45% of phlebitis cases appears more than 24 hours after catheter removal. If a functional catheter remains in place for 12 hours after the onset of phlebitis symptoms, the duration and severity of symptoms increase markedly.⁶¹

CRBSI is characterized by (1) isolation of the same organism from the catheter and the blood, (2) clinical (or autopsy) and microbiologic data disclosing no other source of the bloodstream infection, and (3) clinical features of bloodstream infection (e.g., fever and leukocytosis).⁶² For indwelling, long-term central venous catheters (e.g., Hickman, Broviac, and Groshong), infections have been classified as exit-site and tunnel infections. Infections at the exit site are defined as the presence of erythema, tenderness, induration, or purulence within 2 cm of the skin around the exit site. They are presumably confined to the portion

of the catheter external to the subcutaneous Dacron cuff. Tunnel infections are defined as the presence of the same signs along the subcutaneous tract, at a distance more than 2 cm from the tract.^{63,64} The importance of this distinction is that many infections at the exit site are successfully treated with antibiotic therapy and local wound care, whereas tunnel infections usually necessitate removal of the catheter.^{63,64}

A semiquantitative technique for culturing intravascular catheters has been shown to distinguish between infection and contamination of the catheter and is more specific in the diagnosis of CRBSI than is broth culture of the catheter.⁶² The catheter is removed from the patient after antiseptic cleansing of the insertion site to prevent contamination from surrounding skin. A 5 to 6 cm segment of the catheter is aseptically removed; transported to the laboratory in a dry, sterile tube; placed on the surface of an agar culture plate; and rolled at least four times across the surface of the plate [see Figure 1]. If the plate grows at least 15 colonies, the culture is positive. Most catheters associated with bloodstream infection actually grow more than 1,000 colonies [see Figure 1]. For peripheral catheters, the entire catheter is cultured. For central catheters that are longer than 6 cm, either the distal tip or both the intracutaneous segment and the distal tip should be cultured [see Figure 2].

The most common source of bacteria involved in catheter infection is the skin around the insertion site.^{65,66} Patients who have a skin colonization at the insertion site of greater than 10^3 colony-forming units/ 25 cm^2 are 10 times more likely to have a catheter infection than those whose skin colonization is less. Of catheters that test positive with the semiquantitative culture technique, 16% to 44% appear to be primary sources of septicemia.^{62,67-69}

The catheter hub and lumen are recognized as important routes of infection. Colonization at these sites is detected not by roll-plate cultures but by sonication culture of catheter segments or by simultaneous cultures of blood drawn through the suspect catheter and from a distant site. Either sonication cultures recovering more than 10^2 colonies or catheter cultures more than five times the number recovered from distant sites are sensitive and specific indicators of catheter infection.^{70,71}

For catheters that are only locally infected and not responsible for CRBSI, removal is adequate treatment; the same is true for most catheters that cause bloodstream infection. If the patient's temperature and white blood cell (WBC) count return to normal within 24 hours after removal of the catheter and if local signs of inflammation at the catheter insertion site resolve within that period, antibiotics are not necessary. However, if the patient continues to show clinical signs of infection or has a documented bacteremia, a brief course of specific antibiotic therapy is indicated. Specific antibiotic therapy is also indicated if semiquantitative catheter culture reveals a large number of *S. aureus* organisms in conjunction with systemic signs of infection. If empirical therapy for CRBSI is undertaken before culture and sensitivity results are available, the antibiotic regimen should include vancomycin or another antibiotic known to be effective against methicillin-resistant *S. aureus* (MRSA): coagulase-negative staphylococci are the most commonly implicated pathogens,^{58,70,72} and there is a high rate of methicillin resistance among these organisms. In candidemic patients with I.V. catheters in place, candidemia resolves an average of 3 days earlier if the catheters are removed at the time of diagnosis and initiation of antifungal therapy.⁷³

For patients with documented catheter-associated bacteremia, treatment depends on the organism or organisms present. The available data on the necessary duration of treatment for coagulase-negative staphylococci are inconclusive. Often, good results

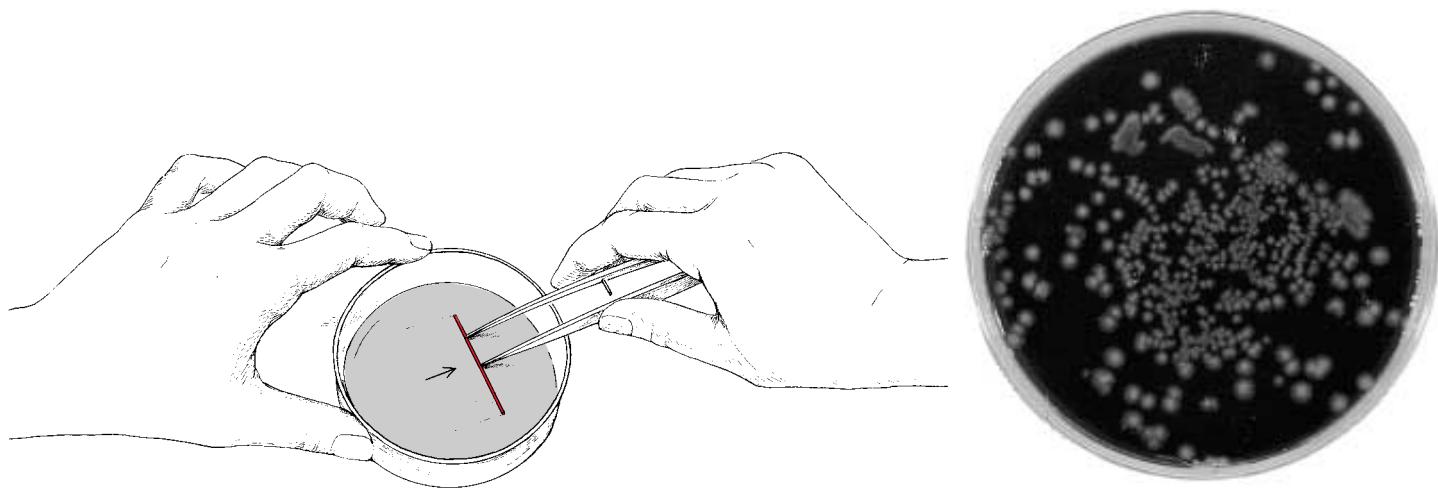

Figure 1 In a semiquantitative technique used to distinguish between infection and contamination of intravascular catheters, a 5 to 6 cm segment of the catheter is rolled at least four times across the surface of an agar culture plate (left). Typically, a positive culture grows far more than 15 colonies (right).

are achieved with catheter removal and either no antibiotics or a short course (1 to 3 days) of antibiotics; some experts recommend a 5- to 7-day course, but there is no compelling evidence that this is necessary. For *S. aureus* bacteremia, a 10- to 14-day antibiotic course is recommended if the infection is uncomplicated and a 4- to 6-week course if the infection is complicated. The relevant data on CRBSI caused by gram-negative bacilli or *Candida* are even sparser. Current recommendations call for antibiotic treatment lasting 10 to 14 days for gram-negative pathogens and 14 days or longer for *Candida*.⁷⁴

In a small proportion of patients, local catheter-related infection may progress to a life-threatening condition characterized by the formation of microabscesses within the cannulated vein and by persistent bacteremia after catheter removal. Septic thrombophlebitis can occur in a broad range of hospitalized patients and should be suspected when clinical signs of systemic sepsis, local signs of inflammation, and positive blood cultures persist after removal of the catheter. A surgical approach to the affected vein is required. When possible, the vein should be excised over the affected area and the wound left open. The presence of gross pus within the vein wall is not necessary for the diagnosis. The wall of the affected vein may simply appear thickened, with inflammation surrounding it and an edematous, pale thrombus enclosed within it. Fungal peripheral thrombophlebitis may be especially difficult to diagnose because the local site often does not appear infected. In the presence of continued candidemia without an obvious source, any palpably thrombosed vein near a site of present or previous catheterization must be suspected. Gram staining and hematoxylin-eosin staining of the vein contents or the vein wall are significantly less sensitive than silver staining and culture.⁵⁹

Even more rare is catheter-related septic central venous thrombosis. The diagnosis is made by the occurrence of (1)

thrombosis of the internal jugular, subclavian, or brachiocephalic vein proved by venography or duplex Doppler examination; (2) central venous catheter infection with positive catheter tip culture and positive peripheral blood cultures; and (3) persistent bacteremia or candidemia after catheter removal.^{75,76} Initial therapy consists of catheter removal, systemic antibiotics based on sensitivity testing and administered in a quantity and duration appropriate to treatment of endocarditis, and systemic anticoagulation during the same period. Surgical excision or drainage is reserved for failure of nonoperative measures.

At one time, it was common practice for both central and peripheral venous catheters to be either completely changed or exchanged over a guide wire at fixed intervals to reduce the risk of infection. Data from randomized, controlled, prospective trials did not demonstrate any advantage to this policy.^{60,70,77,78} These trials demonstrated that the risk of infection is linear, increasing with the duration of I.V. catheterization, whether one or multiple catheters are used.

Current practice is to change catheters when infection is suspected when the catheters are not working or not needed.^{60,70,77,79,80} Clearly, any catheter that is a cause of bloodstream infection must be removed, as should infected catheters that may not yet have caused such infection. The practical problem is that not all infected catheters show external evidence of infection. In addition, catheter culture and the subsequent clinical course confirm infection in only a small proportion of patients with central venous catheters or pulmonary artery catheters in place who are suspected on clinical grounds of having CRBSI.⁸¹ Changing central venous catheters over a guide wire circumvents most of the mechanical complications associated with central venous catheterization, saves time, and is more comfortable for the patient.⁸² However, if a culture of the first catheter is positive, the second catheter should be removed immediately, and any new

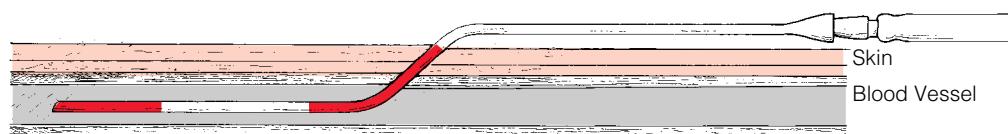

Figure 2 When a catheter is longer than 6 cm, either 5 to 6 cm of the catheter tip or both this segment and a 5 to 6 cm intracutaneous segment (red) can be cultured.

catheter should be placed in a different location.^{60,70,77,79-81}

Recommendations for changing central venous and pulmonary artery catheters are as follows:

1. Signs of inflammation, skin irritation, or purulence at the insertion site should prompt immediate removal of the catheter. Any new catheter should be inserted in a different site. In a patient with systemic signs of infection (fever, leukocytosis, malaise), culture of the insertion site or of the catheter, or both, is indicated to identify potential pathogens and to direct therapy. In a patient without systemic signs of infection, culture is not necessary.
2. If a patient with a catheter experiences systemic signs and symptoms of infection without a readily apparent source, the catheter should be removed even in the absence of inflammation at the insertion site. In this setting, however, approximately 75% of catheters are not infected, and a new catheter can be inserted at the same site over a guide wire placed through the first catheter.^{81,83-85} However, a catheter exchange places the new catheter in the old subcutaneous tunnel, which would be the most likely origin of catheter infection. The first catheter should be cultured semiquantitatively. If the culture is negative (i.e., < 15 colonies), the second catheter can be left in place. If the culture is positive (i.e., ≥ 15 colonies), the second catheter should be removed immediately, and any new catheter should be placed at a different site.

Sterile technique is always required for catheter insertion. However, most authorities advocate a surgical approach to preparation of the insertion site, with the operator wearing gown, gloves, mask, and hat for the procedure, if any of the following risk factors is present^{70,86}: (1) the location is central, (2) catheterization will probably be long term, (3) the patient is seriously ill, or (4) parenteral nutrition is to be employed. Educational efforts to reinforce these guidelines in the hospital setting can reduce the incidence of catheter-related infections.⁸⁷

Traditionally, central venous catheters have been inserted most commonly via either the subclavian or the internal jugular route. There is a well-demonstrated increase in infection risk when catheters are inserted by the jugular route instead of the subclavian.^{69,80,88} The infection rate for the femoral route of insertion appears to be higher than that for the subclavian route and possibly higher than that for the internal jugular route⁸⁹; however, it can be reduced by tunneling.⁹⁰ The femoral route can be used if other access routes are not available, but at the cost of a higher rate of thrombotic complications.⁹¹

A promising approach to prevention of catheter infection is antibiotic bonding of the entire catheter surface. Two trials reported fewer catheter and bloodstream infections in patients with antimicrobial-bonded catheters than in patients with unbonded catheters,^{92,93} and one trial reported a lower infection rate with a catheter coated on both internal and external surfaces with minocycline and rifampin than with a catheter coated only on the external surface with chlorhexidine and silver sulfadiazine.⁹⁴

The ideal method of caring for intravascular catheters after insertion is not firmly established. Sterile dressings of gauze and tape, as well as a variety of commercially available transparent dressings, have been advocated. The transparent dressings appear to save nursing time and permit the insertion site to be inspected without changing the dressing, but they promote bacterial growth on the underlying skin, as compared with gauze and tape dressings.⁹⁵ Transparent dressings have also been associated with an increased number of cases of catheter infection and CRBSI in

patients with central venous catheters.⁹⁶ Thus, use of transparent dressings is not recommended, at least for central lines.

In addition, there is no firm evidence that the use of polyanitibiotic ointments or iodophor ointments at the insertion site prevents infection, though such ointments have not been associated with an increase in infections with resistant organisms. Catheter teams are recommended to care for vascular catheters. Regular inspection of insertion sites and adherence to a specific protocol for catheter care can result in acceptably low infection rates.⁷⁰

Catheters with two or three internal lumina have become widely available and are often sold in kits that include equipment for guide-wire insertion. These catheters are more convenient when a patient requires multiple lines for monitoring and for delivery of intravenous medications and parenteral nutrition. However, these multiple-lumen lines may be associated with a higher incidence of catheter-associated bloodstream infection than are single-lumen catheters^{97,98}; the data are inconclusive.^{85,99} In one small study, the insertion of two single-lumen catheters did not result in a lower complication rate than the insertion of one double-lumen catheter.¹⁰⁰ A catheter with multiple infusion ports is likely to be manipulated more often than a single-lumen catheter, but it is unclear whether the extra manipulation results in a higher infection rate. In situations in which one lumen would suffice, the temptation to insert a multiple-lumen line in case additional lumina are needed later should be resisted. One study showed that 53% of all triple-lumen lines observed had only one lumen in use, indicating that multiple-lumen lines are often used unnecessarily.⁹⁷

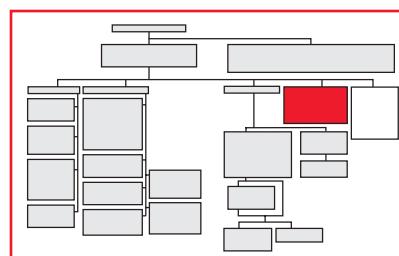

When long-term use of catheters is required, insertion of a Silastic catheter with a subcutaneous Dacron cuff (e.g., Broviac, Hickman, or Groshong) is associated with the lowest rate of catheter-associated infection and the longest useful catheter life.⁶³ In the largest reported study of these catheters, the incidence of infection was only 0.14 infection per 100 catheter-days (range, 0.0 to 0.8).⁶³ The study also showed that double-lumen catheters did not have a higher rate of infection than single-lumen catheters, but the rate of catheter infections was increased 10-fold in patients who had catheter-related thrombosis. The mean catheter life span in this report was greater than 120 days.

Very low infection rates and long catheter life are also reported with nontunneled Silastic catheters and with peripherally inserted central catheters (PICC).^{70,101} The lowest infection rates are associated with totally implantable devices with subcutaneous reservoirs.¹⁰²

Use of warfarin to prevent thrombosis may result in a reduced rate of catheter infection. A prospective trial found a clinically and statistically significant reduction in the incidence of catheter-associated thrombosis (from 38% to 10%) over 90 days with the administration of 1 mg of warfarin daily, beginning 3 days before catheter insertion.¹⁰³ Measured prothrombin times did not increase, and no bleeding complications occurred.

Urinary Tract Infection

The traditional definition of urinary tract infection in patients without urinary catheters specifies the presence of at least 10^5 organisms/ml, but this criterion is probably not appropriate for catheterized patients. Research has

shown that of catheterized patients who have any detectable organisms in their urine (even < 10^2 /ml), whose catheters remain in place, and who receive no specific antimicrobial therapy, 96% have organism counts higher than 10^5 /ml within 3 days.¹⁰⁴ (By comparison, 27% of patients with sterile urine subsequently have colony counts higher than 10^5 /ml before catheter removal.)

Although a catheter-associated UTI is a significant nosocomial infection with measurable morbidity and mortality [see Discussion, below], not all cases of bacteriuria should be treated with antibiotics. If a patient with bacteriuria is symptomatic, treatment should be initiated according to culture results and sensitivity testing. Although bacteriuria can sometimes be cleared without removal of the catheter, the risk of a new episode continues while the catheter is in place.¹⁰⁵ Ideally, the catheter should be removed as soon as possible. In one study, only 36% of untreated women with asymptomatic bacteriuria had sterile urine within 2 weeks after catheter removal, and 17% progressed to symptomatic bacteriuria; however, 81% of patients treated with a single dose of trimethoprim-sulfamethoxazole had sterile urine within 2 weeks after catheter removal.¹⁰⁶ Thus, it is prudent to obtain a culture at the time of catheter removal and to treat any bacteriuria detected.

A condom catheter is often used in male patients in place of a urethral catheter when neurologic injury or incontinence mandates long-term drainage. The available data are not sufficient to establish the ideal care of these devices and the true infection rate associated with their use. UTI rates as low as 0% in 79 patients managed with condom catheter drainage¹⁰⁷ and as high as 53%¹⁰⁵ to 63%¹⁰⁸ have been reported. Severe noninfectious local complications (e.g., ulceration and maceration of the penis) also can occur.^{107,108}

Because indwelling urinary catheters are a major source of nosocomial infection, they should be employed only when necessary and removed as soon as practicable. The most effective method of reducing infections among patients with urinary catheters is to use completely closed urinary drainage systems and to limit breaks in the closed system.¹⁰⁹ The incidence of new infections doubles on any day in which a closed urinary drainage system is opened.¹¹⁰ Urine samples for culture should be aspirated with a needle and syringe from the catheter lumen after antiseptic cleansing of the catheter sampling port. The catheter junction should not be disconnected to obtain a specimen. The use of a preconnected and sealed catheter and drainage bag system has been shown to result in a 2.7-fold reduction in the rate of catheter-associated UTIs and an adjusted risk ratio for death of 0.29.¹¹¹

Antibiotic irrigation systems do not reduce infections, but they do increase the incidence of resistant organisms.¹¹⁰ Systemic antibiotics reduce infections to a modest degree in the first 4 days of catheterization but at the expense of an increase in resistant organisms. The infection rate is higher in females than in males, in older patients than in younger ones, and in patients with critical illness than in those without critical illness.¹⁰⁹ Patients with nosocomial diarrhea and an indwelling bladder catheter have a ninefold higher risk of subsequent UTI than patients with an indwelling bladder catheter who do not have diarrhea.¹¹²

Although most UTIs acquired by hospitalized patients are assumed to be simple bladder infections, there is no strong correlation between location of infection and clinical symptoms.^{113,114} Many patients with upper UTIs do not have flank pain, fever, or other signs of systemic infection, and patients with a bladder infection may not have dysuria or suprapubic tender-

ness. Many patients with upper UTIs are treated without the diagnosis ever being made. Systemic infection and associated bacteremia or complications such as intrarenal or perinephric abscesses occur more commonly in immunocompromised patients (e.g., those with urinary tract obstruction or diabetes).¹¹⁵ In patients with a neurogenic bladder or indwelling bladder catheters, urinary sepsis may develop without symptoms referable to the urinary tract. However, symptoms of localized flank or low back pain, along with systemic signs, such as fever, rigors, sweats, and nausea, are relatively specific indicators of renal infection.¹¹⁶

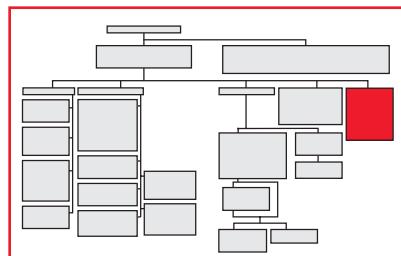

If a patient has fever and bacteriuria during the postoperative period, the surgeon should perform a careful evaluation to determine whether he or she has pyelonephritis or a postoperative intra-abdominal infectious complication. Pyelonephritis can be treated solely with antimicrobial therapy in most cases, whereas all postoperative intra-abdominal infectious complications call for surgical intervention as well as antimicrobial therapy. No simple methods are available to distinguish between these diagnoses. The operating surgeon should carefully evaluate all of the patient's clinical signs and symptoms. A hospitalized patient with pyelonephritis should usually receive antimicrobial therapy for at least 14 days. An agent demonstrated to be effective against the causative organism by in vitro sensitivity testing should be used. In any patient who has severe signs of systemic infection or does not respond promptly to treatment, ultrasonography, renal scanning, or I.V. pyelography should be done to rule out obstruction. If obstruction is found, it must be corrected. If the patient has an indwelling bladder catheter, the catheter should be removed, appropriate therapy started, and a new, clean catheter inserted.¹¹⁶

Enteric Infection

Any organism that can cause food-borne enteric infection in the community can do so in the hospital,¹¹⁷ but cultures for routine enteric pathogens are not useful for patients who have been hospitalized for more than 3 days.¹¹⁸ The most important nosocomial enteric disease to confront most surgeons is antibiotic-associated diarrhea, which can range from trivial, self-limited episodes of diarrhea to fulminant disease with systemic signs of sepsis, collapse, and death.

The first step in diagnosis is to consider antibiotic-associated colitis in any hospitalized patient with diarrhea. Mild cases may not be associated with any systemic signs or pathologic findings in the colon, and in the majority of mild episodes, there are no identifiable pathogens. More severe cases are marked by one or more of the following signs: nonspecific hyperemia, edema, granularity, or ulceration of colonic mucosa. The most severe cases are marked by pseudomembrane formation.

The single most efficient measure for detecting *C. difficile*-associated diarrhea is to send a stool sample for cytotoxin determination, a procedure that has a sensitivity of 70% to 100%. By sending a sample is sent for stool culture as well, one can increase sensitivity slightly (to 96%); however, if *C. difficile* is grown on the culture, the organism must still be tested for cytoxin production, and this takes another day.^{118,119} Rectal swab cultures transported in anaerobic containers are at least as sensitive as conventional stool cultures,¹²⁰ but they are not adequate for detection of cytoxin.¹¹⁹ Although it is possible that poly-

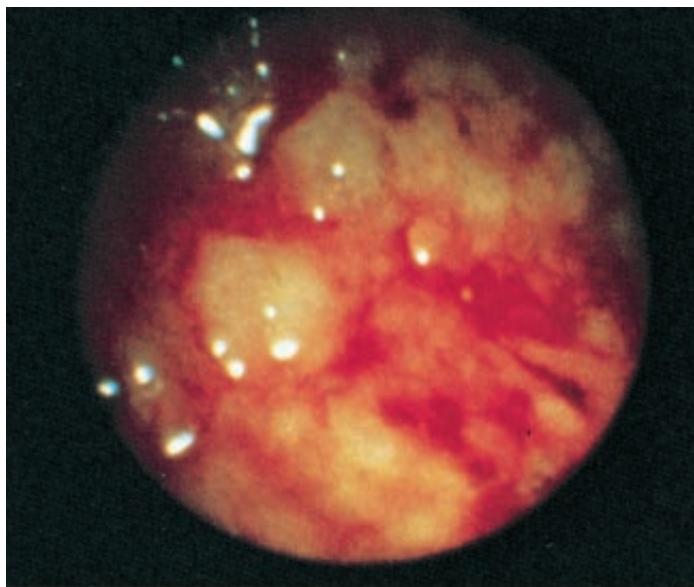

Figure 3 An endoscopic view of pseudomembrane formation is shown.

merase chain reaction assays for the cytotoxin gene in stool can eventually be developed, such assays are not available at present. Stool smears for detection of WBCs are not helpful.^{118,119} Endoscopy to detect pseudomembranes is indicated if the patient is seriously ill and a prompt diagnosis and initiation of specific treatment are desired. Administration of empirical therapy until a specific pathogen is identified is appropriate in this circumstance.¹¹⁹

Severe and persistent cases of antibiotic-associated diarrhea are most commonly associated with the recovery of *C. difficile* by culture and of *C. difficile* toxin by tissue culture assay.¹²¹ In more than 90% of patients who have pseudomembranous colitis, *C. difficile* toxin will be present on tissue culture assay. In antibiotic-associated diarrhea without pseudomembrane formation, positive toxin titers may be found in 70% of patients with signs of colitis and in 11% to 27% of patients without colitis.¹²²⁻¹²⁴

Pseudomembranes, present in about half of patients with *C. difficile*-associated diarrhea,¹¹⁹ are elevated, whitish plaques that vary in size from a few millimeters to 1 to 2 cm and may coalesce and slough. Histologically, the plaques show epithelial debris, polymorphonuclear infiltrate, chronic inflammatory cells, and fibrin deposition.¹²¹ The diagnosis of pseudomembrane formation is made by endoscopy [see Figure 3]. Most cases involve the rectum and the left colon, but as many as 25% may be missed by rigid sigmoidoscopy; by comparison, the false negative rate with flexible endoscopy is only 10%.¹²⁵ Although the great majority of cases involve only the colon, two fatal cases that primarily involved the ileum and the jejunum have been recorded.^{126,127} The clinical picture of pseudomembranous colitis includes watery diarrhea in 90% to 95% of cases, with bloody diarrhea in the remaining cases. Abdominal cramps, leukocytosis, and elevated temperature are present in approximately 80% of cases.¹²¹

All commonly employed antibiotics have been implicated in cases of antibiotic-associated pseudomembranous colitis, including vancomycin¹²⁸⁻¹³⁰ and antibiotics used for perioperative antibiotic prophylaxis, even in a single dose.¹³¹ Treatment should include cessation of the offending antimicrobial agent, if possible. In mild cases, this step may be all that is necessary: in 23% of

such cases, resolution occurs within 2 to 3 days of discontinuance of antibiotic therapy.¹¹⁹

A patient with systemic symptoms should also receive one of the agents with proven efficacy against the disease. The agent with which there has been the most recorded experience is vancomycin, but it is more expensive than the alternatives. The usual dosage is 500 mg/day orally in four divided doses. Metronidazole, 500 mg three or four times daily for at least 10 days, is an effective alternative.¹³² Bacitracin, 20,000 to 25,000 units four times daily, is also effective but should be considered the third choice.^{119,132} The current recommendation is to begin therapy with metronidazole to reduce the risk of inducing vancomycin-resistant enterococci [see Pathogens, below].^{119,133}

Relapses after treatment for *C. difficile* colitis are common, occurring in 5% to 30% of cases, perhaps because of persistence of the organism in spore form; 92% of these cases respond to a second course of treatment without relapse.^{119,132} Cases that do recur involve both persistent infection and new reinfection.¹³²

A profound ileus is sometimes associated with the severe form of the disease and may prevent the delivery of oral antibiotics to the site of infection. Limited experience suggests that parenteral metronidazole may be effective in these cases. However, there have been several cases of unsuccessful treatment of *C. difficile*-associated colitis with I.V. metronidazole and of the development of *C. difficile* colitis in patients receiving I.V. metronidazole alone or together with other antibiotics.^{132,134} In the most severe cases, the clinical evolution resembles that of toxic colitis associated with inflammatory bowel disease, and the patient may require a colectomy if the disease is unresponsive to nonoperative management. If operative treatment proves necessary, subtotal colectomy is preferred to hemicolectomy.¹³² In as many as 5% of cases, colitis may present as acute abdominal pain and tenderness and leukocytosis without diarrhea.^{135,136} Any patient with acute abdominal symptoms who has received antibiotics within the past 2 months should be considered for the diagnosis of *C. difficile*-associated colitis.¹³² If colitis is suspected because of previous antibiotic administration, sigmoidoscopy may facilitate the correct diagnosis and avert unnecessary abdominal exploration. CT may show thickening of the bowel wall, but operative exploration often does not yield significant findings.¹³⁶ Extraintestinal infections have also been reported.¹³⁷

Transfusion-Associated Infection

The transfusion of blood would seem to be an excellent method for transmitting blood-borne diseases; however, transmission of disease by blood transfusion is rare.^{138,139} Transfusion-associated malaria is occasionally reported in North America but occurs quite infrequently. The primary method for preventing malaria transmission is careful screening of donors by history. A handful of cases of babesiosis, Chagas disease, trypanosomiasis, toxoplasmosis, and infections with various herpesviruses, parvovirus, or West Nile virus have been reported over many years, but these are rare as well.¹³⁸⁻¹⁴¹

In the early years of blood collection and transfusion, cases of syphilis related to blood transfusion were reported infrequently. The practice of refrigerating blood, which kills circulating spirochetes within 1 to 2 days, is probably responsible for the absence of transfusion-associated syphilis today. Unfortunately, refrigerating blood does not kill all potential pathogens. Bacterial pathogens that can survive blood storage and cause subsequent symptomatic infection include *Yersinia enterocolitica*, *Pseudomonas fluorescens*, *P. putida*, *Campylobacter jejuni*, *Escherichia coli*, *Serratia*

species, *Salmonella* species, *Enterobacter* species, *Providencia* species, *S. aureus*, and streptococci. When transfusion-associated bacteremia or endotoxemia is suspected, the residual blood product in the bag should be examined by means of a hematologic stain, and the blood in the bag and samples of the recipient's blood should be cultured.

Bacterial contamination of transfused blood components accounted for 11% of all fatal transfusion reactions reported to the FDA between 1985 and 1999. In 2001, CDC investigators published a prospective survey of bacterial infections resulting from blood component transfusion in the United States between January 1998 and December 2000.¹⁴² This survey covered approximately 60% to 70% of all transfusions recorded in the United States during that period. The investigators identified 34 confirmed cases of bacterial infection from transfused blood components, nine (27%) of which were responsible for deaths. The estimated rates of transfusion-transmitted bacteremia were one per 100,000 single or pooled units of platelets and one per 5 million units of red blood cells. The estimated fatality rates were one per 500,000 units of platelets and one per 8 million units of red blood cells.

Until recently, the most severe and most common disease transmitted by blood transfusion in North America was viral hepatitis [see 8:20 *Viral Infection*]. With the development of specific and sensitive tests for detecting hepatitis B surface antigen (HBsAg), the incidence of posttransfusion hepatitis B dropped from 25% to 30% of all cases of transfusion-associated hepatitis to 5% to 10%. However, the advent of serologic tests for hepatitis B did not result in an overall decrease in posttransfusion hepatitis (PTH), because 80% to 90% of cases of PTH were caused by hepatitis C virus (HCV). Since the development of sensitive antibody tests for HCV, the incidence of PTH has dropped dramatically, and since the introduction in 1999 of nucleic acid amplification technology (NAT) (e.g., PCR and transcription-mediated amplification), it has fallen even further, to the point where the current estimated risk is one per 1.9 million transfused units.¹⁴³

The spread of AIDS [see 8:21 *Acquired Immunodeficiency Syndrome*] brought a new risk of transfusion-associated viral disease. The risk of acquiring transfusion-associated HIV infection is extremely low compared with posttransfusion hepatitis; transfusion-associated HIV infection is vastly less likely to occur and

has accounted for fewer deaths. Nevertheless, transfusion-associated AIDS is much more frightening to most patients and physicians than PTH because of its usually fatal prognosis. Prevention of HIV transmission during transfusion is accomplished by screening potential donors to eliminate those at high risk for infection and by testing all donated units for HIV with both antibody tests and NAT.¹⁴³⁻¹⁴⁵ It has been estimated that predonation screening is 98% effective in eliminating donation of positive units and that postdonation antibody testing is more than 95% effective, for a combined effectiveness of approximately 99.9%.¹⁴⁴ Overall, posttransfusion HIV infections were reduced by 76% between 1985 and 1988, a time during which the overall prevalence of the condition was increasing.¹⁴⁴

The continued concern about possible HIV transmission during transfusion arises from the so-called window of seronegativity between the time at which a potential donor becomes infected and the time at which the donor's antibody test becomes positive. A 1989 analysis of available data from most United States blood banks concluded that the risk of receiving a unit of blood that contained HIV but was negative for anti-HIV antibody in 1987 was approximately one per 153,000 transfusions on the basis of an average window period of 8 weeks.¹⁴⁴ A 2002 report, making use of data obtained since the introduction of NAT, established the current risk at one per 2.1 million transfusions.¹⁴³ In comparison, the risk of experiencing a fatal hemolytic transfusion reaction is one per 100,000 transfusions.¹⁴⁵ Thus, a transfusion recipient is much more likely to die of a hemolytic reaction than of infection.

Analysis of transfusion practices in the United States between 1982 and 1988 reveals a decrease in the number of blood, platelet, and plasma transfusions after 1986; before 1986, the number of these transfusions increased each year. In addition, between 1982 and 1987, the number of autologous units donated increased from 30,000 to 397,000 a year. In 1987, autologous units accounted for 3% of all blood transfused.¹⁴⁶ Since 1987, refinements of operative techniques have reduced the need for transfusion in many procedures, and research has demonstrated that in many cases, transfusion can safely be withheld until hemoglobin levels lower than 7 g/dl are reached [see 1:4 *Bleeding and Transfusion*.]¹⁴⁷ In addition to the overall decline in transfusions since the late 1980s, the number of autologous units of blood transfused yearly has declined.¹⁴⁸

Discussion

Postoperative Fever

Many patients experience fever in the postoperative period without infection. In a prospective study of 871 general surgery patients, 213 (24%) had a documented infection or an unexplained fever in the postoperative period.¹⁴⁹ The most common occurrence was unexplained fever in 81 cases (38%), followed by wound infection in 55 (26%), UTI in 44 (21%), respiratory tract infection in 27 (13%), and other infections in 6 (3%). Of all unexplained fevers, 72% occurred in the first 2 days, and of all occurrences in the first 3 days, 67 (71%) of 95 were unexplained, with only 18 (27%) representing true infection. In another study, 73 (45%) of 162 patients experienced unexplained fever after general surgical or orthopedic procedures; 25% of the unexplained fevers were at least 38.3° C (101° F).¹⁵⁰

At Harborview Medical Center, 316 (98%) of 322 patients who underwent laparotomy for penetrating trauma had a temperature of at least 37.5° C (99.5° F) orally during the first 5 days after operation. Of these patients, however, only 67 (21%) actually acquired any infection during a 30-day follow-up. Even for the 80 patients whose temperatures were as high as 39° C (102.2° F) orally, only 48% actually acquired an infection before discharge. Fever that persisted or began after postoperative day 4 was more likely to represent true infection. Similarly, an elevated WBC count was nonspecific during the first 5 postoperative days: 89% of all patients had a WBC count greater than 10,000/mm³.^{151,152} A high fever should prompt examination of the patient, but in the absence of systemic signs of sepsis, an extensive laboratory or radiologic workup during the first 4 to 5 days is usually unhelpful.¹⁵³

Magnitude and Significance of Nosocomial Infection

An understanding of the prevalence of nosocomial infections and of the factors predisposing to their occurrence will help in prevention, diagnosis, and treatment. Since 1970, the NNIS system has collected and analyzed data on the frequency of nosocomial infections in a voluntary sample of hospitals (currently numbering 280) in the United States.¹⁵⁴ Although it has been suggested that the NNIS system underestimates the true incidence of nosocomial infections by 30% to 40%,^{3,155,156} the large number of cases studied during consecutive years provides a useful description of the most frequently encountered infections, their relative incidences, and the responsible pathogens.

INCIDENCE
