Amsterdam criteria II ⁵¹	Three or more relatives with an HNPCC-associated cancer (in colorectum, endometrium, small bowel, ureter, or renal pelvis) One first-degree relative of the other two Two or more successive generations One CRC diagnosed at age < 50 yr FAP excluded

surement of CA125 levels starting at 25 to 35 years of age, as well as annual endometrial aspiration.⁵⁶ Annual EGD is recommended for patients belonging to kindreds with a history of gastric cancer. Finally, ultrasonography and urine cytology every 1 to 2 years may be considered to screen for urinary tract malignancy.

MANAGEMENT

Surgical Therapy

Although the development of CRC in persons with HNPCC is not a certainty, the 80% lifetime risk,¹ the 45% rate of metachronous tumors, and the possibility of an accelerated adenoma-carcinoma sequence⁴ mandate consideration of prophylactic surgical options. Patients who have HNPCC as defined by their genotype or the Amsterdam criteria [see Table 3] and who have a colon cancer or more than one advanced adenoma should be offered either (1) prophylactic total abdominal colectomy with IRA or (2) segmental colectomy with yearly colonoscopy [see 5.34 *Laparoscopic Colectomy*.]^{11,57,58} (The first option, however, is open only to patients with normal rectal and anal sphincter function.) Although the risk of metachronous colon cancers may be higher after partial colectomy than after total colectomy with IRA, intensive colonoscopic surveillance and polypectomy may minimize the number of metachronous cancers in the remaining colon.^{52,59} Careful surveillance is also necessary after total colectomy and IRA, given that the risk of metachronous rectal cancer after total colectomy is approximately 12% at 10 to 12 years.⁶⁰

HNPCC patients with an index rectal cancer that is amenable to a sphincter-preserving resection should be offered either (1) total proctocolectomy with IPAA [see 5.33 *Procedures for Ulcerative Colitis*] or (2) low anterior resection (LAR) with primary reconstruction [see 5.35 *Procedures for Rectal Cancer*.]^{11,58} The rationale

Table 4 Revised Bethesda Guidelines for Testing CRC Patients for MSI⁵⁵

CRC diagnosed at age < 50 yr
Presence of synchronous or metachronous CRC or other HNPCC tumors (regardless of age)
CRC with HNPCC-like histology at age < 60 yr
CRC in one or more FDR with an HNPCC-related tumor (one diagnosed at age < 50 yr)
CRC in two or more first- or second-degree relatives with HNPCC-related tumors (regardless of age)
FDR—first-degree relative

for total proctocolectomy is based on the 17% to 45% rate of metachronous cancer in the remaining colon associated with an index rectal cancer in HNPCC patients.⁶¹ The decision between the two procedures depends in part on the patient's willingness to undergo intensive surveillance of the retained proximal colon, as well as on the level of bowel function.

Mutation-positive patients with a normal colorectum may also be offered prophylactic colectomy in selected cases.^{56,62} This approach is supported by the similarity of lifetime cancer risk between patients with germline *APC* mutations and those with MMR mutations, as well as by the observation that total abdominal colectomy with IRA yields less functional disturbance than the prophylactic procedure recommended for FAP (total proctocolectomy with IPAA).^{56,62} An alternative strategy in these patients is to carry out colonoscopic surveillance at 1- to 3-year intervals. This strategy has proved to be cost-effective⁶³ and to reduce both the rate of CRC development and overall mortality.^{52,64,65} There is a risk that CRC may develop in the intervals between colonoscopies^{64,66}; however, when the surveillance interval is shorter than 2 years, tumors tend to be found in their early stages and to be curable when found.^{52,64}

A study using a decision-analysis model suggested that prophylactic total abdominal colectomy at the age of 25 might offer a survival benefit of 1.8 years when compared with colonoscopic surveillance. The benefit of prophylactic colectomy decreased when surgery was delayed until later in life and became negligible when it was performed at the time of cancer development.⁶⁵ However, surveillance provided a greater benefit with respect to quality of life (measured in quality-adjusted life years).⁶⁵ On the basis of this evidence, some surgeons recommend that prophylactic colectomy be performed only in highly selected situations (e.g., when colonoscopic surveillance is not technically possible or when a patient refuses to undergo regular surveillance). Thus, the decision between prophylactic surgery and surveillance for gene-positive unaffected patients is based on many factors, including the penetrance of disease in a family, the age of cancer onset in family members, functional and quality-of-life considerations, and the likelihood of patient compliance with surveillance.

Extracolonic Disease

Management of extracolonic cancers in HNPCC patients is not yet well defined. Female patients with a family history of uterine cancer should be offered prophylactic total abdominal hysterectomy (TAH) if their childbearing is complete or if they are undergoing abdominal surgery for other conditions.¹¹ This recommendation is based on the high (43%) rate of endometrial cancer in mutation-positive persons,⁵³ particularly those with *HMSH2* mutations, and on the inefficacy of screening in some studies.⁶⁷ Oophorectomy should be added to TAH because of the high (9%) incidence of ovarian cancer in HNPCC patients⁵³ and the frequent coexistence of endometrial cancer with ovarian cancer.⁶⁸ The optimal timing for prophylactic TAH is unclear; however, endometrial cancer has been reported in HNPCC patients before the age of 35. At present, it seems reasonable to begin surveillance at the age of 25 and delay prophylactic surgery until childbearing is complete.¹¹

Peutz-Jeghers Syndrome

Like FAP and HNPCC, PJS follows an autosomal dominant pattern of inheritance with variable penetrance. It is caused in part by mutations in the gene *LKB1/STK11*, which maps to the telomeric region of chromosome 19p13.3. This gene, which codes for

a multifunctional serine-threonine kinase, is thought to function as a tumor suppressor gene.^{69–72} Germline mutations in *LKB1/STK11* can be demonstrated in 18% to 63% of PJS patients, which suggests the existence of additional PJS loci.^{72–75} Genetic testing for PJS can be accomplished through direct sequencing of the *LKB1/STK11* gene [see Table 2]; however, such testing is not widely available. In families with an established mutation, genetic testing of at-risk individuals is informative, with a reported accuracy of 95%.⁷⁶

CLINICAL EVALUATION

PJS is a hereditary polyposis syndrome characterized by hamartomas of the GI tract, as well as by mucocutaneous melanin pigmentation. Hamartomatous polyps may occur throughout the GI tract but are most frequently found in the small intestine (90%). Other common sites of hamartomas in PJS are the large intestine (50%) and the stomach; less common sites are the renal pelvis, the bile ducts, the urinary bladder, the lungs, and the nasopharynx.^{1,77,78} Mucocutaneous pigmentation generally appears during infancy. The perioral and buccal areas are involved in 95% of cases; the periorbital and facial areas, the genital region, and the acral areas (including the hands and feet) may be involved as well.¹ The average age of diagnosis of PJS is 22 years in men and 26 years in women.

In as many as 86% of cases, the initial presentation of PJS is small bowel obstruction secondary to intussusception of hamartomas. Other presentations include acute or chronic GI bleeding, biliary and gastric outlet obstruction, and anal protrusion of polyps. The diagnosis of PJS is established by the presence of histologically confirmed hamartomas of the GI tract plus two of the following three criteria: (1) small bowel polyposis, (2) mucocutaneous melanotic pigmentation, and (3) a family history of PJS [see Table 1].⁷⁹

Patients with PJS are at significantly increased risk for both intestinal and extraintestinal malignancies. A meta-analysis found that in comparison with the general population, PJS patients were at a relative risk of 15.2 for the development of any malignancy.⁸⁰ The relative risks for the development of specific cancers were as follows: small bowel, 520; gastric, 213; pancreatic, 132; colorectal, 84; esophageal, 57; ovarian, 27; lung, 17; endometrial, 16; and breast, 15. The cumulative risk for the development of any cancer between the ages of 15 and 64 was 93%.⁸⁰ Other cancers associated with PJS are cholangiocarcinomas, testicular neoplasms, and duodenal tumors.¹

Although the relative risk for the development of CRC was high in this study,⁸⁰ the reported magnitude of risk in the individual studies included in the meta-analysis varied considerably. Previous studies also reported a wide range of CRC incidences in these patients.¹ Thus, the true incidence of CRC in PJS patients remains unclear.

INVESTIGATIVE STUDIES

Pathologic Findings

The polyps seen in PJS are hamartomas characterized by hypertrophy or hyperplasia of the smooth muscle of the muscularis mucosa. Smooth muscle extends into the superficial epithelial layer of the bowel wall in a treelike fashion (a process referred to as arborization). Epithelial cells may become entrapped within the muscle layer, and this "pseudoinvasion" can be mistaken for malignant transformation. Therefore, to diagnose a malignancy in a PJS polyp, cellular atypia or an elevated mitotic rate must be documented.⁸¹ Sporadic PJS polyps do occur, generally secondary

to somatic *LKB1/STK11* mutations in one or both alleles, and are histologically identical to their hereditary counterparts. These sporadic polyps appear not to be associated with an increased risk of GI cancer.⁸²

Histologically, areas of cutaneous pigmentation reveal an increased number of melanocytes at the dermal-epidermal junction, with elevated melanin levels in the basal cells. These lesions do not appear to have any malignant potential.

Screening and Surveillance

Clinical screening of asymptomatic persons is facilitated by the appearance of perioral hyperpigmentation during early childhood. Once the diagnosis of PJS is made, patients generally enter a surveillance program. Recommended surveillance for GI disease includes annual serum hemoglobin measurement and EGD every 2 to 3 years, beginning between the ages of 10 and 25.^{79,83-85} Contrast radiography is employed to examine the remainder of the small bowel, beginning at the age of 10 and repeated every 2 to 3 years.^{79,85} The frequency of surveillance examinations may be modified in individual circumstances. Colonoscopic surveillance is also important, commencing between puberty and the age of 25 and repeated every 2 to 3 years.^{83,85} Sigmoidoscopy should not be employed for surveillance, because the rectum may be spared in some patients with more proximal disease. Organ-specific surveillance for other associated malignancies should also be initiated in accordance with current high-risk recommendations.

MANAGEMENT

Medical Therapy

Cyclooxygenase-2 (COX-2) is known to be overexpressed in the hamartomatous tissue of PJS patients, and there is a correlation between expression of the COX-2 protein and expression of the *LKB1/STK11* protein in PJS polyps and cancers.^{86,87} These findings suggest that COX-2 may be a potential target for chemoprevention of PJS.

Surgical Therapy

Indications for surgical management of PJS include the presence of polyps larger than 1.5 cm that cannot be removed endoscopically, incomplete removal of polyps with adenomatous changes, the development of polyp-associated complications (e.g., obstruction, intussusception, and bleeding), and the management of malignant disease.⁸⁸

Endoscopic polypectomy is generally employed as initial therapy when it is technically feasible. For some polyps, however, operative polypectomy performed through an enterotomy is required. Segmental resection should be avoided. In the context of a laparotomy, intraoperative endoscopy (either peroral or via an enterotomy) allows direct visualization of the remainder of the small bowel and endoscopic clearance of any synchronous polyps. This procedure significantly reduces the need for subsequent laparotomy. The St. Mark's Hospital group in London found that none of 25 patients who underwent enteroscopy during laparotomy required subsequent laparotomy within a 4-year period, whereas 17% of historical control patients who did not undergo intraoperative enteroscopy required repeat laparotomy within a 1-year period.⁸⁹

Laparoscopy-assisted polypectomy and laparoscopic management of small bowel intussusception are additional surgical options.

Given the risk of CRC development in PJS patients, careful colonoscopic surveillance is clearly warranted. However, the role of prophylactic colectomy in patients who are at risk or are mutation

positive is unclear. Because the true risk of CRC in these patients is unknown and genetic testing for PJS is not widely available, no recommendations can be made at present regarding the role of prophylactic colectomy in the PJS population.⁸⁸

Juvenile Polyposis Syndrome

Initial evidence suggested that mutations in the *PTEN* gene were responsible for JPS⁹⁰; however, subsequent evidence implicated *SMAD4/DPC4* at 18q21.1 as a more common cause, accounting for as many as 50% of familial cases.⁹¹⁻⁹³ Mutations in *BMPR1A* at 10q22-q23 have also been reported to cause JPS but display variable penetrance [see Table 2].^{94,95} Clonal genetic alterations are detected in stromal rather than epithelial cells, which suggests that the genetic changes in juvenile polyps originate in the nonepithelial component of the polyps.

CLINICAL EVALUATION

Like PJS, JPS is characterized by the development of multiple hamartomas throughout the GI tract. Isolated juvenile polyps are common in children and are found in approximately 1% of persons younger than 21 years. Juvenile polyposis, however, is much less common. A family history of juvenile polyposis is present in 20% to 50% of patients.¹ Although JPS is an autosomal dominant disorder, its variable penetrance results in a less obvious pattern of inheritance than is seen with FAP or HNPCC.

JPS affects the two sexes equally and generally manifests itself during the first or second decade of life (mean age at diagnosis, 18.5 years).¹ Common presenting symptoms include chronic anemia, acute GI bleeding, prolapse of rectal polyps, protein-losing enteropathy, and intussusception with or without obstruction.¹

Extracolonic manifestations of JPS include gastroduodenal and small bowel polyps, malrotation of the midgut, and mesenteric lymphangiomas. Extraintestinal manifestations include clubbing, hypertrophic pulmonary osteoarthropathy, hydrocephalus and macrocephaly, alopecia, cleft lip and palate abnormalities, supernumerary teeth, porphyria, congenital cardiac and arteriovenous malformations, psoriasis, vitellointestinal duct abnormalities, renal structural abnormalities, and bifid uterus and vagina. JPS is also part of the phenotype for Ruvalcaba-Myhre-Smith syndrome and Gorlin syndrome. Cowden disease, which is characterized by hamartomatous polyposis and is associated with breast and thyroid cancer, may be a phenotypic variant of JPS.^{1,95}

The diagnostic criteria for JPS are as follows: (1) the presence of three or more juvenile polyps of the colon; (2) the presence of juvenile polyps throughout the entire GI tract; or (3) the presence of any number of polyps in a patient with known family history of JPS [see Table 1].⁸⁵ The clinical presentation of JPS can be divided into three main clinical variants: (1) JPS of infancy, which is a non-sex-linked recessive condition characterized by failure to thrive, susceptibility to infections, protein-losing enteropathy, bleeding, diarrhea, rectal prolapse, intussusception, and death by the age of 2 years in severe cases; (2) generalized JPS, which occurs in the first decade of life and is characterized by juvenile polyps throughout the GI tract; and (3) JPS of the colon, the most common presentation, which is characterized by colonic polyposis only.¹

Patients with JPS appear to be at increased risk for GI malignancies, especially CRC. One study estimated the risk of CRC to be 15% by age 35 and 68% by age 65.⁹⁶ In another study, GI malignancies (mostly CRC) were diagnosed in 36 (17%) of 218 JPS patients at a mean age of 33 years.⁹⁷ Associated gastric, pancreatic, and duodenal cancers have also been reported. CRCs are thought to arise from malignant transformation of dysplastic

polyps.¹ Adenocarcinomas occur, on average, 15 years after diagnosis of JPS and generally are poorly differentiated or mucinous tumors with a poor prognosis.¹

INVESTIGATIVE STUDIES

Pathologic Findings

The number of polyps seen in JPS patients varies but typically ranges from 50 to 200. The polyps are usually smaller than 1.5 cm but can be as large as 3 cm. Grossly, they appear as red-brown, smooth, pedunculated lesions with lobulated or spherical heads and superficial ulceration; the cut surface demonstrates cystic spaces corresponding to mucus-filled glands. Histologically, polyps are characterized by an inflammatory infiltration of the lamina propria, an attenuated smooth muscle layer, and cystically dilated mucus-filled glands lined by columnar epithelium. Focal epithelial hyperplasia and dysplasia may be present.

Screening and Surveillance

Initial evaluation of the proband and the first-degree relatives, which ideally would be done in the middle to late teenage years, should include colonoscopy, EGD, and a small bowel series. If the

initial evaluation yields negative results, a repeat evaluation should be performed in 3 years, then every 3 years thereafter as long as the results remain negative. If disease is encountered, random biopsies of polyps and intervening mucosa should be performed to detect adenomatous and dysplastic changes. Management depends on the presence of symptoms and on the extent and severity of polyposis. When polyposis is mild, endoscopic management may be feasible. Continued annual surveillance after endoscopic management is required; the surveillance interval may be lengthened to 3 years if subsequent evaluations reveal no disease.^{1,85}

MANAGEMENT

Surgical Therapy

When polyposis is severe or significant symptoms are apparent, prophylactic colectomy with IRA may be considered for suitable surgical candidates. Although rectal polyposis can generally be managed with rigid or flexible proctoscopy, IPAA may be considered if the polyposis is extensive. Continued annual surveillance of the rectal remnant (after IRA) or the ileal pouch (after IPAA) is required initially. Surveillance intervals may be increased to 3 years if subsequent evaluations find no evidence of disease.^{1,85}

15 ADENOCARCINOMA OF THE COLON AND RECTUM

Bruce M. Brenner, M.D., F.A.C.S., and David M. Ota, M.D., F.A.C.S.

Colorectal cancer (CRC) remains a major public health problem throughout the world. In the United States, CRC is the third most frequently diagnosed cancer in both men and women and the second most common fatal cancer (behind lung cancer).¹ During 2004, there were an estimated 106,000 cases of colon cancer and 41,000 cases of rectal cancer in the United States, resulting in 57,000 total deaths.¹ The cost of treating colorectal cancer in the United States is believed to be between 5.5 and 6.5 billion dollars a year.² Worldwide, the risk of death from CRC is highest in developed countries and especially low in Asia and Africa.³

Data from the Surveillance, Epidemiology, and End Results (SEER) program indicate that the overall incidence of and mortality from CRC have been decreasing in the United States among both men and women,⁴ though they remain generally higher among men than among women. Overall, the incidence of and mortality from CRC are highest among African Americans, somewhat lower among European Americans, and lowest among Native, Asian, and Hispanic Americans [see Table 1].⁵ Most CRCs still occur in the distal colon (beyond the splenic flexure), but the incidence of proximal adenocarcinomas relative to that of distal adenocarcinomas has been increasing over the past 25 years [see Figure 1].⁶ The cause of this shift is not known.

Genetics

The development of CRC involves a progression from normal mucosa through adenoma to carcinoma.⁷ A genetic model of colorectal carcinogenesis has been proposed that describes a sequence of key mutations driving the process of colorectal carcinogenesis [see Figure 2].⁸ This process may involve the accumulation of mutations in both tumor suppressor genes and proto-oncogenes, as well as epigenetic phenomena such as DNA hypermethylation or hypomethylation.⁹ The onset of genomic instability increases the mutation rate and accelerates this progression. Inactivation of the adenomatous polyposis coli (*APC*) gene on chromosome 5q is thought to be one of the earliest mutations in sporadic cancers and is seen as a germline mutation in patients with familial polyposis [see 5:14 Hereditary Colorectal Cancer and Polyposis Syndromes]. Mutations in other tumor suppressor genes play an important role

in this pathway as well, including mutations in *DCC*, *SMAD2*, and *SMAD4* on chromosome 18q and *p53* on chromosome 17p; these events are thought to occur at a later stage of tumor progression. Mutations in the *K-ras* oncogene occur at an intermediate stage. The accumulation of additional mutations (as yet poorly defined) allows metastases to develop.

Microsatellite instability (MSI) is an alternative pathway to genomic instability and subsequent colorectal carcinogenesis. This phenomenon arises from defects in mismatch repair genes, which cause significantly increased mutation rates in comparison with those in normal cells. MSI in hereditary nonpolyposis colorectal cancer (HNPCC) [see Risk Factors, below] is most commonly attributable to germline mutations in the *hMLH1* and *hMSH2* genes.¹⁰ MSI in sporadic CRC is most frequently associated with hypermethylation of the promoter region of the *hMLH1* gene,¹¹ which leads to inactivation of the gene and loss of expression of the *hMLH1* protein.

Risk Factors

A number of risk factors for CRC have been described, including a family history of cancer or adenomatous polyps, familial CRC syndromes, inflammatory bowel disease (both ulcerative colitis and Crohn disease), and dietary and lifestyle factors.^{12,13} The vast majority of CRCs worldwide are sporadic—that is, they are not associated with known genetic syndromes. In the United States, no more than 5% of CRCs are associated with known genetic syndromes.

In a meta-analysis of studies addressing CRC risk and family history, the relative risk of CRC in those with an affected first-degree relative was 2.25; this figure rose to 4.25 if more than one relative was involved and to 3.87 if CRC was diagnosed before the age of 45.¹⁴ The National Polyp Study found that the relative risk of CRC was 1.78 in first-degree relatives of patients with adenomatous polyps.¹⁵ In another study, the relative risk of CRC was 1.74 in first-degree relatives of patients with adenomatous polyps and was especially high (4.36) in those diagnosed with polyps at or before the age of 50.¹⁶

The most common of the genetic syndromes known to be asso-

Table 1 Incidence and Mortality of CRC by Race and Sex⁵

Race	Incidence (No./100,000)		Mortality (No./100,000)	
	Male	Female	Male	Female
White	64.1	46.2	25.3	17.5
African American	72.4	56.2	34.6	24.6
Asian/Pacific Islander	57.2	38.8	15.8	11.0
Native American	37.5	32.6	18.5	12.1
Hispanic	49.8	32.9	18.4	11.4

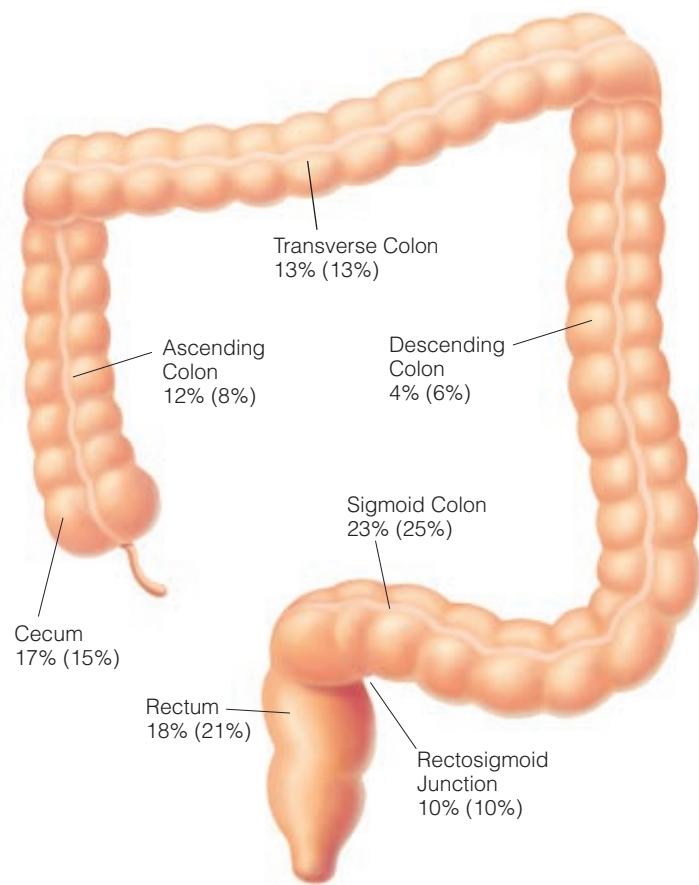

Figure 1 Shown are the relative frequencies of CRC for various anatomic subsites of the colon in 1996. For comparative purposes, figures for 1976 are provided in parentheses.

ciated with CRC is HNPCC, which accounts for the majority of patients with familial CRC. MSI is the characteristic finding of HNPCC, though it is also present in approximately 15% of all sporadic CRCs. HNPCC can be diagnosed clinically on the basis of what are known as the Amsterdam Criteria.¹⁷ Polyposis syndromes (e.g., familial polyposis and juvenile polyposis) account for the remainder of patients with familial CRC syndromes. HNPCC and polyposis syndromes are discussed further elsewhere [see 5:14 Hereditary Colorectal Cancer and Polyposis Syndromes].

As determined by a 2001 meta-analysis, the lifetime risk of CRC for patients with ulcerative colitis is 3.7%, which increases to

5.4% for patients with pancolitis and rises further with greater duration of disease.¹⁸ Despite the common misconception, Crohn disease may be associated with a similarly increased risk of CRC.¹⁹

Numerous lifestyle and dietary factors have been put forward as potential causes of increased CRC risk. Lower levels of physical activity and increased body mass are associated with an increased risk of CRC in both men and women.²⁰ The Western-style diet, which is high in calories and fat and low in fiber, is associated with high rates of CRC. There is evidence that increased dietary intake of calcium may confer some protection against the development of CRC and adenomatous polyps. The Calcium Polyp Prevention Study, a large randomized trial done in the United States, reported a small but statistically significant reduction in the incidence of recurrent colorectal adenomas with dietary calcium supplementation.²¹ To date, the evidence from randomized trials has not shown dietary fiber supplementation to have a similar effect. In Japan, where the incidence of CRC has traditionally been low, CRC has become considerably more common in the past few decades.²² This increased incidence is believed to be the result of post-World War II lifestyle changes (e.g., increased consumption of animal fat and decreased expenditure of energy) that mirror Western habits.

Screening

Early diagnosis of colorectal neoplasms at a presymptomatic stage is important for improving survival. Polypectomy has consistently been shown to decrease the subsequent development of CRC: the National Polyp Study found that the incidence of CRC in patients who underwent colonoscopic polypectomy was as much as 90% less than would otherwise have been expected.²³ Identifying patients with early-stage disease that has not yet metastasized can prevent many CRC-related deaths. Early detection of and screening for CRC have become important components of routine care and public health programs both in the United States and abroad. The benefits of screening for CRC are especially substantial in patients who are at high risk for CRC (e.g., those with affected first-degree relatives), but even average-risk patients derive some benefit.

There is no ideal method of screening for CRC that is applicable to all patients. Physical examination is generally not helpful in making the diagnosis; various investigative tests are used instead. Modalities commonly employed for CRC screening and early detection include fecal occult blood testing (FOBT), double-contrast barium enema (DCBE), flexible sigmoidoscopy, and colonoscopy. Of these, only FOBT and sigmoidoscopy have been

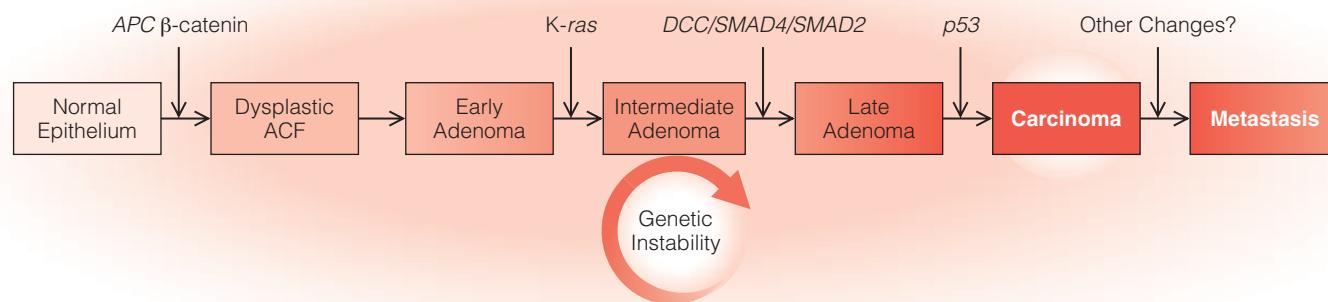

Figure 2 Diagram illustrates genetic model of colorectal tumorigenesis.⁸

Table 2 American Joint Committee on Cancer TNM Clinical Classification of Colorectal Cancer

Primary tumor (T)	T0	No evidence of primary tumor
	Tis	Carcinoma-in-situ, intraepithelial or invasion of lamina propria
	T1	Tumor invades submucosa
	T2	Tumor invades muscularis propria
	T3	Tumor invades through muscularis propria
Regional lymph nodes (N)	T4	Tumor invades other organs or perforates visceral peritoneum
	N0	No regional lymph node metastases
	N1	Metastases in 1 to 3 regional lymph nodes
Distant metastasis (M)	N2	Metastases in 4 or more regional lymph nodes
	M0	No distant metastasis
	M1	Distant metastasis

tested in randomized trials.²⁴ It is clear, however, that these tests are less sensitive and specific than colonoscopy. There is evidence that colonoscopy detects many CRCs in asymptomatic patients that would not be detected by sigmoidoscopy.^{25,26} Colonoscopy has been shown to be a safe and effective method of CRC screening in asymptomatic, average-risk patients.²⁷

Newer screening modalities, such as virtual colonoscopy and stool DNA assays, are currently being developed and tested. Virtual colonoscopy, which uses high-resolution computed tomographic scanning to image the colon, has been evaluated in at least two multicenter trials in the United States, with varying results.^{28,29} One of the studies reported a sensitivity and a specificity of 89% and 80%, respectively, for polyps larger than 6 mm and up to 94% and 96%, respectively, for polyps larger than 10 mm.²⁸ The sensitivities were equivalent to those of optical colonoscopy in this group of asymptomatic average-risk patients. The second study, however, found that virtual colonoscopy had a sensitivity of only 39% for lesions larger than 6 mm and 55% for lesions larger than 10 mm.²⁹ Given these divergent findings, it appears that there are issues related to equipment, software, and training that remain to be addressed before virtual colonoscopy can be recommended as a routine screening modality. Another consideration is that patients with lesions detected by means of virtual colonoscopy must still undergo optical colonoscopy for treatment or tissue diagnosis. Fecal DNA assays have been developed to test for mutations in multiple genes known to be involved in colorectal neoplasia and are currently being evaluated in clinical trials.³⁰ These assays are not as sensitive as colonoscopy but may be useful in patients who are unable or unwilling to comply with endoscopic screening.³¹

Many groups have advocated CRC screening, and published guidelines are available from several organizations, including the American Cancer Society,³² the American Gastroenterologic Association,³³ and the U.S. Preventive Services Task Force.³⁴ All of these guidelines recommend that screening begin at age 50 for average-risk patients. The recommended screening options are consistent among the various organizations and include (1) FOBT yearly, (2) flexible sigmoidoscopy every 5 years, (3) yearly FOBT and flexible sigmoidoscopy every 5 years, (4) DCBE every 5 years, and (5) colonoscopy every 10 years. In high-risk patients (e.g., those with a family history of CRC), screening may begin at an earlier age—generally, 10 years younger than the age of the affected first-degree relative. There are also specific intensive screening and follow-up regimens for patients with known or suspected familial cancer syndromes.

Clinical Evaluation

As a consequence of the use of screening modalities, patients with CRC are often asymptomatic at diagnosis. Some CRC patients present with occult GI bleeding and anemia. Many patients do not exhibit symptoms until relatively late in the course of the disease. The duration of symptoms, however, is not necessarily associated with the stage of the tumor.³⁵

The most common symptoms of CRC are bleeding per rectum, abdominal or back pain, and changes in bowel habits or stool caliber. Other symptoms are fatigue, anorexia, weight loss, nausea, and vomiting. Some patients present with acute bowel obstruction or perforation.

Staging and Prognosis

Accurate staging of CRC is extremely important for determining patient prognosis and assessing the need for adjuvant therapy. Traditionally, staging of CRC has been based on modifications of the Dukes classification, which was initially developed as a prognostic tool for rectal cancer in the 1930s.³⁶ Since this classification was first implemented, it has undergone multiple modifications, of which the most widely used is the modified Astler-Coller system, initially introduced in the 1950s.³⁷ Currently, the TNM classification, developed by the American Joint Committee on Cancer (AJCC) and the International Union against Cancer (UICC), is the preferred staging system [see Tables 2 and 3].³⁸ This system takes into account the depth of penetration into the bowel wall (T) [see Figure 3], the presence and number of involved mesenteric nodes (N), and the presence of distant metastases (M).

CLINICAL STAGING

Clinical staging is based on the history and the physical examination, endoscopic findings, and biopsy results. If colonoscopy cannot be completed, an air-contrast barium enema study should be performed to evaluate the remainder of the colon. Additional staging information may be obtained by means of imaging studies (e.g., roentgenography, CT, magnetic resonance imaging, and positron emission tomography [PET]). A chest x-ray is routinely obtained to rule out metastases and prepare for operation.

There is some debate regarding the utility of preoperative CT scans in the management of primary colon cancer. The rationale for obtaining these scans includes evaluation of potential metastatic disease and assessment of the local extent of disease. In a 2002 study of preoperative CT in patients with intraperitoneal colon

Table 3 American Joint Committee on Cancer Staging of Colorectal Cancer

Stage	T	N	M
Stage 0	Tis	N0	M0
Stage I	T1, T2	N0	M0
Stage IIA	T3	N0	M0
Stage IIB	T4	N0	M0
Stage IIIA	T1, T2	N1	M0
Stage IIIB	T3, T4	N1	M0
Stage IIIC	Any T	N2	M0
Stage IV	Any T	Any N	M1

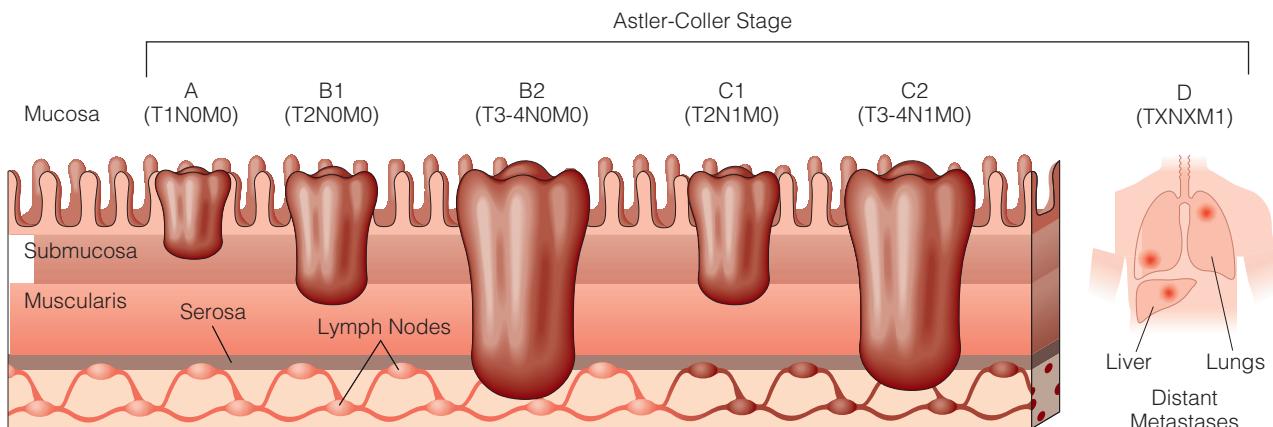

Figure 3 Classification of CRC takes into account depth of tumor penetration and involvement of lymph nodes.

cancer, however, the results of the imaging changed management in only 19% of patients, and CT had a sensitivity of only 78% for all metastatic disease.³⁹ Nonetheless, many surgeons routinely perform staging CT in patients with primary colon cancer. PET is a sensitive study, but its routine use for staging primary CRC is not generally recommended. PET may be considered for high-risk patients in whom the detection of metastases would change initial management.⁴⁰

In cases of rectal cancer, locoregional staging may significantly affect therapeutic decision making. Such staging includes determination of the depth of invasion of the rectal wall and the degree of regional node involvement. Modalities commonly used include CT, MRI, and endoscopic ultrasonography (EUS). In a 2004 meta-analysis that examined the relative utility of each of these studies in rectal cancer staging,⁴¹ EUS proved to be the most accurate technique for evaluating muscularis propria involvement and perirectal tissue invasion. The various techniques were equally accurate in assessing lymph node involvement, with none of them being highly sensitive.

PATHOLOGIC STAGING

Definitive pathologic staging is carried out after surgical exploration and examination of the resected specimen. The final stage of the cancer is then determined on the basis of the TNM system [see Tables 2 and 3]. Survival is correlated with the stage of the tumor [see Figures 4 and 5]. In the current (sixth) edition of the AJCC staging system,³⁸ stage II is subdivided into stages IIA and IIB, and stage III is subdivided into stages IIIA, IIIB, and IIIC on the basis of both the extent of wall penetration and the number of nodes involved. These changes were implemented as a result of studies demonstrating differences in survival among these subgroups [see Figure 6].⁴²

Numerous other criteria have been evaluated as additional prognostic factors in CRC. The degree of lymphatic invasion and the extent of vascular invasion are important adjuncts to the TNM staging system and are incorporated in the current schema.³⁸ Certain histologic types, including signet-ring and mucinous carcinomas, are associated with poor outcomes. The preoperative serum carcinoembryonic antigen (CEA) level may be an independent prognostic factor that is predictive of resectability and the presence of distant metastases.⁴³

MOLECULAR MARKERS

Various molecular markers have been investigated with respect to prognosis and response to therapy in CRC patients. Unfortunately, there are conflicting data on the prognostic impact and clin-

ical utility of most of these markers. As noted [see Risk Factors, above], MSI is seen in as many as 15% of patients with sporadic CRC. Patients with MSI typically have proximal, poorly differentiated tumors with mucinous or signet-ring components, but they usually exhibit improved overall survival.⁴⁴ These patients may be less sensitive to 5-fluorouracil (5-FU)-based chemotherapy.⁴⁵

The long arm of chromosome 18 (18q) harbors at least three candidate tumor suppressor genes, including *DCC*, *SMAD2*, and *SMAD4*. Deletions of chromosome 18q in CRC patients are associated with decreased survival. One study found that patients with stage II cancers and 18q allelic loss had a prognosis similar to that of patients with stage III disease.⁴⁶ In addition, *p53* mutations and overexpression are associated with poor outcomes in CRC.⁴⁷ Thymidylate synthase is an enzyme active in DNA synthesis that is targeted by 5-FU and similar chemotherapeutic agents. Overexpression of this enzyme is associated with a poor prognosis but also with improved sensitivity to 5-FU-based chemotherapy.⁴⁸

All of these molecular alterations, as well as others (e.g., *K-ras* mutations and 5q deletions), are commonly observed in CRC patients, but further study is required to establish their real prognostic significance.

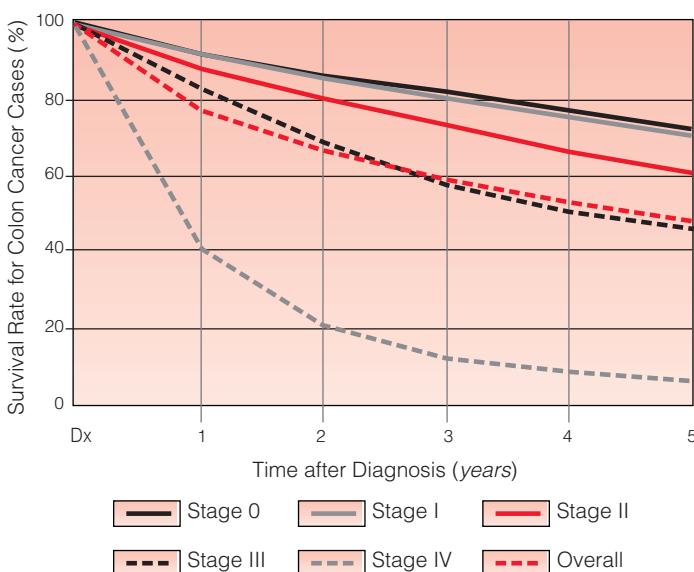

Figure 4 Shown are 5-year survival rates for cases of colon cancer diagnosed in 1,735 U.S. hospitals in 1995 and 1996.

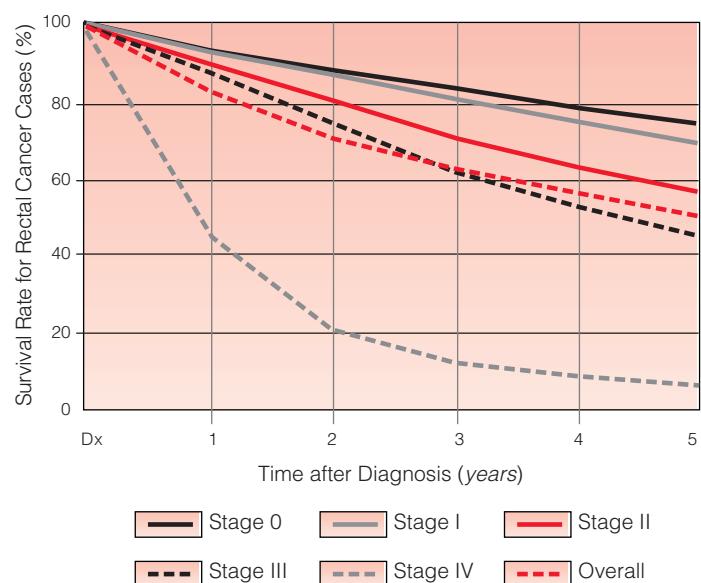

Figure 5 Shown are 5-year survival rates for cases of rectal cancer diagnosed in 1,683 U.S. hospitals in 1995 and 1996.

Management of Colon Cancer

SURGICAL THERAPY

Surgery with curative intent remains the mainstay of therapy for colon cancer [see Figure 7]. Complete R0 resection (leaving no gross or microscopic disease) with wide margins along the bowel wall, coupled with regional lymphadenectomy, is the standard of care. The major arterial vessels supplying the segment of the colon containing the tumor should be excised at their origins. A minimum margin of 5 cm of normal bowel on each side of the tumor is considered adequate.

Extent of Resection

The standard extent of resection for various colon cancers has been defined. For tumors of the cecum and the ascending colon, a right hemicolectomy that includes the right branch of the middle colic artery at its origin should be performed. For tumors of the hepatic flexure, an extended right colectomy that includes the entire middle colic artery is indicated. For tumors of the transverse colon, an extended right or left colectomy or a transverse colectomy may be performed. For tumors of the splenic flexure region, a left hemicolectomy is performed, and for sigmoid tumors, a sigmoid colectomy is performed.

In patients who have small or flat tumors or who are undergoing resection after a polypectomy, intraoperative identification of the tumor may be difficult. This is especially true with laparoscopic procedures, in which the bowel often cannot be palpated. If the lesion is in the cecum, the ileocecal valve and the appendiceal orifice are visualized endoscopically, and localization of the tumor is simple. If the lesion is at another location, endoscopic measurements of the distance from the anus or estimates of the location of the tumor may be inaccurate. Endoscopic tattooing, a process in which an agent is injected into the bowel wall submucosally at or near the site of the lesion, has been employed to facilitate intraoperative identification of the tumor site. India ink is the agent most commonly used for this purpose and generally yields excellent results.⁴⁹ As an alternative, many institutions use a commercially available sterile suspension of carbon particles, which is also very safe and effective.⁵⁰ Intraoperative endoscopy is another option for locating these lesions.

Surgical Staging

The selection of patients for adjuvant therapy relies heavily on accurate staging. A significant percentage of patients with early-stage node-negative disease present with recurrences or metastases; such a presentation implies that the patients had occult metastatic disease at the time of operation. Surgical resection of CRC should include division of the appropriate mesenteric vessels at their origins, along with resection of the regional nodes. Optimal staging of CRC patients, especially with regard to nodal status, remains controversial. One area of debate is the number of nodes that must be examined to confirm node-negativity. This number depends both on the surgeon's technique (i.e., how many nodes were resected) and on the pathologist's efforts to harvest nodes from the specimen. Most groups recommend analysis of at least 12 nodes to confirm node-negativity.⁵¹

Because of the importance of nodal status, ultrastaging of harvested nodes with techniques such as serial sectioning, immunohistochemistry (IHC), and reverse transcriptase polymerase chain reaction (RT-PCR) has been proposed as a means of detecting micrometastases. All of these techniques may result in upstaging of patients who are node negative on standard pathologic analysis, which involves only bivalving the nodes and examining a limited number of sections. The prognostic impact of micrometastases that are detected only by IHC or RT-PCR and are not verified by hematoxylin-eosin staining remains unclear. It is impractical to perform these assays on all nodes harvested; accordingly, the use of lymphatic mapping to identify sentinel lymph nodes (SLNs) has been proposed as a means of selecting a small number of nodes for further analysis.

SLN biopsy in the setting of CRC remains investigational. Lymphatic mapping may be done with either *in vivo* or *ex vivo* injection of tracer dye. The dye rapidly diffuses through the lymphatic vessels, and SLNs can be identified and marked in the mesocolon within minutes. This procedure has been shown to be feasible in a number of studies⁵²; however, its sensitivity and false negative rates have been variable. In a 2004 multicenter trial, SLN biopsy with serial sectioning had a false negative rate of 54% in patients with node-positive colon cancer.⁵³ In a large single-institution study, the sensitivity of SLN biopsy was 91% and the false negative rate was 11%.⁵⁴

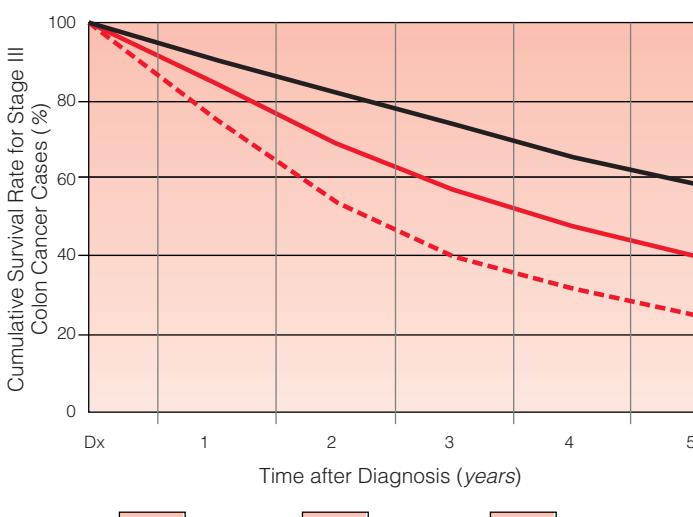

Figure 6 Shown are 5-year survival rates for cases of stage III colon cancer diagnosed between 1987 and 1993, stratified according to stage III subgroups established by 6th edition of AJCC Staging Manual.³⁸

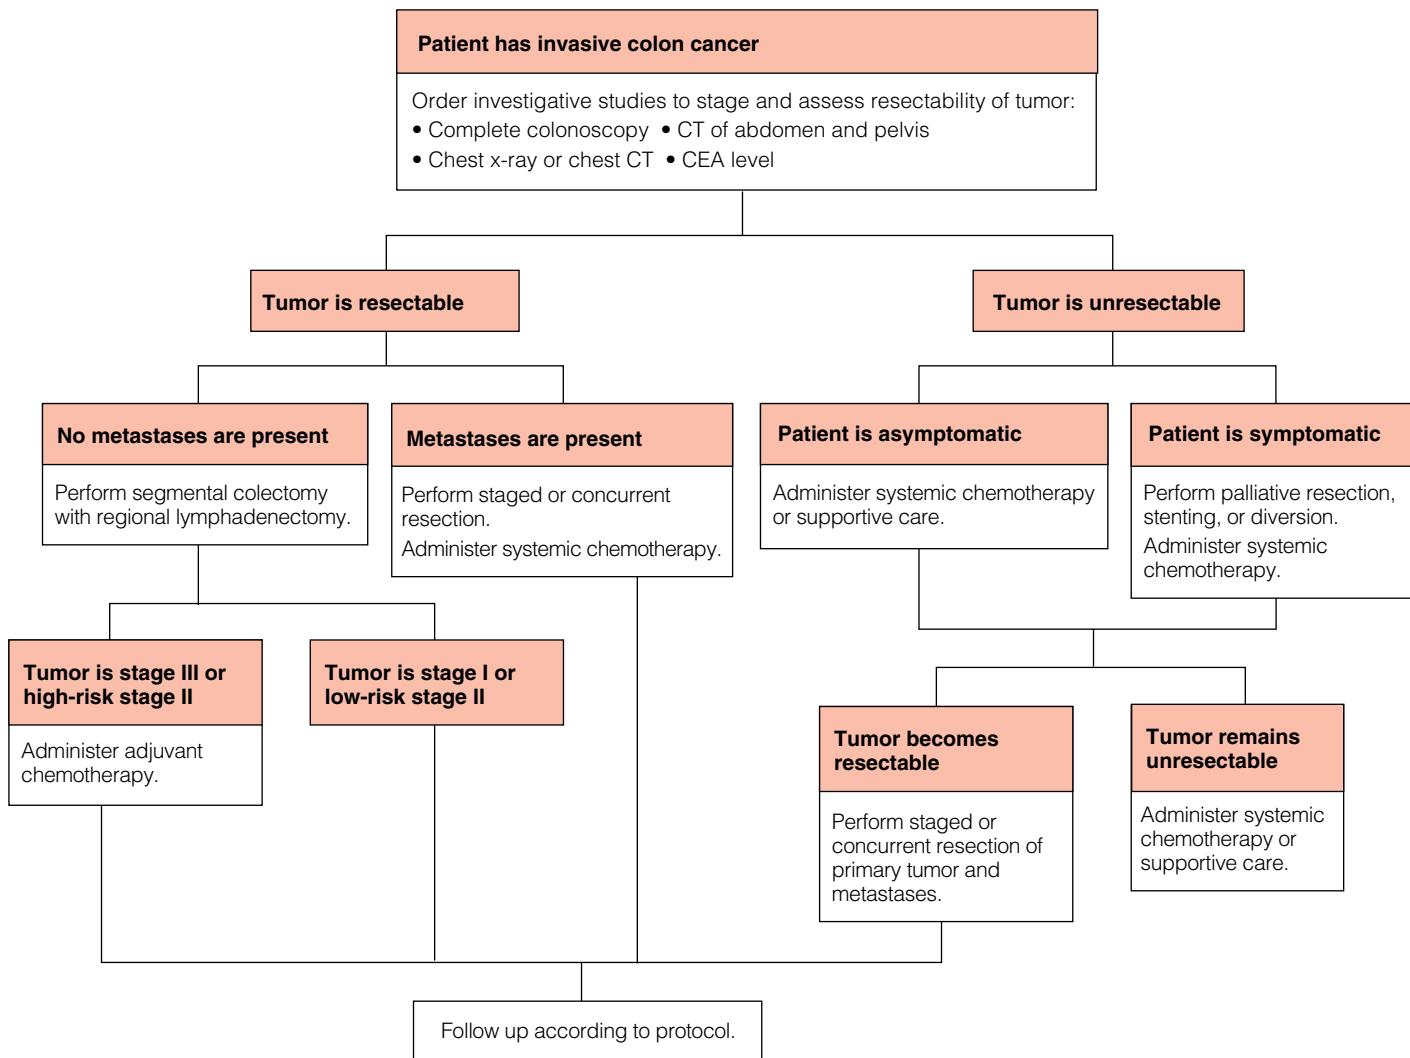

Figure 7 Algorithm outlines treatment of colon cancer.

tution trial, both SLNs and non-SLNs were studied with serial sectioning and IHC in patients who were node negative on routine pathologic analysis⁵⁴; 19.5% of patients were upstaged by the combination of serial sectioning and IHC of SLNs. These results imply that the main role of this technique may be in upstaging patients who are node negative on routine pathologic analysis. Further study is required before the use of SLN techniques in the context of CRC becomes standard clinical practice.

Occult metastatic disease may also be present in the peritoneal cavity or systemically in the blood or bone marrow at the time of operation. The presence of tumor cells in the peritoneum may be detected by performing cytologic analysis of washings done at the time of operation. In one study, disseminated tumor cells were identified in peritoneal washings or blood in 25% of patients, and their presence was found to be an independent prognostic factor for survival.⁵⁵ In another study, patients with positive peritoneal washings had significantly higher rates of local recurrence and peritoneal carcinomatosis but manifested no differences in survival.⁵⁶ Again, further study is required before these assays can be routinely used for staging CRC.

Laparoscopic versus Open Colectomy

At present, open colectomy is the most widely accepted treatment of resectable colon cancer. Laparoscopic techniques have

been developed and are being tested in prospective, randomized multicenter trials [see 5:34 *Laparoscopic Colectomy*]. Initially, there were concerns about port-site recurrences,⁵⁷ but current data suggest that these concerns are unfounded.⁵⁸ With respect to comparative cost, data from a subset of patients in the European COlon cancer Laparoscopic or Open Resection (COLOR) trial demonstrated that although the total cost to society from laparoscopic colectomy is similar to that from open colectomy, the costs to the health care system are significantly higher with the former.⁵⁹ The Clinical Outcomes of Surgical Therapy (COST) study group, a large, randomized, multicenter trial conducted in the United States, found that laparoscopic-assisted colectomy conferred only minimal (though statistically significant) short-term quality-of-life benefits when compared with open colectomy.^{60,61} Cancer-specific outcomes (e.g., recurrence rates, wound recurrences, and overall survival rates) were similar with the two approaches.⁶¹ The COST investigators concluded that laparoscopic colectomy is an acceptable alternative to open colectomy. Recurrence and survival data from other large multicenter trials (e.g., the COLOR trial⁶²) are not yet available.

Special Situations

Obstructing and perforated cancers Obstructing and perforated colon cancers are associated with a poor prognosis and

with increased surgical morbidity (as a consequence of the need for emergency surgery). Perforation can occur either via direct erosion of the tumor through the wall of the colon or secondary to obstruction with resultant bowel distention proximal to the tumor. Patients with perforated colon cancer are managed with emergency laparotomy, washout, and resection of the primary lesion to prevent further soiling. A diverting stoma is usually indicated, with either a Hartmann pouch or a mucous fistula constructed distally. Select patients may be managed by means of primary anastomosis, with or without a proximal diverting colostomy or ileostomy.

Obstructing right-side cancers (up to the splenic flexure) can usually be treated with resection and primary anastomosis. The traditional emergency treatment of obstructing left-side colon cancers is a diverting colostomy, with or without resection of the lesion. In many such cases, the stoma is never taken down. Some surgeons advocate emergency treatment of these lesions with total abdominal colectomy and ileorectal anastomosis as a means of improving outcomes.⁶³ Another treatment option is primary resection and anastomosis, with or without on-table intestinal lavage. Yet another option for managing obstructing left-side colon and rectal cancers is the use of colorectal stents with the aim of avoiding emergency surgery. Stents can serve as a bridge to definitive resection by decompressing the colon and thereby allowing subsequent bowel preparation. In patients with advanced disease, stents may also be employed for palliation as an alternative to surgical resection or a diverting stoma.

Synchronous primary colorectal cancers The incidence of synchronous CRCs is reported to range from 3% to 5%^{64,65} but may be as high as 11%.⁶⁶ Stage for stage, there appear to be no differences in survival between synchronous cancers and single primary cancers.^{67,68} Synchronous adenomatous polyps are present in as many as 35% of patients undergoing surgical treatment of CRC.^{65,68} In one study, the presence of synchronous lesions made the surgical procedure more extensive than was initially planned for resection of the primary tumor in 11% of patients.⁶⁵

Most synchronous polyps are identified on preoperative colonoscopy, and the colon can often be cleared of these lesions before operation. Management of adenomas not amenable to endoscopic resection and management of synchronous cancers are more challenging. Each primary cancer must be managed surgically according to sound oncologic principles. One option is to perform multiple segmental resections with multiple anastomoses. Another is to perform an extended resection that encompasses all of the lesions or even total abdominal colectomy if needed. The presence of a rectal cancer and a second synchronous lesion makes surgical treatment even more challenging, especially if sphincter preservation and a low rectal or coloanal anastomosis are contemplated.

ADJUVANT THERAPY

Significant progress in systemic adjuvant therapy for patients undergoing resection of a colorectal adenocarcinoma has been made in the past 20 years, primarily through a series of phase III randomized trials and the development of new drugs. The evolution of adjuvant therapies is likely to continue for the foreseeable future, and surgeons will play a pivotal role as the primary entrance point for standard adjuvant therapy and new phase III randomized trials. Surgeons' awareness of past accomplishments, current study findings, and future phase III trials is crucial for improving the survival of potentially cured patients.

The 5-year survival rate after resection of colon cancer is inversely correlated with the pathologic stage [see Figure 4]. The diminishing 5-year survival rates for stage II and III colon cancer became

the basis of several phase III randomized trials designed to test the hypothesis that postoperative systemic adjuvant chemotherapy would significantly improve survival in patients with resected but high-risk cancers. Multi-institutional, cooperative cancer group trials were necessary to obtain populations large enough to test this hypothesis. The North Central Cancer Treatment Group (NCCTG) initiated a randomized trial of postoperative systemic adjuvant 5-FU plus levamisole for Dukes stage B and C (AJCC stage II and III) colon carcinomas.⁶⁹ Patients were randomly assigned to receive either levamisole alone or 5-FU plus levamisole. Overall survival was significantly improved in stage C patients treated with 5-FU plus levamisole. This was the first randomized trial to demonstrate the efficacy of systemic adjuvant therapy.

The NCCTG trial led to second-generation trials of adjuvant therapy for patients with resected colon cancers. In one such study, patients with high-risk stage II or stage III colon cancer were randomly assigned to receive either 5-FU plus leucovorin and levamisole or 5-FU plus levamisole.⁷⁰ Survival rates after 12 months of adjuvant chemotherapy were no better than those after 6 months of chemotherapy; however, 5-FU plus levamisole proved to be inferior to 5-FU plus leucovorin and levamisole with respect to survival.

National Surgical Adjuvant Breast and Bowel Project (NSABP) protocol C-04 randomly assigned Dukes stage B and C colon cancer patients to receive (1) postoperative 5-FU plus leucovorin, (2) 5-FU plus levamisole, or (3) 5-FU plus leucovorin and levamisole.⁷¹ A slight improvement in 5-year disease-free survival was noted with 5-FU plus leucovorin, but overall 5-year survival did not differ significantly among the three treatment arms. Accordingly, 5-FU plus leucovorin became the standard adjuvant regimen.

Intergroup Trial 0089 randomly assigned patients with high-risk stage II and III disease to receive either 5-FU plus high-dose leucovorin or 5-FU plus low-dose leucovorin. The investigators concluded that (1) the high-dose and low-dose regimens were equivalent, (2) a regimen consisting of four cycles of 5-FU with high-dose weekly leucovorin was equivalent to the low-dose leucovorin Mayo Clinic regimen, and (3) the addition of levamisole to the 5-FU plus leucovorin regimen did not improve survival.

These clinical trials have established 5-FU plus leucovorin as standard therapy for patients with high-risk stage II and stage III colon cancer. The next generation of clinical investigations should provide data on the potential benefits of augmenting this regimen with irinotecan or oxaliplatin in an adjuvant setting.⁷²

Routine use of systemic adjuvant therapy for stage II colon cancer remains controversial. Patients with stage II colon cancers, including those at high risk (e.g., those who present with large bowel obstruction or perforation), are typically included in adjuvant chemotherapy trials. A meta-analysis of stage II patients included in NSABP colon cancer trials demonstrated that adjuvant chemotherapy did confer a survival benefit at this disease stage.⁷³ This study was criticized, however, for having included patients from trials that lacked a surgery-only arm, as well as from trials that employed outmoded chemotherapeutic regimens.⁷⁴ Another meta-analysis, which included only trials that compared 5-FU plus leucovorin with observation after curative resection in stage II patients, found no statistically significant survival benefit with chemotherapy.⁷⁵ A 2004 meta-analysis formulated recommendations on this controversial topic and provided a Web-based tool for calculating risk.⁷⁶ This report included data from seven randomized trials that compared surgery alone with surgery plus chemotherapy. Patients with node-negative disease derived a much lower reduction in risk and no statistically significant improvement in overall survival. The authors concluded that the

use of postoperative adjuvant chemotherapy for stage II colon cancer patients should be individualized on the basis of the estimated prognosis and the potential treatment benefit.

In summary, postoperative systemic adjuvant therapy is the standard of care in patients with stage III disease. In stage II colon cancer patients who have undergone complete surgical resection, the relative risk of recurrence is small enough that adjuvant chemotherapy yields relatively little benefit in terms of survival. There is, however, a subgroup of patients who have recognized prognostic factors that significantly reduce survival and in whom adjuvant therapy is therefore more likely to be beneficial. These risk factors include (1) bowel obstruction, (2) colonic perforation, (3) high-grade or lymphovascular invasion, and (4) the presence of fewer than 12 lymph nodes in the resected specimen.

Management of Rectal Cancer

Rectal cancer presents special management issues with respect to local recurrence after surgical resection. With cancer of the intraperitoneal colon, local recurrence is rare. With rectal cancer, however, surgical treatment alone results in recurrence rates of 16.2% after low anterior resection (LAR) and 19.3% after abdominoperineal resection (APR).⁷⁷ Higher stages are associated with higher recurrence rates: 8.5% for Dukes stage A, 16.3% for stage B, and 26% for stage C.⁷⁷ Multimodality management, including adjuvant radiation therapy or chemotherapy (or both) in combination with appropriate operative therapy, can reduce local recurrence rates significantly.

SURGICAL THERAPY

Extent of Resection

Sphincter preservation has become a major goal in the multimodality treatment of rectal cancer. Surgical procedures are chosen and performed with this goal firmly in mind.

Radical resection Traditionally, tumors of the rectum have been treated with either LAR or APR [see *Figure 8*]; in numerous series, APR rates of 60% or higher have been reported. Surgical techniques such as stapled or handsewn coloanal anastomoses [see 5:29 *Intestinal Anastomosis*], when combined with total mesorectal excision (TME), have led to excellent cancer-related outcomes without the need for permanent colostomy. The use of preoperative chemoradiation therapy for tumor downstaging may also reduce the need for APR.⁷⁸ Technical details of surgical procedures for rectal cancer are discussed elsewhere [see 5:35 *Procedures for Rectal Cancer*].

The morbidity associated with radical rectal resection can be substantial. Anastomotic leakage rates vary widely, ranging from less than 10% to more than 30% after resection with anastomosis. Leaks can lead to substantial morbidity and mortality and can necessitate reoperation. Such concerns have prompted the use of temporary diverting ileostomies or colostomies in patients with low rectal anastomoses. Defunctioning stomas may be overused, however, thereby increasing the cost of care in low-risk patients.⁷⁹ Preoperative chemoradiation therapy has not been shown to increase anastomotic leakage rates. Urinary and sexual dysfunction are also fairly common after radical resection of rectal cancer. Autonomic nerve preservation in conjunction with TME may improve the functional results of these procedures.⁸⁰ The use of local resection techniques (see below) is another means of reducing surgical morbidity and mortality in rectal cancer patients.

Local excision Local excision—including transanal, transsphincteric, and transcoccygeal techniques, as well as transanal endoscopic microsurgery (TEM) [see 5:35 *Procedures for Rectal Cancer*—is another option for curative resection of low rectal cancers with preservation of sphincter function. These procedures were initially implemented for local control in patients who were medically unfit for or unwilling to undergo major resections. Transsphincteric and transcoccygeal resections have been associated with an increased incidence of complications, including fecal fistulas and incontinence, and have largely been abandoned now that other, better techniques are available.

Local excision with curative intent is generally reserved for the treatment of early-stage (T1–T2N0) lesions. Selection of patients for these procedures is critical and is based on preoperative staging and on the probability of harboring nodal metastases, which increases with the T stage. EUS has become an important staging procedure in these patients, both for assessing the depth of tissue invasion and for detecting the presence of nodal disease. CT is generally performed to rule out distant metastases. Palliative procedures (e.g., fulguration and endocavitary irradiation) may also be considered in patients who are unfit for major surgery.

Several criteria have been established to identify patients who may be candidates for transanal excision (TAE).⁸¹ Generally, the lesion must be no more than 4 cm in diameter, must encompass no more than one third of the circumference of the rectum, and must be less than 8 cm from the anal verge. With the advent of TEM, these criteria have been expanded to include patients with higher lesions. Poorly differentiated tumors and the presence of lymphovascular invasion may also be associated with increased nodal involvement and higher recurrence rates. At least two prospective trials have reported their results with TAE.^{82,83} Local recurrence rates ranged from 5% to 7% for T1 lesions treated with surgery alone. Results were not as promising for T2 lesions: local recurrence rates ranged from 14% to 16%, even when adjuvant radiation or chemoradiation therapy was provided.

The use of local excision in patients with more locally advanced disease is even more controversial. Such patients are at considerably greater risk for nodal metastases and thus for local recurrence even after adequate resection of the primary lesion. Traditionally, local excision in patients with locally advanced disease has been associated with unacceptably high recurrence rates. Some authors advocate combining chemoradiation therapy with local excision to manage these patients. In a 2004 retrospective series, the results of local excision were comparable to those of radical resection in T3 patients who had a good response to preoperative chemoradiation therapy and who refused or were medically unfit for major surgery.⁸⁴ The role of local excision in these patients remains poorly defined.

Patients undergoing local resection must receive careful follow-up, including digital examination, measurement of CEA levels, proctoscopy, and, possibly, transanal ultrasonography. A subset of these patients with local-only recurrences who are medically fit for surgery may be candidates for resection. At present, few good data are available on the results of salvage surgery for local recurrence after local excision of rectal cancer, but it is unlikely that outcomes are equivalent to those of initial radical resection.⁸⁵

Importance of Radial and Distal Resection Margins

There has been a great deal of debate about what constitutes an adequate margin of resection in surgical treatment of rectal cancer. With respect to distal margins, 2 to 5 cm has traditionally been considered to be the minimum necessary for curative resection. Growing interest in sphincter preservation has led investigators to consider smaller distal margins (i.e., < 2 cm).

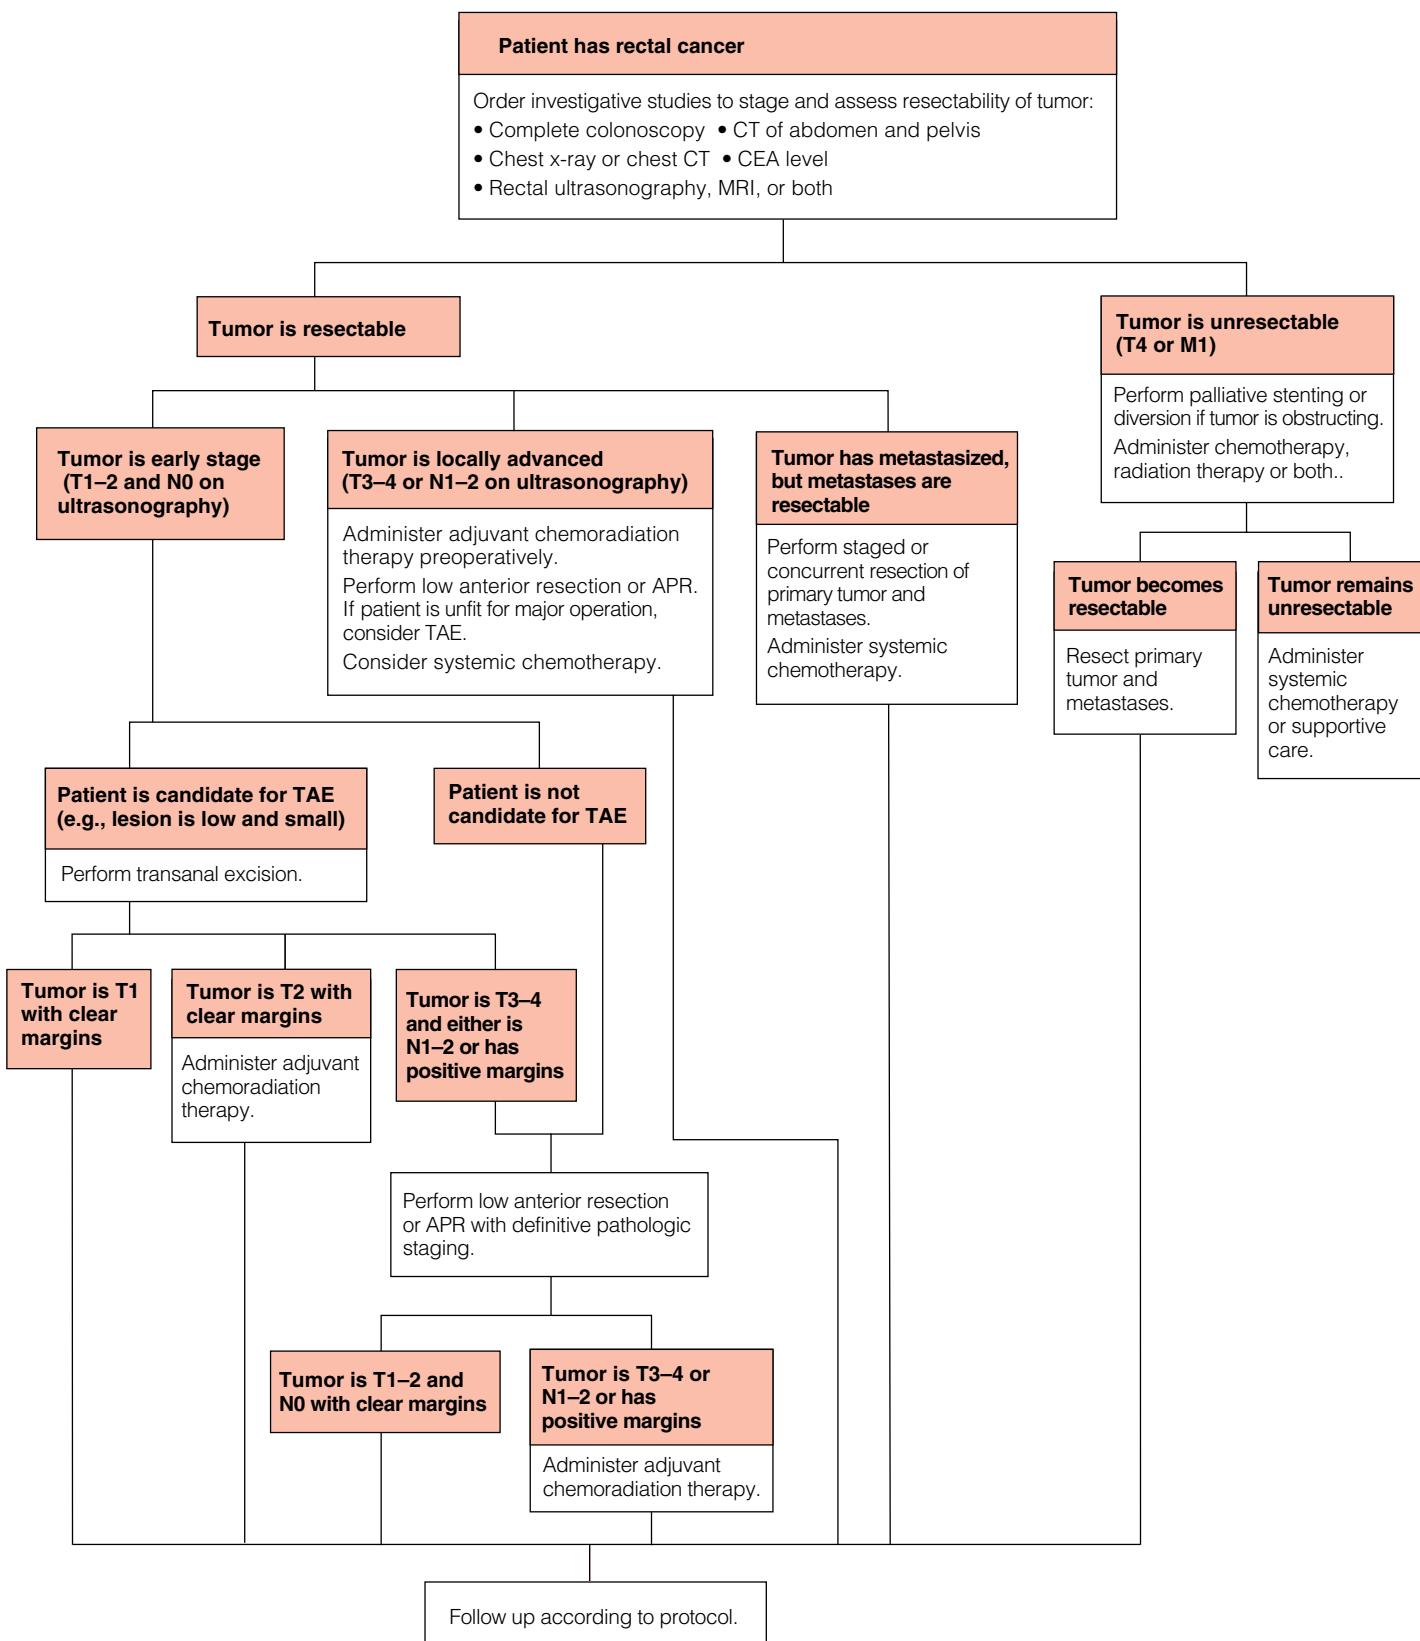

Figure 8 Algorithm outlines treatment of rectal cancer.

Studies have shown that clear margins smaller than 2 cm are not associated with higher local recurrence rates or reduced survival.⁸⁶ Subsequent reports have suggested that even smaller histologically negative margins (i.e., < 1 cm) may be adequate in

patients receiving adjuvant chemoradiation therapy.^{87,88}

The importance of radial margin involvement after rectal cancer resection was not recognized until comparatively recently.⁸⁹ Radial margins are assessed by means of serial slicing and evalua-

tion of multiple coronal sections of the tumor and the mesorectum.⁸⁹ Involvement of radial margins is a predictor of both local recurrence and survival after potentially curative rectal cancer surgery⁹⁰ and may be associated with an increased risk of distant metastases.⁹¹ Radial margins smaller than 2 mm are associated with increased local recurrence rates.⁹¹ Adjuvant radiation therapy does not compensate for the adverse impact of positive margins on local recurrence rates.⁹²

ADJUVANT THERAPY

Adjuvant therapy for rectal cancer has focused both on locoregional control of disease and on treatment of systemic disease. Several large studies have evaluated local recurrence of disease after surgical resection alone. Local failure rates of 30% to 40% for T2N0 disease and 50% to 70% for node-positive disease strongly suggested that postoperative adjuvant therapy was needed.⁹³⁻⁹⁵ In distinct contrast to these data, however, other series in which TME was performed reported extremely low local recurrence rates with surgery alone.^{96,97}

A series of randomized trials were conducted to assess adjuvant therapy for rectal cancer. Initial studies reported a decrease in local recurrence rates with postoperative radiation therapy.^{98,99} In a multi-institutional trial conducted by the NCCTG, the combination of 5-FU with radiation therapy led to improvements in local control rates and in survival.¹⁰⁰ These results were confirmed in large intergroup trials, the results of which indicated that continuous infusion of 5-FU during radiation therapy resulted in significantly better disease-free survival and overall survival than bolus infusion of 5-FU.

Simultaneously with the ongoing development of postoperative locoregional adjuvant therapy for rectal cancer, interest in preoperative therapy has been growing. Preoperative radiation therapy has been associated with excellent local control of disease, sphincter preservation, and acceptable postoperative recovery. There is evidence that rectal adenocarcinoma is sensitive to preoperative radiation therapy, with or without 5-FU. Pathologic complete response rates of 10% to 20% have been noted in resected rectal specimens¹⁰¹; pathologic complete response is associated with improved outcomes.¹⁰²

Perhaps the strongest reason to consider preoperative therapy for rectal cancer is its potential for inducing significant tumor regression before surgical resection. Such regression makes clear radial and distal margins easier to obtain. Moreover, tumor regression with preoperative therapy may result in higher sphincter preservation rates. In many published series, the APR rate in rectal cancer patients is between 40% and 60%; more aggressive preoperative efforts to induce regression may give surgeons a better chance to achieve sphincter preservation without compromising local control of disease.¹⁰¹

There remains significant controversy regarding the choice between preoperative and postoperative radiation therapy for rectal cancer. An advantage of the postoperative approach is that the disease is more accurately staged before adjuvant therapy begins, and thus, patients with early-stage disease are less likely to be overtreated. Two trials attempted to compare preoperative and postoperative radiation therapy for rectal cancer in an effort to determine their relative effects on local control, overall survival, and sphincter preservation. Both studies were unsuccessful, however—probably because of bias on the part of the treating physicians in favor of either preoperative or postoperative radiation therapy—and were closed because of slow accrual. At present, there is greater enthusiasm for preoperative therapy and pretreatment staging with transrectal ultrasonography, which is 90% accurate for determining the

T stage. Patients with T3 or T4 rectal cancer on ultrasonography would be eligible for preoperative treatment.

Two Swedish studies studied the role of preoperative radiation therapy in treating rectal cancer. The first demonstrated that a short course of preoperative radiation therapy (2.5 Gy in 5 fractions) was comparable to high-dose postoperative radiation therapy (60 Gy over a period of 8 weeks). The local recurrence rate was significantly lower with the short-course preoperative regimen (12% versus 21%), and there was no overall survival difference between the two regimens.¹⁰³ In the second trial, patients received either a short course of preoperative radiation therapy or surgery alone.¹⁰⁴ The local recurrence rate for preoperative therapy plus surgery was 11%, compared with 27% for surgery alone. The combined regimen also resulted in significantly better 5-year survival (58% versus 48%).

The question of the relative merits of preoperative and postoperative radiation therapy may be resolved by the findings from a 2004 German trial that randomly assigned patients to receive either preoperative or postoperative 5-FU plus radiation, followed by systemic 5-FU therapy.⁷⁸ This study was limited to patients with locally advanced disease, including those who had T3 or T4 disease or were node positive on ultrasonography. TME was performed in all patients and was done 6 weeks after treatment in patients receiving preoperative chemoradiation therapy. The primary end point of this study was overall survival; secondary end points included disease-free survival, local and distant control of disease, sphincter preservation, toxicity of adjuvant therapy, surgical complications, and quality of life. There was no difference between the preoperative group and the postoperative group with respect to 5-year survival, but the local recurrence rate was significantly lower with the former (6% versus 13%), as were both the short-term and the long-term toxicity of adjuvant therapy. Although overall, the rates of complete (R0) resection and sphincter preservation were similar in the two groups, the APR rate was significantly lower in patients determined by the surgeon to require APR before randomization.

Special Considerations

SYNCHRONOUS METASTATIC (STAGE IV) DISEASE

As many as 20% of CRC patients have metastatic disease at the time of initial presentation. The need for surgical intervention in this group of patients is not well defined. Clearly, surgical resection or diversion is indicated in patients who present with significant bleeding, perforation, or obstruction. In asymptomatic patients with unresectable metastatic disease, the role of surgical resection of the primary lesion remains controversial. In patients with resectable metastatic disease (e.g., isolated liver or lung metastases), curative resection may be undertaken.

In a retrospective review of patients presenting with unresectable stage IV CRC, there was no difference in survival between those who were initially managed surgically and those who were initially managed nonoperatively.¹⁰⁵ In the surgical group, the morbidity rate was 30% and the mortality 5%. Only 9% of the nonoperative patients subsequently required surgical intervention for bowel obstruction. In another retrospective series, patients managed surgically had significantly better overall survival than those managed nonoperatively but had a lesser tumor burden¹⁰⁶; 29% of the nonoperative patients eventually required surgery for bowel obstruction. When prognostic factors were evaluated in the surgical arm of this series, the only factor associated with improved outcomes was a less than 25% extent of liver involvement. On the basis of these and other studies, asymptomatic patients with unre-

sectable metastatic CRC should be managed selectively: those with limited tumor burdens may benefit from surgical treatment, whereas those with more extensive disease (especially extensive liver involvement) may initially be managed nonoperatively.

Management of patients with synchronous resectable isolated liver metastases continues to evolve. Many studies have documented improved survival after liver resection in patients with metastatic disease that is confined to the liver. Patients presenting with synchronous lesions have a worse prognosis than those presenting with metachronous lesions.¹⁰⁷ Many of these patients have been managed with staged resections of the primary cancers and the liver metastases. Several groups have reported that such combined procedures do not substantially increase surgical morbidity and mortality or compromise cancer survival.^{108,109} These combined procedures should be done only in carefully selected patients at specialized centers with significant experience in resection of both CRC and liver tumors.

PERITONEAL CARCINOMATOSIS

Peritoneal carcinomatosis develops in approximately 13% of all CRC patients.¹¹⁰ The survival rate of patients who present with peritoneal carcinomatosis from CRC is dismal. In patients with stage IV CRC, the presence of carcinomatosis is associated with a significant reduction in survival (from 18.1 months to 6.7 months).¹¹¹ Treatment has traditionally included systemic chemotherapy, with surgery reserved for palliation of symptoms such as bowel obstruction. Newer chemotherapy regimens that include agents such as oxaliplatin may improve survival, but they certainly are not curative.

Peritoneal carcinomatosis is often associated with hematogenous metastases, but in some 25% of patients, the peritoneal cavity is the only site of disease. Several groups have advocated the use of cytoreductive surgery and hyperthermic intraperitoneal chemotherapy (HIPEC) as a means of improving survival in these patients.¹¹² This treatment, however, is associated with significant morbidity and mortality.¹¹³ A randomized trial from the Netherlands that compared cytoreduction surgery plus HIPEC with systemic chemotherapy plus palliative surgery found that patients in the former group exhibited a statistically significant improvement in median survival (22.3 months versus 12.6 months).¹¹⁴ Cytoreductive surgery plus HIPEC seems to be a viable option for the treatment of peritoneal carcinomatosis. Patient selection for these aggressive procedures remains a major issue, given the substantial morbidity and mortality associated with them.

Follow-up and Management of Recurrent Colorectal Cancer

The goal of any CRC follow-up regimen should be to detect any recurrences or metachronous lesions that are potentially curable. In a large, multicenter trial, the incidence of second primary CRCs in patients with resected stage II and III lesions was found to be 1.5% at 5 years.¹¹⁵ Between 40% and 50% of patients experience relapses after potentially curative resection of CRC. Detection and treatment of recurrent disease before symptom development may improve survival. The time to recurrence is critical, in that as many as 80% of recurrences occur within the first 2 years and as many as 90% within the first 4 years. Patterns of recurrence should also be taken into account—for example, the markedly increased risk of local recurrence in rectal cancer patients compared with that in colon cancer patients. Even when recurrent CRC is detected, only a small percentage of patients are candidates for reoperation, and resection in these patients may not improve overall survival.

Systemic therapy may improve survival in some patients who have unresectable recurrent lesions.

Various modalities are available for follow-up after surgical treatment of CRC. The history and the physical examination continue to be useful, in that a significant percentage of patients present with symptomatic recurrences. Measurement of serum CEA levels has proved effective in detecting asymptomatic recurrences. Other studies, such as liver function tests (LFTs), complete blood count (CBC), chest x-ray, and imaging studies (e.g., CT and ultrasonography), have not been consistently shown to detect asymptomatic resectable recurrences. One study that evaluated routine CEA measurement and CT scanning of the chest, the abdomen, and the pelvis for follow-up of stage II and III CRC demonstrated that both modalities were able to identify asymptomatic patients with resectable disease.¹¹⁶ Colonoscopy is valuable for detecting metachronous cancers and polyps.

Some authorities advocate so-called intensive follow-up. However, this term lacks a standard definition, and such follow-up has not been conclusively shown to be beneficial. In a meta-analysis that compared an intensive follow-up regimen (including history, physical examination, and CEA measurement) with no follow-up, the former detected more candidates for curative re-resection and led to improvements in both overall survival and survival of patients with recurrences.¹¹⁷ Two other meta-analyses have been published that assessed the value of intensive follow-up of CRC patients.^{118,119} Both of these meta-analyses included only randomized, controlled trials, and both documented a survival advantage with intensive follow-up. Some caution is required in interpreting these results, however, because the meta-analyses included trials with vastly different follow-up regimens in their baseline and intensive groups.

At present, the ideal follow-up regimen for CRC patients remains to be determined. Intensive follow-up regimens obviously are more costly. Patients with stage I disease are at very low risk for recurrence and therefore do not require intensive follow-up.¹²⁰ Patients with stage II and III disease are at significantly higher risk for recurrence and therefore need more specific cancer-related follow-up, but how intensive such a follow-up regimen should be is still a matter of debate.

Several organizations, including the American Society of Clinical Oncology,¹²¹ the National Comprehensive Cancer Network (NCCN),^{122,123} and the American Society of Colon and Rectal Surgeons,¹²⁴ have developed algorithms for postoperative surveillance of CRC patients. Their recommendations generally apply to patients with stage II or III disease (and sometimes patients with T2 lesions) who are candidates for resection of recurrent disease. The recommendations vary somewhat among groups, but the following are generally agreed on:

1. Measurement of CEA levels every 2 to 3 months for 2 years, then every 3 to 6 months for 3 years, then annually.
2. Clinical examination every 3 to 6 months for 3 years, then annually.
3. Colonoscopy perioperatively, then every 3 to 5 years if the patient remains free of polyps and cancer (the NCCN also recommends colonoscopy 1 year after primary therapy).

Imaging studies (e.g., CT and chest x-ray) are not routinely recommended, nor are other blood tests (e.g., CBC and LFTs).

A complete review of the treatment of recurrent CRC is beyond the scope of this chapter. The primary aim of postoperative surveillance is the detection of treatable recurrences or metastatic disease. The most common sites of metastasis in CRC patients are the liver and the peritoneal cavity. Surgery is the only potentially curative

therapy for recurrent CRC. Only a select group of patients with isolated peritoneal, liver, or lung metastases are candidates for surgical resection. As noted [see Special Considerations, Peritoneal Carcinomatosis, above], cytoreductive surgery and HIPEC improve survival in patients with peritoneal carcinomatosis and may lead to long-term survival in a very select group of patients.

Numerous studies have addressed the treatment of patients with isolated liver metastases from CRC. Resection of isolated hepatic metastases has been reported to yield 5-year survival rates higher than 30%, with acceptable surgical morbidity and mortality. Investigators from the Memorial Sloan-Kettering Cancer Center developed a staging system known as the clinical score in an attempt to predict which patients are likely to benefit from aggressive surgical resection.¹²⁵ This system used five factors that were found to be independent predictors of poor outcome: (1) node-positive primary disease, (2) a disease-free interval shorter than 12 months, (3) the presence of more than one hepatic tumor, (4) a maximum hepatic tumor size exceeding 5 cm, and (5) a CEA level higher than 200 ng/ml. Patients who met no more than two of these criteria generally had good outcomes, whereas those who met three or more were recommended for inclusion in adjuvant therapy trials.

PET scanning has also been used to detect occult metastatic disease and thus to aid in the selection of patients for surgical resection. In one series, a 5-year overall survival of 58% was reported after resection of CRC liver metastases in patients screened with PET.¹²⁶ When combined with the clinical risk score, PET was found to be helpful only in patients with a score of 1 or higher.¹²⁷

Modalities for treating unresectable disease confined to the liver include cryotherapy, radiofrequency (RF) ablation, hepatic artery infusion of chemotherapeutic agents, and hepatic perfusion. Of these, RF ablation is the one most commonly employed. It may be performed via an open approach, percutaneously, or laparoscopically; it may also be combined with resection and with local or systemic chemotherapy. The survival benefit (if any) associated with use of these modalities has not been well established.

Patients with isolated lung metastases from CRC may also benefit from surgical resection. Because there are relatively few of

these patients, treatment of such metastases has not been studied as well as treatment of liver metastases. Some series have reported 5-year survival rates higher than 40% after complete resection. Patient selection remains a major issue. Several prognostic factors that may predict poor outcomes have been identified, including (1) a maximum tumor size greater than 3.75 cm, (2) a serum CEA level higher than 5 ng/ml, and (3) pulmonary or mediastinal lymph node involvement.^{128,129} Patients with both pulmonary and hepatic metastases may also be considered for surgical resection.

Pelvic recurrences of rectal cancer present another difficult management issue. These tumors may cause significant pain and disability, and if they are not treated, survival is measured in months. Radiation and chemotherapy provide symptomatic relief and yield a modest increase in survival. Surgery may provide excellent palliation and is potentially curative in patients who do not have distant metastases.

Multimodality therapy has been advocated as a means of improving the chances of cure. In one study, a 37% 5-year survival rate was reported in patients who underwent multimodality therapy, including resection with negative margins.¹³⁰ A subgroup of patients in whom complete resection was impossible underwent intraoperative radiation therapy; the 5-year survival in this subgroup was 21%. Several predictors of poor outcomes were identified, including incomplete resection, multiple points of tumor fixation, and symptomatic pain. In another series, hydronephrosis was associated with the presence of unresectable disease.¹³¹ Selection of appropriate patients for curative surgery remains a major issue in the management of locally recurrent rectal cancer.

Chemotherapy is the mainstay of palliative treatment for patients with CRC and unresectable recurrent or metastatic disease. Combinations of 5-FU and leucovorin with newer agents such as irinotecan and oxaliplatin define the current standard. Patients in whom these regimens fail may be considered for treatment with other newer agents, including cetuximab, a monoclonal antibody against epidermal growth factor receptor, and bevacizumab, a monoclonal antibody against the vascular endothelial growth factor receptor.

16 MOTILITY DISORDERS

Nancy N. Baxter, M.D., Ph.D., F.R.C.S.C., F.A.S.C.R.S., and Robert D. Madoff, M.D., F.A.C.S., F.A.S.C.R.S.

Surgeons commonly encounter patients with gastrointestinal motility disorders. The management of such patients is frequently challenging, in that the etiology of the disorder is often multifactorial. Furthermore, even when surgical therapy is appropriate, management of symptoms remains a key component of effective treatment.

In what follows, we discuss two of the most common motility disorders, constipation and fecal incontinence. Although constipation usually is not treated surgically, surgeons regularly see patients with this presenting symptom. It is therefore critical that surgeons have a practical method of diagnosing and managing the primary and secondary causes of constipation. Fecal incontinence is an understudied and undertreated condition that can have a dramatic impact on quality of life. Effective treatment of incontinence has a dramatic positive influence on patients' lives; thus, it is important for surgeons to have both an effective approach to diagnosis and an informed awareness of the various therapeutic options available (including experimental treatments).

Constipation

CLINICAL EVALUATION

History

Constipation is the most common digestive complaint, with as much as 20% of the population reporting this symptom.¹ The meaning of the term constipation, however, is variable: when patients describe themselves as constipated, they may be referring to decreased stool frequency, reduced stool volume, altered stool consistency, or difficulty with defecation.² Accordingly, when a patient presents with a complaint of constipation, a thorough history of the presenting illness is essential [see Figure 1].

The patient should be asked about the frequency of bowel movements, the volume of stool per movement, the caliber of the stool, and, in particular, any changes in bowel habits over time. Patients with idiopathic constipation tend to have long-standing problems, with no abrupt change in bowel habits. Thus, if the history reveals constipation of sudden onset, an underlying cause (e.g., cancer) is more likely and should be sought. Other important symptoms that should lead to a search for a secondary cause are weight loss, anorexia, nausea and vomiting, rectal bleeding, changes in stool caliber, and fever. The patient should always be asked about previous colon cancer screening or other GI investigations. Although chronic constipation is common, severe constipation that has been present since early childhood should alert the clinician to the possibility of undiagnosed short-segment Hirschsprung disease; this rare diagnosis is easily missed if it is not given appropriate consideration. Other symptoms may be indicative of an outlet problem (e.g., rectocele or nonrelaxing puborectalis syndrome); such symptoms include requiring a prolonged period to evacuate stool from the rectum, a feeling of incomplete rectal emptying, and the need to support the per-

ineum (through digitation of the vagina or rectum) to achieve complete evacuation.

Diet can contribute significantly to constipation. Because high-fiber foods tend to increase stool bulk and frequency, detailed information on dietary fiber intake should be obtained. Because dehydration increases fluid resorption from stool and thereby results in the formation of hard stools, total daily fluid intake should be determined as well. A specific effort should be made to assess intake of fluids that contain caffeine, which exerts a diuretic effect. Most patients with long-standing constipation will already have tried some form of self-medication. Such attempts should be documented, both to help assess the severity of the symptom and to determine the likelihood of response to simple measures.

Various other diseases and certain common medications [see Table 1] also can cause or contribute to constipation. When such factors are present, treating the underlying condition or changing medications can result in substantial improvement. Therefore, a thorough past medical history and an accurate medication history are essential. A family history of colonic neoplasia or inflammatory bowel disease is potentially suggestive and may lead to a more intensive search for secondary causes. Victims of physical or sexual abuse may present with constipation; however, they are unlikely to mention the abuse if not directly questioned about the possibility.

Physical Examination

During physical examination, it is important to make a quick assessment of the patient's nutritional status. In general, patients with idiopathic constipation should not appear malnourished; the appearance of malnutrition should prompt a more extensive search for a secondary cause. An abdominal examination should be conducted to look for any significant abdominal distention, tenderness, or masses. Distention is a common and expected finding with idiopathic constipation, but significant tenderness or masses should prompt a full investigation.

All patients presenting with constipation should undergo a rectal examination. The anus should be examined for evidence of scarring or stricture. A digital rectal examination should be done to assess anal tone; high anal tone and inability to increase pressure when asked to squeeze are common findings in patients with obstructed defecation resulting from a nonrelaxing puborectalis. An effort should be made to look for any anterior defect in the rectovaginal septum, which would indicate the presence of a rectocele; such a defect, if present, may be made more prominent by having the patient strain. The finding of a rectal mass warrants further investigation.

INVESTIGATIVE STUDIES

In general, diagnostic studies are conducted to rule out an underlying cause of constipation (e.g., partially obstructing colon cancer) and to diagnose specific disorders associated with severe constipation (e.g., a nonrelaxing puborectalis and slow-transit constipation). Therefore, the choice of investigative studies should be individualized according to the clinical situation. In

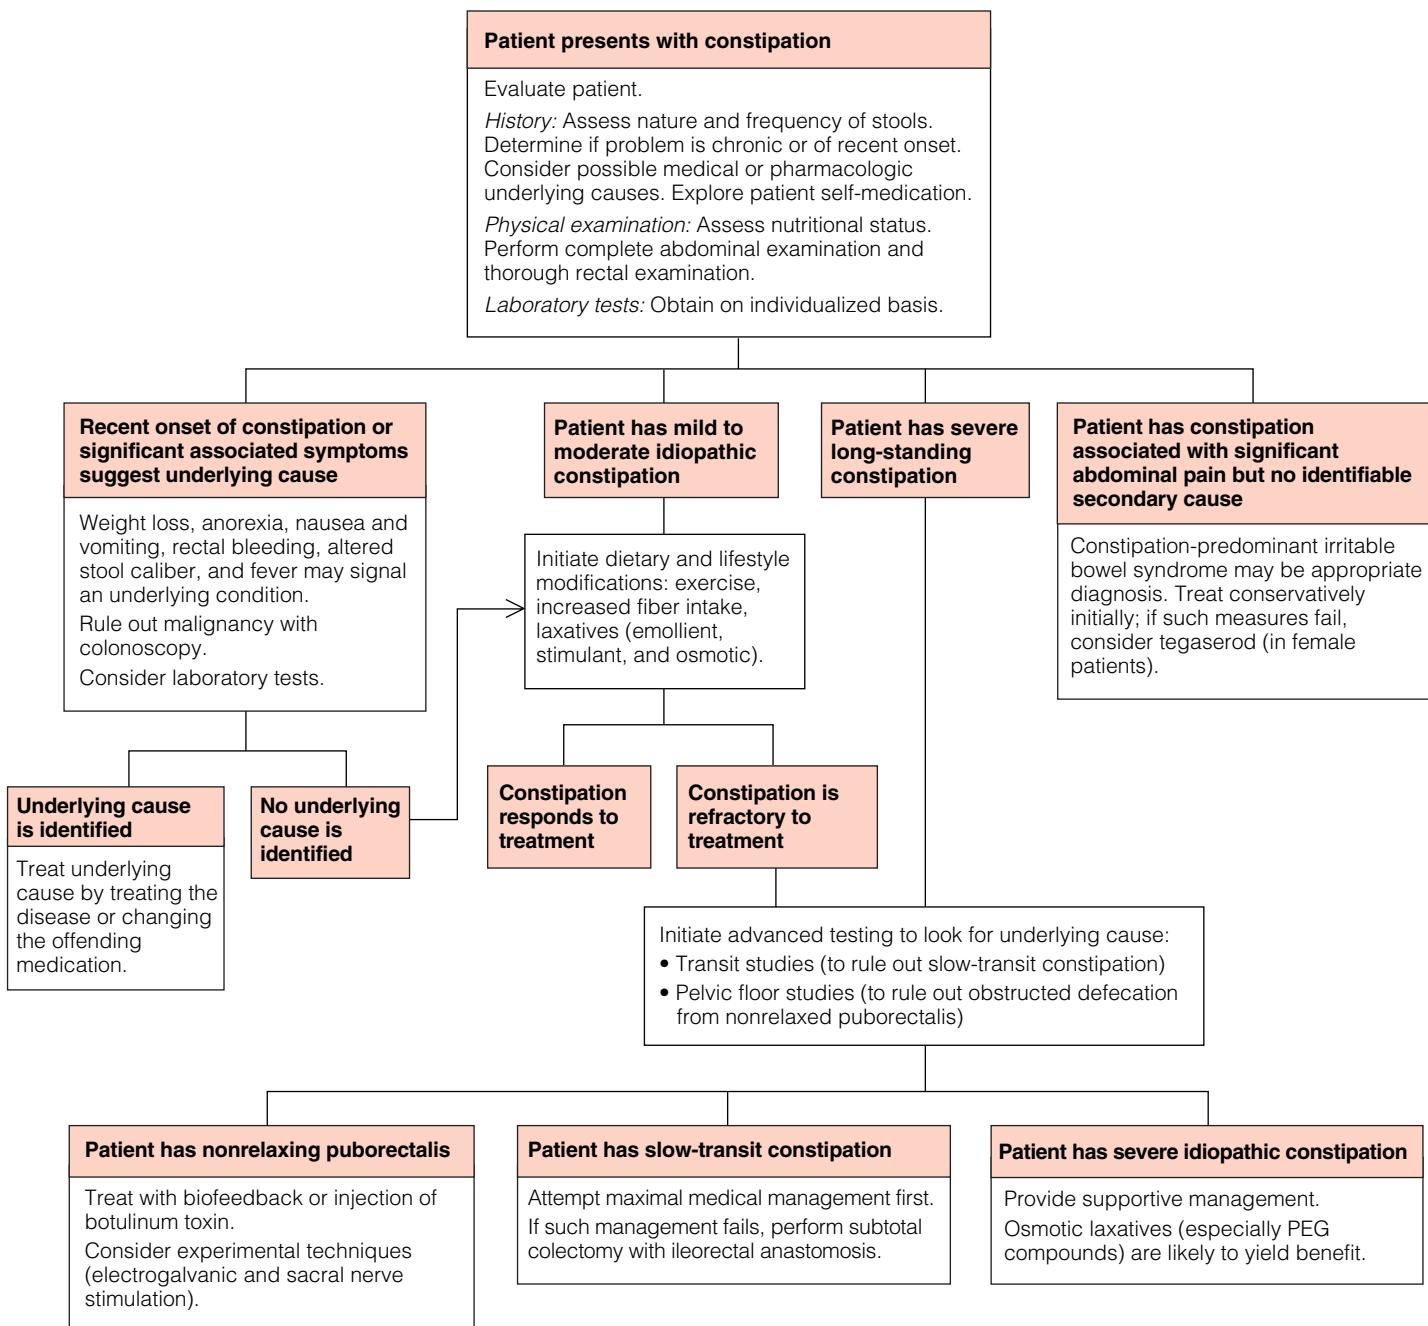

Figure 1 Algorithm outlines workup and management of constipation.

patients with mild symptoms and poor dietary habits who have no indications of any secondary causes of constipation, no investigations need be done on a routine basis. In patients with severe constipation, however, serum calcium concentrations, thyroid function tests, hemoglobin concentrations, glucose levels, serum electrolyte levels, and creatinine concentrations may be helpful.

Constipation with Suspected Underlying Cause

Whenever any of the findings from the history or the physical examination indicate a possible secondary cause of constipation, further investigation is mandatory. In particular, if a patient presents with any sign, symptom, or laboratory test result consistent with colorectal cancer (e.g., a sudden change in bowel habits, blood in the stool, weight loss, anorexia, a suggestive family history, abdom-

inal masses, or anemia), colonoscopy is necessary, irrespective of the patient's age or history of previous colonic investigations.

Patients with other secondary causes of constipation (e.g., hypothyroidism and hypercalcemia) often respond to treatment of the underlying disease or manipulation of medications. If such measures are ineffective, the constipation should be treated symptomatically, in much the same fashion as idiopathic constipation is. Patients requiring long-term opioid administration for pain control generally experience constipation as a side effect, and this effect does not dissipate with time. Thus, many of these patients will require laxative therapy for the duration of their opioid use.³

Mild to Moderate Idiopathic Constipation

In patients who have mild to moderate symptoms and no

Table 1 Causes of Secondary Constipation

Neuromuscular disorders	Spinal cord injury Parkinson disease Multiple sclerosis Stroke Autonomic neuropathy/diabetes Depression Hirschsprung disease
Metabolic abnormalities	Hypercalcemia Hyperparathyroidism Hypothyroidism Multiple endocrine neoplasia type IIB Chronic renal failure
Medications	Opioids Anticholinergics (tricyclic antidepressants, levodopa, antipsychotics) Supplements (iron, calcium) Antacids (calcium- or aluminum-containing) Anticonvulsants (phenytoin, valproic acid) Antihypertensives (calcium channel blockers, diuretics, clonidine) Cholestyramine
Others	Pregnancy Amyloidosis Scleroderma Chagas disease Anorexia nervosa

findings from the history or the physical examination that would indicate a secondary cause, extensive investigations are not necessary. Routine colonoscopy is not mandatory for patients younger than 50 years. For patients older than 50 years, the baseline risk of colorectal cancer is sufficiently high that screening colonoscopy is recommended even in the absence of symptoms. These older patients should therefore undergo routine colonoscopy, and many authors recommend that patients younger than 50 years undergo routine flexible sigmoidoscopy. Random endoscopic biopsies are unnecessary, because idiopathic constipation is not associated with abnormalities on routine processing of mucosal biopsies.

Severe, Long-standing Constipation or Refractory Constipation

In patients who have very severe constipation or in whom medical management fails, further investigative tests are warranted. These tests are conducted to classify patients into three categories, each of which calls for a different treatment approach: (1) slow-transit constipation, (2) nonrelaxing puborectalis, and (3) normal-transit constipation.⁴ The initial investigations should include assessment of colonic transit time to determine if slow-transit constipation is present, as well as evaluation of pelvic floor function to determine if a nonrelaxing puborectalis is present.

There are two main methods for evaluating colonic transit: the radiopaque marker study and colonic scintigraphy. Both tests have advantages and disadvantages. In general, the choice between them depends on local expertise; the radiopaque marker study is more widely available. For the radiopaque marker study, 20 radiopaque markers (prepackaged in gelatin capsules) are ingested, and an abdominal x-ray (which includes the pelvis) is taken on day 5. The patient abstains from laxatives for the duration of the study. At 3 days, most patients with normal transit have excreted more than 80% of the markers; however, because there is substantial variation among asymptomatic persons, only patients who retain more than 20% of the markers for at least 5 days are considered to have abnormal transit. Abnormal transit may be demonstrated either throughout the colon or within a limited portion thereof (most commonly, the sigmoid and the rectum) [see Figure 2].

Colonic scintigraphy shares certain principles with the radiopaque marker study. Patients ingest a meal containing a radioactive isotope, and abdominal images are obtained with a gamma camera at 12, 24, and 48 hours. The results provide a quantitative assessment of colonic transit. In addition, unlimited numbers of images may be taken with the single isotope dose, and this feature of the test may be especially useful in children. For optimal accuracy, this technique requires standardization, and its availability is generally limited to centers with specific interest and expertise in it.

Pelvic floor studies are valuable for ruling out obstructed defecation as a cause of constipation. The balloon expulsion test can be performed in the office as an initial screening measure.⁵ A balloon filled with 50 ml of water is attached to tubing and placed in the rectum; patients with a nonrelaxing puborectalis generally can-

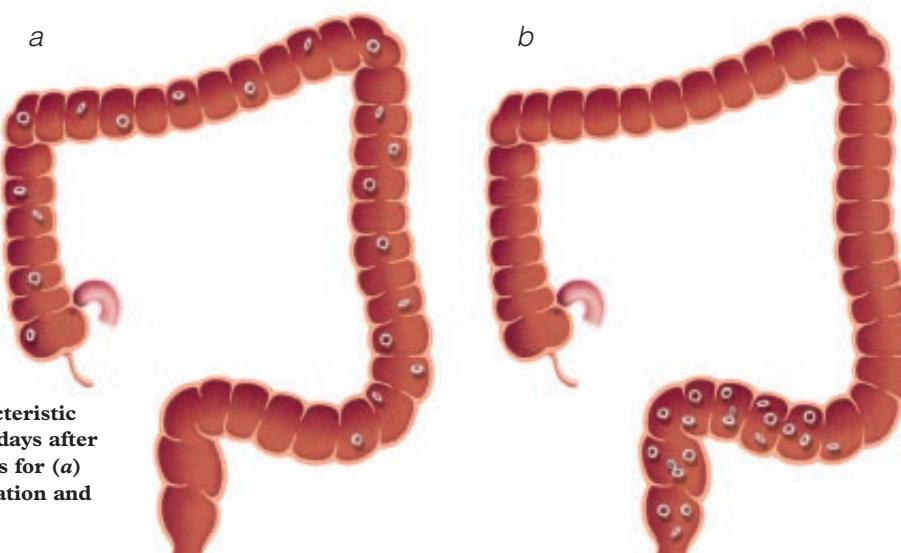

Figure 2 Illustrated are characteristic colonic transit study findings 5 days after ingestion of radiopaque markers for (a) pancolonic slow-transit constipation and (b) outlet obstruction.

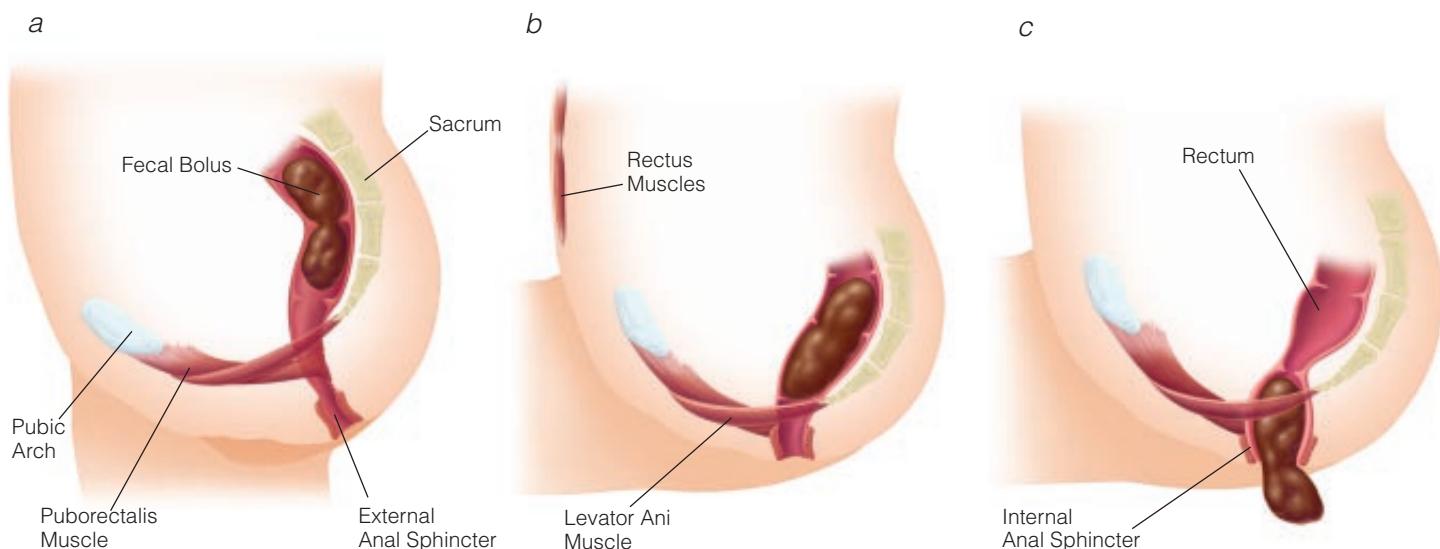

Figure 3 Schematic representation of normal defecation depicts (a) initial contraction of pelvic floor muscles with urge to defecate, (b) relaxation of puborectalis and external sphincter, and (c) relaxation of internal sphincter and evacuation of stool with rectal contraction.

not expel the balloon from the rectum in 1 minute while sitting on a commode. It should be kept in mind, however, that as many as 12% of patients with normal pelvic floor function will have difficulty with balloon expulsion in this setting.⁶

A thorough pelvic floor evaluation is best conducted in a pelvic floor laboratory with a specific interest in anorectal function. In addition to the balloon expulsion test, the evaluation generally involves manometry, including assessment of the reflexive relaxation of the internal sphincter after rectal distension. The presence of this reflexive relaxation rules out Hirschsprung disease as a cause of constipation. In patients with a nonrelaxing puborectalis, manometry during straining effort demonstrates abnormal function of the external sphincter—either failure to relax to enable expulsion or, on occasion, paradoxical contraction. Similar findings during straining can be documented by means of electromyography (EMG) with a sponge electrode in the anal canal.

Defecography is commonly performed as well. Barium paste is formulated so as to simulate a fecal bolus and placed in the rectum. The patient is asked to defecate on a radiolucent commode, and the event is recorded with fluoroscopy. During normal defecation, the puborectalis and the anal sphincter muscles relax, and the rectum assumes a more vertical position with respect to the anal canal, facilitating evacuation of stool [see Figure 3]. In a patient with a nonrelaxing puborectalis, defecography typically demonstrates failure to open the anorectal angle and persistence of the puborectalis impression during defecation, as well as failure to empty completely.⁷ Other important findings that may be noted include rectocele, internal intussusception, and rectal prolapse. When appropriately selected, patients with obstructed defecation resulting from such abnormalities may benefit from surgical correction; however, even when these anatomic abnormalities are present, they may not be the underlying cause of constipation. Interpretation of defecography is subjective, and there is wide normal variation. Therefore, the diagnosis of a nonrelaxing puborectalis should be based not on a single test result but, rather, on the totality of the diagnostic findings.

The diagnosis of nonrelaxing puborectalis syndrome is made in persons with constipation in whom there is evidence of failure of

the pelvic floor to relax appropriately (or paradoxical contraction of the pelvic floor) with defecation. The cause of this condition is not known; however, the syndrome is thought to be acquired over time. Patients with an underlying neurologic disorder (e.g., multiple sclerosis or Parkinson disease) are prone to spasticity of the puborectalis and may experience severe constipation as a result.

MANAGEMENT

Mild to Moderate Idiopathic Constipation

Many cases of constipation can be managed with dietary and lifestyle changes, such as modifying the diet to include foods high in fiber and drinking adequate amounts of water. Physical inactivity is associated with constipation, and encouraging moderate exercise may lead to significant symptomatic relief. Fiber supplementation is a key component of therapy for mild constipation.⁸ Fiber products (e.g., psyllium, methylcellulose, and polycarbophil) increase stool bulk and stimulate colonic motility. Such products must be taken with sufficient amounts of fluid, or they may lead to stool hardening. Often, patients have already tried fiber products but did not achieve satisfactory results because the quantities were insufficient; daily doses as high as 20 g may be necessary for a therapeutic effect. Patients taking fiber products may experience an increase in flatulence, particularly with fermentable fiber products. To improve tolerance, the amount of fiber should be increased gradually, and patients should be informed that the effect of fiber may not be seen immediately.

Nonlaxative therapy should be stressed; however, if dietary changes and fiber supplementation fail, judicious use of laxatives can bring about significant symptomatic relief. It should be kept in mind that tachyphylaxis to laxatives is common and may lead to chronic dependence. Stool softeners, or emollient laxatives (e.g., docusate sodium and mineral oil), enhance penetration of water and fat into the stool, thereby making it less hard. These agents may be of use on a relatively short-term basis. Docusate sodium is less effective than fiber supplementation⁹; stool softeners should not be used as a substitute for fiber.

Stimulant laxatives, including cascara, anthraquinones (senna and rhubarb), castor oil, and bisacodyl, are common components

of popular over-the-counter medications. These agents have direct neuromuscular or mucosal effects, resulting in enhanced GI motility and altered mucosal transport (and thus increased intestinal secretion).⁸ Long-term use or abuse of anthraquinones can lead to melanosis (discoloration of the colonic mucosa caused by pigment deposition in colonic macrophages).

Osmotic laxatives contain compounds that either are not absorbed or are poorly absorbed. If the solutions are hypertonic, they cause water to move into the bowel lumen to maintain tonicity.¹⁰ Common preparations include magnesium and phosphate salts. Ingestion of large amounts of such preparations can lead to hypermagnesemia or hyperphosphatemia, mainly in patients with renal failure. The large fluid shifts that result when these compounds are used for bowel preparation may be dangerous in patients with underlying heart disease. Polyethylene glycol (PEG) is a high-molecular-weight compound that is not absorbed and thus functions as an osmotic laxative. PEG preparations are commonly administered as isotonic solutions and therefore cause only minimal fluid or electrolyte shifts when consumed rapidly (as in bowel preparation). PEG compounds are available as laxatives that can be taken either intermittently or regularly.

Tegaserod, a 5-HT₄ partial agonist, has been shown to alleviate bloating and increase stool frequency by improving gut motility and decreasing visceral sensitivity.¹¹ It may be prescribed for women with constipation-predominant irritable bowel syndrome (IBS) (see below) and for either male or female patients younger than 65 years who have idiopathic constipation. Tegaserod has been associated with the development of diarrhea; typically, the diarrhea resolves when the drug is discontinued, but occasionally, it is severe. In addition, several cases of ischemic colitis have been reported in patients receiving tegaserod. Although no causal relation has been established, patients should be warned to cease taking tegaserod and immediately contact their physician if abdominal pain worsens.

Enemas and suppositories act via a number of mechanisms, including softening of the stool, stimulation of rectal contraction by rectal distention, and direct alteration of mucosal secretion. They may be useful for occasional administration.

Constipation-Predominant Irritable Bowel Syndrome

In patients with constipation, significant abdominal pain, and no identifiable secondary cause of constipation, the diagnosis of constipation-predominant IBS may be appropriate [see Table 2].^{12,13} Often, patients with constipation-predominant IBS respond to reassurance and fiber supplementation. Tegaserod may be

Table 2 Rome II Criteria for Diagnosis of Constipation-Predominant Irritable Bowel Syndrome⁸

At least 12 wk of abdominal pain or discomfort in the past year, with at least 2 of the following:

1. Relief with defecation
2. Onset associated with a change in frequency of stool
3. Onset associated with a change in form (appearance) of stool

Supportive symptoms of constipation-predominant IBS:

1. Abnormal stool frequency (< 3 bowel movements/wk)
2. Abnormal stool form (hard or lumpy stools)
3. Abnormal stool passage (straining during bowel movement, feeling of incomplete evacuation)

employed in female patients who do not respond to conservative measures.

Severe, Long-standing Constipation or Refractory Constipation

Nonrelaxing puborectalis Patients with constipation arising from a nonrelaxing puborectalis often benefit from biofeedback.¹⁴ In this modality, a device (e.g., an anorectal manometer) is used to monitor pelvic floor activity; electrodes may also be used for EMG biofeedback. Patients observe pressure changes (or EMG activity) during attempts to evacuate. Through trial and error, they are taught to modify their responses until appropriate relaxation is achieved, the aim being to retrain the pelvic floor to relax during defecation. Training may have to be reinforced at intervals. Accurate determination of the success rate of biofeedback is difficult, in that the published literature consists primarily of case series and most of the trials that have been conducted have not included a placebo arm. It has been estimated that the success rate may be as high as 70%; however, this estimate is probably overoptimistic.¹⁵

If biofeedback fails, injection of botulinum toxin into the puborectalis under ultrasonographic guidance may be attempted. To date, published reports have evaluated this approach only in relatively small study groups; the results, though not decisive, are promising, in that the use of botulinum toxin clearly brought about noticeable improvements in manometric and defecographic findings¹⁶ and symptomatic improvements in the majority of patients.¹⁷ Other experimental techniques available for treatment of nonrelaxing puborectalis syndrome are electrogalvanic stimulation¹⁸ and sacral nerve stimulation (SNS).¹⁹ Currently, surgical approaches do not play a role in the treatment of constipation secondary to a nonrelaxing puborectalis.

Slow-transit constipation Slow-transit constipation, also known as colonic inertia, is most common in young women and often starts at puberty. It is characterized by abnormally slow forward propulsion of colonic contents. The cause of slow-transit constipation is unknown, though abnormalities in a number of cellular and neuromuscular modulators of GI motility have been found in patients with this condition.^{20,21} Although patients with idiopathic slow-transit constipation are frequently resistant to laxative therapy, many respond to osmotic PEG laxatives. Surgery should be considered as an option only in the most severely affected patients, in whom aggressive laxative therapy has repeatedly failed over a prolonged period. Even in specialized centers, only about 5% of patients presenting with constipation are considered appropriate candidates for surgical treatment.²²

The operation most commonly performed to treat slow-transit constipation is subtotal colectomy with ileorectal anastomosis, performed via either an open or a laparoscopic approach. The colon is removed to the level of the sacral promontory in a standard fashion; the ileorectal anastomosis may be either stapled or handsewn. Constipation is less likely to recur with this anastomosis than with an ileosigmoid anastomosis.²³

Surgical therapy is generally successful in improving bowel function: in most patients, stool frequency rises to one to three bowel movements a day. Unfortunately, surgery may not satisfactorily alleviate other symptoms (e.g., abdominal discomfort or bloating),²⁴ and patients should be made aware of this possibility before operation. The key to successful surgical treatment is patient selection. Overall, the majority of well-selected patients are satisfied with the results of surgical treatment^{25,26}; however, long-term postoperative complications, particularly small bowel obstruction, are common. In addition, patients may manifest symptoms of a more global GI dysmotility disorder in the long term.

Figure 4 Shown is an obstetric sphincter injury.

Other surgical approaches sometimes employed in this setting are ileostomy [see 5:30 *Intestinal Stomas*], total proctocolectomy with ileal pouch-anal anastomosis (IPAA) [see 5:33 *Procedures for Ulcerative Colitis*], segmental colectomy [see 5:34 *Laparoscopic Colectomy*], and colectomy with cecorectal anastomosis; however, data on the long-term effectiveness of these approaches in large numbers of patients are lacking. Completion proctectomy with IPAA and ileostomy are options for patients who remain severely symptomatic after ileorectal anastomosis but who manifest no evidence of proximal dysmotility.

Not infrequently, patients have both slow-transit constipation and a nonrelaxing puborectalis. In such cases, it is essential that the obstructed defecation be addressed before any surgical treatment is carried out. Even after biofeedback, if surgical therapy is attempted in this setting, as many as 50% of patients will be dissatisfied with the results.²⁷

Severe idiopathic constipation Patients who have severe constipation but show no signs of slow-transit constipation, pelvic floor dysfunction, or IBS should be treated with reassurance and symptomatic management. Osmotic laxatives—in particular, PEG products—may be very useful in this group. Operative treatment plays no role in management; however, experimental approaches (e.g., SNS) are being evaluated for possible use in this setting.

Fecal Incontinence

Fecal incontinence may be defined as the involuntary loss of rectal contents through the anal canal. It is a relatively common condition, occurring in an estimated 2.2% of persons in the United States.²⁸ Its exact prevalence is unknown, however, and appears to vary with the population being studied. For example, nearly 50% of nursing home patients are incontinent to stool.²⁸ Fecal incontinence is often treated inadequately, either because of underreporting of symptoms to the physician²⁹ or because of ignorance or disinterest on the physician's part.

Fecal incontinence makes a significant contribution to medical morbidity (e.g., urinary tract infections and decubitus ulcers),

but its main impact is on quality of life. Affected patients experience embarrassment and shame, and many dramatically alter their lifestyle in an effort to avoid accidents.

Normal continence depends on a chain of interdependent processes, and disruption of any of the links in the chain can lead to incontinence. Frequently, a combination of factors is responsible for the incontinence.

To care about continence, persons must have adequate mental function, and to maintain normal continence, they must have an intact neurologic arc from the brain to the anal sphincter. A wide array of neurologic disorders can lead to incontinence, including dementia, strokes, spinal cord injury, multiple sclerosis, and diabetic autonomic neuropathy. So-called idiopathic fecal incontinence is caused by pelvic floor denervation resulting from traction injury to the pudendal nerves.³⁰ The injury is usually caused by straining and consequent pelvic floor descent during obstetrical delivery or by chronic straining at stool.

Conditions characterized by abnormal GI function, especially diarrheal states, can cause or exacerbate incontinence. Common causative conditions include infectious diarrhea and inflammatory bowel disease. Diarrhea-predominant IBS can contribute to incontinence in patients with other associated disorders. Fecal impaction is an important cause of incontinence, particularly in older and institutionalized populations.³¹

Abnormalities of the pelvic floor are frequent causes of incontinence. Some such abnormalities are congenital malformations (e.g., imperforate anus, rectal agenesis, and cloacal defect). More often, abnormalities are attributable to acquired sphincter injuries. Common causes of sphincter injury include obstetric injury, pelvic fracture, and traumatic impalement [see Figure 4]. One of the most frequent causes is an anorectal procedure, such as fistulotomy,³² sphincterotomy,³³ or anal dilatation.³⁴ Sphincter-sparing rectal resections can also lead to incontinence as a consequence of both the loss of the normal rectal reservoir and the sphincter injury caused by transanal introduction of intraluminal staplers.

CLINICAL EVALUATION

History

A careful patient history and a directed physical examination are the most important elements of clinical evaluation for a patient with fecal incontinence [see Figure 5]. The patient should be asked about the onset and nature of the incontinence (e.g., whether the stool is liquid or solid and whether flatus is present), any associated changes in stool consistency or bowel habits, and the frequency of incontinence. A pertinent but thorough medical, surgical, and obstetric history should be obtained, and any underlying contributory conditions (e.g., colitis) should be treated. The impact of the incontinence on the patient's quality of life should be assessed, at least qualitatively.

Physical Examination

Physical examination should focus primarily on the perineum. Seepage and secondary perineal skin breakdown should be noted, as should scars from previous surgical treatment or trauma. Perineal body deformity is an important sign of obstetric injury, and gaping of the anus with traction on the buttocks is suggestive of rectal prolapse. When prolapse is suspected but not evident, the patient should be asked to strain while seated on a commode. Digital rectal examination is useful for detecting low rectal tumors and fecal impaction; it also provides a qualitative assessment of both resting sphincter tone and voluntary squeeze pressure.

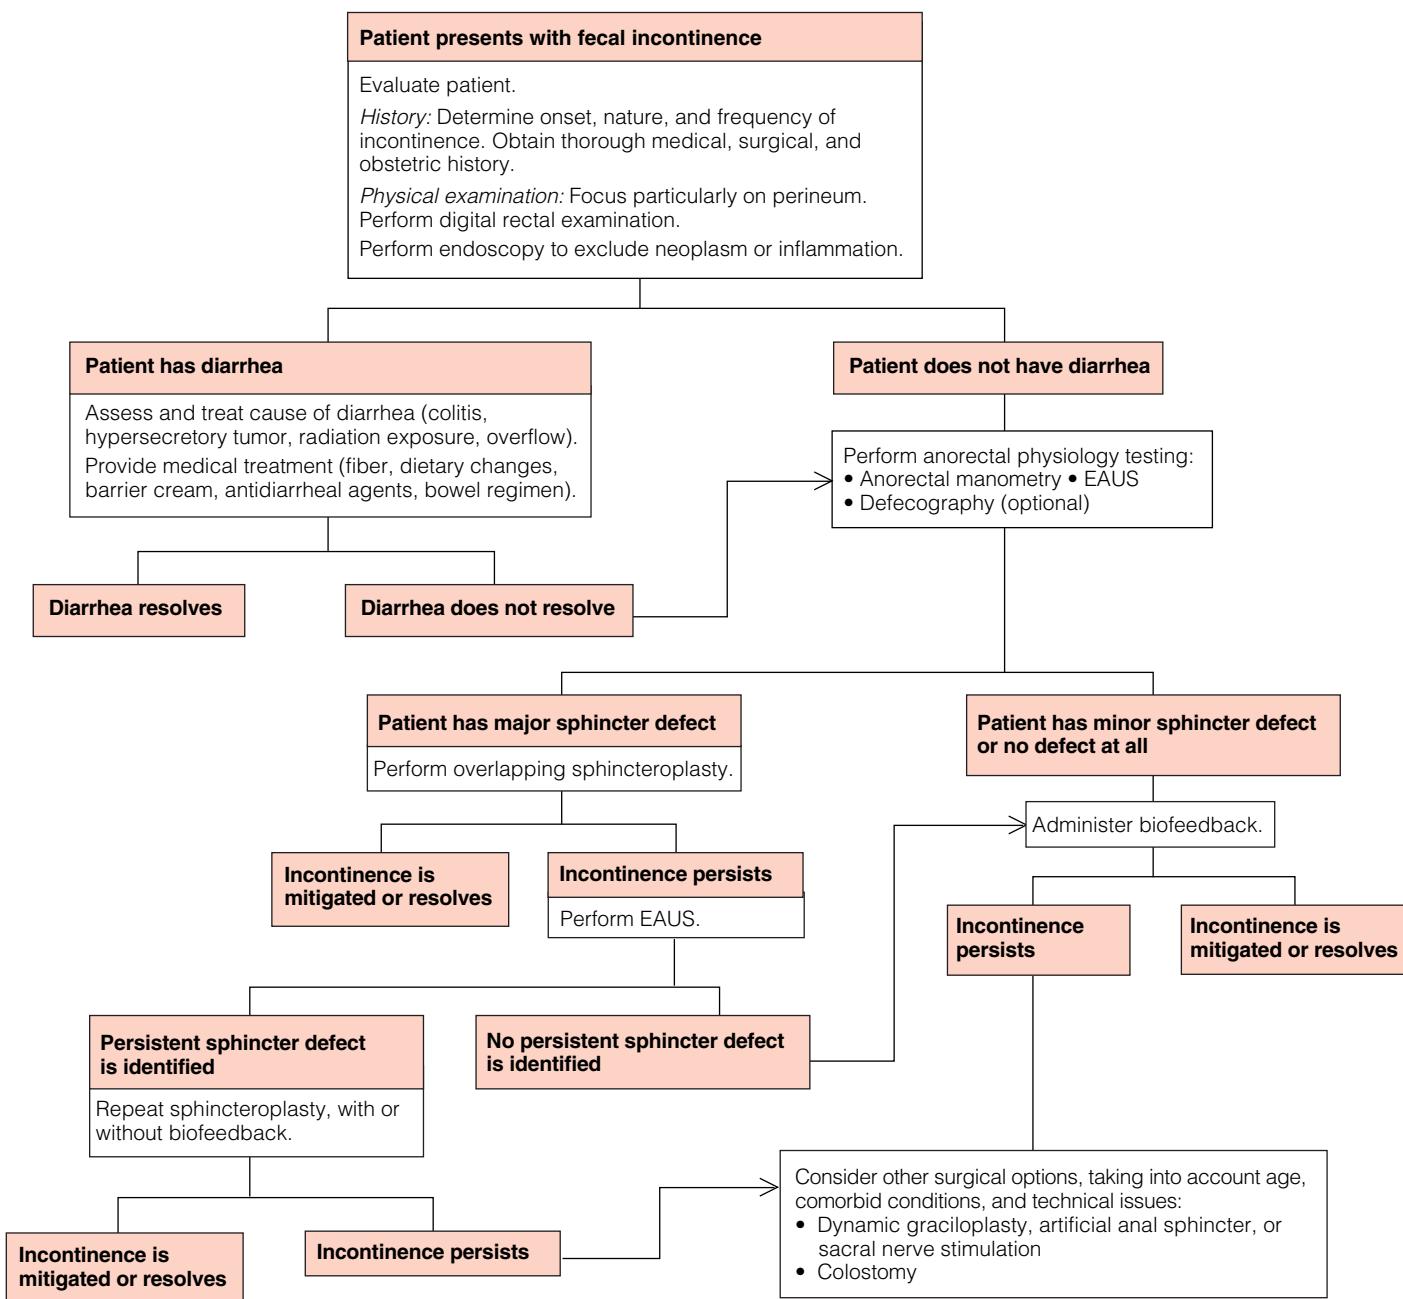

Figure 5 Algorithm outlines workup and management of fecal incontinence.

INVESTIGATIVE STUDIES

Endoscopy should be performed on all incontinent patients to exclude a neoplastic or inflammatory condition. In most cases, flexible sigmoidoscopy is adequate, but if the patient has unexplained diarrhea, bleeding, or changed bowel habits, complete colonoscopy should be performed.

Anorectal testing is indicated for most patients with significant incontinence, particularly if operative treatment is being considered. The most important test is endoanal ultrasonography (EAUS), which yields a highly accurate assessment of sphincter integrity [see Figure 6].³⁵ At some centers, magnetic resonance imaging has become the test of choice for evaluating the pelvic floor. Anal manometry provides a quantitative assessment of resting and squeeze anal pressures, which serve as indicators of internal anal sphincter function and external anal sphincter function,

respectively. EMG may be used to diagnose neuropathic injury of the pelvic floor. Although concentric-needle EMG is the most accurate technique, most centers employ a glove-mounted intra-anal electrode to measure pudendal nerve conduction time (i.e., pudendal nerve terminal motor latency [PNTML]). The practical utility of PNTML testing is debatable, however, and opinions vary regarding the test's ability to predict successful outcomes after anal sphincter repair.^{36,37} When the cause of incontinence is uncertain, dynamic imaging of the pelvic floor with defecography or MRI may reveal an occult pathologic state (e.g., occult rectal prolapse).

MANAGEMENT

Conservative Management

Minor incontinence should be treated first with conservative mea-

sures. Dietary changes (e.g., avoidance of foods that cause diarrhea or urgency), fiber supplementation, and bowel habit training are helpful for most patients, as is regular use of loperamide. Perianal skin excoriation should be treated with a barrier cream, and seepage may be controlled either with placement of a small cotton wick at the anal orifice or, occasionally, with rectal washouts.

Biofeedback

Biofeedback appears to be an effective therapy for fecal incontinence in a high percentage of patients.^{38,39} It is an inherently attractive approach because it is simple, painless, and risk-free. However, the biofeedback literature consists mostly of small, uncontrolled, retrospective studies; a randomized, controlled trial from 2003 found that biofeedback had no advantages over standardized medical and nursing care (i.e., advice) or advice plus sphincter exercises.⁴⁰

Sphincteroplasty

Anal sphincter repair is the most widely accepted operation for fecal incontinence [see Figure 7]. In acute situations (e.g., when an obstetric sphincter injury is recognized), immediate direct repair is generally recommended. Unfortunately, as many as 75% of women have persistent external anal sphincter defects after primary repair, and about 60% have some degree of incontinence.⁴¹ If immediate repair is not attempted, surgical treatment should be delayed at least 3 to 6 months to permit resolution of local tissue inflammation and edema.

For incontinent patients with established sphincter defects, overlapping sphincteroplasty is the procedure of choice. Complete bowel preparation is carried out before the procedure, and prophylactic antibiotics are administered.

Operative technique *Step 1: initial dissection.* The patient is placed in the prone jackknife position, with the buttocks taped apart and a large roll beneath the hips. A curvilinear incision is made over the perineal body, and the anoderm and the anal canal mucosa are raised as an endodermal flap [see Figure 7a]. The vaginal wall is mobilized anteriorly.

Step 2: mobilization of sphincter muscle. It is often easiest first to identify normal muscle laterally in the ischiorectal fossa and then

to work medially toward the attenuated tissue in the midline. Lateral dissection is extended back on either side until enough healthy muscle is mobilized to allow overlapping without tension. Generally, however, lateral dissection should not extend beyond the midcoronal line, so as not to risk injury to the inferior rectal branches of the pudendal nerves, which cross the ischiorectal fossae posterolaterally. Dissection is then carried out cranially in the rectovaginal septum to the level of the puborectalis. The muscle is divided through its midline scar, but the scar is preserved to help prevent the sutures from tearing through.

Step 3: overlapping repair. The tapes on the buttocks are then released, and an overlapping sphincter repair is performed with absorbable mattress sutures [see Figures 7b, c]. A snug plication is universally advocated, but unfortunately, there are no generally accepted objective criteria to define exactly what “snug” means in this context. Many authorities advise plication of the puborectalis (so-called levatorplasty) at the cranial aspect of the repair to maximize the length of the anal canal.⁴² Others favor individual dissection and repair of the internal and external sphincter muscles, but at present, there is no compelling evidence for the superiority of this approach.

Step 4: restoration of perineal body. The skin incision is closed in a V-Y configuration [see 3:7 Surface Reconstruction Procedures] to restore the perineal body and maximize the distance between the anus and the vaginal introitus. The wound is left partially open or closed loosely over small Penrose drains to minimize the risk of surgical site infection [see Figure 7d]. A diverting stoma is not generally indicated but may be considered in special situations (e.g., multiple previous failed repairs, Crohn disease, or various chronic diarrheal states).

Outcome evaluation Overlapping sphincteroplasty yields substantial clinical improvement in approximately 65% to 80% of patients.^{43,44} Unfortunately, current data indicate that results deteriorate significantly over time.⁴⁵⁻⁴⁷ When sphincteroplasty fails, repeat EAUS evaluation should be done to confirm that the muscle wrap is intact, and another repair should be performed after 6 to 12 months if a significant defect persists.⁴⁸ If the muscle wrap is intact, the functional outcome can often be improved by means of biofeedback.⁴⁹

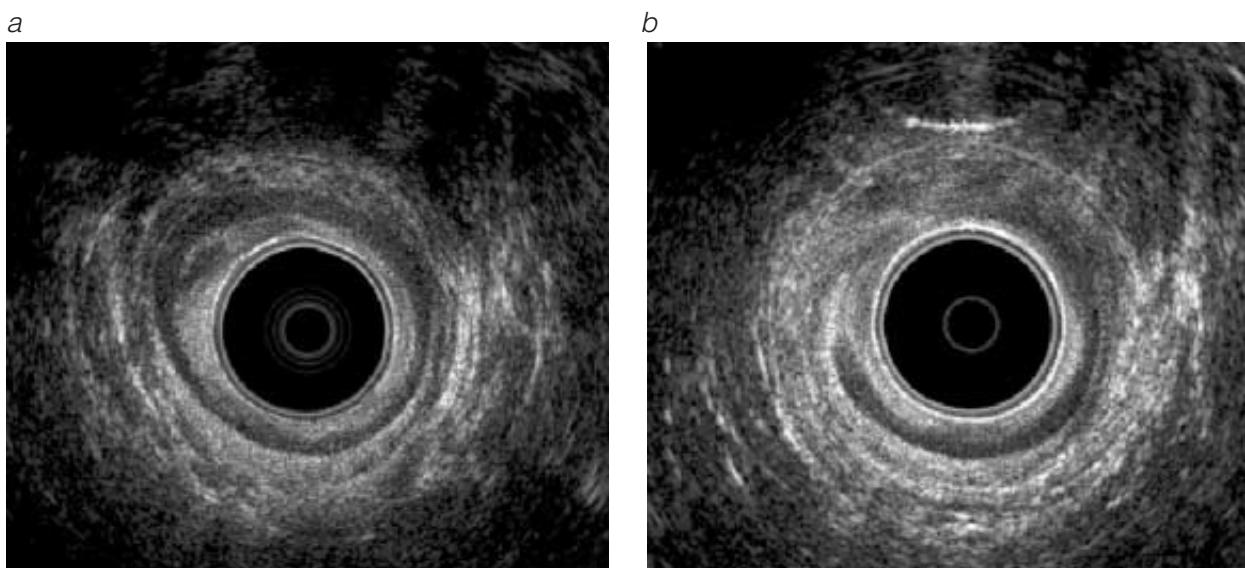

Figure 6 Endoanal ultrasonograms show (a) a normal anal sphincter and (b) a sphincter defect.

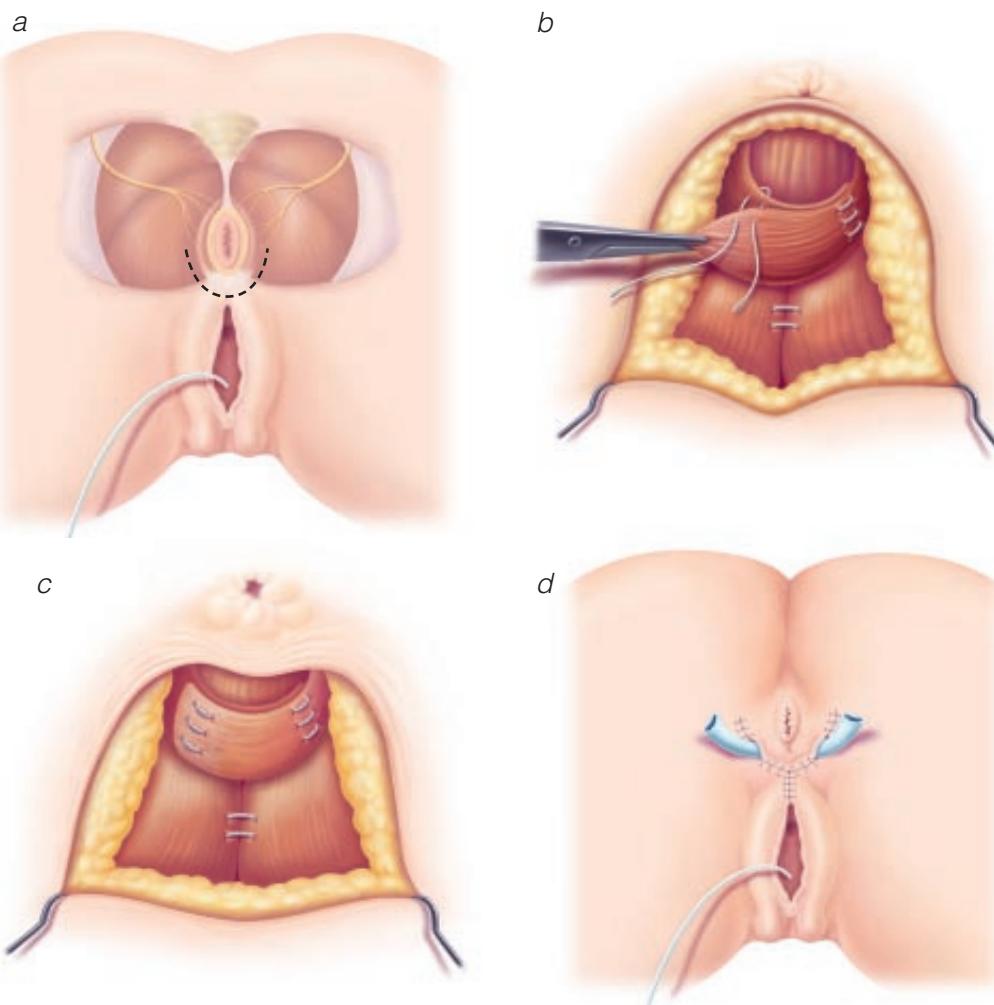

Figure 7 Sphincteroplasty. (a) With the patient in the prone jackknife position, a curvilinear incision is made. Inferior rectal nerves cross the ischiorectal fossa posterolaterally. (b) Anterior levatorplasty is performed, and overlapping sphincter repair is then initiated. (c) Sphincter repair is completed. (d) The incision is closed, with drains in place (optional), and V-Y plasty is done to restore the perineal body.

Various surgical options are available for patients in whom sphincteroplasty has failed or who are not candidates for the procedure (e.g., those with pudendal neuropathy and an anatomically intact sphincter). A number of these options are investigational, and further study is needed to determine their eventual role (if any) in incontinence therapy.

Postanal Repair

Sir Alan Parks devised the postanal repair in 1975 to treat patients with incontinence and intact sphincters. The initial results were encouraging but tended to deteriorate over time. Consequently, despite evidence of lasting improvement in some patients, this operation is rarely performed today.^{50,51}

Injectable Biomaterials

A number of studies have explored the use of injectable biomaterials to provide bulk around the anal sphincter and thereby improve continence. The materials employed have included autologous fat, cross-linked collagen, silicone, and carbon-coated beads.^{52,53} Several small, uncontrolled studies have reported promising results, but larger series with longer follow-up times are needed.

Nonstimulated Muscle Transposition

Attempts to restore continence by creating a neosphincter from transposed skeletal muscle date back to the early 20th century. Most such attempts have made use of either the gluteus maximus⁵⁴ or the gracilis.⁵⁵ Good results have frequently been reported, but many authorities believe that the quality of the resulting continence is poor. One of the main limitations of nonstimulated muscle transposition is that patients are typically unable to maintain voluntary contraction of the transposed muscle over the long term.

Stimulated (Dynamic) Graciloplasty

Successful electrical stimulation of a transposed gracilis by means of an implantable pulse generator was first reported in 1988.⁵⁶ Such stimulation has two main effects. First, it converts the fast-twitch, rapidly fatigable gracilis to a slow-twitch, fatigue-resistant muscle that is capable of tonic contraction for prolonged periods.⁵⁷ Second, electrical stimulation maintains tonic muscle contraction without the need for continuous voluntary control on the part of the patient. A small number of centers with particular expertise in dynamic graciloplasty and high patient volumes have

reported good results with acceptable morbidities⁵⁸; however, three large multicenter trials have reported less encouraging results with prohibitive morbidities.⁵⁹⁻⁶¹ In the United States, dynamic graciloplasty is not available, because it has not been approved by the Food and Drug Administration. Elsewhere in the world, the operation can be considered a salvage option at centers with the requisite expertise and experience.

Artificial Anal Sphincter

The artificial anal sphincter is an implantable system consisting of three parts: an inflatable perianal cuff, a pressure-regulating balloon, and a control pump that is implanted in the scrotum or the labia majora [see Figure 8]. Good results have been reported in individual case series,⁶² but device infection has been a problem.^{63,64} In a large multicenter trial, 46% of patients required surgical revision of the device, including 25% who required revision or explantation because of infection. Of the patients who underwent implantation, 53% had successful results; among those with a functioning device in place, the success rate was 85%.

Sacral Nerve Stimulation

In SNS, an electrode is inserted through a sacral foramen and used to stimulate the sacral nerves. To date, the procedure has been employed mainly in patients with intact anal sphincters (including those with intact repairs). It is available for treatment of fecal incontinence in Europe but has not yet received FDA approval for this indication in the United States.

SNS is generally carried out in two stages. The first stage, peripheral nerve evaluation (PNE), is performed to confirm a muscular response to stimulation of the sacral nerves, to identify the optimal site for stimulation (S2, S3, or S4) and to determine the clinical response to stimulation with an external pulse generator. In most cases, stimulation of the S3 nerves provides the optimal response.

PNE is performed with the patient prone and under local anesthesia, with or without sedation. The sacral foramina are located

by means of bony landmarks; S3 is typically about 1.5 cm off the midline at the level of the sciatic notch.⁶⁵ Initial testing is performed with an insulated spinal needle and an external pulse generator. Stimulation of each foramen leads to a typical response: S3 causes a bellows-type contraction of the pelvic floor and dorsiflexion of the ipsilateral great toe. Usually, several levels are tested until the optimal site is identified. A temporary pacing wire or a permanent quadripolar lead is then inserted and connected to an external stimulator [see Figure 9].

Patients are asked to provide a baseline continence diary, and a second diary is recorded during the test stimulation period. If continence is significantly improved (e.g., by 50% or more), the second stage of SNS, implantation of a permanent lead (if not already in place) and a pulse generator, is carried out. This second stage is also performed with the patient prone, under local anesthesia, and sedated. The pulse generator is implanted in a subcutaneous pocket on the same side as the stimulating electrode.

Both stages of SNS are performed as outpatient procedures. The pulse generator is activated and its stimulation parameters set by means of a telemetric programmer. If problems (e.g., pain) develop or if the results of stimulation are inadequate, the system can be reprogrammed in a variety of ways: stimulation frequency can be altered, voltage can be increased or decreased, and the configuration of the stimulating electrodes can be modified.

SNS has been shown to be a highly effective treatment for fecal incontinence.⁶⁶⁻⁶⁸ Unlike dynamic graciloplasty and the artificial anal sphincter, SNS is associated with only minimal morbidity. In a multicenter prospective trial, the frequency of incontinent events dropped from 16.4/wk at baseline to 3.1/wk at 12 months after SNS and 2.0/wk at 24 months. Fecal incontinence-related quality of life was significantly improved.

Because of its high success rate and excellent safety profile, many authorities now consider SNS the salvage procedure of choice for patients with refractory incontinence. If SNS fails, more aggressive treatments may still be tried at a later time.

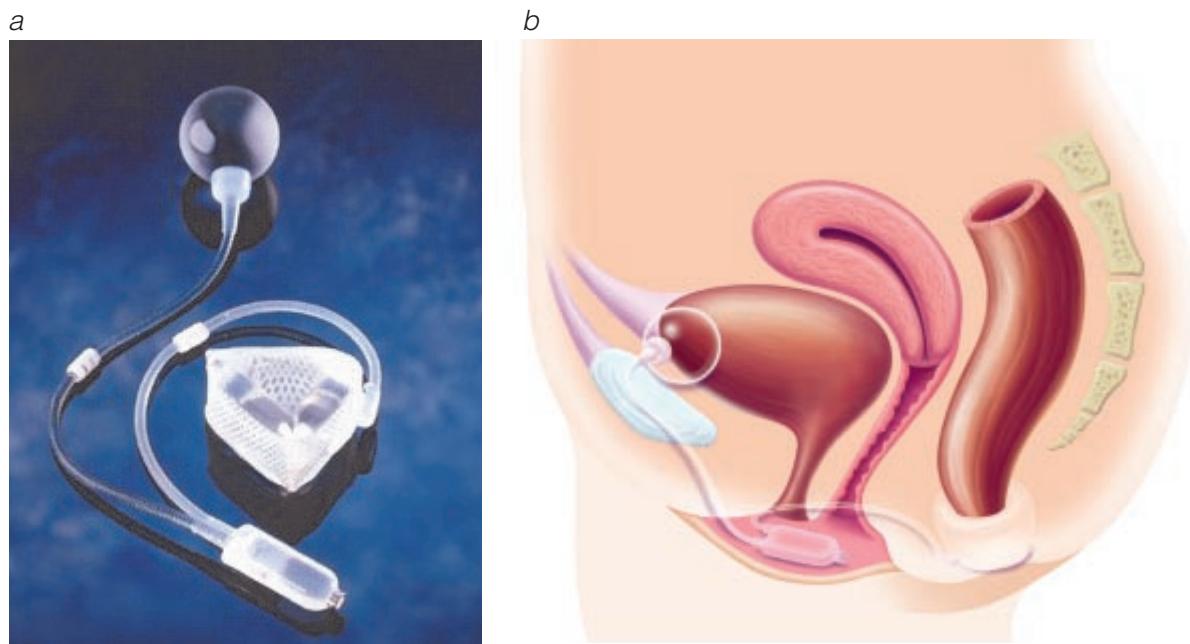

Figure 8 Artificial anal sphincter. (a) A three-part implantable system is used (shown is Acticon; American Medical Systems, Minneapolis, Minnesota). (b) Depicted is the recommended placement of the artificial sphincter device in the patient.

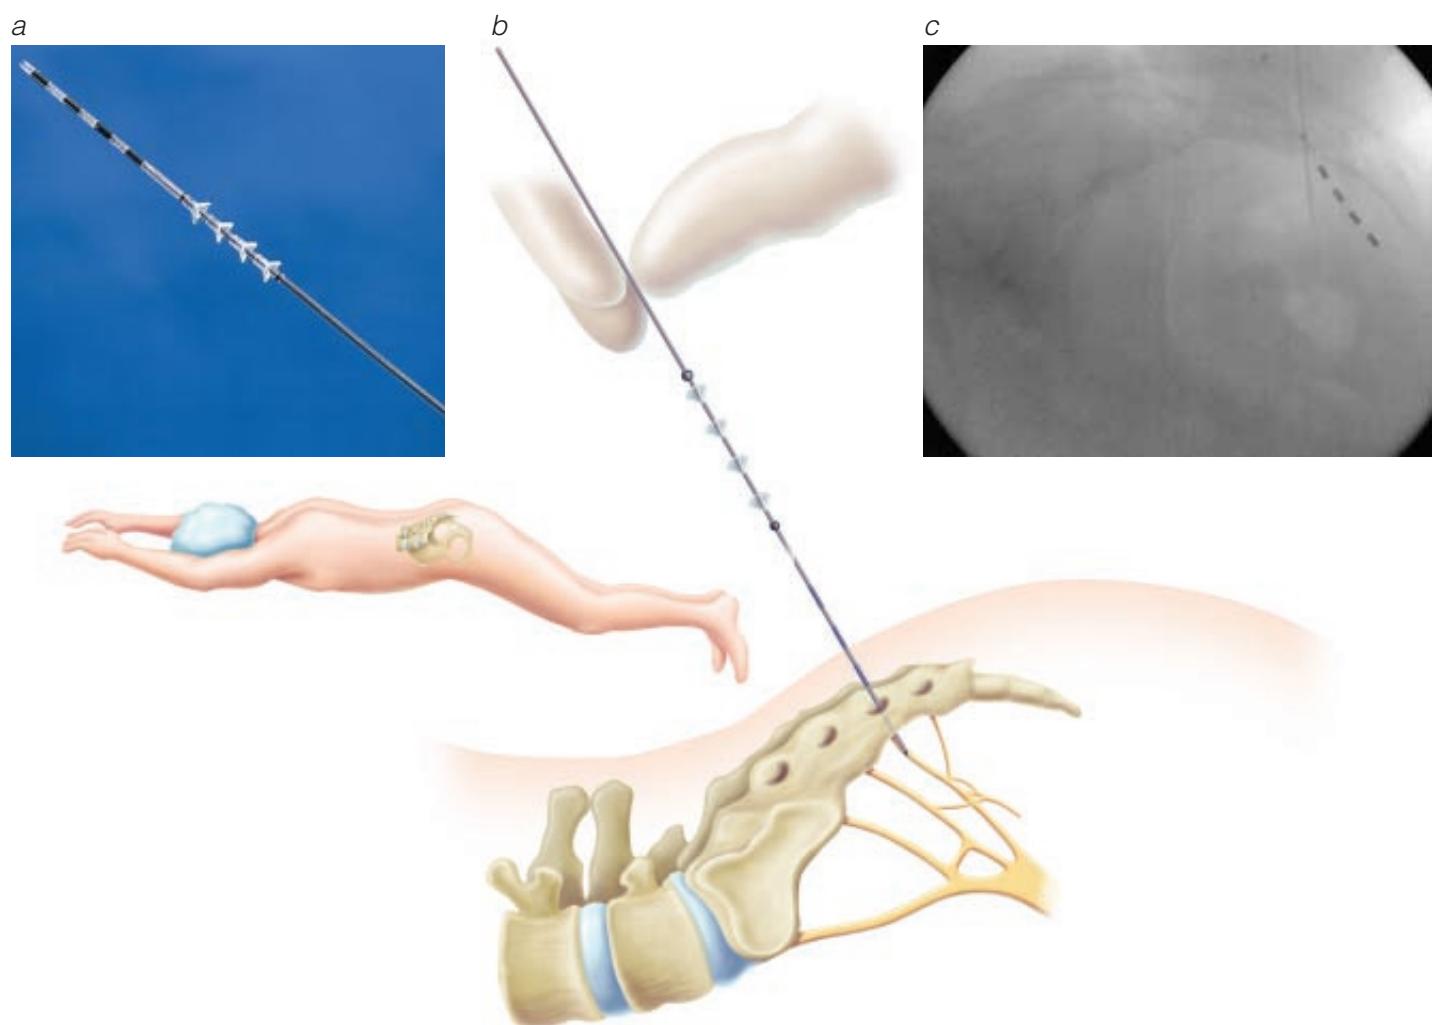

Figure 9 Sacral nerve stimulation. (a) A lead containing four electrodes is used for SNS. (b) The sacral foramina are identified; in most cases, S3 is the optimal choice for stimulation. (c) Shown is the quadripolar lead in position.

Colostomy

Although creation of a colostomy does not restore continence, it does provide a degree of bowel control in a manner that allows patients to resume their normal activities without fear of accidents. Surprisingly few data are available regarding colostomy for incontinence; however, one questionnaire study of patients who underwent colostomy for incontinence reported extremely high levels of

patient satisfaction and marked improvements in subjective quality of life.⁶⁹ In most cases, a simple end sigmoid colostomy with a Hartmann pouch is the appropriate procedure, and it can often be performed with relatively little operative trauma by using a laparoscopic or minilaparotomy technique. Patients should receive pre-operative counseling from an enterostomal therapist, and the optimal stoma site should be marked before the procedure is initiated.

17 BENIGN RECTAL, ANAL, AND PERINEAL PROBLEMS

David E. Beck, M.D., F.A.C.S., F.A.S.C.R.S.

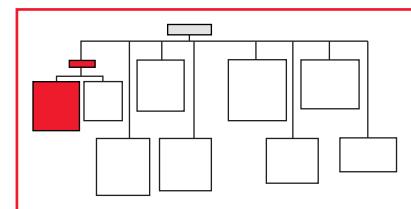

In this chapter, I briefly review the evaluation and management of common benign conditions affecting the rectum, the anus, and the perineum: hemorrhoidal disease, anal fissures, anorectal abscesses and fistulas, pilonidal disease, hidradenitis suppurativa, pruritus ani, and solitary rectal ulcer syndrome (SRUS). For proper diagnosis and treatment of these conditions, an understanding of the relevant anatomy is essential [see Figure 1].¹

The dentate line divides the rectal mucosa, which is generally insensate and is lined with columnar mucosa, from the anoderm below it, which is highly sensitive (because of the somatic innervation provided by the inferior hemorrhoidal nerve) and is lined with modified squamous mucosa. The anal canal is surrounded by two muscles. The internal anal sphincter, innervated by the autonomic nervous system, maintains resting anal tone and is under involuntary control. The external sphincter, innervated by somatic nerve fibers, generates the voluntary anal squeeze and plays the key role in maintaining anal continence. The area surrounding the anorectum is divided into four spaces—perianal, ischioanal, suprlevator, and intersphincteric (intermuscular)—familiarity with which is particularly important in the evaluation of perirectal abscesses and fistulas.

Hemorrhoids

Hemorrhoids are fibromuscular cushions that line the anal canal. They are classically found in three locations: right anterior, right posterior, and left lateral.^{2,3} On occasion, smaller secondary cushions may be found lying between these main cushions. Contrary to popular belief, hemorrhoids are not related to the superior hemorrhoidal artery and vein, to the portal vein, or to portal hypertension.⁴ In fact, hemorrhoids are part of the normal anal anatomy. Their engorgement during straining or performance of the Valsalva maneuver is a component of the normal mechanism of fecal continence: it most likely completes the occlusion of the anal canal and prevents stool loss associated with nondefecatory straining. In the medical literature, however, the term hemorrhoid is used almost exclusively to refer to pathologic hemorrhoids, and I follow this usage throughout the remainder of the chapter.

Hemorrhoids are broadly classified as either internal or external. Internal hemorrhoids are found proximal to the dentate line, whereas external hemorrhoids occur distally [see Figure 2]. External hemorrhoids are redundant folds of perianal skin that generally derive from previous anal swelling; they remain asymptomatic unless they are thrombosed and are treated entirely differently from internal hemorrhoids.

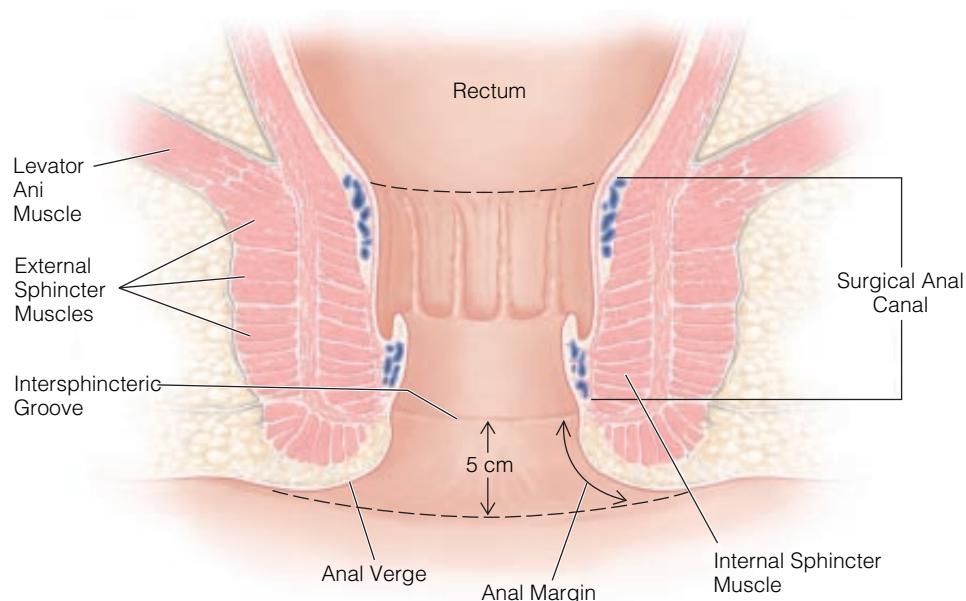

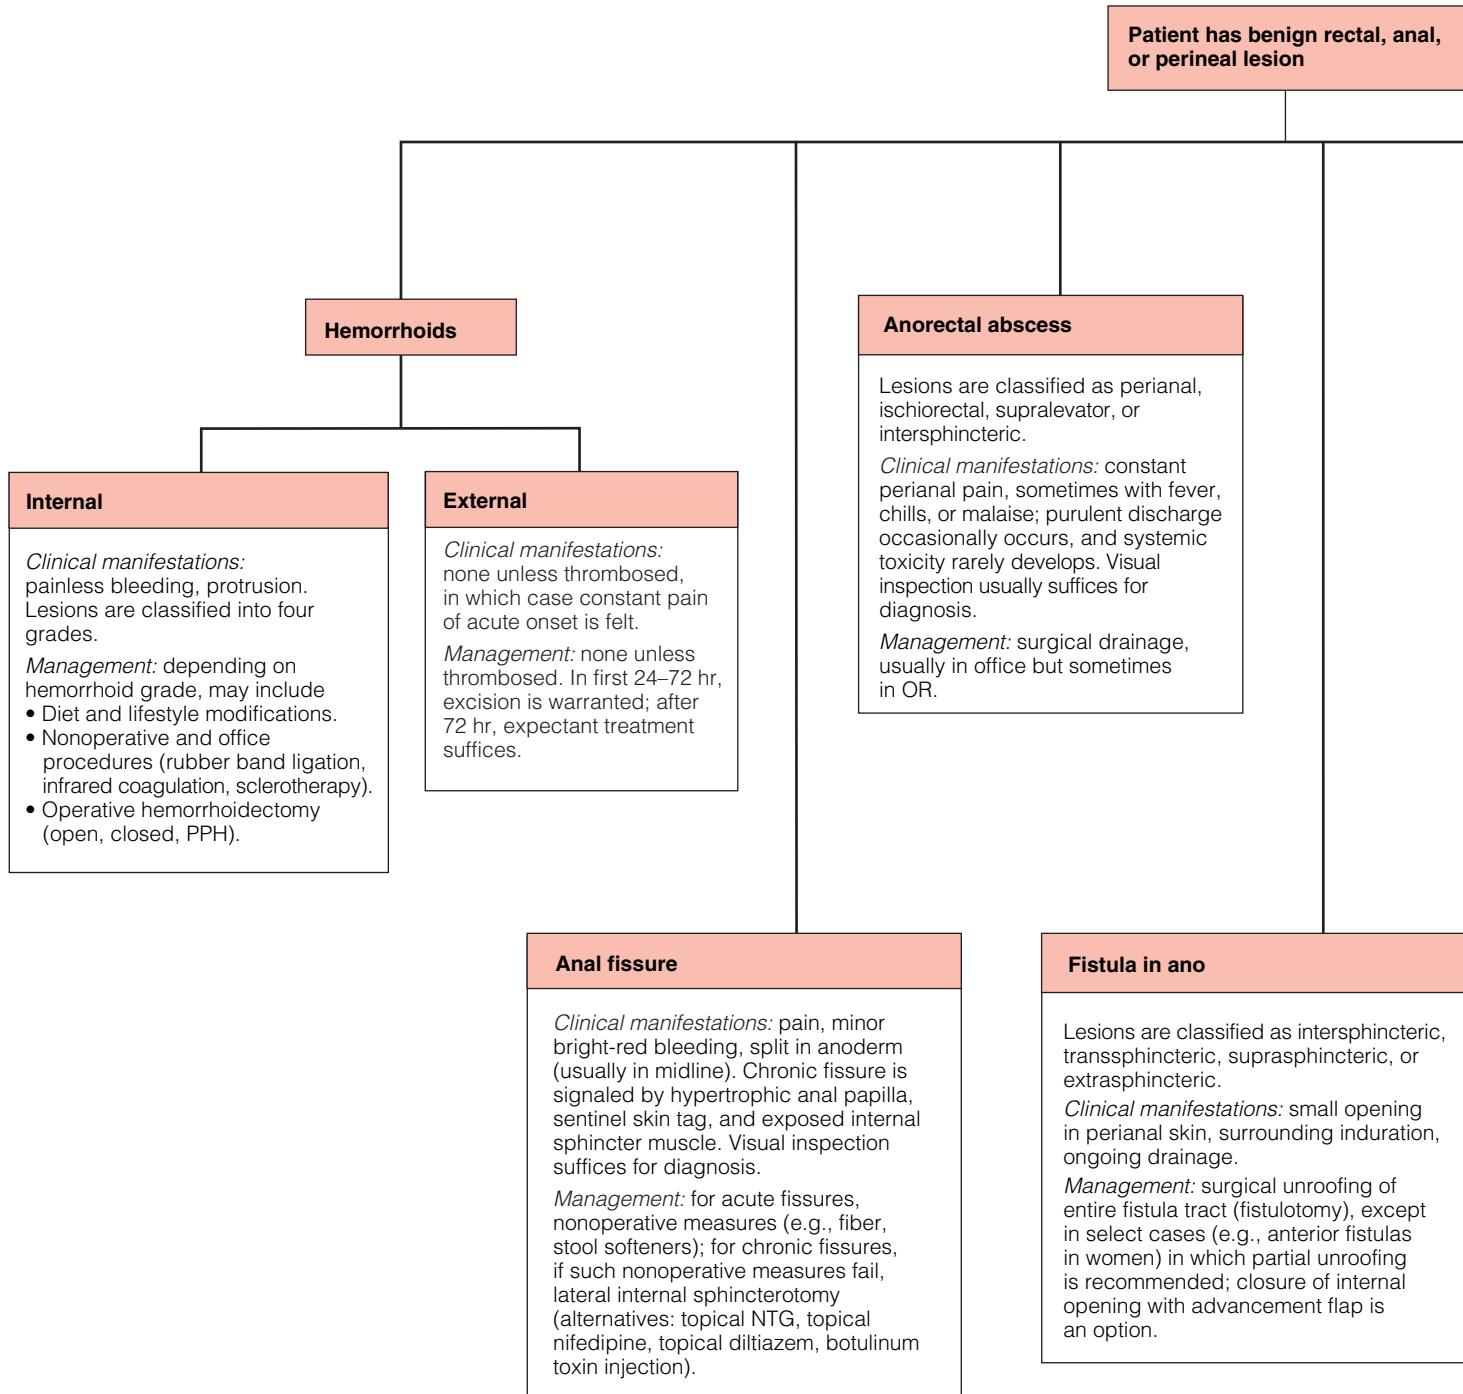

Figure 1 Depicted is the anatomy of the anal canal.³⁵

Approach to Benign Rectal, Anal, and Perineal Problems

Pilonidal disease <i>Clinical manifestations:</i> <ul style="list-style-type: none">• Acute abscess (nearly all patients)• Pilonidal sinus after resolution of abscess (many patients)• Chronic or recurrent disease after treatment (few patients) <i>Management:</i> <ul style="list-style-type: none">• Abscess: drainage• Sinus: closed techniques; unroofing with healing by granulation, wide and deep excision of sinus alone, or excision and primary closure; nonoperative approach is an option• Persistent, nonhealing disease: wide excision with split-thickness graft, cleft closure, or excision with flap closure	Pruritus ani <i>Clinical manifestations:</i> uneasiness or itching around anus, reddened or thickened perianal skin (sometimes with excoriation or ulceration, occasionally with large weeping ulcer). <i>Management:</i> identification and treatment of precipitating condition if possible; establishment and maintenance of healthy, clean, and dry perianal skin (washing, dietary changes, and topical hydrocortisone or antifungal if indicated). If standard measures fail, evaluation for fungal or neoplastic cause is indicated.		
Hidradenitis suppurativa <i>Clinical manifestations:</i> chronic inflammation of apocrine glands, pain, chronically draining wounds and sinus tracts. <i>Management:</i> surgical. Wide excision with secondary granulation is most definitive therapy; local excision may be particularly suitable for perianal disease; incision and drainage or unroofing of sinus may be used for early acute disease.	Solitary rectal ulcer syndrome <i>Clinical manifestations:</i> bleeding, pain, mucous discharge, difficult evacuation. <i>Management:</i> conservative (high-fiber diet, lifestyle changes, biofeedback). Pharmacologic therapy may be considered. In select patients, localized resection may be considered if symptoms persist.		

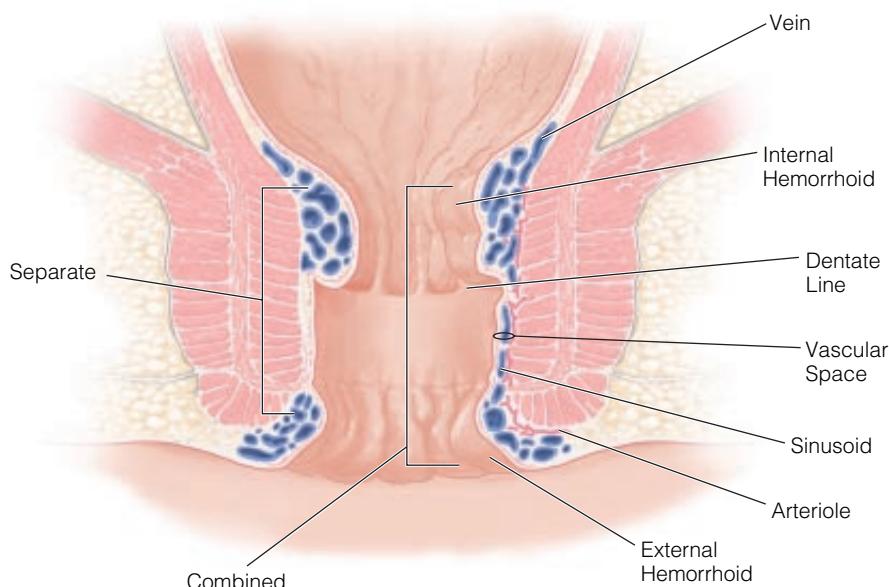

Figure 2 External and internal hemorrhoids may occur either separately (left) or in combination (right).

INTERNAL

Clinical Evaluation

Internal hemorrhoidal disease is manifested by two main symptoms: painless bleeding and protrusion.⁴ Pain is rare because internal hemorrhoids originate above the dentate line in the insensitive rectal mucosa. The most popular etiologic theory states that hemorrhoids result from chronic straining at defecation (with upright posture and heavy lifting possibly playing contributing roles as well). This straining not only causes hemorrhoidal engorgement but also generates forces that reduce the attachment between the hemorrhoids and the anal muscular wall. Continued straining causes further engorgement and bleeding, as well as hemorrhoidal prolapse. Internal hemorrhoids are classified into four grades on the basis of clinical findings and symptoms. Grade 1 represents bleeding without prolapse; grade 2, prolapse that spontaneously reduces; grade 3, prolapse necessitating manual reduction; and grade 4, irreducible prolapse.

Questioning often reveals a long history of constipation and straining at defecation. Many patients with internal hemorrhoids are extensive bathroom readers, spending many hours in the bathroom each week. Symptoms start with painless bleeding and may progress to anal protrusion. The physical examination begins with visual inspection and may reveal prolapsing hemorrhoidal tissue appearing as a rosette of three distinct pink-purple hemorrhoidal groups. Hemorrhoidal prolapse must be distinguished from true full-thickness rectal prolapse. When hemorrhoidal prolapse is not present, anoscopy typically reveals redundant anorectal mucosa just proximal to the dentate line in the classic locations.

Surgical treatment of hemorrhoids in a patient whose main disease process is Crohn disease, a pelvic floor abnormality, or fissure disease invariably yields imperfect results. It is especially important to recognize the anal pain and spasm associated with anal fissure because in patients with this problem, excision of the hemorrhoids without concomitant management of the fissure leads to increased postoperative pain and poor wound healing. Not uncommonly, patients are treated for hemorrhoids when the true primary condition is fissure disease.

Management

Treatment of symptomatic internal hemorrhoids ranges from simple reassurance to operative hemorrhoid excision, depending on hemorrhoid grade [see Table 1]. Therapies may be classified into three categories: (1) diet and lifestyle modifications, (2) nonoperative and office procedures, and (3) operative hemorrhoidectomies.

Diet and lifestyle modifications For all patients with grade 1 or 2 hemorrhoids and most patients with grade 3 hemorrhoids, treatment should begin with efforts to correct constipation. Recommendations should include a high-fiber diet, liberal water intake (six to eight 8 oz glasses of water daily), and fiber supplements (e.g., psyllium, methylcellulose, calcium polycarbophil, and gum). Sitz baths are recommended for their soothing effect and their ability to relax the anal sphincter muscles. Topical creams may reduce some of the associated symptoms, though they do not affect the hemorrhoids themselves. Suppositories are not helpful, because they deliver medication to the rectum, not the anus. Patients are instructed to avoid prolonged trips to the bathroom and to read in the bathroom only when sitting atop the toilet lid.

Table 1 Treatment Alternatives for Hemorrhoids

Treatment	Internal Hemorrhoids				External Hemorrhoids	
	Grade					
	1	2	3	4		
Diet modification	X					
Sclerotherapy	X	X				
Infrared coagulation	X	X	(X)			
Rubber band ligation	(X)	X	X			
Stapled hemorrhoidopexy (PPH)		X	X			
Excisional hemorrhoidectomy		(X)	X	X	X	

(X)—selected patients PPH—procedure for prolapsing hemorrhoids

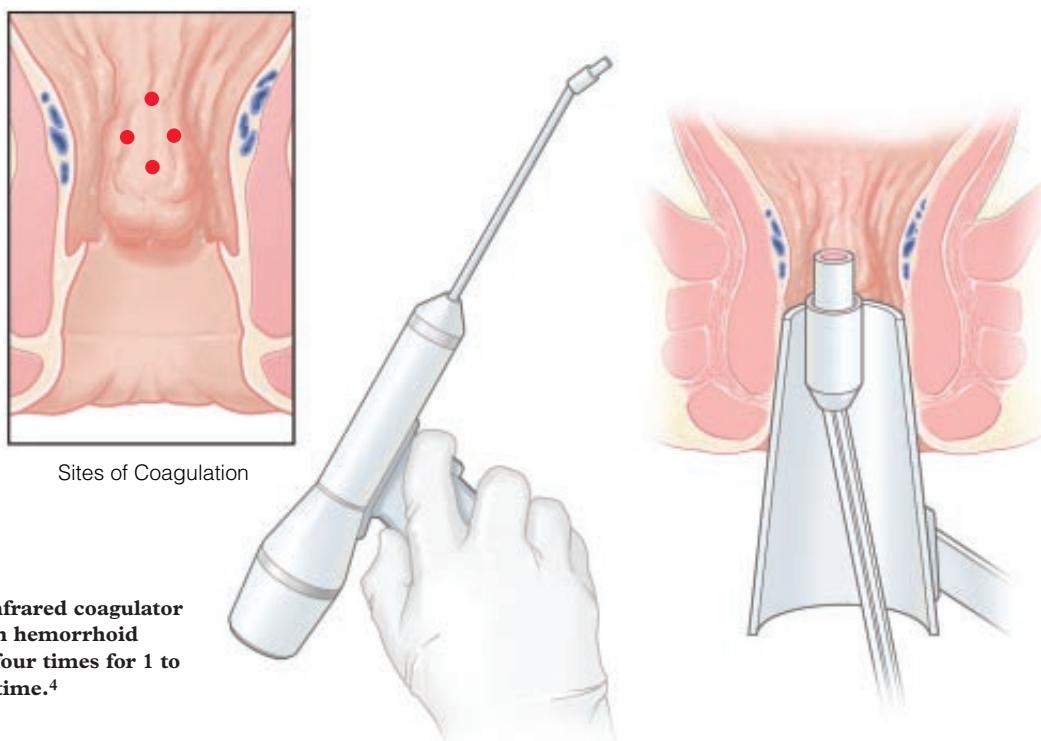

Figure 3 The infrared coagulator is applied to each hemorrhoid bundle three or four times for 1 to 1.5 seconds at a time.⁴

Nonoperative and office procedures If initial diet and lifestyle modifications are not effective, there are a number of nonoperative therapies that may be tried next. At present, the main recommended options are rubber band ligation, infrared photoocoagulation, and sclerotherapy.

Rubber band ligation. Ligation of hemorrhoids with elastic bands is the method most commonly used in the outpatient setting [see 5.37 *Anal Procedures for Benign Disease*.⁵] It is successful in two thirds to three quarters of all patients with grade 1 or 2 hemorrhoids.² Repeated banding may be necessary to resolve all symptoms. On rare occasions, patients do not respond to banding at all or cannot tolerate it. Some of these patients will respond to infrared coagulation; others may require formal hemorrhoidectomy.

Complications of rubber band ligation include bleeding, pain, thrombosis, and life-threatening perineal sepsis.^{5,6} The cardinal signs of perineal sepsis are significant pain, fever, and difficult urination. Patients in whom any of these symptoms develop require urgent evaluation and treatment with broad-spectrum antibiotics, coupled with selective debridement of any necrotic anal tissue.

Infrared coagulation. The infrared coagulator generates infrared radiation, which coagulates tissue protein and evaporates water from cells.⁷ The extent of the tissue destruction depends on the intensity and duration of the application. An anoscopy examination is performed, and the infrared coagulator is applied to the apex of each hemorrhoid at the top of the anal canal [see Figure 3]. Each hemorrhoid bundle receives three to four applications, each lasting 1 to 1.5 seconds.

The infrared coagulator was designed to decrease blood flow to the region. It is not particularly effective for treating large amounts of prolapsing tissue; it is most useful for treating grade 1 and small grade 2 hemorrhoids. Overall, it is slightly less painful than rubber banding. Infrared coagulation is especially beneficial for patients in whom rubber band ligation fails because of pain or who have symptomatic internal hemorrhoids that are too small to band.

Sclerotherapy. Sclerotherapy was once commonly employed to

treat internal hemorrhoids, but with the advent of rubber band ligation, it has become less popular. The technique involves injection of a sclerosant into the anorectal submucosa to decrease vascularity and increase fibrosis. The agents used include phenol in oil, sodium morrhuate, and quinine urea.² Hemorrhoids are identified via anoscopy, and the sclerosant is infiltrated at the apex of the hemorrhoid (at the proximal anal rectal ring). After injection, patients occasionally experience a dull ache lasting 24 to 48 hours, but substantial bleeding and other significant complications are uncommon. Misplacement of the sclerosant, resulting in significant perianal infection and fibrosis, has been reported, albeit rarely.

Comparison of methods. A meta-analysis comparing a variety of modalities used to treat hemorrhoids found that rubber band ligation was superior to sclerotherapy for grade 1 through grade 3 hemorrhoids.⁸ Patients who were treated with sclerotherapy or infrared coagulation were more likely to require further treatment than those treated with rubber band ligation. The authors concluded that hemorrhoidectomy should be reserved for patients in whom rubber band ligation or infrared coagulation fails or who have associated external hemorrhoidal disease.

Hemorrhoidectomies Various hemorrhoidectomies have been developed throughout the years. Although they differ with respect to detail, they incorporate similar basic principles—namely, reduction of blood flow to the anorectal ring, removal of redundant hemorrhoidal tissue, and fixation of redundant mucosa and anoderm.⁹

Open and closed hemorrhoidectomy. In the United Kingdom, open (Milligan and Morgan) hemorrhoidectomy, in which hemorrhoids are ligated and excised with the wound left open, is the most commonly performed operative excision procedure. In the United States, closed (Ferguson) hemorrhoidectomy is most commonly performed¹⁰; this procedure is described more fully elsewhere [see 5.37 *Anal Procedures for Benign Disease*]. With either type of hemorrhoidectomy, one, two, or three hemor-

rhoidal bundles may be excised. In performing a closed hemorrhoidectomy, it is essential to excise as little of the anoderm as possible: if large amounts are excised, closing the anal wounds or secondary healing can result in significant postoperative pain and perhaps even long-term anal stenosis.

Stapled hemorrhoidectomy. Stapled hemorrhoidectomy or anoplasty (commonly known as the procedure for prolapsing hemorrhoids [PPH]) is increasingly being performed as an alternative to standard open or closed hemorrhoidectomy with the aim of reducing the pain associated with traditional surgical techniques.⁹ PPH involves transanal circular stapling of redundant anorectal mucosa with a modified circular stapling instrument (PPH-01, Ethicon Endo-Surgery Inc., Cincinnati, Ohio).¹¹ Because no incisions are made in the somatically innervated, highly sensitive anoderm, there should, theoretically, be significantly less postoperative pain.

Randomized, prospective trials comparing PPH with various operative hemorrhoidectomies and other therapies found it to be associated with significantly less pain than conventional treatments and to have similar complication rates.⁹ PPH may, however, have a greater potential for disastrous complications (e.g., rectovaginal or rectourethral fistula from inclusion of too much tissue within the purse-string suture, perforation caused by placing the purse-string too high, and incontinence caused by placing the purse-string too low or too deep). Bleeding also remains a problem with PPH, and leaks have been reported. Finally, stapled hemorrhoidectomy has not yet been adequately compared with office procedures for grade 1 and 2 hemorrhoids and thus should not replace these techniques for treatment of minimally symptomatic hemorrhoidal disease.

EXTERNAL

Clinical Evaluation

External hemorrhoids are asymptomatic except when secondary thrombosis occurs. Thrombosis may result from defecatory straining or extreme physical activity, or it may be a random event.¹ Patients present with constant anal pain of acute onset and often report feeling the sensation of sitting on a tender marble. Physical examination identifies the external thrombosis as a purple mass at the anal verge.

Management

Treatment depends on the patient's symptoms [see Figure 4].⁴ In the first 24 to 72 hours after the onset of thrombosis, pain increases, and excision is warranted. After 72 hours, pain generally diminishes, and expectant treatment is all that is necessary. Patients should be advised that some drainage may occur. If operative treatment is chosen, the entire thrombosed hemorrhoid is excised with the patient under local anesthesia. Incision and drainage of the clot are avoided because they typically lead to rethrombosis and exacerbation of symptoms.

Anal Fissure

Anal fissures are tears or splits in the anoderm just distal to the dentate line.¹² They are characterized as acute or chronic. Generally, acute fis-

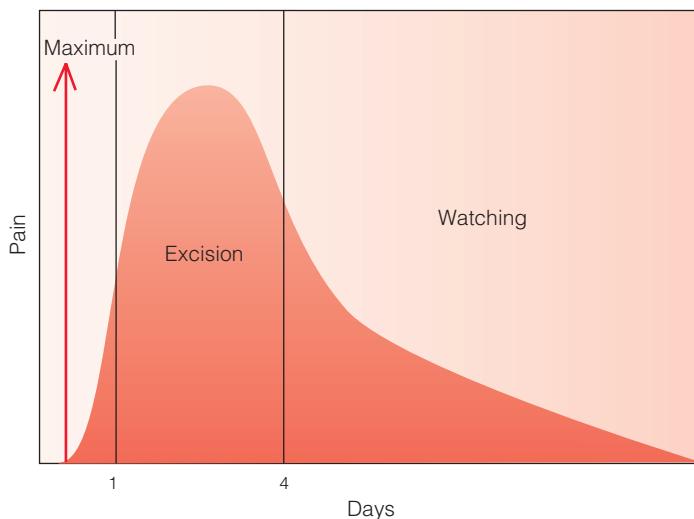

Figure 4 Depicted is the timing of excision of thrombosed external hemorrhoids.³⁶

sures are caused by the mechanical force generated by the passage of a large, hard bowel movement through an anal canal that is too small to accommodate it safely and easily (though they can also be caused by diarrhea). These mechanical forces usually cause a split to occur in the posterior midline: 90% of the fissures in females and 99% of those in males are located posteriorly. Either decreased local blood flow or increased mechanical stress may account for the propensity of these fissures to occur in this location.¹³ Repeated injury (e.g., from hard or watery bowel movements) may result in the development of a chronic fissure.

CLINICAL EVALUATION

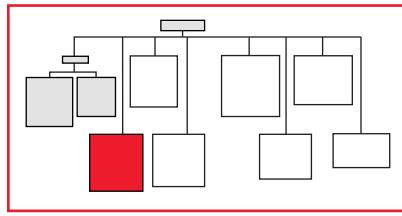

Symptoms associated with anal fissures include anal pain and bright-red rectal bleeding after bowel movements. The pain is usually described as a knifelike or tearing sensation, and the associated anal sphincter spasm may persist for several hours after each bowel movement. The bleeding is usually minor and is seen mainly on the toilet paper.

Physical examination is difficult because the patient has an extremely tender anus and is fearful of further pain. Often, visual inspection with gentle eversion of the anoderm in the posterior midline is all that is required. Physical findings include a split in the anoderm approximately 1 cm long in the posterior midline just distal to the dentate line. In chronic fissures, the classic triad may be present: hypertrophy of the anal papilla, an anal fissure, and a sentinel skin tag [see Figure 5]. Once an anal fissure has been diagnosed, further examination is very painful, unrewarding, and unnecessary; more extensive investigations can be performed after the fissure has healed.

Multiple fissures are unusual, as are fissures that occur away from the anterior or posterior midline; either should raise suspicions that other problems may be present [see Figure 6].

MANAGEMENT

Acute fissures usually have been present for less than 4 to 6 weeks. As a rule, they are treated nonoperatively: fiber supplements, stool softeners, and generous intake of water, along with sitz baths and local anesthetic ointments, rapidly alleviate symptoms and usually bring about complete healing. Anal suppositories are avoided both because they are painful and because they rest in the rectum rather than the anal canal.

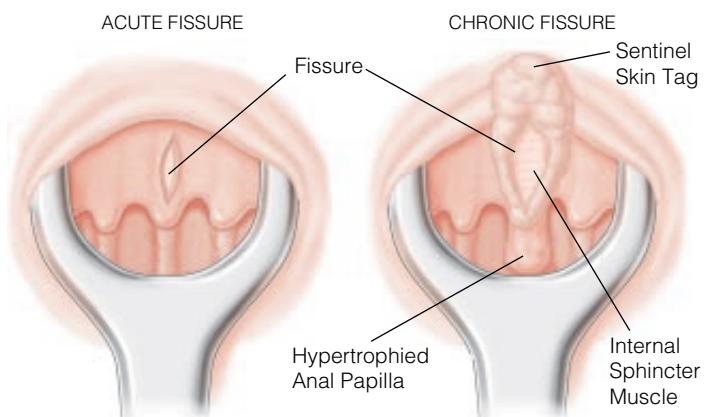

Figure 5 Chronic anal fissures, as opposed to acute fissures, are characterized by hypertrophy of the anal papilla, a sentinel skin tag, rolled skin edges, and exposed internal anal sphincter muscle.

Chronic fissures have been present for periods longer than 4 to 6 weeks. As noted (see above), they are typically characterized by an associated hypertrophied papilla, a skin tag, rolled skin edges, and exposed internal anal sphincter muscle at the base of the fissure. Chronic fissures respond less well to nonoperative measures than acute fissures do. The surgical procedure most frequently performed for anal fissure is lateral internal anal sphincterotomy [see 5:37 *Anal Procedures for Benign Disease*],¹⁴ which results in cure in 95% to 98% of patients. Complications of this procedure include incontinence to flatus (0% to 18% of cases), soiling (0% to 7%), fecal incontinence (0% to 0.17%), and various other problems (0% to 7%).¹⁴

Several therapeutic alternatives for anal fissures have been proposed with the aim of avoiding the need for operation and the consequent risk of surgical complications.¹⁵ On the basis of the

theory that a fissure is actually an ischemic ulcer of the anoderm, topical nitroglycerin (NTG) ointment has been used to treat fissures, with success rates ranging from 48% to 78%. When metabolized, NTG releases nitric oxide, which is believed to be an inhibitory neurotransmitter for smooth muscle. The resulting neurogenic relaxation of the internal sphincter brings about a reduction in anal canal pressure, which diminishes pain and spasm. Typically, NTG is given in a concentration of 0.2% three to five times daily, but concentrations as high as 0.5% have been recommended. In practice, dosing is limited by NTG's side effects, which arise in as many as 88% of patients. Headaches are the predominant complaint, but dizziness, lightheadedness, and hypotension have also been reported. Caution must be exercised when NTG therapy is employed in patients receiving cardiac medications or those with sensitivities to nitrates. A meta-analysis comparing topical NTG therapy with sphincterotomy demonstrated that sphincterotomy results in better healing of chronic fissures.¹⁶

Another nonsurgical option is the use of nifedipine gel or ointment, which also has met with varying degrees of success. Nifedipine acts as a calcium antagonist, preventing calcium from flowing into the sarcoplasm of smooth muscle and thereby reducing local demand for oxygen and mechanical contraction of the muscle.¹² Like NTG ointment, nifedipine ointment is usually applied topically in a 0.2% concentration, but it seems to have fewer side effects than NTG does. Nifedipine should be used with caution in cardiac patients and patients who have demonstrated previous sensitivities. One multicenter study reported a 95% complete healing rate after 21 days of treatment.¹²

Topical 2% diltiazem has also been employed to treat chronic anal fissures, yielding a 67% healing rate.¹²

Botulinum toxin has been reported to facilitate healing in 78% to 90% of anal fissure patients, with an 8% recurrence rate at 6 months.^{15,17} The toxin, produced by the bacterium *Clostridium botulinum*, acts by inhibiting the release of acetylcholine at the presynaptic membrane. The resulting blockage of neurotransmission diminishes or eliminates spasms and contractions of the sphincter mechanism. Typically, 2.5 to 10 units are injected at two to four sites in the internal sphincter at the level of the dentate line.¹⁸ Pain relief is generally noted within 24 hours, though it still takes days for the fissure to heal. Postinjection incontinence is rare.¹² The major drawback is the cost of the toxin, which may be as high as \$400 per 100 unit vial.

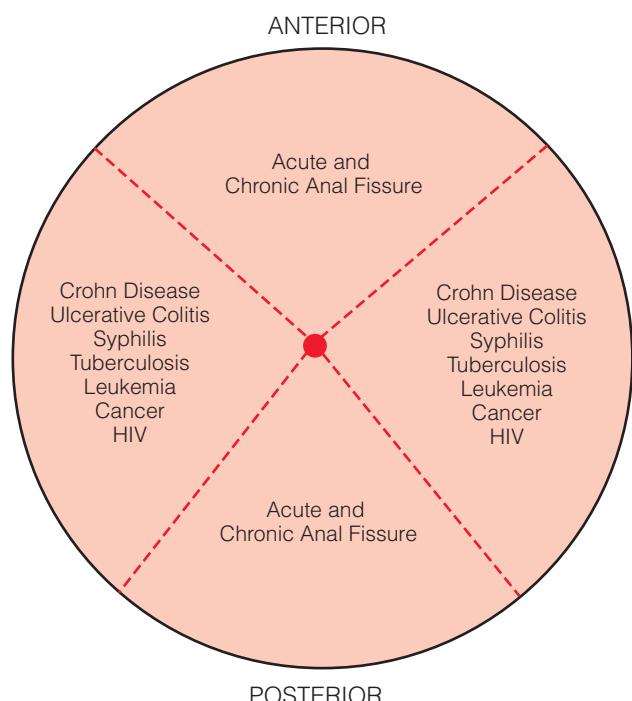

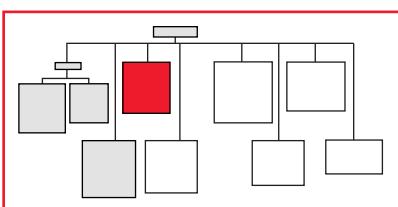

Figure 6 Fissures occurring away from the anterior or posterior midline are likely to be associated with other conditions.⁴

Anorectal Abscess

Anorectal abscesses, like abscesses elsewhere in the body, are the result of local, walled-off infections. Most perirectal abscesses are of cryptogenic origin—that is, they begin as infections in the anal glands that surround the anal canal and empty into the anal crypts at the dentate line.^{18,19} It is thought that the ducts leading to and from these glands become obstructed by feces or traumatized tissue, and a secondary infection then develops that follows the path of least resistance, resulting in an anorectal abscess.

CLINICAL EVALUATION

Abscesses are categorized according to the space in which they occur: perianal, ischioanal, supralevator, or intersphincteric (intermuscular) [see Figure 7]. Perianal abscesses are the most

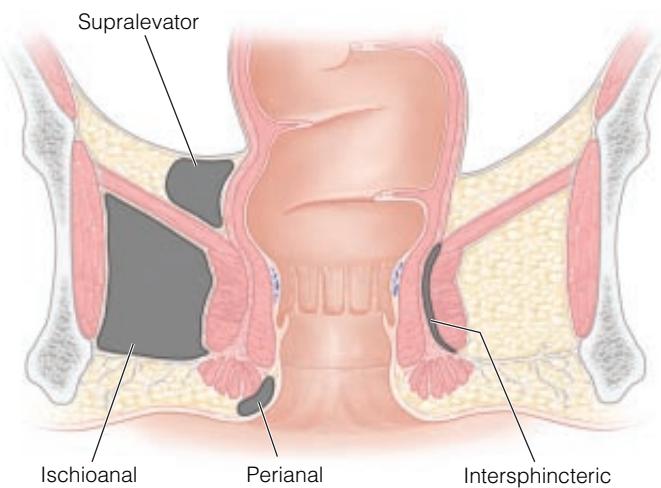

Figure 7 Anorectal abscesses are classified according to the space in which they develop.

common—together with ischioanal abscesses, they account for more than 90% of perianal infections. Perianal abscesses occur in the perianal space immediately adjacent to the anal verge. Ischioanal abscesses are larger and often more complex than their perianal counterparts, and they usually manifest themselves as a tender buttock mass. Supralelevator abscesses occur above the levator ani muscles and are characterized by poorly localized pain; they are exceedingly rare. Intersphincteric abscesses occur in the plane between the internal and external sphincter muscles, high within the anal canal; these are also rare. The location of an abscess is important in that it dictates subsequent therapy.²⁰

Regardless of location, all anorectal abscesses are associated with constant perianal pain. Accompanying symptoms may include fever, chills, and malaise. In rare cases, systemic toxicity may be evident. The history reveals rectal pain of gradual onset that progressively worsens until the time of presentation. Occasionally, spontaneous drainage decompresses the abscess, and the patient presents with a purulent discharge.

As with fissures, visual inspection of the perineum often clinches the diagnosis. A fluctuant, erythematous, tender area identifies the abscess. In the rare event of a supralelevator or intersphincteric abscess, there may be no external manifestations. When this is the case, the presence of a tender mass on digital examination above the anal canal, either adjacent to the rectal ampulla (supralelevator abscess) or within the anal canal (intersphincteric abscess), provides the clue to the diagnosis.

MANAGEMENT

Treatment of anorectal abscesses consists of adequate drainage performed in the office, in the emergency department, or in the operating room.¹⁸ Most abscesses can be drained in the office, but recurrent or complex abscesses, abscesses in immunosuppressed hosts (including some diabetic patients), intersphincteric abscesses, and supralelevator abscesses are more appropriately drained in the OR.

Adequate drainage is essential and may be established in several ways. One method is to place a catheter (e.g., a 10 to 16 French Pezzar catheter) through a small stab incision [see 5:37 *Anal Procedures for Benign Disease*.]¹⁸ This measure allows the pus to drain through the catheter as the cavity closes down. A second option involves creating a larger elliptical incision.²⁰ Unroofing the abscess cavity allows it to heal without any need for packing. A

small incision should be avoided because it would require painful packing to keep the skin open until the abscess cavity heals.

The most difficult abscess to diagnose and manage is a deep postanal space abscess. Such abscesses are caused by fistulization from the posterior anal canal, usually in the bed of a chronic posterior fissure. The patient is highly uncomfortable and febrile, but there is no apparent sign of a problem perianally. A simple digital examination pushing posteriorly towards the coccyx and the deep postanal space will evoke severe pain, and this response should lead the examiner to suspect the diagnosis. The patient should be taken to the OR and anesthetized. On digital examination, the deep postanal space is often felt to be bulging. The diagnosis is confirmed by aspirating the space with an 18-gauge needle. Once the diagnosis is confirmed, an incision is made in the perianal skin posterior to the anal verge and deepened into the space, and the space is drained. In selected patients, a cutting seton is placed from the primary site in the posterior anal canal directly into the deep postanal space abscess. Horseshoe fistulas are dealt with as described elsewhere [see 5:37 *Anal Procedures for Benign Disease*].

Fistula in Ano

An anal fistula is a communication between the anal canal and the perianal skin. It usually begins in a crypt at the dentate line and follows a course either between the internal and external sphincters (the most common location), resulting in an ischioanal abscess, or above the sphincters, leading to a supralelevator abscess.^{18,20} After drainage of an abscess, one of three things typically occurs if a fistula is present: (1) the fistula heals spontaneously, and the patient

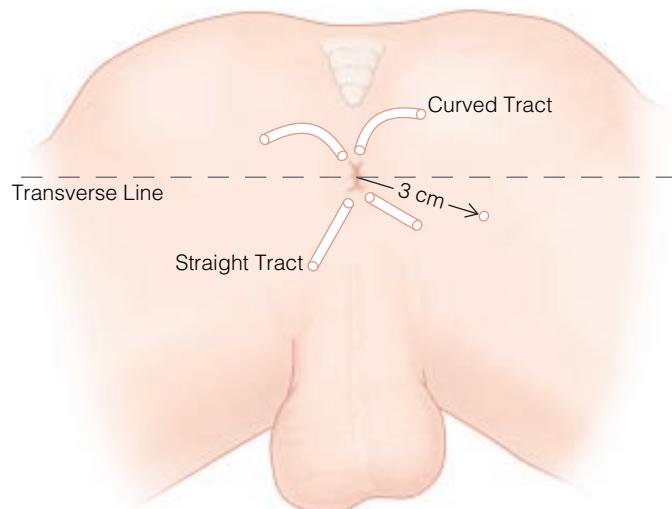

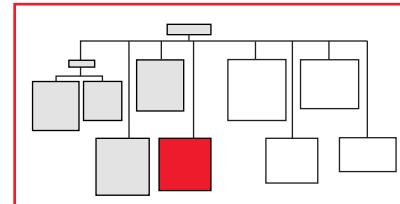

Figure 8 The relation of the external opening of an anal fistula to the internal opening is suggested by Goodsall's rule. When the external opening is posterior to a line drawn transversely across the perineum, the fistula typically follows a curved course to an internal opening in the posterior midline. When the external opening is anterior to this line, the fistula typically follows a short, straight course to an internal opening in the nearest crypt (though this often does not hold true if the anterior exterior opening is more than 2 to 3 cm from the anus).⁴

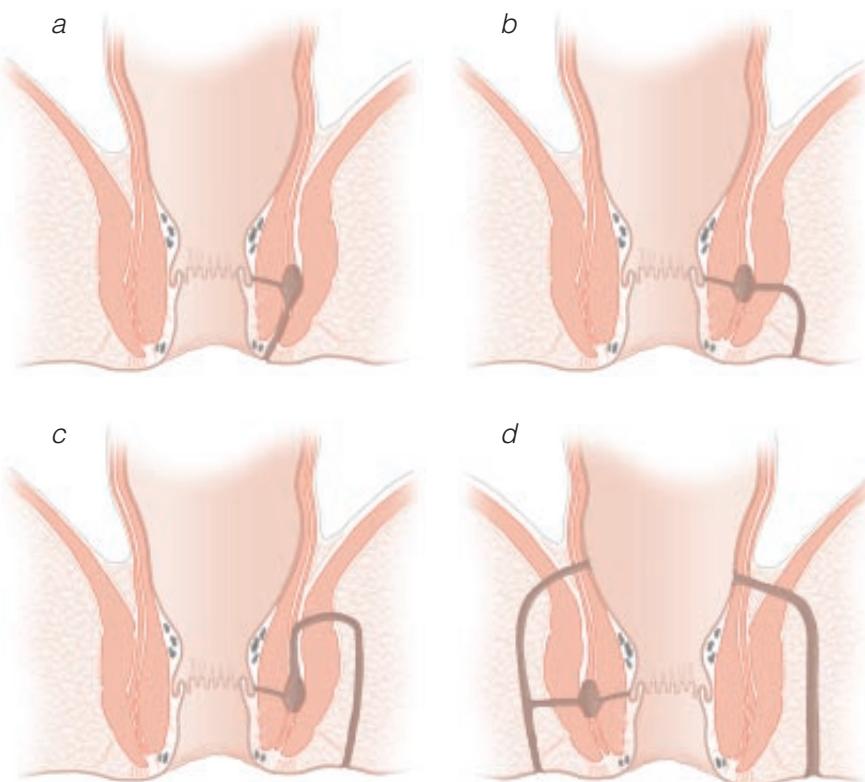

Figure 9 Fistula in ano is classified on the basis of its relation to the anal sphincter muscles. Shown are (a) intersphincteric fistula, (b) transsphincteric fistula, (c) suprasphincteric fistula, and (d) extrasphincteric fistula.

experiences no further symptoms; (2) the abscess heals, only to recur in the future; or (3) the abscess heals, but a chronic draining fistula remains. Only the third scenario is addressed here.

CLINICAL EVALUATION

After drainage of one or more abscesses, a fistula is usually associated with chronic serosanguineous to seropurulent drainage. As long as the fistula remains open and draining, patients report little pain. If the fistula closes externally, however, an anorectal abscess may develop.

Physical examination reveals a 2 to 3 mm opening in the perianal skin, with surrounding induration. Often, a fistula tract can be palpated as a firm cord running between the external opening and the anal canal. The relationship of the external opening to the internal opening is suggested by Goodsall's rule [see Figure 8]. Fistulas are classified into four main categories according to their relation to the anal sphincters [see Figure 9]: intersphincteric, transsphincteric, suprasphincteric, and extrasphincteric.²¹

MANAGEMENT

Essentially, all chronic fistulas call for surgical treatment, which consists of unroofing the entire fistula tract (fistulotomy) and leaving the wound open to heal secondarily. Fistulas that course through significant amounts of sphincter muscle, anterior fistulas in women, and fistulas associated with inflammatory bowel disease or weakened sphincter muscles, however, cannot be opened entirely, because incontinence will result. These fistulas may be partially opened, with the anal musculature left intact and encircled with a seton [see 5:37 *Anal Procedures for Benign Disease*.²⁰ Although some surgeons sequentially tighten the seton (making it a cutting seton), I prefer not to, because of the resultant patient discomfort. Another surgical option is to close the internal fistula opening with an advancement flap.²² Advancement flap repairs result in high success rates with minimal effects on continence.

Pilonidal Disease

The term pilonidal disease is derived from the Latin words *pilus* ("hair") and *nidus* ("nest").²³ It denotes a chronic subcutaneous infection and foreign-body reaction to hairs embedded in the skin or to abnormalities of hair follicles in the natal cleft.²³ Pilonidal disease is most commonly seen in men between the onset of puberty and 40 years of age and in obese persons.²³

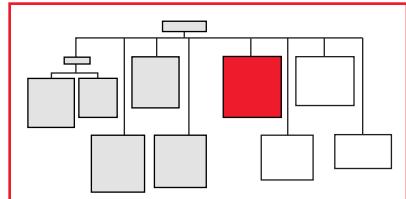

CLINICAL EVALUATION

Pilonidal disease has three common presentations. First, nearly all patients experience an episode of acute abscess formation. Second, after the abscess resolves, either spontaneously or with medical assistance, a pilonidal sinus tract develops in many cases. Third, although most of these sinus tracts resolve, chronic disease or recurrent disease after treatment develops in a small minority of cases.

Physical examination typically reveals one or more small (1 to 2 mm) dermal pits at the base of the intergluteal cleft [see Figure 10]. Tracking from the pits (usually proceeding in a cranial and lateral direction) appears as areas of induration. If there is an associated abscess, the diseased area may be tender and erythematous, and draining pus may be evident. The more extensive the disease, the more prominent the findings. Treatment varies according to the stage of the disease.

MANAGEMENT

Abscesses must be drained. In one study, incision and drainage in an office setting with local anesthesia led to healing in 60% of patients.²⁴ As many as 40% of acute pilonidal abscesses treated with incision and drainage develop into chronic sinus-

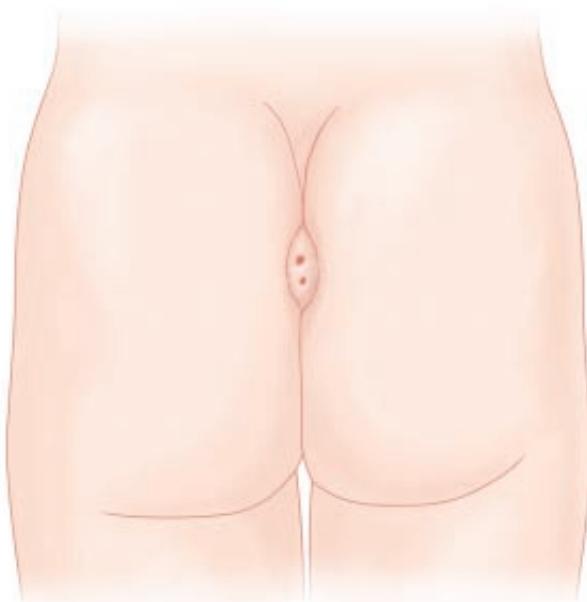

Figure 10 Patients with pilonidal disease generally have one or two dermal pits in the intergluteal cleft, often associated with a sinus and an abscess.

es for which additional treatment is necessary.

Several different approaches have been employed in the surgical treatment of pilonidal sinus tracts. A review of articles published over a period of 30 years on the treatment of pilonidal disease divided the procedures into the following four broad categories and reported the following findings.²⁵

1. Closed techniques (coring out follicles and brushing the tracts). These techniques necessitated shaving of the area but could be performed on an outpatient basis. Mean healing time was about 40 days, and recurrence rates were slightly higher than those seen with other forms of treatment.
2. Laying open (unroofing) the tracts with healing by granulation. This approach resulted in average healing times of 48 days and necessitated frequent outpatient dressing changes. The incidence of recurrent sinus formation was lower than 13%.
3. Wide and deep excision of the sinus alone. This procedure resulted in an average healing time of 72 days. The recurrence rate was similar to that of simple unroofing of the sinus tract with healing by granulation.
4. Excision and primary closure. This technique resulted in wound healing within 2 weeks in successful cases (19 days overall). However, primary wound healing failed in as many as 30% of patients, and the average recurrence rate was 15%.

A nonoperative or conservative approach—involved meticulous hair control (through natal cleft shaving), improved perineal hygiene, and limited lateral incision and drainage for treatment of abscess—has been suggested as an alternative to conventional excision.²⁶ This approach has brought about a significant reduction in the number of excisional procedures and occupied-bed days.

Even with proper treatment of pilonidal abscesses and sinuses, a small number of patients are left with persistent, nonhealing wounds. A number of more aggressive approaches have been advocated for treatment of complex or recurrent disease, including wide excision with split-thickness skin grafting, cleft closure, and excision with flap closure.^{24,27} Flap techniques, as a group, have been found to lead to primary healing within 15 days in

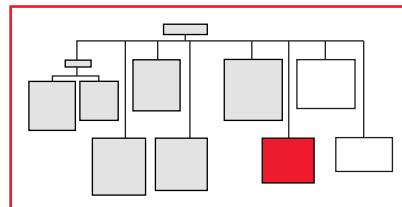

90% of cases.²⁴ These aggressive approaches nevertheless have certain disadvantages. For nearly all of them, hospitalization and general anesthesia are mandatory. In addition, as many as 50% of procedures involving the use of skin flaps for wound coverage or closure in this setting result in some loss of skin sensation or some degree of flap-tip necrosis.

My policy is to treat acute abscesses with drainage, followed by measures aimed at keeping the cleft free of hair. If a chronic sinus develops, it is managed with unroofing or, in selected patients, excision and closure. Flap procedures are reserved for cases of extensive, recurrent, and complex disease.²³

Hidradenitis Suppurativa

CLINICAL EVALUATION

Hidradenitis suppurativa is a chronic, recurrent inflammatory process involving the apocrine glands of the axilla, the groin, the perineum, and the perianal region.²⁸ The disease can result in chronically draining wounds and sinus tracts and can become quite painful and debilitating.²⁹ Occlusion of follicles and abnormalities of apocrine ducts are believed to be causative factors.

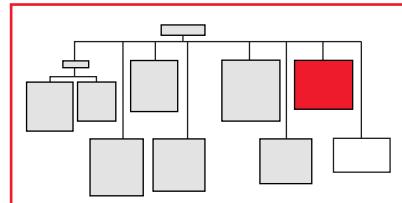

MANAGEMENT

Medical management may afford temporary relief of symptoms; however, most patients eventually require surgical therapy.³⁰ In select patients, incision and drainage or unroofing of sinuses may provide relief, but these measures should be reserved for cases of early and acute disease. Local excision provides adequate control of symptoms; however, recurrence rates higher than 50% may be anticipated. Wide excision with secondary granulation of perineal wounds constitutes the most definitive therapy and generally can be accomplished safely.²⁹ Perianal disease is associated with considerably lower recurrence rates than perineal disease is and thus can more often be managed with local excision alone.

Pruritus Ani

Pruritus ani is a dermatologic condition of the perianal skin characterized by uneasiness or itching in the area around the anus.^{12,31} Multiple factors may predispose this area to irritation, including poor perianal hygiene (related to incontinence, diarrhea, or excessive hair), excessive moisture, irregularities of the perianal skin (from hemorrhoids, fistulas, or previous surgery), skin hypersensitivity, diet, decreased resistance to infection, and injury to the perianal skin.³¹ The variety of possible causes is what often makes pruritus ani difficult to treat. Some patients improve only after the offending agents or conditions are identified and specific therapy instituted. Fortunately, many patients' symptoms can be alleviated by the application of nonspecific treatments.

CLINICAL EVALUATION

A thorough history and physical examination are necessary to suggest possible causes of pruritus. Initial inspection of the perianal skin should be conducted with gentle retraction of the buttocks under bright lighting. A characteristic finding is erythema-

Figure 11 A characteristic finding in idiopathic pruritus ani is erythematous or thickened perianal skin.

tous or thickened perianal skin [see *Figure 11*]. This thickening results in a pale, whitish appearance, with accentuation of the radial anal skin creases. In addition, the skin may be excoriated or ulcerated; this process, when combined with thickening, is referred to as lichenification. Occasionally, the skin is so excoriated that a large, coalescing, weeping ulcer forms. Digital rectal examination should be performed to assess the competence of the anal sphincter both at rest and during maximal squeeze. Anoscopy and proctosigmoidoscopy may be performed after the administration of an enema.

MANAGEMENT

The basic principles of therapy for pruritus ani are uncomplicated. If an inciting cause can be identified, it should of course be eliminated or corrected. Frequently, the inciting cause is elusive, but even so, most patients can still be effectively managed by applying several simple measures.

Generally, patients should keep the perianal area dry and avoid further trauma to the area. The perianal area should be gently washed, never scrubbed. After showering, the area should be patted dry or dried with a hair dryer on a low heat setting. After bowel movements, the anus should be cleaned with moistened toilet paper. Excessive rubbing or wiping should be discouraged: scratching or rubbing the anal area damages the perianal skin, making it more susceptible to irritation. Patients should also be instructed to avoid irritating foods and drinks, such as tomatoes, peppers, citrus fruits and juices, coffee, colas, beer and other alcoholic beverages, milk, nuts, popcorn, and any other foodstuffs found to be associated with increased gas, indigestion, or diarrhea. After 2 weeks, food items eliminated from the diet can be reintroduced one at a time in an attempt to identify the offending agent more specifically.

A regular bowel habit should be maintained with the help of fiber supplementation or a high-fiber diet. Patients should be instructed to eschew all proprietary creams, lotions, and emol-

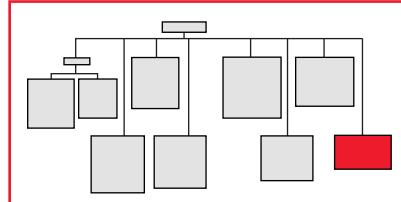

lients. If prescribed and supervised by a physician, however, a hydrocortisone cream may be applied sparingly to the affected area for a period of 1 week or less to attain control of symptoms. Occasionally, when pruritus ani is refractory to treatment, a candidal yeast infection is found to be present, in which case a trial of antifungal lotion, solution, or powder is worthwhile.

The fundamental goal in the treatment of pruritus ani is to establish and maintain intact, healthy, clean, and dry perianal skin. When standard measures fail to elicit improvement, fungal and viral cultures and perhaps even biopsy may be necessary to exclude an infectious or neoplastic cause.

Solitary Rectal Ulcer Syndrome

CLINICAL EVALUATION

SRUS is a clinical condition characterized by rectal bleeding, copious mucous discharge, anorectal pain, and difficult evacuation.³² The name of the condition notwithstanding, SRUS patients can have a single rectal ulcer, multiple ulcers, or even no ulcers at all. When present, the ulcers usually occur on the anterior rectal wall, just above the anorectal ring; less commonly, they occur from just above the dentate line to 15 cm above it. The ulcers usually appear as shallow lesions with a punched-out gray-white base that is surrounded by hyperemia.³³

Colitis cystica profunda (CCF) is a benign condition that is related to SRUS and is characterized by mucin-filled cysts located deep to the muscularis mucosae. CCF is a pathologic diagnosis, of which the most important aspect is differentiation of CCF from colorectal adenocarcinoma.

Precisely what causes SRUS and CCF remains unclear, but both conditions are known to be associated with chronic inflammation or trauma (e.g., internal intussusception or prolapse of the rectum, direct digital trauma, or the forces associated with evacuating a hard stool). Endoscopic evaluation of the distal colon and rectum reveals the lesions described. For both CCF and SRUS, the differential diagnosis includes polyps, endometriosis, inflammatory granuloma, infection, drug-induced colitis, and mucus-producing adenocarcinoma. These entities can be confirmed or excluded by means of an adequate biopsy.

MANAGEMENT

Treatment is directed at alleviating symptoms or interfering with some of the proposed etiologic mechanisms. Conservative therapy (e.g., a high-fiber diet, lifestyle changes, and biofeedback) reduces symptoms in most patients and should be tried first. Patients without rectal intussusception are offered biofeedback for retraining their bowel function. Pharmacologic therapy (e.g., anti-inflammatory enemas and suppositories) has had only limited success but nonetheless may be worth trying before the decision is made to embark on surgery.

If symptoms persist, localized resection may be considered in selected patients. Patients with prolapse are considered for perineal procedures (i.e., mucosal or perineal proctectomy) and abdominal procedures (i.e., fixation or resection and rectopexy). Patients without prolapse may be offered excision, for which the options range from a transanal excision to a major resection with coloanal pull-through. Understandably, surgeons have been hesitant to offer surgical therapy for this benign condition; the results are often unsatisfactory.³⁴

18 GASTROINTESTINAL ENDOSCOPY

Alicia Fanning, M.D., and Jeffrey L. Ponsky, M.D., F.A.C.S.

Since the beginning of the 1970s, flexible endoscopy of the gastrointestinal tract has been the dominant modality for the diagnosis of gastrointestinal disease. Over the same period, developments in technology and methodology have made possible the use of endoscopy to treat a host of conditions that once were considered to be manageable only by means of open surgical procedures. The integration of flexible endoscopic techniques into the armamentarium of the GI surgeon permits a more multidimensional approach to the treatment of digestive disease. The modern GI surgeon should be conversant in and adept at many of these procedures.

Diagnostic Esophagogastroduodenoscopy

Diagnostic esophagogastroduodenoscopy (EGD) is indicated when a patient has abnormal findings on traditional GI x-ray series, dysphagia, odynophagia, epigastric pain that does not respond to medical therapy, persistent heartburn, or upper GI bleeding; it is also indicated for surveillance of patients at high risk for malignancy and for sampling of GI tissue or fluid. One prepares for the examination by ensuring the patient's hemodynamic stability, having the patient fast for 6 to 8 hours beforehand, and performing conscious sedation, which generally involves applying a topical anesthetic to the posterior pharynx and administering a narcotic and a benzodiazepine intravenously. Monitoring of arterial blood pressure and oxygen saturation throughout the procedure is now standard practice.

TECHNIQUE

With the patient in the left lateral decubitus position, a topical anesthetic is applied to the posterior pharynx and an intravenous sedative administered. The forward-viewing panendoscope—a small-caliber instrument that is long enough to permit examination of the foregut from the mouth to the third portion of the duodenum—is employed.

The endoscope may be introduced either blindly, via finger-guided palpation of the pharynx, or under direct vision. The latter approach is preferable. In this approach, the instrument is advanced slowly until the epiglottis and vocal cords are visualized [see Figure 1]; it is then angled posteriorly to the esophageal introitus and gently advanced as the patient is asked to swallow. Insufflation of air is begun to distend the esophagus, which appears as a long, round tube. Frequent peristaltic waves are seen; these are normal. Mucosal surfaces must be closely inspected for signs of ulceration, stricture, tumor, or Barrett's (columnar) epithelium, which manifests itself as orange patches in otherwise pale salmon-pink esophageal (squamous) mucosa. When abnormalities are noted, biopsy, brushing for cytologic evaluation, or both should be performed. Staining of the esophagus with methylene blue may be useful in the search for Barrett's mucosa: the blue dye is avidly absorbed by

the intestinal absorptive cells of the columnar epithelium. Darkly stained areas may be biopsied for confirmation.

As the endoscope is advanced, insufflation is continued, and the curve of the lumen is followed to the left as the esophagus traverses the diaphragm to enter the stomach. There is a pinched area where the diaphragm compresses the esophagus; the pinching is exaggerated when the patient is asked to sniff. If gastric folds are seen above this pinched area, a hiatal hernia is present. When the stomach is entered, the tip of the endoscope is elevated so as to center it within the gastric lumen. It should be noted that with the patient lying in the left lateral decubitus position, the stomach is also on its side, with the greater curvature at 6 o'clock, the lesser curvature at 12 o'clock, the posterior wall at 3 o'clock, and the anterior wall at 9 o'clock. Air should be insufflated to distend the stomach fully and permit careful inspection of the mucosal surfaces.

As the instrument is advanced toward the gastric antrum, its tip should be slightly elevated because the stomach has a J shape and the prepyloric region curves upward. The pylorus is normally round and may be seen to open and close with gastric peristalsis. With the tip of the endoscope positioned at the proximal gastric antrum, just under the incisura angularis, a retroflex view of the cardia and the fundus is obtained by elevating the tip of the scope and rotating the shaft to the left. This maneuver provides visual and therapeutic access to the proximal stomach.

After the stomach has been viewed, the instrument is advanced under direct vision through the pylorus and into the duodenal bulb. Insufflation of air should continue as the scope is

Figure 1 Diagnostic esophagogastroduodenoscopy. As the endoscope is introduced under direct vision, the vocal cords are clearly noted. The esophageal opening is posterior to the cords.

pressed against the pylorus to facilitate passage of the instrument. The scope tends to pop into the duodenal bulb rather than slide smoothly; it should be pulled back slightly to allow one to observe the mucosal surfaces of the bulb before moving ahead. Unlike the rest of the small bowel, the duodenal bulb has no semicircular folds. The tip of the scope must be rotated slightly to permit examination of the walls of the bulb. It is advisable to pull the instrument back into the stomach while observing the walls of the bulb and the pyloric channel for lesions; several such withdrawals may be required for full assessment of this area.

Once the duodenal bulb has been examined, the endoscope is advanced just past the bulb to the point where the first duodenal folds are observed. Here, the duodenum turns sharply to the rear and downward as it becomes retroperitoneal. Advancement of the scope into the second portion of the duodenum is one of the few endoscopic maneuvers that cannot be accomplished under direct vision. Because of the sharp angle of the turn, one will experience a moment of so-called red out as the tip of the endoscope touches the mucosa during the turn. To ensure that the turn is accomplished safely, the instrument is advanced as far through the bulb as is possible under direct vision. The control handle of the scope is then rotated approximately 90° to the right as the tip of the scope is turned to the right and angled first upward, then downward. As the second portion of the duodenum appears, the scope is rotated back to its neutral position. When done correctly, the turn is actually quite easy. It should never be forced: if the instrument does not proceed easily into the descending duodenum, the scope should be pulled back and the attempt repeated. Pushing against resistance may result in perforation.

Entering the descending duodenum causes the scope to form a large loop in the stomach. Therefore, once the second portion of the duodenum is successfully entered, the shaft of the instrument is pulled back. Paradoxically, as this movement straightens the gastric loop, it also advances the tip of the instrument deeper into the duodenum. Further advancement of the instrument under direct vision often permits entry into the third or even the fourth portion of the duodenum. Once the distal limit of intubation is reached, the scope is withdrawn and the luminal surfaces are carefully examined. Rotating the scope with small right-left movements of the controls and side-to-side movements of the control handle itself will help demonstrate the more subtle details of duodenal anatomy. Often, the upper GI tract is inspected more completely while the instrument is being withdrawn than while it is being advanced.

Mucosal abnormalities should be biopsied; liberal use of brush cytology in combination with biopsy enhances the yield.

COMPLICATIONS

EGD is an extremely safe procedure. Perhaps the most common problems associated with the technique arise from the preparatory sedation and analgesia. Respiratory depression and aspiration may occur during the procedure. Careful attention must be paid to the patient's state of consciousness and airway during the endoscopic procedure, appropriate drugs must be available to reverse sedative effects, and a suction apparatus must be ready for use at all times. Blind advancement of the endoscope by force may lead to perforation of the esophagus; this problem may be avoided by taking care never to advance the instrument against resistance.

Therapeutic Esophagogastroduodenoscopy

CONTROL OF VARICEAL HEMORRHAGE

In patients with massive upper GI hemorrhage, the first priori-

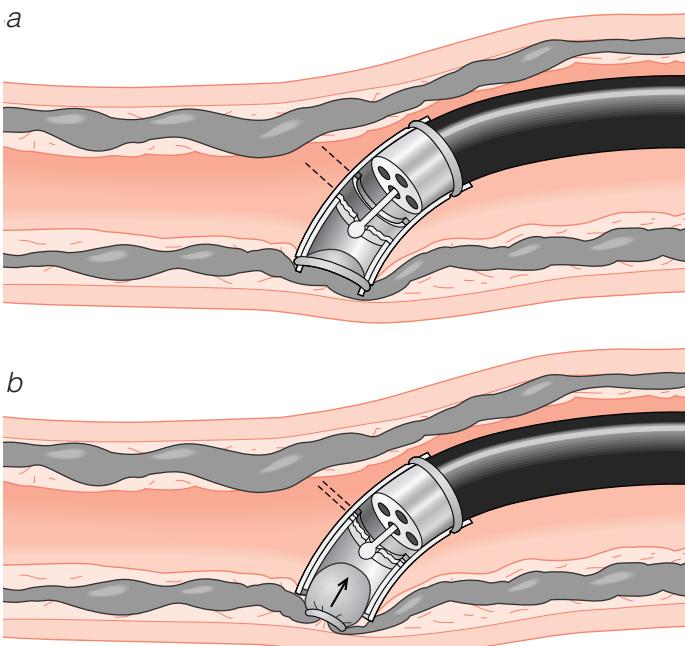

Figure 2 Therapeutic esophagogastroduodenoscopy: control of variceal hemorrhage. (a) A plastic tip on the endoscope is used to create a chamber. (b) An esophageal varix is suctioned into the chamber, and a rubber band is released around it.

ties are to establish a secure airway and to ensure hemodynamic stability. These priorities must be addressed before endoscopy is attempted. If the bleeding is thought to be coming from esophageal varices, it is frequently useful to perform endotracheal intubation for control of the airway before the endoscopic intervention.

Technique

A rapid but complete diagnostic upper GI endoscopic procedure is performed to determine whether varices are present and to identify the exact site of hemorrhage. Endoscopic therapy for variceal disease is then delivered by means of either sclerotherapy or rubber band ligation.

Sclerotherapy is commenced in the distal esophagus at the site of active or suspected bleeding: 2 to 3 ml of a sclerosant solution (e.g., sodium tetradecyl sulfate) is injected directly into the lumen of the varix. Additional varices can be treated in the same fashion. After the bleeding has stopped, further therapy is usually delivered at weekly intervals until total variceal obliteration is achieved.

Rubber band ligation of varices has become extremely popular and has been shown to possess some clear advantages over sclerotherapy [see Figure 2]. Originally, multiple passages of the endoscope were required to allow for reloading of the bands; however, newer ligating devices permit ligation of as many as 10 varices with a single passage of the endoscope. As with sclerotherapy, the site of active or suspected bleeding is attacked first; it is most often near the esophagogastric junction. The offending varix is centered in the field of view, and suction is applied to pull it into the ligator cup, which sits on the end of the endoscope. When the varix is deep within the cup, the trigger string on the ligator is pulled, and a rubber band is released around the varix. Suction is then released, and the ligated varix is visualized. Additional ligations may be performed at the initial session; follow-up sessions are usually held at weekly intervals until total variceal obliteration is achieved.

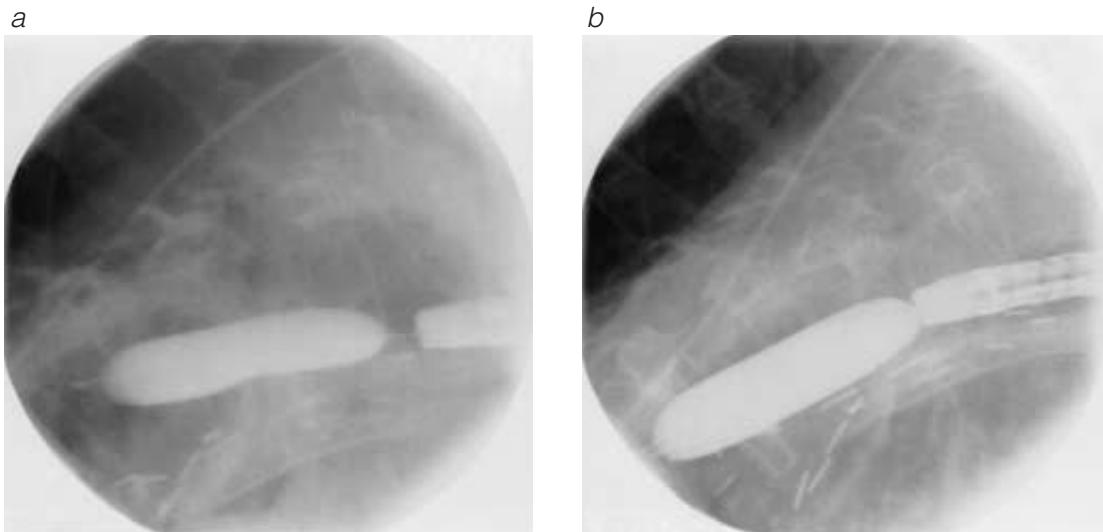

Figure 3 Therapeutic esophagogastrroduodenoscopy: dilation of esophageal strictures. (a) A hydrostatic dilating balloon filled with a contrast agent is inflated within the stricture under fluoroscopic guidance. Initially, a “waist” appears at the stricture site. (b) Inflation of the balloon is continued until the waist is ablated, which indicates complete dilation of the stricture.

Complications

Because aspiration of blood and gastric contents may occur during endoscopic control of variceal hemorrhage, endotracheal intubation must be considered when bleeding is massive. In many cases, general anesthesia will permit adequate airway control and a quiet operating field. Violent patient motion when the injection needle is in a varix may result in perforation of the esophagus. This is a rare complication, however; tearing of the varix, with resultant hemorrhage, is more frequent. Injection of excessive amounts of sclerosant may lead to significant ulceration and necrosis of esophageal tissue. Fever, severe infection, pleural effusion, and subsequent esophageal stricture occasionally occur after sclerotherapy. Ulceration and necrosis of tissue, with subsequent stricture, occur after rubber band ligation as well, but severe infection is less common in this setting.

CONTROL OF NONVARICEAL HEMORRHAGE

Bleeding from peptic ulcer disease, gastritis, or vascular malformations is a common indication for EGD. Once the patient has been adequately resuscitated, endoscopy should be performed, and the entire esophagus, stomach, and duodenum should be examined thoroughly. Before the procedure is begun, the stomach should be vigorously irrigated through a large-bore tube so that as much clotted blood as possible can be evacuated. If a pool of blood is noted in the stomach, the position of the patient should be changed so as to move the pool and permit complete examination of the stomach.

The therapeutic modalities available for control of nonvariceal bleeding include (1) the injection of hypertonic saline, epinephrine (in a 1:10,000 solution), or 98% alcohol, (2) bipolar electrocoagulation, (3) the use of heater probes, (4) argon beam coagulation, (5) the application of acrylic glue, (6) the application of hemostatic clips, and (7) the use of the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser.

Technique

The most popular therapeutic modalities are injection therapy, bipolar coagulation, and the use of the heater probe. Injection

therapy is performed around the bleeding lesion to create edema and vasospasm in the area. The bipolar coagulator or the heater probe is applied directly to the bleeding lesion in an attempt to coapt the bleeding vessel as heat is delivered. Frequently, injection therapy is employed in conjunction with coagulation; this combination is very effective.

If there is a clot covering the ulcer base, it must be removed with suction or a snare before coagulation is attempted. If a rapidly bleeding lesion is present, the best approach often is injection therapy in adjacent areas to slow or stop the bleeding, followed by coagulation by direct coaptation. Vascular lesions are often multiple or diffuse, as in so-called watermelon stomach. Such lesions are most effectively treated by means of modalities that can be applied in a spraying fashion, such as the Nd:YAG laser or the argon beam coagulator.

Complications

Nonvariceal hemorrhage is successfully controlled by endoscopic means in more than 90% of cases. At times, however, attempts at endoscopic control may exacerbate the bleeding. Several therapeutic modalities should always be available: one may succeed when another fails. Excessive injection therapy or persistent attempts at coagulation may lead to tissue necrosis and subsequent perforation. Although the argon beam coagulator can injure tissue only to a depth of several millimeters, excessive application may result in massive distention of the bowel if care is not taken to aspirate the constantly infused argon gas frequently. The Nd:YAG laser has the potential to cause full-thickness injury to the gastric wall.

DILATION OF ESOPHAGEAL STRICTURES

When patients complain of dysphagia or odynophagia, prompt endoscopic investigation is warranted. Strictures may be secondary to reflux disease, secondary to caustic burns, or of neoplastic origin.

Technique

Endoscopy is performed in the usual fashion. It is imperative that the endoscope be advanced only under direct vision. When a stricture is encountered, its location, morphology, and length should be determined. Biopsy and cytology specimens should be

gathered from the circumference of the stricture. When a stricture is present at the esophagogastric junction and the scope can easily be passed by the stricture, it is helpful to view the area from below with the tip of the scope retroflexed.

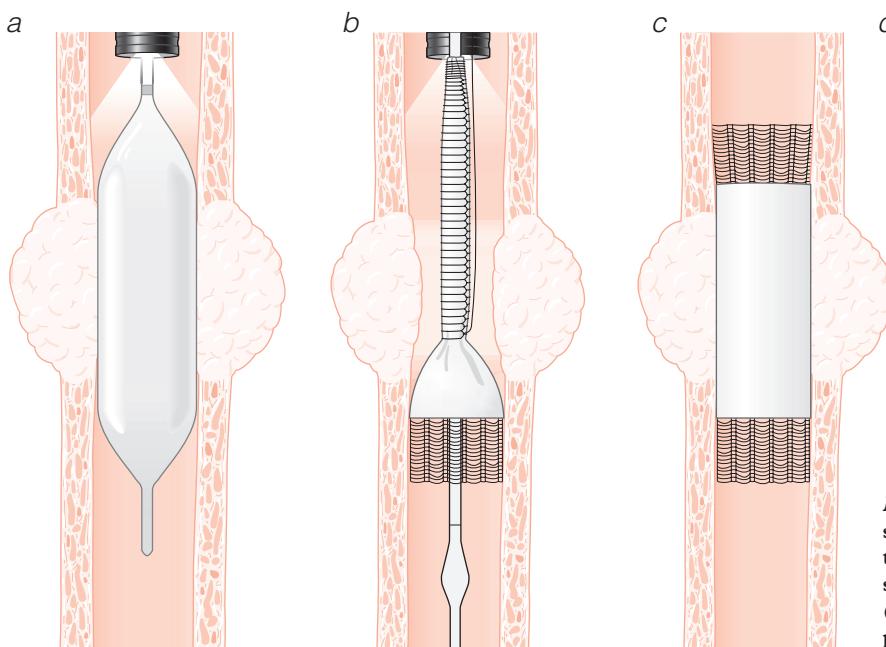

Stricture dilation can be accomplished in several different ways and with several different kinds of dilators. One commonly employed method is to use the endoscope to guide the passage of a soft-tipped guide wire through the stricture; the scope is then removed, leaving the wire in place. Subsequently, dilators are passed over the guide wire, usually under fluoroscopic control. Another method for endoscopic dilation of strictures is the use of through-the-scope (TTS) hydrostatic dilating balloons. A balloon of the appropriate inflated diameter (usually no larger than 18 mm or 54 French) is selected, passed through the biopsy channel of the endoscope, and advanced under direct vision until its middle portion passes through the stricture. At the stricture site, the balloon is compressed, giving the appearance of a waist. The balloon is then inflated until the waist is fully expanded [see Figure 3]. Full expansion is verified by fluoroscopic surveillance and the use of contrast to inflate the balloon. This second method is extremely useful for initial dilation of tight strictures in preparation for the use of other, nonendoscopic dilators or the placement of an esophageal stent.

Complications

Dilation of esophageal strictures may result in bleeding (usually minor) or perforation of the esophagus. When a patient experiences severe pain after dilation, a chest x-ray is imperative. The finding of mediastinal or subcutaneous air should prompt the immediate performance of a contrast study with a water-soluble agent to determine whether a perforation is present. Some small perforations can be managed with intravenous antibiotics and observation, but most must be managed surgically. The incidence of perforation can be minimized by avoiding excessive or forceful dilation.

STENTING OF ESOPHAGEAL TUMORS

Under optimal circumstances, esophageal tumors should be treated by means of extrapleural surgery. When surgical cure or palliation seems to have little to offer, placement of an esophageal prosthesis by endoscopic means is a reasonable approach.

Technique

Modern esophageal prostheses are placed under fluoroscopic guidance, frequently after endoscopic balloon dilation of the tumor. During the endoscopic examination, it is useful to inject a small amount of water-soluble contrast material into the muscular wall of the esophagus just above and below the tumor; this enables one to measure the length of the tumor and select the correct stent. Once the tumor has been dilated and marked endoscopically, the scope is removed, and the expandable stent is passed into the esophagus and positioned between the endoscopic injection markings seen on fluoroscopy. The stent is then deployed and allowed to expand [see Figure 4]. The endoscope may then be reintroduced to ensure that the prosthesis is patent and is correctly placed.

Complications

Incorrect positioning of the prosthesis is a frequent problem. Attention to the details of endoscopic marking is very important. Also crucial is correct selection of a stent: stents shorten from both ends as they are deployed, and this must be taken into account in selecting the correct stent length. On occasion, the stent may migrate as a result of tumor-related necrosis or incorrect placement. If it migrates into the stomach, it can usually be captured in a snare and retrieved.

RETRIEVAL OF FOREIGN BODIES

Many ingested foreign bodies pass through the GI tract uneventfully, but a good number must be removed by endoscopic means—in particular, foreign bodies in the esophagus, sharp objects that are likely to perforate the bowel, and objects that do not progress from the stomach.

If the ingested object is of an unfamiliar type, it is an extremely good idea to practice with a similar object outside the patient before attempting endoscopic retrieval. This preparatory step allows one to select the most appropriate accessory and technique for removing the object.

Technique

Objects with sharp edges should be removed with the sharp end trailing to prevent perforation. In some cases, this means that the object must be pushed into the stomach and turned

Figure 4 Therapeutic esophagogastroduodenoscopy: stenting of esophageal tumors. (a) An esophageal tumor is dilated. (b, c) A compressed expandable metal stent is positioned within the tumor and deployed. (d) The expanded stent yields a large enough lumen to permit the patient to continue oral alimentation.

around before being removed. If multiple foreign bodies are present or if it is highly likely that the foreign body will injure the esophagus if removed in the standard manner, an overtube should be placed over the scope before insertion. The overtube enables one to pass the instrument several times and retrieve any sharp objects without injuring the esophagus; it also helps ensure that the object is not aspirated into the airway. If the patient is a child, general anesthesia may be advisable.

Perhaps the best method of removing foreign bodies is to surround them with a simple polypectomy snare and secure them in the endoscope's grasp. Meat boluses that form in the esophagus or proximal to a gastric band may be extremely difficult to dislodge; the use of a variceal ligator cap to produce a suction chamber can be helpful in such situations.

Complications

Endoscopic removal of foreign bodies is extremely safe and effective. Care must be taken to ensure that the esophagus is not injured during removal of the object. If the object is deeply embedded or refractory to removal, a surgical approach is preferred.

PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

Since 1980, endoscopically guided placement of a tube gastrostomy has been widely employed to provide access to the GI tract for feeding or decompression. Indications for percutaneous endoscopic gastrostomy (PEG) include various disease processes that interfere with swallowing, such as severe neurologic impairment, oropharyngeal tumors, and facial trauma. PEG has also been employed to establish a route for recycling bile in patients with malignant biliary obstruction, to provide supplemental feeding in selected patients with inflammatory bowel disease, and to accomplish gastric decompression in patients with conditions such as carcinomatosis, radiation enteritis, and diabetic gastropathy.

Technique

The patient fasts for 8 hours beforehand, and a single prophylactic dose of an antibiotic is administered just before the procedure is begun. The patient is placed in the supine position, a topical anesthetic is applied to the posterior pharynx, and intravenous sedation is begun. A forward-viewing endoscope is passed into the esophagus and advanced into the stomach. The abdomen is prepared in a sterile fashion and draped. The stomach and the duodenum are then inspected.

The room lights are dimmed, and the light of the endoscope is used to transilluminate the abdominal wall so as to indicate a point where the gastric wall and the abdominal wall are in close proximity. Finger pressure is applied to various areas of the abdomen until a spot is identified at which such pressure produces clear indentation of the gastric wall. An endoscopic snare is deployed through the biopsy channel of the endoscope to cover this spot, and a local anesthetic is infiltrated into the overlying skin [see Figure 5]. A 1 cm skin incision is made at the chosen spot, and a needle is passed through the incision and into the gastric lumen. The endoscopic snare is tightened around the needle, and a wire is passed through the needle and into the gastric lumen. The snare is moved so as to surround the wire, which is then pulled out of the patient's mouth. The gastrostomy tube is fastened to the wire and pulled in a retrograde manner down the esophagus and into the stomach. The gastroscope is subsequently reinserted to ensure that the head of the catheter is correctly positioned against the gastric mucosa [see Figure 6].

An outer crossbar is put in place to prevent inward migration of the tube and to hold the stomach in approximation to the

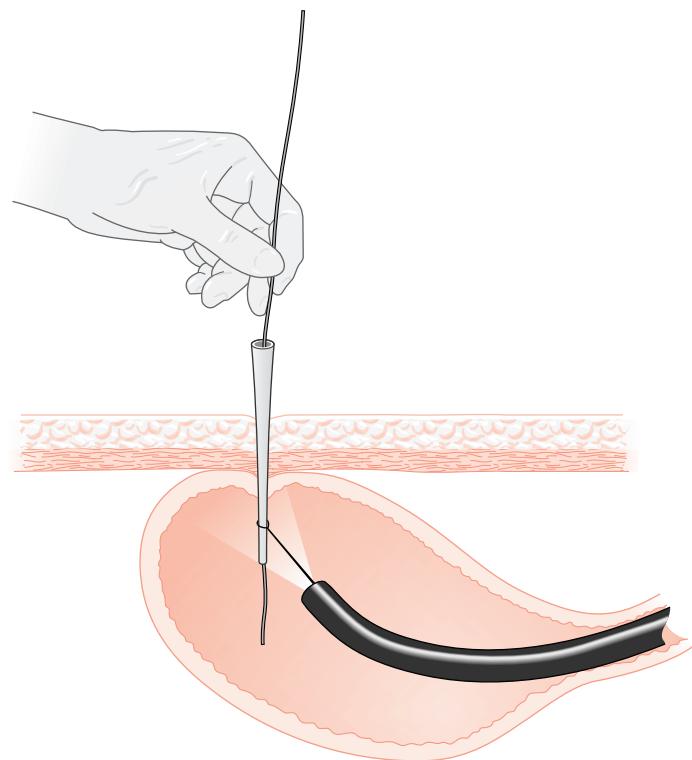

Figure 5 Therapeutic esophagogastroduodenoscopy: percutaneous endoscopic gastrostomy. The first steps in the procedure involve selecting a proper site in the stomach and using a snare to surround a needle that has been passed through the abdominal and gastric walls.

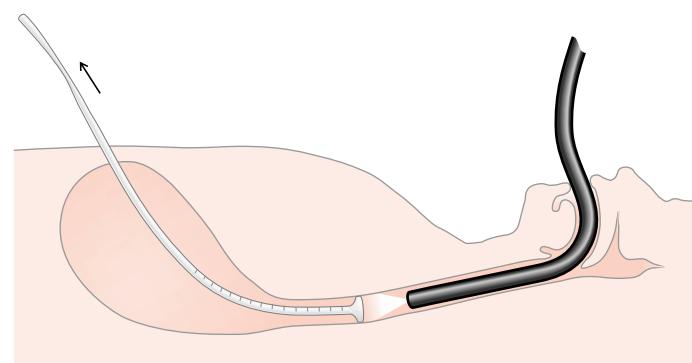

Figure 6 Therapeutic esophagogastroduodenoscopy: percutaneous endoscopic gastrostomy. After the suture is retrieved from the stomach, it is affixed to the gastrostomy tube and used to pull the tube back into the stomach and out the abdominal wall. The gastroscope is reinserted to follow the process and ensure that the final position of the tube is correct.

abdominal wall. The crossbar should remain several millimeters from the skin to prevent excessive tension, which would cause ischemic necrosis of the underlying tissue.

Complications

Local wound infections are the most common complications of PEG. They can be minimized by administering preoperative antibiotics and ensuring that excessive tension is not applied to the crossbar at the end of the procedure. When such infections do occur, they can usually be treated via simple drainage and local

wound care; sacrifice of the gastrostomy is rarely necessary. Several other complications, such as early extrusion of the tube, progressive enlargement of the tract, and separation of the gastric and abdominal walls with leakage of feedings into the abdominal cavity, are also most often attributable to excessive crossbar tension and subsequent ischemia. Gastrocolic fistula can occur after PEG. This problem may not be obvious for months afterward, but severe diarrhea after feedings is grounds for suspicion. Once the PEG tract is mature, gastrocolic fistulas usually close quickly after simple removal of the gastrostomy tube.

Diagnostic Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) is an advanced procedure that is technically more challenging than standard upper GI endoscopy; however, it can be mastered by most endoscopists who are willing to dedicate sufficient time to learning the method. ERCP yields a radiologic image of the pancreatic and biliary trees, and in many cases, it provides access for therapy. Indications for ERCP include suspected benign or malignant maladies of the common bile duct (CBD), the ampulla of Vater, or the pancreas. Cholelithiasis per se is not an indication for ERCP unless choledocholithiasis is suspected.

TECHNIQUE

As with standard upper GI endoscopy, the patient fasts for 6 to 8 hours beforehand. Intravenous sedation is administered, and prophylactic antibiotics are given when biliary obstruction is suspected. The patient is initially placed in the left lateral decubitus position but is later rotated to the prone position after the scope is in place in the second portion of the duodenum. A side-viewing endoscope is employed because it allows the best visualization of the ampulla of Vater. The instrument is passed into the esophagus and maneuvered through the stomach, across the pylorus, and into the duodenum. Manipulation of a side-viewing instrument is a bit awkward for the novice but is easily learned.

Once the endoscope is in the second portion of the duodenum, it is pulled back so that the gastric loop is straightened and the tip of the scope occupies a better position with regard to the papilla. This so-called short scope position is generally best for work in the CBD [see Figure 7]. The papilla of Vater (also known as the major duodenal papilla) appears as a small longitudinal nubbin crossing the horizontal semicircular folds of the duodenum, generally in the 12 to 1 o'clock position. At its tip, a small, soft, reticulated area may be noted; this is the papillary orifice. Often, a small mucosal protuberance is seen just proximal and to the right of the papilla of Vater; this is the minor duodenal papilla.

A small plastic cannula is passed through the channel of the endoscope and introduced into the ampullary orifice, and contrast material is injected under fluoroscopic control to provide visualization of the CBD and the pancreatic duct. The two may share a single orifice within the ampulla or may have separate orifices. The CBD exits the papilla in a cephalad direction, tangential to the duodenal wall. The bulge of the ampulla within the duodenum represents the intramural segment of the duct. The orifice of the CBD is typically found at the 11 o'clock position in the ampulla. The pancreatic duct leaves the papilla in a perpendicular fashion. Its orifice is usually in the 1 o'clock area of the papilla [see Figure 8].

COMPLICATIONS

When contrast material is being injected into the pancreatic ductal system, care must be taken to avoid overfilling, which can

lead to acinarization, or rupture of the small ductules, with extravasation of contrast material into the pancreatic parenchyma; pancreatitis is a frequent consequence of acinarization. Cholangitis may result when contrast is injected proximal to an obstruction of the biliary tree. When obstruction is demonstrated, drainage of the system by means of stone extraction, stenting, or nasobiliary intubation is important to prevent cholangitis.

Therapeutic Endoscopic Retrograde Cholangiopancreatography

Therapeutic interventions that may be accomplished at the time of ERCP include sphincterotomy for ductal access or ampillary stenosis, removal of CBD stones, dilation of benign and malignant biliary strictures, and insertion of stents to maintain ductal patency. Pancreatic duct interventions include removal of stones, bridging of ductal disruptions, and drainage of pseudocysts.

TECHNIQUE

All therapeutic applications of ERCP must begin with selective cannulation of the duct being treated. Frequently, a guide wire is then introduced deep into the duct to provide a means of obtaining access to the duct on an ongoing basis and to ensure correct

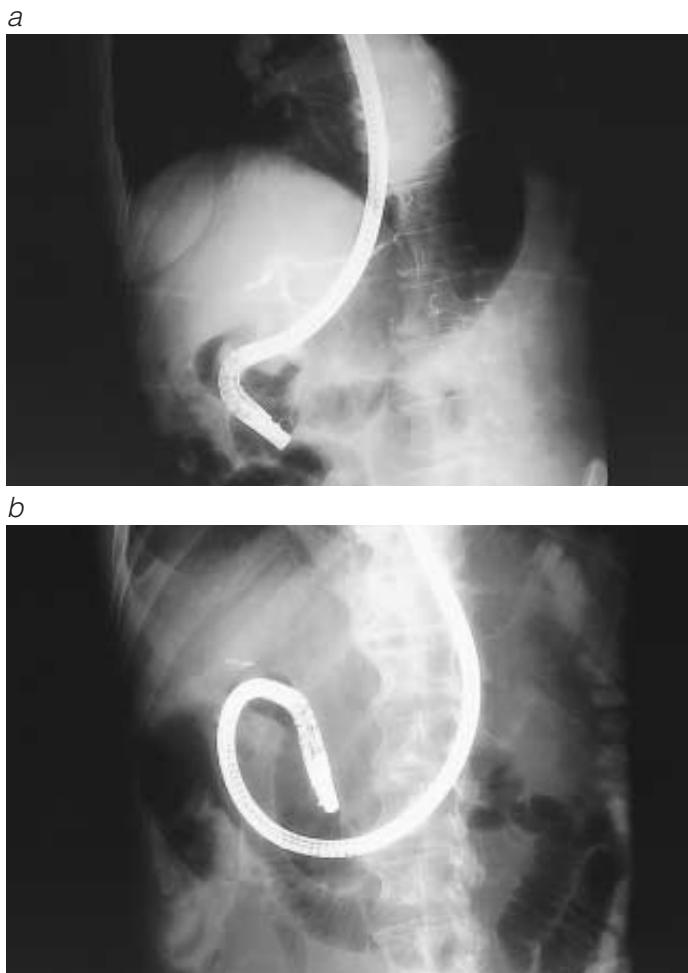

Figure 7 Diagnostic endoscopic retrograde cholangiopancreatography. (a) The so-called short scope position, along the lesser curve of the stomach, is usually the most effective in biliary interventions. (b) The so-called long scope position may be necessary at times.

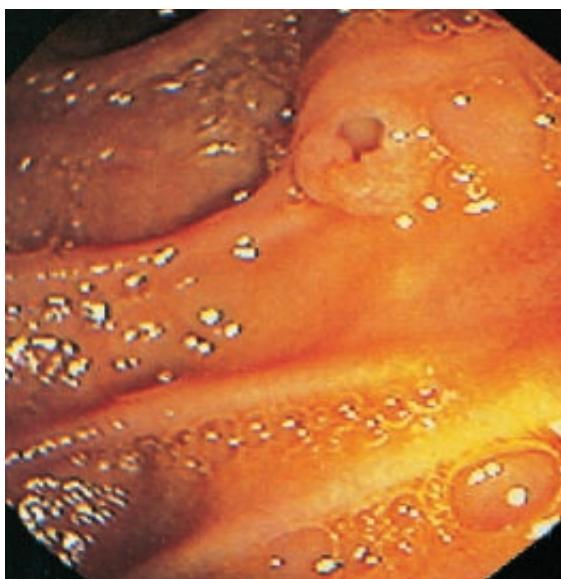

Figure 8 Diagnostic endoscopic retrograde cholangiopancreatography. The so-called long scope position, along the greater curve of the stomach, may be useful in some pancreatic interventions; shown is the pancreatic duct orifice.

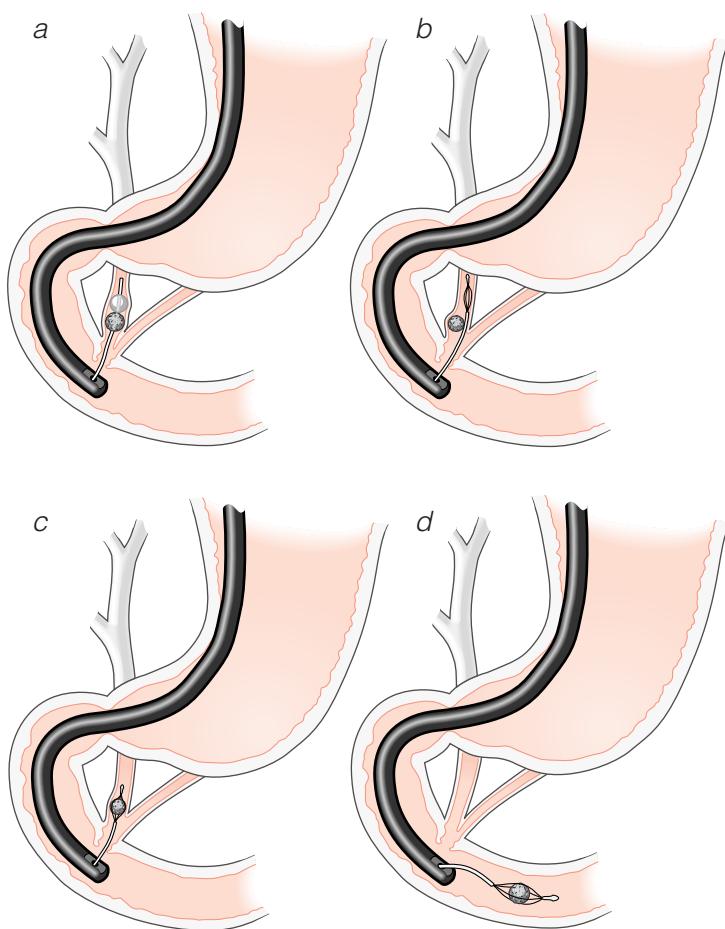

Figure 9 Therapeutic endoscopic retrograde cholangiopancreatography. After endoscopic sphincterotomy, CBD stones may be retrieved with balloons (a) or baskets (b, c, d).

positioning for intraductal manipulations. After electrosurgical division of the papilla, biliary stones are retrieved with balloon or baskets [*see Figure 9*]. Often, large stones can be captured within the duct in mechanical lithotripsy baskets and crushed before removal.

Strictures should be brushed for cytologic evaluation once they have been traversed by a wire. They may then be dilated with hydrostatic balloons under fluoroscopic guidance and stented [*see Figure 10*]. Plastic stents are used for most benign and many malignant strictures; however, self-expanding metal stents are now being used more frequently for malignant strictures because they remain patent longer [*see Figure 11*].

COMPLICATIONS

Perforation can occur during endoscopic sphincterotomy as a result of extension or tearing of the papilla beyond the junction of the CBD with the duodenal wall. Retroperitoneal or free intraperitoneal air may be seen. In many cases, intravenous antibiotics, hydration, and avoidance of oral intake are sufficient to manage such complications. If the patient's condition deteriorates, surgical exploration is indicated.

Bleeding may also occur with sphincterotomy. It is usually controllable with injection of epinephrine solution (1:10,000), electrocoagulation, or balloon tamponade. Arteriographic embolization of the gastroduodenal artery may be helpful in some cases. As with diagnostic ERCP, pancreatitis may occur; it usually responds to conservative measures.

Diagnostic Colonoscopy

Colonoscopy has become one of the most frequently performed endoscopic examinations. It has revolutionized the diagnosis and treatment of colonic disease and offers the promise of reducing the occurrence of colon cancer. Indications for colonoscopy include iron deficiency anemia, frank or occult rectal bleeding, a history of colonic cancer in the patient or in first-degree family members, a history or suspicion of colonic polyps, inflammatory bowel disease, and a persistent change in bowel habits. Preparation involves purging the bowel mechanically by placing the patient on a clear liquid diet for several days, then giving cathartics and enemas; alternatively, one may use osmotic lavage, in which 1 gal of lavage fluid is administered orally over a period of 4 hours. It is often helpful to administer 10 mg of metoclopramide to enhance gastric motility as preparation begins.

TECHNIQUE

Sedation is accomplished as for upper GI endoscopy, and the patient fasts for 6 to 8 hours before the procedure. With the patient in the left lateral decubitus position, a rectal examination is performed. This step helps relax the anal sphincter in preparation for insertion of the scope and ensures that low-lying rectal lesions are not overlooked.

The colonoscope is introduced into the rectal vault, and insufflation of air is commenced. The instrument is advanced only when the lumen is clearly apparent. At times, only a portion of the lumen may be visible, but this is usually enough to guide advancement of the scope. Frequently, when the lumen itself is not visible, light reflected onto the colonic folds can guide one to the lumen, with the concavity of the fold indicating the direction of the lumen. In contrast with upper GI endoscopy, in which torsion on the shaft of the endoscope is rarely necessary, such torsion is the rule in colonoscopy. The shaft of the instrument is rotated with the right hand to facilitate

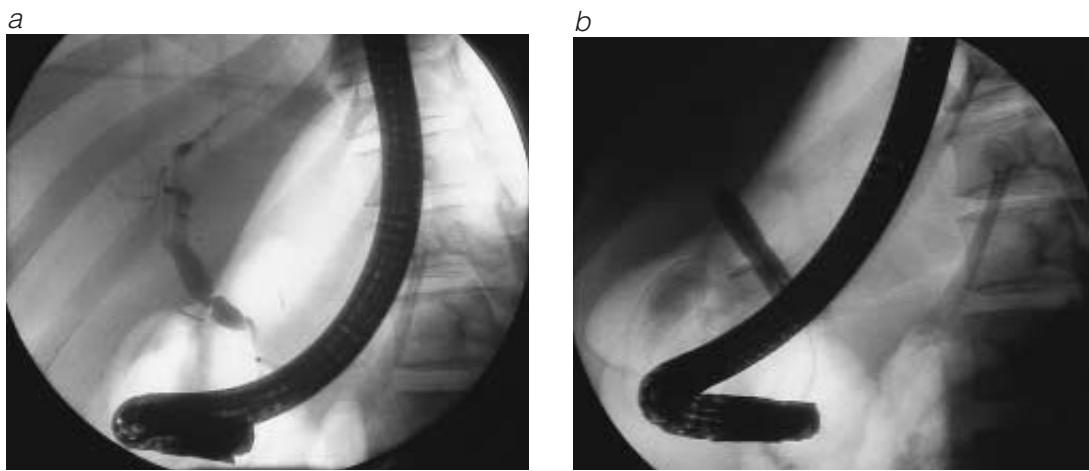

Figure 10 Therapeutic endoscopic retrograde cholangiopancreatography. CBD strictures (a), whether benign or malignant, may be dilated effectively with hydrostatic balloons under fluoroscopic guidance (b).

straightening and intubation of the colon. By applying torsion to the shaft frequently and pulling back the scope as necessary, one can pleat the colon on the instrument as it is advanced. Pulling back is one of the most useful techniques for advancing the colonoscope through the colon.

The colon exhibits a number of characteristic anatomic features that are readily observed during colonoscopy. The sigmoid colon, because of its frequent turns, yields elliptical views of the lumen. The descending colon appears as a long, round tunnel with little haustration. The transverse colon has well-defined triangular folds, and the hepatic flexure may exhibit a blue hue resulting from the proximity of the liver. The cecum is recognized on the basis of the appearance of the ileocecal valve on the lateral wall, the convergence of the colonic taenia to form the cecal strap (the so-called Mercedes sign), and the presence of the appendiceal orifice.

Insertion of the colonoscope as far as the hepatic flexure is rarely difficult. Occasionally, the sigmoid colon presents a chal-

lenge, in which case placement of the patient on the back or the abdomen to change the orientation may be helpful. Once again, pulling back and straightening the scope is a highly useful maneuver. Once the scope is in the hepatic flexure looking down the right colon, pulling back, counterclockwise torsion, and the application of suction may all assist in advancing the instrument into the cecum. Changing the patient's position or applying pressure to various points in the abdomen may also be helpful. Once the cecum is reached, the instrument is slowly withdrawn while the colonic parietes are carefully examined. Biopsy and cytologic brushing may be done as appropriate, and colonic contents may be aspirated into a suction trap for examination.

COMPLICATIONS

Perforation is the most common complication of diagnostic colonoscopy. It may result from direct tip pressure, bowing of the shaft of the scope while a large loop is being formed, blowout of a diverticulum secondary to air insufflation, or tearing of an adhesion of the colon to an adjacent structure. The risk of perforation can be minimized by observing the lumen directly as the scope is advanced, avoiding excessive insufflation, and minimizing loop formation. Close attention to patient discomfort is important. If the patient feels poorly after the procedure, an upright chest x-ray, an upright abdominal x-ray, or a lateral decubitus abdominal x-ray should be obtained to determine whether there is any free air, which would indicate a perforation. Such situations have been successfully managed by nonoperative means in some cases, but in most cases, prompt operative intervention with primary repair of the perforation is the best approach.

Therapeutic Colonoscopy

By far the most common use of therapeutic colonoscopy is for the excision of polyps. Other applications include control of bleeding, dilation of strictures, and placement of enteral stents.

TECHNIQUE

The development of colonoscopic polypectomy—electrosurgical excision of the polyp with a wire snare—has rendered operative colotomy unnecessary in the management of colonic polyps. Pedunculated polyps are approached by placing the snare over the polyp's head and tightening the loop around the

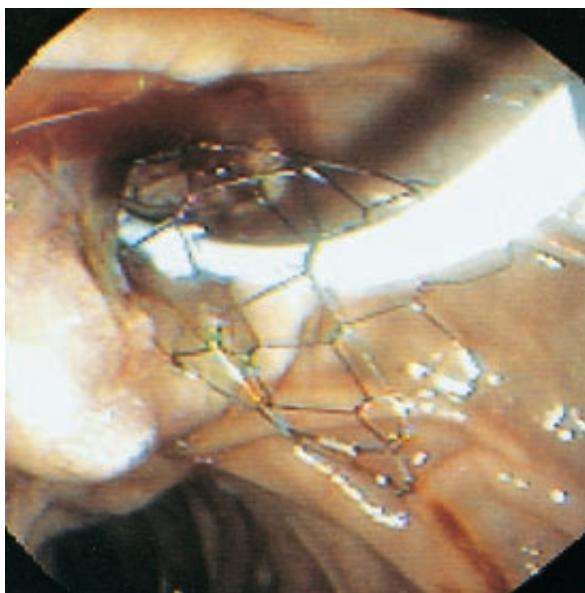

Figure 11 Therapeutic endoscopic retrograde cholangiopancreatography. Self-expanding metal stents may provide effective long-term palliation of malignant biliary obstruction.

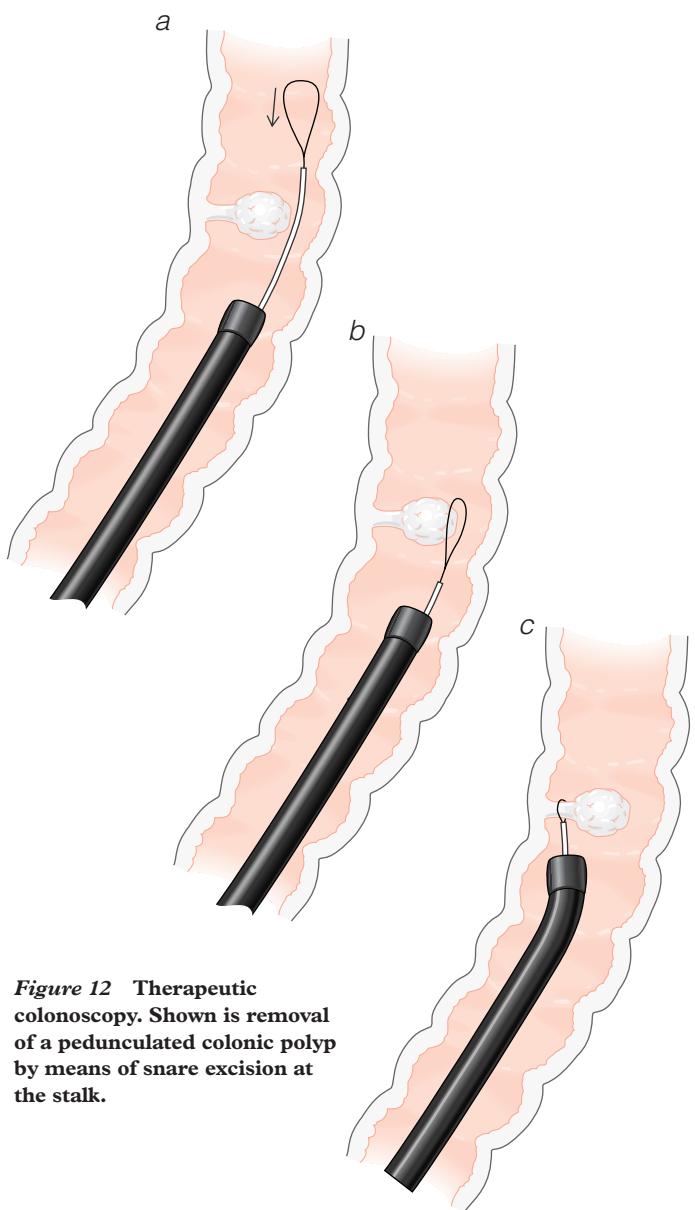

Figure 12 Therapeutic colonoscopy. Shown is removal of a pedunculated colonic polyp by means of snare excision at the stalk.

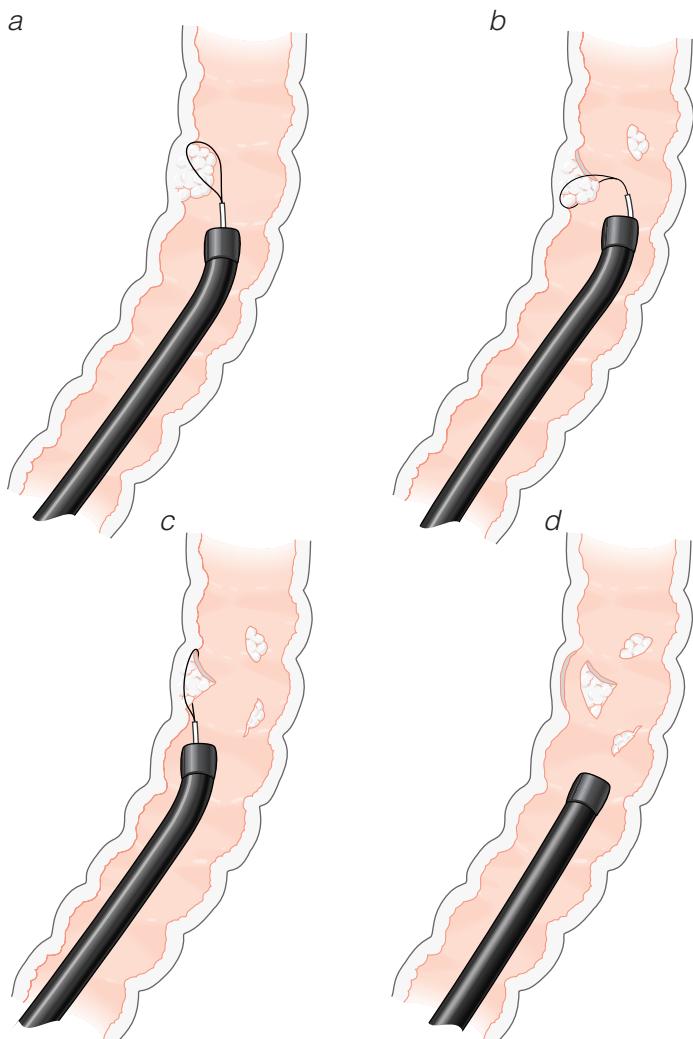

Figure 13 Therapeutic colonoscopy. Illustrated is piecemeal excision of a sessile colonic polyp.

stalk near the junction of the head and the stalk [see *Figure 12*]. Because the stalk is an extension of normal mucosa, it is unnecessary—and often unwise—to excise the stalk close to the colonic wall; excision near the head of the polyp is usually sufficient. Short bursts of coagulating current are applied to transect the stalk. During excision, the polyps must be moved around to prevent conduction burns to the opposing colonic wall. Once transection is complete, if the polyp is small, it may be suctioned into a trap; if it is large, it may be suctioned onto the tip of the scope and retrieved or captured in a snare or basket. Sessile polyps are more challenging and risky to excise. Accordingly, it is often preferable to excise such polyps in a piecemeal fashion [see *Figure 13*]. The snare is applied several times to successive portions of the polyp until it is excised down to the colonic wall. The excised fragments are then retrieved. Difficult or large sessile polyps may be elevated before excision by injecting epinephrine solution or saline submucosally into the polyp or the surrounding tissue. This maneuver makes transmural injury less likely (see below).

Although the use of colonoscopy to define the site of colonic bleeding is commonplace, its use to treat such bleeding is not.

Figure 14 Therapeutic colonoscopy. Shown is an angiodysplasia of the right colon, a frequent cause of lower GI hemorrhage.

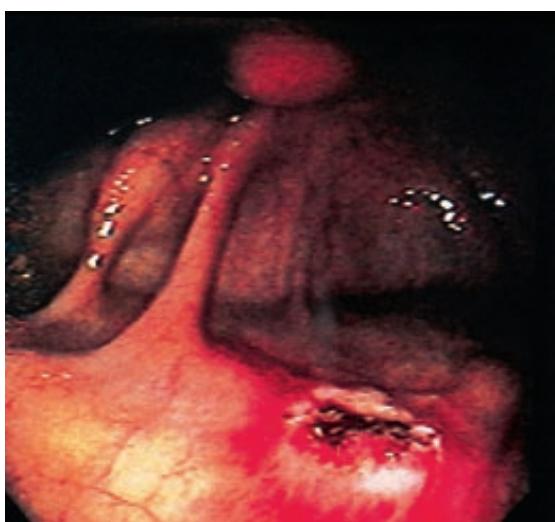

Figure 15 Therapeutic colonoscopy. Shown is a right colonic angiodysplasia after treatment with bipolar electrocoagulation.

Diverticular bleeding often stops when colonoscopy is done, and only in rare instances is the actual bleeding diverticulum seen. In such cases, injection of epinephrine solution around the mouth of the offending diverticulum is often effective. Angiodysplasias are frequently found in the right colon, though they are rarely identified while they are bleeding [see Figure 14]. They may be treated with a variety of modalities, including bipolar electrocoagulation, injection of a sclerosant solution, and laser therapy [see Figure 15]. Currently, the argon plasma coagulator is often employed for obliteration of these lesions. This device has the advantage of being able to obliterate angiodysplasias with minimal wall penetration, thereby increasing the safety of this intervention in the thin-walled right colon.

Strictures may occur in the colon, as in the rest of the GI tract. Colonic strictures usually develop at an anastomosis, though they may also be the result of ischemia. Hydrostatic balloon dilation is very effective in treating such strictures. The balloon is introduced through the lumen of the endoscope, and dilation is carried out under direct vision, often in conjunction with fluoroscopic observation to confirm that dilation is complete. In patients with fully or almost fully obstructing tumors of the colon, self-expanding metal stents may be placed to provide decompression and at least temporary relief of obstruction. This step may avert emergency surgery or, if the tumor is inoperable, provide palliation.

COMPLICATIONS

Perforation may occur as a result of transmural thermal injury during polypectomy. Some perforations are immediately apparent, but others may not be noticed for several days. When perforation is documented, surgical exploration is indicated. Occasionally, a patient may present with fever and abdominal tenderness several days after polypectomy but show no free air on abdominal films. Such a patient may have a thermal injury to the bowel wall or so-called postpolypectomy syndrome and can usually be treated with intravenous fluids, antibiotics, and observation. Bleeding from the stalk of a pedunculated polyp may occur after excision; it may present immediately or may be delayed until the coagulum on the stalk separates 3 to 5 days after polypectomy. Such bleeding is a rare occurrence. When it does occur, it can be treated by injecting epinephrine solution (1:10,000) into the stalk.

Chromoendoscopy

The development of extirpative endoscopy has allowed physicians to treat several conditions that previously required open or laparoscopic surgical procedures. However, it is not always possible to see the difference between diseased and healthy tissue on endoscopy, and this limitation has precluded one-stage procedures. Identification of tissue types required biopsy, and lesion margins were impossible to determine at the time of the procedure.

Chromoendoscopy can help to identify diseased tissue and define lesion borders. This process is essentially an *in vivo* staining technique in which a variety of specialized stains are applied to tissues to improve their characterization. It differs from carbon-dye injection (tattooing), a technique that is used for later surgical identification, in that the stains used for chromoendoscopy are specific to the anatomic area being examined. Several chromoendoscopic dyes are commercially available in the United States [see Table 1]. Selection of a particular agent is based on the type of tissue being studied, the disease state, and physician familiarity.

One of the first agents used for chromoendoscopy was methylene blue. It was initially used in Japan in the 1970s to detect intestinal metaplasia in the stomach. Subsequent studies in the United States, Japan, and Europe independently demonstrated that methylene blue will selectively stain metaplasia in Barrett's esophagus (see above). On routine screening endoscopy in patients with Barrett's esophagus, methylene blue chromoendoscopy offers improved detection of dysplasia and early malignancy compared with four-quadrant random biopsy studies. Other reported applications include esophageal carcinoma, gastric metaplasia, oropharyngeal cancer, mucosal lesions, and heterotopic gastric mucosa.

Endoscopic Mucosal Resection

Endoscopic polypectomy marked the beginning of extirpative procedures. Subsequently, endoscopic resection techniques have continued to advance, as a result of improvements in imaging and instrumentation, along with the development of chromoendoscopy and specific techniques designed as adjuncts to tissue removal. One such technique is endoscopic mucosal resection (EMR).

EMR has its basis in the anatomy of the GI tract. Histologically, the GI tract has three layers: a superficial mucosal, a middle submucosal, and an outer muscular layer. EMR is designed to help the endoscopist remove superficial mucosal tissue while leaving the deeper submucosal and muscular layers intact. These layers can be relatively easily separated from each other by injecting a liquid that spreads within the plane of injection. This step elevates the layers superficial to the injection, thus facilitating the resection of those layers. Advantages over other resection techniques include the preservation of histologic architecture (in contrast to electrocautery or laser ablation), which allows improved pathologic assessment; the ease with which EMR can be combined with endoscopic ultrasonography; and its safety and minimal invasiveness.

EMR was first described in 1955, when submucosal saline injections through a rigid sigmoidoscope were used in the resection of rectal and sigmoid polyps. In 1973, a submucosal saline injection was employed to assist with the removal of sessile polyps throughout the colon. Additional development was accomplished in Japan in 1983, when mucosal resection was used in the treatment of early gastric carcinoma in a technique termed strip-off biopsy. The technique has been refined and is now routinely used for lesions in the esophagus, stomach, duodenum, colon, and rec-

tum. It is widely incorporated into aggressive screening programs designed to detect early GI cancers.

EMR can be used to treat dysplastic and other premalignant lesions, as well as superficial cancers of the GI tract. One must be careful to comply with all standard principles of cancer resection, including knowledge of the depth of the lesion, its radial extent, and staging. Consequently, several criteria must be fulfilled before EMR can be viewed as a curative intervention. Classification of lesions on the basis of their endoscopic appearance can be combined with information obtained through the use of chromoendoscopy and EUS to determine the potential for EMR.

Lesion location within the GI tract is important with respect to long-term outcomes. For example, EMR can be used to treat circumferential colonic lesions but is inappropriate for esophageal lesions that extend beyond one third of the circumference, because of the risk of a late stricture.

Although specific methods differ among practitioners, several generalizations about the technical aspects can be made. First, a liquid must be injected deep to the mucosal layer, allowing separation of the wall components. Although the ideal solution for injection has not been determined, the liquid chosen must be biodegradable, biocompatible, noninflammatory, and have viscoelastic properties allowing the development of an adequate bleb. Saline, hypertonic saline, epinephrine, hyaluronic acid, and glycerol solutions are all in current use. The elevated tissue is then held in place with a grasper or suction mechanism, and snares, needle knives, or lasers are used to cut the tissue at its base. Optimal results are obtained on nonulcerated lesions that are less than 2 cm after elevation; other lesions have a high probability of submucosal lymphatic and vascular invasion.

Although complications can occur, with proper patient selection and procedural refinement they are relatively rare. Perforation has been noted, particularly when submucosal bleb formation is suboptimal. Inadequate blebs may result from insufficient liquid being injected, improper needle depth, or severe scarring of the local tissues. Bleeding has been reported to occur in 1.6% of EMR cases. This complication is relatively easily handled with a combination of electrocautery and epinephrine injection. Infection in the absence of perforation is uncommon.

Overall, EMR provides a minimally invasive means to treat early cancers in favorable locations. Patients must understand that additional resection may be required if histopathologic assessment does not show curative margins. Future development of endoscopic instruments and injection liquids will likely broaden the applicability of the procedure.

Endoscopic Ultrasonography

The 1980s saw the introduction of EUS. Extracavitary ultrasonographic methods have been hampered by the presence of air within the GI tract, which precludes high-resolution imaging. Consequently, they had been relegated to gross estimates of disease and detection of displacement of other tissues or fluid accumulation proximal to stenoses, such as ductal dilation in patients with common bile duct stones.

Three advances have proved invaluable in allowing EUS to carve out a niche in the field of GI diagnosis. First is the improvement in endoscopes that allows transducer and receiver channels to traverse a tortuous path. Second is the development of multiple frequency options in conjunction with circumferential visualization. Higher frequencies provide higher resolutions, allowing useful differentiation of the various layers of the intestinal tract. Third is the evolution of treatment protocols keyed to the accu-

Table 1 Special Stains Used in Endoscopy

Stain	Site of Use	Comment
Lugol solution (2% iodine)	Esophagus	Normal mucosa stains green-brown (as a result of intracellular glycogen); dysplastic cells do not stain
Indigo carmine (0.4% solution)	Stomach, colon	Enhances contour of mucosa, giving tissue a three-dimensional appearance
Toluidine blue	Oropharynx, esophagus	Absorbed by the nucleic acid component of malignant epithelial cells
Congo red	Acid-secreting areas of gastric mucosa	Turns a blue-black color when pH < 3
Methylene blue (0.5% solution)	Intestinal metaplasia, Barrett's esophagus	Absorbed only by dysplastic tissue; however, absorption decreases as severe dysplasia develops

rate staging of tumors—information that is sometimes unobtainable from other imaging techniques.

This technology has now been firmly established as an accurate way to identify carcinoma. Subsequent developments are allowing EUS to expand from the field of diagnosis into the realm of intervention. Examples of EUS-guided procedures include fine-needle aspiration, lymph node sampling, and drainage of pancreatic pseudocysts.

EUS devices come in both linear and radial transducers. Radial transducers have the advantage of providing circumferential visualization that parallels the standard modes of perceiving the GI tract. Linear images allow EUS-directed biopsies and have the potential to provide color and pulsed Doppler imaging. Probes can be mounted on the top of an oblique viewing fiberoptic scope, or come in an over-the-wire format for use in the pancreaticobiliary tree. A series of frequencies is available, with the higher frequencies providing greater resolution but less tissue depth penetration. Lower-frequency probes allow deeper tissue assessment and a broader view, but at the price of reduced resolution. Nevertheless, any form of EUS will provide better resolution than transcutaneous ultrasonography, allowing markedly improved two-point discrimination and hence more accurate tissue diagnosis.

The benefits of accurate staging of GI tumors paved the way for EUS development. Tissue sampling techniques are further benefited by this technology. The sensitivity of EUS makes it one of the best modalities for the evaluation and detection of pancreatic tumors. Its sensitivity, which is in excess of 95%, contrasts favorably with those of other modalities, including ultrasonography (75%), computed tomography (80%), and angiography (89%). The accuracy of T staging by EUS in esophageal cancer (80% to 90%) is greater than that of staging determined by CT scanning (50% to 60%). This finding has led to the development of several staging schemes that are based solely on EUS findings. EUS has established a role in the identification of early pancreatitis; the detection of common bile duct stones and mediastinal masses; and the assessment of anastomotic strictures, thickened gastric folds, and the integrity of the anal sphincter. It has also

proved a useful adjunct in the determination of whether a tumor is amenable to EMR techniques or is better served by adjuvant therapies or surgical interventions.

The sensitivity of EUS is rooted in its ability to delineate the various layers of the alimentary canal. Experienced endoscopists can easily evaluate the submucosa and differentiate intramural from extrinsic masses. Characteristic patterns are readily learned and rapidly recognized, obviating tissue diagnoses in straightforward cases. Criteria have also been established to aid in the differentiation of benign and malignant lesions. With the continued use of this technique, additional algorithms will be established in conjunction with more innovative interventional adjuncts. However, two limitations have caused many practitioners to remain skeptical: cost and training issues. Other imaging modalities, such as CT and magnetic resonance imaging, have also made tremendous strides in the recent past. Although these various modalities are often considered competitors—a view arising from the perceived need for a single imaging modality—the issue of which is superior to the others pales in comparison to the benefits that can be gained from combining imaging techniques in appropriate circumstances.

Endoscopic Suturing

The ability to suture through an endoscope would open up an entire arena of new possibilities, including antireflux procedures, morbid obesity surgery, and advances in the control of acute hemorrhage, as well as improved ability to manage com-

plications of other endoscopic techniques. Despite the development and commercial availability of numerous devices, however, design problems have relegated most applications to investigational status. For such devices to enter clinical practice, they must encompass fundamental surgical techniques: the ability to cut, suture, tie knots, and staple. These are critical for maintaining hemostasis and constructing durable anastomoses. Although these techniques are plausible with modern devices, continued innovation and experience in conjunction with a new paradigm of disease management will direct the future of endoscopic interventions.

Natural Orifice Transvisceral Endoscopic Surgery

A new area of endoscopic exploration is emerging—namely, the performance of intraperitoneal surgical procedures by means of a flexible endoscope passed through the wall of a gastrointestinal viscus. This approach, referred to as natural orifice transvisceral endoscopic surgery (NOTES), is still investigational, but it has generated a great deal of excitement in the surgical and gastroenterologic communities. Transgastric gastrojejunostomy, liver biopsy, tubal ligation, and splenectomy in a porcine model have been reported. In addition, there have been anecdotal reports and presentations of natural orifice transvisceral appendectomy in human beings in India; however, to date, there have been no published cases. Extensive laboratory investigation and clinical trials will have to be carried out before the true utility and safety of NOTES can be established.

19 BARIATRIC PROCEDURES

Eric J. DeMaria, M.D., F.A.C.S.

It is clear that severe obesity is associated with a significant increase in morbidity¹ and a decreased life expectancy.² Morbid obesity has been shown to have a significant genetic basis.^{3,4} To date, attempts to manage morbid obesity with medical weight reduction programs have met with an unacceptably high incidence of recidivism.⁵ The approach that has had the greatest and longest-lasting success in achieving weight loss is bariatric surgery.

Operative Planning

CHOICE OF SURGICAL PROCEDURE

The gastric operations performed for morbid obesity include gastric bypass (GBP) procedures and gastric restrictive procedures (i.e., gastroplasty and gastric banding). Randomized, prospective trials have conclusively shown that GBP is as effective for weight control as the malabsorptive jejunoileal (JI) bypass is, while resulting in significantly fewer complications.^{6,7} JI bypass is associated with a substantial incidence of both early complications (e.g., acute cirrhosis, electrolyte imbalance, and fulminant diarrhea)⁸ and late complications (e.g., cirrhosis, interstitial nephritis, arthritis, enteritis, nephrocalcinosis, and recurrent oxalate renal stones).⁹ If evidence of cirrhosis, renal failure secondary to interstitial nephritis, or other complications mandates reversal of a JI bypass, the patient, if not extremely ill, should be converted to a GBP; otherwise, all the lost weight is sure to be regained, and the obesity-related comorbidity will return. Admittedly, however, many patients have done well after JI bypass and do not need to have the operation reversed.

Several randomized, prospective trials have found that horizontal gastroplasty yields poorer results than GBP.¹⁰⁻¹² Failure of horizontal gastroplasty has generally been attributed to technical causes, such as enlargement of the proximal pouch or the stoma or disruption of the staple line. Vertical banded gastroplasty (VBG) was developed in the hope that it would solve these technical problems and yield weight loss comparable to that seen after GBP without incurring the significant risk of iron, calcium, and vitamin B₁₂ deficiencies associated with GBP. In the 1990s, a procedure known as adjustable silicone gastric banding was developed, which involved placement of a restrictive ring around the proximal stomach to create a small gastric pouch. In this restrictive procedure, which can be done laparoscopically in the vast majority of patients, weight loss can be enhanced and vomiting minimized by adjusting the ring diameter via transcutaneous access to the subcutaneous reservoir.

Although VBG and, presumably, other restrictive procedures appear to be excellent from a technical point of view,¹³ multiple randomized, prospective trials have found such approaches to be significantly less effective than standard GBP. In one comparison trial, patients addicted to sweets lost much more weight after GBP than after VBG because they experienced symptoms of dumping syndrome when ingesting sweets.¹⁴ The failure rate was high after

VBG because these patients experienced no difficulties when eating candy or drinking nondietetic sodas. Subsequent randomized, prospective trials confirmed the superiority of GBP.^{15,16} Furthermore, maintenance of successful weight loss after GBP appears to continue for as long as 14 years after operation: in the average patient, weight loss amounts to about two thirds of excess weight at 1 to 3 years after operation, three fifths at 5 years, and more than half in years 5 through 10.^{17,18} It has been suggested that standard, or proximal, GBP will fail in 10% to 15% of patients because these patients will frequently nibble on high-fat snacks (e.g., corn chips, potato chips, and buttered popcorn). Such patients may have to be converted to a combined restrictive and malabsorptive procedure, such as partial biliopancreatic bypass (BPB).¹⁹

The original BPB involves hemigastrectomy and anastomosis of the distal 250 cm of intestine to the stomach; the bypassed small intestine is reanastomosed to the ileum 50 cm from the ileocecal valve. BPB with duodenal switch is a variant of the original procedure in which a linear gastric tube based on the lesser curvature is created (sleeve gastrectomy), with the pylorus left intact, and an ileal Roux limb is brought up for anastomosis to the proximal duodenum. BPB has been associated with a high incidence of deficiencies of fat-soluble vitamins, hypocalcemia-induced osteoporosis, and protein-calorie malnutrition.²⁰ These nutritional deficiencies may be more common in the United States, where fat intake is high, than in many other countries. In Italy, for example, starch intake (as in pasta) probably outstrips fat intake; still, a number of Italian patients have had to be readmitted for parenteral nutrition and extension of the common absorptive intestinal tract because of refractory malnutrition. In some patients, it might be possible to convert a failed proximal GBP into a modified BPB with a 150 cm absorptive ileal limb (a procedure often referred to as distal gastric bypass); however, these patients also must be monitored carefully for deficiencies of fat-soluble vitamins, for osteoporosis, and for malnutrition.

Superobese patients, defined as those whose weight is 225% of ideal body weight or greater or whose body mass index (BMI) is 50 kg/m² or higher, will lose, on average, only about half of their excess weight, rather than two thirds, after standard GBP. In these patients, a 150 cm proximal Roux-en-Y procedure (so-called long-limb GBP [see Proximal Gastric Bypass, Operative Technique, below]) may increase weight loss in the first few years after operation without causing an increase in nutritional complications.²¹

In choosing the appropriate surgical approach, it is important to take into account the tremendous surgical revolution that laparoscopy has brought about in the treatment of morbid obesity. Every operation performed to treat obesity can now be done laparoscopically, and laparoscopic bariatric surgery is now common in many centers. For this reason, as well as because laparoscopic obesity treatment requires advanced technical skills, minimally invasive bariatric procedures have become a cornerstone of training for surgeons now learning laparoscopic surgery.

PREPARATION FOR OPERATION

Many surgeons, exercising good clinical judgment and fearing increased perioperative morbidity and mortality, hesitate to operate on morbidly obese patients for routine elective problems. Complications do occur more often in this population than in the nonobese population, and even the simplest surgical treatment involves a measurable risk of morbidity and even mortality. Given that morbidly obese patients are at greater risk for complications and adverse results, it is all the more remarkable that they can undergo major abdominal surgery for weight loss with the low complication rates and mortalities reported in the literature. These results, however, can only be achieved if a comprehensive program for preoperative and postoperative surgical care is rigorously planned and followed. The key elements of preparation for operation in the morbidly obese patient are discussed in greater detail elsewhere [see 5:7 *Morbid Obesity*].

Vertical Banded Gastroplasty

OPERATIVE TECHNIQUE

The first step in VBG is to make a circular stapled opening in the stomach 5 cm from the esophagogastric junction. A 90 mm bariatric stapler with four parallel rows of staples is then applied once between this opening and the angle of His. (At this point, according to Mason, the originator of the procedure, the volume of the pouch should be measured by means of an Ewald tube placed by the anesthetist; ideally, pouch volume should be 15 ml.)

Next, a strip of polypropylene mesh is wrapped around the gastrogastric outlet on the lesser curvature and sutured to itself—but not to the stomach—in such a way as to create an outlet with a circumference of 5 cm for the small upper gastric pouch [see Figure 1a]. Some surgeons have used a stoma outlet 4.5 cm in circumference, but this smaller outlet has not led to better weight loss; in fact, many patients with the 4.5 cm outlet exhibit maladaptive eating behavior, drinking high-calorie liquids because meat tends to get caught in the small stoma.

Silastic ring gastroplasty [see Figure 1b] is a variant of VBG that uses a vertical staple line and a stoma reinforced with Silastic tubing.

COMPLICATIONS

Complications of VBG include erosion of the polypropylene mesh used to restrict the gastroplasty stoma into the gastric lumen, enlargement of the pouch, stomal stenosis, reflux esophagitis, and mild vitamin deficiencies.²² To date, mesh erosion has been infrequently observed after VBG. Pouch enlargement is fairly common with horizontal gastroplasty but is much less likely to occur with VBG, in which the vertical staple line is placed in the thicker, more muscular part of the stomach. In addition, stomal diameter remains fixed with the mesh band. If mesh erosion, pouch enlargement, stomal stenosis, disabling GI reflux, or recurrent vomiting occurs, it is probably best to convert the patient to GBP. In particular, patients with a Silastic ring VBG may exhibit intractable vomiting of solid foods with no evidence of mechanical obstruction. In our experience, conversion of these patients to GBP yields good results and eliminates the vomiting problem. Finally, vitamin deficiencies can usually be prevented by having VBG patients take a standard multivitamin daily for life.

Laparoscopic Adjustable Gastric Banding

Gastric banding is another form of gastroplasty, in which a synthetic band is placed around the stomach just below the esophagogastric junction. In several series, gastric banding has yielded markedly variable results with respect to achievement of weight loss. Furthermore, it has been associated with slipping or kinking of the banded stoma, obstruction at the band, and intractable vomiting.

Laparoscopic adjustable gastric banding is potentially a significant advance over open gastric banding procedures, primarily because of the adjustability of the band. Open gastric banding procedures have used a variety of materials to constrict the gastric lumen and carry a recognized risk of postoperative nausea and vomiting that do not respond to any treatment short of reoperation. The adjustable gastric band (BioEnterics, Carpinteria, California) used in the laparoscopic procedure [see Figure 2] is a silicone device with an inflatable reservoir that can be inflated or deflated postoperatively through a subcutaneous port placed deep in the abdominal wall for percutaneous access. Saline is injected

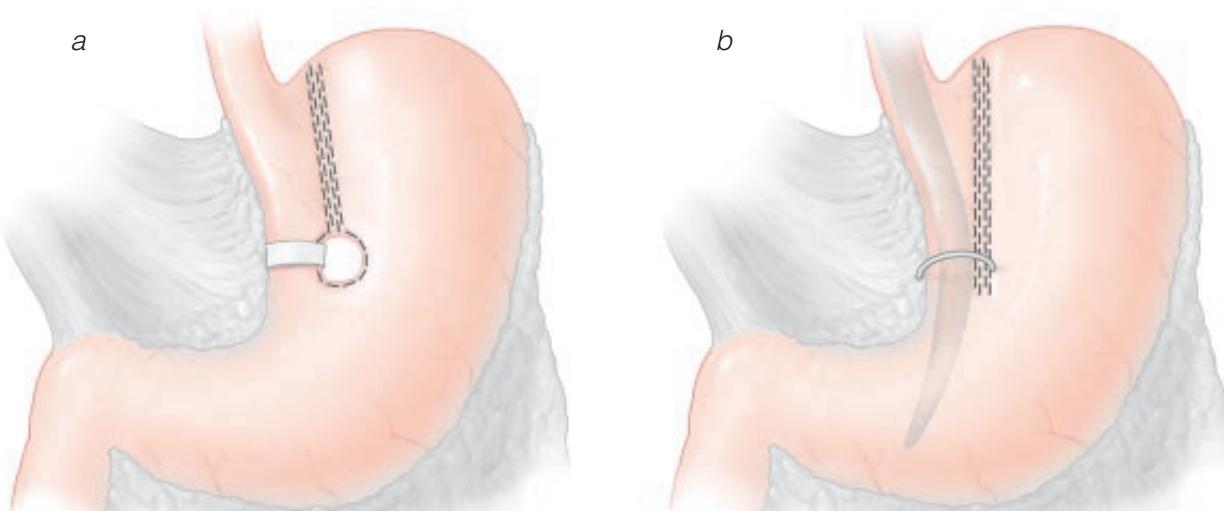

Figure 1 Vertical banded gastroplasty. Depicted are (a) standard VBG and (b) Silastic ring gastroplasty, a variant of VBG in which the stoma is reinforced with a Silastic tube.

Figure 2 Laparoscopic adjustable gastric banding. Shown is the adjustable gastric banding device used in the procedure.

into or withdrawn from the reservoir to adjust gastric luminal diameter, as measured by barium contrast evaluations. Thus, if intractable vomiting develops, saline can be removed from the band to alleviate the problem; similarly, if the patient fails to lose weight after operation, additional saline may be injected into the band to narrow the gastric lumen further.

In June 2001, use of the laparoscopically placed adjustable gastric band was approved by the Food and Drug Administration. Key data on safety and effectiveness were provided by a prospective, single-arm trial involving 299 patients at eight centers in the United States. In this study, patients who completed 36 months of follow-up achieved a mean reduction in BMI of 39% and a mean overall loss of 18% of baseline body weight. However, 28% of patients lost less than 10% of their initial body weight (a clear definition of weight-loss failure). More than half (62%) of these patients lost more than 25% of their excess weight. Most patients (76%) experienced at least one adverse event, and 33% of patients required removal of the banding system.

OPERATIVE TECHNIQUE

Laparoscopic adjustable gastric banding is performed by using a six-port technique. Initial abdominal access is obtained via a supraumbilical trocar, and the remaining five ports are placed sequentially along the right and left costal margins. The liver is retracted via the right lateral port, and the proximal stomach is visualized via a laparoscope inserted through the umbilical port. A 20 ml balloon catheter is sometimes placed perorally into the proximal stomach to define an appropriately small pouch size.

Subsequent steps are done according to the pars flaccida technique. A retrogastric tunnel for band insertion is created at the posterior confluence of the diaphragmatic crura in a plane of dissection that is easily developed with minimal blunt dissection and electrocauterization. This tunnel is placed above the posterior peritoneal reflection, so that the free space of the lesser sac posterior to the stomach is not entered. Additional dissection is then carried out laterally at the angle of His to open the peritoneum and start clearing a plane behind the proximal stomach.

Once the plane is completely cleared from the lesser curvature to the angle of His, a specially designed implement is inserted behind the stomach and used to grasp the tubing of the banding device and pull it around the stomach. The banding device is then locked into place at the chosen location on the stomach [see Figure 3]. The band tubing is brought through the left midclavicular trocar port, which is placed via the left midclavicular line subcostal trocar incision and fixed to the abdominal wall fascia with sutures. The tubing is connected to the reservoir, which is filled with saline.

TROUBLESHOOTING

It is essential to place the band properly during the initial procedure. Early results suggest that the proximal pouch must be very small to optimize weight loss. In addition, proper placement minimizes—though it does not eliminate—the risk of band slippage and the complications thereof.

Several techniques have been suggested for posterior fixation of the band, but they are more difficult than anterior fixation techniques. With the pars flaccida technique, posterior fixation of the band is not usually necessary to prevent band slippage. Anterior fixation, however, is routinely performed, with interrupted sutures of nonabsorbable material placed between the distal and the proximal stomach to allow tissue to be apposed over the band and held in place.

Although laparoscopic adjustable gastric banding appears easier than many of the procedures done to treat obesity, there is a definite learning curve. A number of surgical misadventures have been reported, including gastric perforation, splenic injury, and malposition of the band.

COMPLICATIONS

Band slippage (usually posterior rather than anterior) may occur even after proper placement, resulting in intolerance of oral intake and vomiting. Such complaints are an indication for an upper GI series, which usually reveals dilatation of the proximal pouch and rotation of the band [see Figure 4]. Initial treatment consists of evacuating all saline from the band. Frequently, however, the proximal pouch does not return to its normal size, and symptoms recur or fail to resolve. Laparoscopic or open revision of the banding procedure is then required; if the patient also has not lost a sufficient amount of weight, conversion to GBP may be recommended. It is noteworthy that band erosion into the stom-

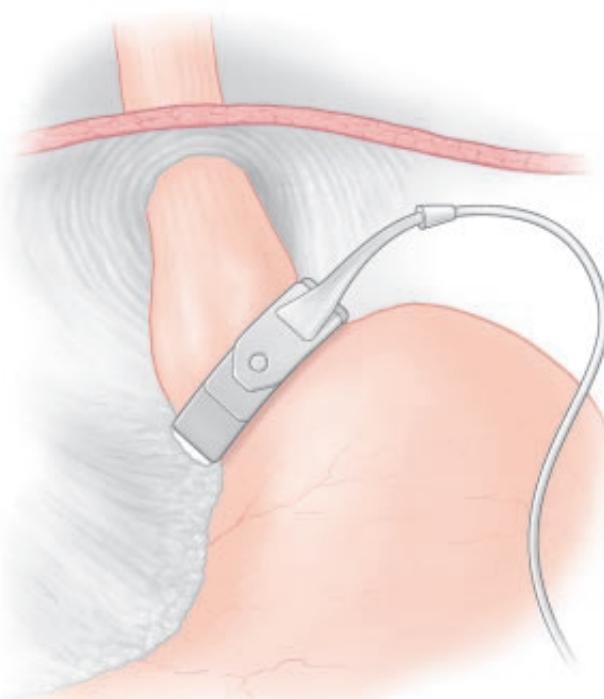

Figure 3 Laparoscopic adjustable gastric banding. Once in the correct position on the proximal stomach, the adjustable band is locked into place.

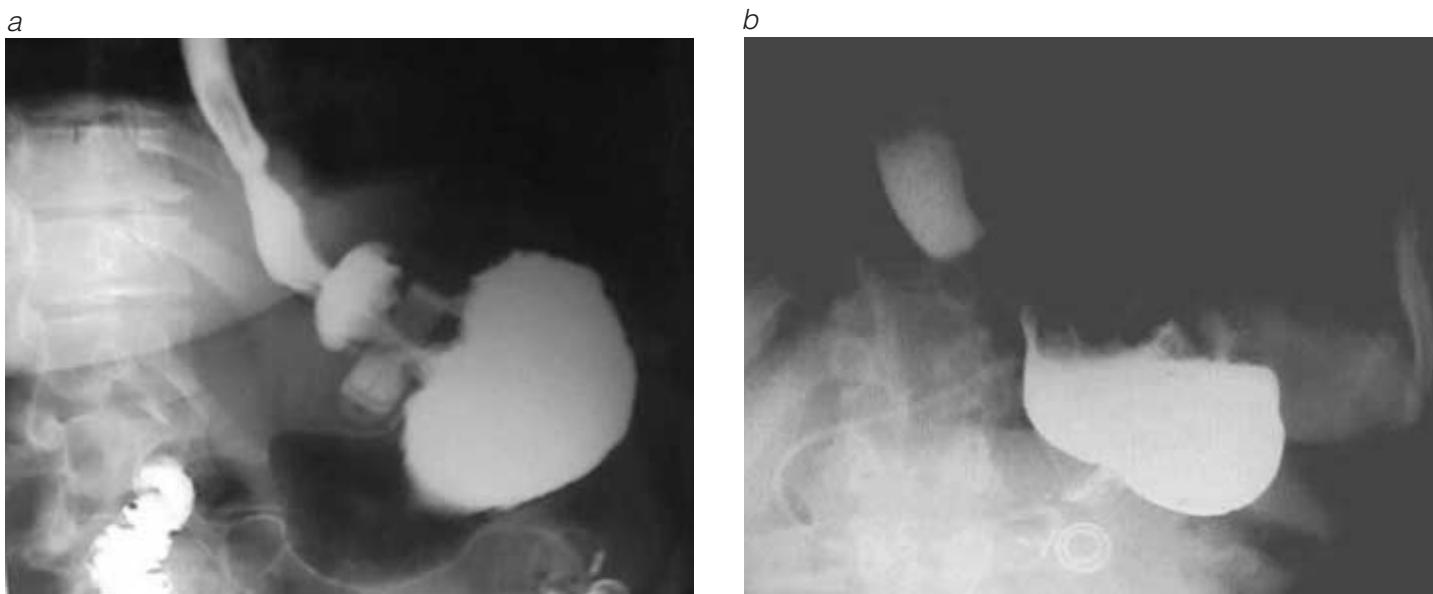

Figure 4 Laparoscopic adjustable gastric banding. Contrast studies illustrate (a) a normally positioned laparoscopic adjustable gastric band and (b) a slipped band.

ach, a not infrequent complication of the use of mesh in VBG or in the Angelchik prosthesis for gastroesophageal reflux treatment, has not been frequently reported. Longer follow-up will be necessary to evaluate the true extent of this risk.

As after any form of gastroplasty, the patient may fail to lose weight or may regain lost weight. Inappropriate eating behaviors (e.g., intake of high-calorie sweets) are the most likely cause. If obesity-related comorbid conditions persist, conversion to proximal GBP is appropriate.

OUTCOME EVALUATION

How successful laparoscopic adjustable gastric banding is at achieving weight loss over the long term remains unclear. The adjustability and reversibility of the operation, as well as the decreased disability that results, make it attractive to both patients and physicians. The procedure appears to avoid some of the major postoperative complications associated with open GBP (e.g., incisional hernia, marginal ulcer, and stoma stenosis). Band slippage remains a major postoperative concern, however, though the incidence of slippage does appear to decrease as one's experience with the procedure increases. More significant, there appears to be a high frequency of failed weight loss—as high as 15% to 20% of all patients undergoing the procedure and possibly even higher. European and Australian data confirm that there is a significant failure rate but also suggest that the remaining patients achieve a degree of weight loss approaching that seen with proximal GBP. Whether these reports will withstand the scrutiny of long-term follow-up remains to be seen.

Now that the laparoscopic adjustable gastric band has received the approval of the FDA, this procedure may come to play an important role in the management of more and more morbidly obese patients in the United States.

Proximal Gastric Bypass

Proximal GBP results in greater weight loss than the gastric restrictive procedures (see above) and carries a lower incidence of weight regain; consequently, it should be considered the superior procedure. At our institution, the focus since the beginning of the

1990s has been on developing techniques for minimizing complications after laparoscopic proximal GBP. Any surgeon currently performing this procedure ought to be able to achieve a gastrojejunostomy leakage rate lower than 5%; many groups, in fact, report rates lower than 3%. In addition, other postoperative complications (e.g., acute dilatation of the excluded portion of the stomach) are usually preventable if strict attention is paid to mastering the technical aspects of the operation.

Compared with the version of GBP performed at our institu-

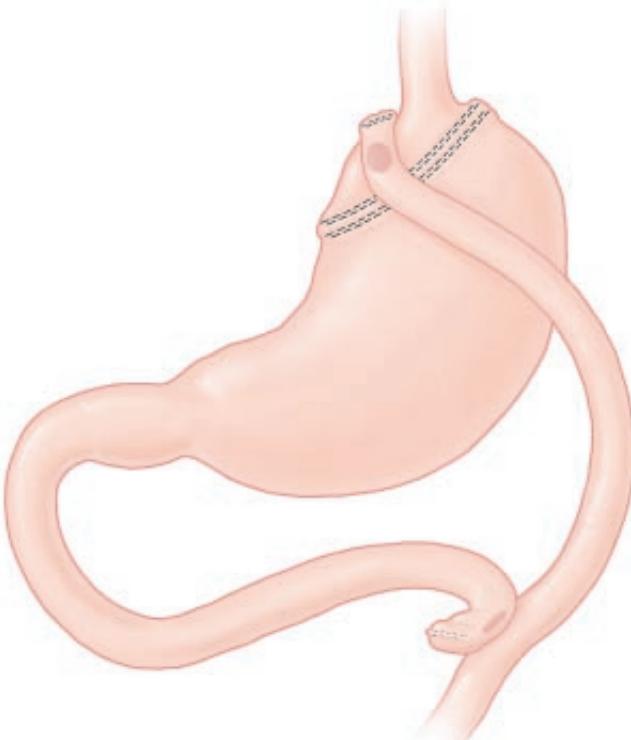

Figure 5 Proximal gastric bypass. Depicted is the completed procedure.

tion, the original GBP created a much larger proximal gastric pouch and a much wider anastomotic opening, and it was often associated with inadequate weight loss. In the later version, three superimposed 55 or 90 mm staple lines are placed across the proximal stomach in such a way as to create a gastric pouch no larger than 30 ml with a Roux limb at least 45 cm long and a stoma no larger than 1 cm [see *Figure 5*]. This anatomic situation is largely replicated when GBP is done laparoscopically, but an isolated gastric pouch is created with stapled transection of the stomach.

OPERATIVE TECHNIQUE

Step 1: Initial Incision and Abdominal Exploration

Once the patient is anesthetized, the abdomen receives a thorough, careful cleansing with povidone-iodine and is draped in a sterile fashion. An upper midline incision is made and extended through the fascia alongside the xiphoid process to facilitate cephalad exposure. The incision is routinely carried down to the supraumbilical area. The deep layer of subcutaneous fat can often be separated bluntly with aggressive lateral traction applied by the surgeon and the assistant, and the midline usually can then be identified for fascial incision. The electrocautery is used to enter the abdominal cavity, and a thick layer of subfascial preperitoneal fat is often encountered before entry into the peritoneal cavity. Abdominal exploration is undertaken in every patient, including examination of the liver for possible signs of liver disease. Other incidental findings may become apparent as well.

Troubleshooting Unexpected significant liver disease is occasionally discovered at the time of operation. If the patient has cirrhosis without portal hypertension, one should perhaps proceed with bypass if the patient's comorbid conditions make it mandatory; liver transplantation carries increased risk in morbidly obese patients. The gallbladder should be palpated for gallstones, which, if found, should be considered an indication for cholecystectomy at the time of the bypass procedure. If there are no visual or palpable gallbladder abnormalities, intraoperative ultrasonography may be used to examine the gallbladder, and cholecystectomy is performed if small stones, sludge, or polyps are identified.

It is not unusual to discover other previously unrecognized conditions during GBP, primarily because symptoms may not be obvious in morbidly obese patients and because their large size tends to make radiologic imaging difficult or even impossible. For example, intraoperative discovery of pelvic cysts and tumors is not uncommon in obese female patients. Such lesions may be excised during GBP; on occasion, if they appear benign and their location prevents safe excision, they may be managed with careful follow-up.

Step 2: Mobilization of Esophagus

The bypass procedure itself is begun by mobilizing the distal esophagus and encircling it with a soft rubber drain 0.5 in. in diameter. The gastrohepatic omentum is bluntly entered at a point overlying the caudate lobe, with care taken to look for and avoid injury to an aberrant left hepatic artery. The phrenoesophageal ligament overlying the anterior and lateral distal esophagus is sharply incised to facilitate subsequent blunt mobilization of the distal esophagus. To prevent esophageal injury, the nasogastric tube is carefully palpated within the lumen of the esophagus during mobilization, and blunt dissection proceeds widely around this important landmark. Laterally, dissection must be at the level of the esophagus or higher.

Troubleshooting If dissection is too low laterally, it may result in blunt injury to the short gastric vessels, bleeding, and the need for urgent splenectomy, which is no easy task in a morbidly obese patient. In addition, it may lead to creation of an inappropriately large pouch by keeping the surgeon from recognizing that some of the stomach is above the level at which the encircling rubber drain is placed.

Step 3: Division of Mesentery and Dissection around Stomach

Once the esophagus is mobilized, the assistant's left hand is placed through the gastrohepatic omental opening behind the stomach wall on the lesser curvature. The space between the first and second branches of the left gastric artery is then identified as a landmark for location of the gastric staple line, both to ensure that the pouch created is no larger than 30 ml and to prevent injury to the left gastric artery, which usually runs cephalad to this location. With the surgeon's posterior finger pressing anteriorly to place tension on the tissue, a fine-tip right-angle clamp and the electrocautery pencil are used to divide the mesentery carefully at this level immediately alongside the stomach wall so as to create a mesenteric opening that will admit a large right-angle clamp.

The avascular tissue on the posterior wall of the stomach is then bluntly dissected between the opening in the gastrohepatic omentum and the lateral angle of His, which is identified by the encircling rubber drain. The blunt tip of a large 28 French red rubber tube is placed behind the stomach in a medial-to-lateral direction along this dissected path to encircle the stomach [see *Figure 6*]. The open end of the red rubber tube is subsequently brought through the previously created mesenteric opening with a large right-angle clamp. The stomach is now ready for stapling, and the red rubber tube serves as a guide for introduction of the stapler. At this point, all intraluminal tubes and devices (e.g., the nasogastric tube and the esophageal stethoscope) are removed from the esophagus by the anesthetist.

Troubleshooting When a tube is inadvertently stapled within the stomach, excising it from the staple line can become a technical nightmare. To remove the stapled tube, it is usually necessary

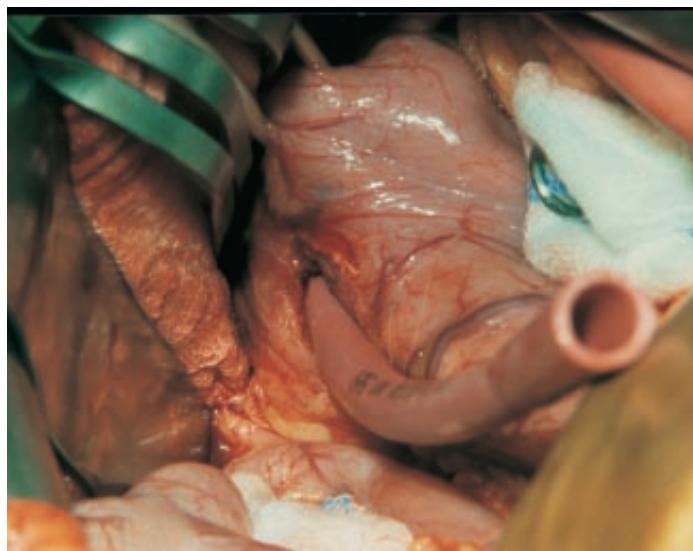

Figure 6 Proximal gastric bypass. After dissection of the avascular tissue on the posterior gastric wall, a red rubber catheter is passed through the resulting space to encircle the stomach.

to transect the stomach, thereby creating the potential for significant injury to the gastric tissue and possibly compromising the eventual anastomosis.

Step 4: Creation and Mobilization of Roux Limb and Jejunoojejunostomy

The ligament of Treitz is identified, and the jejunum is measured to a point 45 cm beyond the ligament, where the jejunum is divided with a stapler. An 8 to 12 cm segment of jejunum is resected at this point to create a larger mesenteric defect, which should facilitate mobilization of the limb to the proximal stomach. Mesenteric dissection is carried posteriorly in fat with the sequential application of clamps until further dissection appears either unnecessary for mobilization or unwise (i.e., likely to cause mesenteric vascular injury).

A side-to-side jejunoojejunostomy is then created with a 60 mm linear stapler either 45 cm beyond the initial point of jejunal division, for standard proximal GBP, or 150 cm downstream, for the long-limb modification of the procedure used in superobese patients [see Operative Planning, Choice of Surgical Procedure, above]. It is important not to narrow the efferent lumen at the jejunoojejunostomy site, particularly with the long-limb modification, in which the lumen at the distal end of the Roux limb may be quite small. The enterotomies made to allow placement of the stapler can usually be closed with a 55 mm stapler loaded with 3.5 mm staples; however, if stapling would cause undue narrowing of the lumen, the closures should be handsewn instead.

Troubleshooting It may be preferable to mobilize the Roux limb before committing to stapling the stomach so that it can be determined whether the limb can be extended to reach the proximal stomach without tension being placed on it. In those rare cases in which the mesentery is too foreshortened to permit the limb to reach the proximal stomach, it is advisable to change the procedure to VBG rather than create a gastrojejunal anastomosis under tension and thereby incur the increased risk of leakage.

Step 5: Gastric Stapling and Gastrojejunostomy

The Roux limb is brought through the mesentery of the transverse colon with blunt dissection and then brought up to the proximal stomach. The 55 or 90 mm stapler, loaded with 4.8 mm staples, is guided behind the stomach by inserting its open-mouthed end into the lumen of the previously positioned red rubber tube. Once it is determined that the staple line will reach completely across the stomach and that the stomach is not folded on itself, the stomach is stapled three times in such a way that the three staple lines are superimposed [see Figure 7].

A 1 cm anastomosis is created between the proximal stomach pouch and the Roux limb, with an outer layer composed of interrupted 3-0 silk sutures and an inner layer composed of a continuous absorbable 2-0 polyglycolic acid (Dexon) suture. When the posterior aspect of the anastomosis is complete, a 30 French dilator is placed with the patient under anesthesia and is guided through the anastomosis by the surgeon to ensure that the stoma has the appropriate diameter [see Figure 8]. The anterior aspect of the anastomosis is then completed.

Troubleshooting A significant concern for many bariatric surgeons has been a high incidence of staple line disruption causing failed weight loss or weight regain; in one series, the incidence of such disruption was 35%. To minimize this risk, some surgeons

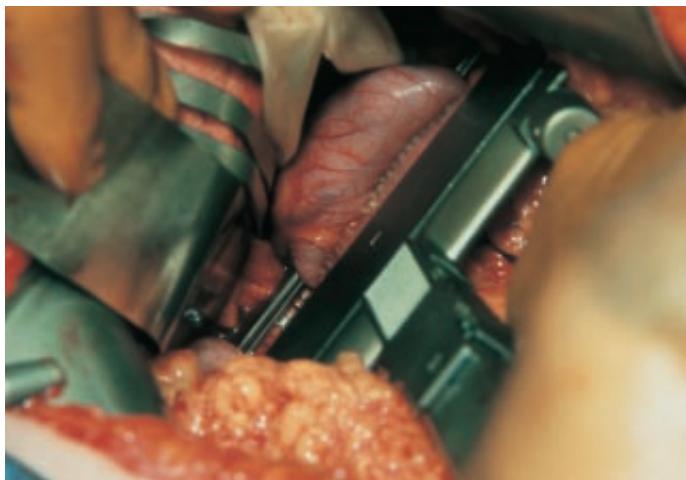

Figure 7 Proximal gastric bypass. The stomach is stapled to create the small proximal pouch. The stapler is fired three times to create three superimposed staple lines, thereby decreasing the risk of staple line disruption.

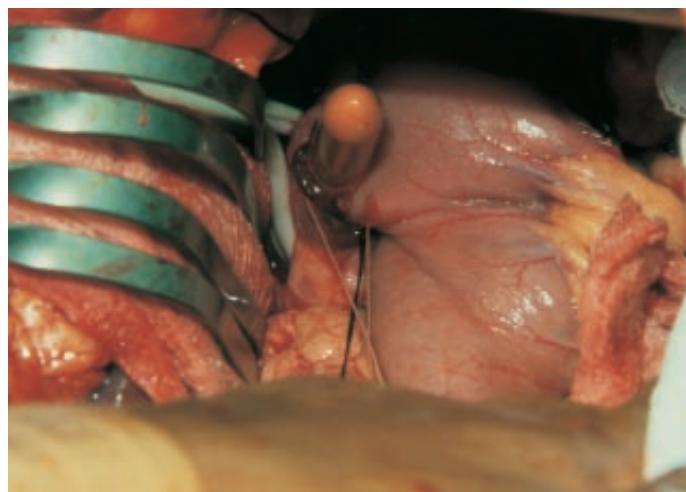

Figure 8 Proximal gastric bypass. When the posterior aspect of the gastrojejunostomy anastomosis has been completed, a 30 French dilator is placed through the stoma to confirm that the opening is correctly sized.

advocate transecting the stomach. This is done by inserting two parallel TA-90 staplers and cutting between them with a scalpel after the staplers are fired. Other surgeons, however, prefer to oversew the staple line. Using the technique of three superimposed staple lines has made it possible to reduce the incidence of staple line disruption to less than 2%; consequently, gastric transection is unnecessary on a routine basis (though occasionally useful in selected cases) and may increase the risk of the procedure.

Another advantage of gastric transection besides reduction of staple line disruption is that it allows the Roux limb to be brought up to the gastric pouch via a retrocolic and retrogastric tract, which is significantly shorter and places less tension on the limb. This approach is particularly helpful in severely obese patients with a fatty and foreshortened mesentery, in whom it is difficult to free the Roux limb sufficiently to reach the proximal stomach without tension. The possibility that gastric transection may prove helpful in a specific patient is another reason why it is advisable to delay stapling the stomach until the Roux limb is mobilized.

Step 6: Assessment of Anastomosis

When the entire anastomosis is complete, the dilator is removed and the tip of an 18 French nasogastric tube is advanced by the anesthetist and carefully guided through the anastomosis by the surgeon. The Roux limb is occluded with the assistant's left hand or with an atraumatic intestinal clamp, and the anesthetist injects a series of 10 ml aliquots of methylene blue dye through the nasogastric tube to determine whether the anastomosis is leaking. A total of 30 to 60 ml of methylene blue must usually be injected; lesser amounts will not stress the suture line enough to constitute an adequate test.

Troubleshooting When an intraoperative leak is identified, the area of leakage should be oversewn with silk sutures until injection of additional methylene blue dye via the nasogastric tube yields no further leakage. The most difficult area to repair is the posterior suture line, which is quite close to the gastric staple line. Posterior leaks are usually repaired by reinforcing the posterior suture line with additional sutures between the excluded stomach and the jejunal limb; often, the entire posterior suture line is oversewn. In addition, a viable pedicle of omentum may be mobilized and placed around the anastomosis for additional reinforcement. Closed suction drains may also be placed in this area, both to detect possible postoperative leakage and to control a postoperative fistula.

Finally, a gastrostomy tube may be placed in the excluded portion of the stomach. This measure provides postoperative decompression, which should prevent the development of undue tension on the Roux limb as a result of gastric distention, and establishes a route for enteral feeding if a fistula develops. Fortunately, such fistulas are rare. When they do occur, they often heal if (1) they are well drained, (2) there is no distal obstruction or local abscess, and (3) the patient is receiving nutritional support with no oral intake. A gastrostomy tube should also be placed in the distal gastric pouch when extensive adhesions from a previous procedure or a difficult gastric reoperation increases the risk of postoperative gastric distention.

Step 7: Closure

When the absence of leakage is confirmed or when any leaks identified have been controlled, the tip of the nasogastric tube may be positioned further down in the Roux limb and left to continuous suction overnight. All mesenteric defects—at the jejunoojejunostomy, at the mesocolon, and behind the Roux limb (Peterson hernia)—are then closed to prevent an internal hernia. The abdominal fascia is reapproximated with a continuous No. 2 nonabsorbable suture, subcutaneous tissues are irrigated with a crystalloid solution containing 1% neomycin, and the skin is closed with skin staples. No subcutaneous sutures or drains are used in routine cases.

COMPLICATIONS

Proximal GBP is associated with a significant incidence of stomal stenosis and with marginal ulcer.²³ The former responds to endoscopic stomal dilatation, and the latter usually responds to H₂ receptor blocker or proton pump inhibitor therapy.

Iron, vitamin B₁₂, and folic acid deficiencies may occur but can usually be corrected with oral supplements²²; accordingly, GBP patients, like VBG patients, should be advised to take a multivitamin daily for life. Compared with VBG, GBP results in significantly lower serum hemoglobin and iron concentrations. This is primarily a problem in menstruating women. All menstruating

women who have undergone GBP should be treated prophylactically with supplemental oral ferrous sulfate, 325 mg/day. As many as six iron tablets a day may be required if menstrual bleeding is heavy. On occasion, intramuscular iron injections or, rarely, hysterectomy may be necessary. The risk of vitamin B₁₂ deficiency is higher after GBP than after VBG, but this condition can be prevented with supplemental oral vitamin B₁₂, 500 mg/day. A few patients may require (or prefer) monthly B₁₂ injections, which they can learn to administer themselves.

Concerns have been expressed that GBP can lead to other divalent cation deficiencies. Our group has not encountered zinc deficiencies 5 to 9 years after GBP, though we have observed calcium deficiencies leading to osteoporosis, which may take many years to become manifest and may not be biochemically evident because of normal serum calcium levels. It is therefore recommended that all GBP patients take oral calcium supplements. Magnesium deficiencies should be treated with MgSO₄ supplementation.

Although nutritional deficiencies do not appear to be a greater problem with long-limb GBP than with standard proximal GBP, monitoring patients for possible malabsorption of the fat-soluble vitamins A, D, and E after long-limb GBP is advisable.

BPB may be associated with all of the complications seen after GBP. In addition, patients who undergo BPB may experience diarrhea, severe protein malnutrition (manifested as hypoalbuminemia), and deficiencies of vitamins A (manifested as severe night blindness), D (manifested as severe osteoporosis), and E.²⁰ Hypoalbuminemia may respond to oral pancreatic enzymes but often must be treated with total parenteral nutrition. In some patients, it may prove necessary to lengthen the absorptive intestinal tract from 50 cm to 200 cm.

OUTCOME EVALUATION

A series of 672 open proximal GBP procedures reported a 1.2% incidence of anastomotic leak with peritonitis, a 4.4% incidence of severe wound infection (defined as infection serious enough to delay hospital discharge), an 11.4% incidence of minor wound infections and seromas (which were easily treated at home), a less than 1% incidence of gastric staple line disruption with the use of three superimposed applications of a 90 mm linear stapler, a 15% incidence of stomal stenosis, a 13% incidence of marginal ulcer, a 16.9% incidence of incisional hernia, and a 10% incidence of cholecystitis necessitating cholecystectomy.¹⁷ Gallstones developed in 32% of the GBP patients who had a normal intraoperative gallbladder ultrasonogram within 6 months of surgery, and sludge was observed in another 10%. In a multicenter randomized, prospective trial,²⁴ the incidence of gallstones within 6 months of GBP was reduced from 32% to 2% by giving patients ursodeoxycholic acid, 300 mg twice daily. Gallstone formation beyond 6 months is very rare. The operative mortality in this series was less than 1%. Patients with respiratory insufficiency of obesity had a 2.2% operative mortality, whereas those without pulmonary dysfunction had a 0.4% mortality.

Neither the data from this randomized, prospective trial nor the data from selective studies support the contention that VBG is safer than GBP. Although GBP includes one more anastomosis than VBG, complications such as leaks and peritonitis occur with both operations. A common criticism of GBP is that it is difficult to evaluate the distal gastric pouch and duodenum after the operation. Such evaluation, however, can be done in 75% of patients by means of retrograde passage of an endoscope into the duodenum and the stomach and in others by means of percutaneous

distal distention gastrography (DeMaria EJ, Sugerman HJ, unpublished data, 2000). Bleeding from either the distal gastric pouch or a duodenal ulcer is rare. In one patient, a perforation of the proximal gastric pouch developed after administration of high-dose nonsteroidal anti-inflammatory medication. Gastric mucosal metaplasia of the bypassed portion of the stomach was noted in 5% of patients after retrograde endoscopy, a finding that has raised concerns regarding the risk of carcinoma arising at that location. However, tens of thousands of these procedures have been performed since 1967, and only two cases of cancer in the bypassed stomach have been reported to date.

Laparoscopic Gastric Bypass

One would anticipate that laparoscopic GBP would yield much the same weight-loss results as open GBP but with less pain, reduced disability, and a shorter hospitalization period. In addition, one would anticipate a decrease in major wound infections as well as fewer incisional hernias. On the face of it, it seems likely that the laparoscopic procedure, though more expensive, would be cost-effective, but proving it is so will probably require an analysis of long-term follow-up that documents decreased subsequent hospitalizations for wound infections, hernia repairs, and complications of intra-abdominal adhesions (e.g., bowel obstruction), given that early results have not demonstrated a dramatic reduction in the length of hospitalization after the procedure. If the additional benefit of reduced disability-related absence from work is realized, this would help reduce overall costs as well.

TOTAL INTRACORPOREAL LAPAROSCOPIC GASTRIC BYPASS

Laparoscopic GBP poses significant technical challenges, even for surgeons with advanced laparoscopic skills. Most of the variations seen at different institutions are related to creation of the gastrojejunial anastomosis, with some groups using a circular stapler and others a linear stapler. The anvil of the circular stapler may be placed within the proximal gastric pouch either by means of flexible upper GI endoscopy, through an approach similar to the snare-and-wire technique used for placement of a percutaneous endoscopic gastrostomy (PEG) tube [see 5:18 *Gastrointestinal Endoscopy*], or by means of a gastrotomy of the pouch for intra-abdominal anvil placement followed by staple closure of the gastrotomy. Peroral placement of the stapler's anvil can be problematic: even the small 21 French anvil is hard to pass through the proximal esophagus in some patients. I routinely use the linear stapling method to create the gastrojejunial anastomosis; it is easier than circular stapling in this setting, and there is no risk of esophageal trauma from anvil passage.

Operative Technique

Step 1: initial access and trocar placement Initial access to the abdomen is obtained through a left subcostal incision with either a Veress needle or a commercially available device that allows direct vision through the scope while a 12 mm trocar is inserted. Gas is then insufflated into the abdomen to a pressure of 15 mm Hg; on occasion, a pressure of 18 mm Hg may be necessary. Additional trocars are placed in specific locations [see Figure 9]. The liver is retracted with a metal Nathanson liver retraction device anchored to the bed, which is inserted after a 5 mm sharp trocar is used to enter the abdominal cavity in the subxiphoid position and removed. If the left lateral segment of the liver is very large (as in patients with steatosis), additional liver retractors may be necessary.

The enlarged fatty falciform ligament must occasionally be dis-

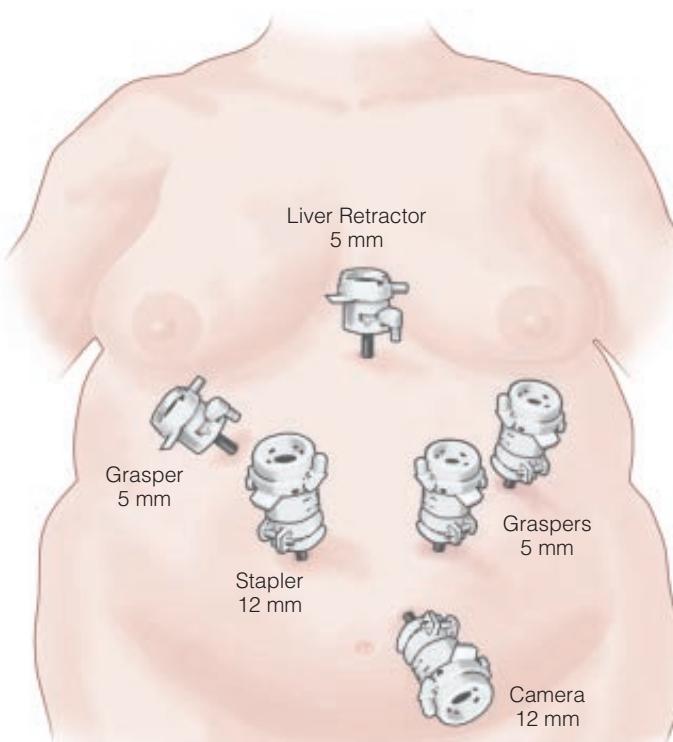

Figure 9 Laparoscopic gastric bypass: total intracorporeal approach. Shown are the trocar incision sites for laparoscopic GBP.

sected from the anterior abdominal wall with an ultrasonic scalpel. Trocar incisions near the costal margin and midline have been rendered unnecessary by the advent of long laparoscopic graspers, staplers, and ultrasonic dissectors, which facilitate operation on the proximal stomach. A 12 mm port placed in the right paramedian position serves as the surgeon's primary operative port; two lateral subcostal 5 mm ports allow both surgeon and assistant to employ two-handed techniques for the entire procedure.

Step 2: dissection around stomach and creation of gastric pouch The mesentery of the lesser curvature is transected with a linear stapler loaded with 2.0 mm staples in a vascular cartridge to provide hemostasis. Despite the potential for problems with transection of the neurovascular bundle, no clear evidence of such problems has been found in hundreds of procedures performed with this access technique. Dissection posterior to the stomach is performed in the avascular free plane of the lesser sac. Additional dissection along the lesser curvature is not recommended, because it may increase the devascularization of the pouch. Further dissection is done with the ultrasonic scalpel at the angle of His to create a connection with the posterior gastric space. A linear endoscopic gastrointestinal anastomosis (GIA) stapler loaded with 3.5 mm staples in 60 mm cartridges is then used to transect the stomach and create the proximal gastric pouch; three firings are usually necessary [see Figure 10]. When reoperation is indicated or when buttressing materials are used to reinforce the staple line, 4.8 mm staples are usually required.

Step 2a (circular stapling): placement of stapler in gastric pouch As noted (see above), surgeons use several different techniques to complete the gastrojejunial anastomosis. With linear

stapling, the surgeon proceeds directly from creation of the gastric pouch to mobilization of the Roux limb [*see Step 3, below*]. With the technique reported in Wittgrove's original description of the procedure,²⁵ however, in which the anvil of a circular stapler is passed down the patient's esophagus, the next step in the procedure is to have an assistant perform flexible upper GI endoscopy of the gastric pouch. The pouch wall is transilluminated by the endoscope light, and a site is chosen for the gastrojejunostomy. The endoscopist then places an endoscopic snare, which can be seen pressing against the tissue of the pouch wall. A small opening is made in the pouch with the electrocautery scissors so that the snare can be pushed through the gastric wall at this location. The snare is then used to grasp a wire placed through a needle across the abdominal wall in the left abdomen, and snare and wire are withdrawn through the mouth along with the scope.

The anvil of the stapler is attached to the end of the wire that was drawn through the mouth, and the surgeon pulls on the other end of the wire to deliver the anvil through the mouth, down the esophagus, and into the gastric pouch, where it can be visualized. The electrocautery attached to the scissors is used to enlarge the opening in the gastric wall slightly, and the stem of the stapler is then brought through the gastrotomy. To prevent anastomotic leakage after stapling, the gastrotomy should be no larger than the diameter of the stem; if it is too large, it can be closed around the stem by placing one or two simple sutures.

Troubleshooting. Difficulty in passing the anvil perorally may arise at the level where the trachea separates from the esophagus in the deep pharynx. This difficulty can usually be overcome either by having the endoscopist perform a jaw-thrust maneuver or by placing a large laryngoscope blade deep in the pharynx to make the anvil visible in the proximal esophagus and then nudging the anvil forward with either the tip of the blade or a McGill forceps. Deflating the endotracheal tube balloon may also help. Occasionally, a large, blunt esophageal dilator is used to place pressure on the top of the anvil. Given the potential for esophageal injury if the anvil will not advance, it is important not to apply excessive force. I have seen a case in which the anvil became

lodged in the proximal esophagus beyond the laryngoscopic view and the long suture holding it broke; retrograde passage of an esophageal dilator was required to dislodge the anvil. Other surgeons who use wire to draw the anvil down the esophagus have identified nontransmural esophageal injuries on postoperative contrast studies or have seen subcutaneous emphysema in the neck after operation.

Step 3: creation and mobilization of Roux limb and jejunojejunostomy In most reports of laparoscopic GBP, regardless of how the gastrojejunostomy is done, the approach to creating the Roux limb is essentially the same. The patient is placed in a supine position, and graspers are used to bring the omentum upward into the upper abdomen so that the transverse colon and the underlying mesocolon are exposed. Graspers are then placed on the transverse mesocolon and used to elevate it anteriorly so that the ligament of Treitz is exposed. The position of the ligament of Treitz is confirmed by careful manipulation and verification that the bowel is attached to the retroperitoneum at this location; this may be a more difficult task in patients who have previously undergone abdominal procedures.

With the help of a measuring instrument inserted into the abdomen, the small bowel is measured to a point 30 to 40 cm from the ligament of Treitz, where it is transected with the endoscopic GIA stapler, loaded with 2.5 mm staples. A 0.5 in. Penrose rubber drain is sutured to the cut end of the Roux limb so that it is not confused with the other cut end of the bowel. The Roux limb is then measured to a length of 45 to 60 cm. (As in open GBP, the Roux limb should be significantly longer—up to 150 cm—if the long-limb modification is being performed.) The afferent side of the previously transected small bowel is then attached with a simple absorbable suture to the proposed jejunojjunostomy site on the Roux limb. Intracorporeal suturing is facilitated by using an automatic suturing device. Positioning is important: the afferent limb should be kept toward the mesocolon, with the Roux limb brought toward the surgeon on the patient's right side.

A small (1 cm) enterotomy is then made in each of the two adjacent bowel limbs in preparation for passage of the linear stapler, loaded with 2.5 mm staples in a 60 mm cartridge, into the bowel. Two holding sutures are placed, one proximal to the enterotomy and the other distal, to help manipulate the bowel onto the stapler. The stapler is then fired, creating a 60 mm side-to-side anastomosis. A third suture is placed at the midpoint of the enterotomy, and all three sutures are grasped to facilitate closure of the enterotomy with another application of the linear stapler. Once completed, the anastomosis is inspected both for integrity and for possible narrowing. At this point, anterior traction is applied to the three sutures to facilitate placement of a continuous suture to close the mesenteric defect.

Next, the greater omentum is divided from its free edge to its junction with the transverse colon so as to facilitate passage of the Roux limb in an antecolic location. Alternatively, a retrocolic, retrogastric tunnel is created so that the Roux limb can be advanced to the proximal stomach for anastomosis. The retrocolic, retrogastric approach is superior if the antecolic approach appears to be placing undue tension on the limb as it is advanced to the proximal pouch. The ligament of Treitz is identified by lifting the transverse mesocolon anteriorly, and a spot 1 to 2 cm anterior and to the left of the ligament is chosen as the starting point for dissection with the ultrasonic scalpel. The middle colic artery should be visualized medial to this point of entry into the mesocolon. The goal of the dissection is to identify the posterior wall of the stomach, which may be difficult in patients who are extremely obese,

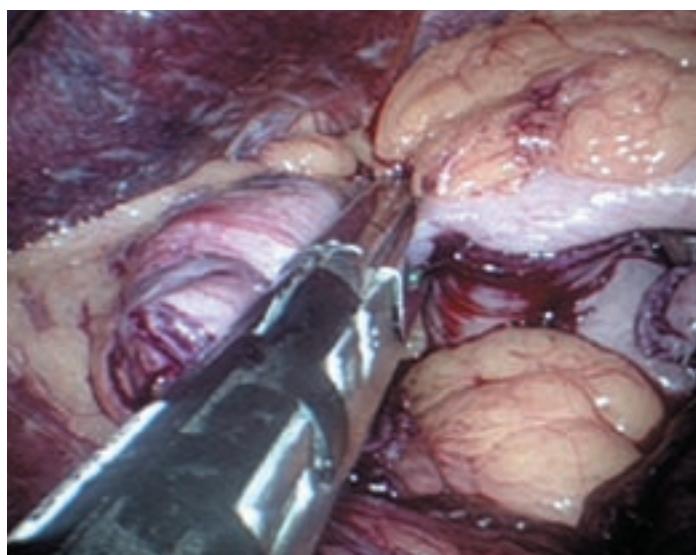

Figure 10 Laparoscopic gastric bypass: total intracorporeal approach. Much as in open GBP, a linear endoscopic GIA stapler is fired three times to transect the stomach and create the gastric pouch.

have a fatty, foreshortened mesocolon, or have previously undergone abdominal surgery.

Once the stomach is visible, it is grasped and elevated through the mesocolic window, and the end of the Penrose drain is grasped and brought through the mesocolic defect into the lesser sac. When the Penrose is in place in the lesser sac, the omentum is pulled down from the epigastrium to allow visualization of the drain, now posterior to the divided distal stomach. The Penrose drain is grasped, and the patient is placed back into a steep reverse Trendelenburg position. Traction is applied to the Penrose drain to deliver the cut end of the Roux limb up into the lesser sac for anastomosis.

Troubleshooting. Some surgeons prefer to create a loop gastrojejunostomy, thus avoiding the technical challenges of creating a Roux limb laparoscopically. This approach was abandoned years ago in open GBP because of postoperative bile reflux and an increased severity of complications resulting from high output of digestive juices when a leak occurs at the gastrojejunostomy anastomosis; it should be abandoned in laparoscopic GBP as well. The practice of using such suboptimal methods for the purpose of performing this complex operation more expeditiously is poorly conceived and is to be condemned.

Step 4 (circular stapling): gastrojejunostomy In the circular stapling technique, the stapled end of the Roux limb is open to permit introduction of the stapler. The 12 mm trocar site in the left upper quadrant is dilated so that the circular stapler can be inserted through the abdominal wall without the need for a trocar; lubrication is helpful for this step. The stapler then cannulates the Roux limb. This step is facilitated by holding the open mouth of the limb in three locations, with one of the three holds involving traction on the Penrose drain previously sutured to the bowel. The stapler is advanced 3 to 4 cm down the limb, and the spike on the stapler is brought through the antimesenteric portion of the bowel by unscrewing the stapler under direct vision. Once the stapler has been opened completely, it is laparoscopically joined to the anvil in the gastric pouch, then closed and fired.

Once fired, the stapler is removed from the abdominal wall, and a balloon trocar device is used to close the dilated abdominal wall opening. A single firing of the endoscopic GIA stapler, loaded with 2.5 mm staples, is often all that is required to reclose the cut end of the small bowel. Interrupted or continuous absorbable sutures are then placed around the stapled anastomosis for added security.

Step 4 (linear stapling): gastrojejunostomy Initially, a continuous posterior row of nonabsorbable suture material is placed to secure the Roux limb to the posterior gastric pouch. An enterotomy and a gastrotomy are performed that are large enough to admit the jaws of the endoscopic GIA stapler, which is loaded with 3.5 mm staples in a 45 mm cartridge for a side-to-side anastomosis [see Figure 11] by means of the same techniques employed in creating the jejunojejunostomy. The cartridge is inserted to a distance of 2.5 to 3.0 cm and fired to create an inner stapled layer [see Figure 12]. A 30 French dilator or a flexible gastroscope is then passed into the pouch and guided through the anastomosis under direct vision to maintain the appropriate stomal diameter (10 to 12 mm) during closure of the open end. The subsequent defect is closed in two layers with continuous sutures (absorbable for the inner layer and nonabsorbable for the outer). The linear GIA stapler can generally be placed and retrieved without the need for dilatation of a trocar site, which appears to increase postoperative pain.

Figure 11 Laparoscopic gastric bypass: total intracorporeal approach. A 30 French dilator is placed into the proximal gastric pouch before closure of the gastrojejunostomy with the endoscopic GIA stapler.

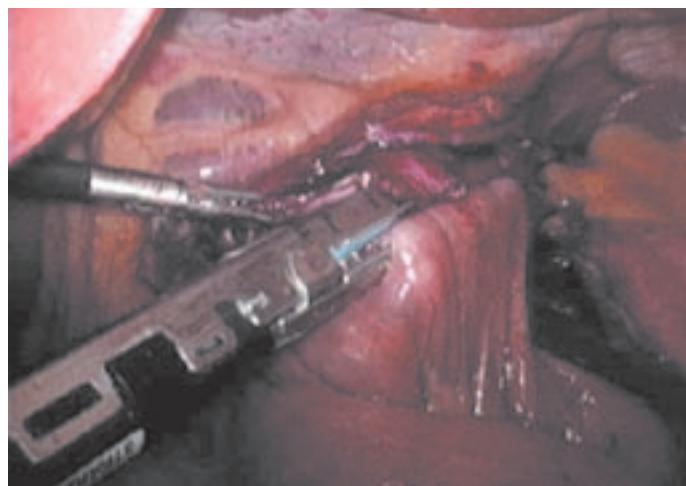

Figure 12 Laparoscopic gastric bypass: total intracorporeal approach. The gastrojejunostomy anastomosis is closed with the linear endoscopic GIA stapler.

In my experience, using the linear stapler for the gastrojejunostomy simplifies the procedure, reduces operating time, and eliminates the concerns about injury to the body of the esophagus that arise with passage of the circular stapler.

Step 5: assessment of anastomosis In every case, regardless of which stapling technique is employed, flexible upper GI endoscopy is performed to assess the anastomosis. The Roux limb is occluded with an intestinal clamp to prevent excessive bowel and distal gastric dilatation. The patient is placed in the supine

position, and the area around the anastomosis is irrigated with saline; the presence of air bubbles, easily detectable in the irrigant, indicates that the anastomosis is leaking. In most cases, the pouch and the Roux limb can be distended tightly, and even tiny air leaks are reinforced with additional sutures. The anastomosis and the staple lines are visualized, and the endoscope is navigated through the anastomosis into the Roux limb whenever possible. After adequate visualization and testing, the gas is suctioned from the intestine, the Roux limb is unclamped, and the endoscope is removed.

Step 6: closure Finally, in selected cases, a 10 mm closed suction drainage tube is placed adjacent to the anastomosis to permit monitoring for postoperative leaks. This drain is removed after the patient begins oral intake if an upper GI series reveals no postoperative leakage [see Figure 13]. In antecolic Roux-en-Y procedures in which the greater omentum is divided, I routinely wrap the lateral tongue of greater omentum in a lateral-to-medial direction posteriorly around the gastrojejunostomy, then suture it to anterior gastrocolic fat so as to reinforce the anastomosis. The liver retractor is removed under direct vision to ensure that no bleeding occurs. Trocar sites 10 mm in diameter or larger are closed by using a needle suture passer to place 0 absorbable sutures under direct endoscopic visualization. Skin wounds are closed with skin staples or absorbable subcutaneous sutures.

HAND-ASSISTED LAPAROSCOPIC GASTRIC BYPASS

Because total intracorporeal laparoscopic GBP is such a challenging technical adventure, a hand-assisted version of the procedure was initially developed at our institution on the basis of previously published work.²⁶ This technique served as a bridge to the total intracorporeal approach, in that it made it possible to learn the technical aspects of a difficult, highly advanced laparoscopic procedure while enjoying the security provided by the presence of an intra-abdominal hand for palpation and manipulation during the procedure. This added security is the major advantage of the

hand-assisted approach. The major disadvantage is the potential for complications at the incision used for manual access. The complications seen at this site are reminiscent of those seen after open GBP, including major wound infection, dehiscence, and hernia formation.

In a series of hand-assisted laparoscopic GBP procedures from our institution, there was one major wound infection in the hand incision and one instance of postoperative fascial dehiscence. Subsequent study suggested that the hand-assisted procedure did not reduce the incidence of wound-related complications and incisional hernias and that it significantly increased the cost of surgical treatment when compared with open GBP. It appears, therefore, that the primary role of hand-assisted gastric bypass may be in helping surgeons to negotiate the steep learning curve associated with total laparoscopic GBP.

Operative Technique

Step 1: initial access and placement of hand-assisted device A left subcostal incision is made, a Veress needle is inserted, and gas is insufflated into the abdomen to a pressure of 15 mm Hg. A periumbilical location for a midline incision is then identified. This incision will allow insertion of the hand at a later point in the procedure; thus, its length in centimeters should roughly correspond to the surgeon's glove size. The assisting hand gains access to the abdomen via a device called the Pneumo Sleeve (Dexterity Surgical, Inc., Roswell, Georgia). This device includes a ring system at one end. Once pneumoperitoneum is obtained, the ring is glued to the skin of the abdominal wall in such a way that the proposed line of incision is in the middle of the ring.

Step 2: creation and mobilization of Roux limb, jejunoojejunostomy, and creation of gastric pouch With the ring of the Pneumo Sleeve secured to the skin, the small midline incision is opened and extended directly through the midline fascia. The pneumoperitoneum is released as this incision is opened, and the ligament of Treitz is identified by palpation. Retractors are placed into the incision, and the Roux limb is constructed with an open surgical technique. The small bowel is mobilized into the wound to the extent possible and is transected 20 to 30 cm from the ligament of Treitz. A side-to-side stapled jejunoojejunostomy is then constructed with an open technique. In my experience, using an endoscopic GIA stapler rather than a traditional surgical stapler for this step is both technically superior and more cost-efficient.

Once the anastomosis is created and the enterotomy is closed, the mesenteric defect is sutured in the usual fashion with an open technique. A Penrose drain is sutured to the cut end of the Roux limb. The surgeon, standing on the patient's left side, attaches the Pneumo Sleeve to the nondominant hand and places this into the abdominal cavity. Pneumoperitoneum is reestablished. The ligament of Treitz can then be manually identified, and a blunt mesocolic dissection into the retrogastric space can be performed. This manipulation can be visualized through a laparoscope with the placement of additional trocars, including two in the right subcostal area (as in total intracorporeal laparoscopic GBP); the laparoscope is usually placed through a left subcostal trocar site. The Penrose drain is then grasped with the surgeon's fingers and advanced through the mesocolic tunnel into the retrogastric space. The hand is then brought anterior to the stomach, and the patient is placed in a steep reverse Trendelenburg position.

The Nathanson liver retractor is inserted through a subxiphoid puncture as described earlier [see Total Intracorporeal Laparoscopic Gastric Bypass, above] and positioned to allow visualization

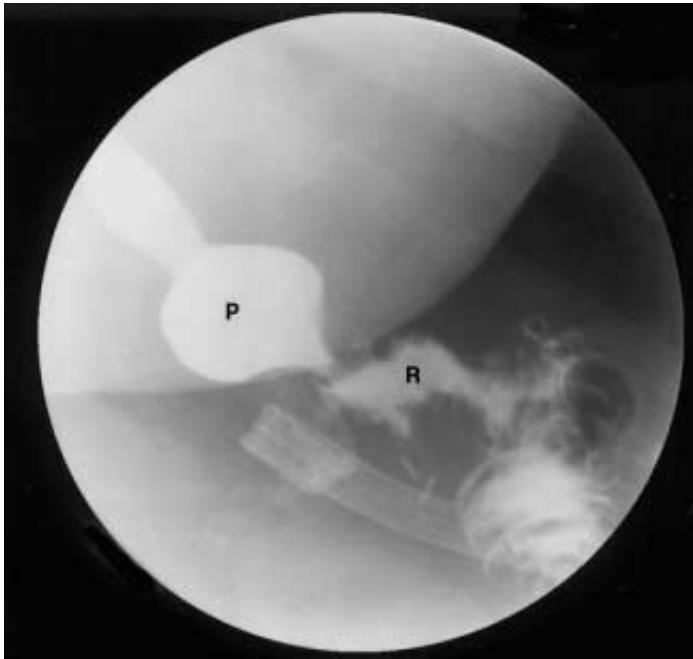

Figure 13 Laparoscopic gastric bypass: total intracorporeal approach. Flexible upper GI endoscopy is performed to assess the completed anastomosis.

of the esophagogastric junction and proximal stomach. The gastrohepatic ligament is bluntly opened, and the surgeon's hand is extended behind the stomach into the lesser sac to retrieve the Penrose drain. The hand is then used to facilitate the mesenteric dissection on the lesser curvature of the stomach 2 to 3 cm from the esophagogastric junction. An endoscopic GIA stapler loaded with 3.5 mm staples in 60 mm cartridges is fired three times to create the gastric pouch (as in total intracorporeal laparoscopic GBP).

Step 3: gastrojejunostomy Again, the gastrojejunal anastomosis can be created with either a circular stapler or a linear stapler [see Total Intracorporeal Laparoscopic Gastric Bypass, above]. The Roux limb is manipulated into view with the surgeon's hand. In the circular stapling technique, the stapler is placed into the Roux limb with the help of the intra-abdominal hand so that it can be opened, penetrating the antimesenteric portion of the bowel, and joined to the anvil in the gastric pouch. The hand also facilitates removal of the circular stapler, which is occasionally difficult.

Step 4: assessment of anastomosis The open end of the Roux limb is then stapled closed, and flexible upper GI endoscopy is performed as in total intracorporeal laparoscopic GBP, with the hand (rather than an intestinal clamp) occluding the limb to allow insufflation and testing of the anastomosis. Additional absorbable sutures can be placed around the anastomosis for added security; an automatic suturing device such as the Endostitch (United States Surgical, Norwalk, Connecticut) may be used for this purpose. If the sutures are left long, the surgeon can tie knots intra-abdominally, using the sleeved hand in a one-handed technique.

Step 5: closure Except for the hand incision, closure is accomplished in the same way as for total laparoscopic GBP. Although the hand incision is small, it may be difficult to close in severely obese patients who have a thick layer of subcutaneous fat. I typically use a continuous fascial closure with a heavy No. 1 or 2 nonabsorbable suture.

COMPLICATIONS

The complications observed to date after laparoscopic GBP include the usual problems that occur in some patients after open GBP, including marginal ulcer and stenosis at the gastrojejunostomy necessitating dilatation. On rare occasions, a gastrogastric fistula may lead to a treatment-resistant marginal ulcer. The major advantage of laparoscopic GBP over open GBP is likely to be reduced wound complications (e.g., major wound infection and incisional hernia). I have seen several relatively minor trocar site infections but none carrying the long wound care disability characteristic of a major wound infection after open GBP. In my experience to date, weight loss with laparoscopic GBP is identical to that with open GBP.

Postoperative Management

For optimal results after bariatric surgery, postoperative management must be as well planned as preoperative preparation. The basic principles of postoperative care, including intubation, ambulation, feeding, and monitoring for complications (e.g., anastomotic leakage, abdominal catastrophe, acute gastric distention, and internal hernia), are discussed more fully elsewhere [see 5.7 *Morbid Obesity*].

These basic principles generally apply to laparoscopic cases as well, but with some differences. Unlike patients who have undergone open GBP, those who have undergone laparoscopic GBP do not have a nasogastric tube left in place. In addition, a contrast study of both the pouch and the anastomosis is ordered on postoperative day 1. A water-soluble contrast agent is initially used for this study, followed by barium if no leak or abnormality is identified. The patient may then begin to drink small amounts of liquids and may advance to a pureed diet with no sugar or concentrated sweets as soon as he or she can tolerate it. Discharge usually takes place 2 or 3 days after operation. Vitamin administration should be initiated early after operation; chewable tablets may be used if necessary. Thiamine deficiency may develop within weeks in patients who are kept on a liquid-only diet or who experience persistent vomiting.

FAILED WEIGHT LOSS AND WEIGHT REGAIN

A postoperative problem that deserves special mention is the risk of failed weight loss or weight regain. This is one of the greatest problems associated with bariatric surgery and may arise after any gastric procedure for morbid obesity. Approximately 20% of vertical banded gastroplasty patients have difficulty with solid foods and come to exhibit a maladaptive eating behavior involving frequent ingestion of high-calorie liquid carbohydrates; in about 10% of VBG patients, the procedure fails for this reason. In a study in which 53 VBG patients were converted to gastric bypass,²⁷ the average loss of excess weight after VBG was $31 \pm 5\%$; 2 years after conversion to GBP, it was $67 \pm 2\%$, a value virtually identical to that in the primary GBP group. Thirteen patients became sweets eaters and had lost only $15 \pm 5\%$ of their excess weight more than 1 year after VBG, though there were no radiographically demonstrated problems with the procedure; 1 year after conversion to GBP, they had lost an average of $78 \pm 11\%$ of their excess weight.

Inadequate weight loss is also seen in GBP patients. In some, stomal dilatation eventually develops after the procedure; however, no correlation between stomal size and weight loss has been demonstrated for GBP patients, and reoperation to make the pouch or the stoma smaller has not yielded any benefit when the initial procedure has failed. It appears that failure of GBP is generally due either to the loss or absence of dumping syndrome symptoms in a small percentage of patients, leading to resumption of high-calorie sweets ingestion or, more often, to frequent ingestion of high-fat junk foods (e.g., potato or corn chips, microwave popcorn, or peanut butter crackers) that crumble easily and empty quickly from the pouch, thereby keeping the patient from feeling full. Repeated dietary counseling over a period of years is required to educate patients to eat low-calorie, high-fiber foods (e.g., raw carrots, broccoli, cauliflower, apples, and oranges) that will stay in the small gastric pouch longer and provide a sensation of early satiety.

At our institution, the philosophy is to make clear to patients, well in advance of the operation, that bariatric surgery is designed to help them help themselves. Obesity can be beaten by surgical treatment, but to maintain the victory, patients must continue to make good food choices and exercise appropriately for the rest of their lives. Patients who begin to ingest more than 1,100 kcal/day often begin to gain weight; even if weight gain is only 0.5 lb/mo, this amounts to 6 lb/yr, or 60 lb in 10 years. Bariatric surgical patients need lifelong nutritional counseling to optimize the results of surgical management of morbid obesity.

20 PROCEDURES FOR BENIGN AND MALIGNANT GASTRIC AND DUODENAL DISEASE

Thomas E. Clancy, M.D., and Stanley W. Ashley, M.D., F.A.C.S.

Procedures for Benign Gastric and Duodenal Disease

Advances in the medical management of peptic ulcer disease, including the use of effective acid-suppressing medications (e.g., histamine receptor antagonists and proton pump inhibitors [PPIs]) and the treatment of *Helicobacter pylori*, have led to a dramatic decrease in the need for elective surgical management of uncomplicated duodenal and gastric ulcers. In the past, surgery was the only effective long-term option for peptic ulcer disease, but over the past two decades, it has become an increasingly rare choice.¹ Currently, operative therapy for peptic ulcer disease is largely reserved for the management of complications such as hemorrhage, perforation, and obstruction. The recognition that medical management successfully prevents ulcer recurrence in most patients has caused surgical management of complicated ulcer disease to evolve into a more minimalist strategy that favors damage-control surgery for complications and only infrequently resorts to acid-reducing operations.²

In this section of the chapter, we focus primarily on procedures performed to treat peptic ulcer disease, though we also briefly address diverticulectomy for duodenal diverticular disease. Other gastroduodenal procedures for nonmalignant disease are described in more detail elsewhere: gastric restrictive procedures and gastric bypass are discussed in the context of bariatric surgery [see 5:19 *Bariatric Procedures*]; choledochoduodenostomy and transduodenal sphincteroplasty are discussed in the context of biliary tract surgery [see 5:22 *Procedures for Benign and Malignant Biliary Tract Disease*]; cystogastrostomy for intractable pancreatic pseudocysts is discussed in the context of pancreatic surgery [see 5:24 *Procedures for Benign and Malignant Pancreatic Disease*]; and duodenal diverticularization is discussed in the context of pancreatic and duodenal trauma [see 7:8 *Injuries to the Pancreas and Duodenum*].

PREOPERATIVE EVALUATION

The appropriate extent of preoperative evaluation for a patient undergoing surgery for a benign gastroduodenal disorder is dictated primarily by the nature of the presenting problem. In the case of gastric outlet obstruction or a rare condition such as intractable peptic ulcer disease that is refractory to medical management, the preoperative workup may be extensive and include detailed endoscopy, contrast studies of the upper abdomen, cross-sectional imaging with computed tomography, and full laboratory panels. In most cases of complicated peptic ulcer disease, however, the emergency nature of the situation necessarily renders an extensive preoperative workup impractical. For instance, patients with perforated duodenal ulcers typically present in distress with an acute abdomen. A chest x-ray that demonstrates free intraperitoneal air is all that is needed before the patient is taken to the operating room; the decision to proceed to operation should not be delayed by waiting for further images (e.g., CT scans).

Patients who are experiencing upper GI hemorrhage secondary to peptic ulcer disease should undergo endoscopy to identify the source of bleeding [see 5:5 *Upper Gastrointestinal Bleeding*]. In many cases, endoscopic management of bleeding ulcers is possible, rendering sur-

gical management unnecessary. Definitive surgical management is indicated, however, if bleeding leads to hemodynamic instability, an extensive transfusion requirement (i.e., more than 6 units), or rebleeding after initial endoscopic management. Objective criteria for surgery must be determined on a patient-by-patient basis. Precise preoperative localization of the bleeding source is essential; a bleeding posterior or duodenal ulcer, for example, cannot be managed in the same way as hemorrhage from diffuse severe gastritis. Endoscopy should therefore be performed whenever possible. Alternatively, if brisk bleeding prevents clear intraluminal visualization of a bleeding site, angiographic localization may be attempted.

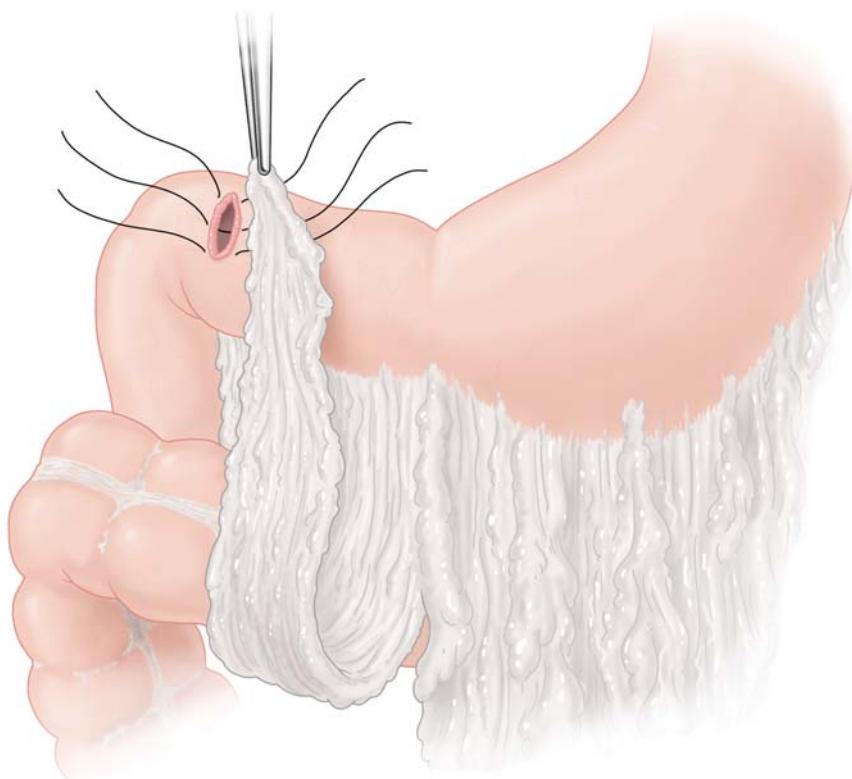

Occasionally, patients present for surgery with refractory gastric ulcers. If the ulcer has not healed after 12 weeks of optimal medical therapy, resection is indicated to rule out an occult gastric malignancy. In such cases, the preoperative workup should include endoscopic biopsies of the ulcer base and the surrounding gastric mucosa so that a preoperative diagnosis of malignancy can be made if possible. In view of the concern about a possible gastric malignancy, it is reasonable to obtain a preoperative chest x-ray and a CT scan of the abdomen so as to detect possible nodal or distant metastases.

OPERATIVE PLANNING

Patients undergoing gastroduodenal procedures should receive general anesthesia and have a nasogastric tube and Foley catheter in place. The supine position is preferred. The operation is usually done via an upper midline incision or, occasionally, via a bilateral subcostal incision, with fixed retractors used in either case.

The choice of procedure is primarily dictated by the indication for operation. Usually, several options are available. The first priority is to manage complications (e.g., bleeding and perforation); whether an accompanying acid-suppressing procedure is indicated and which one should be done depend on the clinical setting. Most commonly, duodenal perforation is treated with closure and omental patching, with or without an acid-reducing procedure. A bleeding ulcer is treated with oversewing of the bleeding vessel, with or without an acid-reducing vagotomy and pyloroplasty. Gastric outlet obstruction may be managed with several different approaches, including vagotomy with antrectomy and vagotomy with drainage via pyloroplasty or gastroenterostomy. In the rare cases of intractability, highly selective vagotomy (HSV) is the procedure of choice.

An important component of preoperative evaluation is determination of the severity and duration of disease. If symptoms are long-standing or recurrent—particularly when the patient has already received acid-reducing or anti-*H. pylori* therapy—a definitive acid-reducing procedure should be considered. As has been demonstrated,³ however, ulcer recurrence is significantly reduced even without an acid-reducing procedure when perforated ulcers are managed with anti-*H. pylori* agents in conjunction with a PPI. Therefore, a compliant patient who is presumed to be infected with *H. pylori* may not need to undergo an additional acid-reducing procedure. The evidence for this strategy is less clear with respect to bleeding or obstructing ulcers.

OMENTAL PATCH FOR DUODENAL PERFORATION (GRAHAM PATCH)

Operative Technique

Perforated duodenal ulcers are typically treated by oversewing the perforation, then placing a portion of the greater omentum over the suture line. The duodenal ulcer wall is carefully debrided and closed with three or four interrupted silk sutures; the tails of the sutures may be used to hold the omentum in place. Alternatively, if the ulcer edges are edematous and not expected to close easily, the perforation may be closed with a true Graham patch, which involves plugging the defect with a well-vascularized omental pedicle [see Figure 1]. Care should be taken to avoid tying sutures too tightly; this can lead to devascularization of the omental pedicle. Once the operation has been completed, the abdomen is generously irrigated to remove any contamination, and a search is made for occult collections in the subphrenic space and the pelvis.

Troubleshooting

To avoid placing excessive tension on the repair, primary closure should not be attempted if the duodenal wall is overly edematous and thickened. For large perforations that are expected to result in gastric outlet obstruction if closed, consideration should be given to incorporating the closure into a pyloroplasty.

There is some controversy regarding whether an acid-reducing operation should be added to the omental patch procedure. If the patient is stable and has a history of peptic ulcer disease, a definitive ulcer operation is included; HSV may be preferable to truncal vagotomy and pyloroplasty, in that it is less likely to give rise to dumping syndrome and postvagotomy diarrhea. If the patient has no history of peptic ulcer disease, has a severe medical illness, is hemodynamically unstable, has a long-standing perforation, or exhibits gross abdominal contamination, a definitive ulcer operation is omitted. In cases of gross contamination of the abdomen, it is probably inappropriate to divide the peritoneum over the esophagus during vagotomy and thereby expose the mediastinum to infection.

Figure 1 Omental (Graham) patch.
Three or four interrupted sutures are placed along the ulcer edge. If possible, the ulcer is closed primarily and reinforced with omentum. Primary closure may be difficult; in a true Graham patch, primary closure is not attempted, and omentum is used to cover the tissue defect.

Complications

Persistent leakage should be uncommon after adequate closure. Duodenal scarring at the area of perforation and repair may lead to gastric outlet obstruction. Incomplete exploration and irrigation of the abdomen may result in late infection.

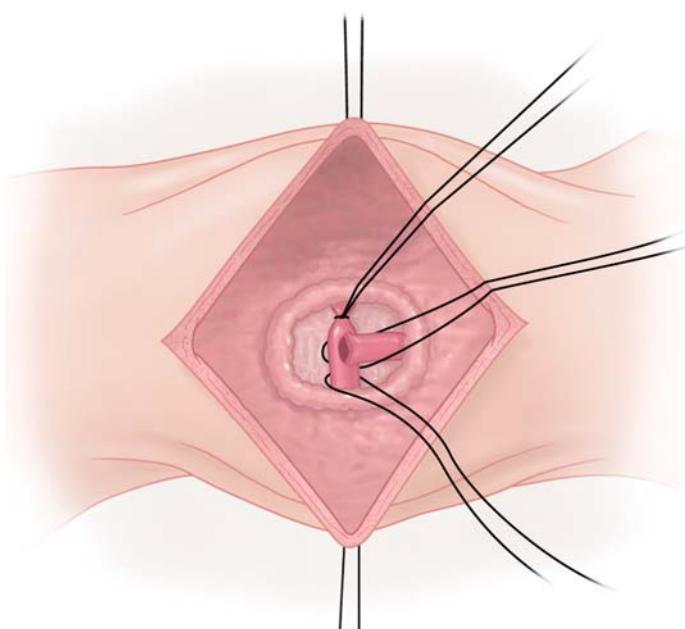

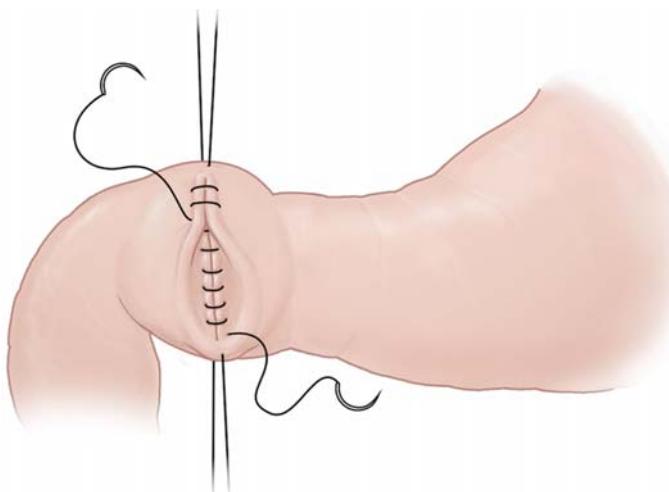

Figure 2 Vagotomy and pyloroplasty. To control a bleeding duodenal ulcer, traction sutures are placed along the cephalad and caudad borders of a longitudinal incision across the pylorus. Figure-eight sutures are placed at the cephalad and caudad portions of the ulcer to occlude the gastroduodenal artery. An additional U-stitch is placed to control small transverse pancreatic branches that may cause late bleeding. Care should be taken to avoid the underlying CBD.

Figure 3 Vagotomy and pyloroplasty. For a Heineke-Mikulicz pyloroplasty, a full-thickness longitudinal incision is made that extends from a point 1 cm proximal to the pylorus to a point 1 to 2 cm distal to the pylorus. The incision is closed transversely in two layers. Superior and inferior stay sutures help align the incision for closure.

Outcome Evaluation

With adequate acid suppression and anti-*H. pylori* therapy, symptoms of duodenal ulcer are unlikely to recur. The 1-year recurrence rate after omental patching is substantially lower when both therapies are employed than when only a PPI is given (5% versus 38%).³

VAGOTOMY AND PYLOROPLASTY FOR BLEEDING DUODENAL ULCER

Truncal vagotomy with pyloric drainage via pyloroplasty is rarely employed as primary therapy for peptic ulcer disease, but it does play a role in emergency management of bleeding duodenal ulcers. This approach to acid suppression fits well with the proximal duodenotomy used to control the hemorrhage. Exposure of the first portion of the duodenum via a longitudinal incision in the pylorus is combined with truncal vagotomy; the pylorus is then closed in a transverse fashion to prevent the development of gastric outlet obstruction.

Operative Technique

Step 1: exposure and pyloric division A Kocher maneuver is performed. The pylorus is identified through palpation and through identification of the pyloric vein as it courses anteriorly. Two traction sutures are placed in the anterior aspect of the pylorus, one superiorly and one inferiorly. A longitudinal incision is made that extends approximately 2 to 3 cm on either side of the pylorus.

Step 2: ligation of bleeding vessel The bleeding ulcer bed is directly oversewn with at least three sutures. Figure-eight sutures are placed on the superior and inferior borders of the ulcer bed to ligate the gastroduodenal artery proximal and distal to the ulcer, and a third figure-eight suture is placed medially to control the transverse pancreatic branch [see Figure 2].

Step 3: pyloroplasty Tension is applied to the previously placed traction sutures to convert the longitudinal incision to a transverse one. The incision is then closed transversely in two layers with full-thickness bites of 3-0 or 2-0 nonabsorbable suture material (Heineke-Mikulicz pyloroplasty) [see Figure 3]. Tension-free closure is facilitated by adequate duodenal mobilization (by means of the Kocher maneuver) and lysis of surrounding adhesions.

Step 4: vagotomy To perform the vagotomy, further exposure may be needed, including mobilization of the left lateral section of the liver and division of the triangular ligament. Downward traction on the greater curvature of the stomach is essential to apply gentle tension to the esophagogastric junction and the proximal vagi. The peritoneum over the esophagus is divided transversely with the electro-

cautery; exposure may be facilitated by surrounding the distal esophagus with a Penrose drain for downward traction. The left (anterior) vagus is best identified by applying traction to the right and posteriorly, so that the nerve can be traced into the posterior mediastinum. All fibers entering the distal esophagus are divided. The main nerve trunk is clipped proximally and distally, and a 2 cm long segment is excised. The right (posterior) vagus is exposed by applying traction to the left and anteriorly; the nerve can then be palpated as a taut cord and divided in much the same manner as the anterior vagus. For a complete vagotomy, the distal esophagus must be skeletonized for approximately 5 cm [see Figure 4].

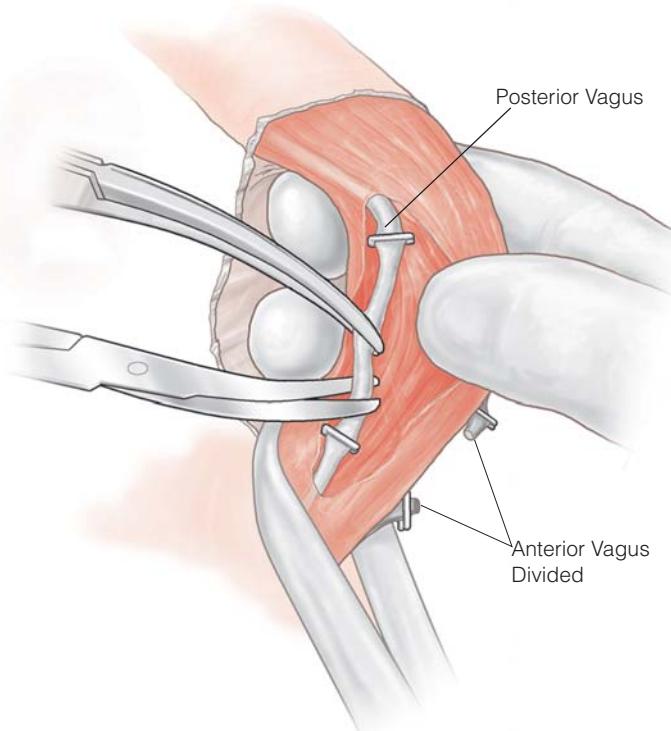

Figure 4 Vagotomy and pyloroplasty. For the truncal vagotomy, the peritoneum over the esophagogastric junction is opened widely to afford exposure. Gentle downward traction is applied to the stomach to facilitate identification of the two vagus nerves. Surgical clips are applied to each nerve in turn, and a 2 to 3 cm nerve segment is removed between the clips. These segments should be inspected to confirm removal of neural tissue.

Troubleshooting

As this procedure becomes less frequent and surgeons' experience with it dwindles, location of the vagus nerves may prove an increasingly troublesome task. In most cases, complete skeletonization of the distal esophagus in conjunction with appropriate traction should allow palpation of the main vagal trunks.

If substantial duodenal scarring is present, a tension-free Heineke-Mikulicz pyloroplasty may not be possible, and a Finney pyloroplasty may be preferable. The Finney procedure is essentially a side-to-side anastomosis that is created in two layers between the distal stomach and the proximal duodenum [see Figure 5]. Complete mobilization of the duodenum, including adhesiolysis and a generous Kocher maneuver, is required.

Care should be taken to keep from injuring the common bile duct

(CBD), particularly when the vascular inflow to a deeply penetrating duodenal ulcer is being sutured.

Complications

Leakage from a pyloroplasty is rare. Gastric outlet obstruction may occur secondary to either scarring or edema at the operative site; often, it is relieved by nasogastric decompression and conservative management. The incidence of ulcer recurrence and rebleeding is quite low with adequate anti-*H. pylori* treatment.

ANTRECTOMY

The primary indication for gastric resection in the setting of peptic ulcer disease is chronic obstruction caused by scarring, typically from a pyloric channel ulcer. Antrectomy removes the gastrin-secreting por-

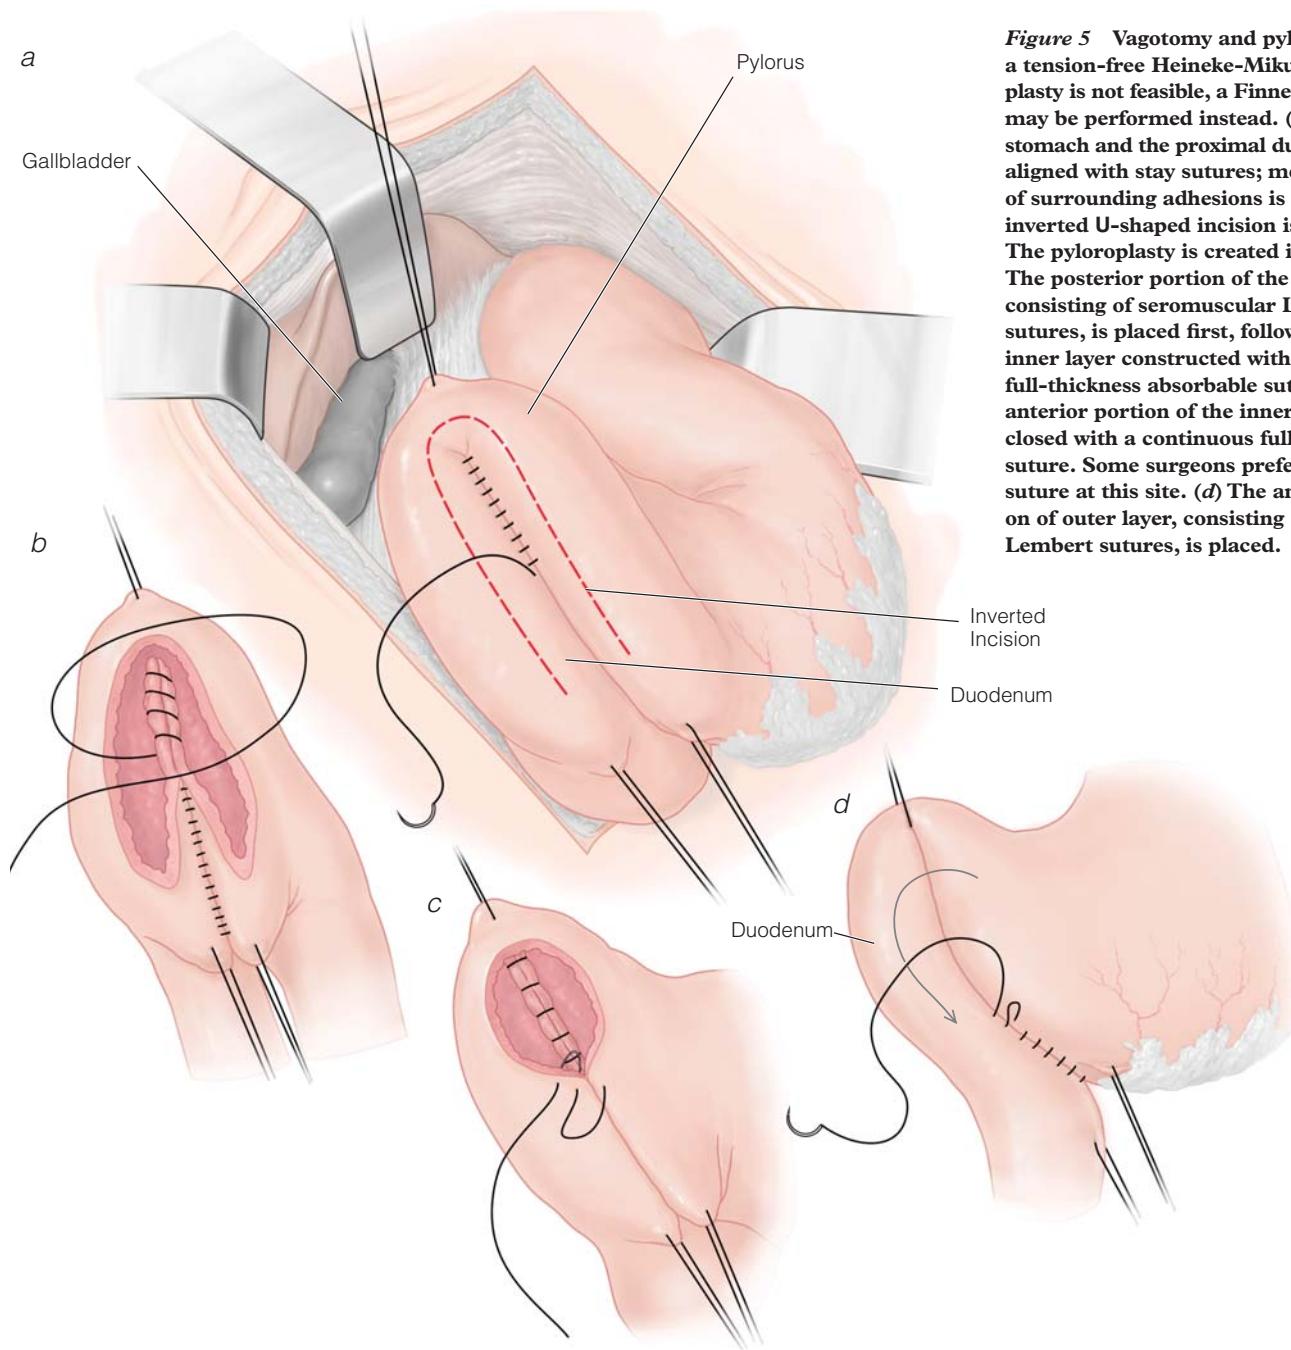

Figure 5 Vagotomy and pyloroplasty. If a tension-free Heineke-Mikulicz pyloroplasty is not feasible, a Finney pyloroplasty may be performed instead. (a) The distal stomach and the proximal duodenum are aligned with stay sutures; meticulous lysis of surrounding adhesions is essential. An inverted U-shaped incision is made. (b) The pyloroplasty is created in two layers. The posterior portion of the outer layer, consisting of seromuscular Lembert sutures, is placed first, followed by an inner layer constructed with a continuous full-thickness absorbable suture. (c) The anterior portion of the inner layer is closed with a continuous full-thickness suture. Some surgeons prefer a Connell suture at this site. (d) The anterior portion of outer layer, consisting of silk Lembert sutures, is placed.

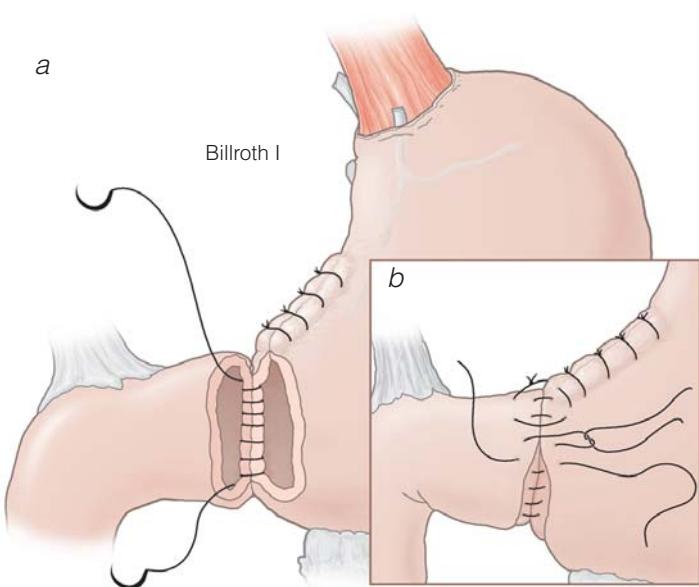

Figure 6 Antrectomy: Billroth I reconstruction (gastroduodenostomy). (a) The anastomosis is done in two layers. The inner layer is constructed by placing a continuous full-thickness suture. (b) The outer layer is constructed with silk Lembert sutures. The junction of the anastomosis and the gastric staple line has been referred to as the angle of sorrow, a term that reflects the common complication of leakage at the intersection of suture or staple lines. This junction may be reinforced with additional Lembert sutures.

tion of the stomach. In addition, antrectomy may be required for recurrent bleeding after an adequate vagotomy and pyloroplasty for a bleeding duodenal ulcer. Alternatively, antrectomy may be the elective operation of choice for intractable type I, II, and III gastric ulcers, as well as a primary emergency surgical option for perforated or bleeding gastric ulcers. Historically, a primary Billroth I gastroduodenostomy has been the preferred procedure, but surrounding scar tissue may limit the mobility of the duodenum, in which case a Billroth II gastrojejunostomy may be required for a tension-free anastomosis. Antrectomy is typically combined with truncal vagotomy.

Operative Technique

Step 1: exposure The lesser sac is entered via the avascular plane in the greater omentum, the plane between the stomach and the pancreas is developed, and the lesser omentum is divided. The proximal border of the antrum must be identified before the stomach is divided [see Step 2, below]. On the greater curvature, the antrum extends to a point between the pylorus and the fundus; on the lesser curvature, it extends to a point just above the incisura. Distally, the dissection is carried past the pylorus. Along the lesser curvature, dissection necessitates division of the descending branch of the left gastric artery, as well as the right gastric artery. Dissection along the pylorus must be meticulous to ensure that the pancreas is not damaged. If a Billroth I anastomosis is planned, dissection should continue 1 cm beyond the pylorus to expose a sufficient length of duodenum for the anastomosis. If a Billroth II reconstruction is planned, dissection need extend only far enough to allow division of the duodenum past the pylorus.

Step 2: division of stomach A gastrointestinal anastomosis (GIA) stapler is used to divide the stomach at the estimated borders of the antrum [see Step 1, above]. The antrum is gently retracted anteriorly and to the patient's left. The right gastroepiploic artery and vein

are divided just distal to the pylorus. The duodenum is then divided distal to the pylorus with a tranverse anastomosis (TA) stapler.

Step 3: reconstruction When feasible, a Billroth I reconstruction (primary gastroduodenostomy) is preferred for maintenance of physiologic antegrade flow (though there are no data establishing that this maintenance of flow is beneficial). In addition, this reconstruction avoids the complications associated with a Billroth II reconstruction (e.g., afferent and efferent loop syndromes and duodenal stump leaks). A generous Kocher maneuver, if not already performed, is necessary to minimize tension on the anastomosis. The lower portion of the staple line is removed for the width of the duodenal stump, and the anastomosis is performed in two layers or fashioned with a GIA stapler through a gastrotomy [see Figure 6].

If a primary gastroduodenostomy is not possible, a Billroth II reconstruction (gastrojejunostomy) is indicated. This procedure involves a number of technical considerations: management of the duodenal stump, the length of and placement of the afferent limb, and the placement and method of the anastomosis. If the duodenum is not scarred or inflamed, simple staple closure will suffice; if closure proves difficult, a lateral duodenostomy tube may help decompress the stump. The duodenal stump should be covered with an omental patch.

The segment used for the anastomosis should be as short as possible while still being able to reach the stomach without tension; approximately 20 cm of proximal jejunum should be sufficient to serve as the afferent limb. Passing the jejunum through a retrocolic window places less tension on the mesentery than an antecolic approach does, though gastric emptying will occur with either method. If a retrocolic approach is used, a window is created for the jejunum; this must be closed and fixed to the small bowel.

The gastrojejunostomy may be constructed either to the posterior wall of the stomach or to the inferior portion of the excised staple line. If the anastomosis is placed at the gastric staple line, the inferior portion of the staple line is excised, often together with a wedge of stomach behind the staple line. A two-layer anastomosis is created with an outer layer of Lembert sutures and an inner layer of absorbable full-thickness sutures; the gastric staple line may be oversewn [see Figure 7]. Alternatively, the gastrojejunostomy may be created by means of stapling. A GIA stapler is introduced via a gastrotomy and a small enterotomy, and the defect is subsequently closed with a TA stapler. Additional reinforcement is not necessary for this staple line.

Some authors recommend the use of a Braun enterenterostomy between the efferent and afferent limbs to reduce bile reflux and decompress the duodenal stump [see Figure 8a]. Staple closure of the afferent limb above the enterenterostomy may also be performed to limit bile reflux into the stomach; this measure creates a configuration referred to as an uncut Roux-en-Y [see Figure 8b]. Enterenterostomy at this site may also be performed on an emergency basis to treat afferent limb syndrome. Staple closure of the afferent limb may discourage bile reflux, but it may also lead to long-term bile reflux gastritis and esophagitis.⁴

Troubleshooting

In most instances, a noninflamed duodenum can readily be closed with a TA stapler. However, the thickened and inflamed tissue present in the setting of inflammation with duodenal perforation is not amenable to easy closure. Furthermore, poor afferent limb drainage can lead to increased pressure in the afferent limb, thus contributing to leakage. Lateral duodenostomy tubes may be used for decompression. The duodenum should be sutured to the abdominal wall in a Stamm fashion at the exit site of the tube. Alternatively, if the duodenum cannot be closed without significant tension, closure may be

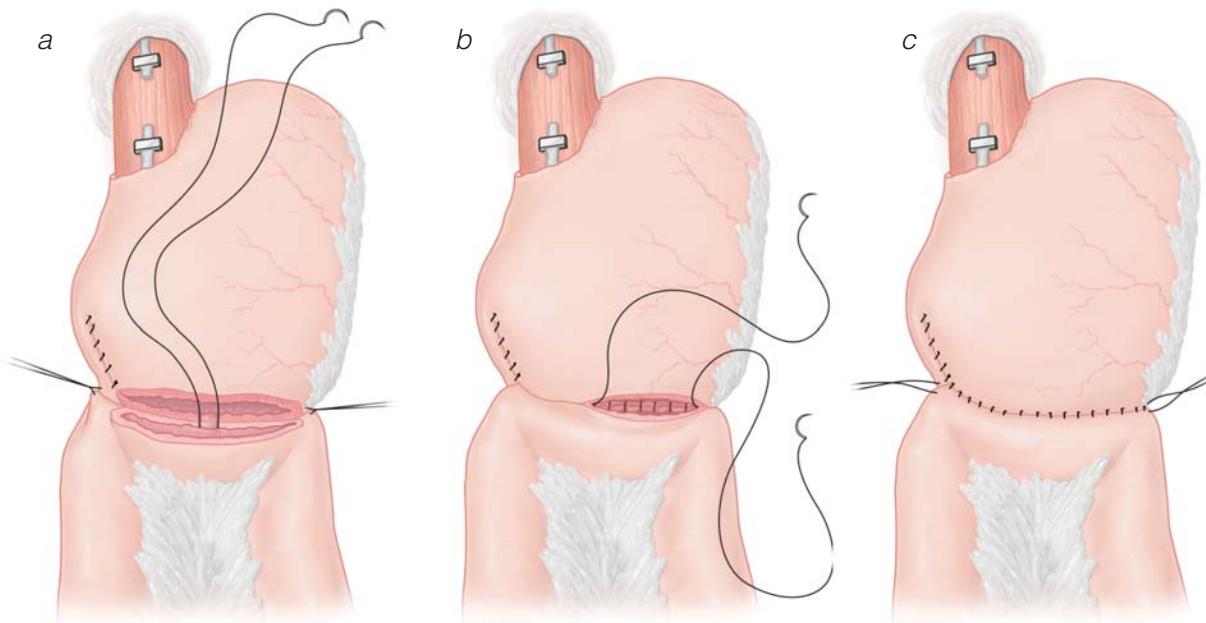

Figure 7 Antrectomy: Billroth II reconstruction (gastrojejunostomy). (a) The inferior portion of the gastric resection line is excised, along with a small wedge of the stomach. (b, c) A two-layer anastomosis is created, with an outer layer of Lembert sutures and an inner layer of full-thickness absorbable sutures. The upper gastric staple line may be oversewn with interrupted Lembert sutures.

accomplished around a red rubber or mushroom catheter. For especially thick tissue, primary suture closure is preferable to staple closure. Inversion of the duodenal suture line with Lembert sutures is not necessary. In addition, omental patch reinforcement of the duodenal stump may be desirable.

Complications

Leakage from the duodenal stump is a potentially devastating complication that necessitates prompt reoperation, washout, and drainage. The diagnosis of duodenal stump leakage is confirmed by aspirating bilious fluid from a right upper quadrant fluid collection or by per-

forming a technetium-99m (^{99m}Tc)-labeled hepto-iminodiacetic acid (HIDA) scan.

Duodenal leaks can rarely be closed primarily. Duodenostomy may be indicated to further decompress the afferent limb and prevent continuous leakage. The goals are to create a controlled fistula to the skin and to prevent the accumulation of biliary fluid in the abdomen.

Delayed gastric emptying after gastrojejunostomy may occur and is generally managed conservatively. On rare occasions, reoperation is required for delayed anastomotic function. In the case of a Billroth I reconstruction, takedown of the anastomosis is associated with devascularization and duodenal stump leakage. It is therefore preferable to

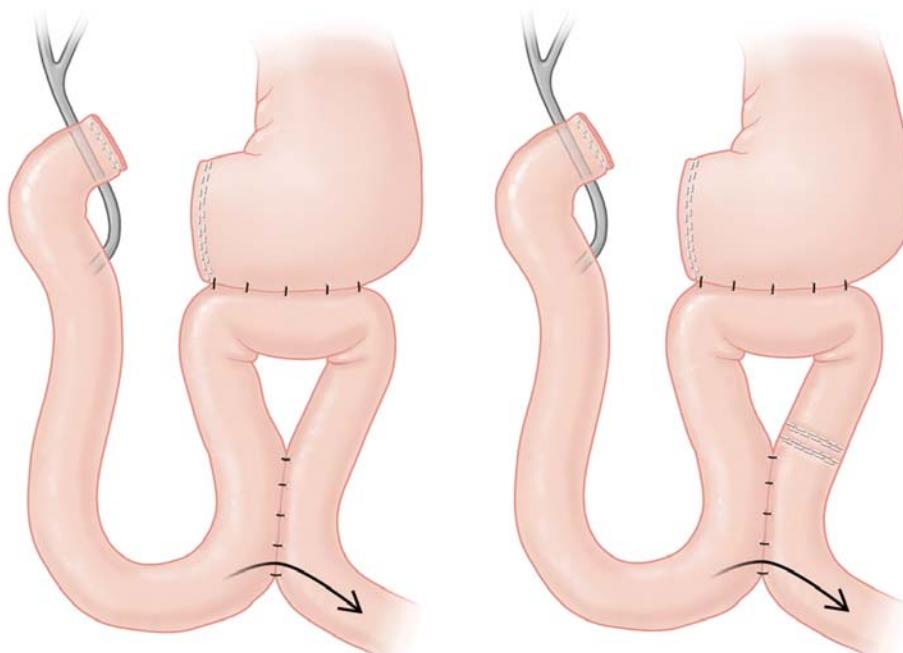

Figure 8 Antrectomy: Billroth II reconstruction (gastrojejunostomy). (a) A Braun enterenterostomy facilitates decompression of the afferent limb in a Billroth II gastrojejunostomy. It may be done as either a sutured or a stapled anastomosis. (b) An option is to close the afferent limb above the enterenterostomy with a TA stapler (so that the jejunal lumen is occluded but not divided). This configuration, often referred to as an uncut Roux-en-Y, temporarily discourages, but does not prevent, reflux of bile into the stomach.

leave the anastomosis in place and perform a gastrojejunostomy along the greater curvature of the stomach. In the case of a Billroth II reconstruction, revision may be required for better positioning of the anastomosis.

Afferent limb obstruction may occur as a consequence of adhesions, internal herniation, volvulus, or a kink at the angle formed with the gastric remnant. Obstruction to outflow of the afferent limb creates a closed-loop obstruction, with persistent secretion of bile and pancreatic fluids into the loop. Such obstruction often presents as recurrent pancreatitis. The diagnosis is facilitated by CT scanning; if it is confirmed, prompt exploration is mandated. Correction of the obstruction may necessitate conversion to a Roux-en-Y reconstruction, shortening of the afferent limb, or a side-to-side enteroenterostomy with the efferent limb (see above).

Bleeding, generally in the form of intraluminal blood loss, is a frequent occurrence after gastrectomy. A bloody aspirate from the nasogastric tube is a common presentation. If bleeding persists for more than 5 days after the initial operation, endoscopy with endoscopic coagulation or epinephrine injection may be considered. Endoscopic approaches should be undertaken with care to minimize the risk of distending the new anastomosis.

Alkaline reflux gastritis is one of the most common long-term complications of gastrectomy, developing in 5% and 15% of patients after gastric surgery.⁵ This complication is most frequently associated with Billroth II reconstructions. Although reflux is common, symptoms (e.g., epigastric pain, nausea, and bilious emesis) are relatively rare. Medical management is generally ineffective. If surgery is required, conversion of the Billroth II reconstruction to a Roux-en-Y reconstruction is indicated. In those patients who have a Roux-en-Y rather than a Billroth II reconstruction, the preferred treatment is to divert alkaline contents to a location 45 to 60 cm beyond the gastric remnant.

HIGHLY SELECTIVE VAGOTOMY

Although both vagotomy with antrectomy and vagotomy with pyloroplasty drainage provide relief from duodenal ulcers, they are also associated with significant complications, including dumping syndrome, diarrhea, bile reflux, and poor gastric emptying. Highly selective vagotomy, also referred to as parietal cell vagotomy, was developed with these complications in mind; the idea was to avoid vagal denervation of viscera other than the parietal cell mass while keeping the pylorus mechanically and functionally intact.^{6,7} HSV was found to reduce postvagotomy diarrhea and dumping dramatically; however, it was also found to be associated with a much higher rate of recurrent ulceration (greater than 10% at 5 years). Today, in an era characterized by greatly improved medical management of peptic ulcer disease, most GI surgeons perform HSV very rarely, if at all. One possible use for this procedure in the current context might be to treat intractable ulcer disease in young patients.

Operative Technique

Step 1: exposure and gastric mobilization Wide exposure is obtained with the help of upward retraction on the costal margin. The gastrocolic omentum is entered outside the gastroepiploic vessels to preserve the blood supply to the greater curvature. Adhesions to the peritoneum over the pancreas are divided sharply, and the stomach is rotated upward to allow visualization of the posterior leaf of the lesser omentum and the posterior nerve of Latarjet, which runs adjacent to the descending branch of the left gastric artery.

Step 2: dissection of anterior and posterior nerve branches to lesser curvature The distal branches of the nerve of Latarjet are defined, with care taken to preserve the so-called crow's foot, which is

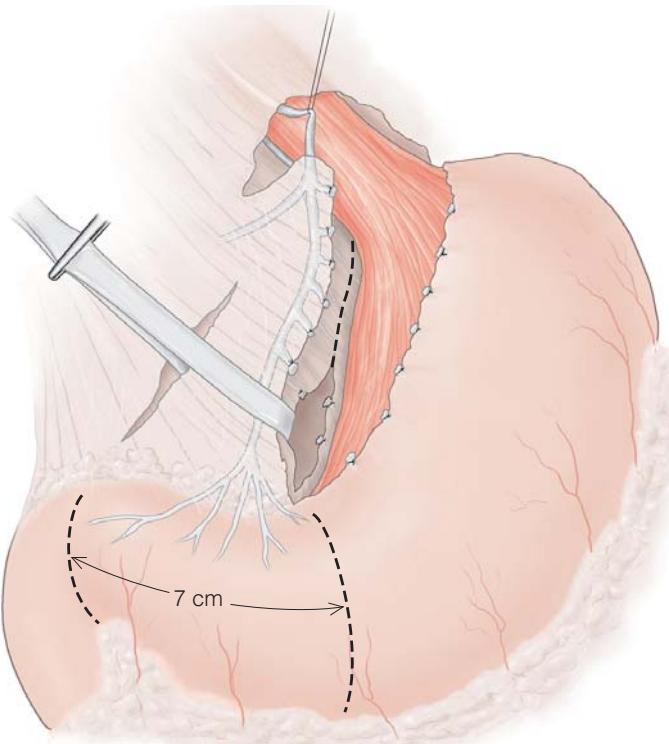

Figure 9 Highly selective vagotomy. Anterior and posterior branches of the nerve of Latarjet to the lesser curvature are ligated and divided. The distal branches, comprising the so-called crow's foot, are left intact. The posterior branches may be approached via the lesser omentum.

typically located near the incisura angularis, approximately 6 to 7 cm proximal to the pylorus. Gentle downward traction is applied to the stomach, the left gastric vascular arcade is identified, and all tissue between this arcade and the lesser curvature is divided and ligated. The dissection therefore includes individual branches of the vagus nerve to the stomach. It should proceed upward as far as the esophagogastric junction. The posterior branches are approached either by rotating the stomach or by proceeding directly through the lesser omentum [see Figure 9].

Step 3: dissection of esophagogastric junction The distal esophagus is cleared of all nerve fibers for a distance of approximately 5 cm above the esophagogastric junction. The dissection must stay close to the lesser curvature and the esophagus, avoiding the tissues to the right of the esophagus, where the main vagal trunks lie. The posterior esophagogastric junction is exposed by means of gentle traction and slight rotation of the distal esophagus. Exposure is facilitated by downward traction provided by a Penrose drain placed around the esophagogastric junction.

Troubleshooting

Incomplete denervation of the parietal cell mass is prevented by paying meticulous attention to dissection, particularly at the esophagogastric junction. The left side of the distal esophagus must be manually stripped so that the so-called criminal nerve of Grassi can be identified and ligated. About 4 to 5 cm of the distal esophagus should be stripped of vagal input.

Complications

The primary complication of HSV is recurrent ulceration. The reported rates vary, but the general view is that the 5-year ulceration

recurrence rate may be higher than 10%.⁸ Most recurrent ulcers occur in the setting of incomplete vagal denervation. Given the small number of patients for whom HSV is indicated, few GI surgeons are likely to have accumulated sufficient experience with this technique to be proficient at it. Fortunately, most recurrent ulcers can now be managed medically, and few call for surgical management.

LAPAROSCOPIC TREATMENT OF PEPTIC ULCER DISEASE

Numerous reports of laparoscopic approaches to truncal vagotomy and HSV have been published over the past two decades. The laparoscopic versions of these procedures proceed in much the same way as the traditional open versions. In a laparoscopic HSV, the ultrasonic shears are frequently used to divide the anterior and posterior vagal branches to the lesser curvature from the crow's foot to the esophagogastric junction. Mixed procedures that combine posterior truncal vagotomy with more selective anterior gastric denervation are common. In the Taylor procedure, an anterior seromyotomy is performed from the angle of His to the crow's foot, and the seromuscular layers are subsequently closed primarily.⁹ A variant of the laparoscopic Taylor procedure includes a anterior linear gastrectomy, in which a linear strip of the stomach wall is removed parallel to the lesser curvature with an endoscopic GIA stapler. This procedure seems to be functionally equivalent to HSV. The majority of the studies of laparoscopic vagotomy, however, have been individual case series that do not compare the laparoscopic approach with a traditional open approach. Undoubtedly, the scarce comparative data reflect the declining indications for vagotomy for intractable peptic ulcer disease. Thus, whereas laparoscopic HSV has been well described, it is by no means clear that it should be recommended over open HSV for those rare patients in whom this procedure is indicated.

More data are available on laparoscopic treatment of perforated duodenal ulcers. A meta-analysis of 13 studies comparing laparoscopic and open approaches to perforated peptic ulcers found that laparoscopic repair yielded excellent results, albeit with a small but insignificant increase in the reoperation rate.¹⁰ The laparoscopic approach is therefore considered as safe and effective as open Graham patch repair. The procedures generally involve either suture closure of the perforation followed by omentopexy or omentopexy alone, and they should be attempted only by surgeons with advanced laparoscopic skills. The threshold for conversion to an open procedure should be low if the ulcers are particularly large ulcers or prove difficult to localize.

DUODENAL DIVERTICULECTOMY

Incidental duodenal diverticula are common. Such diverticula consist of a sac that includes only mucosa and submucosa, and most occur within 2 cm of the ampulla of Vater. Complications include ulceration and bleeding, compression of the CBD with cholangitis or pancreatitis, and, in cases of perforation, abscess formation with peritonitis. CT scanning is useful for differentiating this condition from cholecystitis or pancreatitis. Surgery is rarely required; it is indicated primarily for complications such as bleeding, perforation, and biliary or duodenal obstruction.

Operative Technique

The main surgical options are simple diverticulectomy with drainage and transduodenal diverticulectomy (as described by Iida¹¹). If the duodenum is free of inflammation, the transduodenal approach is preferred because it minimizes the need for dissection of the diverticulum from the surrounding pancreas. However, if the diverticulum does not involve the pancreas, simple excision flush with the duodenal wall, followed by closure in two layers, may be sufficient. The ensuing technical description focuses on transduodenal diverticulectomy.

Step 1: exposure and duodenotomy A generous Kocher maneuver is performed to elevate the head of the duodenum. The duodenum is then opened by making a 4 cm longitudinal incision along the antimesenteric border, and the ampulla is either visualized or palpated. To identify the ampulla, it may be necessary to place a catheter into the CBD via a separate choledochotomy.

Step 2: diverticulectomy The orifice of the diverticulum is identified, and the mucosa is inverted into the lumen of the duodenum. The neck of the diverticulum is transected 2 mm from the junction with the duodenal wall. The diverticular opening is then closed with interrupted seromuscular Lembert sutures of 3-0 silk and interrupted mucosal sutures of 4-0 polyglactin. The duodenum is closed in two layers, also with an inner layer of 4-0 polyglactin and an outer layer of seromuscular Lembert sutures of 3-0 silk. Closed suction drainage adjacent to the duodenum is indicated.

Special case: perforated duodenal diverticulum. In the setting of acute inflammation, duodenotomy is avoided. Instead, the abscess is evacuated, and the diverticulum is excised along with just enough of the adjacent duodenal wall to ensure that only healthy tissue is left. If the resulting duodenal defect is large, either sleeve resection of the duodenum or drainage of the open duodenal defect into a Roux-en-Y jejunal limb may be required.

Troubleshooting

Inadvertent closure of the CBD may be prevented by inserting a catheter into the duct. If the duodenum is markedly inflamed, suture line breakdown is likely, eventually leading to a duodenal fistula. The area can be isolated by means of pyloric exclusion or antrectomy with Billroth II reconstruction. In addition, bile flow can be diverted by performing a choledochojejunostomy to a Roux-en-Y intestinal limb to prevent combined leakage of pancreatic fluid and bile.

Diverticula arising from the third or the fourth portion of the duodenum may be approached via the transverse mesocolon and may be excised either primarily or via a transduodenal approach. Inverting the diverticulum without excising it is not recommended, because it may lead to duodenal obstruction.

Procedures for Gastric Cancer

Surgical resection remains the primary therapeutic modality for gastric cancer [see 5:8 *Tumors of the Stomach, Duodenum, and Small Bowel*]. The diagnosis of gastric cancer is primarily made by means of endoscopy with biopsy. There are numerous considerations that must be addressed before operation, including the stage of the cancer on diagnostic imaging, the use of staging laparoscopy, the extent of the planned gastrectomy, the extent of the planned lymphadenectomy, the placement of feeding enterostomies, and the patient's overall medical fitness for surgery.

PREOPERATIVE EVALUATION

Endoscopy, with or without endoscopic ultrasonography (EUS), is essential for diagnosis. Preoperative biopsy is helpful for confirming the suspected pathologic process, particularly because the extent of resection will be different if a less common lesion, such as a gastrointestinal stromal tumor (GIST), is identified. Endoscopic localization is critical because the extent of the gastrectomy will depend on the precise location of the tumor. It should be noted, however, that the true location of the tumor, as determined at laparotomy, may differ significantly from the preoperative estimate made on the basis of endoscopy. Abdominal CT scanning and chest radiography are indicated to rule out obvious metastatic disease, which would be an indication for a more conserva-

tive surgical approach or even for nonoperative therapy. The preoperative physical examination should also focus on the detection of occult metastatic disease, concentrating on such sites as the supraclavicular lymph nodes and the pouch of Douglas. A bone scan is indicated if metastasis to bone is suspected. Laparoscopic staging (see below) may be performed to identify occult metastatic disease (and, possibly, to prevent an unnecessary laparotomy in an otherwise ill patient).¹² If the tumor is not bleeding or causing an obstruction, palliative resection might be avoided. Generally, curative surgery should be attempted only when the tumor is believed to be limited to the stomach and the perigastric lymph nodes. On occasion, however, curative-intent surgery may be considered for tumors that involve nearby resectable structures (e.g., the transverse colon), provided that these structures can be removed en bloc with the primary lesion.

In Japan, where screening endoscopy is widespread, early gastric cancer is identified with some frequency. In Western countries, however, the situation is different, and patients tend to present with more advanced cancers. Accordingly, although procedures such as wedge resection for early gastric cancer have been described, most gastric cancer patients in the United States require formal gastrectomy and lymphadenectomy.

OPERATIVE PLANNING

Extent of Resection

The extent of the resection required for treatment of a gastric malignancy is determined primarily by the preoperative pathologic diagnosis and the site of the tumor. Considerably smaller surgical margins are required for rare mesenchymal tumors (e.g., GISTs) than are necessary for gastric adenocarcinomas, which tend to spread microscopically well beyond the gross extent of the tumor. Most mesenchymal tumors can be adequately treated with a wedge resection or partial gastrectomy that achieves a 1 cm gross margin. Laparoscopic approaches to such tumors have been described that employ either the endoscopic GIA stapler or excision with suture closure [see Laparoscopic Resection of Malignant Gastric Tumors, *below*]. Such approaches may be facilitated by endoscopic tattooing of an appropriate margin or by intraoperative endoscopic guidance. For adenocarcinomas, a margin of at least 5 cm is recommended.

A 5 cm margin may be particularly difficult to achieve when the tumor is located along the lesser curvature. In many such cases, although the tumor appears to be distal and possibly amenable to a subtotal gastrectomy, a 5 cm negative margin along the lesser curvature would place the proximal resection margin far above the incisura angularis and near the esophagogastric junction, thus necessitating total or near-total gastrectomy. For lesser-curvature tumors whose location allows adequate margins to be obtained, distal gastrectomy with Billroth II gastrojejunostomy is preferred; for more proximal tumors, total gastrectomy with esophagojejunostomy may be required.

Special consideration must be given to tumors of the esophagogastric junction. In the classification scheme described by Siewert and colleagues,¹³ such tumors are defined as lying within 5 cm of the anatomic esophagogastric junction in either direction along the craniocaudal axis of the esophagus and the stomach. They are classified into three types as follows:

1. Type I: the center of the tumor lies 1 to 5 cm proximal to the esophagogastric junction.
2. Type II: the center of the tumor lies within 1 cm of the esophagogastric junction proximally or within 2 cm distally.
3. Type III: the center of the tumor lies 2 to 5 cm distal to the esophagogastric junction.

It is generally agreed that total esophagectomy is required for type I esophagogastric junction tumors [see 4.4 *Open Esophageal Procedures*]. The necessary extent of resection for type II and III esophagogastric junction tumors has been more controversial. A microscopically negative (R0) surgical margin is closely associated with survival after resection of esophagogastric junction adenocarcinomas, though R0 resection can be quite difficult to achieve, given the propensity of these tumors for intramural spreading. In our experience, positive margins have not been found in patients with T1 or T2 tumors, even when the margins are smaller than 4 cm. In patients with T3 or T4 tumors, however, proximal margins of at least 6 cm have proved necessary. For T1 and T2 tumors, total gastrectomy without thoracotomy may yield adequate margins. For T3 and T4 tumors, however, extended gastrectomy with thoracotomy or esophagectomy may be required.¹⁴ It is well documented that the margin lengths measured on prefixed esophageal specimens are only about 50% of the corresponding lengths measured *in situ* before completion of resection.¹⁵ Accordingly, intraoperative decisions about the extent of resection should be based on margin length requirements that may be considerably greater than those derived from resection specimens.

Extent of Lymphadenectomy

Considerable controversy has surrounded the question of how extensive lymphadenectomy should be for curative resection of gastric adenocarcinoma. One aspect of the controversy has to do with the minimum number of lymph nodes required for analysis. It has been suggested that a minimum of 15 lymph nodes must be removed during gastrectomy. In a study published in 2000, 5-year survival rates were significantly lower in patients with fewer than 15 lymph nodes sampled than in those with 15 or more lymph nodes examined.¹⁶ This decreased survival has been attributed primarily to understaging as the result of inadequate lymphadenectomy (though, admittedly, there is some disagreement on this point).

The particular lymph node basins that should be sampled during gastrectomy has also been the subject of debate. Western surgeons have usually limited lymphadenectomy to the perigastric (D1) lymph nodes. Surgeons in other countries, particularly Japan, have tended to prefer a much more radical lymph node dissection that includes the second-order (D2) nodes [see Figure 10]. Whereas Japanese surgeons have reported better overall long-term stage-for-stage survival with D2 lymph node dissections, Western surgeons have not found this approach to be quite so beneficial. Consequently, it has not been clear whether more extensive lymph node dissection actually provides a survival benefit or simply improves surgical staging. To date, four randomized, controlled trials have failed to show any significant benefit from extended lymph node dissection. In the largest such study, performed by the Dutch Gastric Cancer Group, more than 700 patients were randomly assigned to undergo either D1 or D2 lymphadenectomy.¹⁷ The 5-year survival rate was essentially the same in the two groups; perioperative morbidity and mortality were significantly higher after D2 lymphadenectomy.

A subsequent study from the same group found that at 10 years after operation, D2 lymphadenectomy provided a benefit (in terms of lower local recurrence) only in the subgroup with positive second-order nodes; however, these patients could not be identified preoperatively.¹⁸ For the cohort as a whole, extended lymph node dissection generated no long-term survival benefit. Therefore, although some surgeons extend the lymphadenectomy to include lymph nodes along the left gastric, celiac, and common hepatic arteries (a so-called D1+ dissection), the standard of care for surgeons in the United States continues to be a D1 lymphadenectomy that includes all perigastric lymph nodes and the greater omentum.

TOTAL GASTRECTOMY

Operative Technique

Step 1: incision and exposure The abdomen is entered via a midline or bilateral subcostal incision. If a subcostal incision is utilized, it may have to be extended past the xiphoid process in the midline for optimal exposure. Thorough exposure of the peritoneal cavity (including the liver, all peritoneal surfaces, and, in women, the ovaries) is undertaken to search for signs of metastatic disease. If the patient has a proximal lesion near the gastric cardia, there may be a need for a thoracotomy if the distal thoracic esophagus is to be included in the resection specimen. If an incision into the thoracic cavity is being considered, the left chest should be surgically prepared at the time of initial draping to allow extension of the incision across the lower left costal margin if desired. In this setting, if thoracotomy is possible, preoperative placement of a double-lumen endotracheal tube should be considered. The abdominal portion of a thoracoabdominal incision should be performed first to allow assessment of resectability.

Step 2: dissection of omentum from colon The omentum is separated from the colon with an electrocautery or scissors through

the relatively avascular plane. Gentle upward traction is placed on the omentum to facilitate entry into the correct surgical plane [see *Figure 11*]. If the procedure involves a formal D2 lymph node dissection, this is also a convenient time to enter the anterior leaf of the transverse mesocolon, which is resected with the anterior covering of the pancreas. (As noted, most U.S. surgeons perform a D1 resection or some modification thereof and thus do not dissect the anterior peritoneal surface of the mesocolon and pancreas.)

With the dissection starting on the right side, the right gastroepiploic artery is identified and ligated where it originates from the gastroduodenal artery. The short gastric vessels are divided as the dissection proceeds along the greater curvature. The lesser omentum is also divided near the liver and is included with the specimen; care should be taken to identify an aberrant left hepatic artery in the lesser omentum (if present). The dissection is continued onto the peritoneal surface of the distal esophagus.

Step 3: division of duodenum The duodenum is divided just distal to the pyloric ring either with a GIA stapler or with a TA stapler applied twice [see *Figure 12*]. The right gastric artery is identified and ligated near its base. Division of the duodenum allows elevation and

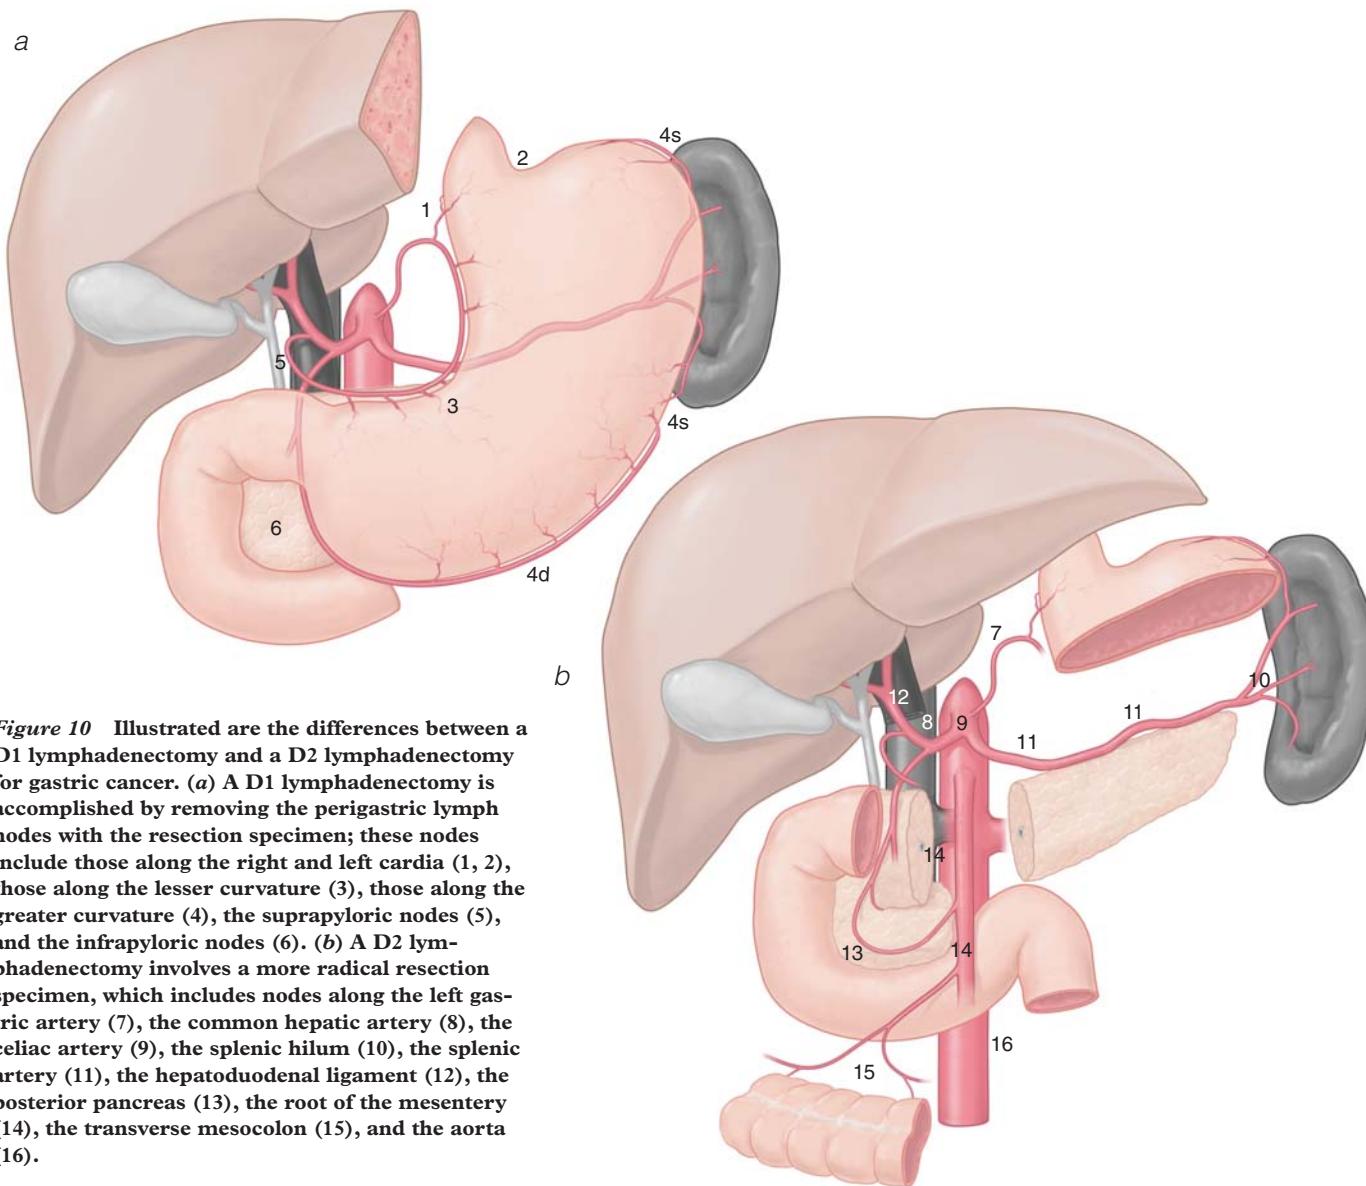

Figure 10 Illustrated are the differences between a D1 lymphadenectomy and a D2 lymphadenectomy for gastric cancer. (a) A D1 lymphadenectomy is accomplished by removing the perigastric lymph nodes with the resection specimen; these nodes include those along the right and left cardia (1, 2), those along the lesser curvature (3), those along the greater curvature (4), the suprapyloric nodes (5), and the infrapyloric nodes (6). (b) A D2 lymphadenectomy involves a more radical resection specimen, which includes nodes along the left gastric artery (7), the common hepatic artery (8), the celiac artery (9), the splenic hilum (10), the splenic artery (11), the hepatoduodenal ligament (12), the posterior pancreas (13), the root of the mesentery (14), the transverse mesocolon (15), and the aorta (16).

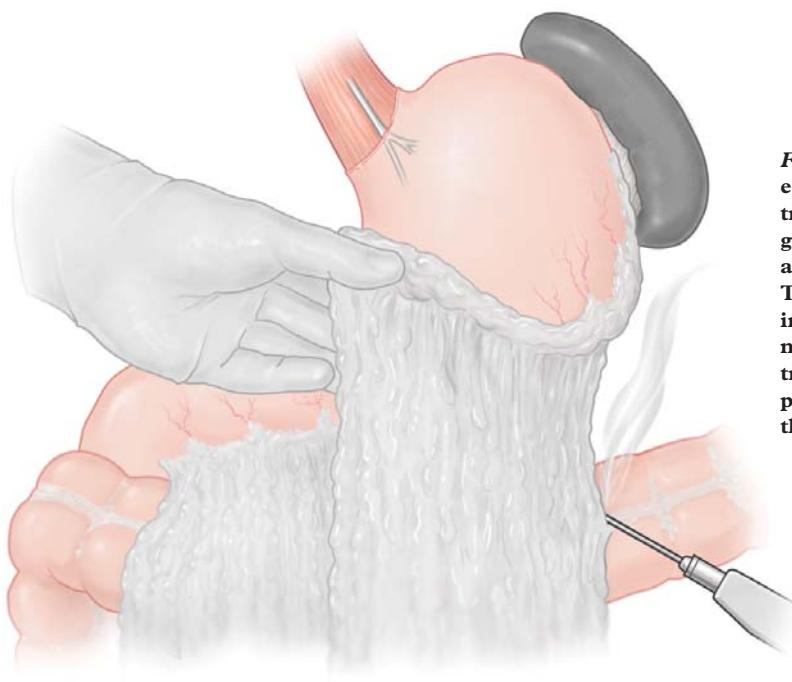

Figure 11 Total gastrectomy. The omentum is dissected from the transverse colon with scissors or the electrocautery. In the course of this dissection, the right gastroepiploic artery is encountered near the pylorus and divided near its base at the gastroduodenal artery. The dissection continues along the greater curvature, including ligation of the short gastric vessels. In a formal D2 lymphadenectomy, the anterior leaf of the transverse mesocolon and the anterior capsule of the pancreas are dissected. In a D1 lymphadenectomy, these structures are left alone.

rotation of the stomach, thereby facilitating access to the left gastric artery and the surrounding node-bearing tissue.

With the stomach gently retracted upward and anteriorly, dissection identifies the celiac axis and the left gastric artery [see Figure 13a]. The origin of the left gastric artery is ligated and divided, and a suture ligature is placed on the proximal end.

A standard D1 lymphadenectomy does not include splenectomy and distal pancreatectomy. The spleen and pancreas are left in situ and are separated from the resection specimen by dividing and ligating the short gastric vessels (see above).

Troubleshooting. Leakage from the duodenal stump is a potentially disastrous complication. If the stapled duodenum appears

ischemic, the staple line may be inverted with Lembert sutures of 3-0 silk.

Step 4: inclusion of necessary lymph nodes The degree of dissection to be performed in the porta hepatis depends on the extent of the planned lymphadenectomy. A D1 lymphadenectomy does not require any of the lymph nodes in this area, but a D1+ lymphadenectomy includes lymph nodes along the common hepatic artery. Gentle left lateral traction is placed on the stomach before division of the left gastric artery to apply some tension to the hepatic artery. The dissection proceeds along the celiac and hepatic arteries to the porta hepatis. The tissue surrounding the common hepatic artery and the left gastric artery is swept medially with the specimen.

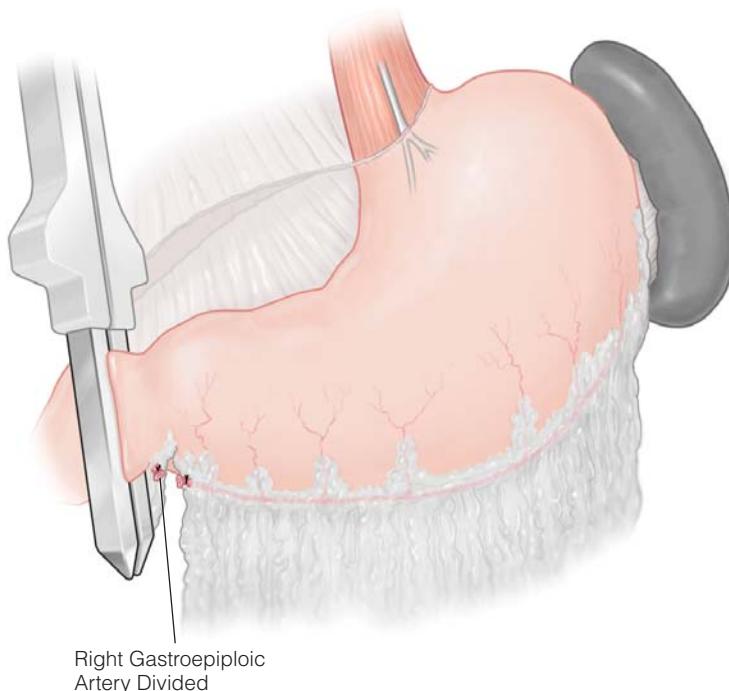

Figure 12 Total gastrectomy. The duodenum is divided just beyond the pylorus with a GIA or TA stapler. The duodenal staple line may be reinforced with interrupted Lembert sutures.

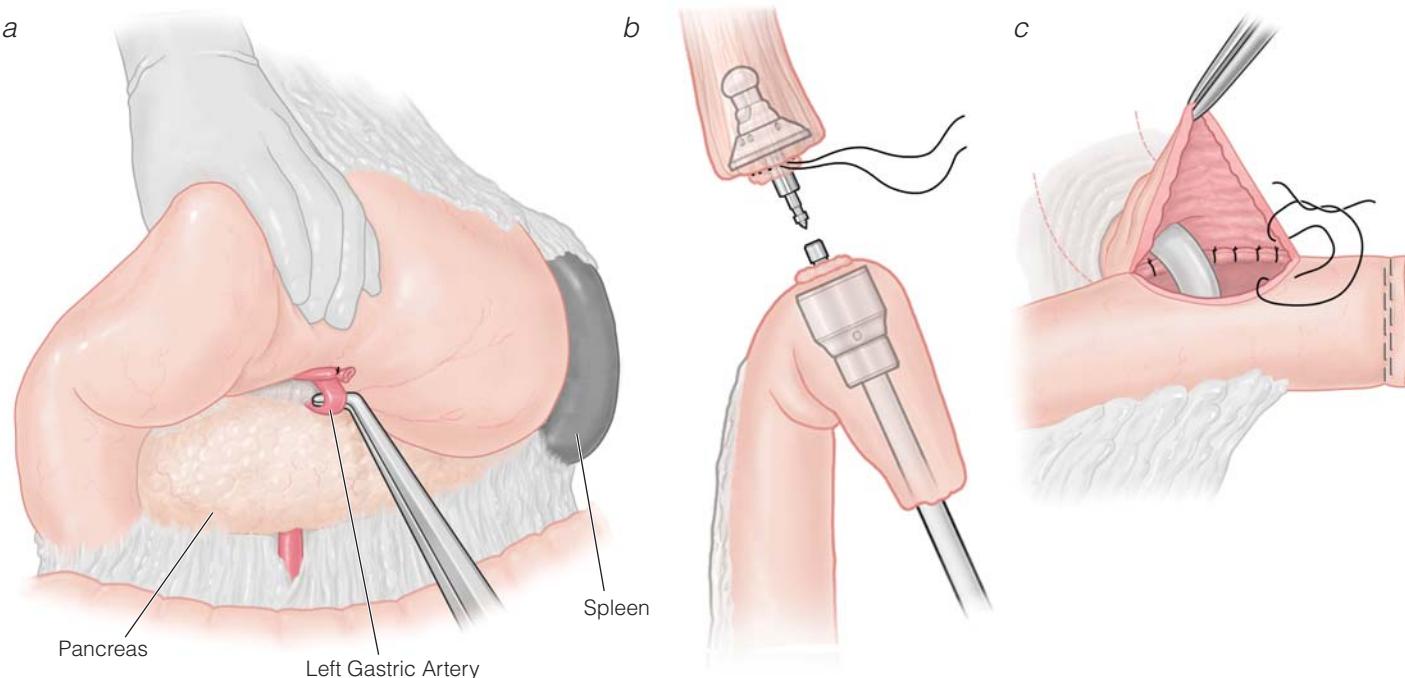

Figure 13 Total gastrectomy. (a) The stomach is retracted cephalad to expose the left gastric vessels, which may be divided and suture-ligated on the proximal side. Division of the distal esophagus should be preceded by placement of several stay sutures on the proximal esophagus to prevent it from retracting into the posterior mediastinum. Reconstruction is then carried out; options include stapled end-to-side esophagojejunostomy, hand-sewn end-to-side esophagojejunostomy, side-to-side esophagojejunostomy, and anastomosis to a jejunal pouch. (b) In a stapled esophagojejunostomy, the anvil is secured in the esophagus with a purse-string suture, an EEA stapler is inserted through the distal end of the Roux limb, and the anastomosis is created to the antimesenteric side of the bowel. Once the anastomosis is complete, the end of the Roux limb is amputated with a single firing of a GIA stapler. (c) A hand-sewn esophagojejunostomy may be fashioned with interrupted full-thickness sutures (as shown), with a continuous full-thickness suture, or as a two-layer anastomosis. After completion of the posterior row, a sump tube may be placed across the anastomosis into the proximal jejunum. After completion of the anterior row, several reinforcing seromuscular sutures may be placed to reduce tension on the anastomosis.

Step 5: division of esophagus The peritoneum is divided over the anterior esophagus, and the esophagus is completely dissected free of surrounding tissue. The esophagus is then divided either with a TA stapler or with a scalpel after the placement of a noncrushing bowel clamp. To keep the stump from retracting too far proximally, stay sutures of 2-0 silk should be placed in the proximal esophagus before division. Alternatively, the specimen may be left attached and used as a handle to retract the proximal esophagus inferiorly. The esophagus may then be divided after placement of the posterior suture line. Evaluation of the proximal resection margin with frozen-section analysis is advisable.

Troubleshooting. The proximal margin may be found to harbor malignancy; if so, re-resection of the proximal margin should be performed. Placement of stay sutures in the proximal esophagus is important; if this is not done, the retracting esophagus may migrate into the posterior mediastinum.

Step 6: reconstruction via esophagojejunostomy The options for reconstruction after gastrectomy include stapled end-to-side esophagojejunostomy, hand-sewn end-to-side esophagojejunostomy, side-to-side esophagojejunostomy, and anastomosis to a jejunal pouch. A Roux-en-Y jejunal limb is fashioned; to prevent biliary reflux, it should be at least 40 to 50 cm long. The Roux limb is then brought up behind the colon to the esophagus. Some authors recommend antecolic placement of the Roux limb to prevent obstruction in the setting of recurrent disease; however, retrocolic placement may facilitate a more tension-free anastomosis.

For a stapled end-to-side esophagojejunostomy, a purse-string

suture of 3-0 or 2-0 polypropylene is placed in the esophagus and used to secure the anvil of an end-to-end anastomosis (EEA) stapler. The body of the stapler is placed into the Roux limb, with the tip protruding through the end, and the esophagojejunostomy is created on the antimesenteric border of the jejunum [see Figure 13b]. The open end of the Roux limb is then closed with a TA stapler. To reduce tension on the anastomosis, the staple line may be reinforced with interrupted Lembert sutures of 3-0 silk.

A hand-sewn end-to-side esophagojejunostomy is created in a similar fashion at a point near the end of the Roux limb on the antimesenteric border. The posterior row is placed first, with interrupted 3-0 silk sutures as the outer layer and interrupted full-thickness 3-0 absorbable sutures as the inner layer [see Figure 13c]. The knots are tied on the inside of the bowel. The anterior row is then placed, with an inner layer of interrupted full-thickness 3-0 absorbable sutures and an outer layer of interrupted 3-0 silk sutures. Some surgeons prefer a single-layer anastomosis, either with a continuous suture or with interrupted full-thickness sutures. The available data do not favor either single-layer or two-layer anastomosis in this setting.

Side-to-side esophagojejunostomy requires a substantial length of intra-abdominal esophagus and necessitates extensive mobilization of the distal esophagus. The jejunum may be sutured to the underside of the diaphragm to relieve tension on the anastomosis.

Some authors report improved postoperative quality of life with a jejunal pouch reconstruction. For most patients with gastric cancer, however, pouch reconstruction offers no distinct advantage.

Drains are not routinely placed; drain placement may increase the rate of leakage from the esophagojejunostomy.

Troubleshooting. Without a sufficient length of intra-abdominal esophagus, primary reconstruction can be difficult. Full mobilization of the intra-abdominal esophagus is essential. Because the esophagus lacks a serosa, transversely oriented Cushing-type sutures may be preferable to Lembert sutures on the anterior and posterior outer layer of a hand-sewn anastomosis.

Step 7 (optional): feeding enterostomy Many patients with gastric adenocarcinoma become significantly malnourished after gastrectomy. The loss of the gastric pouch may adversely affect their ability to fulfill their caloric requirements in the early postoperative period. To prevent further malnutrition, some authors recommend creating a feeding jejunostomy at the time of total gastrectomy with esophagojejunostomy. The jejunostomy should be placed downstream from the jejunoojejunostomy (i.e., more than 50 cm distal to the anastomosis). When a feeding enterostomy is indicated, we prefer a Witzel jejunostomy.

Complications

D2 lymphadenectomy has been associated with numerous complications, including increased blood loss, longer operating time, colonic devascularization, pancreatitis, and pancreatic leakage. Although complication rates appear to be acceptably low when the procedure is done by an experienced surgeon, there is still the potential for the benefits of extensive lymphadenectomy to be outweighed by the additional complications.

Anastomotic leakage at an esophagojejunostomy may lead to postoperative infection. Intra-abdominal leaks may be managed by drainage via percutaneous drains or laparotomy, as well as by proximal nasogastric drainage. High anastomotic leaks may result in contamination of the posterior mediastinum or the pleural space, and thoracotomy or tube thoracostomy may be necessary to achieve external drainage.

Occasionally, bleeding may be substantial enough to necessitate reoperation. In this situation, the gastric remnant may be entered via a transverse incision just proximal to the anastomosis. As a rule, the bleeding can be successfully controlled by placing simple figure-eight sutures.

DISTAL OR SUBTOTAL GASTRECTOMY

Cancers of the distal stomach or antrum may be addressed by means of a distal gastrectomy. Particular attention should be paid to tumors on the lesser curvature, where obtaining an adequate proximal margin may be a problem [see Operative Planning, Extent of Resection, above]. The dissection proceeds as in a total gastrectomy,

but without division of the short gastric vessels. The omentum is separated from the transverse colon with the electrocautery, and the entire omentum is taken with the specimen. A 5 cm proximal margin is ideal. Commonly, the stomach is divided at a point inferior to the short gastric vessels and proximal to the *incisura angularis*.

Additional operative details and comments on postgastrectomy complications are available elsewhere [see Procedures for Benign Gastric and Duodenal Disease, Antrectomy, above].

LAPAROSCOPIC STAGING FOR GASTRIC CANCER

The goal of laparoscopic staging before attempted curative resection of gastric carcinoma is to detect occult metastatic disease, the presence of which may affect management. For example, if laparoscopy reveals peritoneal studding in a patient who does not have symptoms such as bleeding or obstruction, a decision may be made to forgo attempts at resection. In the setting of T2 or T4 tumors, laparoscopic staging has been shown to detect occult metastases in 20% to 30% of patients.¹²

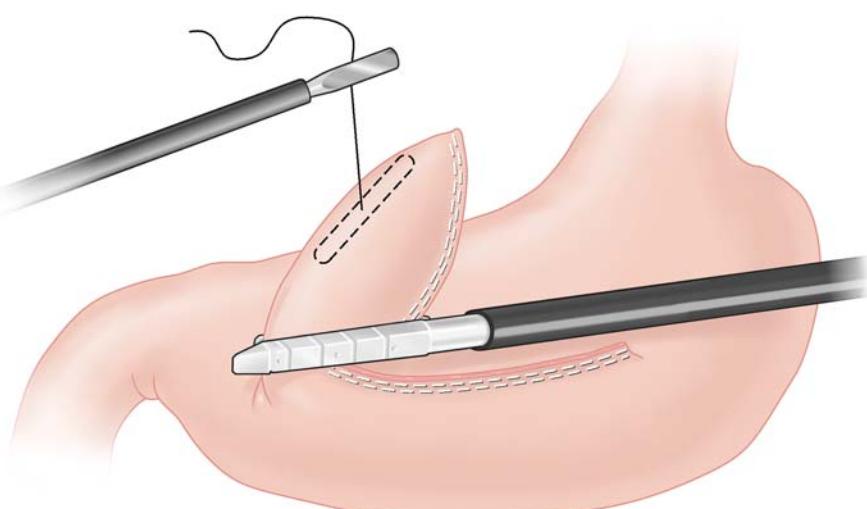

The abdomen is explored with a 30° laparoscope inserted via an umbilical port. To facilitate exposure, additional 5 mm ports may be placed in the right upper and left upper quadrants. If laparoscopic ultrasonography is available, one of the port sites should be 10 mm to allow passage of the ultrasound probe. Any suspicious lesion encountered is sampled and sent for frozen-section analysis.

LAPAROSCOPIC RESECTION OF MALIGNANT GASTRIC TUMORS

Laparoscopic gastrectomy is being performed with increasing frequency. The principles of laparoscopic gastric resection are similar to those of the corresponding open procedure, though extensive lymph node dissections may be considerably more difficult with the minimally invasive approach. Currently, there are only a few centers where laparoscopic resection of advanced gastric carcinoma is being performed with any frequency. Accordingly, it seems appropriate, for the time being, to reserve laparoscopic gastrectomy for patients who have very early cancers and those who are candidates only for palliative resection.

Laparoscopic wedge resection may be appropriate for small lesions that are potentially benign or for malignant lesions for which extensive surgical margins are not required (e.g., GISTs [see Figure 14]). The lesion is visualized intraoperatively by means of endoscopy or marked preoperatively with India ink. Laparoscopic sutures are placed in the tissue surrounding the lesion, then retracted upward so that the portion of the gastric wall containing the lesion is elevated. A

Figure 14 Laparoscopic resection of GIST. The tumor is visualized preoperatively and marked with India ink; alternatively, the tumor may be identified intraoperatively by means of endoscopy and its location marked with a suture. Traction sutures may be employed to "tent up" the lesion, thereby isolating it from the remainder of the stomach. The tumor is then resected with several firings of an endoscopic linear stapler. For lesions higher along the greater curvature near the cardia, wedge resection should be performed with an esophageal bougie in place to prevent inadvertent narrowing of the esophagogastric junction.

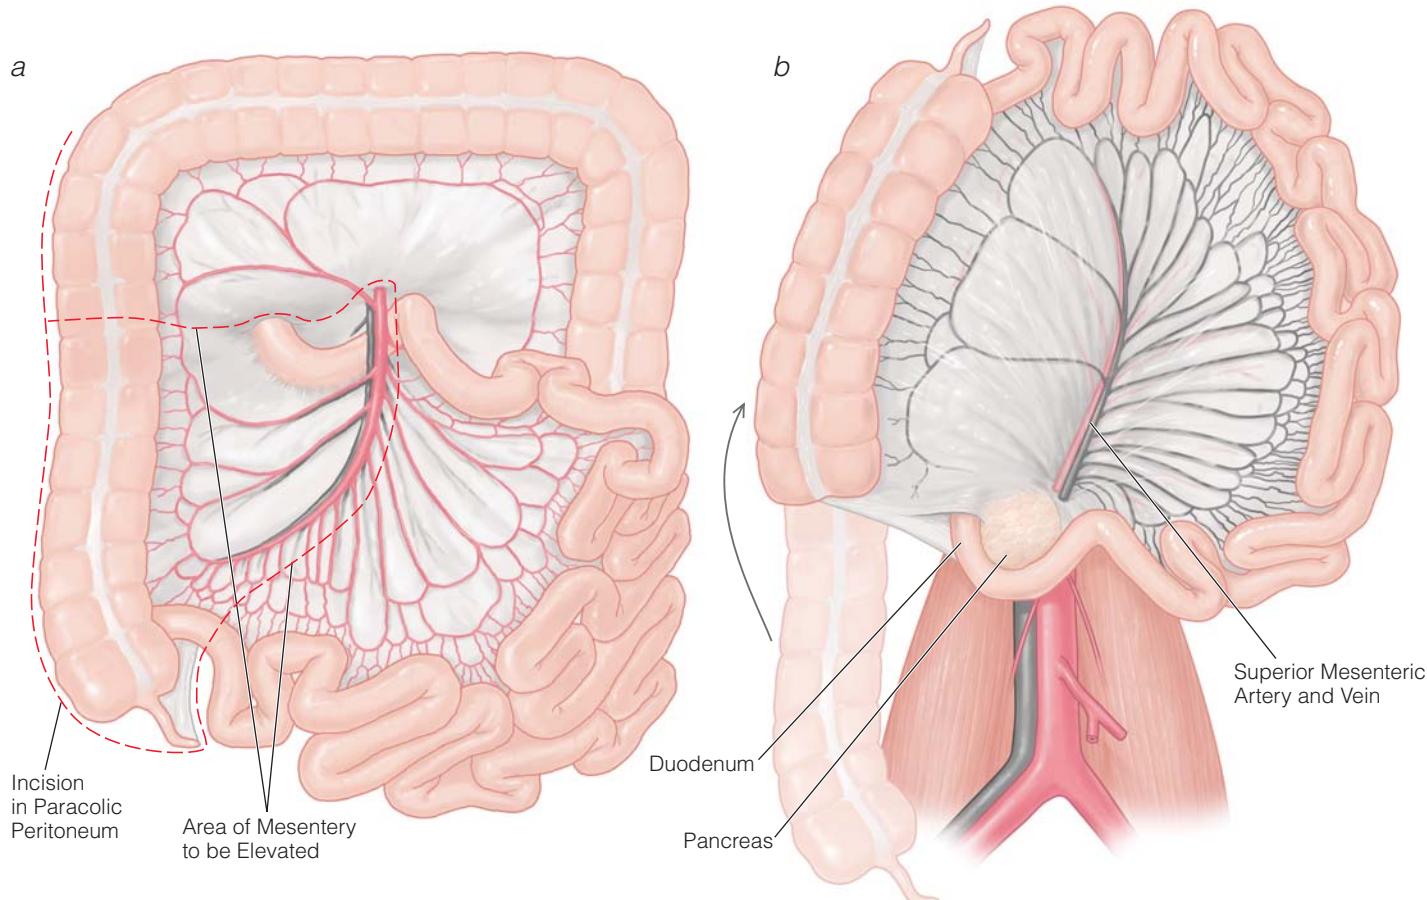

Figure 15 Local resection of duodenal tumors. Mobilization of the right colon and upward retraction of the small bowel mesentery allows direct access to the third and fourth portions of the duodenum. Sleeve resection of the duodenum with subsequent duodenojejunostomy can then be performed. (a) Avascular peritoneal attachments of the right colon are divided, as well as avascular attachments underneath the small bowel mesentery. Dotted lines enclose the area of mesentery to be elevated from posterior attachments. (b) Cephalad retraction of the right colon, the small bowel, and the mesenteric vessels allows exposure of the third and fourth portions of the duodenum.

wedge resection is then performed with an endoscopic stapler. Intraoperative assessment of the surgical margin by a pathologist is useful to ensure that the margin is negative.

Procedures for Duodenal Cancer

LOCAL RESECTION OF DUODENAL TUMORS

Small duodenal tumors (e.g., polyps, villous adenomas, small GISTs, and neuroendocrine tumors) are occasionally amenable to local surgical resection. The diagnosis must be confirmed by endoscopic biopsy before resection. Endoscopy is also useful for localization of the lesion with respect to the ampulla and pancreatic head. Lateral lesions are removed by local resection far more easily than lesions on the medial wall are.

Operative Planning

Endoscopic confirmation of the diagnosis and localization of the lesion are crucial for operative planning. In addition, appropriate patient selection is essential. Local resection may be inappropriate for lesions close to the ampulla of Vater, for large duodenal lesions, for carcinomas, or for lesions on the medial aspect of the duodenum abutting the pancreas. For lesions in the second or third portion of the duodenum that are not amenable to local excision, pancreaticoduodenectomy may be required. Exposure may be achieved through an upper midline or right upper quadrant incision.

denectomy may be required. Exposure may be achieved through an upper midline or right upper quadrant incision.

Operative Technique

The duodenum is mobilized with an extensive Kocher maneuver. The tumor is palpated and approached via a longitudinal duodenotomy. The tumor is grasped and everted, and a full-thickness portion of the duodenal wall is resected with the mass. Stay sutures are placed at the ends of the duodenotomy, and the duodenotomy is closed transversely, either with a TA stapler or with sutures. If a transverse closure would place too much tension on the suture line, a longitudinal closure is undertaken. If possible, omentum is placed over the duodenal closure.

Troubleshooting

Intraoperative endoscopy may be required to locate small duodenal lesions that cannot be palpated. During dissection, the location of the ampulla can be determined by passing a Fogarty catheter into the cystic duct, down the CBD, and through the ampulla. This measure requires that a cholecystectomy be done.

RESECTION OF DISTAL DUODENAL TUMORS

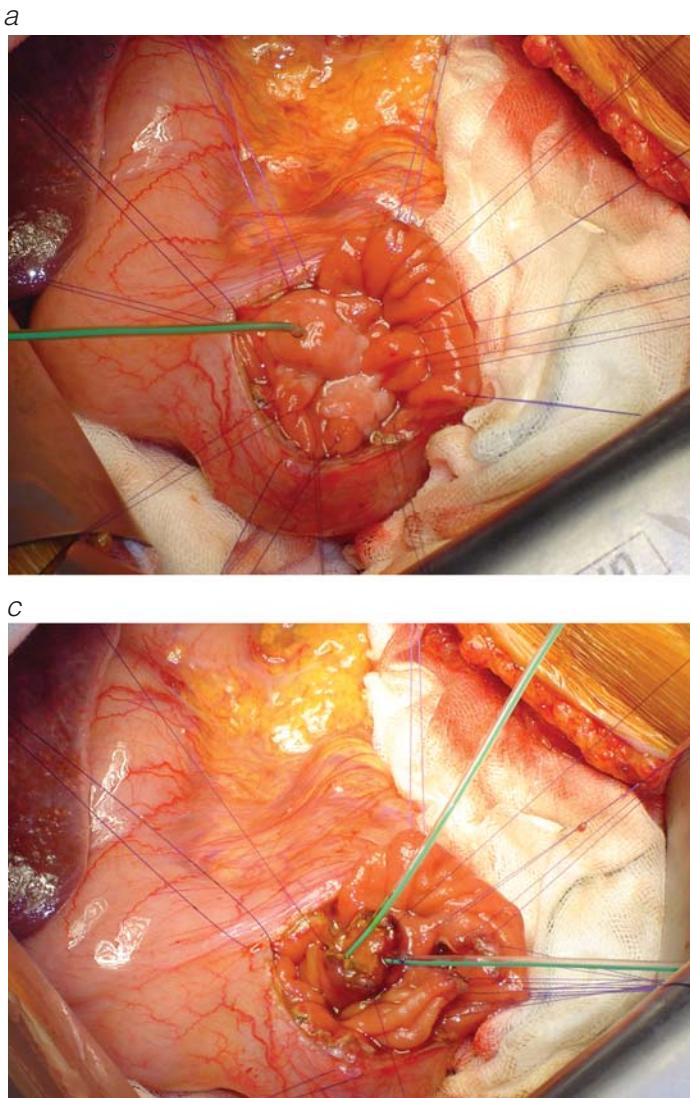

Lesions of the distal duodenum (e.g., GISTs, carcinoids, and, rarely, adenocarcinomas) are occasionally amenable to sleeve resection. Preop-

erative CT and endoscopy are essential to the workup of such lesions. Endoscopic biopsy should be performed if it is technically feasible.

Operative Technique

Step 1: exposure of duodenum Operative access to the distal duodenum is limited by the presence of the superior mesenteric vessels and the transverse mesocolon. The third and fourth portions of the duodenum may be approached either by moving the duodenum under the mesenteric vessels or by temporarily mobilizing the mesenteric vessels. In the first approach, the distal duodenum and the proximal jejunum are mobilized upward by dissecting the ligament of Treitz away from its mesenteric attachments. The proximal jejunum is divided with a stapler. After extensive mobilization, the duodenum is passed under the superior mesenteric vein and artery and moved to the right side of the abdomen.

In the second approach, the superior mesenteric vessels are mobilized upward to expose the third portion of the duodenum. The right colon is mobilized cephalad by incising the peritoneum along the white line of Toldt from the hepatic flexure to the cecum [see Figure 15a]. Division of the peritoneum is then continued along the cecum and medially to liberate the terminal ileum. The avascular attachments between the small bowel mesentery and the retroperitoneum are divided by means of cauterization and gentle blunt dissection [see Figure 15b].

Step 2: resection and anastomosis The duodenum is divided with the stapler approximately 1 cm proximal to the tumor. If pancreatic invasion is identified, pancreaticoduodenectomy should be considered. The distal bowel is brought through the transverse mesocolon, and a side-to-side duodenojejunostomy is created with an outer layer of 3-0 silk and inner layer of 3-0 polyglaclin. Alternatively, the anastomosis may be performed to the second portion of the duodenum.

Troubleshooting

The blood supply to the third portion of the duodenum arises from numerous branches of the inferior pancreaticoduodenal arcade, each of which must be meticulously dissected, divided, and ligated to prevent pancreatic trauma. The distal duodenum receives its blood supply from branches of the superior mesenteric artery.

The duodenum should not be simply closed distally and drained via a gastrojejunostomy; if this is done, the proximal duodenum will not be properly decompressed.

Complications

Delayed gastric emptying is common with duodenojejunostomy; it generally responds to prolonged conservative therapy. A delay in the return of bowel function should generally be treated with nasogastric suction; on occasion, a percutaneous gastrostomy

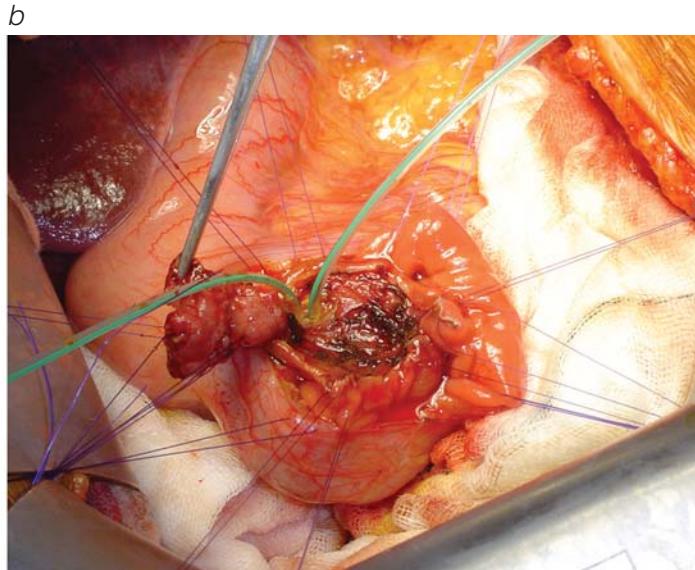

Figure 16 Ampullectomy. (a) After a longitudinal duodenotomy is made, the CBD is cannulated. Circumferential stay sutures of 4-0 polydioxanone are placed in the duodenal mucosa. A 2 cm periampullary tumor is visualized. (b) The ampullary tumor is removed from the underlying duodenum with the electrocautery. The CBD and the pancreatic duct are entered and separately cannulated. The CBD duct is typically seen at the 11 o'clock position, and the pancreatic duct is typically encountered at the 3 o'clock position. (c) The duodenal mucosa is sutured directly to the CBD and the pancreatic duct with 4-0 polydioxanone. In addition, the CBD and pancreatic duct are carefully connected with 4-0 polydioxanone sutures.

is required for proximal decompression. Postoperative pancreatitis may occur secondary to operative trauma; conservative management is usually sufficient.

AMPULLECTOMY

Local periamppillary resection is indicated primarily for rare benign lesions, small neuroendocrine tumors of the pancreas, and small adenomatous or villous polyps. The likelihood of occult malignancy in an adenomatous periamppillary tumor is significantly higher when the lesion is larger than 2 cm; caution is therefore indicated in attempting local resection of lesions of this size. The recurrence rate is high after local resection of any periamppillary adenocarcinoma. The preoperative workup should include endoscopy with biopsy, EUS or transabdominal ultrasonography, CT scanning, and endoscopic retrograde cholangiopancreatography (ERCP).

Operative Technique

The ampulla of Vater is resected together with the distal CBD and

the distal pancreatic duct [see Figure 16]. A Kocher maneuver is performed, and a longitudinal duodenotomy is made to expose the ampulla. Identification of the ampulla may be facilitated by placing a Fogarty catheter in the CBD via the cystic duct after a cholecystectomy. If the ampulla is identified during exploration, it may simply be cannulated. Circumferential stay sutures are placed in the mucosa. The CBD is entered at approximately the 11 o'clock position, and duodenal mucosa is reattached to the duct with 4-0 polydioxanone sutures. The pancreatic duct is encountered at approximately the 3 o'clock position; it may be cannulated separately to facilitate identification. The pancreatic duct is approximated to the CBD, and the inferior pancreatic duct is sewn to the duodenal wall. The duodenum is closed transversely in two layers.

Troubleshooting

Frozen-section analysis may identify invasive adenocarcinoma, which is an indication for pancreaticoduodenectomy. This possibility should be carefully considered before the operation.

21 CHOLECYSTECTOMY AND COMMON BILE DUCT EXPLORATION

Gerald M. Fried, M.D., F.A.C.S., Liane S. Feldman, M.D., F.A.C.S., and Dennis R. Klassen, M.D.

Cholecystectomy is the treatment of choice for symptomatic gallstones because it removes the organ that contributes to both the formation of gallstones and the complications ensuing from them.¹ The morbidity associated with cholecystectomy is attributable to injury to the abdominal wall in the process of gaining access to the gallbladder (i.e., the incision in the abdominal wall and its closure) or to inadvertent injury to surrounding structures during dissection of the gallbladder. Efforts to diminish the morbidity of open cholecystectomy have led to the development of laparoscopic cholecystectomy, made possible by modern optics and video technology.

Carl Langenbuch performed the first cholecystectomy in Berlin, Germany, in 1882. Erich Mühe performed the first laparoscopic cholecystectomy in Germany in 1985,² and by 1992, 90% of cholecystectomies in the United States were being performed laparoscopically. Compared with open cholecystectomy, the laparoscopic approach has dramatically reduced hospital stay, postoperative pain, and convalescent time. However, rapid adoption of laparoscopic cholecystectomy as the so-called gold standard for treatment of symptomatic gallstone disease was associated with complications, including an increased incidence of major bile duct injuries.

Since the early 1990s, considerable advances have been made in instrumentation and equipment, and a great deal of experience with laparoscopic cholecystectomy has been amassed worldwide. Of particular significance is the miniaturization and improvement of optics and instruments, which has reduced the morbidity of the procedure by making possible ever-smaller incisions. With proper patient selection and preparation, laparoscopic cholecystectomy is being safely performed on an outpatient basis in many centers.³

The primary goal of cholecystectomy is removal of the gallbladder with minimal risk of injury to the bile ducts and surrounding structures. Our approach is designed to maximize the safety of both routine and complicated cholecystectomies. In what follows, we describe our approach and discuss current indications and techniques for imaging and exploring the common bile duct (CBD).

Laparoscopic Cholecystectomy

PREOPERATIVE EVALUATION

To plan the surgical procedure, assess the likelihood of conversion to open cholecystectomy, and determine which patients are at high risk for CBD stones, the surgeon must obtain certain data preoperatively. Useful information can be obtained from the patient's history, from imaging studies, and from laboratory tests.

Preoperative Data

History and physical examination A good medical history provides information about associated medical problems that

may affect the patient's tolerance of pneumoperitoneum. Patients with cardiorespiratory disease may have difficulty with the effects of CO₂ pneumoperitoneum on cardiac output, lung inflation pressure, acid-base balance, and the ability of the lungs to eliminate CO₂. Most bleeding disorders can also be identified through the history. A disease-specific history is important in identifying patients in whom previous episodes of acute cholecystitis may make laparoscopic cholecystectomy more difficult, as well as those at increased risk for choledocholithiasis (e.g., those who have had jaundice, pancreatitis, or cholangitis).⁴⁻⁹

Physical examination identifies patients whose body habitus is likely to make laparoscopic cholecystectomy difficult and is helpful for determining optimal trocar placement. Abdominal examination also reveals any scars, stomas, or hernias that are likely to necessitate the use of special techniques for trocar insertion.

Imaging studies Ultrasonography is highly operator dependent, but in capable hands, it can provide useful information. It is the best test for diagnosing cholelithiasis, and it can usually determine the size and number of stones.⁴ Large stones indicate that a larger incision in the skin and the fascia will be necessary to retrieve the gallbladder. Multiple small stones suggest that the patient is more likely to require operative cholangiography (if a policy of selective cholangiography is practiced) [see Operative Technique, Step 5, below]. A shrunken gallbladder, a thickened gallbladder wall, and pericholecystic fluid on ultrasonographic examination are significant predictors of conversion to open cholecystectomy. The presence of a dilated CBD or CBD stones preoperatively is predictive of choledocholithiasis. Other intra-abdominal pathologic conditions, either related to or separate from the hepatic-biliary-pancreatic system, may influence operative planning.

Preoperative imaging studies of the CBD may allow the surgeon to identify patients with CBD stones before operation. Such imaging may involve endoscopic retrograde cholangiopancreatography (ERCP) [see 5:18 *Gastrointestinal Endoscopy*],¹⁰ magnetic resonance cholangiopancreatography (MRCP) [see Figure 1],^{11,12} or endoscopic ultrasonography (EUS). These imaging modalities also provide an anatomic map of the extrahepatic biliary tree, identifying unusual anatomy preoperatively and helping the surgeon plan a safe operation. Endoscopic sphincterotomy (ES) is performed during ERCP if stones are identified in the CBD. MRCP has an advantage over ERCP and EUS in that it is noninvasive and does not make use of injected iodinated contrast solutions.¹¹ Most surgeons would probably recommend that preoperative cholangiography be performed selectively in patients with clinical or biochemical features associated with a high risk of choledocholithiasis. The specific modality used in such a case varies with the technology and expertise available locally.

Laboratory tests Preoperative blood tests should include

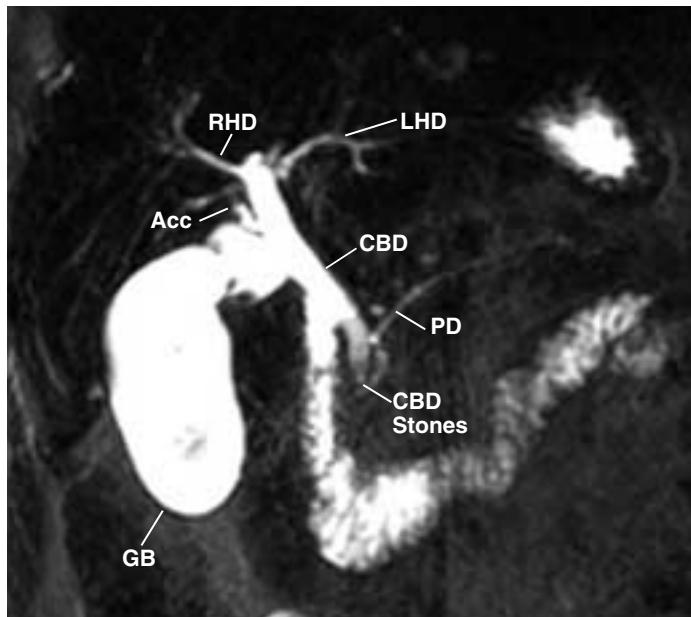

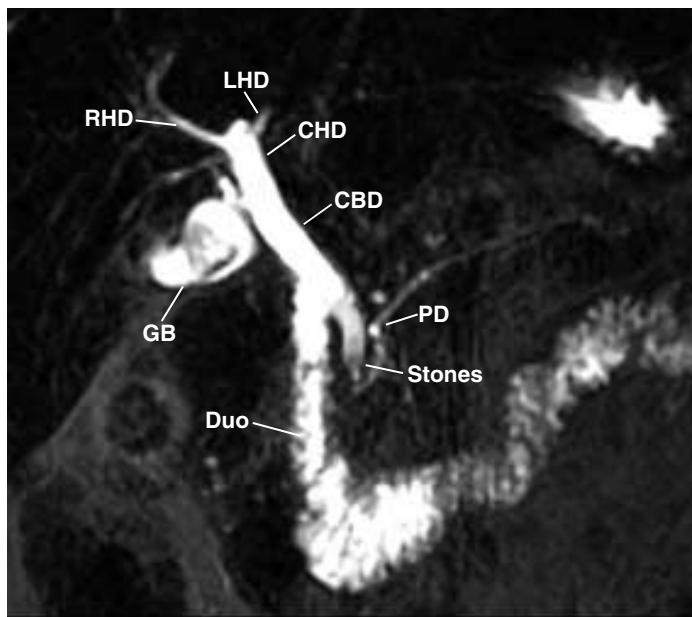

Figure 1 Laparoscopic cholecystectomy. Preoperative MRCP alerts the surgeon to abnormal anatomy and the presence of stones in the distal CBD. (GB—gallbladder, containing stones; RHD—right hepatic duct; LHD—left hepatic duct; CHD—common hepatic duct; Acc—accessory duct entering common hepatic duct near neck of gallbladder; PD—pancreatic duct; Duo—duodenum)

liver function, renal function, electrolyte, and coagulation studies. Abnormal liver function test results may reflect choledocholithiasis or primary hepatic dysfunction.

Selection of Patients

Patients eligible for outpatient cholecystectomy Patients in good general health who have a reasonable amount of support from family or friends and who do not live too far away from adequate medical facilities are eligible for outpatient cholecystectomy, especially if they are at low risk for conversion to laparotomy [see Special Problems, Conversion to Laparotomy, below].³ These patients can generally be discharged home from the recovery room 6 to 12 hours after surgery, provided that the operation went smoothly, their vital signs are stable, they are able to void, they can manage at least a liquid diet without vomiting, and their pain can be controlled with oral analgesics.

Technically challenging patients Before performing laparoscopic cholecystectomy, the surgeon can predict which patients are likely to be technically challenging. These include patients who have a particularly unsuitable body habitus, those who are highly likely to have multiple and dense peritoneal adhesions, and those who are likely to have distorted anatomy in the region of the gallbladder.

Morbidly obese patients present specific difficulties [see Operative Technique, Step 1, Special Considerations in Obese Patients, below].¹³ Small, muscular patients have a noncompliant abdominal wall, resulting in a small working space in the abdomen and necessitating high inflation pressures to obtain reasonable exposure.

Patients with a history of multiple abdominal operations, especially in the upper abdomen, and those who have a history of peritonitis are likely to pose difficulties because of peritoneal adhesions.¹⁴ These adhesions make access to the abdomen more risky and exposure of the gallbladder more difficult. Patients who have undergone gastroduodenal surgery, those who have any history of acute cholecystitis, those who have a long history of recurrent gall-

bladder attacks, and those who have recently had severe pancreatitis are particularly difficult candidates for laparoscopic cholecystectomy. These patients may have dense adhesions in the region of the gallbladder, the anatomy may be distorted, the cystic duct may be foreshortened, and the CBD may be very closely and densely adherent to the gallbladder. Such patients are a challenge to the most experienced laparoscopic surgeon. When such problems are encountered, conversion to open cholecystectomy should be considered early in the operation.^{14,15}

Predictors of choledocholithiasis CBD stones may be discovered preoperatively, intraoperatively, or postoperatively. The surgeon's goal is to clear the ducts but to use the smallest number of procedures with the lowest risk of morbidity. Thus, before elective laparoscopic cholecystectomy, it is desirable to classify patients into one of three groups: high risk (those who have clinical jaundice or cholangitis, visible choledocholithiasis, or a dilated CBD on ultrasonography), moderate risk (those who have hyperbilirubinemia, elevated alkaline phosphatase levels, pancreatitis, or multiple small gallstones), and low risk.

In our institution, where MRCP and EUS are available and reliable and where ERCP achieves stone clearance rates higher than 90%, we recommend the following approach: (1) preoperative ERCP and sphincterotomy (if required) for high-risk patients and (2) MRCP, EUS, or intraoperative fluoroscopic cholangiography for moderate-risk patients. Patients at low risk for CBD stones do not routinely undergo cholangiography [see Figure 2]. Laparoscopic CBD exploration and postoperative ERCP appear to be equally effective in clearing stones from the CBD.

Ultimately, surgeons and institutions must establish a reasonable approach to choledocholithiasis that takes into account the expertise and equipment locally available.

Contraindications There are few absolute contraindications to laparoscopic cholecystectomy. Certainly, no patient who poses an unacceptable risk for open cholecystectomy should be

considered for laparoscopic cholecystectomy, because it is always possible that conversion will become necessary. Of the relative contraindications, surgical inexperience is the most important.

Neither ascites nor hernia is a contraindication to laparoscopic cholecystectomy. Ascites can be drained and the gallbladder visualized. Large hernias may present a problem, however, because with insufflation, the gas preferentially fills the hernia. Patients with large inguinal hernias may require an external support to minimize this problem and the discomfort related to pneumosrotum. Patients with umbilical hernias can have their hernias repaired while they are undergoing laparoscopic cholecystectomy. For such patients, the initial trocar should be placed by open insertion according to the Hasson technique [see Operative Technique, Step 1, below], with care taken to avoid injury to the contents of the hernia. The sutures required to close the hernia defect can be placed before insertion of the initial trocar. A similar technique can be applied to patients with incisional hernias, although for large incisional hernias, laparoscopic cholecystectomy may have no advantages over open cholecystectomy if a large incision and dissection of adhesions are required. Patients with stomas may also undergo laparoscopic cholecystectomy, provided that the appropriate steps are taken to prevent injury to the bowel during placement of trocars and division of adhesions.

Patients with cirrhosis or portal hypertension are at high risk for morbidity and mortality with open cholecystectomy.^{16,17} If absolutely necessary, laparoscopic cholecystectomy may be attempted by an experienced surgeon. The risk of bleeding can be minimized by rigorous preoperative preparation, meticulous dissection with the help of magnification available through the laparoscope, and use of the electrocautery.

Patients with bleeding diatheses, such as hemophilia, von Willebrand disease, and thrombocytopenia, may undergo laparoscopic cholecystectomy. They require appropriate preoperative and postoperative care and monitoring, and a hematologist should be consulted.

Questions have been raised about whether laparoscopic cholecystectomy should be performed in pregnant patients; it has been

argued that the increased intra-abdominal pressure may pose a risk to the fetus. Because of the enlarged uterus, open insertion of the initial trocar is mandatory, and the positioning of other trocars may have to be modified according to the position of the uterus. Inflation pressures should be kept as low as possible, and prophylaxis of deep vein thrombosis (DVT) is recommended. Despite these potential problems, safe performance of laparoscopic cholecystectomy and other laparoscopic procedures in pregnant patients is increasingly being described in the literature. If cholecystectomy is necessary before delivery, the second trimester is the best time for it.¹⁸⁻²¹

Patients in whom preoperative imaging gives rise to a strong suspicion of gallbladder cancer should probably undergo open surgical management.

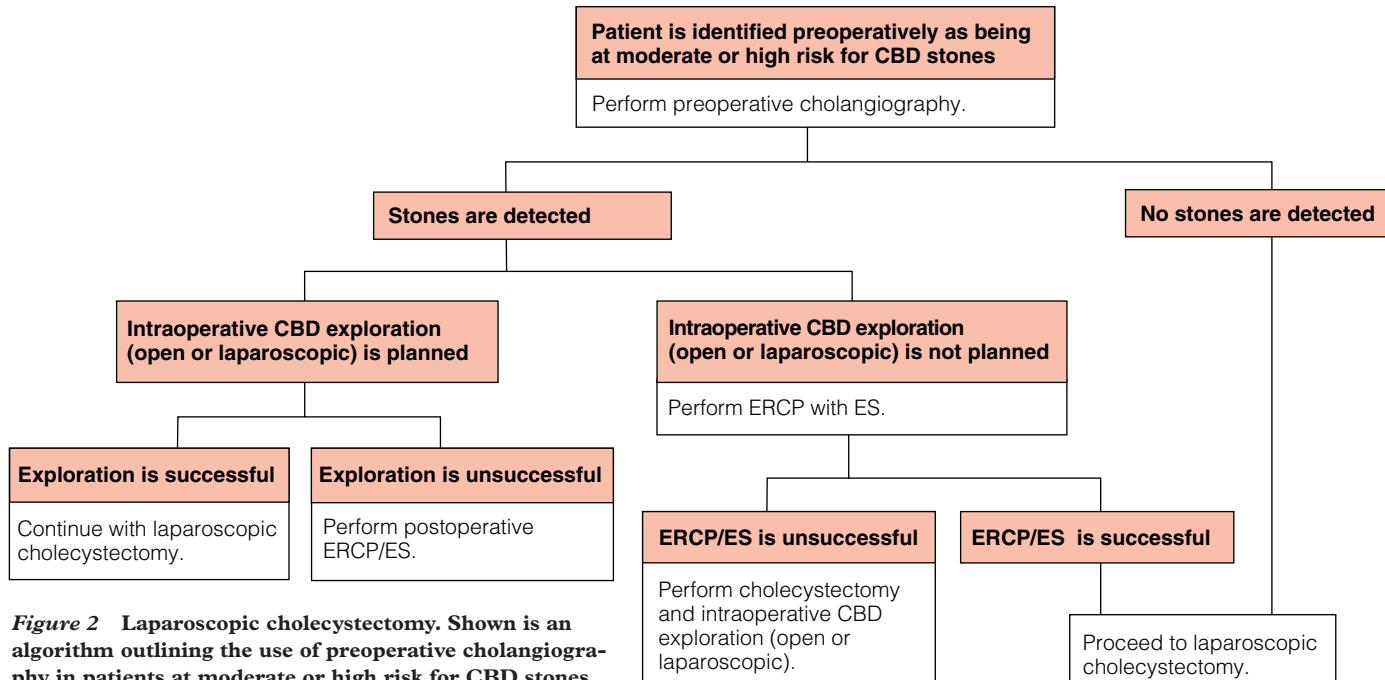

OPERATIVE PLANNING

Antibiotic Prophylaxis

Some surgeons recommend routine preoperative administration of antibiotics to all patients undergoing cholecystectomy, on the grounds that inadvertent entry into the gallbladder is not uncommon and can lead to spillage of bile or stones into the peritoneal cavity. Other surgeons do not recommend routine prophylaxis. Resolution of this controversy awaits appropriate prospective trials. We recommend selective use of antibiotic prophylaxis for patients at highest risk for bacteria in the bile (including those with acute cholecystitis or CBD stones, those who have previously undergone instrumentation of the biliary tree, and those older than 70 years) and for patients with prosthetic heart valves and joint prostheses.

Prophylaxis of DVT

The reverse Trendelenburg position used during laparoscopic cholecystectomy, coupled with the positive intra-abdominal pressure generated by CO₂ pneumoperitoneum and the vasodilatation induced by general anesthesia, leads to venous pooling in the lower extremities. This consequence may be minimized by using antiem-

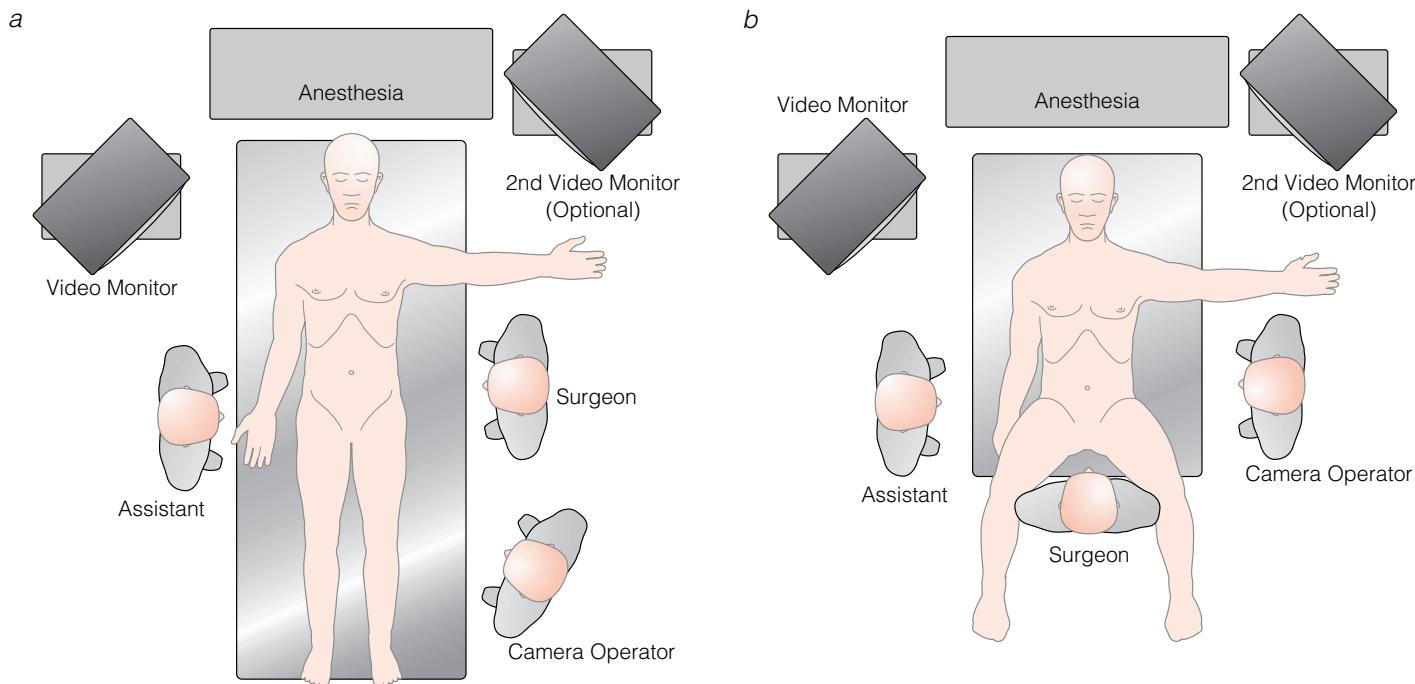

Figure 3 Laparoscopic cholecystectomy. A patient undergoing laparoscopic cholecystectomy should be positioned so as to allow easy access to the gallbladder and a clear view of the monitors. Shown are the positions of the surgeon, the camera operator, and the assistant in the OR according to (a) North American positioning and (b) European positioning.

bolic stockings or by wrapping the legs with elastic bandages. Subcutaneous heparin and pneumatic compression devices may be employed for patients at increased risk for DVT [see 6.6 Venous Thromboembolism]. As yet, however, there is no convincing evidence that the incidence of DVT is higher with laparoscopy than with open surgery.

Patient Positioning

In North American positioning, the patient is lying supine and the surgeon is positioned on the patient's left side [see Figure 3a]. In European positioning, the patient is in low stirrups and the surgeon is on the patient's left or between the patient's legs [see Figure 3b].

With North American positioning, the camera operator usually stands on the patient's left and to the left of the surgeon, while the assistant stands on the patient's right. The video monitor is positioned on the patient's right above the level of the costal margin. If a second monitor is available, it should be positioned on the patient's left to the right of the surgeon, where the assistant can have an unobstructed and comfortable view. Exposure can be improved by tilting the patient in the reverse Trendelenburg position and rotating the table with the patient's right side up. Gravity pulls the duodenum, the colon, and the omentum away from the gallbladder, thereby increasing the working space available in the upper abdomen.

The OR table should allow easy access for a fluoroscopic C arm, to facilitate intraoperative cholangiography. The table cover should be radiolucent.

Equipment

The equipment required for laparoscopic cholecystectomy includes an optical system, an electronic insufflator, trocars (cannulas), surgical instruments, and hemostatic devices [see Table 1].

Optical system The laparoscope can provide either a straight, end-on (0°) view or an angled (30° or 45°) view. Scopes that provide an end-on view are easier to learn to use, but angled scopes are more versatile. Scopes with a 30° angle cause less disorientation than those with a 45° angle and are ideal for laparoscopic cholecystectomy. Excellent 30° scopes are currently available in diameters of 10 mm, 5 mm, and 3.5 mm.

Fully digital flat-panel displays are now available that yield better resolution than analog video monitors, take up less space, are less subject to signal interference, and require less power.

The resolution and quality of the final image depend on (1) the brightness of the light source; (2) the integrity of the fiberoptic cord used to convey the light; (3) clean and secure connections between the light source and the scope; (4) the quality of the laparoscope, the camera, and the monitor; and (5) correct wiring of the components. The distal end of the scope must be kept clean and free of condensation: bile, blood, or fat will reduce brightness and distort the image. Lens fogging can be prevented by immersion in heated water or by antifogging solutions.

Insufflator CO_2 is the preferred insufflating gas for laparoscopic procedures because it is highly soluble in water and it does not support combustion when the electrocautery is used. The CO_2 should be insufflated with an electronic pump capable of a flow rate of at least 6 L/min; most current systems have a maximum flow rate of 20 L/min or higher. The insufflator is connected to one of the trocars by means of a flexible tube and a stopcock.

Trocars For cholecystectomy, at least one trocar site must be large enough to allow passage of the gallbladder and any stones removed. Most surgeons prefer to use a 10/12 mm trocar at the umbilicus for this purpose. The other trocars can range from 2 to 12 mm, depending on the size of the instruments to be placed through them. The conventional approach is to use a 10/12 mm

Table 1 Equipment for Laparoscopic Cholecystectomy

Instrument/Device	Number	Size	Comments
Laparoscopic cart High-intensity halogen light source (150–300 watts) High-flow electronic insufflator (minimum flow rate of 6 L/min) Laparoscopic camera box Videocassette recorder (optional) Digital still image capture system (optional)			
Laparoscope	1	3.5–10 mm	Available in 0° and angled views; we prefer to use a 30° 5 mm diameter laparoscope
Atraumatic grasping forceps	2–4	2–10 mm	Selection of graspers should allow surgeon choice appropriate to thickness and consistency of gallbladder wall; insulation is unnecessary
Large-tooth grasping forceps	1	10 mm	Used to extract gallbladder at end of procedure
Curved dissector	1	2–5 mm	Should have a rotatable shaft; insulation is required
Scissors	2–3	2–5 mm	One curved and one straight scissors with rotating shaft and insulation; additional microscissors may be helpful for incising cystic duct
Clip applicators	1–2	5–10 mm	Either disposable multiple clip applicator or 2 manually loaded reusable single clip applicators for small and medium-to-large clips
Dissecting electrocautery hook or spatula	1	5 mm	Available in various shapes according to surgeon's preference; instrument should have channel for suction and irrigation controlled by trumpet valve(s); insulation required
High-frequency electrical cord	1		Cord should be designed with appropriate connectors for electrosurgical unit and instruments being used
Suction-irrigation probe	1	5–10 mm	Probe should have trumpet valve controls for suction and irrigation; may be used with pump for hydrodissection
10-to-5 mm reducers	2		Allow use of 5 mm instruments in 10 mm trocar without loss of pneumoperitoneum; these are often unnecessary with newer disposable trocars and may be built into some reusable trocars
5-to-3 mm reducer	1		Allows use of 2–3 mm instruments and ligating loops in 5 mm trocars
Ligating loops			
Endoscopic needle holders	1–2	5 mm	
Cholangiogram clamp with catheter	1	5 mm	Allows passage of catheter and clamping of catheter in cystic duct
Veress needle	1		Used if initial trocar is inserted by percutaneous technique
Allis or Babcock forceps	1–2	5 mm	Allow atraumatic grasping of bowel or gallbladder
Long spinal needle	1	14-gauge	Useful for aspirating gallbladder percutaneously in cases of acute cholecystitis or hydrops
Retrieval bag	1		Useful for preventing spillage of bile or stones in removal of inflamed or friable gallbladder; facilitates retrieval of spilled stones

trocar at the operating port site and 5 mm trocars for the other instruments; however, if a 5 mm laparoscope and a 5 mm clip applier are used, the operating port size can be reduced to 5 mm. Although 2 mm instrumentation is also available, it must be remembered that as a rule, the smaller the working port, the less versatile the instruments. In our experience, the combination of a 10 mm umbilical trocar, a 5 mm operating port, and 2 mm ports for grasping forceps is a good one: optical quality is maintained, little flexibility is lost with respect to selecting operating instruments, trocar size is minimized, and the cosmetic result is excellent.

Hemostatic devices Hemostasis can be achieved with monopolar or bipolar electrocauterization. A monopolar electrocautery can be connected to most available instruments; however, bipolar electrocauterization may eventually prove safer. With a monopolar electrocautery, depth of burn is less predictable, current can be conducted through noninsulated instruments and tro-

cars, and any area of the instrument that is stripped of insulation may conduct current and result in a burn. Caution is essential when the electrocautery is used near metallic hemostatic clips because delayed sloughing may occur.

Electrocauterization should be avoided near the CBD because delayed bile duct injuries and leaks may occur as a result of sloughing from a burned area and devascularization of the duct. Care must be exercised when a cautery is employed near the bowel and when intra-abdominal adhesions are being taken down. The electrocautery can be used with a forceps, scissors, hooks (L or J shaped), a spatula, and other instruments. Some cautery probes incorporate nonstick surfaces to prevent buildup of eschar. The use of hand-activated cautery probes and the presence of a channel that allows suction and irrigation through the cautery probes are especially convenient.

More advanced energy sources and instruments are also available. Bipolar devices designed to weld tissues have proved capable

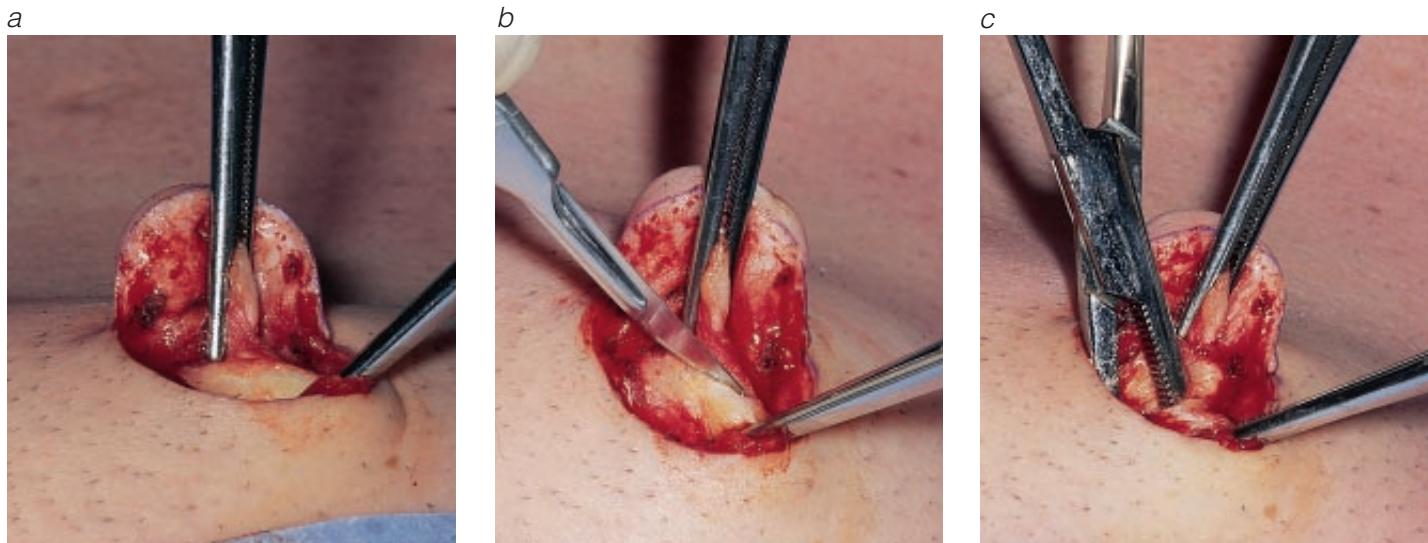

Figure 4 Laparoscopic cholecystectomy. With the open insertion technique, the initial trocar is placed under direct vision. (a) The umbilical skin is elevated with a sharp towel clip. A curvilinear incision is made in the inferior umbilical fold. The skin flap is elevated, and the raphe leading from the dermis to the fascia is thereby exposed. (b) The fascia is grasped in the midline between forceps and elevated. The fascia and the underlying peritoneum are incised under direct vision. (c) A blunt instrument is placed into the peritoneum to ensure that the undersurface of the peritoneum is free of adhesions. The opening can be enlarged sufficiently to allow placement of a blunt 10/11 mm trocar.

of achieving superb hemostasis. Ultrasonic dissecting shears can also be used to dissect and coagulate tissues effectively and precisely. For laparoscopic cholecystectomy, however, such advanced—and costly—devices are rarely needed.

OPERATIVE TECHNIQUE

Step 1: Placement of Trocars and Accessory Ports

Placement of initial trocar The first step in laparoscopic cholecystectomy is the creation of pneumoperitoneum and the insertion of an initial trocar through which the laparoscope can be passed. This step is critical because complications resulting from improper placement may cause serious morbidity and death. The surgeon may use either a percutaneous technique or an open technique. We prefer the open technique, which eliminates the risks inherent in the blind puncture [see Figure 4].^{22,23}

Scars Patients who have previously undergone abdominal surgery may have adhesions, both to the undersurface of the abdominal wall and intra-abdominally. Adhesions to the undersurface of the abdominal wall make access to the abdominal cavity potentially hazardous, particularly when the percutaneous method is used for placement of the initial trocar. Scars from previous operations may affect insertion of the initial trocar, depending on its orientation and location. If a patient has a scar in the lower abdomen (e.g., from a Pfannenstiel incision or an incision in the right lower quadrant for an appendectomy), the position of the initial trocar need not be changed. If the scar is in the upper abdomen, the initial trocar may be inserted below the umbilicus in the midline. If there is a long midline scar that is impossible to avoid, careful dissection of the peritoneum through a vertical incision that is somewhat longer than usual affords safe access to the peritoneum in most cases.

An alternative is to insert the initial trocar high in the epigastrium or in the right anterior axillary line, where bowel adhesions are less common. The laparoscope is inserted through this trocar and

used to examine the undersurface of the old scar for a clear site near the umbilicus where a 10 mm trocar can be placed. Previous laparoscopy, which rarely creates significant intra-abdominal adhesions, rarely necessitates modification of trocar insertion.

The surgeon should also consider the reason for the previous surgery. For example, a patient who underwent an appendectomy for perforating appendicitis may have had diffuse peritonitis and may have adhesions well away from the old scar.

Placement of accessory ports In most cases, four ports are necessary. The first port is for the laparoscope; the remaining ports are for grasping forceps, dissectors, and clip appliers. The precise position of the accessory ports depends on the surgeon's preference, the patient's body habitus, and the presence or absence of previous scars or intra-abdominal adhesions. A rigid approach to port placement is inappropriate: trocar placement determines operative exposure, and improper placement will haunt the surgeon throughout the procedure. In some cases, a fifth trocar is required to elevate a floppy liver or to depress or retract the omentum or a bulky hepatic flexure of the colon. In trocar placement, as in patient positioning, European practice tends to differ from North American practice [see Figure 5].

Most surgeons elect to place one of the grasping forceps on the fundus of the gallbladder through an accessory port placed approximately in the anterior axillary line below the level of the gallbladder. Because the level of the gallbladder varies from patient to patient, the placement of this accessory port should not be decided on until the gallbladder is visualized. If the gallbladder is low lying and the trocar is placed too high, the surgeon will have difficulty achieving the appropriate angle of retraction. As a general rule, positioning the trocar in the anterior axillary line approximately halfway between the costal margin and the anterosuperior iliac spine provides the appropriate exposure. A 2 to 5 mm port usually suffices at this site because its only likely function is to allow retraction of the gallbladder. In some cases of acute cholecystitis, however, a larger port may be preferable, so that a larger grasper

can be inserted and used to hold the gallbladder without tearing it.

A second accessory port (also 2 to 5 mm) allows the surgeon to grasp the gallbladder in the area of Hartmann's pouch for retraction. This port is usually positioned just beneath the right costal margin. Some surgeons prefer it to be approximately at the mid-clavicular line; others prefer it to be higher and more medial, just to the right of the falciform ligament.

The main operating port should be 5 or 10 mm in diameter, so that clip appliers can be readily placed through it and the laparoscope can be moved to this port at the end of the procedure. The positioning of this port is determined by the surgeon's preference and, in particular, by the patient's body habitus. The optimum placement is at about the same horizontal level as the gallbladder or slightly higher, so that during the operation, the laparoscope and the operating instrument form an angle of about 90°. Some surgeons prefer to place the operative port in the midline, to the right of the falciform ligament; others prefer to place it to the left of the falciform, passing the trocar underneath the ligament and elevating it with the trocar.

Surgeons should be encouraged to use both hands when performing laparoscopic cholecystectomy. One hand should control the grasping forceps holding Hartmann's pouch, so that the gallbladder can be moved to provide the best possible exposure. The other hand should control the dissecting instruments placed through the operating port.

Special considerations in obese patients Port placement in obese patients may be complicated by the thick abdominal wall, the large amount of intra-abdominal fat, or both. A thick abdominal wall makes it more difficult to rotate the trocar around the normal fulcrum point in the abdominal wall. Consequently, the trocar must be placed at the angle most likely to be used during the procedure. When a trocar is tunneled through the abdominal

wall, more of the cannula is within the abdominal wall than if the trocar had been placed perpendicularly; accordingly, the trocar is less mobile. If the trocars are not easily rotated, the instruments placed through them will be difficult to manipulate smoothly. Thus, in the patient with a very thick pannus, a standard-length trocar may be too short. Displacement of trocars can lead to insufflation into the abdominal wall and consequently to subcutaneous emphysema, which further thickens the abdominal wall and hinders exposure.

To prevent such problems, special extra-length trocars designed for morbidly obese patients have been developed. It may also be necessary to place the trocars closer to the area of the gallbladder to ensure that the operating instruments can reach the gallbladder. For example, the initial port may have to be placed above the umbilicus.

In obese patients, the bulky falciform ligament and the large omentum may adversely affect exposure. A 30° laparoscope may help the surgeon see over the omentum and the high-lying hepatic flexure of the colon. In some cases, it is useful to place a fifth port so that the surgeon can retract the hepatic flexure downward. Fat may envelop the cystic duct and artery and the portal structures, obscuring normal anatomic landmarks. When the electrocautery is used, the heat melts the fat and causes it to sizzle and spray onto the lens of the laparoscope, resulting in a blurry image. To prevent this, the camera operator should pull the scope slightly away from the operative field during electrocauterization, then advance the scope during dissection. This should also be done when an ultrasonic dissector is being used.

Given that obese patients are more difficult candidates for open cholecystectomy and have a higher complication rate with laparotomy, the advantages of laparoscopic cholecystectomy in these individuals justify the effort needed to overcome the technical problems.

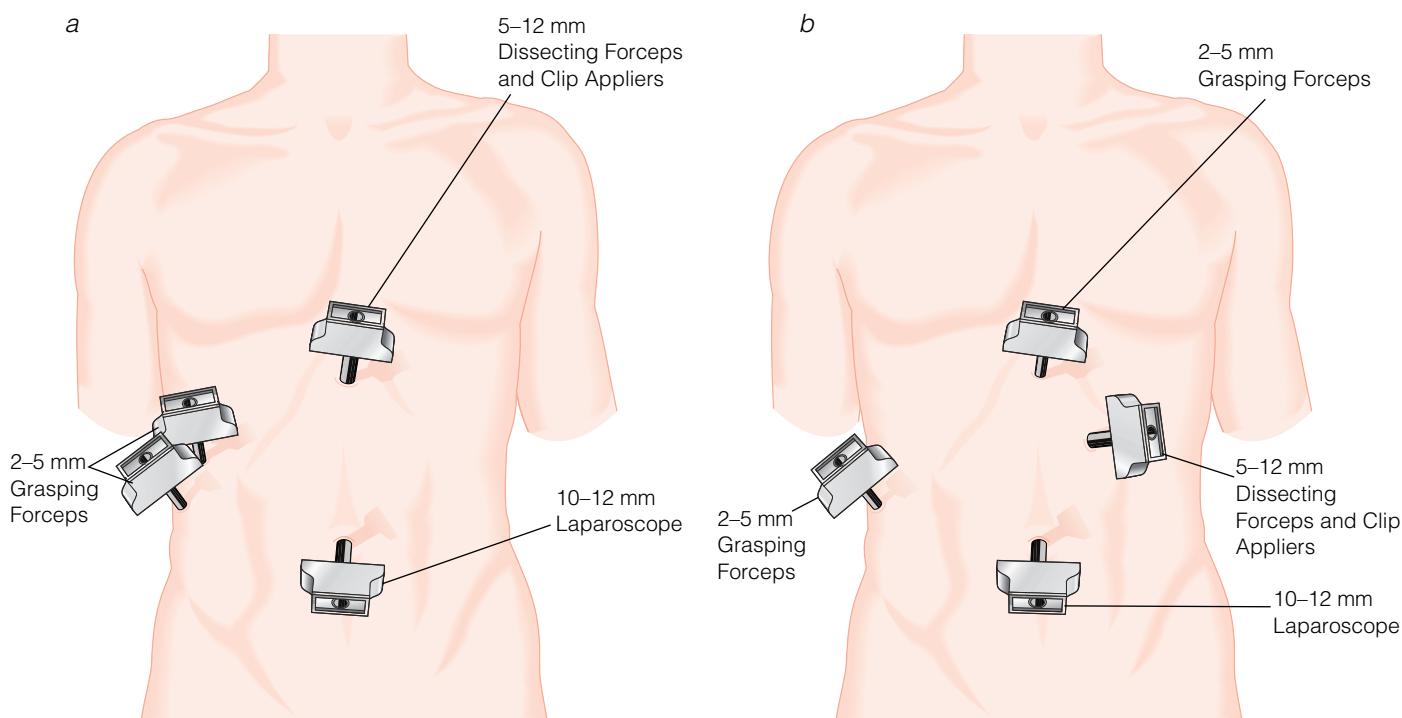

Figure 5 Laparoscopic cholecystectomy. Illustrated are the differences between typical North American practice (a) and typical European practice (b) with respect to the placement of the trocars and the instruments inserted through each port.

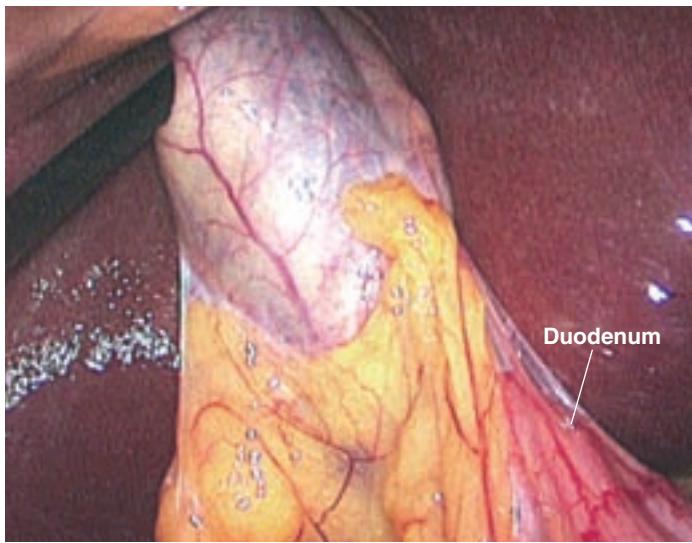

Figure 6 Laparoscopic cholecystectomy. Adhesions of duodenum and omentum to gallbladder wall obscure view of structures of Calot's triangle.

Step 2: Exposure of Gallbladder and Calot's Triangle

Dissection of adhesions Adhesions must be dissected to provide an unimpeded view of the gallbladder through the laparoscope. Not all intra-abdominal adhesions must be taken down, just enough to allow entry of accessory trocars under direct vision and thus permit access to the gallbladder. This process is facilitated by pneumoperitoneum, which provides traction on adhesions to the abdominal wall, and by the magnification provided by the optical system, which allows identification of the avascular plane of attachment.

The most difficult problem is positioning the dissecting instruments so that they can reach the undersurface of the anterior abdominal wall. A rigid trocar inserted through the anterior abdominal wall cannot be rotated enough to allow scissors passed through this port to cut adhesions to the anterior abdominal wall. In such cases, one or two trocars should be placed laterally, near the anterior axillary or midaxillary line. Instruments passed through these ports can easily be angled parallel to the anterior abdominal wall, and the adhesions can then be dissected without difficulty.

Bowel adhesions should be taken down with endoscopic scissors at their insertion to the abdominal wall, where they are least vascular. Electrocauterization, generally unnecessary, should be avoided because of the risk of thermal injury to the bowel. Interloop adhesions, which rarely interfere with exposure of the gallbladder, need not be dissected. Frequently, adhesions to the gallbladder occur as a reaction to inflammatory attacks [see Figure 6]. They are usually relatively avascular. Dissection of these adhesions should begin at the fundus of the gallbladder and should then proceed down toward the neck of the gallbladder. The best way to take them down is to grasp the gallbladder with one grasping forceps at the site where the adhesions attach and gradually place traction on the adhesions with the other hand. Usually, the adhesions peel down in an avascular plane. Dissection should continue until all adhesions to the inferolateral aspect of the gallbladder have been taken down. It is not necessary to divide adhesions between the superior surface of the liver and the undersurface of the diaphragm unless they impede superior retraction of the liver.

Exposing Calot's triangle Obtaining adequate exposure of Calot's triangle is a key step. First, the patient is placed in a reverse Trendelenburg position, with the table rotated toward the left side. Next, the fundus of the gallbladder and the right lobe of the liver are elevated toward the patient's right shoulder. One grasping forceps, inserted through the most lateral right-side port and held by an assistant, is placed on the fundus of the gallbladder [see Figure 7], and the gallbladder is retracted superiorly and laterally above the right hepatic lobe. This maneuver straightens out folds in the body of the gallbladder and permits initial visualization of the area of Calot's triangle. If Calot's triangle is still obscured, the patient can be placed in a steeper reverse Trendelenburg position, the stomach can be emptied of air via an orogastric tube inserted by the anesthetist, or, if necessary, a fifth trocar can be inserted on the patient's right side to push down the duodenum.

In some patients, such as those with acute cholecystitis and hydrops of the gallbladder, the gallbladder is tense and distended, making it difficult to grasp and easy to tear. In these patients, retraction of the fundus is difficult, and exposure of Calot's triangle is unsatisfactory. This problem is best managed by aspirating the contents of the gallbladder either percutaneously with a 14- or 16-gauge needle inserted into the fundus of the gallbladder under laparoscopic vision or by using the 5 mm trocar in the right upper abdomen to puncture the fundus and then aspirate with the suction irrigator. After the needle is withdrawn, a largeatraumatic grasping forceps can be used to hold the gallbladder and occlude the hole; a 10 mm forceps may be preferred if the wall is markedly thickened. An alternative is to place a stitch or a ligating loop around the fundus of the collapsed gallbladder; the tail of the suture can then be grasped with a forceps to achieve a secure grip and also prevent further leakage of gallbladder contents from the needle hole.

Once the fundus of the gallbladder is retracted superiorly by the assistant, the surgeon places a grasping forceps in the area of Hartmann's pouch. Using both hands, the surgeon controls the grasper on Hartmann's pouch as well as the operating instrument. The surgeon maneuvers Hartmann's pouch to provide various angles for safe dissection of Calot's triangle. Initially, lateral and

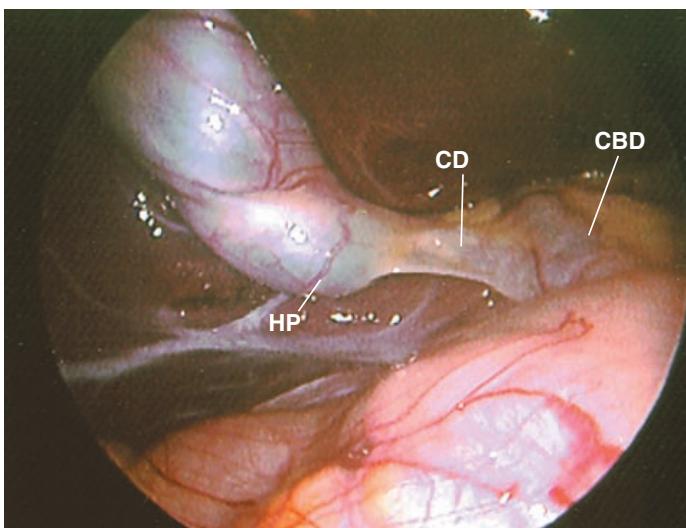

Figure 7 Laparoscopic cholecystectomy. Initial view of gallbladder and related structures is facilitated by appropriate tilting of the operating table. Hartmann's pouch (HP), the cystic duct (CD), and the common bile duct (CBD) can be readily identified before any dissection.

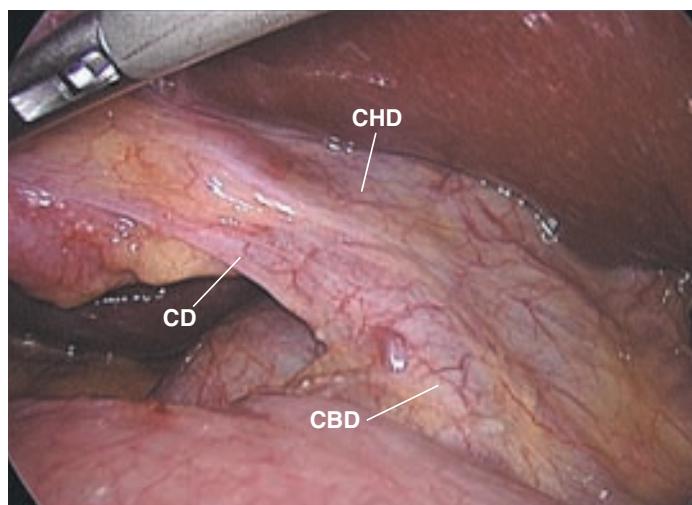

Figure 8 Laparoscopic cholecystectomy. The area of Hartmann's pouch is retracted laterally. The cystic duct (CD) is seen at an angle to the common hepatic duct (CHD) and the common bile duct (CBD).

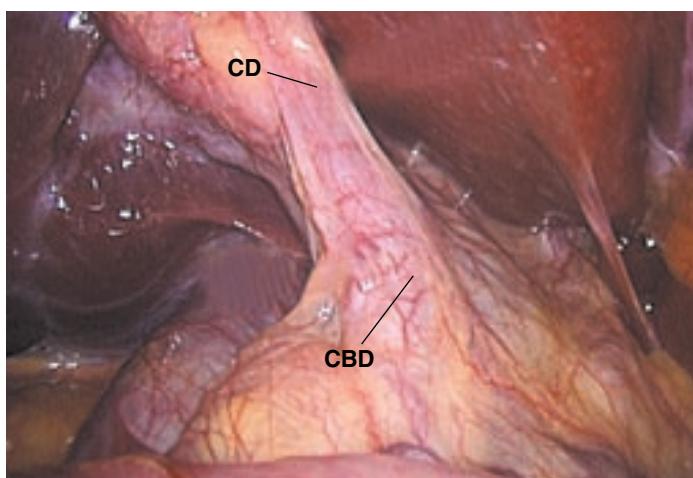

Figure 9 Laparoscopic cholecystectomy. In this case, the gallbladder is retracted cephalad. The cystic duct (CD) can be seen running in the same direction as the common bile duct (CBD). The CBD may be misinterpreted as being the cystic duct and consequently is at risk for injury.

inferior traction are placed on Hartmann's pouch, opening up the angle between the cystic duct and the common ducts [see Figure 8], avoiding their alignment [see Figure 9].

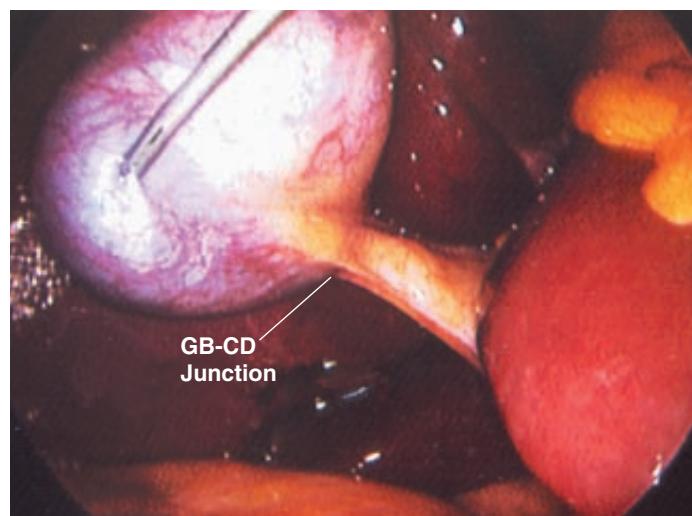

A large stone impacted in the gallbladder neck may impede the surgeon's ability to place the forceps on Hartmann's pouch. This problem can usually be managed by dislodging the stone early in the operation, as follows: the gallbladder is grasped as low as possible with one grasping forceps; a widely opening dissecting instrument, such as a right-angle dissector, a Babcock forceps, or a curved dissector, is used to dislodge the stone and milk it up toward the fundus; with the same forceps or another large grasper, the stone is held up and away from the neck of the gallbladder, and appropriate retraction is provided.

If the stone cannot be disimpacted, an instrument can be used to elevate the infundibulum of the gallbladder superiorly, allowing exposure of Calot's triangle. Alternatively, one can attempt to crush the stone, but small pieces of the stone may fall into the cys-

tic duct. A third option is to place a stitch in Hartmann's pouch and grasp the end of the stitch to provide exposure.

Step 3: Stripping of Peritoneum

The key to avoiding injury to the major ducts during laparoscopic cholecystectomy is accurate identification of the junction between the gallbladder and the cystic duct [see Figure 10]. Unless the gallbladder–cystic duct junction is immediately obvious upon examination of Calot's triangle anteriorly, our approach is to begin dissection of Calot's triangle posteriorly [see Figure 11]. From this approach, the insertion of the gallbladder neck into the cystic duct is usually more clearly identified, especially with the aid of a 30° laparoscope. Exposure is obtained by retracting Hartmann's

pouch superomedially and is facilitated by looking from below with a 30° scope.

Dissection should always start high on the gallbladder and hug

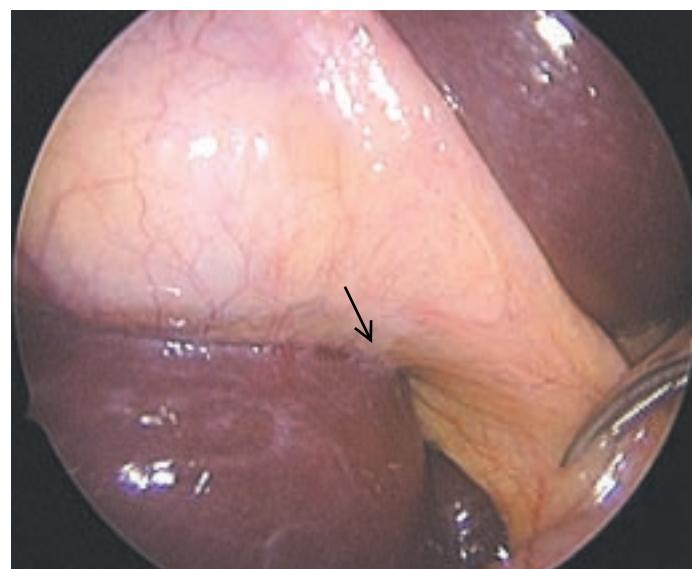

Figure 11 Laparoscopic cholecystectomy. A view from below with a 30° laparoscope demonstrates the point for beginning dissection (arrow), where the gallbladder funnels down to its junction with the cystic duct. Just below this point can be seen a cleft in the liver known as Rouvier's sulcus. This cleft, present in 70% to 80% of livers, reliably indicates the plane of the CBD.

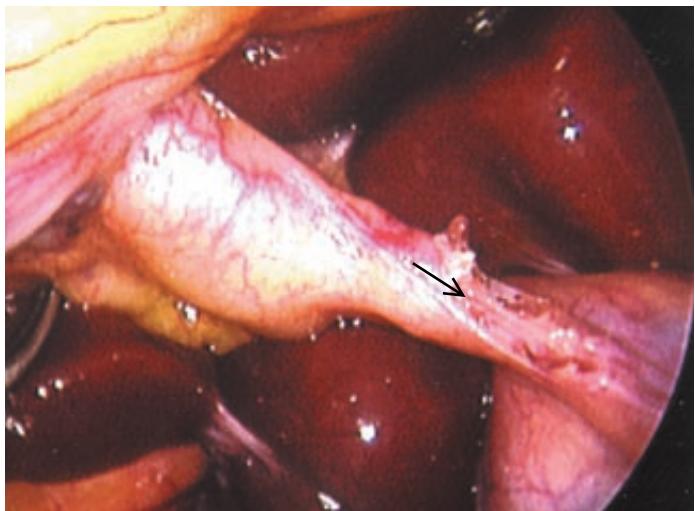

Figure 12 Laparoscopic cholecystectomy. The peritoneum is dissected from the gallbladder–cystic duct junction (arrow), as seen from below through a 30° angled laparoscope.

Figure 13 Laparoscopic cholecystectomy. Arterial bleeding can be seen (arrow) from a branch of the cystic artery injured during dissection from the posterior approach.

the gallbladder closely until the anatomy is identified clearly. Using a curved dissector, the surgeon gently teases away peritoneum attaching the neck of gallbladder to the liver posterolaterally to visualize the funneling of the neck of the gallbladder into the cystic duct [see Figure 12]. Only the posterior layer of peritoneum is dissected; care must be taken not to dissect deeply in this area because of the risk of injury to the cystic artery [see Figure 13].

In some problem cases, edema, fibrosis, and adhesions make identification of the gallbladder–cystic duct junction very difficult. An anatomic landmark on the liver known as Rouvier's sulcus may be helpful in such circumstances [see Figure 11]. This sulcus, or the remnant of it, is present in 70% to 80% of livers and usually contains the right portal triad or its branches. Its location is consistently to the right of the hepatic hilum and anterior to the caudate process (Couinaud segment 1). This landmark reliably indicates the plane of the CBD. Therefore, dissection dorsal to it should be done with caution. Once the funneling of the gallbladder into the cystic duct has been identified, the area of Hartmann's pouch

should be again pulled laterally and inferiorly so that the anterior peritoneum can be dissected, while the 30° scope is angled to view the area. The two-handed technique facilitates the surgeon's movement between the posterior and anterior aspects of Calot's triangle, providing complete visualization. Dissection should always take place at the gallbladder–cystic duct junction, staying close to the gallbladder to avoid inadvertent injury to the CBD. A curved dissecting forceps is used to strip the fibroareolar tissue just superior to the cystic duct. The superior border of the cystic duct can then be identified and the cystic duct gently and gradually dissected [see Figure 14]. The cystic duct lymph node is a useful landmark at this location and may facilitate identification of the gallbladder–cystic duct junction.

When traction is placed as described, the cystic artery tends to run parallel and somewhat cephalad to the cystic duct. This artery can often be identified by noting its close relation to the cystic duct lymph node. Complete dissection of the area between the cystic duct and the artery develops a window through which the liver should be visible. The cystic duct is then encircled with a curved dissecting instrument or an L-shaped hook. Downward traction should be applied to the cystic duct to open this window and ensure that there is no ductal structure running through this space in Calot's triangle to join the cystic duct (i.e., the right hepatic duct).

Dissection of Calot's triangle should be completed before the cystic duct is clipped or divided. This is best accomplished by dissecting the neck of the gallbladder from the liver bed. Unequivocal identification of the gallbladder–cystic duct junction is imperative.^{24,25} The cystic duct should be dissected for a length sufficient to permit secure placement of two clips; it is not necessary, and indeed may be hazardous, to attempt to dissect the cystic duct–CBD junction.

The cystic artery is exposed next [see Figure 15]. A small vein can usually be identified in the space between the cystic duct and the cystic artery; it can usually be pulled up anteriorly and cauterized. Because dissection is done near the gallbladder, it is not unusual to encounter more than one branch of the cystic artery. Each of these branches should be dissected free of the fibroareolar tissue. Care should also be taken to ensure that the right hepatic artery is not inadvertently injured as a result of being mistaken for the cystic artery.

Step 4: Control and Division of Cystic Duct and Cystic Artery

At this point, the cystic duct is clipped on the gallbladder side, and a cholangiogram is obtained if desired [see Step 5, below]. If a cholangiogram is not desired, three or four clips should be placed on the cystic duct and the cystic duct divided between them. Two or three hemostatic clips are placed on the cystic artery, and the vessel is divided. It is prudent to incise the artery partially before transecting it completely to ensure that the clips are secure and that there is no pulsatile bleeding. Once the artery is completely divided, the proximal end will retract medially, making it more difficult to expose and control the artery safely if bleeding occurs. Electrocautery should be avoided near the cystic duct and all metallic clips. Electrical current will be conducted through metallic clips and may result in delayed sloughing of the duct or a clip. Delayed injuries to the CBD may be caused by a direct burn to the duct or by sparking from noninsulated instruments or clips during dissection. An alternative is to use locking polymer clips that fit through 5 mm ports, clip across a greater width of tissue, and do not conduct electricity.

Control of short or wide cystic duct Edema and acute inflammation may lead to thickening and foreshortening of the

cystic duct, with subsequent difficulties in dissection and ligation. If the duct is edematous, clips may cut through it; if the duct is too wide, the clip may not occlude it completely. A modified clipping technique can be employed, with placement of an initial clip to occlude as much of the duct as possible. The occluded portion of the duct is then incised, and a second clip is placed flush with the first so as to occlude the rest of the duct. Alternatively, wider polymer clips may be used.

Because this technique is not always possible, the surgeon should be familiar with techniques for ligating the duct with either intracorporeal or extracorporeal ties. It is extremely helpful to

know how to tie extracorporeal ties so that the cystic duct can be ligated in continuity before it is divided. In some cases, the duct can be divided, held with a forceps, and controlled with a ligating loop. If there is concern about secure closure of the cystic duct, a closed suction drain may be placed. If inflammation, as in cholecystitis, has caused the duct to be shorter than usual, dissection must be kept close to the gallbladder to avoid inadvertent injury to the CBD. A short cystic duct is often associated with acute cholecystitis. Patient blunt dissection with the suction-irrigation device may be the safest technique.

Cystic duct stones Stones in the cystic duct may be visualized or felt during laparoscopic cholecystectomy. Every effort should be made to milk them into the gallbladder before applying clips. Placing a clip across a stone may push a fragment of the stone into the CBD and will increase the risk that the clip will become displaced, leading to a bile leak. If the stone cannot be milked into the gallbladder, a small incision can be made in the cystic duct (as is done for cholangiography), and the stone can usually be expressed and retrieved. Given that cystic duct stones are predictive of CBD stones, cholangiography or intraoperative ultrasonography is indicated.²⁶

Step 5: Intraoperative Cholangiography

Whether intraoperative cholangiography should be performed routinely is still controversial. Advocates believe that this technique enhances understanding of the biliary anatomy, thus reducing the risk of bile duct injury^{27,28}; at present, however, there are no objective data to confirm this impression. Cholangiography is not a substitute for meticulous dissection, and injuries to the CBD can occur before cystic duct dissection reaches the point at which cholangiography can be performed. Catheter-induced injuries and perforations of the biliary tree have been reported, and cholangiograms have been misinterpreted. On the other hand, one of the main advantages of cholangiography is that injuries can be recognized during the operation and promptly repaired. Another advantage of routine cholangiography is that it helps develop the skills required for more complex biliary tract procedures, such as transcystic CBD exploration.

The two methods of laparoscopic cholangiography differ in their technique for introducing the cholangiogram catheter into the cystic duct. In both approaches, a clip is placed at the gallbladder-cystic duct junction and a small incision made in the anterior wall of the cystic duct. In the first technique, a specially designed 5 mm cholangiogram clamp (the Olsen clamp) with a 5 French catheter is inserted via a subcostal trocar. For easy guidance of the catheter into the incision in the cystic duct, the catheter should be parallel, rather than perpendicular, to the cystic duct. This angle is facilitated by placing the subcostal port directly below the costal margin, near the anterior axillary line. A fifth trocar may occasionally be needed if exposure is lost when one of the grasping forceps is removed to allow passage of the cholangiogram clamp. The clamp and the catheter are then brought to the cystic duct under direct vision, and the catheter is steered into the duct [see Figure 16]. The clamp is then closed, holding the catheter in position and sealing the duct to avoid extravasation of dye.

In the second method, the cholangiogram catheter is introduced percutaneously through a 12- to 14-gauge catheter, inserted subcostally as described (see above). The surgeon then grasps the cholangiogram catheter and directs it into the cystic duct. A hemostatic clip is applied to secure the catheter in place. If passage of the catheter into the cystic duct is prevented by Heister's valve, a guide wire can be passed initially.

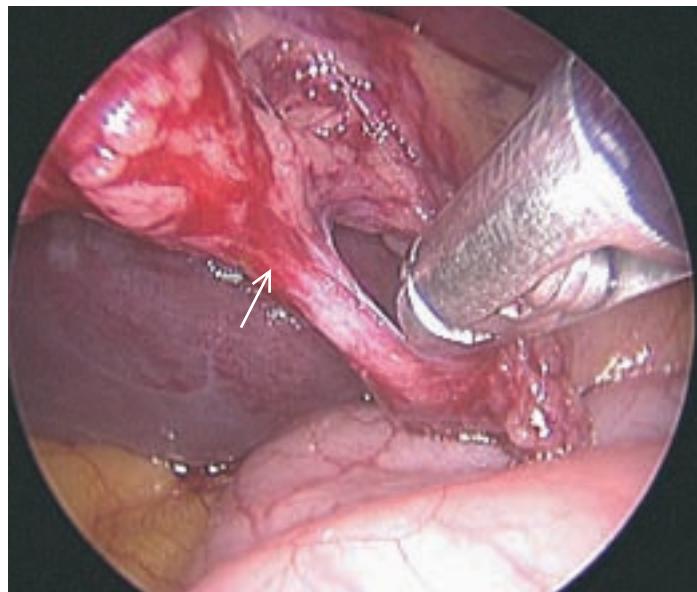

Figure 14 Laparoscopic cholecystectomy. The superior border of the cystic duct has been dissected. Funneling of the gallbladder into the cystic duct is clearly seen (arrow).

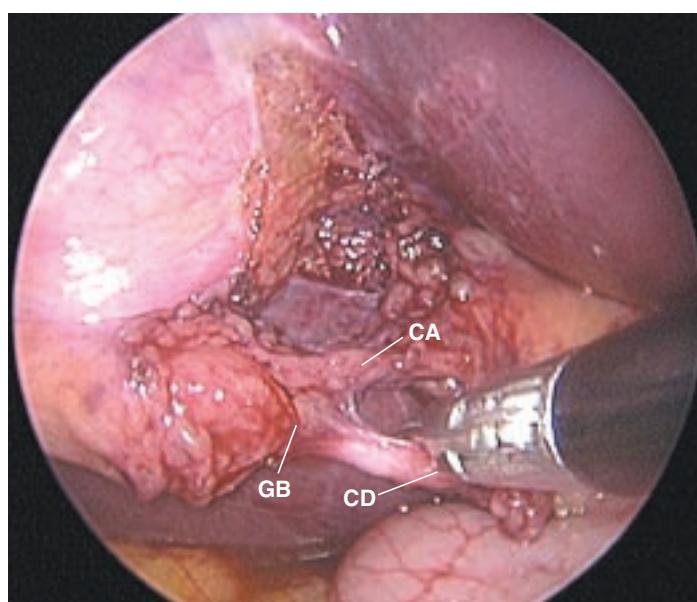

Figure 15 Laparoscopic cholecystectomy. Dissection of Calot's triangle further exposes the cystic duct (CD) and the cystic artery (CA) near their entry into the gallbladder (GB) in preparation for clipping and division.

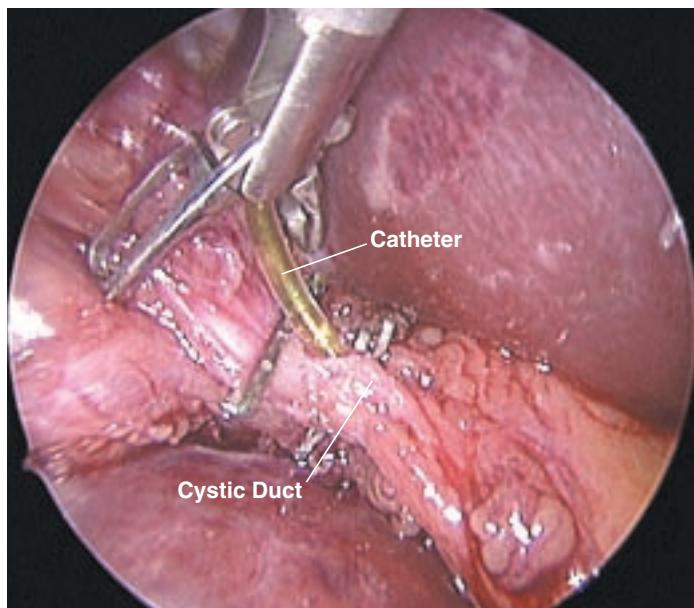

Figure 16 Laparoscopic cholecystectomy. The cystic duct has been clipped, a small incision has been made for placement of the cholangiogram catheter, and the catheter has been advanced through the specialized cholangiogram clamp into the cystic duct.

If the cystic duct is tiny and cannulation is expected to be difficult or impossible, the gallbladder can be punctured, bile aspirated, and contrast material injected through the gallbladder until the biliary tree is filled.

The cannulas and operating instruments should be positioned so as not to obstruct the view of the biliary tree. If the cannulas cannot be positioned outside the x-ray window, radiolucent cannulas should be used, or the cannulas should be removed and replaced after the cholangiogram. A cholangiogram that does not visualize the biliary tree from the liver to the duodenum is inadequate.

Fluoroscopic cholangiography [see *Figure 17*] may be performed either with hard-copy film or with digital imaging and storage. After the C arm is positioned, with the operating staff protected behind a lead screen, full-strength contrast is slowly injected under fluoroscopic control. The goal is to visualize the biliary tree in its entirety, including the right and left hepatic ductal systems as well as the distal duct. Once the cholangiogram is obtained, the catheter is removed, and the cystic duct is double-clipped and transected.

Laparoscopic ultrasonography Evaluation of the biliary tree with intraoperative laparoscopic ultrasonography appears to be as accurate as intraoperative fluorocholangiography in identifying biliary stones.^{28,29} This modality has several advantages over conventional cholangiography: it does not expose patients and staff to radiation; contrast agents are unnecessary; there is no need to cannulate the cystic duct; significantly less time is required; the capital cost of most ultrasound units is less than that of fluoroscopic equipment; and disposable cholangiogram catheters are not needed.

Most of the laparoscopic ultrasound devices in use at present are 7.5 MHz linear-array rigid probes 10 mm in diameter. Flexible probes capable of multiple frequencies are also available, and it is likely that future probes will be increasingly versatile. The probe is inserted through a 10/12 mm port (usually a periumbilical or epigastric port) and placed directly on the porta hepatis, perpendicular

to the structures of the hepatoduodenal ligament. The probe is then moved to the cystic duct–CBD junction. The transverse image obtained should show the three tubular structures of the hepatoduodenal ligament in the so-called Mickey Mouse head configuration: the CBD, the portal vein, and the hepatic artery [see *Figure 18*]. As the probe is moved distally, it is rotated clockwise to allow identification of the distal CBD and the pancreatic duct where they unite at the papilla. Instillation of saline into the right upper quadrant can enhance acoustic coupling and improve visualization.

Because of its many advantages, intraoperative laparoscopic ultrasonography may eventually replace fluorocholangiography in this setting, particularly for surgeons who practice routine intraoperative evaluation of the CBD.³⁰ Although the learning curve for effective performance of laparoscopic ultrasound examination is not long, surgeons should receive expert mentoring and formal instruction in ultrasonography before attempting it. During the first few attempts, it may be instructive to perform intraoperative laparoscopic ultrasonography in conjunction with fluorocholangiography. It should be emphasized that intraoperative laparoscopic ultrasonography is not a replacement for intraoperative cholangiography if the purpose of the examination is to define an anomalous anatomy or to evaluate a suspected injury or leak.

Step 6: Dissection of Gallbladder from Liver Bed

The gallbladder is grasped near the cystic duct insertion and pulled down toward the right anterosuperior iliac spine, placing the areolar tissue between the gallbladder and liver anteriorly

Figure 17 Laparoscopic cholecystectomy. Shown is a normal intraoperative cholangiogram.

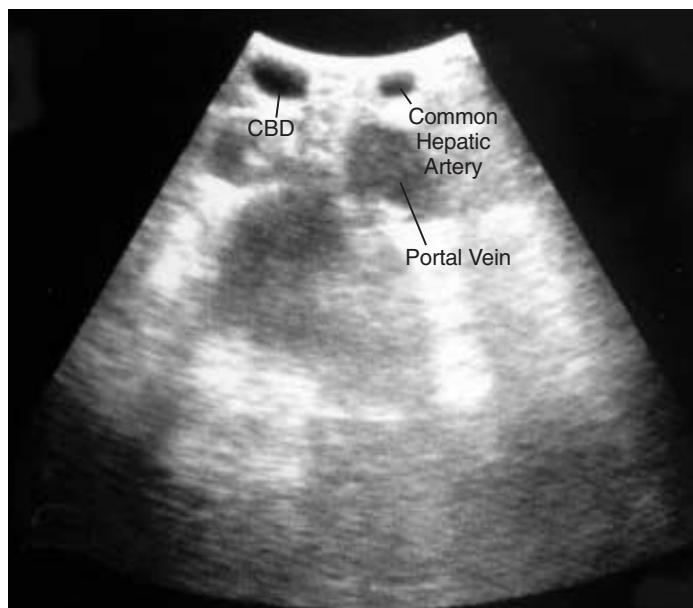

Figure 18 Laparoscopic cholecystectomy. A transverse intraoperative ultrasound scan of the hepatoduodenal ligament reveals a typical "Mickey Mouse head" appearance. Visible are the CBD, the common hepatic artery, and the portal vein.

under tension. The areolar tissue is cauterized with an L-shaped hook dissector or spatula, and dissection is carried upward as far as possible for as long as there is sufficient exposure. When exposure begins to diminish, the cystic duct end of the gallbladder should be pulled up toward or over the left lobe of the liver to expose the posteroinferior attachments of the gallbladder. A two-handed approach by the surgeon facilitates this dissection. It is sometimes helpful to apply downward and lateral traction on the forceps grasping the fundus. Bleeding during this stage generally indicates that the surgeon has entered the wrong plane and dissection has entered the liver. Bleeding can usually be readily controlled with the electrocautery. In some difficult cases (e.g., an intrahepatic gallbladder), it may be prudent to leave some of the posterior wall of the gallbladder *in situ* and cauterize it rather than persist with an excessively bloody dissection.¹⁶

Dissection continues until the gallbladder is attached only by a small piece of peritoneum at the fundus. Before the last attachment to the gallbladder is completely divided, the vital clips are reinspected to ensure that they have not slipped off, and the operative field is checked for hemostasis and the presence of any bile leakage. The final attachment to the gallbladder is then divided. The gallbladder is placed over the right lobe of the liver and laterally so that it can be found again to be retrieved. The grasping forceps on the gallbladder should not be removed.

Perforation of gallbladder The gallbladder may be accidentally breached at some point in the operation, with the result that bile and stones spill into the peritoneal cavity.^{31,32} Efforts should be made to suction the spilled bile, which accumulates in the suprahepatic space, the right subhepatic space, and the lower abdomen because of the patient's position. Each of these areas should be irrigated and the effluent aspirated until it is clear. Stones should be located and removed whenever possible. An effective way of removing small stones is to irrigate the subhepatic space copiously. Cholesterol stones usually float on the irrigation fluid and can then be suctioned through a 10 mm suction

probe or through a 32 French chest tube passed through the 10 mm operating port. Unfortunately, small stones may be lost in the omentum or between bowel loops. In such cases, it is probably appropriate to leave the stones within the peritoneum rather than perform a laparotomy to attempt to retrieve them. However, there have been reports of serious morbidity, including intra-abdominal abscess, fistula, empyema, and bowel obstruction, resulting from lost stones.

If the gallbladder is perforated and it seems likely that multiple stones will be spilled, the surgeon should introduce a sterile bag into the peritoneal cavity, placing it close to the perforation. Spilled stones can then be transferred immediately into the bag. After the gallbladder is removed from the liver bed, it too is placed in the bag, affording some protection to the wound when it is removed from the abdominal cavity.

Step 7: Extraction of Gallbladder

The laparoscope is moved to the epigastric port, and a large-tooth grasping forceps is inserted through the umbilical port to grasp the gallbladder at the area of the cystic duct. Under direct vision, the gallbladder is then retrieved and pulled out as far as possible through the umbilical port. If the gallbladder is small enough, it can be drawn right into the trocar sleeve, and it and the trocar can then be removed together. It is sometimes necessary to stretch the fascial opening with a Kelly clamp or to aspirate bile from the gallbladder. It is far preferable to enlarge the incision than to have stones or bile spill into the abdominal cavity from a ripped gallbladder. Enlargement of this incision is easier if initial access was obtained via the Hasson technique. All of the other ports are then removed from the abdominal wall under direct vision to ensure that there is no bleeding. All residual CO₂ should be removed to prevent postoperative shoulder pain. The fascial opening at the umbilicus should be sutured closed to prevent subsequent herniation, and all skin incisions should be closed.

Need for drainage The decision to place a drain after laparoscopic cholecystectomy should be governed by the same principles applied to patients undergoing open cholecystectomy. There are two main indications for drainage: (1) the cystic duct was not closed securely, and (2) the CBD was explored by either a direct or a transcystic approach.

Drain placement is easily accomplished. A closed suction drain is inserted intra-abdominally through the 10 mm operative port. A grasping forceps placed through the right lateral port is used to pull one end of the drain out through the abdominal wall. The other end is then positioned according to the surgeon's preference, usually in the subhepatic space.

COMPLICATIONS

Intraoperative

Veress needle injury A syringe must always be attached to the Veress needle, and fluid must be aspirated before insufflation is initiated: failure to do so may lead to insufflation into a vessel and consequently to massive gas embolism. If the aspirate from the syringe attached to the Veress needle contains copious amounts of blood, a major vascular injury may have occurred, and immediate laparotomy is indicated. Because the problem at this point is a needle injury, it can usually be repaired easily and without serious sequelae.

Puncture of the bowel by a Veress needle is usually signaled by aspiration of bowel contents through the needle. If this occurs, the needle should be withdrawn and the approximate course and

direction of the puncture remembered. The initial trocar should then be inserted by means of the open technique, under direct vision, to ensure that the undersurface of the abdominal wall is free of adherent bowel. Once pneumoperitoneum is created, careful examination of the abdomen through the laparoscope is undertaken. In most cases, either further leakage of bowel contents, staining of the serosal surface with bowel contents, or an ecchymosis on the serosal surface of the bowel helps the surgeon locate the site of the bowel injury. If ecchymosis is present without spillage of bowel contents, the bowel loop should be marked with a suture and re-inspected at the end of the procedure. If ongoing leakage of bowel contents is noted, the injured loop of bowel can be either repaired by means of laparoscopic suturing or grasped with an atraumatic forceps and gently withdrawn through an enlarged umbilical incision for suture repair. The bowel is returned to the peritoneal cavity and the laparoscopic cholecystectomy completed.

Improper placement of the Veress needle into the omentum, the retroperitoneum, or the preperitoneal space may be signaled by high inflation pressures, uneven distribution of the gas on percussion, or marked subcutaneous emphysema. If such misplacement goes unrecognized, creation of a safe intraperitoneal space is impossible, and subsequent blind insertion of the trocar may result in injury to an intraperitoneal structure.

Trocar injury Trocar injury to blood vessels or bowel is much more dangerous than Veress needle injury to the same structures. Major vascular injuries virtually never occur when trocars are placed under direct vision; however, they remain a potentially lethal—though rare—complication of percutaneous trocar insertion. If active bleeding follows removal of the trocar from the cannula, prompt laparotomy is mandatory; if bleeding passes unnoticed and insufflation begins, massive air embolism will result. At the time of laparotomy, both the anterior and the posterior wall of the vessel must be examined after proximal and distal control of the vessel have been obtained.

Bowel injuries can result from either percutaneous or open insertion of the initial trocar. With open insertion, the bowel injury should be immediately obvious and can be repaired after the injured bowel is pulled through an enlarged umbilical incision; laparoscopic cholecystectomy can then proceed. Bowel injuries caused by percutaneous insertion may occur even in the absence of abdominal wall adhesions and can be managed in the same way as those caused by open insertion. The one caveat is that it is possible to spear the bowel in a through-and-through fashion so that when the laparoscope is inserted through the trocar, the view is normal and the injury is not recognized. This type of injury can be diagnosed only if the laparoscope is repositioned to the operating port at some time during the procedure and the undersurface of the umbilical site is carefully examined. This step is mandatory during the course of the operation, preferably early.

Bleeding Abdominal wall. Bleeding from the abdominal wall can usually be prevented by careful trocar placement. The abdominal wall should be transilluminated before percutaneous trocar insertion and the larger vessels avoided. If a vessel is speared, the cannula usually tamponades the bleeding reasonably effectively during the procedure.

Once the procedure is completed, each trocar is removed under direct vision. If bleeding follows the removal of a trocar, the puncture hole can be occluded with digital pressure to maintain pneumoperitoneum and the bleeding controlled by cauterization or suture repair. Alternatively, the surgeon may place a Foley catheter through the trocar site with a stylet, inflate the balloon, and place

traction on the catheter for 4 to 6 hours; however, tissue ischemia can make this technique quite painful.

Omental or mesenteric adhesions. Generally, omental adhesions can be bluntly teased from their attachments to the gallbladder, with the plane of dissection kept close to the gallbladder, where the adhesions are less vascular. Adhesions to the liver should be taken down with the electrocautery to prevent capsular tears. Persistent bleeding from omental adhesions is unusual but can be managed by means of electrocauterization (with care taken to avoid damage to the duodenum or colon) or the application of hemostatic clips or a pretied ligating loop.

Cystic artery branch. Arterial bleeding encountered during dissection in Calot's triangle is usually from loss of control of the cystic artery or one of its branches. Biliary surgeons must be aware of the many anatomic variations in the vasculature of the gallbladder and the liver. Because the main cystic artery frequently branches, it is common to find more than one artery if dissection is maintained close to the gallbladder. If what seems to be the main cystic artery is small, a posterior cystic artery may be present and may have to be clipped during the dissection.

Prevention of arterial bleeding begins by dissecting the artery carefully and completely before clipping and by inspecting the clips to ensure that they are placed completely across the artery without incorporating additional tissue (e.g., a posterior cystic artery or right hepatic artery). When arterial bleeding is encountered, it is essential to maintain adequate exposure and to avoid blind application of hemostatic clips or cauterization. The laparoscope should be withdrawn slightly so that the lens is not spattered with blood. The surgeon should then pass an atraumatic grasping forceps through a port other than the operating port and attempt to grasp the bleeding vessel. An additional trocar may have to be inserted for simultaneous suction-irrigation. Once proximal control is obtained, the operative field should be suctioned and irrigated to improve exposure. Hemostatic clips are then applied under direct vision; in addition, a sponge may be introduced to apply pressure to the bleeding vessel. Conversion to open cholecystectomy is indicated whenever bleeding cannot be promptly controlled laparoscopically.

Liver bed. Bleeding from the liver bed may be encountered when the wrong plane is developed during dissection of the gallbladder. Patients who have portal hypertension, cirrhosis, or coagulation disorders are at particularly high risk. Control of bleeding requires good exposure, accomplished via lateral and superior retraction of the gallbladder; hence, all bleeding should be controlled before the gallbladder is detached from the liver bed. Most liver bed bleeding can be controlled with the electrocautery, and it should be controlled as it is encountered to allow exposure of the specific bleeding site. Either a hook-shaped or a spatula-shaped coagulation electrode is effective. If oozing continues, oxidized cellulose can be placed as a pack through the operative port and pressure applied on the raw surface of the liver. If needed, fibrin glue can be applied to the bleeding raw surface.

Postoperative

If a patient (1) complains of a great deal of abdominal pain necessitating systemic narcotics, (2) has a high or prolonged fever, (3) experiences ileus, or (4) becomes jaundiced, an intra-abdominal complication may have occurred. Blood should be drawn for assessment of the white blood cell count, hemoglobin concentration, liver function, and serum amylase level. Abdominal ultra-

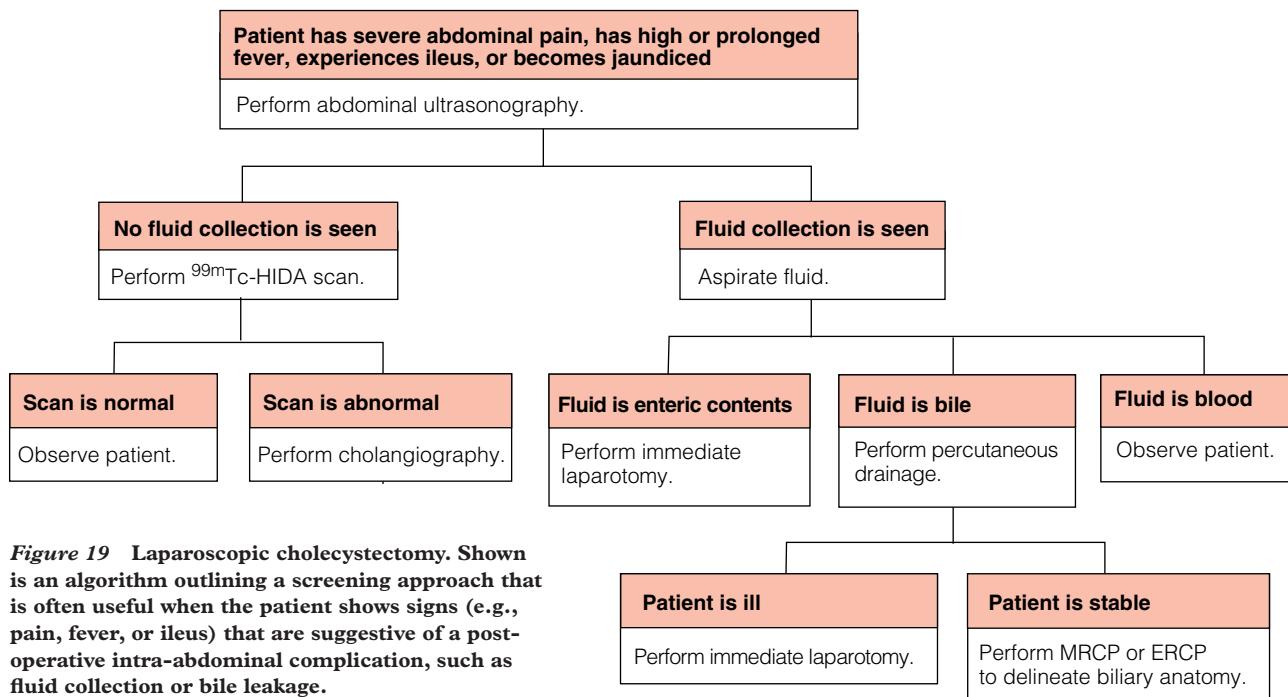

Figure 19 Laparoscopic cholecystectomy. Shown is an algorithm outlining a screening approach that is often useful when the patient shows signs (e.g., pain, fever, or ileus) that are suggestive of a post-operative intra-abdominal complication, such as fluid collection or bile leakage.

sonography may help diagnose dilated intrahepatic ducts and subhepatic fluid collections [see Figure 19].

Fluid collection or bile leakage When a significant fluid collection is seen, it should be aspirated percutaneously under ultrasonographic guidance. If the fluid is blood and the patient is hemodynamically stable and requires no transfusion, observation of the patient and culture of the fluid are usually sufficient. If the fluid is enteric contents, immediate laparotomy is indicated. If the fluid is bile and the patient is ill, immediate laparotomy should be considered; if the patient is stable and the appropriate facilities are available, MRCP or ERCP may be performed to identify the site of bile leakage, determine whether obstruction is also present, and assess the integrity of the extrahepatic biliary tree. If the bile ducts are in continuity and the bile is coming from the cystic duct stump or a small lateral tear in the bile duct, ES, with or without stenting, usually controls the leak. Percutaneous placement of a drain under ultrasonographic guidance allows control of the bile leakage and measurement of the quantity of fluid present.

Fever Postoperative fever is a common complication of laparoscopic cholecystectomy. As noted, it may be indicative of a complication such as a bile collection or bile leakage. Other common reasons for postoperative fever (e.g., atelectasis) should also be considered.

Abnormal liver function When postoperative blood tests indicate significantly abnormal liver function, possible causes include injury to the biliary tree and retained CBD stones [see Figure 20].³³ Cholangiography is required, even if it was performed intraoperatively. If MRCP or ERCP yields normal results, observation is sufficient; the abnormalities may be attributable to a passed stone or drug-related cholestasis. If stones are present, ES can usually solve the problem. If ERCP demonstrates extravasation of bile, it is important to establish whether the CBD is in continuity. If the duct is interrupted, early reoperation, ideally at a specialized center, is the best option. If the duct is in continuity, endoscopic and radiologic techniques may successfully resolve the

problem without substantial morbidity.^{34,35} Percutaneous drainage is instituted to control the fistula, and sphincterotomy or stenting is useful to overcome any resistance at the sphincter of Oddi. Any retained stones causing distal obstruction should also be removed. Major ductal injuries usually call for operative repair. When such an injury is identified at operation, the surgeon must decide whether to attempt repair immediately; this decision should be based on the surgeon's experience with reconstructive biliary surgery and on the local expertise available. At a minimum, adequate drainage must be established. Most major ductal injuries are not in fact identified intraoperatively. When such an injury is identified postoperatively, adequate drainage must be established and the anatomy of the injury clarified as well as possible before repair. MRCP or transhepatic cholangiography may be required to delineate the anatomy of the proximal biliary tree when ERCP does not opacify the biliary tract above the injury. If surgical repair is indicated, it should be performed by a surgeon experienced in complex biliary tract procedures. Often, referral to a specialized center is the most appropriate decision, especially in the case of more proximal biliary injuries.

SPECIAL CONSIDERATIONS

Conversion to Laparotomy

Conversion from laparoscopy to laparotomy may be required in any laparoscopic cholecystectomy, in accordance with the judgment of the surgeon. The most common reason for such conversion is the inability to identify important anatomic structures in the region of the gallbladder. Distorted anatomy may be the result of previous operations, inflammation, or anatomic variations. Conversion may also be required because of an intraoperative complication [see Complications, Postoperative, above]. Ideally, the surgeon would wish to convert before any complication occurs. It must be emphasized that conversion to open surgery should not be considered a failure or a complication. Rather, it should be considered a prudent maneuver for achieving the desired objective—namely, safe removal of the gallbladder. Accordingly, every patient consent obtained for a laparoscopic cholecystectomy must explic-

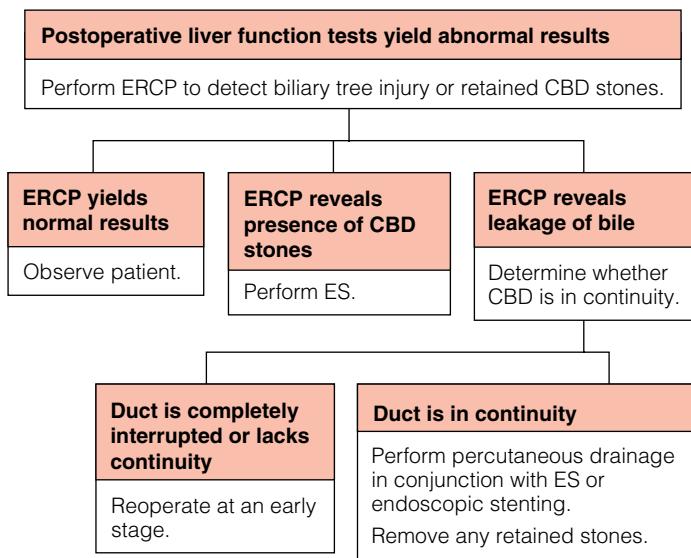

Figure 20 Laparoscopic cholecystectomy. Shown is an algorithm outlining an approach to abnormal liver function test results after laparoscopic cholecystectomy.

itly allow for the possibility of conversion to an open procedure. Attempts have been made to predict the probability of conversion on the basis of preoperative information.^{36,37} It is clearly useful to stratify patients according to likelihood of conversion. This information is helpful in selecting patients for laparoscopic cholecystectomy in an outpatient versus hospital setting, in determining the resources required in the OR, and in assisting patients in planning their work and family needs around the time of surgery.

Factors found to be predictive of an increased probability of conversion include acute cholecystitis, either at the time of surgery or at any point in the past; age greater than 65 years; male sex; and thickening of the gallbladder wall to more than 3 mm as measured by ultrasonography. Other factors more variably associated with an increased likelihood of conversion are obesity, previous upper abdominal operations (especially gastroduodenal), multiple gallbladder attacks over a long period, and severe pancreatitis. Factors not associated with an increased likelihood of conversion are jaundice, previous ES, previous lower abdominal procedures, stomas, mild pancreatitis, and diabetes.

On the basis of our data, a 45-year-old woman with no history of acute cholecystitis and no gallbladder wall thickening has a probability of conversion lower than 1%; such a patient is a good candidate for laparoscopic cholecystectomy in an outpatient setting. Conversely, a 70-year-old man with acute cholecystitis and ultrasonographic evidence of gallbladder wall thickening has a probability of conversion of about 30%; such a patient would be better managed in a traditional hospital environment.

Acute Cholecystitis

Laparoscopic cholecystectomy has been shown to be safe and effective for treating acute cholecystitis.^{38,39} There are, however, several technical problems in this setting that must be addressed if the procedure is to be performed with minimal risk. It should also be recognized that the probability of conversion to laparotomy is greatly increased in these circumstances. There appears to be no advantage to delaying surgery in patients with acute cholecystitis, even if rapid improvement is noted with nonoperative management.^{40,41} Many patients return within a short time with recurrent attacks, and delaying surgery does not reduce the probability of

conversion.

Technical difficulties associated with cholecystectomy for acute cholecystitis include dense adhesions, the increased vascularity of tissues, difficulty in grasping the gallbladder, an impacted stone in the gallbladder neck or the cystic duct, shortening and thickening of the cystic duct, and close approximation of the CBD to the gallbladder wall.

The surgeon should not hesitate to insert additional ports (e.g., for a suction-irrigation apparatus) if necessary. Because the tense, distended gallbladder is difficult to grasp reliably, it should be aspirated through the fundus early in the procedure, as previously described. If the graspers fail to grasp the wall or cause it to tear, exposure of Calot's triangle can be achieved by propping up or levering the neck of the gallbladder and the right liver with a blunt instrument. A sponge can be used for this purpose, thereby reducing the potential trauma of the retraction. This maneuver is also useful when an impacted stone in the neck of the gallbladder prevents the surgeon from grasping the gallbladder in the area of Hartmann's pouch. Dense adhesions that may be present between the gallbladder and the omentum, duodenum, or colon should be dissected bluntly (e.g., with a suction tip). Because the tissues are friable and vascular, oozing may be encountered. Electrosurgery should be only sparingly employed until the vital structures in Calot's triangle are identified. Instead, the surgeon should move to another area of dissection, allowing most of the oozing to coagulate on its own. Liberal use of suction and irrigation will keep the operative field free of blood.

In the identification of anatomic structures, it is important to keep dissection close to the gallbladder wall, working down from the gallbladder toward Calot's triangle. Dissection of the lower part of the gallbladder from the liver bed early in the operation may aid in identification of the gallbladder neck–cystic duct junction (analogous to an open, retrograde dissection). The surgeon should be aware that edema and acute inflammation may cause foreshortening of the cystic duct. If the anatomy cannot be identified, preliminary cholangiography through the emptied gallbladder may indicate the position of the cystic duct and the CBD.

Often, the obstructing stone responsible for the acute attack is in the neck of the gallbladder; thus, the cystic duct will be normal and easily secured with clips. If the stone is in the cystic duct, it must be removed before the duct is clipped or ligated. A thickened, edematous cystic duct is better controlled by ligation with an extracorporeal tie or a ligating loop than by clipping. If closure of the cystic duct is tenuous, closed suction drainage is advisable. Obviously, conversion to open cholecystectomy is indicated if the anatomy remains obscure. Conversion should also be considered if no progress is made after a predesignated period (e.g., 15 minutes) because at this point, the surgeon is unlikely to make any headway.

CBD Stones

Identification of patients at risk About 10% of all patients undergoing cholecystectomy for gallstones will also have choledocholithiasis. To select from the various diagnostic and therapeutic options for managing choledocholithiasis, it is helpful to know preoperatively whether the patient is at high, moderate, or low risk for stones. Patients with obvious clinical jaundice or cholangitis, a dilated CBD, or stones visualized in the CBD on preoperative ultrasonography are likely to have choledocholithiasis (risk > 50%). Patients who have a history of jaundice or pancreatitis, elevated preoperative levels of alkaline phosphatase or bilirubin, or ultrasonographic evidence of multiple small gallstones are somewhat less likely to have choledocholithiasis (risk, 10% to 50%). Patients with large gallstones, no history of jaundice or pancreati-

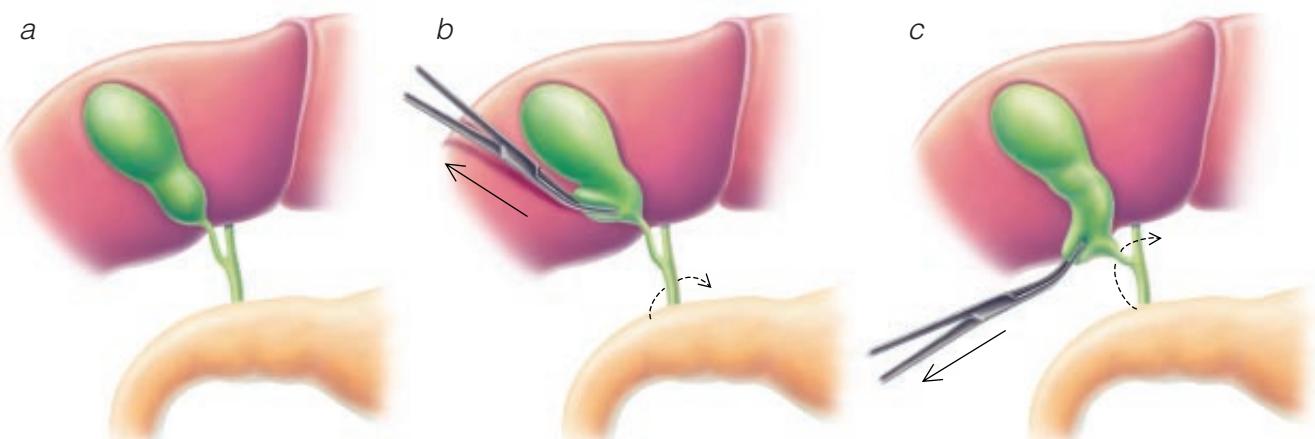

Figure 21 Open cholecystectomy. (a) Shown are the resting positions of the cystic duct and the CBD (with Calot's triangle closed). (b) Improper upward retraction of Hartmann's pouch lines up the CBD and the cystic duct so that one can easily encircle the CBD or clamp the cystic duct and the CBD. (c) Correct downward and rightward retraction opens Calot's triangle; dissection proceeds lateral to the CBD.

tis, and normal liver function are unlikely to have choledocholithiasis (risk < 5%).

Diagnostic and therapeutic options One argument for routine intraoperative cholangiography is that it is a good way of identifying unsuspected CBD stones. However, more selective approaches to diagnosing choledocholithiasis make use of preoperative cholangiography via MRCP, EUS, or, more invasively, ERCP [see 5:18 *Gastrointestinal Endoscopy*]. Preoperative identification of choledocholithiasis allows the surgeon to attempt preoperative clearance of the CBD by means of ES or intraoperative clearance during laparoscopy, depending on his or her expertise. Preoperative cholangiography is suggested when the patient's history and the results of laboratory and diagnostic tests suggest that there is a moderate or high risk of CBD stones. It is our practice to have patients at high risk for CBD stones undergo ERCP and ES if warranted. For patients at moderate risk, MRCP or EUS is done first, followed by therapeutic ERCP if CBD stones are identified. Intraoperative cholangiography can also be used to identify choledocholithiasis. ERCP with ES may result in pancreatitis, perforation, or bleeding and carries a mortality of approximately 0.2%.

When stones are detected during the operation, the options include laparoscopic transcystic duct exploration, laparoscopic choledochotomy and CBD exploration, open CBD exploration, and postoperative ERCP/ES.^{10,42} If a single small (~ 2 mm) stone is visualized, it can probably be flushed into the duodenum by flushing the CBD via the cholangiogram catheter and administering glucagon, 1 to 2 mg I.V., to relax the sphincter of Oddi. Even if a stone of this size does not pass intraoperatively, it will usually pass on its own postoperatively.

Laparoscopic transcystic CBD exploration Access to biliary tree. The cholangiogram is reviewed; the size of the cystic duct, the site where the cystic duct inserts into the CBD, and the size and location of the CBD stones all contribute to the success or failure of transcystic CBD exploration.⁴³⁻⁴⁵ For example, transcystic exploration is extremely challenging in a patient who has a long, spiraling cystic duct with a medial insertion. The size of the stones to be removed dictates the approach to the CBD: stones smaller than 4 mm can usually be retrieved in fluoroscopically directed baskets and generally do not necessitate cystic duct dilatation; larger stones (4 to 8 mm) are retrieved under direct

vision with the choledochoscope.

A hydrophilic guide wire is inserted through the cholangiogram catheter into the CBD under fluoroscopic guidance. The cholangiogram catheter is then removed. If the largest stone is larger than the cystic duct, dilatation of the duct is necessary, not only for passage of the stone but also to allow passage of the choledochoscope, which may be 3 to 5 mm in diameter.

Dilatation is accomplished with either a balloon dilator or sequential plastic dilators. Because plastic dilators may cause the cystic duct to split, balloon dilatation is recommended. A balloon 3 to 5 cm in length is passed over the guide wire and positioned with its distal end just inside the CBD and its proximal end just outside the incision in the cystic duct. The balloon is then inflated to the pressure recommended by the manufacturer and observed closely for evidence of shearing of the cystic duct. The cystic duct should not be dilated to a diameter greater than 8 mm. Larger stones in the CBD may be either fragmented with electrohydraulic or mechanical lithotripsy, if available, or removed via choledochotomy.

Once dilatation is complete, the guide wire may be removed or left in place to guide passage of a choledochoscope or baskets. When the choledochoscope is used, a second incision in the cystic duct, close to the CBD, avoids Heister's valves and allows removal of the guide wire. If baskets are used, a 6 French plastic introducer sheath may be inserted through the trocar used for cholangiography into the cystic duct. This sheath is especially useful if multiple stones must be removed.

Fluoroscopic wire basket transcystic CBD exploration. Stones smaller than 2 to 4 mm that do not pass with irrigation through the cholangiocatheter after injection of glucagon can usually be retrieved by using a 4 French or 5 French helical stone basket passed into the CBD over a guide wire under fluoroscopic guidance. The baskets can be passed alongside the cholangiocatheter or inserted via a plastic sheath replacing the cholangiocatheter. The basket is opened in the ampulla of Vater, pulled back into the CBD, and rotated clockwise until the stone is entrapped. The stone and basket are then removed together. A Fogarty catheter should not be used, because the stones are likely to be pulled up into the hepatic ducts, where they are much more difficult to remove.

Endoscopic transcystic CBD exploration. When stones are 4 to 8

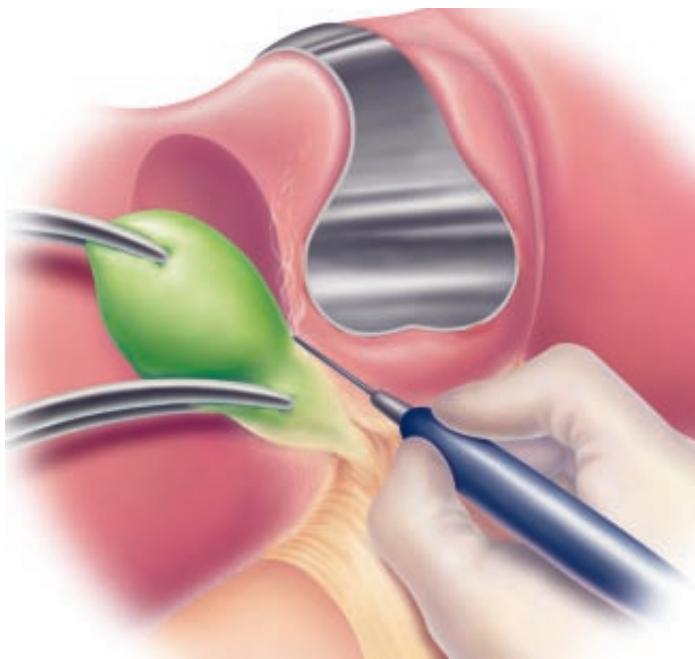

Figure 22 Open cholecystectomy. In so-called fundus down dissection, the fundus and infundibulum are retracted up and away from the liver while dissection is performed with electrocautery. Sharp dissection with scissors or scalpel or blunt digital dissection all may be used, at the surgeon's discretion.

mm in diameter, the helical stone basket wires are generally too close together to permit retrieval. Hence, choledochoscopic basketing is utilized. A 7 to 10 French choledochoscope with a working channel is either passed over the guide wire or inserted directly into the cystic duct. Because the usual grasping forceps may damage the choledochoscope, forceps with rubber-covered jaws should be used. A separate camera should be inserted onto the choledochoscope, and the image it produces can be displayed on the monitor by means of an audiovisual mixer (i.e., a picture within a picture) or displayed on a separate monitor.

Once the choledochoscope enters the cystic duct, warm saline irrigation is begun under low pressure to distend the CBD and provide a working space. The choledochoscope usually enters the CBD rather than the common hepatic duct. When a stone is seen, a 2.4 French straight four-wire basket is inserted through the operating port. The stones closest to the cystic duct are removed first, by advancing the closed basket beyond each stone, opening the basket, and pulling the basket back, thereby trapping the stone. The basket is then closed and pulled up against the choledochoscope so that they can be withdrawn as a unit. Multiple passes may be required until the duct is clear. A completion cholangiogram is done to ensure that the duct is clear and to rule out proximal stones. The dilated, traumatized cystic duct is ligated with a ligating loop rather than a hemostatic clip. If drainage is required, a red rubber catheter can be inserted into the CBD via the cystic duct.

Because of the angle created by the cephalad and superior retraction of the gallbladder, it may be difficult to pass the choledochoscope into the proximal ducts. If a common hepatic duct stone is seen on the cholangiogram, the patient is placed in a steep reverse Trendelenburg position. In this position, any nonimpacted stones may fall into the distal duct for retrieval. It may be possible to pass the choledochoscope into the proximal ducts by applying caudal traction to the cystic duct so as to align it with the common hepatic duct. An additional access port in the right upper quadrant

may be needed. If the cystic duct is long or spiraling or inserts medially, this measure may not be feasible, in which case access must be obtained by means of choledochotomy.

Laparoscopic CBD exploration Large stones (> 1 cm), as well as most stones in the common hepatic ducts, are not retrievable with the techniques described above. Ductal clearance can be achieved via choledochotomy if the duct is dilated and the surgeon is sufficiently experienced.^{46,47} The anterior wall of the CBD is bluntly dissected for a distance of 1 to 2 cm. When small vessels are encountered, it is preferable to apply pressure and wait for hemostasis rather than use the electrocautery in this area. Two stay sutures are placed in the CBD. An additional 5 mm trocar is placed in the right lower quadrant for insertion of an additional needle driver. A small longitudinal choledochotomy (a few millimeters longer than the circumference of the largest stone) is made with curved microscissors on the anterior aspect of the duct while the stay sutures are elevated. A choledochoscope is then inserted and warm saline irrigation initiated. In most cases, baskets should suffice for stone retrieval; however, lithotriptor probes and lasers are available for use through the working channel of the choledochoscope. The choice of approach depends on availability and individual surgical experience.

Subsequently, a 12 or 14 French latex T tube is fashioned with

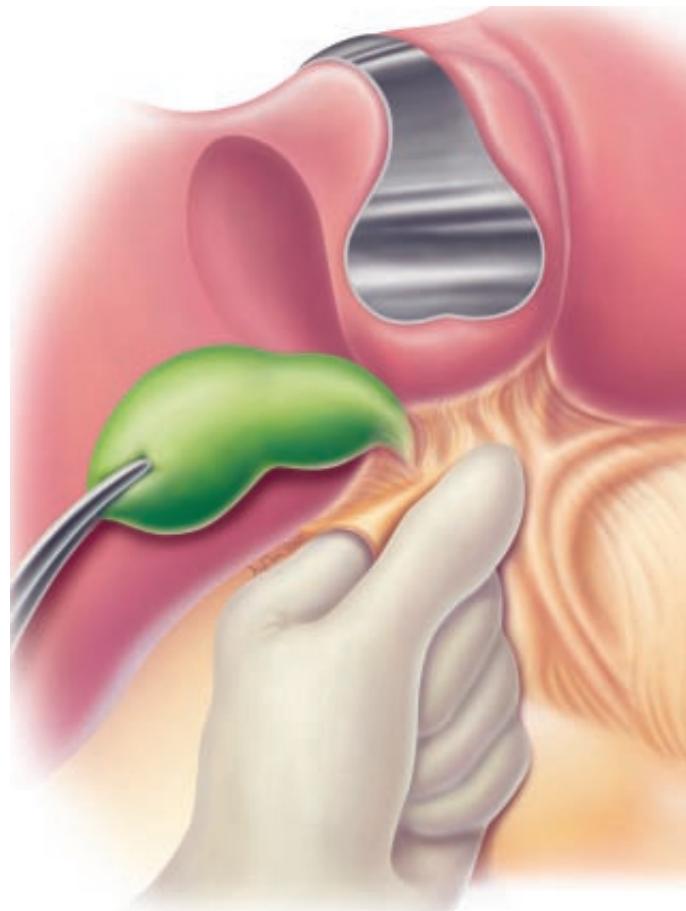

Figure 23 Open cholecystectomy. In patients with severe inflammation and edema, the surgeon must be cautious when approaching Calot's triangle during fundus down dissection. In such circumstances, digital palpation can be very helpful in safely identifying the cystic duct and artery.

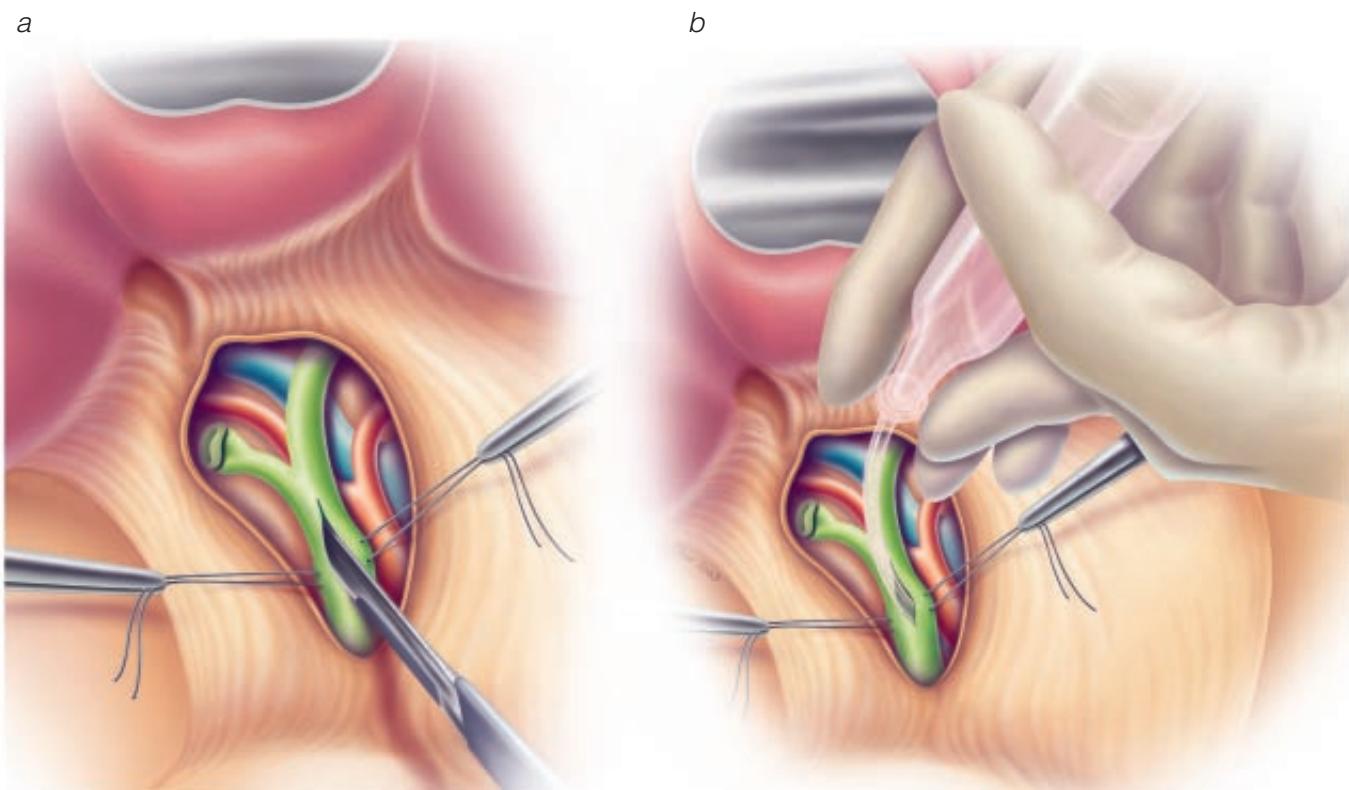

Figure 24 Open common bile duct exploration. (a) The common bile duct is opened vertically between laterally positioned stay sutures. (b) A catheter is then used to irrigate and flush stones from the duct. If stones are impacted within the duct, they can be retrieved with Fogarty catheters, wire stone retrieval baskets, or stone retrieval forceps. The choledochoscope can be used if any of these methods fail or as the initial method of exploration.

short limbs, placed entirely intraperitoneally to prevent CO₂ from escaping, and positioned in the CBD. The choledochotomy is then closed with fine interrupted absorbable sutures. The first suture is placed right next to the T tube, securing it distally, and the second is placed at the most proximal end of the choledochotomy; lifting these two sutures facilitates placement of additional sutures. Intracorporeal knots are preferred to avoid sawing of the delicate tissues. The end of the T tube is then pulled out through a trocar, and cholangiography is performed after completion of the procedure.

Open Cholecystectomy

Open cholecystectomy is usually reserved for patients in whom the laparoscopic approach is not feasible or is contraindicated. As such, it is typically performed only in the most difficult situations or when additional maneuvers such as CBD exploration are anticipated. Conversion from the laparoscopic to the open approach is not considered a complication and does not represent failure. Rather, conversion to this time-honored and effective procedure represents the prudent judgment of a safe surgeon.

OPERATIVE TECHNIQUE

The choice of incision depends on the surgeon's experience and preference, along with patient factors such as previous surgical procedures and body habitus. Typically, open cholecystectomy is performed through a right subcostal (Kocher) incision, but it can also be approached through an upper midline incision or, less commonly, through a right paramedian or transverse incision. A mechanical retraction system should be used, if available, so that the hands of the participating surgeons are free; there is no good

rationale for struggling to perform difficult biliary surgery with handheld retractors.

The abdomen is opened and then explored; the abdominal viscera are inspected and palpated and a retraction system is put in place. Long curved or angled clamps, such as Kelly or Mixter, are placed on the gallbladder fundus and infundibulum for the application of gentle traction. The fundus is elevated and the infundibulum is pulled laterally and away from the liver [see Figure 21]. If the gallbladder is not too inflamed and edematous, the procedure may be performed similarly to the typical laparoscopic approach: the surgeon identifies and ligates the cystic duct and artery, and then removes the gallbladder from the liver bed.

With more difficult open cases, the above technique may not be possible. In such cases, a retrograde or so-called fundus down approach is usually employed. Staying as close to the gallbladder wall as is possible, the surgeon uses electrocautery or sharp and digital blunt dissection to remove the gallbladder from the liver bed, continuing downward to the cystic duct and artery [see Figure 22]. Anatomic variations of the duct and artery must always be anticipated. These structures can be very difficult to identify and safely dissect in cases of severe inflammation and markedly edematous tissues. In such cases, palpation and gentle digital blunt dissection of the duct and artery between thumb and index finger is useful [see Figure 23]. Opening the gallbladder to remove stones or aspirate bile or pus may be necessary when it is tense and distended or necrotic and gangrenous. As with laparoscopic cholecystectomy, it is critical to identify the cystic duct and artery and their anatomic relations to the gallbladder and common bile duct before division and to avoid injury to the common bile duct or common hepatic duct. The cystic duct and artery may be suture

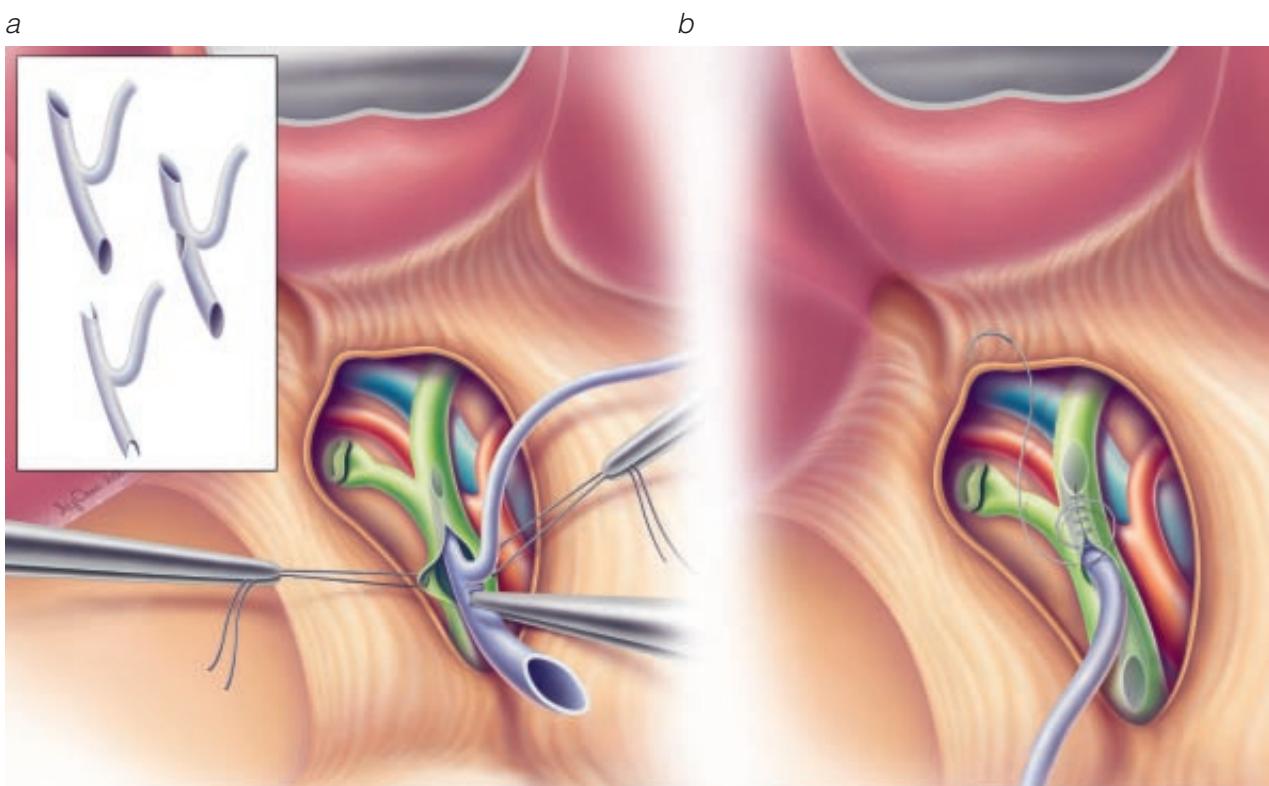

Figure 25 Open common bile duct exploration. (a) After common bile duct exploration, a T tube is fashioned and is placed into the duct. (b) Interrupted 4-0 absorbable sutures are used to close the chole-dochotomy snug around the tube. A completion cholangiogram may then be performed. The tube is brought out through the right abdominal wall, through a separate stab incision, and secured to the skin.

ligated or divided between clips. Stones found in the cystic duct should be gently milked back into the gallbladder.

SPECIAL CONSIDERATIONS

Cholangiography

The indications for cholangiography are the same as for laparoscopic cholecystectomy. Several techniques for the performance of cholangiography can be utilized. Usually the same technique as for laparoscopic cholecystectomy is employed; the cystic duct is ligated or clipped high near the infundibulum and incised just below this point for insertion of a cholangiography catheter, which is secured against leakage by another clip or ligature. Alternatively, the cystic duct can be divided near the infundibulum and the gallbladder removed; then the cystic duct is cannulated. Needle puncture cholangiography can also be performed via the cystic duct or the common duct. Once cholangiography is complete, the gallbladder is removed and sent for pathologic examination. The operative field is inspected for hemostasis and irrigated. Any bile leak is identified. Drains are not routinely placed but can be used at the surgeon's discretion. If drains are used, a closed suction Jackson-Pratt or similar drain is recommended; the drain should be brought out through a separate stab incision.

Open CBD Exploration

Open common bile duct exploration has become a rare procedure, but it remains a skill that surgeons require. If ERCP has failed or is not possible, if the surgeon does not have the experience and necessary tools to perform laparoscopic duct exploration, or if laparoscopic efforts have failed, then open exploratory

tion becomes necessary. Ductal stones are identified either preoperatively or intraoperatively by ultrasound, cholangiography, or palpation.

Appropriate retraction and exposure are crucial. The anterior aspect of the duct is exposed over a distance of 1 to 2 cm, avoiding electrocautery during dissection. Two stay sutures of a 3-0 monofilament are placed lateral to the midline of the duct. The common hepatic duct is sharply opened with a No. 11 or No. 15 scalpel and longitudinally incised further with a Potts' arteriotomy or similar scissors. When performing these maneuvers, the surgeon must respect the arterial blood supply of the duct, which courses laterally on either side of the duct in the 3 o'clock and 9 o'clock positions [see Figure 24]. In some cases, stones are immediately visible and can simply be plucked from the duct once it is opened. Flushing the duct with saline, proximally and then distally, through a 12 or 14 French Foley or red rubber catheter may also clear the duct of stones. The intravenous administration of 1 to 2 mg of glucagon will relax the sphincter of Oddi, which may help in the flushing of stones from the duct. In some cases, stones will be impacted within the duct and will require additional maneuvers. Kocher's maneuver (liberally mobilizing the lateral duodenum and head of the pancreas) will allow the surgeon to hold and palpate the duodenum, the head of the pancreas, and stones within the duct, facilitating instrumentation. Stone retrieval forceps, biliary Fogarty catheters, and wire baskets can all be employed to retrieve stones. A choledochoscope can also be used, either at the outset of exploration or for stone retrieval, if simpler maneuvers are not successful.

Either T tube cholangiography or choledochoscopy may be employed to confirm clearance of ductal stones. If no stones are

present, primary closure of the choledochotomy has been successfully employed, although most surgeons will leave in place a 12 or 14 French T tube, which is brought out through a separate stab incision in the right lateral abdominal wall [see Figure 25]. If stone clearance is not achieved, a T tube is mandatory for decompression of the biliary tract and to provide a route for future duct instrumentation. The T tube is connected to a bag for free drainage. Several days later, cholangiography is repeat-

ed. If it shows good flow into the duodenum without obstruction, the tube may be clamped and removed at the 2-week mark. If there are retained stones, a more mature tract must be allowed to develop over 4 to 6 weeks for future instrumentation and stone retrieval. Retained stones may require ERCP, percutaneous transhepatic instrumentation, T tube tract instrumentation, or combinations of these for removal.

22 PROCEDURES FOR BENIGN AND MALIGNANT BILIARY TRACT DISEASE

Bryce R. Taylor, M.D., F.A.C.S., F.R.C.S.C., and Bernard Langer, M.D., F.A.C.S., F.R.C.S.C.

Over the past few decades, remarkable advances in imaging technology have been made that allow more accurate diagnosis of biliary tract diseases and better planning of surgical procedures and other interventions aimed at managing these conditions. Operative techniques have also improved as a result of a better understanding of biliary and hepatic anatomy and physiology. Moreover, the continuing evolution of minimally invasive surgery has promoted the gradual adoption of laparoscopic approaches to these complex operations. Accordingly, biliary tract surgery, like many other areas of modern surgery, is constantly changing.

In what follows, we describe common operations performed to treat diseases of the biliary tract, emphasizing details of operative planning and intraoperative technique and suggesting specific strategies for preventing common problems. It should be remembered that complex biliary tract procedures, whether open or laparoscopic, are best done in specialized units where surgeons, anesthetists, intensivists, and nursing staff all are accustomed to handling the special problems and requirements of patients undergoing such procedures.

Preoperative Evaluation

IMAGING STUDIES

It is essential to define the pathologic anatomy accurately before embarking on any operation on the biliary tract. Extensive familiarity with the numerous variations of ductal and vascular anatomy in this region is crucial. High-quality ultrasonography and computed tomography are noninvasive and usually provide excellent information regarding mass lesions, the presence or absence of ductal dilatation, the extent and level of duct obstruction, and the extent of vessel involvement. Cholangiography—percutaneous transhepatic cholangiography (PTC), endoscopic retrograde cholangiopancreatography (ERCP), or magnetic resonance cholangio-pancreatography (MRCP) [see 5:3 *Jaundice*]¹—can supply more detailed information about ductal anatomy and is used when CT and ultrasonography yield insufficient information. Angiography is rarely required to determine resectability. Magnetic resonance imaging and MRCP, which are noninvasive, are preferred where available. As newer MRCP technology becomes available, further improvements in definition of biliary anatomy appear to be obtainable. It may eventually prove possible to avoid the complications associated with ERCP (a more invasive alternative) entirely, at least for diagnostic indications.

MANAGEMENT OF BILIARY OBSTRUCTION

Although jaundice by itself does not increase operative risk, biliary obstruction has secondary effects that may increase operative mortality and the incidence of complications. There is little evidence to support the practice of routine preoperative biliary drainage in all jaundiced patients, but there are some elective situations in which preoperative drainage is required.

Infection

Patients with clinical cholangitis, whether spontaneous or in-

duced by duct intubation (via PTC or ERCP), should be treated with biliary drainage and appropriate antibiotics until they are infection free; the recommended duration of treatment is at least 3 weeks. In addition, perioperative antibiotic prophylaxis with cefazolin or another agent with a comparable spectrum of activity should be employed routinely before any intervention or operation involving the biliary tract. For certain patients with biliary tract infection (e.g., associated with choledocholithiasis), urgent surgical decompression may be necessary, especially if antibiotics and endoscopic or transhepatic drainage are not immediately effective. If the patient was referred with a stent already in place (a frequent occurrence in our practice), broad-spectrum antibiotics should be given preoperatively to cover the anaerobes inevitably present.

Renal Dysfunction

The combination of a high bilirubin level and hypovolemia is a significant risk factor for acute renal failure, which can occur in the presence of a number of additional factors, such as acute infection, hypotension, and the infusion of contrast material. Patients with biliary obstruction should therefore be well hydrated before receiving I.V. contrast agents or undergoing operative procedures. In patients with acute renal dysfunction secondary to biliary obstruction, decompression of the bile duct until renal function returns to normal is advisable before any major elective procedure for malignant disease.

Impaired Immunologic Function or Malnutrition

Patients with long-standing biliary obstruction have impaired immune function and may become malnourished. Decompression of the bile duct until immune function and nutritional status are restored to normal is indicated before any major elective procedure is undertaken; this may take as long as 4 to 6 weeks.

Coagulation Dysfunction

Prolonged bile duct obstruction may lead to significant deficits in clotting factors. These deficits should be corrected with fresh frozen plasma and vitamin K before an operative procedure is begun. Even if there is no measurable coagulation dysfunction, vitamin K should be given to all patients with obstructive jaundice at least 24 hours before operation to replenish their depleted vitamin K stores.

Projected Major Liver Resection

If resection of an obstructing bile duct tumor is likely to necessitate major liver resection (e.g., a right trisectionectomy), it may be advisable to decompress the liver segments that are to be retained for approximately 4 to 6 weeks; a “normalized” area of the liver presumably regenerates more quickly than an obstructed one.

Operative Planning

PATIENT POSITIONING

The patient is placed in the supine position on an operating

table that can be rotated and elevated. An x-ray cassette and machine should be available during major resections. Slight elevation of the right portion of the chest with an I.V. bag facilitates exposure of the liver and the biliary structures. A choledochoscope and equipment for intraoperative ultrasonography should also be available. Access to a pathology department that can perform cytologic or frozen-section examination of tissue is essential in operations intended as treatment of malignant disease.

GENERAL TECHNICAL CONSIDERATIONS

Exposure of Subhepatic Field in Open Procedures

A right subcostal incision provides excellent exposure for most open procedures on the gallbladder and biliary tract. For more extensive resections or reconstructions, the right subcostal incision can be extended laterally below the costal margin and across the midline to the left as a chevron incision. In patients with very narrow costal margins, a vertical midline incision may be more suitable for limited operations on the gallbladder and biliary tract, and a combination of a unilateral or bilateral subcostal incision and a midline vertical extension to the xiphoid may be required for more extensive operations. In any case, the incision must be long enough to allow sufficient visualization for safe performance of the procedure.

Adequate exposure and lighting are essential. The best retractors are those that can be fixed to the table while remaining flexible in terms of placement and angles of retraction. Modern high-intensity lights with focusing capabilities and headlamps are especially useful when the surgeon wears magnifying glasses.

Good access to the hepatoduodenal ligament and the structures in the porta hepatis is critical. In patients who have never undergone an abdominal procedure, identification of these structures is straightforward. In patients who have undergone previous operations or have a local inflammatory process, however, there may be considerable obliteration of planes. If this is the case, the following techniques may be useful in defining the anatomy.

1. *Using the falciform ligament as a landmark.* In reoperative surgery, the key to opening up the upper abdomen is the falciform ligament. This structure should be found immediately after the opening of the abdominal wall and retracted superiorly. The omentum, the colon, and the stomach are then dissected inferiorly, and a plane that leads to the hepatoduodenal ligament and the porta hepatis is thereby opened.
2. *Taking the right posterolateral approach.* When the colon and the duodenum are adherent to the undersurface of the right hemiliver, separation may be difficult. In most patients, an open space remains that can be approached by sliding the left hand posteriorly to the right of these adhesions and into the (usually open) subhepatic space in front of the kidney and behind the adhesions. Anterior retraction allows identification of the adherent structures by palpation and permits dissection of the adhesions in a lateral-to-medial direction. The undersurface of the liver is thus cleared, and the hepatoduodenal ligament can be approached.
3. *Taking the lesser sac approach.* Ordinarily, the foramen of Winslow is open, and the left index finger can be passed through it from the right subhepatic space. When the foramen of Winslow is obliterated, however, one should approach it from the left, dividing the lesser omentum and passing an index finger from the lesser sac behind the hepatoduodenal ligament to reopen the foramen of Winslow by blunt dissection.
4. *Using the round ligament to find the true porta hepatis.* Patients

who have already undergone one or more operations on the bile duct often have adhesions between the hepatoduodenal ligament and segment 4 of the liver. If one dissects this area via the anterior approach, one may think that the actual porta hepatis has been reached but notice that the hepatoduodenal ligament looks unusually short. In most cases, one can find the true porta more easily by tracing the round ligament to the point where it joins the left portal pedicle (including the ascending branch of the left portal vein) and then following that to the right along the true porta. The adhesions between the hepatoduodenal ligament and segment 4 can then be more easily divided from the left than from the front.

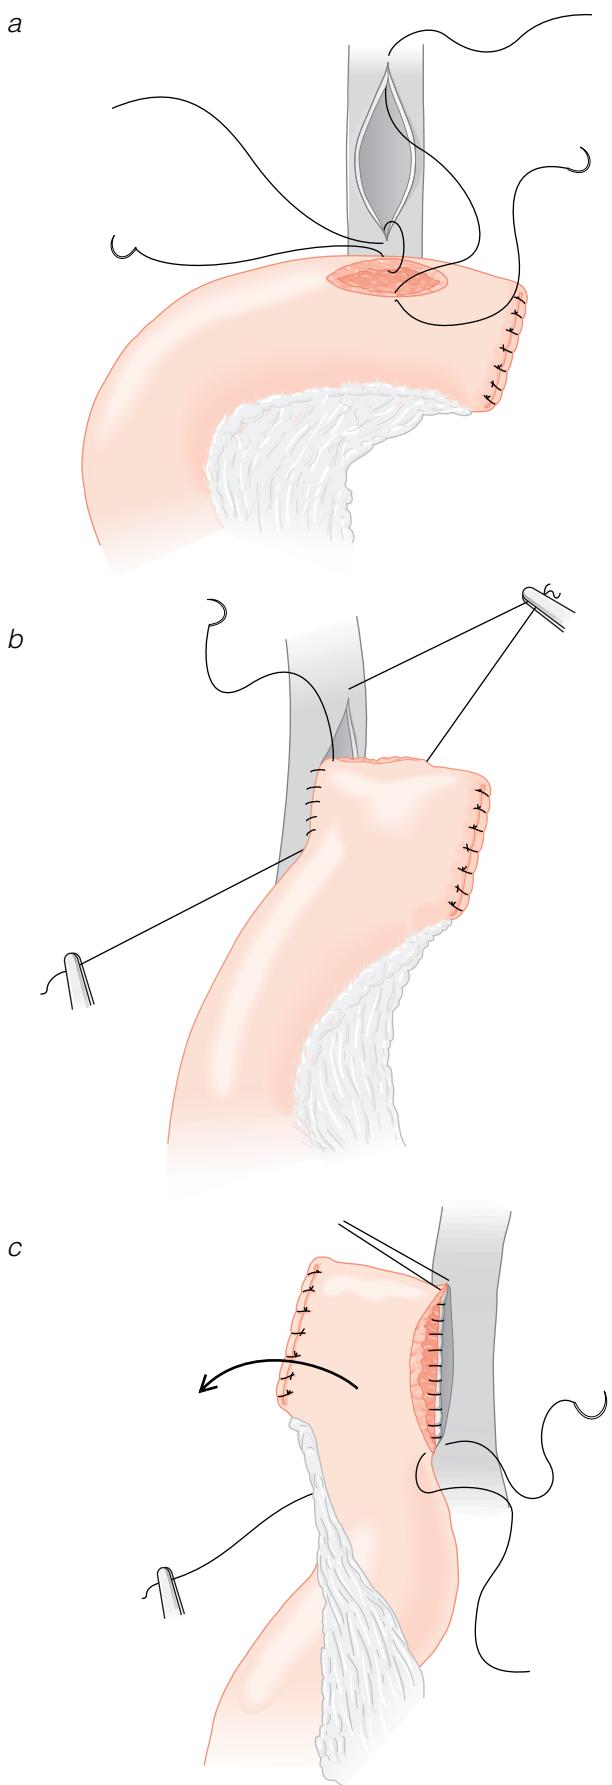

5. *Using aids to dissection.* Usually, structures in the hepatoduodenal ligament can be identified by inspection and palpation, especially if there is a biliary stent in place. In cases in which such identification is not easily accomplished, an intraoperative Doppler flow detector may be useful in identifying the hepatic artery and the portal vein, intraoperative ultrasonography may be helpful in identifying the bile duct (as well as vessels), and needle aspiration may also be used before the duct is incised if there is any doubt about its location. Either blunt or sharp dissection is effective in this area. Our preference is to use a long right-angle clamp (Mixter) to obtain exposure in a layer-by-layer fashion; we then electrocoagulate or ligate and divide the exposed tissue.

Guidelines for Biliary Anastomosis

As a rule, biliary anastomoses, whether of duct to bowel or of duct to duct, heal very well provided that the principles of preservation of adequate blood supply, avoidance of tension, and accurate placement of sutures are followed. In preparing the bile duct for anastomosis, it is essential to define adequate margins while avoiding excessive dissection that might compromise the blood supply to the duct. In repairs that follow acute injuries, it is important to resect crushed or devascularized tissue; however, in late repairs, it is not necessary to resect all scar tissue as long as an adequate opening can be made in the proximal obstructed duct through normal healthy tissue and as long as mucosa, rather than granulation tissue, is present at the duct margin. The length of the corresponding opening in the jejunal loop should be significantly smaller than the bile duct opening because the bowel opening tends to enlarge during the procedure.

Mucosa-to-mucosa apposition is essential for good healing and the prevention of late stricture. Sutures should be of a monofilament synthetic material (preferably absorbable) and should be as fine as is practical (e.g., 5-0 for a normal duct and 4-0 for a thickened duct). Because the bile duct wall has only one layer, biliary anastomoses should all be single layer. Sutures should pass through all layers of the bowel, taking sizable bites of the seromuscular layer and much smaller bites of the mucosa, and should take moderate-sized (1 to 3 mm, depending on duct diameter) bites in the bile duct. Interrupted sutures are used when access is difficult or the duct is small; continuous sutures, when access is easy and the duct is larger. Sutures should be securely placed but should not be so tight as to injure the tissues. It is sometimes wise to vary the spacing of the stitches: placing many stitches close together may cause ischemia of the suture line in a postage-stamp pattern. Magnification with loupes is particularly useful in anastomosing small ducts during open procedures. Stents are not routinely required for biliary anastomoses, and drainage of the operative field is seldom necessary.

There are several principles of suture placement that can be applied to most biliary anastomoses, whether end to side or side to

side. When the bile duct opening has a vertical configuration (as in side-to-side choledochoduodenostomy or choledochojejunostomy), stay sutures are placed inferiorly and superiorly in the duct and at corresponding points in the intestine. Traction is placed on these sutures to line up the adjacent walls. One side of the anastomosis is done first; the bowel is then rotated 180°, and the other side is completed [see *Figure 1*]. This maneuver may be facilitated by retracting the first interrupted posterior stitch to the opposite side to serve as a pivotal stitch. It is advisable to sew about two thirds of the first wall and two thirds of the second, leaving the anterior third of the circumference (the easiest part) to be closed last. This technique can also be used for end-to-side choledochojejunostomy and allows all the knots to be tied outside the lumen. When the bile duct opening lies transversely, as in bifurcation reconstruction, lateral stay sutures are placed first, and the posterior wall stitches are placed from inside the lumen. If interrupted sutures are used, they are all placed individually before any of them are tied, with the untied tails carefully arranged in order. When the posterior wall sutures have been tied, the anterior wall can then be sutured with either continuous or interrupted sutures [see *Figure 2*].

When the intended anastomosis is intrahepatic and access is particularly difficult because of some combination of an unfavorable position, a previous scar, or, perhaps, a stiff liver that is difficult to retract, another technique may be useful. All of the anterior wall stitches are placed into the duct, grouped together on a single retracting forceps with the needles left attached, and retracted superiorly to promote better exposure of the posterior duct wall [see *Figure 2c*]. The posterior stitches are placed into the duct and the bowel as described, tied in order, and cut; the anterior wall stitches are then completed by being placed into the bowel and tied.

When the duct is small, there are three techniques that may be useful for increasing the size of the lumen.

1. An anterior longitudinal incision can be made in a small common bile duct (CBD), and the sharp corners can be trimmed to enlarge the opening [see *Figure 3a*].
2. If the cystic duct is present alongside a divided CBD, an incision can be made in the shared wall to create a single larger lumen [see *Figure 3b*].
3. If the bifurcation has been resected, two small ducts can be brought together and sutures placed into their adjoining walls to form a single larger lumen [see *Figure 3c*].

Construction of Roux Loop

When the jejunum is used for long-term biliary drainage, a Roux loop is used to prevent reflux of small bowel content into the biliary system. In the creation of the loop, it is important to select a segment of jejunum with a well-defined vascular arcade that will be long enough to support a tension-free anastomosis. If access to the biliary system will be required in the future (e.g., in an operation for recurrent intrahepatic stones), the loop should be long enough to allow one to place a tube jejunostomy, fixing the loop to the abdominal wall with nonabsorbable sutures. The site of attachment should be marked with metallic clips to facilitate future percuta-

Figure 1 Technical issues in biliary anastomosis. Shown is a side-to-side choledochojejunostomy using a vertical incision in the bile duct. The same technique can be used for choledochoduodenostomy or end-to-side choledochojejunostomy. (a) Inferior and superior corner continuous sutures are placed. (b) One side of the anastomosis is sewn first (here, the right side). (c) The bowel is rotated 180° so that the other side is exposed. The other side of the anastomosis is then sewn (here, the left side).

neous puncture and cannulation and removal of recurrent or persistent stones. The tube can be removed after postoperative imaging studies confirm that the biliary tree is free of stones.

Principles of Laparoscopic Biliary Tract Procedures

The surgical principles that lead to successful outcomes are much the same for laparoscopic biliary tract procedures as for their open counterparts. An anastomosis that is done under excellent exposure

and lighting, that is fashioned with meticulously placed sutures, and that is completed without tension usually heals without complications and remains patent, regardless of the approach followed. However, because stricturing can occur many years after operation, biliary tract anastomoses must be followed for relatively long periods before success can be claimed. Accordingly, the long-term results of biliary-enteric anastomoses remain to be established.

As a rule, laparoscopic biliary procedures should be performed by surgeons with substantial expertise and experience in both hepatobiliary surgery and minimally invasive surgery.

Most of the conventional biliary tract operations—including choledochooduodenostomy, cholecystojejunostomy, choledochojejunostomy, and choledochal cyst resection—have been successfully performed in small numbers by laparoscopic means. The laparoscopic approach may become a particularly attractive option in the palliative setting if it proves more reliable than endoscopic stenting or percutaneous transhepatic cholangiography and drainage (PTCD) with respect to safety and speed of postoperative recovery.

The laparoscopic approach to biliary anastomosis¹ involves placement of four or five ports in a fan pattern and usually is associated with a longer operating time than the open approach. Liver retraction is achieved with an articulated retractor (e.g., Endoflex; New Dynamics in Medicine, Dayton, Ohio), and dissection may be carried out with sharp instruments and an electrocautery, with or without an ultrasonic scalpel (e.g., Harmonic Scalpel; Ethicon Endo-Surgery, Inc., Cincinnati, Ohio).

Magnification may enhance the surgeon's ability to perform these demanding anastomoses in a meticulous fashion, and robotic assistance (in the form of wrist-type end-effectors) may further improve precision. Advanced intracorporeal knot-tying and suturing skills are a prerequisite, along with personal expertise in intraoperative laparoscopic ultrasonography, which is often helpful in assessing the liver and the porta hepatis. During intracorporeal creation of a biliary anastomosis, small clips may be used to organize multiple interrupted sutures, much as hemostats are used in the corresponding open procedures.

Choledochooduodenostomy

Choledochooduodenostomy is a relatively straightforward side-to-side biliary-enteric bypass procedure that is effective in certain restricted circumstances and has the advantage of being simpler and safer than transduodenal sphincteroplasty. It is most commonly used in patients with multiple bile duct stones when there is concern about leaving residual stones at the time of CBD exploration as well as in patients with recurrent bile duct stones when endoscopic papillotomy either cannot be done or has been unsuccessful. It is also used in patients with benign distal biliary obstruction (e.g., from chronic pancreatitis) and occasionally in patients with malignant distal CBD obstruction whose life expectancy is short. Choledochooduodenostomy works best if the CBD is at least 1 cm in diameter; it should not be used in patients with actual or potential duodenal obstruction.

OPERATIVE TECHNIQUE

The duodenum is mobilized to allow approximation to the CBD without tension. Ordinarily, the first part of the duodenum can easily be rolled up against the CBD; however, in patients who have chronic pancreatitis or have previously undergone an abdominal procedure, extensive kocherization may be required. If satisfactory approximation is not achieved with this maneuver, a choledochojejunostomy should be performed.

The CBD is exposed as described elsewhere [see 5:21 Cholecys-

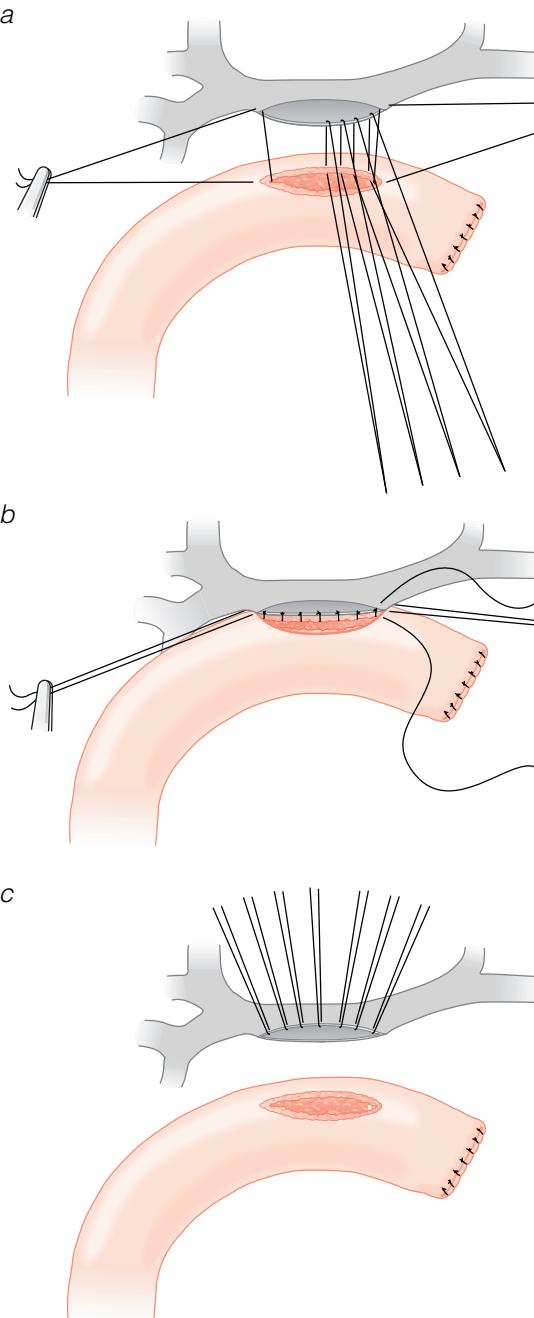

Figure 2 Technical issues in biliary anastomosis. Shown is an end-to-side choledochojejunostomy using a transverse opening in the bile duct. This technique can be used at any level. (a) Corner sutures and posterior wall sutures are all placed before being tied. (b) The posterior wall is completed, and the anterior wall is sewn. (c) In difficult cases, the anterior wall sutures may be placed first, then retracted superiorly.

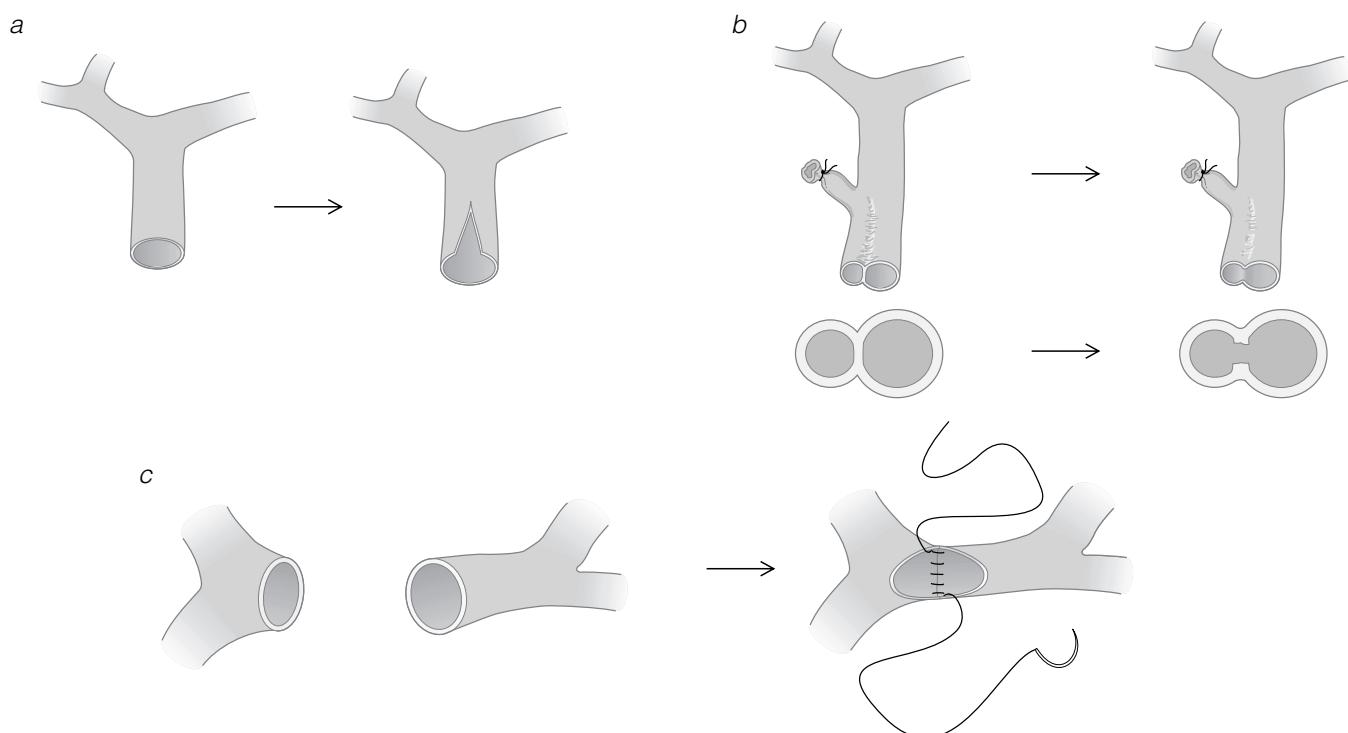

Figure 3 Technical issues in biliary anastomosis. Shown are three methods of enlarging a small duct. (a) An anterior longitudinal incision can be made in the duct wall. (b) A wall shared by the CBD and the cystic duct can be divided. (c) Adjoining walls of two small ducts can be sutured together to make a single opening for anastomosis.

tectomy and Common Bile Duct Exploration]. Longitudinal incisions are made in both the duodenum and the duct [see Figure 1], and the anastomosis is carried out as described previously [see Operative Planning, General Technical Considerations, Guidelines for Biliary Anastomosis, above].

Laparoscopic Considerations

Laparoscopic choledochoduodenostomy,² like all minimally invasive surgical procedures, follows the same principles proven in its open procedural counterpart—namely, adequate exposure, sufficient size of the CBD, and meticulous attention to creating a tension-free anastomosis with intracorporeally placed interrupted sutures. The diamond-shaped anastomosis fashioned should be indistinguishable from that fashioned in the corresponding open procedure.

COMPLICATIONS

Late closure or stricture of the anastomosis may occur if the CBD is small or malignant disease is present. Alternative methods of biliary decompression should be considered in these situations.

Cholangitis related to the presence of food in the CBD distal to the anastomosis (so-called sump syndrome) is an uncommon occurrence. The larger the anastomosis, the smaller the likelihood that this complication will occur.

Cholecystojejunostomy

Cholecystojejunostomy may be performed to treat malignant biliary obstruction in selected patients whose lesions are found to be unresectable at operation and whose life expectancy is expected to be short. Occasionally, it is indicated for patients in whom endoscopic or percutaneous stenting has been unsuccessful. This operation is not the preferred procedure for long-term decompression.

OPERATIVE TECHNIQUE

Step 1: Verification of Feasibility of Procedure

The cystic duct must be patent. Its junction with the CBD must be at least 1 cm above the tumor obstruction [see Figure 4]. The suitability of the anatomy for cholecystojejunostomy may have been verified by preoperative cholangiography; if not, intraoperative cholangiography via the gallbladder or the CBD is mandatory. If one still cannot be certain that the operation is feasible, the CBD should be opened and a choledochoenterostomy performed. The finding of a bile-filled gallbladder is not sufficient evidence that the patient is a suitable candidate for a cholecystojejunostomy. The gallbladder should be normal: there should be no evidence of cholecystitis or stones. Normal status is verified by inspection, palpation (in the open setting), and, if necessary, needle cholecystography. Finally, for the anastomosis to be feasible, one should be able to approximate the jejunum to the gallbladder easily.

Step 2: Preparation for Anastomosis

A site near the fundus is selected for the anastomosis, and an appropriate segment of proximal jejunum is anchored to the gallbladder with two fine stay sutures in anticipation of a transverse incision in the gallbladder and a longitudinal incision in the anti-mesenteric border of the bowel.

Step 3: Anastomosis

A 2 cm opening is made in the gallbladder and the adjacent segment of the jejunum, and a single-layer anastomosis is constructed with a continuous monofilament absorbable suture or a stapler.

Step 4: Optional Additional Procedures

A Roux loop, rather than a simple jejunal loop, may be used in the construction of the choledochojejunostomy, and a gastroje-

junostomy [see 5:20 *Gastroduodenal Procedures*] may be added in patients with pancreatic head cancer in whom duodenal obstruction is either present or anticipated in the near future.

COMPLICATIONS

Bile leakage may occur if there is excessive tension on the anastomosis. In addition, jaundice may persist if there is unrecognized cystic duct obstruction resulting from inflammation or an unnoticed stone in the cystic duct or the gallbladder. Recurrent jaundice is usually the result of extension from an obstructing tumor that has involved the cystic duct–CBD junction.

Choledochojejunostomy

Choledochojejunostomy, one of the most commonly performed biliary tract procedures, is done to provide biliary drainage after CBD resection, repair of ductal injury, or relief of obstruction caused by a benign or malignant stricture. To reduce the likelihood of reflux of intestinal contents into the biliary tract, a Roux-en-Y jejunal loop is usually used for the anastomosis [see Operative Planning, General Technical Considerations, Construction of Roux Loop, *above*]. If long-term access to the biliary tract is required (e.g., in patients with recurrent intrahepatic strictures or stones), the Roux limb may be anchored to the abdominal wall rather than left free in the abdominal cavity.

When the operation is performed after CBD resection, an end-to-side choledochojejunostomy using the proximal transected duct is made. When the operation is performed for bile duct obstruction resulting from tumor or stricture and no resection has been performed, a side-to-side anastomosis is constructed. If a stent has already been placed endoscopically or percutaneously, the bile duct is often thickened.

OPERATIVE TECHNIQUE

Step 1: Preparation for Anastomosis

Preparation for an end-to-side anastomosis includes resection of any crushed or devitalized bile duct tissue. The CBD should be trimmed back to healthy, viable, bleeding duct wall. If the lumen of the duct is small, a short incision on the anterior wall will effectively increase its circumference to facilitate the anastomosis [see Figure 3a]. If the CBD has been transected at the level of the cystic duct, the lumina of the CBD and the cystic duct may be combined by incising and oversewing their common wall [see Figure 3b].

If a side-to-side anastomosis is being performed for stricture or tumor, the proximal duct is almost always dilated and has thicker walls, and thus a vertical incision is made on the anterior surface. When the procedure is being done for malignant disease, the incision should be made as high as possible above the malignancy to delay the eventual obstruction of the anastomosis by tumor growth.

Step 2: Anastomosis

When the duct is large, a secure, tension-free anastomosis can be constructed by means of the techniques previously illustrated [see Figures 1 and 2]. When the duct is small, extra effort must be made to place sutures carefully so as to prevent narrowing of the lumen. The laparoscopic variant of the procedure, like all laparoscopic biliary tract procedures, demands similar attention to detail.^{1,3}

TROUBLESHOOTING

It is essential to preserve the blood supply to the CBD. Adequate debridement of injured ducts is mandatory, even if this means extending the resection of the duct to the bifurcation. Longitudinal

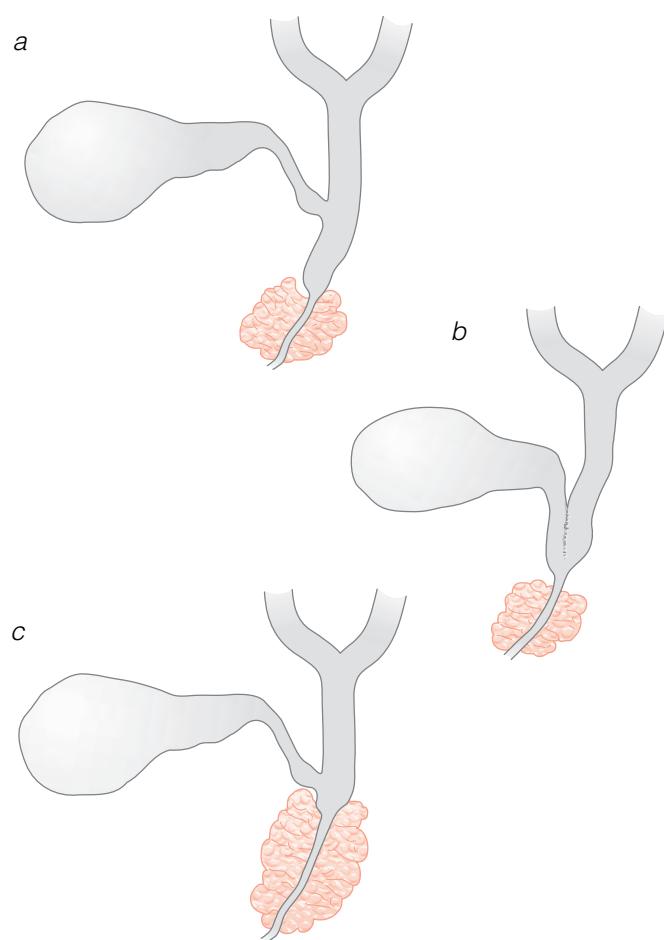

Figure 4 Cholecystojejunostomy. Cholangiography is essential for determining whether the anatomy is suitable (a) or unsuitable (b, c) for the procedure.

incisions should not be made in the medial or lateral portions of the CBD, where the major longitudinal blood supply is found. Finally, extensive mobilization of the duct from the surrounding tissues should be avoided so as to preserve the ductal blood supply.

Meticulous surgical technique is critical for ensuring good healing and preventing stricture. The finest suture material that will do the job should be employed, and magnifying devices should be used to facilitate the accurate placement of sutures. In very small ducts, the temporary placement of a small T tube at the anastomosis will allow most of the circumference to be completed without the risk of either picking up the opposite wall or placing sutures incorrectly. The T tube is then removed and the anastomosis completed. Routine postoperative stenting is unnecessary, but stents may be helpful in those rare cases in which mucosal apposition cannot be accomplished. In these situations, sutures may have to be placed in surrounding liver or scar tissue in much the same way as in a Kasai procedure. In difficult cases of proximal stricture, the surgeon may incise the liver plate and seek out viable duct above the bifurcation.

COMPLICATIONS

The main complications of choledochojejunostomy are bile leakage, late stricture, and recurrent jaundice as a result of tumor extension [see Cholecystojejunostomy and Choledochoduodenostomy, *above*].

Transduodenal Sphincteroplasty

Transduodenal sphincteroplasty is occasionally indicated when an impacted stone at the ampulla of Vater cannot be removed via a choledochotomy. It is also sometimes useful for clarifying the nature of an obstructive process at the ampulla, definitively treating ampullary stenosis, and gaining access to the main pancreatic duct if ERCP has been unsuccessful. Pancreatic sphincteroplasty may be added in selected cases.

Endoscopic techniques are usually successful for these purposes. A frequent use of the transduodenal approach is for local resection of a benign ampullary tumor (e.g., a villous adenoma) with reconstruction of the medial duodenal wall.

OPERATIVE TECHNIQUE

Step 1: Exposure of Ampulla

Mobilization of the duodenum and the pancreatic head is necessary for obtaining exposure of the lateral portion of the second part of the duodenum. The ampulla is located by palpation, which may be facilitated by passage of a sound down the CBD, out the ampulla, and into the duodenum. A longitudinal incision is made on the lateral surface of the duodenum; it should be at least 3 cm long to ensure good exposure. The duodenal edges are retracted gently. Crushing forceps should not be used; they may cause hematomas.

Step 2: Cannulation

If the bile duct has been opened, cannulation of the CBD is done from above. A metal sound may be used, but we generally prefer to insert a fine catheter and pass it through the ampulla, which can then be gently elevated into the field [see Figure 5]. This step facilitates accurate placement of an incision in the ampulla. If the duct has not been opened, cannulation is accomplished from below with a sound. Use of a grooved director may simplify the sphincterotomy.

Step 3: Sphincteroplasty

To prevent injury to the pancreatic duct, the incision in the ampulla is placed at the 11 o'clock position with either scissors or a scalpel rather than with the electrocautery. A so-called cut-and-sew approach, using interrupted 5-0 monofilament absorbable sutures placed 2 mm apart, is followed. The incision is started at the papillary orifice and extended above the ampillary sphincter along the line of the previously inserted catheter. The sutures should include both the bile duct and the duodenal wall. Once the sutures have been placed, lateral traction is applied to provide exposure of the bile duct lumen and to make each subsequent step in the cut-and-sew procedure easier. The pancreatic duct opening (usually found at the 4 o'clock position) must be identified and protected from being incorporated in the sutures.

Step 3 (Alternative): Ampullectomy

As noted, the transduodenal approach is often employed for local excision of a benign (or, sometimes, a malignant) ampullary tumor.⁴ Ampullectomy is described in greater detail elsewhere [see 5:20 *Gastroduodenal Procedures*].

Step 4: Exploration of CBD

Exploration of the CBD should be completed from below with sounds and choledochoscopy to ensure that all stones are removed. If the presence of a tumor is suspected, biopsies of any suspicious areas should be performed.

Step 5: Closure and Postoperative Care

The duodenum is then closed in the direction in which the incision was made. This can be done in either one or two layers, provided that care is taken to prevent inversion and preserve the luminal diameter. Routine drainage is not necessary unless there is concern about the duodenotomy closure or the choledochotomy closure. If a T tube has been left in place, a cholangiogram should be obtained before it is removed.

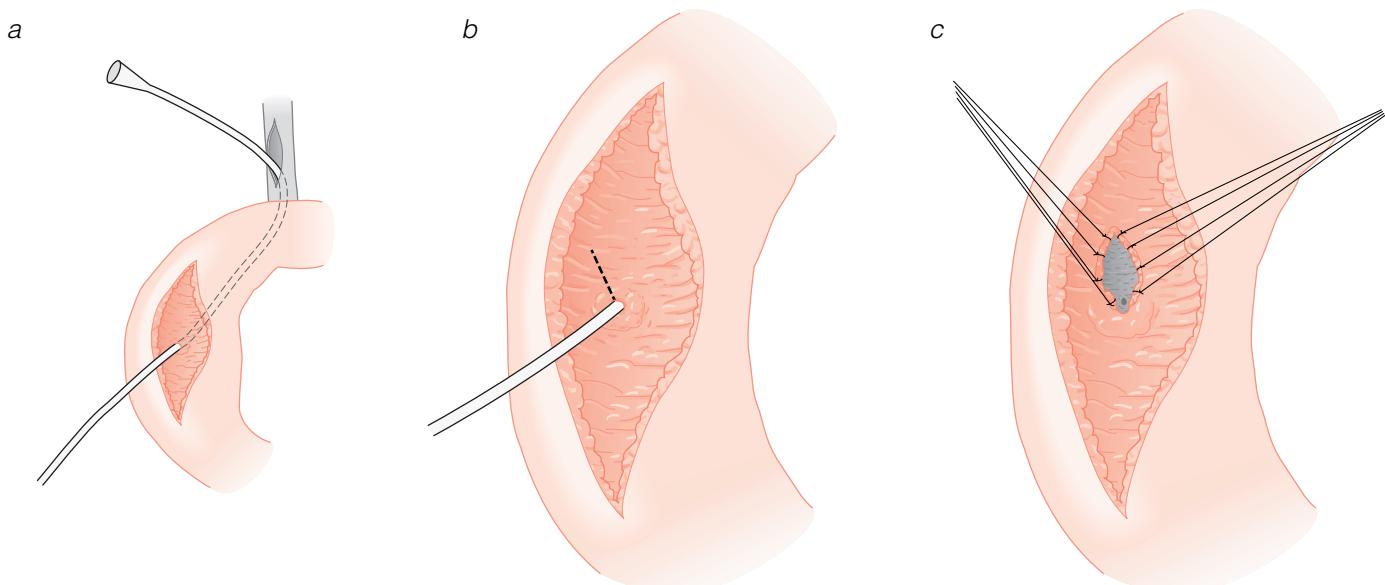

Figure 5 Transduodenal sphincteroplasty. (a) A longitudinal incision is made in the duodenum, and a filiform catheter and a follower are used to find and elevate the ampulla. (b) An incision is made at the 11 o'clock position with scissors or a scalpel. (c) Interrupted sutures are placed through the bile duct wall and the duodenal wall. Lateral traction is applied.

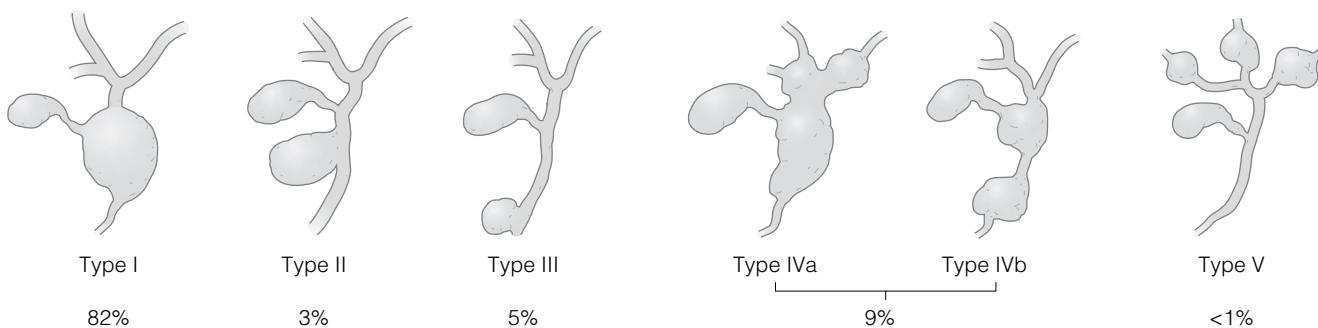

Figure 6 Choledochal cyst resection. Illustrated is the Todani classification of choledochal cysts.

TROUBLESHOOTING

There may be an impacted stone at the distal end of the CBD that prevents cannulation from either above or below. Such a stone can usually be felt through the duodenal wall, in which case a vertical incision can be made in the medial duodenal wall directly onto the stone. Once the stone has been extracted, the incision can be extended down through the ampulla with a sound used as a guide.

Occasionally (e.g., in some patients with chronic pancreatitis), a long stricture of the CBD may extend above the ampulla. In such cases, the sphincteroplasty may have to be extended proximally to the point where it communicates with the retroperitoneal space. This will not be a problem as long as the duodenum-to-CBD repair is carefully executed. If the obstruction cannot be managed with an extended sphincteroplasty, a different decompressive procedure, such as choledochojejunostomy or choledochoduodenostomy, must be chosen.

Postoperative pancreatitis may develop if there was excessive manipulation of the ampulla, if the electrocautery was used at the ampulla, or if the pancreatic duct orifice is occluded by one of the sphincteroplasty sutures.

Choledochal Cyst Resection

Choledochal cysts are generally categorized according to the Todani classification [see Figure 6]. More than 80% are type I cysts that involve the CBD in its accessible portion. The following discussion addresses the resection of type I cysts and those type IV cysts that include the proximal right or left hepatic ducts.

Most choledochal cysts are related to an abnormal junction of the pancreatic duct and the distal CBD. Preoperative cholangiography to clarify the anatomy is important for preventing injury to the pancreatic duct, especially when an intrapancreatic resection may be required. Occasionally, intraoperative cholangiography is required to clarify abnormal anatomy. Patients may be symptomatic as a result of stones within the cyst, infection, or malignancy, any of which is an indication for operation. Because of the high incidence of such conditions and the extremely high mortality associated with carcinoma in this setting, prophylactic cyst resection seems justified even in asymptomatic patients.

The objectives of treatment are (1) to remove the cyst completely, along with the gallbladder and any stones that remain in the bile ducts proximal to the cyst, and (2) to achieve free biliary drainage. Resection of a choledochal cyst may be made more difficult by several factors, such as previous operations, recurrent bouts of infection and inflammation in the cyst, and portal hypertension, which may develop as a result of long-standing cholangitis or portal vein thrombosis.

OPERATIVE TECHNIQUE

Resection of a choledochal cyst may be difficult and bloody, especially if inflammation is present. In addition, dissection of a choledochal cyst in its intrapancreatic portion may be hazardous because of the vascularity of this region and the difficulty of identifying anatomic structures.

Step 1: Clarification of Anatomy

The proximal and distal extent of the cyst and the presence or absence of stones or tumor may be determined preoperatively, as noted, but in many cases, intraoperative verification of the findings is necessary. Intraoperative cholangiography can be carried out by

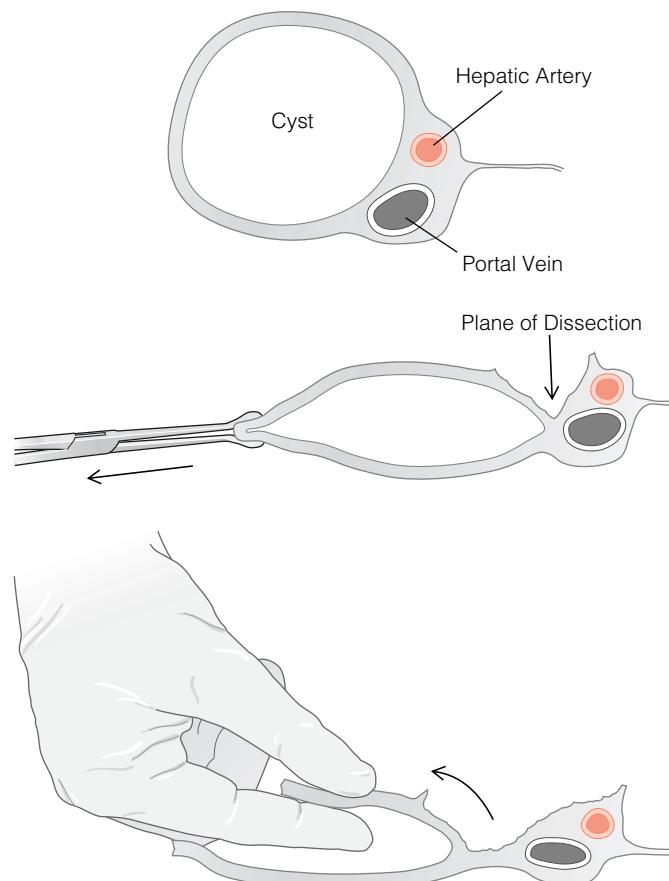

Figure 7 Choledochal cyst resection. Illustrated is the proper plane of dissection in removal of a choledochal cyst. If necessary, dissection can be done with a finger inside the cyst.

inserting a catheter through the gallbladder, by directly needling the cyst, or both. If cholangiography does not yield an accurate definition of the anatomy of the cyst, the cyst may then be opened and digital exploration and choledochoscopy used to clarify the anatomy.

Step 2: Initial Dissection

If the gallbladder is still in place, it is dissected free of the liver and left attached to the cyst via the cystic duct, then retracted to the right. If the patient has already undergone a cystoenteric anastomosis, this should be taken down at the beginning of the procedure, and the opening in the bowel should be carefully closed.

Step 3: Mobilization of Cyst

As noted, the vascularity of the region and the presence of inflammation may render dissection difficult. Rather than cleaning off the hepatic artery and the portal vein and dissecting them off the cyst, the surgeon should find a plane immediately adjacent to the wall of the cyst and remain close to it [see *Figure 7*]. This approach differs significantly from the corresponding approach in resection of a bile duct malignancy [*see Resection of Middle-Third and Proximal Bile Duct Tumors, Operative Technique, below*]. If necessary, the cyst may be opened and the dissection continued with a finger inside the cyst to yield a more accurate definition of its boundaries. The cyst should be cleared circumferentially in the middle third of the CBD so that a tape can be passed around it and traction applied to separate the cyst from the hepatic artery, the portal vein, and any remaining soft tissue in the hepatoduodenal ligament.

Step 4: Distal Dissection

Dissection then proceeds distally along the wall of the cyst until the junction of the cyst with the normal portion of the CBD is reached. If the intrapancreatic portion of the CBD is involved, the cyst must be separated from pancreatic tissue. There are a number of small vessels that must be individually identified and ligated to minimize the risk of early or delayed bleeding. If the cyst is close to the pancreatic duct junction, considerable care must be exercised not to injure the pancreatic duct.

Step 5: Proximal Dissection

If the proximal common hepatic duct is normal (as in a type I cyst), it is transected above the cyst. If the cystic dilatation includes the bifurcation (as in a type IVa cyst), a small button of proximal cyst is usually left attached to the intrahepatic ducts [see *Figure 8*].

Step 6: Reconstruction

Reconstruction is accomplished via an end-to-side anastomosis to a Roux jejunal loop to minimize the likelihood of reflux of enteric contents into the biliary tract.

Step 7: Closure

The abdomen is closed in the standard fashion. Stenting is not required, but the area should be drained with closed suction drains if an intrapancreatic resection has been done.

Laparoscopic Considerations

If the appropriate principles and techniques are used [*see Operative Planning, General Technical Considerations, Principles of Laparoscopic Biliary Tract Surgery, above*], choledochal cyst excision can be performed laparoscopically with excellent results.⁵ A laparoscopic approach faces essentially the same challenges that an open approach does [*see Complications, below*].

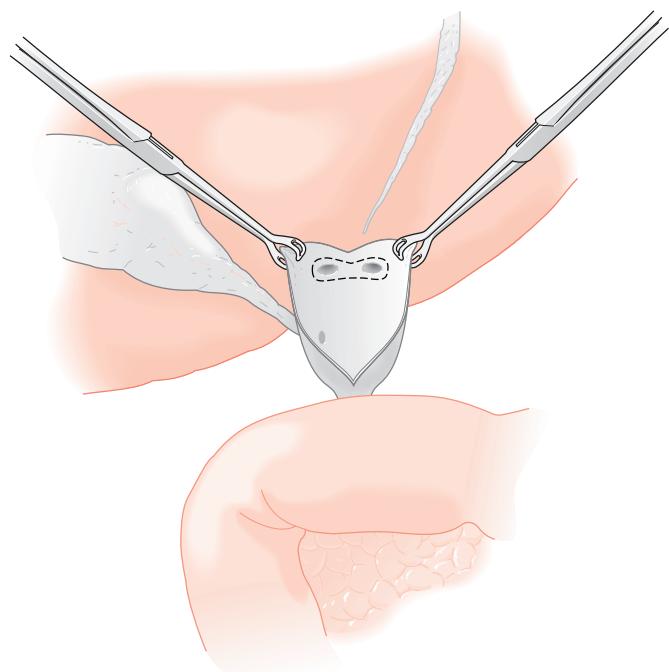

Figure 8 Choledochal cyst resection. If a cyst extends proximally past the bifurcation (e.g., a type IVa cyst), it may be necessary to open the cyst widely to identify the hepatic duct orifices. A small button of cyst wall is left attached to the hepatic ducts.

TROUBLESHOOTING

If dissection of the cyst is carried distally into the pancreas, care must be taken to keep from injuring the pancreatic duct. The cyst should be transected as distally as possible, and the end should be carefully oversewn with absorbable sutures. Somatostatin, 100 µg subcutaneously during the operation and every 8 hours for 5 days afterward, should be given to reduce the likelihood of pancreatitis and pancreatic fistula. Occasionally, intraoperative cholangiography is useful to confirm the relationship of the cyst and the CBD to the pancreatic duct.

If the cystic process extends to include the bifurcation (type IVa), the hepatic ducts should be identified from within the cyst and their orifices preserved by leaving a small button of cyst wall in situ; this is preferable to performing an intrahepatic dissection to remove the entire cyst. The presence of this button simplifies and facilitates the anastomosis to the Roux loop.

COMPLICATIONS

Bleeding and pancreatitis are the main early complications of cystectomy. These can be largely prevented by meticulous dissection and ligation of all fine bleeding vessels as well as tissue adjacent to an intrapancreatic cyst. Late stricture of the anastomosis is an uncommon complication but may occur, especially if a small button of proximal cyst is left in place for the anastomosis; this particular complication is considered an acceptable hazard in a difficult situation.

OUTCOME EVALUATION

The immediate expected outcome is the relief of pain, jaundice, and cholangitis and the return of liver function to normal. The long-term expected outcome is the absence of any recurrence of symptoms of stone disease, cholangitis, or malignancy. Because of the rarity of this condition, no good data on the recurrence rate of problems are available.

Resection of Middle-Third and Proximal Bile Duct Tumors

The most common bile duct tumor is adenocarcinoma [see 5:9 *Tumors of the Pancreas, Biliary Tract, and Liver*]. Because this tumor responds poorly to irradiation and chemotherapy, surgical resection offers the best opportunity for cure. The appropriate operative approach depends on the location and extent of the tumor [see Figure 9]. Tumors in the distal third of the CBD (the pancreatic portion) are treated by means of a Whipple procedure that includes bile duct and periductal tissues right up to the bifurcation [see 5:24 *Pancreatic Procedures*]. Those in the middle third or the proximal third are treated by means of bile duct resection, with or without liver resection [see 5:23 *Hepatic Resection*].

There are certain basic principles underlying bile duct resection for tumor that must be followed. First, the proximal extent of the tumor must be identified so that the correct procedure can be planned. Preoperative PTC is usually not required for staging if high-quality ultrasonography and MRCP are available. Some authorities advocate bilateral percutaneous drainage to facilitate intraoperative dissection. We do not routinely use preoperative drainage tubes, because of the risk of cholangitis.

Second, given that bile duct tumors spread by local extension to lymphatics, along perineural spaces, and along the bile radicles themselves directly into the liver, wide local excision beyond the visible edges of the tumor is required in the performance of curative

resections. In proximal tumors, such excision necessitates resection of the adjacent segments of the liver. The principles of en bloc resection beyond tumor margins must be closely adhered to: dissection into or even close to the tumor must be avoided.

Third, intraoperative biopsy of the tumor should not be done, because of the difficulty of making a firm pathologic diagnosis on the basis of frozen-section examination and because of the risk of tumor dissemination.

Finally, given that liver resection is required in most cases, one must be careful to preserve enough healthy liver tissue to allow regeneration of the remnant. If there has been long-standing obstruction, biliary drainage on the side to be preserved is important for recovery of function in that portion of the liver. Some surgeons advocate preoperative portal vein embolization on the contralateral side to stimulate hepatic regeneration in the segments to be preserved, especially if the future remnant is marginal in size [see 5:9 *Tumors of the Pancreas, Biliary Tract, and Liver*].

On the whole, we are currently more aggressive in treating proximal tumors than we once were, for two main reasons: (1) the accompanying liver resection can now be done with greater safety, and (2) this more radical approach has been shown to yield improved long-term results. For middle-third or type I proximal tumors, we favor resection of the bifurcation in conjunction with intrahepatic cholangiojejunostomy. For types II, III, and IV, we

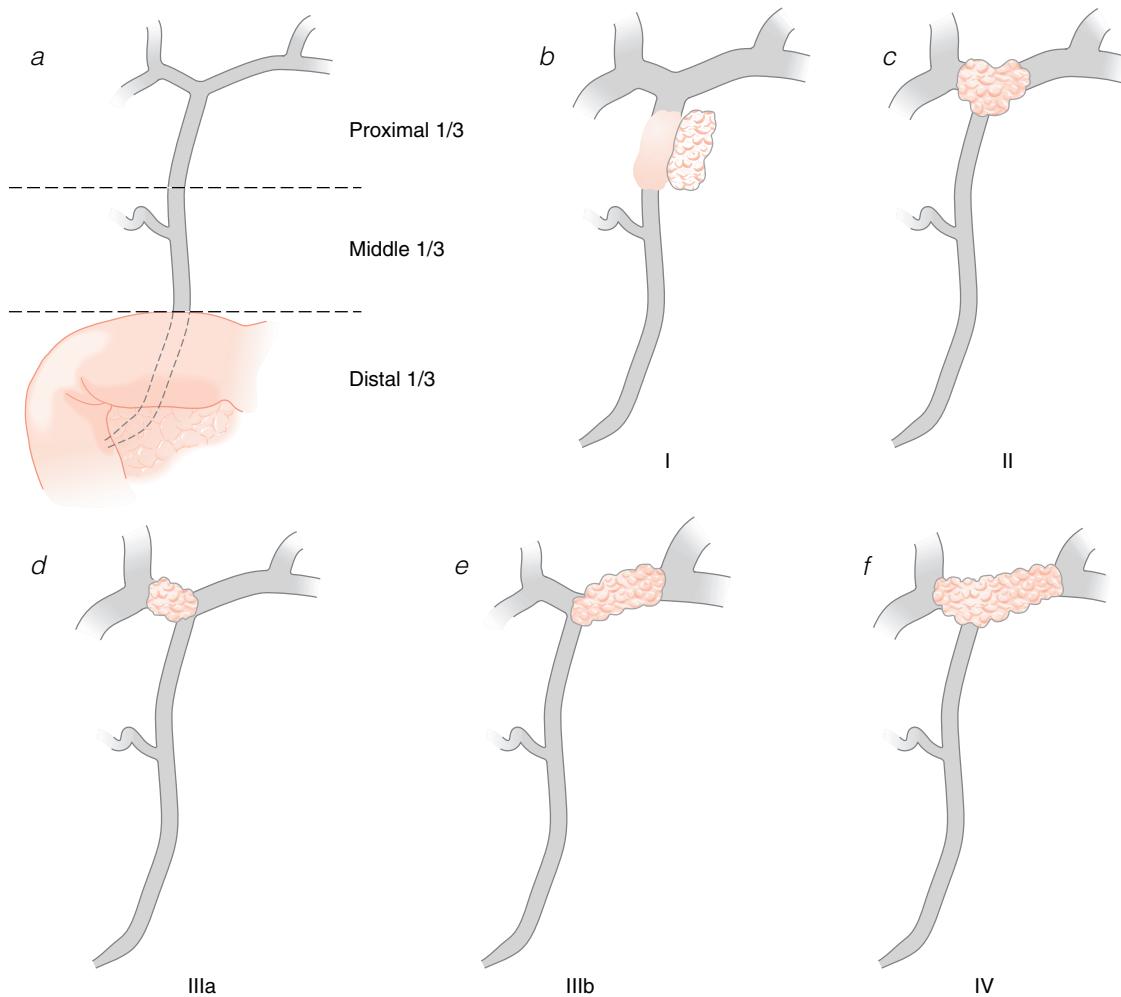

Figure 9 Resection of middle-third and proximal bile duct tumors. The appropriate operation depends on the location and extent of the tumor. (a) Broadly, tumors may be localized to the proximal third, the middle third, or the distal third of the biliary tract. (b through f) Proximal tumors may be further categorized according to the Bismuth classification.

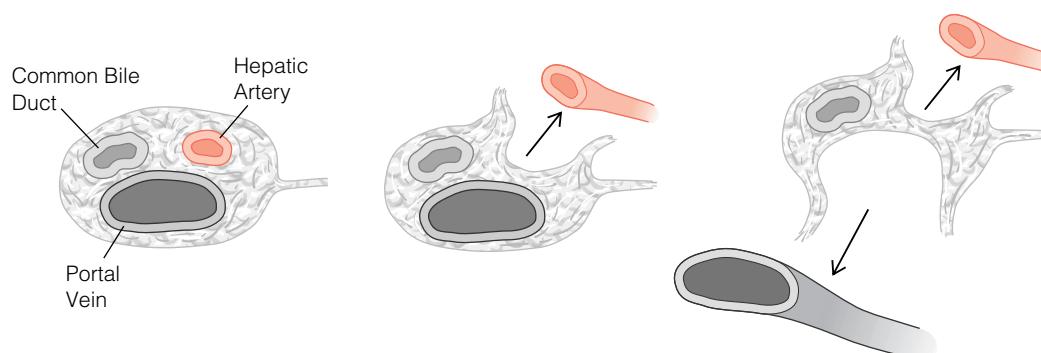

Figure 10 Resection of middle-third and proximal bile duct tumors. Shown is the proper plane of dissection in the removal of a bile duct cancer. Except for the hepatic artery and the portal vein, all tissue stays with the CBD to be resected.

recommend additional liver resection: a right trisectionectomy (resection of segments 4, 5, 6, 7, and 8, along with the caudate lobe) for types II, IIIa, and IV and a formal left hepatectomy (resection of segments 1, 2, 3, and 4) for type IIIb [see 5:23 Hepatic Resection]. There is some controversy as to whether patients with these complex proximal biliary tumors have a better chance of long-term survival with liver transplantation than with a right trisectionectomy. This controversy has yet to be resolved, but given that organ availability remains a major issue, we continue to prefer radical resection in this setting.

OPERATIVE TECHNIQUE

Step 1: Assessment of Resectability

Before any dissection of the tumor or the CBD is done, a careful search for peritoneal metastases is undertaken. Spread within the liver is evaluated via palpation and intraoperative ultrasonography. Lymph nodes are assessed in the immediate and secondary drainage areas. Biopsies of any suspicious areas outside the planned resection margins are carried out. If tumor is found, stenting or a bypass procedure is indicated.

During dissection, determination of resectability is often difficult, especially with respect to assessment of tumor extension into the liver and the degree of vessel involvement. Therefore, any firm commitment to resection (e.g., dividing the blood supply) should be deferred until resectability is confirmed.

The gallbladder is mobilized from the liver bed by entering the usual plane superficial to the liver capsule without dissecting or dividing the cystic artery and the cystic duct. Exposure is improved by mobilizing the gallbladder and, if necessary, emptying the gallbladder of bile. The gallbladder can also be used as a retractor on the bile duct.

Dissection is then begun from below. The common hepatic artery and the portal vein are identified just above the neck of the pancreas and circumferentially cleared of all tissue. Dissection then proceeds proximally, with the hepatic artery retracted to the left and the portal vein to the right. Adjacent areolar tissue, nerve trunks, and lymph nodes are left in place around the CBD and the tumor [see Figure 10]. As noted, this approach differs from that used in resection of choledochal cysts [see Choledochal Cyst Resection, Operative Technique, above].

Step 2: Division of CBD

Once resectability is confirmed, the CBD is divided at the level of the pancreas. A clamp is placed on the upper end of the divided duct, which is then used as a retractor to facilitate the most

proximal dissection of the CBD and the tumor away from the hepatic artery and the portal vein [see Figure 11].

Step 3: Proximal Dissection

With middle-third tumors or Bismuth type I proximal tumors, it is usually possible to palpate the proximal tumor margin and identify uninolved right and left hepatic ducts. If this is not the case, the possibility of a type II or III tumor should be considered, and complete excision of the bifurcation, with or without part of the liver, should be planned.

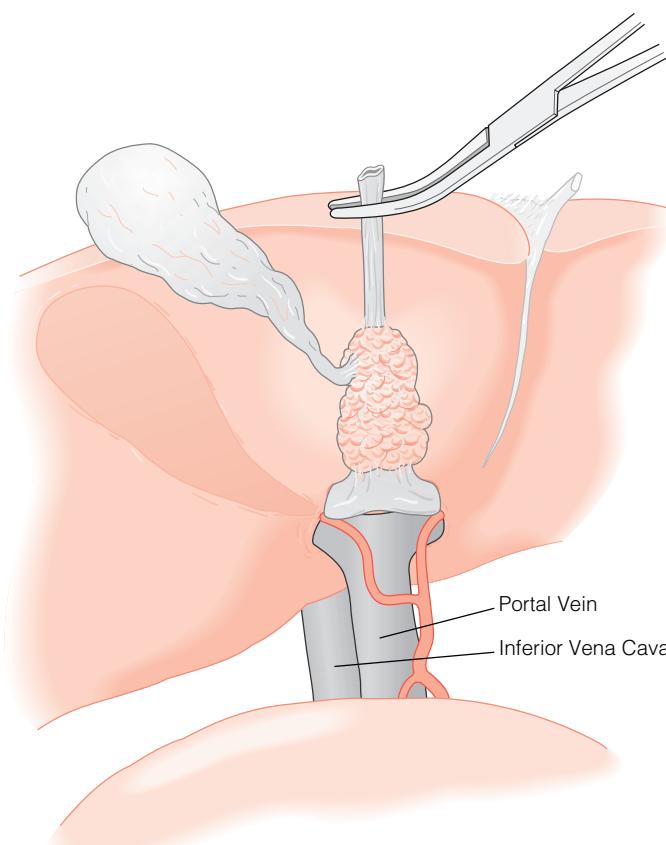

Figure 11 Resection of middle-third and proximal bile duct tumors. When resectability is confirmed, the CBD is transected at the duodenum. The proximal portion of the divided duct is retracted anteriorly, and the CBD is cleaned off the portal vein up to a point above the bifurcation.

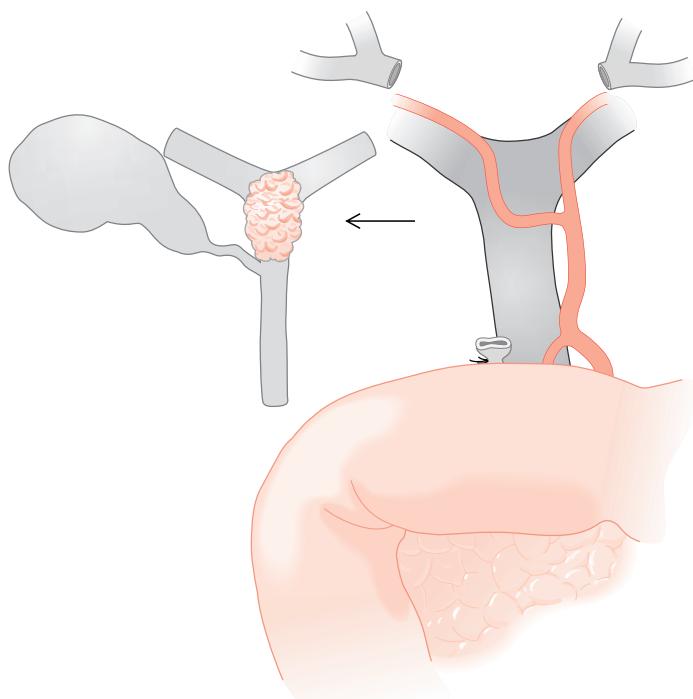

Figure 12 Resection of middle-third and proximal bile duct tumors. Illustrated is the level of resection for middle-third and type I proximal tumors. The CBD is resected from the pancreas to a point above the bifurcation. Reconstruction is accomplished via Roux-en-Y hepaticojjunostomy (involving either one or two separate anastomoses).

The hepatic artery is dissected by retracting the vessel anteriorly and to the left, dividing and ligating the cystic artery where it originates from the right hepatic artery, and clearing all tissue off the right and left branches at least 1 cm proximal to the proximal margin of the tumor. Involvement of the right or left hepatic artery by tumor is almost always a sign of extensive spread on the corresponding side and an indication for resection of that half of the liver.

The portal vein is dissected by retracting the bile duct and the tumor anteriorly and the hepatic artery to the left. All tissue is then cleanly dissected away from the portal vein to expose the bifurcation and the region proximal to it [see Figure 11]. At this point, the duct may be found to be tethered down to the caudate lobe by several small branches. If these branches are clearly proximal to the tumor, they are divided and carefully ligated, and the caudate lobe is preserved. If there is tumor in this area, the caudate lobe is resected along with the bifurcation tumor.

The level at which the proximal bile ducts are transected depends on the proximal extent of the tumor. For all middle-third or proximal tumors that are at least 1 cm beyond the bifurcation, proximal resection should usually be above the level of the bifurcation. For type I or type II proximal tumors, proximal resection should always include all of the bifurcation along with the proximal right and left bile ducts out as far as the first major branch [see Figure 12]. With type III or IV proximal tumors, the proximal extent of the tumor cannot be determined in both right and left ducts unless the main pedicles are dissected out of the liver. Because these tumors tend to infiltrate locally, such dissection is not advisable. A decision on whether liver resection is indicated should be made at an early stage so that the chances of a cure are not compromised. Intraoperative ultrasonography may help verify the extent of tumor at this point in the operation. Any major liver resection for type III or

IV bile duct cancer should include the caudate lobe [see Figure 13].

Once the decision to resect part of the liver has been made, the operation consists of dissecting the hepatic artery and the portal vein branch to the part of the liver to be saved away from the tumor area. The hepatic artery and the portal vein branch to the side to be resected are then divided; this allows the tumor to be retracted further and provides better exposure of the duct to the side to be preserved [see Figures 14 and 15]. In selected cases, resection of an involved portal vein bifurcation may be carried out at this point [see Figure 16]; an end-to-end anastomosis is then fashioned.

The point at which the hepatic parenchyma will be divided is marked, and the parenchymal transection is performed. Division of the hepatic duct (or ducts) to the part of the liver being preserved is done as far from the tumor as possible.

Step 4: Reconstruction

After resection of the bifurcation or intrahepatic bile ducts, an intrahepatic cholangiojejunostomy is performed [see Intrahepatic Cholangiojejunostomy, below]. The duct tissue is usually healthy enough and the duct lumen large enough to allow mucosa-to-mucosa repair without stenting. Some surgeons place transhepatic tubes through these anastomoses to facilitate postoperative treatment with internal radiation sources; however, there is no evidence that this practice reduces local recurrence or prolongs survival.

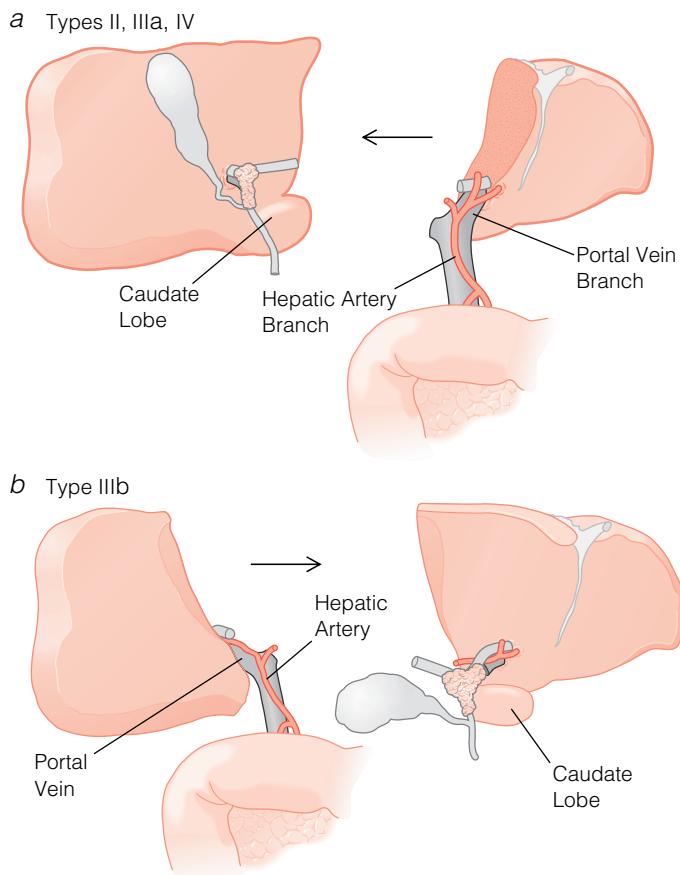

Figure 13 Resection of middle-third and proximal bile duct tumors. Illustrated are (a) a right trisectionectomy (extended right hepatectomy) for type II, IIIa, and IV tumors and (b) a left hepatectomy (including the caudate lobe) for type IIIb tumors.

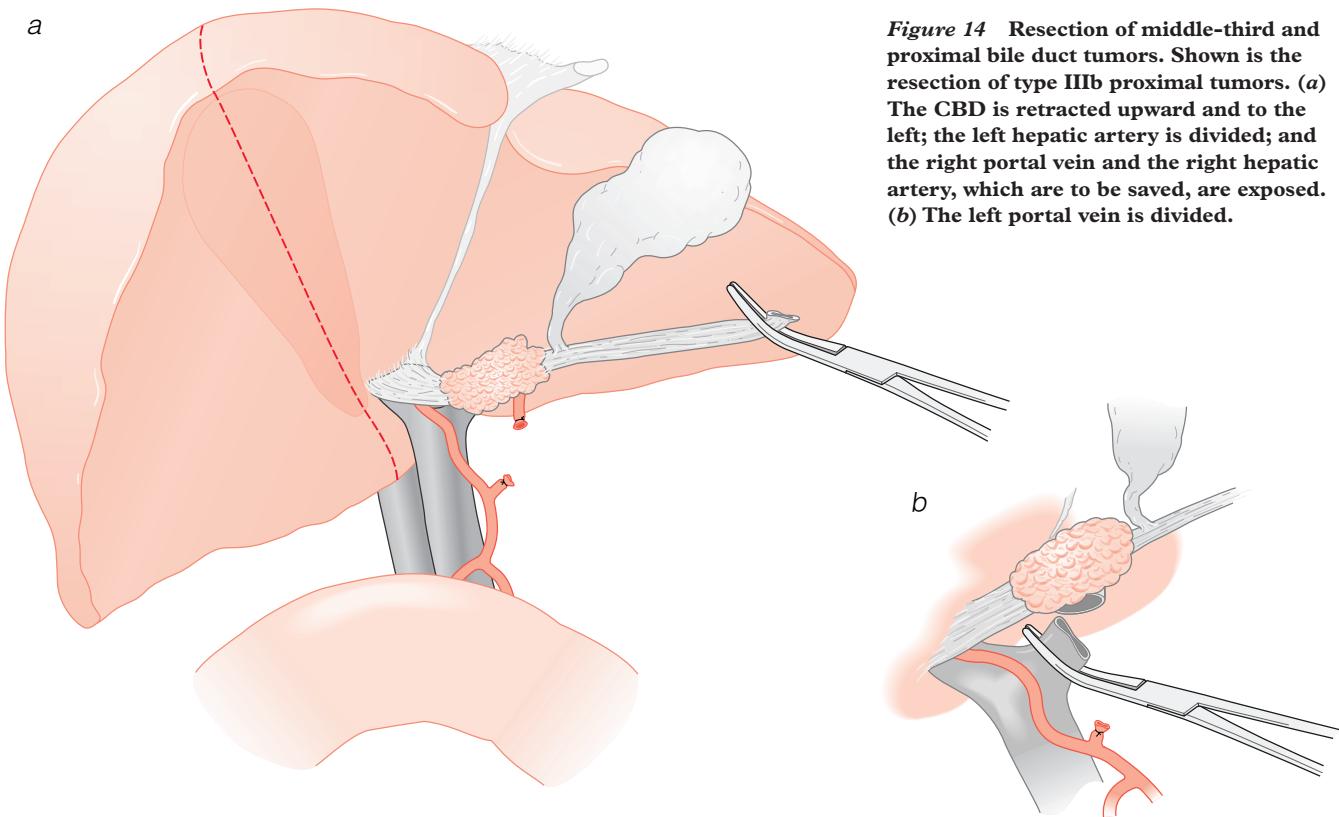

Figure 14 Resection of middle-third and proximal bile duct tumors. Shown is the resection of type IIIb proximal tumors. (a) The CBD is retracted upward and to the left; the left hepatic artery is divided; and the right portal vein and the right hepatic artery, which are to be saved, are exposed. (b) The left portal vein is divided.

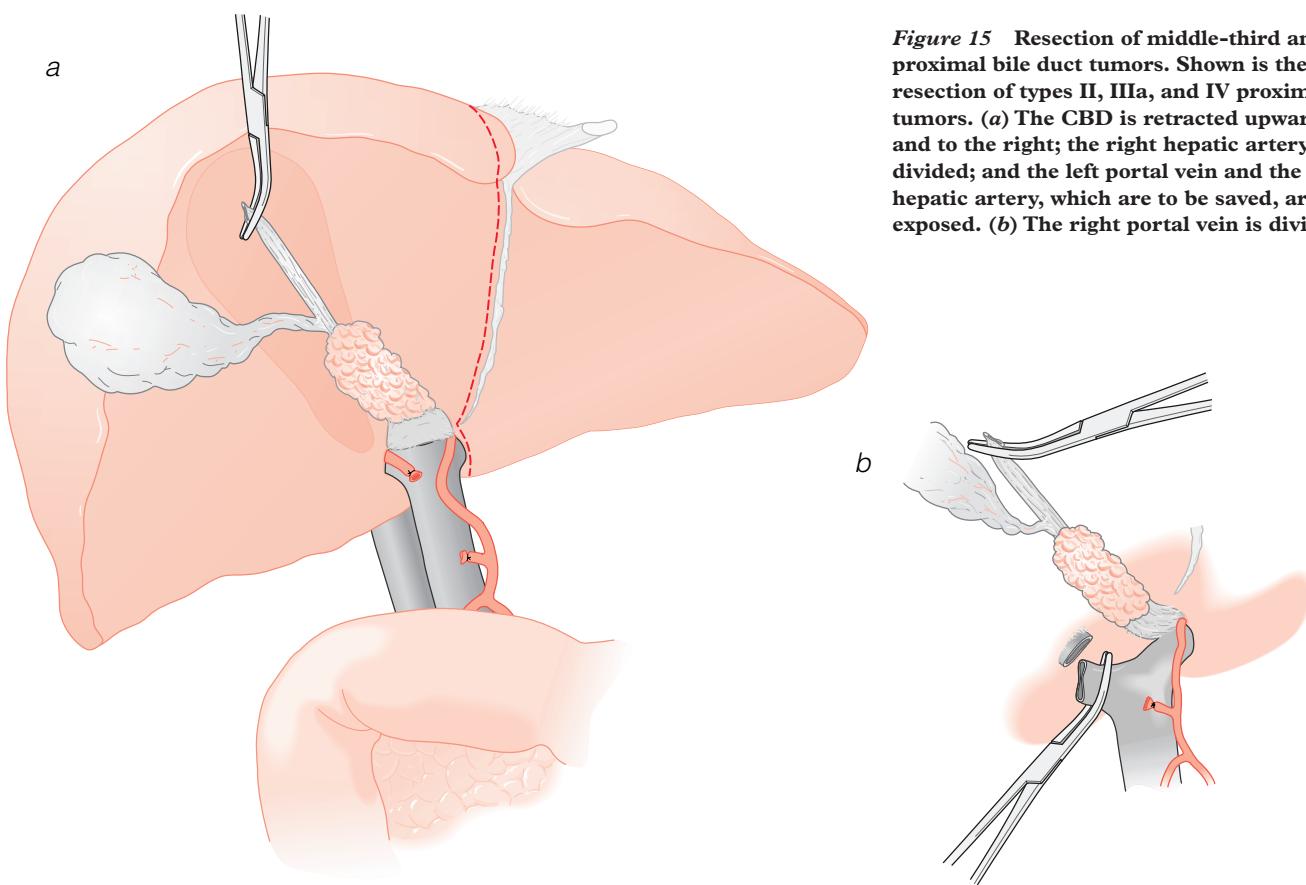

Figure 15 Resection of middle-third and proximal bile duct tumors. Shown is the resection of types II, IIIa, and IV proximal tumors. (a) The CBD is retracted upward and to the right; the right hepatic artery is divided; and the left portal vein and the left hepatic artery, which are to be saved, are exposed. (b) The right portal vein is divided.

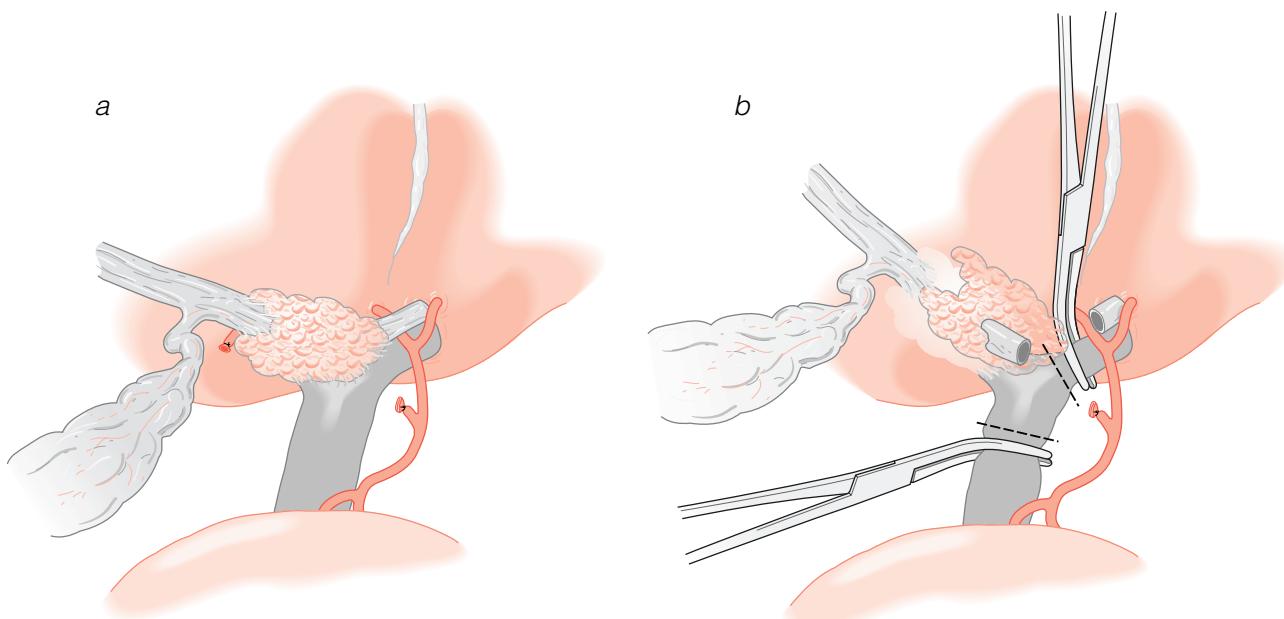

Figure 16 Resection of middle-third and proximal bile duct tumors. (a) Occasionally, a type III or IV proximal tumor will involve the portal vein bifurcation. (b) Shown is the resection of an involved portal vein bifurcation. Reconstruction is accomplished in an end-to-end fashion.

Step 5: Closure and Postoperative Care

The abdomen is closed in the standard fashion, and closed suction drains are placed. Liver function is monitored, particularly when a major liver resection has been done. Mild abnormalities in coagulation test results are common, and soluble coagulation factors are given only if there is evidence of bleeding.

COMPLICATIONS

Bile leakage, bleeding, and infection are the most important complications of bile duct resection for tumor. Parahepatic collections are treated with percutaneous drainage, and significant early bleeding is usually best managed by reexploration.

Intrahepatic Cholangiojejunostomy

Intrahepatic cholangiojejunostomy is commonly performed after resection of the bifurcation for a more proximal tumor; it is also performed to manage injury or stricture at the level of the bifurcation and to bypass an unresectable bifurcation tumor.

Because the ducts are smaller, have thinner walls, and are more adherent to the areolar tissue of the pedicles than either the portal vein branches or the hepatic artery branches, dissection of the ducts must be more meticulous. Magnification is an important aid, particularly in dealing with undilated ducts. Good exposure is essential; if necessary, the liver may be split to allow adequate visualization, access, and lighting. Anatomic mucosal suturing can be achieved in most situations. In rare instances, excessive inflammation, scarring, or tumor makes such suturing impossible, in which case periductal sutures are used and a stent is placed. As described [see General Considerations, Technical Issues in Biliary Anastomosis, *above*], separate ducts that are close together can be first sutured together at their adjacent walls to create a single larger proximal duct lumen so that a safer anastomosis can be created [see Figure 3c].

OPERATIVE TECHNIQUE

Step 1: Definition of Tissues for Anastomosis

In the case of injury, crushed, cauterized, or devitalized tissue must be debrided back to normal healthy tissue before reconstruction is begun. In the case of bile duct resection for tumor, there should be no attempt to clear a length of duct from surrounding areolar or liver tissue; the suturing should take place *in situ*, with the stitches passed through the duct wall and the areolar tissue of the portal pedicles. In the case of bypass for unresectable cancer, the duct being used should be opened as far from the tumor as possible. The left main hepatic duct can be approached between the bifurcation and the umbilical fissure. If the tumor involves the left main hepatic duct, the branch to segment 3 of the liver can be used instead; it can be approached in the umbilical fissure, above the round ligament. Occasionally, incision into the liver or excision of a wedge of liver tissue is necessary to

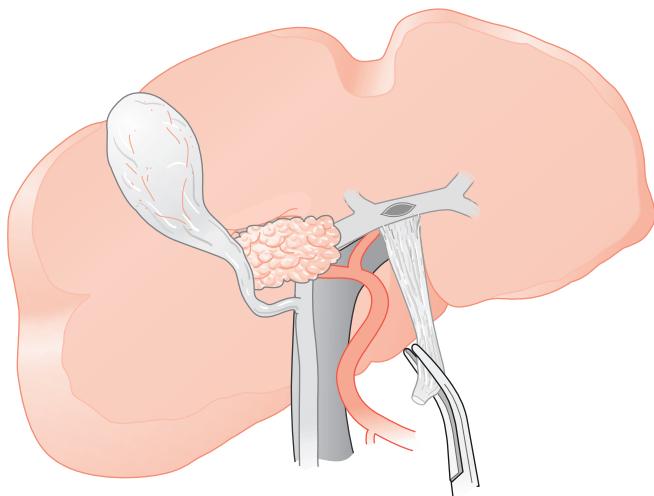

Figure 17 Intrahepatic cholangiojejunostomy. If a tumor involves the left main hepatic duct, the branch of the duct that supplies segment 3 of the liver may be used instead for anastomosis to the jejunum. This branch may be approached in the umbilical fissure, above the round ligament. Incision into the liver or wedge excision may be necessary to ensure adequate exposure.

provide adequate exposure [see *Figure 17*].

If an intrahepatic anastomosis is required for a bifurcation stricture, resection of the stricture is not necessary; however, it is important to identify a normal duct above the level of the bifurcation. If there is no communication from right to left, a horizontal incision can be made in the left duct and carried across into the right duct just above or through the bifurcation stricture, so that a single anastomosis can be made that incorporates both ducts. It is possible to enlarge duct openings by making a small longitudinal incision in the most accessible portion of the duct. This is easier to accomplish in the left hepatic duct (because of its extrahepatic transverse position) than in the right hepatic duct (which tends to run laterally and posteriorly directly in the liver substance).

Step 2: Anastomosis

A Roux-en-Y loop of sufficient length to make a tension-free anastomosis is constructed, and a biliary-enteric anastomosis is then performed. When adequate access is difficult to obtain, interrupted sutures are first placed in the anterior wall of the bile duct. This allows retraction of that wall, and it facilitates the accurate

placement of interrupted sutures in the back wall.

Postoperative Care

In a patient who has impaired liver function or has undergone a major hepatic resection, the results of liver function tests, particularly coagulation studies, should be carefully monitored postoperatively. Transient worsening of these results is not unusual, especially if the procedure was long. Moderately elevated results from coagulation studies (e.g., international normalized ratio < 2.0) are not an indication for treatment with fresh frozen plasma or concentrated coagulation factors unless clinical bleeding is evident.

Postoperative infections may occur as a result of biliary tract contamination, especially if a bile duct stent was placed preoperatively. Antibiotic prophylaxis with broad-spectrum agents for periods longer than usual for perioperative treatment may be appropriate in such cases. If postoperative fever occurs, especially if it is accompanied by unusual pain and tenderness, imaging studies should be promptly obtained and fluid collections sought. In most cases, bile or pus can be drained satisfactorily through percutaneously placed tubes.

23 HEPATIC RESECTION

Yuman Fong, M.D., and Leslie H. Blumgart, M.D.

Liver resections were first described centuries ago, but until the latter half of the 20th century, the majority of such resections were performed for management of either injuries or infections. Today, these procedures are performed not only for treatment of acute emergencies (e.g., traumatic injuries or abscesses) but also as potentially curative therapy for a variety of benign and malignant hepatic lesions.

The first planned anatomic resection of a lobe of a liver is credited to Lortat-Jacob, who in 1952 performed a right lobectomy as treatment for metastatic colon cancer.¹ Major hepatectomies, however, did not become commonplace until the 1980s. Since then, the safety of these operations has improved dramatically, and as safety has improved, the indications for hepatic resection have become better refined as well. Currently, resection of as much as 85% of the functional liver parenchyma is being performed at numerous centers with an operative mortality of less than 2%. The duration of hospitalization is typically less than 2 weeks, and almost all individuals regain normal hepatic function.

In what follows, we focus on the technical aspects of hepatic resection, emphasizing efficiency and safety and taking into account recent developments, current controversies, and special operative considerations (e.g., the cirrhotic patient and repeat liver resection). Detailed discussions of the indications for hepatic resection are available elsewhere.²⁻⁴

Hepatic Anatomy

Familiarity with the surgical anatomy of the liver is essential for safe performance of a partial hepatectomy. The liver can be divided into two lobes (right and left) comprising eight segments [see Figure 1]. Each of these segments is a discrete anatomic unit that possesses its own nutrient blood supply and its own venous and biliary drainage. The right lobe consists of segments 5 through 8 and is nourished by the right hepatic artery and the right portal vein; the left lobe consists of segments 1 through 4 and is nourished by the left hepatic artery and the left portal vein. The anatomic division between the right lobe and the left is not at the falciform ligament (the most readily apparent visual landmark on the anterior liver) but follows a line projected through a plane (the principal plane, or Cantlie's line) that runs posterosuperiorly from the medial margin of the gallbladder to the left side of the vena cava.

The venous drainage of the liver consists of multiple small veins draining directly from the back of the right lobe and the caudate lobe to the vena cava, along with three major hepatic veins. These major hepatic veins occupy three planes, known as portal scissurae. The three scissurae divide the liver into four sectors, each of which is supplied by a portal pedicle; further branching of the pedicles subdivides the sectors into the eight segments [see Figure 1].⁵⁻⁷ (Some surgeons refer to these sectors

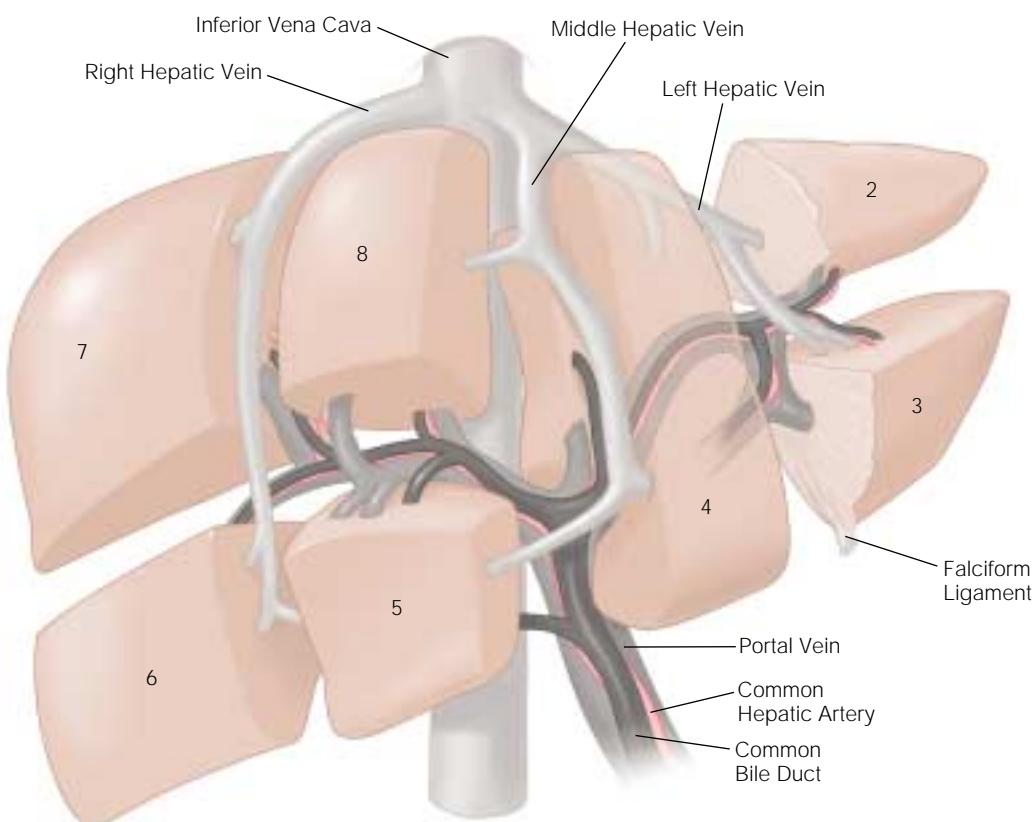

Figure 1 The liver is separated into eight anatomic segments, each with an independent nutrient blood supply and venous and biliary drainage. Appreciation of this segmental anatomy is the basis of anatomic resection of the liver.

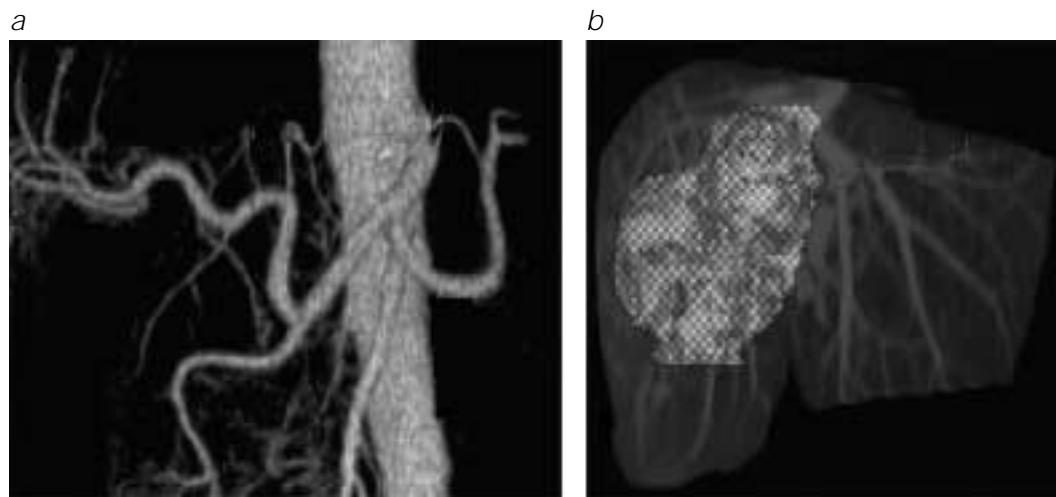

Figure 2 (a) The arterial anatomy of the celiac axis is reconstructed from thin-slice CT images. (b) The hepatic venous anatomy is similarly reconstructed, with the tumor superimposed on the vascular reconstruction.

as segments—hence the term trisegmentectomy.) The right hepatic vein passes between the right anterior sector (segments 5 and 8) and the right posterior sector (segments 6 and 7) in the right scissura. This vein empties directly into the vena cava near the atrio caval junction. The middle hepatic vein passes between the right anterior sector and the left medial sector (segment 4) in the central, or principal, scissura, which represents the division between the right lobe and the left. The left hepatic vein runs in the left scissura between segments 2 and 3. In most persons, the left and middle hepatic veins join to form a common trunk before entering the vena cava. Occasionally, a large inferior right hepatic vein is present that may provide adequate drainage of the right lobe after resection of the left even when all three major hepatic veins are ligated.⁸

The portal vein and the hepatic artery divide into left and right branches below the hilus of the liver. Unlike the hepatic veins, which run between segments, the portal venous and hepatic arterial branches, along with the hepatic ducts, typically run centrally within segments [see Figure 1]. On the right side, the hepatic artery and the portal vein enter the liver substance almost immediately after branching. The short course of the right-side extrahepatic vessels and the variable anatomy of the biliary tree make these vessels vulnerable to damage during dissection.⁹ In contrast, the left branch of the portal vein and the left hepatic duct take a long extrahepatic course after branching beneath segment 4. When these vessels reach the base of the umbilical fissure, they are joined by the left hepatic artery to form a triad, which then enters the left liver substance at this point. It must be emphasized that proximal to the base of the umbilical fissure, the left-side structures are not a triad. A consequence of the long extrahepatic course of the left-side structures is that for tumors that involve the hilus (e.g., Klatskin tumors), when a choice exists between an extended right hepatectomy or an extended left hepatectomy, most surgeons choose the former because the greater ease of dissection on the left side facilitates preservation of the left-side structures. Knowledge of the relative anatomic courses of the portal veins, the hepatic arteries, and the hepatic ducts is the basis of the classical extrahepatic dissection for control of hepatic inflow [see Operative Technique, Right Lobectomy, Step 6 (Extrahepatic Dissection and Ligation), below].

The fibrous capsule surrounding the liver substance was described by Glisson in 1654.¹⁰ It was Couinaud,⁶ however, who demonstrated that this fibrous capsule extends to envelop the portal triads as they pass into the liver substance. Thus, within the liver, the portal vein, the hepatic artery, and the hepatic duct running to each segment of the liver lie within a substantial sheath. This dense sheath allows rapid control of inflow vessels to specific anatomic units within the liver and permits en masse ligation of these vascular structures in a maneuver known as pedicle ligation [see Operative Technique, Right Lobectomy, Step 6—Alternative (Intrahepatic Pedicle Ligation), below].¹¹

Preoperative Evaluation

Cross-sectional imaging modalities such as computed tomography, magnetic resonance imaging, and ultrasonography play an important role in enhancing the safety and efficacy of hepatic resection. These modalities, along with biologic scanning techniques such as positron emission tomography (PET), are also invaluable for staging malignancies so as to improve patient selection and thereby optimize long-term surgical outcome.

At a minimum, all candidates for hepatic resection should undergo either CT or MRI. These imaging tests not only identify the number and size of any mass lesions within the liver but also delineate the relations of the lesions to the major vasculature—data that are crucial for deciding whether to operate and which operative approach to follow.

Use of contrast enhancement during CT scanning is vital for accurate definition of the vascular anatomy. In fact, data from thin-slice (1 to 2 mm) images captured by current spiral, or helical, CT scanners can be reconstructed to provide angiographic pictures whose level of detail rivals that of direct angiograms [see Figure 2]. Triple-phase scans (including a noncontrast phase, an arterial phase, and a venous phase) are recommended; these yield the best definition and characterization of intrahepatic lesions. For example, some vascular tumors become isodense with liver parenchyma after contrast injection. By first obtaining noncontrast scans and then obtaining contrast scans at two different times after contrast injection, the examiner stands a better chance of visualizing such tumors.

For small tumors, a CT variant known as CT portography is recommended. In this technique, contrast material is injected through

the superior mesenteric artery, and images are obtained during the portal venous phase. The normal liver receives the majority of its nutrient blood from the portal vein and is therefore contrast-enhanced in this phase. Tumors, on the other hand, usually derive their nutrient blood from the hepatic artery and therefore appear as exaggerated perfusion defects. CT portography is the most sensitive test available for identifying small hepatic tumors.¹²

MRI may also be valuable for characterizing lesions and defining them vis-à-vis the vasculature. It is particularly helpful in diagnosing benign lesions such as hemangiomas, fibronodular hyperplasia, and adenomas. Whenever any of these benign lesions is suspected, MRI is usually indicated. With regard to surgical planning, MRI angiographic images are useful for identifying the major hepatic veins and clarifying their relations to any tumor masses.¹³

Imaging recommendations may be summed up as follows. A triple-phase CT should be obtained for most patients under consideration for hepatic resection. If diagnostic doubt remains after CT, particularly if the differential diagnosis includes an asymptomatic benign tumor, MRI should be performed. If questions remain after CT as to the extent of hepatic venous or major biliary involvement, MRI or duplex ultrasonography should be considered.¹⁴ If small tumors are encountered, CT portography should be performed. Duplex ultrasonography, by demonstrating the vascular hilar structures, the hepatic veins, and the inferior vena cava, renders angiography unnecessary in many cases.^{13,15} Currently, direct hepatic angiography is rarely required, and inferior vena cavography is almost never needed.

Operative Planning

PREPARATION

In general, preparation for hepatic resection is much the same as that for other major abdominal procedures. All patients who are older than 65 years or have a history of cardiopulmonary disease undergo a full cardiopulmonary assessment. It was once commonly believed that patients 70 years of age or older were poor candidates for major liver resection,^{16,17} but this notion has been dispelled by more recent data.¹⁸⁻²⁰ Advanced chronologic age is not a complete contraindication to hepatectomy.

Anemia and coagulopathy, if present, are corrected. All patients are now encouraged to donate two units of autologous blood before a major hepatectomy. Appropriate single-dose antibiotic prophylaxis is administered [see 1:2 Prevention of Postoperative Infection].

ANESTHESIA

Decisions regarding anesthesia should take into account the possibility of baseline hepatic parenchymal dysfunction as well as the postoperative hepatic functional deficits resulting from resection of a major portion of the hepatic parenchyma.

The most important consideration, however, is the possibility of major intraoperative hemorrhage. Suitable monitoring and sufficient vascular access to permit rapid transfusion should be in place. At some centers, fluid resuscitation and blood transfusion are begun early in the course of resection to increase intravascular volume as a buffer against sudden blood loss. At the Memorial Sloan-Kettering Cancer Center (MSKCC), however, we favor the opposite approach, whereby a low central venous pressure is maintained during resection. The rationale for our preference is that generally, most of the blood lost during hepatic resection comes from the major hepatic veins or the vena cava.^{21,22} If central venous pressure is kept below 5 mm Hg, there is less bleeding from the hepatic venous radicles during dissection.

Reduction of intrahepatic venous pressure can be facilitated by performing the dissection with the patient in a 15°Trendelenburg position, which increases venous return to the heart and enhances cardiac output. Central venous pressure is maintained at the desired level through a combination of anesthesia and early intraoperative fluid restriction. The minimal acceptable intraoperative urine output is 25 ml/hr.

The need for intraoperative blood transfusion can be minimized by accepting hematocrits lower than the common target figure of 30%: 24% in patients without antecedent cardiac disease and 29% in patients with cardiac disease. If blood loss is estimated to reach or exceed 20% of total volume or the patient becomes hemodynamically unstable, transfusion is indicated.²¹

PATIENT POSITIONING

The patient should be supine: to date, we have not found a lateral position to be necessary even for the largest of tumors. Electrocardiographic leads should be kept clear of the right chest wall and the presternal area in case a thoracoabdominal incision is necessitated by the position of a tumor or by intraoperative hemorrhage. Preparation and draping should therefore also allow for exposure of the lower chest and the entire upper abdomen down past the umbilicus. A crossbar or a similar device that holds self-retaining retractors should be used to elevate the costal margin. Some surgeons prefer ring-based self-retaining retractors. In our experience, although these retractors are adequate for most resections, the rings tend to restrict lateral access, thereby potentially hindering posterior dissection, particularly of the vena cava.

ANATOMIC VERSUS NONANATOMIC RESECTION

The key decision in planning a hepatectomy is whether the resection should be anatomic or nonanatomic. For treatment of malignant disease, anatomic resection is usually favored because the long-term outcome is better. Anatomic resections permit excision of parenchymal areas distal to the index tumors, where there is a high incidence of vascular micrometastases. In addition, they are significantly less likely to have positive margins than nonanatomic resections are. In a large series of hepatectomies for metastatic colorectal cancer, wedge or nonanatomic resections were associated with a 19% rate of positive margins.²³ In a recent examination of our increasing preference for anatomic resections over wedge resections, wedge resections were associated with a 16% rate of positive margins, compared with a 2% rate for anatomic resections.²⁴

There are two oncologic settings where nonanatomic resections are favored. In patients with hepatocellular carcinoma, viral hepatitis and cirrhosis are often complicating factors. Cirrhotic patients tolerate resection of more than two segments of functional parenchyma poorly. Accordingly, for these patients, the smallest resection that will achieve complete tumor excision is favored, even if it is a wedge resection. For management of metastatic neuroendocrine tumors, in which resections are merely debulking procedures designed to alleviate symptoms, nonanatomic resections are accepted because cure is highly unlikely.

Hepatic resections for benign hepatic tumors are usually performed for one of three reasons: (1) to relieve symptoms (e.g., pain or early satiety), (2) because the diagnosis is uncertain, or (3) to prevent malignant transformation. A goal of such resections should be to spare as much normal parenchyma as possible. Consequently, lesions such as hemangiomas, adenomas, complex cysts, and fibronodular hyperplasia are often excised by means of enucleation or another nonanatomic resection with limited margins.

Operative Technique

Theoretically, any hepatic segment can be resected in isolation. For practical purposes, however, there are five types of major anatomic resections [see Figure 3]. We follow the most commonly used terminology, that of Goldsmith and Woodburne.²⁵ Some authors prefer other systems of nomenclature, based on the anatomic descriptions of Couinaud⁶ or Bismuth.⁷

The essential principles of all anatomic hepatectomies are the same: (1) control of inflow vessels, (2) control of outflow vessels, and (3) parenchymal transection. To illustrate these principles, we begin by outlining the steps in a right lobectomy [see Figure 3a] in some detail, describing both extrahepatic vascular dissection and ligation and the alternative approach to inflow control, intrahepatic pedicle ligation. Left lobectomy [see Figure 3b] and other common anatomic resections share a number of steps with right lobectomy; accordingly, we discuss them in somewhat less detail. Further detail on these procedures is available in other sources.^{26,27}

RIGHT LOBECTOMY

Step 1: Laparoscopic Inspection

Experience from MSKCC^{28,29} and other centers^{30,31} indicates that laparoscopy allows detection of unresectable disease and prevents the morbidity associated with a nontherapeutic laparotomy. We generally perform laparoscopy immediately before laparotomy during the same period of anesthesia. The laparoscopic port sites are placed in the upper abdomen along the line of the intended incision [see Step 2, below]. The first two ports are usually 10 mm ports placed in the right subcostal area along the midclavicular line and along the anterior axillary line. These

ports allow inspection of the abdomen and of the entire liver, including the dome and segment 7. The port along the right anterior axillary line is particularly suitable for laparoscopic ultrasound devices. If additional ports are necessary, a left subcostal midclavicular port is usually the best choice.

Step 2: Incision

For the majority of hepatic resections, most surgeons use a bilateral subcostal incision extended vertically to the xiphisternum [see Figure 4]. Our own preference, however, is to use an upper midline incision extending to a point approximately 2 cm above the umbilicus, with a rightward extension from that point to a point in the midaxillary line halfway between the lowest rib and the iliac crest [see Figure 4]. We find that this incision provides superb access for either right- or left-side resection, without the wound complications often encountered with trifurcated incisions (e.g., ascitic leakage and incisional hernia). On rare occasions (e.g., in the resection of large, rigid posterior tumors of the right lobe), a right thoracoabdominal incision may be required. In a recent series of nearly 2,000 resections at MSKCC, however, a thoracoabdominal incision proved necessary in only 3% of patients; the most common indication was repeat liver resection after previous right hepatic lobectomy [see Repeat Hepatic Resection, below].

Step 3: Abdominal Exploration and Intraoperative Ultrasonography

The liver is palpated bimanually. Intraoperative ultrasonography is systematically performed to identify all possible lesions and their relations to the major vascular structures. This modality is capable of identifying small lesions that preoperative imaging studies and palpation of the liver may miss.³² The lesser omentum is incised to allow palpation of the caudate lobe and inspection of the celiac region for nodal metastases. A finger is passed from the lesser sac inferior to the caudate lobe through the foramen of Winslow to permit identification of the portal vein and palpation of the portacaval lymph nodes. The hilar lymph nodes are palpated, and any suspicious nodes are removed for frozen section examination. If the operation is being done for cancer, the entire abdomen is inspected for evidence of extrahepatic tumor.

Step 4: Mobilization of Liver

Once the decision is made to proceed with hepatic resection, the liver is fully mobilized by detaching all ligamentous attachments on the side to be resected. (Some surgeons defer completion of mobilization to a later stage in the procedure.) In particular, the suprarectal inferior vena cava and the hepatic veins above the liver are dissected to facilitate the subsequent approach to the hepatic veins [see Step 7, below]. Once the liver is mobilized, further palpation is done to detect any small lesions that may have been obscured initially. This additional palpation is particularly important on the right side because before mobilization, the posterior parts of the liver cannot be effectively palpated, and intraoperative ultrasonography may fail to detect small lesions in this area.³²

If, in the course of mobilization, tumor is found to be attached to the diaphragm, the affected area of the diaphragm may be excised and subsequently repaired.

Step 5: Identification of Arterial Anomalies

Any hepatic arterial anomalies present should be identified before resection is begun. With good preoperative imaging, the arterial anatomy is usually defined with sufficient exactitude before

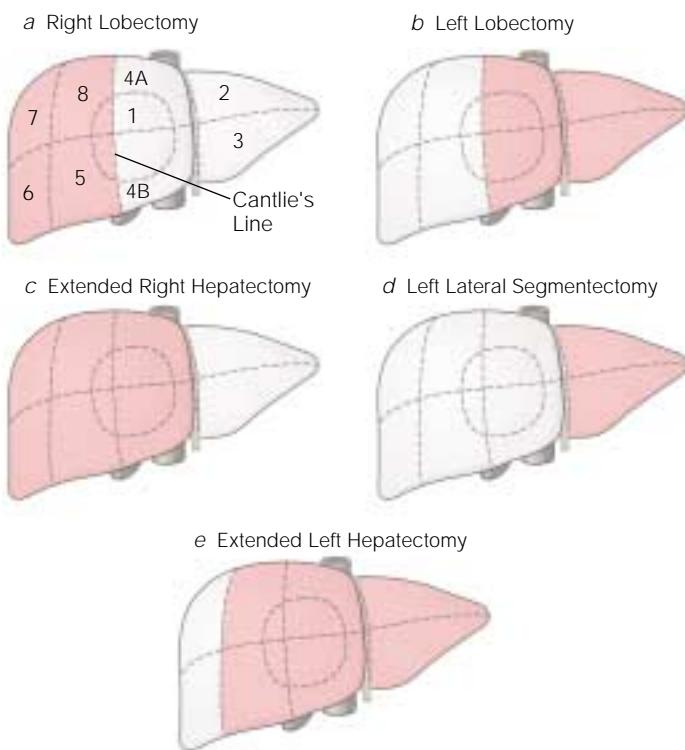

Figure 3 Shown are schematic illustrations of standard hepatic resections, with the shaded areas representing the resected portions: (a) right lobectomy, (b) left lobectomy, (c) extended right hepatectomy (or right trisegmentectomy), (d) left lateral segmentectomy, and (e) extended left hepatectomy (or left trisegmentectomy).

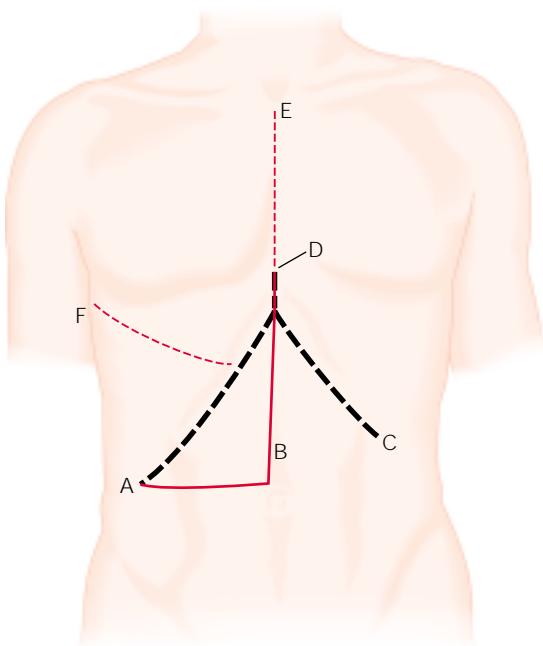

Figure 4 Right lobectomy. A right subcostal incision (A) with a midline extension to the xiphoid (D) is the most common choice; an extension to the left subcostal area (C) is sometimes added to provide further operative exposure. We prefer a long midline incision from the xiphoid (D) to a point approximately 3 cm above the umbilicus (B) along with a rightward extension (A) because this incision provides superb exposure of both the right side and the left without the wound complications of a trifurcated incision. The chest can be entered through either a median sternotomy (E) or an anterolateral right thoracoabdominal incision (F).

laparotomy. It is also possible to gain a clear picture of the arterial anatomy intraoperatively by means of simple maneuvers that do not involve major dissection.

The lesser omentum should be examined to determine whether there is a vessel coursing through its middle to the base of the umbilical fissure, and the hepatoduodenal ligament should be palpated with an index finger within the foramen of Winslow to see whether there is an artery in the gastropancreatic fold on its medial aspect. The usual bifurcation of the hepatic arteries occurs low and medially in the hepatoduodenal ligament, and the left hepatic artery normally travels on the medial aspect of the ligament to reach the base of the umbilical fissure. Thus, if an artery is palpable in the medial upper portion of the hepatoduodenal ligament, it is the main left hepatic artery. Any vessel seen in the lesser omentum must therefore be an accessory left artery. If, however, no pulse is found in the medial upper portion of the hepatoduodenal ligament, the vessel in the lesser omentum must be a replaced left hepatic artery. The right hepatic artery usually travels transversely behind the common bile duct (CBD) to reach the base of the cystic plate. A vertically traveling artery on the lateral hepatoduodenal ligament must therefore be either a replaced or an accessory right hepatic artery, probably arising from the superior mesenteric artery.

Step 6 (Extrahepatic Dissection and Ligation): Control of Inflow Vessels

The classic approach to extrahepatic control of the inflow vessels in a right lobectomy involves extrahepatic dissection and ligation [see Figure 5]. The cystic duct and the cystic artery are li-

gated and divided. The gallbladder may be either removed or left attached to the right liver, according to the surgeon's preference. The usual practice is first to ligate the right hepatic duct, then the right hepatic artery, and finally the right portal vein, working from anterior to posterior. Our preference, however, is to work from posterior to anterior, as follows.

The sheath of the porta hepatis is opened laterally. Dissection is then performed in the plane between the CBD and the portal vein. To facilitate this dissection, the CBD is elevated by applying forward traction to the ligated cystic duct. The portal vein is then followed cephalad until its bifurcation into the left and right portal veins is visible. In a small percentage of patients, the left portal vein arises from the right anterior branch of the portal vein. If the main right portal vein is ligated in a patient who exhibits this anatomic variant, the portion of the liver remaining after resection will lack any portal flow. There is usually a small portal branch that passes from the main right portal vein to the caudate process. Ligation of this branch untethers another 1 to 2 cm of the right portal vein, thereby allowing safer dissection and ligation. The right portal vein is usually clamped with vascular clamps, divided, and oversewn with nonabsorbable sutures. Once this is done, the right hepatic artery is visible behind the CBD and can easily be secured and ligated with nonabsorbable sutures. Because of the multitude of biliary anatomic variations, we usually leave the right hepatic duct intact until parenchymal dissection [see Step 8, below] is begun, when this structure can be secured higher within the hepatic parenchyma and divided with greater safety.

Staple ligation Vascular staplers may be used for stapling the right or the left portal vein during extrahepatic vascular dissection^{33,34}; however, suture ligation of the extrahepatic portal veins is such a straightforward technical exercise that staplers add little except cost.

Step 6—Alternative (Intrahepatic Pedicle Ligation): Control of Inflow Vessels

The observations of Glisson and Couinard (see above) that the nutrient vessels to the liver are contained within a thick connective tissue capsule [see Figure 6] were the basis for the initial proposal by Launois and Jamieson¹¹ that intrahepatic vascular pedicle ligation could serve as an alternative to extrahepatic dissection and ligation for controlling vascular inflow to the liver. This alternative technique has the advantages of being rapid and of being unlikely to cause injury to the vasculature or the biliary drainage of the contralateral liver. Given adequate intrahepatic definition and control of the portal triads supplying the area of the liver to be resected, one can readily isolate the various major pedicles by using simple combinations of hepatotomies at specific sites on the inferior surface of the liver [see Figure 7].

The right liver is completely mobilized from the retroperitoneum. The most inferior small hepatic veins are ligated, and the inferior right liver is mobilized off the vena cava. Incisions are then made in the liver capsule at hepatotomy sites A and B [see Figure 7]. The first incision is made through the caudate process. The full thickness of the caudate process is divided with a combination of diathermy, crushing, and ligation. The second incision is made almost vertically in the medial part of the gallbladder bed. Both incisions must be fairly substantial and reasonably deep. Care must be taken to avoid the terminal branches of the middle hepatic vein, which are the most common source of significant bleeding. By means of either finger dissection or the passage of a large curved clamp, a tape is then placed around the right main sheath [see Figure 8]. This tape can be pulled medial-

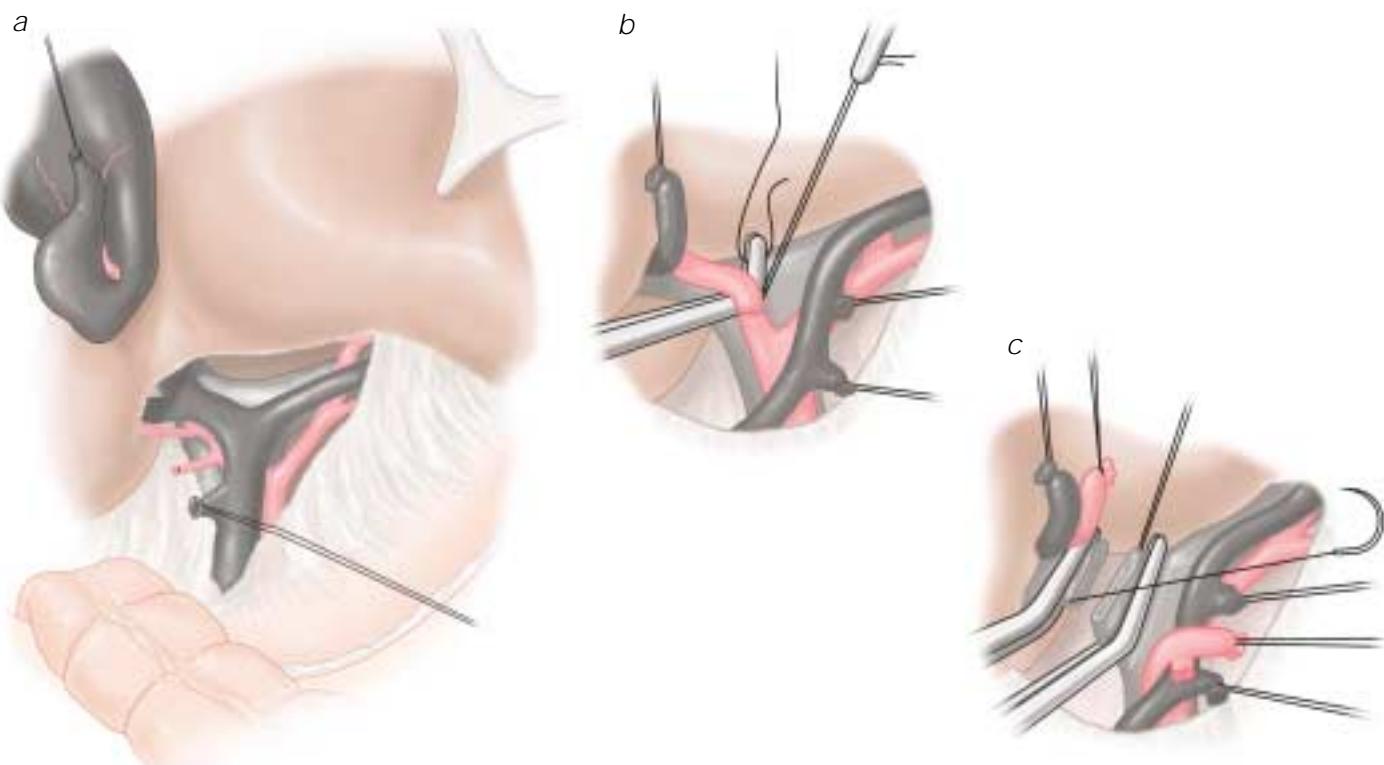

Figure 5 Right lobectomy. For control of the inflow vessels of the right liver, the liver is retracted cephalad to allow exposure of the porta hepatis. (a) The gallbladder is resected to allow access to the bile duct and hepatic vessels. (b) The right hepatic duct is ligated to allow access to the hepatic artery and the portal vein. (c) After the right hepatic artery is divided, the right portal vein is controlled and divided. Alternatively, the vessels may be approached from a posterolateral direction and the portal vein and hepatic artery may be divided first, with the hepatic duct left intact until the parenchymal transection.

ly to provide better exposure of the intrahepatic right pedicle and to retract the left biliary tree and portal vein away from the area to be clamped and divided. Clamps are then applied, the right pedicle is divided, and the stumps are suture-ligated.

In practice, for right lobectomies, we prefer to isolate the right anterior and posterior pedicles separately [see Figure 8] and ligate them individually. This measure ensures that the left-side structures cannot be injured. Any minor bleeding from a hepatotomy

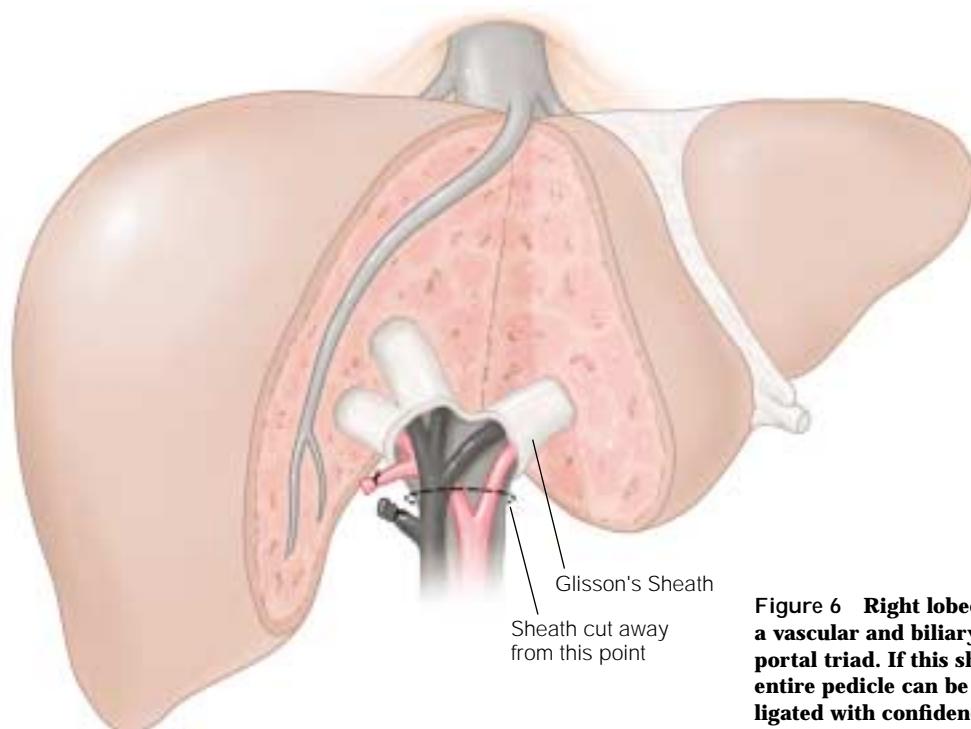

Figure 6 Right lobectomy. Glisson's sheath is a vascular and biliary pedicle that contains the portal triad. If this sheath is not violated, the entire pedicle can be suture-ligated or staple-ligated with confidence and safety.

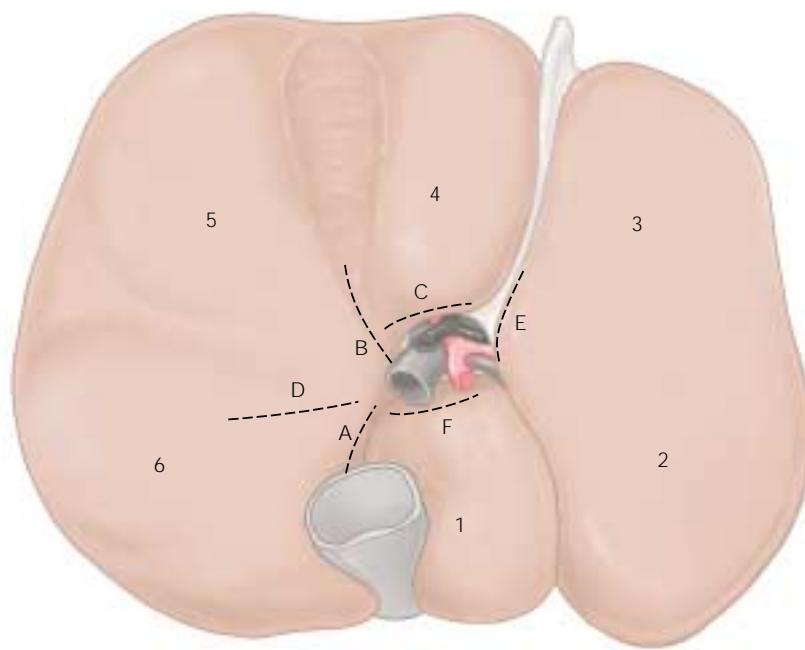

Figure 7 Right lobectomy. Depicted are sites where hepatotomies can be made to permit isolation of various vascular pedicles. Incisions at sites A and B allow isolation of the right main portal pedicle. Incisions at sites A and D allow isolation of the right posterior portal pedicle. Incisions at sites B and D allow isolation of the right anterior pedicle. Incisions at sites C and E allow isolation of the left main portal pedicle; if the caudate is to be removed, incisions are made at sites C and F.

usually ceases spontaneously or else stops when Surgicel is placed into the wound.

Staple ligation The use of staplers is now well established for liver resections,³³⁻³⁸ and we find that staple ligation greatly increases the speed with which intrahepatic portal pedicle ligations can be performed. To control the intrahepatic portal pedicles for a right lobectomy, incisions are made at hepatotomy sites A and B [see Figure 7]. Ultrasonography directed from the inferior aspect of the liver helps determine the depth at which the right pedicle lies, which is usually 1 to 2 cm from the inferior surface. The right main pedicle is then secured either digitally or with a curved blunt clamp (e.g., a renal pedicle clamp), and an umbilical tape is placed around it [see Figure 9a]. The hilar plate in the back of segment 4 is lowered via an incision at hepatotomy site C [see Figure 7] to ensure that the left-side vascular and biliary structures are mobilized well away from the area of staple ligation. A transverse anastomosis (TA) vascular stapler is applied to the right main pedicle while firm countertraction is being applied to the umbilical tape to pull the hilus to the left [see Figure 9a]. The stapler is fired, and the pedicle is divided [see Figure 9b].

Troubleshooting There are several important guiding principles that should be followed in deciding on and performing intrahepatic pedicle ligation. The most important principle is that in patients undergoing operation for cancer, an intrahepatic pedicle approach should not be used when a tumor is within 2 cm of the hepatic hilus. In such cases, extrahepatic dissection should be performed to avoid violation of the tumor margin.

From a technical standpoint, removal of the gallbladder greatly facilitates isolation and control of right-side vascular pedicles in a right lobectomy. Application of the Pringle maneuver decreases bleeding during hepatotomy and isolation of the pedicle. Finally, the lowest hepatic veins behind the liver should be dissected before any attempt is made to isolate the right-side portal pedicles: incising the caudate process without dividing the small hepatic veins draining this portion of the liver to the vena cava can lead to significant hemorrhage.

Step 7: Control of Outflow Vessels

Control of the outflow vasculature begins with division of the hepatic veins passing from the posterior aspect of the right liver directly to the vena cava. After the right lobe is completely mobilized off the retroperitoneum by dividing the right triangular ligament, it is carefully dissected off the vena cava. Dissection proceeds upward from the inferior border of the liver until the right hepatic vein is exposed. Complete mobilization of the right liver

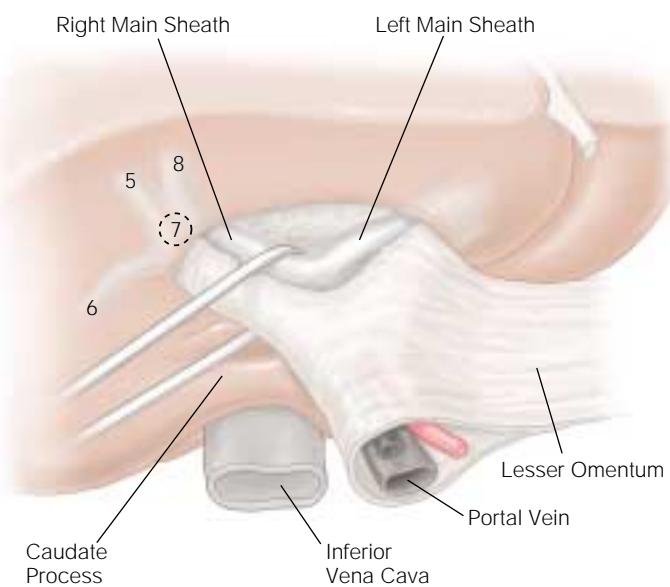

Figure 8 Right lobectomy. Depicted is isolation of the main right portal pedicle. The pedicle is controlled with a vascular tape and retracted from within the liver substance. This tape can be used for countertraction when a vascular clamp or stapler is applied. The main right portal pedicle has anterior and posterior branches. The right anterior pedicle consists of pedicles to segments 5 and 8. The right posterior pedicle usually consists of only the segment 6 pedicle but may also give rise to the segment 7 pedicle.

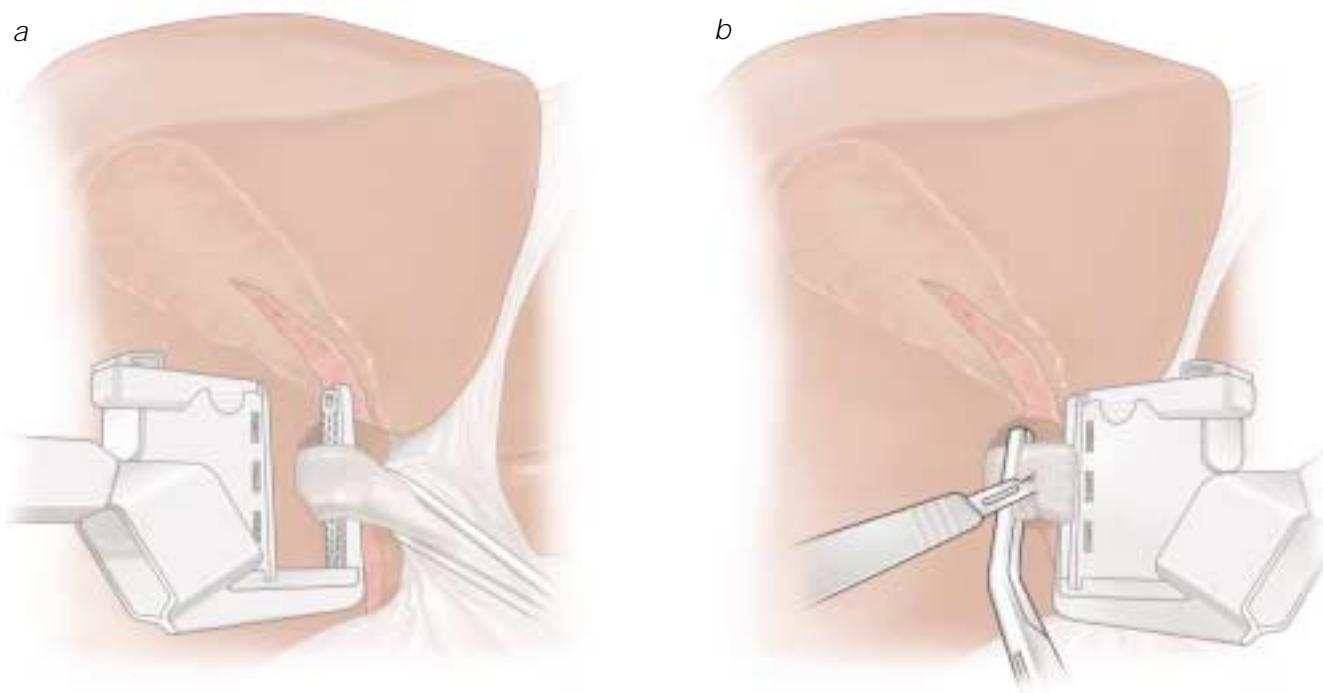

Figure 9 Right lobectomy. Shown is staple ligation of the right portal pedicle. (a) After the liver is incised across the caudate process and along the gallbladder bed, the right main pedicle is isolated and held with an umbilical tape. Countertraction is placed on the umbilical tape while a TA vascular stapler is placed across the pedicle, allowing the left hepatic duct and the left vascular structures to be retracted away from the line of stapling. (b) After the stapler is fired, the pedicle is clamped and divided.

is particularly critical for tumors close to the vena cava. The right hepatic vein is then isolated, cross-clamped, divided, and oversewn [see Figure 10]. Unless the tumor or lesion involves the middle hepatic vein close to its junction with the vena cava, the middle hepatic vein usually is not controlled extrahepatically for right-side resections and is easily secured during parenchymal transection.

If there is a large tumor residing at the dome of the liver, gaining control of the hepatic veins and the vena cava may prove very difficult. If so, one should not hesitate to extend the incision to the chest by means of a right thoracoabdominal extension. The morbidity of a thoracoabdominal incision is preferable to the potentially catastrophic hemorrhage that is sometimes encountered when the right hepatic vein is torn during mobilization of a rigid right hepatic lobe containing a large tumor.

Staple ligation Staple ligation has proved useful for outflow control during hepatectomy. When the tumor is in proximity to the hepatic vein–vena cava junction, extrahepatic control of the hepatic veins is essential for excision of the tumor with clear margins, and it limits blood loss during parenchymal transection.³⁹ Ligating the hepatic veins, particularly with a large and rigid tumor in the vicinity, can be a technically demanding and dangerous exercise. Tearing the hepatic vein or the vena cava during this maneuver is the most common cause of major intraoperative hemorrhage.²⁷ The endoscopic gastrointestinal anastomosis (GIA) stapler is well suited for ligation of the major hepatic veins in that it has a low profile and is capable of simultaneously sealing both the hepatic vein stump on the vena cava side and the one on the specimen side.

For staple ligation of the right hepatic vein, the right liver is mobilized off the vena cava. Any large accessory right hepatic

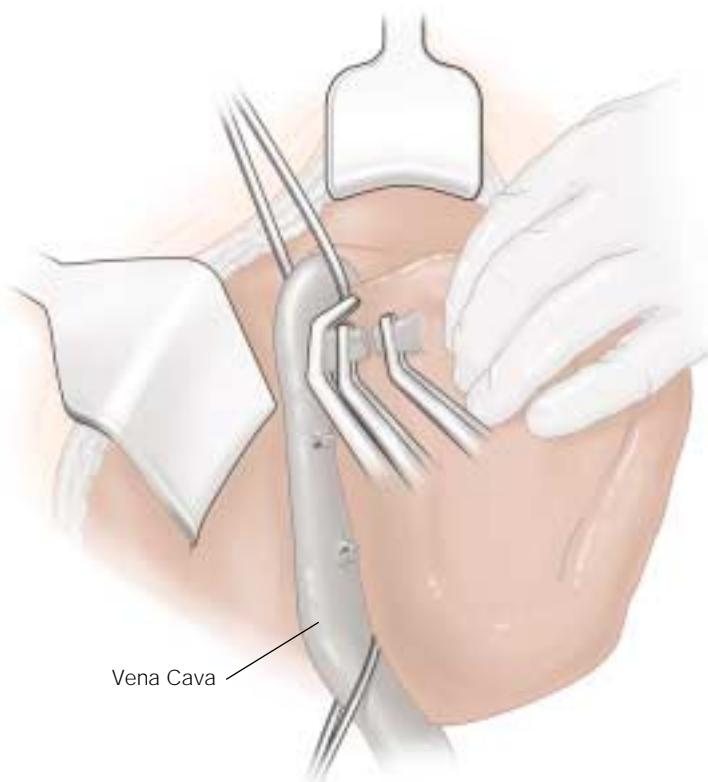

Figure 10 Right lobectomy. Once the small perforating vessels to the vena cava have been ligated, further dissection cephalad leads to the right hepatic vein. This vessel is controlled with vascular clamps and divided.

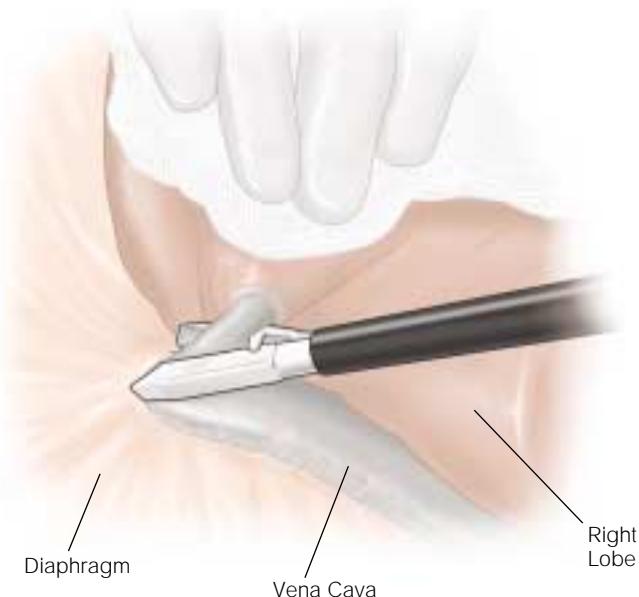

Figure 11 Right lobectomy. As an alternative to clamping and division, the right hepatic vein may be staple-ligated. Once the small perforating tributaries from the right liver to the vena cava have been divided, the right hepatic vein is isolated and ligated with an endoscopic GIA vascular stapler. The safest method for introducing this stapler is to retract the liver cephalad and to the left while advancing the stapler cephalad in the direction of the vena cava.

vein encountered can be staple-ligated, as can the tongue of liver tissue that often passes from the right lobe behind the vena cava to the caudate lobe. The right hepatic vein is then identified and isolated. It is the practice of some authors to introduce the stapler from the top of the liver downward,³⁴ but we find that in most patients, the liver is sufficiently high in the surgical wound

to render this angle of introduction technically impracticable. Accordingly, we introduce the stapler parallel to the vena cava and direct it from below upward [see Figure 11]. To ensure that the stapler does not misfire, care should be taken to confirm that no vascular clips are near the site where the stapler is applied.

Step 8: Parenchymal Transection

Inflow to the left liver is temporarily interrupted by clamping the hepatoduodenal ligament (the Pringle maneuver) [see 7:6 Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm]. The safety of temporary occlusion of the vessels supplying the hepatic remnant is well documented. Even in patients with cirrhosis, the warm ischemia produced by continuous application of the Pringle maneuver is well tolerated for as long as 1 hour.⁴⁰ Our practice is to apply the Pringle maneuver intermittently for periods of 10 minutes, with 2 to 5 minutes of perfusion between applications to allow decompression of the gut.

Parenchymal division is then begun along the line demarcated by the devascularization of the right liver. The line of transection along the principal plane is marked with the electrocautery and then cut with scissors. Stay sutures of 0 chromic catgut are placed on either side of the plane of transection and used for traction, separation, and elevation as dissection proceeds.

Many special instruments have been proposed for use in parenchymal transection, including electrocauteries, ultrasonic dissectors, and water-jet dissectors. We find that for the majority of hepatic resections, blunt clamp dissection is the most rapid method and is quite safe. In essence, a large Kelly clamp is used to crush the liver parenchyma [see Figure 12]. The relatively soft liver substance dissects away, leaving behind the vascular and biliary structures, which are then ligated. With this technique, the principal plane of the liver can usually be transected in less than 30 minutes.

In cirrhotic patients, the clamp-crushing technique may not work as well because of the firmness of the liver substance: the vessels often tear before the parenchyma does. Accordingly, in

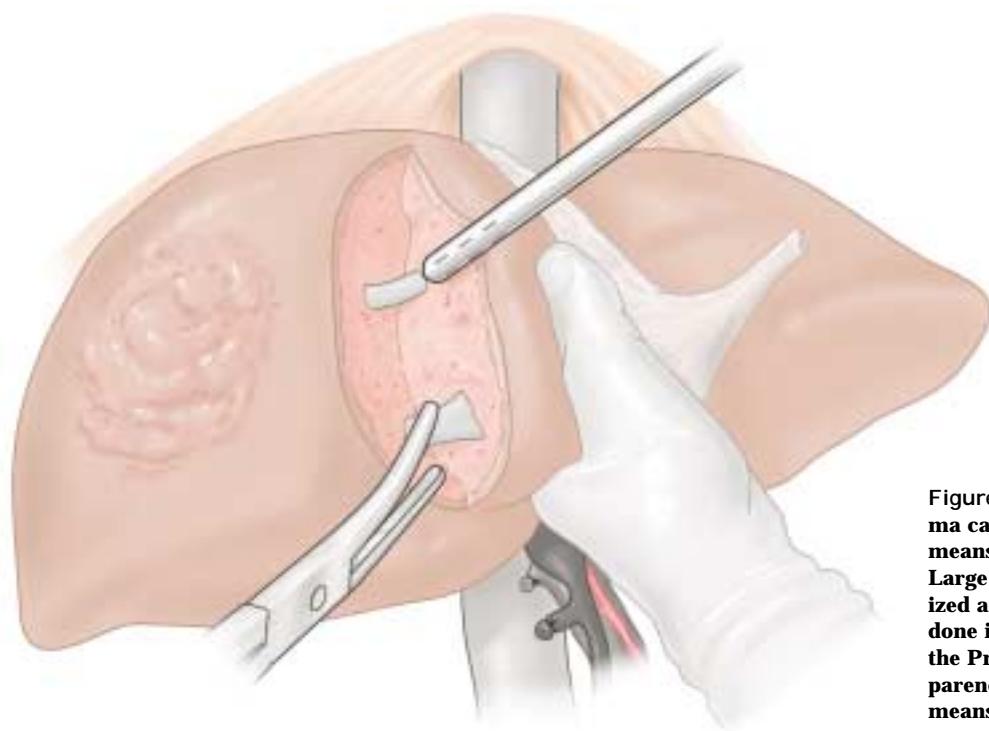

Figure 12 Right lobectomy. The parenchyma can be quickly and safely transected by means of the clamp-crushing technique. Large vessels and biliary radicles are visualized and ligated or clipped. This is usually done in tandem with inflow occlusion (i.e., the Pringle maneuver). Alternatively, the parenchyma can be bluntly dissected away by means of the finger-fracture technique.

cirrhotic patients, ultrasonic dissectors that coagulate while transecting the parenchyma may be a better choice. Water-jet dissectors may be useful in defining the major intrahepatic vascular pedicles or the junction of the hepatic vein and the vena cava, particularly if tumor is in close proximity.

After the specimen is removed, the raw surface of the hepatic remnant is carefully examined for hemostasis and bile leaks. Any oozing from the raw surface may be controlled with the argon beam coagulator. Biliary leaks should be controlled with clipping or suture ligation. The retroperitoneal surfaces should also be examined carefully for hemostasis, and the argon beam coagulator should be used where necessary.

Step 9: Closure and Drainage

The abdominal wall is closed in one or two layers with continuous absorbable monofilament sutures. The skin is closed with staples or with subcuticular sutures. Drains are unnecessary in most routine cases⁴¹; sometimes, in fact, they may exert harmful effects by leading to ascending infection or fluid management problems if ascites develops. There are four clinical situations in which we will routinely place a drain: (1) clear biliary leakage, (2) an infected operative field, (3) a thoracoabdominal incision, and (4) biliary reconstruction. In the case of the thoracoabdominal incision, a drain is placed to ensure that biliary leakage does not develop into a fistula into the chest.

LEFT LOBECTOMY

Steps 1 through 5

Left lobectomy involves removal of segments 2, 3, 4, and sometimes 1. The first five steps of the procedure are much the same as those of a right lobectomy.

Step 6 (Extrahepatic Dissection and Ligation): Control of Inflow Vessels

Extrahepatic control of vascular inflow vessels can be achieved in essentially the same fashion in a right-side resection. Our preference is to start the dissection at the base of the umbilical fissure. The left hepatic artery is divided first. The left branch of the portal vein is then easily identified at the base of the umbilical fissure. The point at which the left portal vein is to be divided depends on the extent of the planned parenchymal resection [see Figure 13]: if the caudate lobe is to be preserved, the left portal vein is ligated just distal to its caudate branch (line B); if the caudate lobe is to be removed, the left portal vein is ligated proximal to the origins of the portal venous branches to this lobe (line A).

Step 6—Alternative (Intrahepatic Pedicle Ligation): Control of Inflow Vessels

If the hepatectomy is being done to treat benign disease or to remove a malignancy that is remote from the base of the umbilical fissure, we highly recommend performing stapler-assisted pedicle ligation in preference to extrahepatic dissection and ligation.

The left portal pedicle is identified at the base of the umbilical fissure. The hilar plate is lowered through an incision at hepatotomy site C [see Figure 7], and a second incision is made in the back of segment 2 at hepatotomy site E [see Figure 7], thereby allowing isolation of the left portal pedicle with minimal risk of injury to the hilus. If the caudate lobe is to be removed as well, incisions should be made at hepatotomy sites C and F [see Figure 7] to allow isolation of the main left portal pedicle proximal to the vessels nourishing the caudate. The portal pedicle is isolated and secured with an umbilical tape. There is some risk that in the

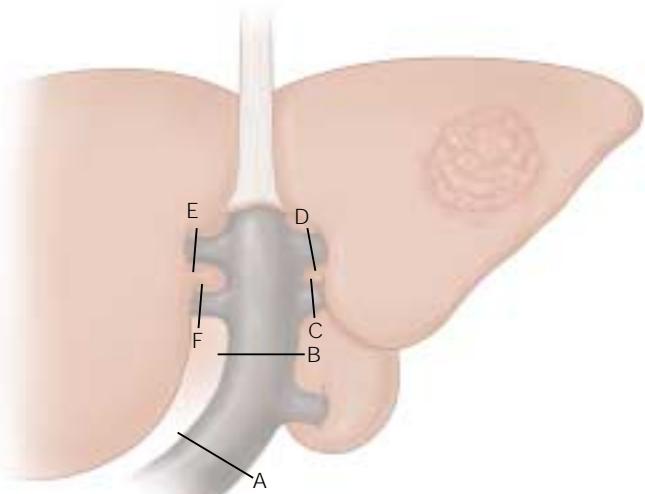

Figure 13 Left lobectomy. Ligation of vascular pedicles at specific sites in the left liver interrupts inflow to specific areas. Ligation at A interrupts inflow to the entire left liver, including the caudate lobe. Ligation at B interrupts blood flow to the left liver while sparing the caudate lobe. Ligation at C devascularizes segment 2, and ligation at D devascularizes segment 3. Ligation at E and F devascularizes segment 4.

course of securing the left portal pedicle, the middle hepatic vein, which lies immediately lateral to the left portal pedicle, may be injured. To minimize this risk, firm downward traction is applied to the umbilical tape, and a TA-30 vascular stapler is placed across the left portal pedicle [see Figure 14]. The pedicle is then stapled and divided.

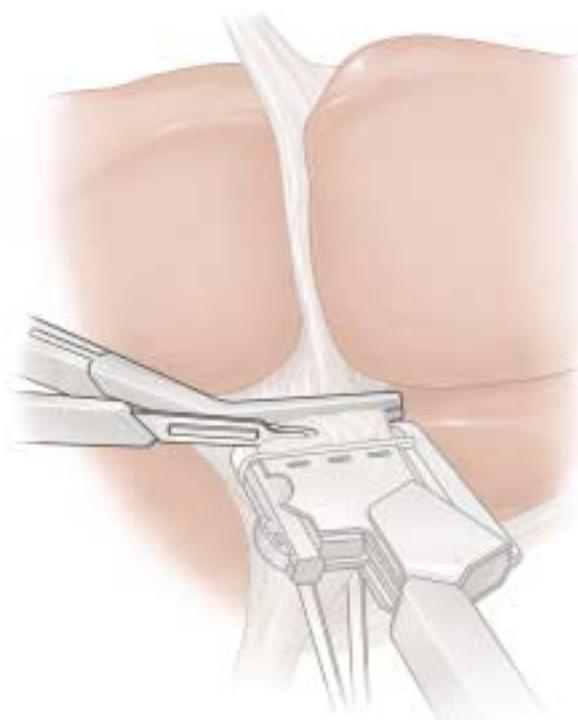

Figure 14 Left lobectomy. After hepatotomies in segment 4 and in the back of segment 2, the left portal pedicle is isolated, stapled, and divided.

Step 7: Control of Outflow Vessels

The left liver is retracted to the patient's right, and the entire lesser omentum is divided. The ligamentum venosum is identified between the caudate lobe and the back of segment 2 and is then divided near its attachment to the left hepatic vein; this measure facilitates identification and dissection of the left and middle hepatic veins anterior to the inferior vena cava. The left and middle hepatic veins are isolated in preparation for division.

Control of the left hepatic vein is quickly and safely accomplished by means of stapled ligation. In approximately 60% of patients, the left and middle hepatic veins join to form a single trunk before entering the vena cava. In a left lobectomy, the middle hepatic vein is often left intact; accordingly, if this is the surgeon's intent, it is vital to protect the middle hepatic vein while ligating the left. After the left hepatic vein is identified, an endoscopic GIA-30 vascular stapler is directed frove downward [see Figure 15] to ligate this vessel. The liver is retracted to the right to permit visualization of the junction of the left and middle hepatic veins. If ligation of the middle hepatic vein is desired as well, as is the case when there is tumor in proximity to the vessel, this can be accomplished with a stapler directed along the same path used for left hepatic vein ligation.

Steps 8 and 9

Parenchymal transection and closure are accomplished in much the same manner in a left lobectomy as in a right lobectomy (see above).

OTHER ANATOMIC RESECTIONS

In the ensuing discussion of the other major anatomic resections, we focus primarily on the major points in which they differ from right and left lobectomy. More detailed discussions of these operations are available in specialty texts on liver resection.^{26,27}

Extended Right Hepatectomy (Right Trisegmentectomy)

An extended right hepatectomy involves removal of the right lobe along with segment 4—that is, all liver tissue to the right of the falciform ligament [see Figure 3c]. The initial steps of this operation are the same as those of a right lobectomy, up through division of the right inflow vessels and the right hepatic vein.

The next step is devascularization of segment 4. The umbilical fissure is dissected to permit identification of the vascular pedicles to segments 2, 3, and 4, which lie within this fissure [see Figure 13]. In most cases, the lower part of the umbilical fissure is concealed by a bridge of liver tissue fusing segments 2 and 3 to segment 4. After this tissue bridge is divided with diathermy, the ligamentum teres is retracted caudally to reveal the vascular pedicles from the umbilical fissure to segment 4 (lines E and F [see Figure 13]). We generally suture-ligate these pedicles before dividing them.

The liver tissue is then transected immediately to the right of the falciform ligament, from the anterior surface back toward the divided right hepatic vein. The middle hepatic vein is generally left intact until it is encountered in the upper part of the dissection, at which point it is controlled and either suture- or staple-ligated.

Left Lateral Segmentectomy

A left lateral segmentectomy involves removal of only segments 2 and 3—that is, all liver tissue to the left of the falciform ligament [see Figure 3d]. These segments are mobilized by dividing the left falciform and triangular ligaments. As this is done, care

Figure 15 Left lobectomy. Staple ligation of the left hepatic vein. After the left lobe is completely mobilized through division of the left triangular ligament and the lesser omentum, the left hepatic vein is isolated and ligated with an endoscopic GIA vascular stapler. The best angle for introducing the stapler is from the xiphoid posteriorly and caudad.

must be taken not to injure the left hepatic and phrenic veins, which lie on the medial portion of the left triangular ligament.

The falciform ligament is retracted caudally, and the bridge of liver tissue between segment 4 and segments 2 and 3 is divided with diathermy. Dissection is then performed within the umbilical fissure to the left of the main triad. The vascular pedicles to segments 2 and 3 usually are then readily dissected and controlled (lines C and D [see Figure 13]). Control of these pedicles within the umbilical fissure is particularly important for tumor clearance if tumor is in proximity to the umbilical fissure: if the condition is benign or if tumor is remote from the umbilical fissure, the liver may be split anteroposteriorly just to the left of the ligamentum teres and the falciform ligament, and the vascular pedicles may be identified and ligated as they are encountered in the course of parenchymal transection.

Once the inflow vessels have been ligated, the left hepatic vein is identified and then divided either before parenchymal transection or as the vessel is encountered near the completion of parenchymal transection. If there is tumor near the dome, it is particularly important for tumor clearance that the left hepatic vein be controlled and ligated early and outside the liver.

Extended Left Hepatectomy (Left Trisegmentectomy)

An extended left hepatectomy involves resection of segments 2, 3, 4, 5, 8, and sometimes 1 [see Figure 3e]. In essence, it is a left lobectomy combined with a right anterior sectorectomy; it may

or may not include excision of the caudate lobe. This complex resection is usually undertaken to excise large tumors that occupy the left lobe and cross the principal fissura into the right anterior sector.

In this procedure, it is essential to preserve the right hepatic vein, which constitutes the sole venous drainage of the hepatic remnant. Usually, however, parenchymal transection must be performed along the course of this vein; thus, the major potential danger in the operation is injury to the vessel, which could lead to hemorrhage or hepatic failure from venous congestion of the hepatic remnant. In addition, because the blood supply to segment 7 often arises from the right anterior portal pedicle or from the junction of the right anterior and posterior pedicles [see Figure 8], there is a risk that the operation may result in devascularization of a large portion of the hepatic remnant. Finally, because of the great variability of the biliary anatomy and the extensive intrahepatic dissection required in this procedure, there is a significant risk of biliary complications.⁴² For all of these reasons, extended left hepatectomies are rarely performed outside major centers.⁴³

In the planning of an extended left hepatectomy, particularly close attention must be paid to preoperative imaging investigations so that the right-side intrahepatic vessels and biliary structures can be accurately delineated. Thin-slice CT or MRI images in the form of arterial, portal venous, and hepatic venous reconstructions [see Figure 2] are quite helpful in this regard. For large tumors encroaching on the hepatic hilum or on the junction of the right anterior and posterior pedicles, direct angiography may still be necessary.

The liver is fully mobilized by dividing not only the left triangular ligament but also the ligaments on the right. This step is essential for identifying the correct plane of parenchymal dissection and for ensuring safe dissection along the right hepatic vein.

The initial dissection is the same as for a left lobectomy. The liver is turned to the right side and the portal triad approached. The inflow vessels to the left liver are ligated, and the left hepatic vein and the subdiaphragmatic inferior vena cava are dissected free. The left and middle hepatic veins are controlled and ligated in the extrahepatic portions of their courses.⁴³ The left liver is thereby freed, and dissection on the right liver is greatly facilitated.

Next, the plane of transection within the right liver is defined. This plane is horizontal and lies lateral to the gallbladder fossa and just anterior to the main right hepatic venous trunk in the right fissura, halfway between the right anterior pedicle and the right posterior pedicle. The plane can be approximated by drawing a line from just anterior to the right hepatic vein at its insertion into the vena cava to a point immediately behind the fissure of Gans. This line can be accurately defined by clamping the portal pedicle to the anterior right sector of the liver.⁴³ If the tumor is remote from the junction of the right anterior and posterior portal pedicles, the anterior pedicle is controlled as outlined earlier [see Right Lobectomy, Step 6—Alternative (Intrahepatic Pedicle Ligation), above]. A vascular clamp is placed on the pedicle and the line of demarcation on the liver surface inspected before the pedicle is divided. If segment 7 appears to be ischemic as well, further dissection must be done to identify and protect the origins of the vessels supplying segment 7.

Parenchymal dissection is then carried out from below upward, with bleeding controlled by means of low central venous pressure anesthesia and intermittent application of the Pringle maneuver. If the caudate lobe is to be removed as part of the total resection, the veins draining the caudate must be controlled before parenchymal transection.

Segment-Oriented Resection

Each segment of the liver can be resected independently. In addition, resections involving only the right posterior sector (segments 6 and 7) or the right anterior sector (segments 5 and 8) are not uncommon. Extensive and excellent descriptions of so-called segment-oriented hepatic resection are available elsewhere.^{44,45}

Postoperative Care

I.V. fluids administered postoperatively should include phosphorus for support of liver regeneration. For large-volume hepatic resections, electrolyte levels, blood count, and prothrombin time (PT) are checked after the operation and then daily for 3 to 4 days. Packed red blood cells are administered if the hemoglobin level falls to 8 mg/dl or lower, and fresh frozen plasma is given if the PT is longer than 17 seconds. Postoperative pain control is best achieved with patient-controlled analgesia (PCA). Because of the decreased clearance of liver-metabolized drugs after a major hepatectomy, selection and dosing of pain medications should be adjusted accordingly. An oral diet can be resumed as early as postoperative day 3 unless a biliary-enteric anastomosis was performed.

Peripheral edema is common after major hepatic resections and may be treated with spironolactone. If an unexplained fever occurs or the bilirubin level rises when other hepatic function parameters are normal, an intra-abdominal bile collection may be present, and a CT scan should be obtained. Percutaneous drain placement usually brings about resolution of such collections after a few days; reoperation is rarely necessary.

Special Considerations

TOTAL VASCULAR ISOLATION FOR CONTROL OF BLEEDING

For control of bleeding during liver parenchymal transection, a technique known as total vascular isolation can be used as an alternative to the Pringle maneuver. In this technique, the liver is isolated by controlling the inferior vena cava (both above and below the liver), the portal vein, and the hepatic artery. This approach is based on techniques developed for liver transplantation and on the observation that the liver is capable of tolerating total normothermic ischemia for as long as 1 hour.⁴⁶ Its primary advantage is that while the liver is isolated, little or no bleeding occurs. It does, however, have disadvantages as well. In some patients, temporary occlusion of the inferior vena cava causes hemodynamic instability as a consequence of reduced cardiac output coupled with increased systemic vascular resistance.⁴⁷ Cardiac failure with marked hypotension, cardiac arrhythmia, and even cardiac arrest may ensue. In addition, when hepatic perfusion is restored, the sudden return of stagnant potassium-rich blood to the systemic circulation can aggravate the situation. For these reasons and because bleeding is generally well controlled with low central venous pressure anesthesia, we believe that total vascular isolation is useful only in rare cases. The clinical data published to date support this view. A prospective study from 1996 found that total vascular isolation had no major advantages over the approach described earlier [see Operative Technique, Right Lobectomy, Step 8, above] and was actually associated with greater blood loss.³⁹

The one setting where we believe that total vascular isolation may have a significant role to play is in the surgical management of hepatic tumors, particularly very large tumors that compro-

mise the vena cava or the hepatic veins. To extend the duration of vascular isolation in this setting, a venovenous bypass that vents the splanchnic blood into the systemic circulation may be used.⁴⁸ To further minimize parenchymal injury during vascular isolation, the liver may be perfused with cold organ preservation solutions. For extensive vascular invasion that necessitates major vena caval or hepatic venous reconstruction, some authors have suggested that the liver can be removed during venovenous bypass and resection and reconstruction performed extracorporeally.⁴⁹

Although there are clinical situations that call for venovenous bypass and ex vivo resection, in practice, these techniques are very rarely necessary: short-length vena caval resection and reconstruction can be performed quite safely without resort to them. In fact, involvement of the retrohepatic vena cava at a level below the major hepatic veins can generally be treated with simple excision of the affected segment without replacement,⁵⁰ particularly if complete obstruction at this level has already led to established collateral circulation.

THE CIRRHTIC PATIENT

Cirrhotic patients, by definition, have reduced hepatic functional capacity and reserve. Accordingly, these patients are at higher risk from hepatectomy and require careful assessment of liver function, appropriate selection for surgery and choice of operation, and greater attention to perioperative care.

Operative Planning

Selection of patients Hepatic failure is the major cause of hospital death and long-term morbidity after hepatic resection in cirrhotic patients.⁵¹⁻⁵⁵ Consequently, determination of a cirrhotic patient's candidacy for hepatectomy is based on preoperative assessment of baseline liver function.

A variety of tests have been proposed for assessment of hepatic reserve, including measurement of clearance of various dyes and metabolic substrates (e.g., indocyanine green^{56,57} and aminopyrine⁵¹). Measurement of the urea-nitrogen synthesis rate has also been suggested as a way of predicting outcome after resection.⁵⁴ Another functional test involves administering lidocaine and measuring levels of monethylglycinexylidide (a metabolite of lidocaine that is generated mostly through the cytochrome P-450 enzyme system in the liver) as a gauge of liver function.⁵⁸ Measurement of the hepatic portal venous pressure gradient via invasive radiologic techniques has been found to predict postoperative hepatic failure.⁵⁹ Assessment of portal venous hemodynamics by means of noninvasive Doppler ultrasonography has also been found to predict outcome after hepatectomy.⁶⁰

Currently, none of these functional tests are routinely done at most major liver resection centers. In practice, the Child-Pugh score [see 5:3 Jaundice] is the most commonly employed clinical tool for selection of surgical candidates. A Child-Pugh score higher than 8 is generally accepted as a contraindication to major hepatic resection.^{53,55,61-64}

Choice of procedure The appropriate extent of resection for cirrhotic patients may be quite different from that for noncirrhotic patients. In cirrhotic patients, the majority of hepatectomies are performed to eradicate hepatocellular carcinoma. A prime consideration in such resections is the margin needed to ensure tumor clearance. Most clinicians aim for a tumor-free margin of 1 cm. A 1989 study, however, found that in cirrhotic patients with hepatocellular carcinoma, as long as the tumor margin was microscopically clear of cancer, the exact size of the margin was not correlated with the incidence of recurrence.⁶⁵ In fact, the acceptance

of limited margins, coupled with the acceptance of nonanatomic resections aimed at preserving as much functional parenchyma as possible, is the single change in technical practice that is most responsible for the great improvements in the safety of hepatic resection observed worldwide in cirrhotic patients.

The guiding principle for hepatectomy in cirrhotic patients is that limited resections should be favored, with as much functional parenchyma spared as possible. In general, even for patients with well-compensated Child's grade A cirrhosis, we try to limit resections to less than two segments of functional liver. Patients with large tumors are more likely to tolerate a major resection because little functional parenchyma must be removed along with the tumor. Major hepatic resections involving removal of at least one lobe are now reported to carry an operative mortality of less than 10% in cirrhotic patients.^{66,67} Such procedures are usually performed in cirrhotic patients who have large tumors replacing most of one lobe, acceptable liver function, and no atrophy of the uninvolved lobe. Small tumors are often more difficult to manage. For patients with small, deeply placed tumors whose resection would necessitate removal of a large amount of functional parenchyma, an ablative alternative or even transplantation might be more suitable.

In an attempt to preserve as much functional liver as possible, many surgeons resort to more technically challenging operations. Most will perform multiple limited resections in order to avoid performing a full lobectomy.^{68,69} Some go so far as to reconstruct the right hepatic vein for the purpose of preserving venous outflow in segments 5 and 6 after resection of segments 7 and 8.

Operative Technique

Hepatic resection in cirrhotic patients is associated with certain specific technical difficulties that substantially increase the complexity of the operation. The liver parenchyma is hard, which makes retraction of the liver difficult. In addition, anatomic landmarks are distorted and difficult to find as a consequence of fibrosis and atrophy-hypertrophy. Finally, portal hypertension and tissue friability contribute to increased blood loss during mobilization and parenchymal transection.

Exposure and mobilization Trifurcated incisions and thoracoabdominal incisions should be avoided in cirrhotic patients because of the potential for ascitic leakage externally or into the chest. The increased firmness of the cirrhotic liver and the consequent difficulty of retraction can lead to significant blood loss from retroperitoneal or phrenic collateral vessels during mobilization. To prevent such bleeding, it may be preferable to use an anterior approach in which the liver parenchyma is split within the principal interlobar plane down to the anterior surface of the vena cava before the right liver is mobilized off the retroperitoneum.⁷⁰ The right lobe is then mobilized in a medial-to-lateral direction, and the right hepatic vein is secured during mobilization of the right lobe off the vena cava.

Inflow control At one time, it was widely doubted whether the Pringle maneuver was safe in cirrhotic patients. Subsequently, however, many studies verified that this maneuver can be performed for extended periods in cirrhotic patients without increasing either morbidity or mortality.⁷¹⁻⁷⁶ Nevertheless, it is advisable to employ the Pringle maneuver sparingly in this population so as to minimize ischemic stress. Our practice is to clamp the portal triad with a vessel loop tourniquet for 10-minute periods with 5-minute breaks in between. We have not found additional protective maneuvers (e.g., topical cooling^{77,78}) to be necessary.

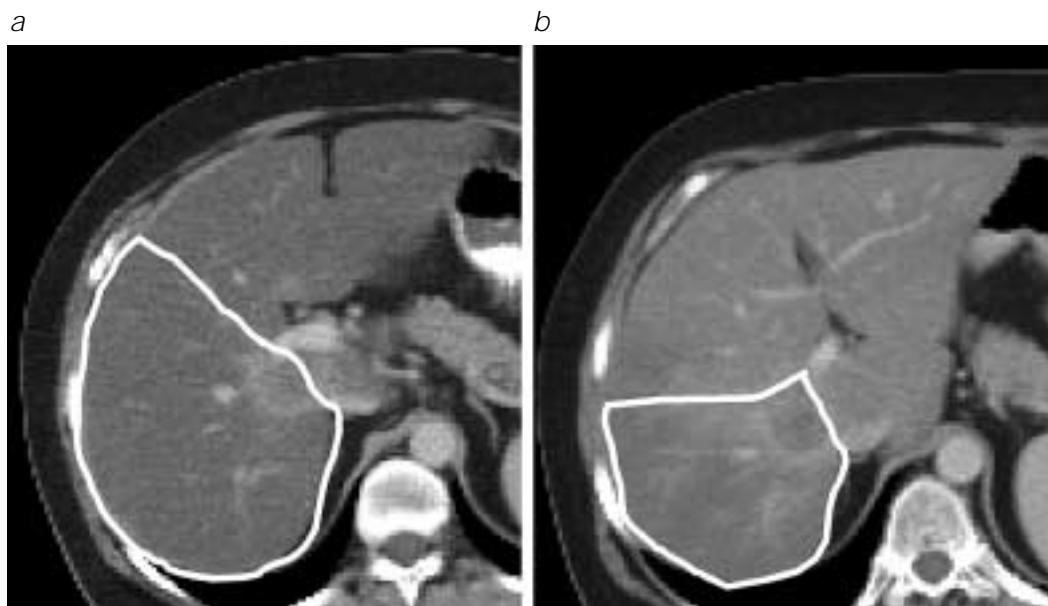

Figure 16 Liver atrophy and hypertrophy occur after right portal vein embolization. Shown are images of the liver (a) at baseline and (b) 6 weeks after PVE. The right liver is outlined in white.

Parenchymal transection In patients with normal liver parenchyma, most experienced hepatic surgeons use blunt dissection, with either the clamp-crushing technique or the finger-fracture technique, to transect the liver tissue.⁷⁹ In patients with cirrhosis, however, the firmness of the parenchyma makes the clamp-crushing technique less than ideal: because the parenchyma is often harder than the underlying vasculature and biliary radicles, blunt dissection is likely to tear these vessels. Accordingly, ultrasonic dissectors that coagulate and seal vessels during dissection are more suitable for parenchymal transection in this population.

Closure and drainage Because of the likelihood of postoperative ascites, the abdominal wall is closed with a heavy continuous absorbable monofilament suture to create a watertight closure. To prevent major fluid and protein losses and ascending infections, abdominal drains generally are not used.⁴¹ Reports specifically examining the role of drainage in cirrhotic patients documented a much lower incidence of postoperative complications and a shorter hospital stay for patients in whom no drains were placed.^{80,81}

Postoperative Care

The focus of postoperative care in cirrhotic patients is on management of cirrhosis and portal hypertension. In most such patients who undergo hepatic resection, transient hepatic insufficiency develops postoperatively, with hyperbilirubinemia, ascites formation, hypoalbuminemia, edema, and worsening of the baseline coagulopathy.

In the first 24 hours after the procedure, crystalloid must be administered at a level sufficient to maintain adequate portal perfusion.⁸² If patients are stable after the first 24 hours, they are subjected to water and sodium restriction and receive liberal amounts of salt-poor albumin for volume expansion if needed. Spironolactone is started in all patients as soon as oral diet is resumed; furosemide is added as needed. On rare occasions, a peritoneovenous shunt may have to be employed to control postoperative ascites,⁸³ but this measure is usually unnecessary if patients were properly selected. The PT is checked twice daily

during the immediate postoperative period: a PT longer than 17 seconds is corrected by administering fresh frozen plasma.

Preoperative Portal Vein Embolization

Most liver surgeons would be reluctant to resect more than the equivalent of two segments of functional liver in a patient with documented cirrhosis.⁸⁴ Consequently, many cirrhotic patients with technically resectable tumors are relegated to noncurative ablative therapy out of concern over possible postoperative hepatic failure. The situation may be changing, however, with the growing use of preoperative portal vein embolization (PVE), a technique that may extend surgeons' ability to resect tumor in cirrhotic patients.

In PVE, access to the portal vein on the side of the liver to be resected is gained via a percutaneous transhepatic approach. The vein is embolized approximately 1 month before the planned resection so as to produce ipsilateral atrophy along with compensatory hypertrophy of the contralateral future hepatic remnant.⁸⁵ The degree of compensatory hypertrophy can be dramatic [see Figure 16] and may modulate postoperative hepatic dysfunction. PVE is also employed in patients with normal parenchyma in whom extensive resection may result in a very small hepatic remnant. In patients undergoing extended right hepatectomy, particularly those with congenitally small left lateral sectors, the entire area of the extended hepatectomy, including the main right portal vein and the segmental branches supplying segment 4, can be embolized.⁸⁶

There is substantial evidence that preoperative PVE can be successfully used in patients with cirrhotic livers or impaired liver function and that such use is generally well tolerated.⁸⁷⁻⁹⁰ This technique can also serve as a test of the regenerative capacity of the hepatic remnant. If no compensatory hypertrophy is seen 4 weeks after PVE, the decision to perform a major hepatectomy should be reconsidered.

Repeat Hepatic Resection

Since 1984, when one of the first reports of repeat hepatic resection was published,⁹¹ a number of reports from around the

world have demonstrated that repeat resection can be done safely and with good long-term results even for recurrent malignancies. The morbidity rates and mortalities reported after repeat hepatectomy for metastatic colorectal cancer^{92–104} and hepatocellular carcinoma^{105–112} are comparable to those reported after initial hepatectomy. Extended survival has been demonstrated, and in some cases, the survival rate is equivalent to or even better than that observed after initial resection.^{93,100,107,113} In the following section, we concentrate on the key technical aspects of repeat hepatic resection. Discussions of indications, patient selection, and outcome are available in other sources.^{93,100,107,113}

Repeat hepatic resection poses certain technical difficulties that are not commonly encountered during initial resection.^{92,114,115} First, adhesions at the previous line of parenchymal transection can make reexposure of the liver difficult. Mobilizing the liver off the vena cava and reexposing the porta hepatis and the hepatic veins can be extremely hazardous if dissection was previously done in these areas. Second, liver regeneration and systemic chemotherapy can induce accumulation of fat within the liver, thereby rendering it more friable⁹³; the increased friability further increases the difficulties of reexposure and predisposes to tearing of Glisson's capsule.¹¹⁴ Third, regeneration alters the normal anatomic configuration of the portal structures [see Figure 17].¹¹⁶ For example, after a right hepatectomy, the porta hepatis is rotated posteriorly and to the right. The normal relationship among the portal structures is altered, with the bile duct displaced posteriorly and the portal vein displaced anteriorly.

Preoperative imaging is even more important for repeat resections than for primary resections. This is because scarring limits access to the liver for intraoperative assessment via palpation or ultrasonography. Before embarking on a repeat resection, it is essential to know the exact number and locations of the lesions to be treated within the regenerated parenchyma. Preoperative imaging also facilitates operative planning by accurately delineating the vasculature within the regenerated liver.

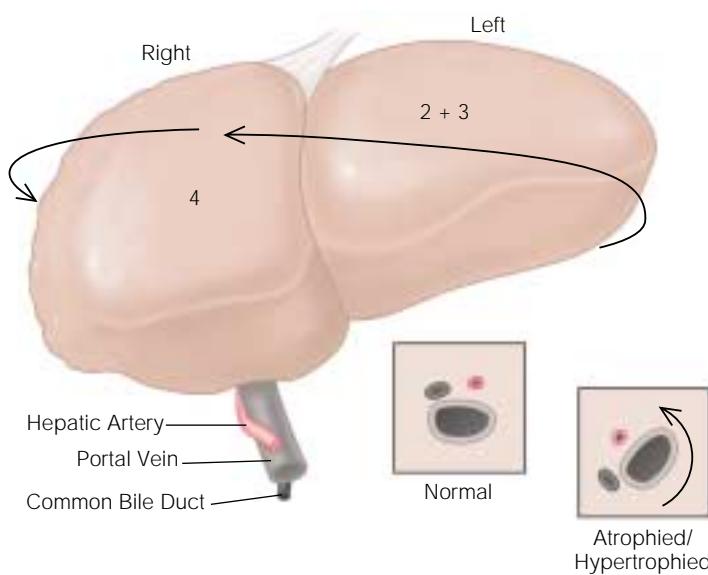

Figure 17 Repeat hepatic resection. Depicted are the changes in the relations of the portal structures that occur as a result of right liver atrophy or resection and left-side hypertrophy. The structures in the porta hepatis rotate to the right, with the CBD coming to rest laterally rather than anteriorly.

In a repeat resection after a previous major right hepatectomy, it is important to be prepared to convert the incision into a thoracoabdominal incision if necessary. Access through the right chest may be required for mobilization of the liver because of adherence of the previous resection margin to the diaphragm, or it may be required for access to the rotated CBD and portal vasculature at the porta hepatis.

In the dissection of the right upper quadrant after a previous right hepatectomy, three landmarks are particularly helpful in defining the anatomic structures within the regenerated left liver. The first landmark is remnants of the ligamentum teres, which defines the demarcation between the left lateral segment and segment 4; these should be found early on. The ligamentum teres may be followed to the base of the umbilical fissure to define the location of the left hepatic artery. Whether this artery arises from the common hepatic artery or from the left gastric artery, it passes into the liver parenchyma at the base of the umbilical fissure. The second landmark is the caudate lobe. The lesser omentum should be opened early on to reveal this lobe. An index finger should then be passed in front of the caudate toward the obliterated foramen of Winslow to define the porta hepatis and the location of the portal vein. The third landmark is the vena cava. Performing the Kocher maneuver to mobilize the duodenum off the vena cava allows this vessel to be dissected, thus further defining the portacaval plane. Definition of this plane leads to the correct plane for dissection and mobilization of the liver off the vena cava; it also allows isolation of the hepatoduodenal ligament for application of the Pringle maneuver and for extrahepatic dissection of the inflow vessels.

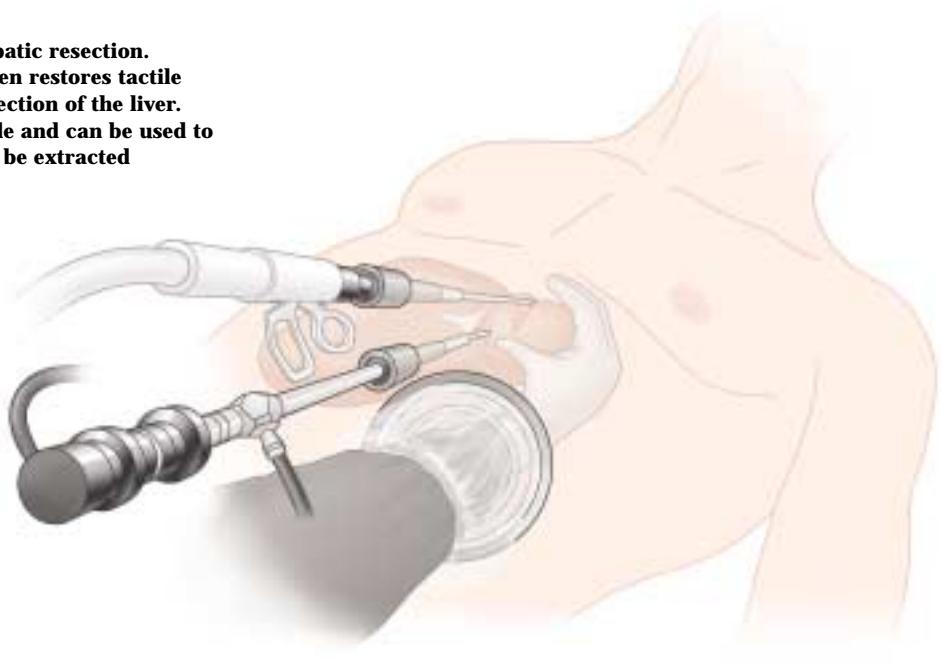

In a repeat resection after a previous left hepatectomy, the main concern with regard to mobilization of the liver is the anterior position of the portal vasculature after right-side hypertrophy. It is therefore prudent to mobilize the right liver, perform a Kocher maneuver, and follow the vena cava caudally to identify the portal vein from the right. The stomach and the colon usually are adherent to the edge of the previous resection and must be carefully dissected free to allow access to the liver. If the middle hepatic vein was preserved in the earlier left hepatectomy, it will lie immediately deep to the plane of the stomach or the colon and thus may be a source of hemorrhage during dissection.

Control of the inflow or outflow vasculature may be compromised by the scarring resulting from the previous operation. If extensive extrahepatic dissection was performed for control of inflow vasculature in the earlier procedure, control of these vessels in the repeat resection is more safely accomplished via intrahepatic pedicle ligation [see Operative Technique, Right Lobectomy, Step 6—Alternative (Intrahepatic Pedicle Ligation), above].

A major concern with repeat hepatectomy is that it is sometimes necessary to perform more limited resections than would otherwise be indicated. Normally, for removal of liver tumors, we avoid wedge excisions because these nonanatomic resections are more often associated with greater blood loss and positive margins than anatomic resections are.^{99,117} In a repeat hepatectomy, however, anatomic considerations arising in the regenerated liver may make a wedge resection the best choice.

With appropriate patient selection and careful operative planning, very favorable perioperative and long-term results can be achieved after repeat hepatic resection. It is noteworthy that studies addressing repeat resection have not documented any substantial increases in blood loss, duration of operation, or rate of complications in comparison with the initial resection.^{93–97,118}

Figure 18 Hand-assisted laparoscopic hepatic resection.
Introduction of the hand within the abdomen restores tactile sensation to the surgeon and facilitates resection of the liver. The hand is the best liver retractor available and can be used to dissect the parenchyma. The specimen can be extracted through the hand access port.

Hand-Assisted Laparoscopic Hepatic Resection

In addition to revolutionizing treatment of gallstone disease,¹¹⁹ laparoscopic techniques are increasingly used for fenestration of benign cysts of the liver^{120,121} and for staging of hepatobiliary malignancies to prevent unnecessary laparotomies.^{29,122,123} Until recently, however, laparoscopic resection of liver tumors was described only in case reports or small series.^{120,124-128} Perhaps the main reason for the strong resistance to laparoscopic hepatic resection has been fear of catastrophic bleeding. If inadvertent damage to a major hepatic vein or the vena cava occurs during an open operation, the bleeding can be controlled with direct manual compression until the vessel is repaired; however, if such damage occurs during a laparoscopic operation, control of the bleeding is considerably more difficult. In addition, damage to a hepatic vein or the vena cava during a laparoscopic procedure can theoretically result in CO₂ embolism. Another concern is that the loss of tactile sensation characteristic of laparoscopic surgery may lead to inadequate tumor clearance. Finally, whereas there are many liver retractors designed to hold the liver in one position, there is no good retractor for repeatedly moving the liver from side to side, as would be necessary during a laparoscopic hepatectomy. The human hand is still the best tool for this purpose.

Laparoscopic hepatic resection has been greatly facilitated by several recent technologic advances, including laparoscopic staplers¹²⁹ and ultrasonic dissectors,¹³⁰ which can be used for ligation of the hepatic vasculature and transection of liver parenchyma. The most important advance, however, is the hand access port, a small port through which one hand can be introduced into the abdomen for a hand-assisted laparoscopic resection [see Figure 18].¹³¹⁻¹³³ With this approach, the surgeon not only regains a measure of tactile sensation but also is able to employ the best liver retractor available. Moreover, direct manual compression of any bleeding vessels is once again possible, and the incision made for the hand access port is also used for extraction of the resected specimen.

Patient selection is essential for safe laparoscopic resection of liver tumors. Resection of any two segments along the lower edge of the liver is easily accomplished laparoscopically. At MSKCC, we have laparoscopically resected lesions from all segments.³⁸

The procedure starts with the placement of a 10 mm port, usually in the right or left upper quadrant on the side opposite that on which the hand access port will be placed. After staging is performed to ensure that the lesion is resectable, a 5 to 6 cm incision is made for placement of the hand access port. The port site should be chosen so as to allow manual retraction of the part of the liver to be resected, with the falciform and triangular ligaments used to provide countertraction. Once the access port is in place, the abdomen is fully palpated under laparoscopic vision. A laparotomy sponge is placed into the abdomen to facilitate retraction and absorb blood, and a long bulldog clamp is inserted for use in the Pringle maneuver. A long umbilical tape is tied to the bulldog clamp beforehand so that the instrument can be easily located throughout the procedure. Additional ports are then placed as necessary for introduction of the stapler or the ultrasonic scalpel.

The area to be resected is outlined with the electrocautery. The liver is manually retracted, intermittent application of the Pringle maneuver is initiated, and the parenchyma is transected. Liver parenchyma remote from the major portal pedicles and hepatic veins may be transected either with the ultrasonic dissector or by means of finger fracture. Near the major portal pedicles and hepatic veins, an endoscopic GIA vascular stapler may be used. After removal of the specimen, the laparoscopic argon beam coagulator (Conmed Corporation, Utica, New York) and hemostatic agents may be used.

The laparoscopic approach is suitable for minor as well as major hepatic resections. At present, however, it is unclear whether this approach constitutes a significant advance in liver surgery. To clarify this issue, further study of laparoscopic hepatic resection with respect to perioperative outcome, quality of life, and long-term survival is required.

24 PROCEDURES FOR BENIGN AND MALIGNANT PANCREATIC DISEASE

Attila Nakib, M.D., F.A.C.S., Keith D. Lillemoe, M.D., F.A.C.S., and John L. Cameron, M.D., F.A.C.S.

Over the past two decades, both the mortality and the morbidity associated with pancreatic surgery have been reduced substantially. In many high-volume centers, the perioperative mortality for pancreatic resection is now less than 3%.¹⁻³ This decline in mortality may be attributed to more careful patient selection, better understanding of surgical anatomy, advances in critical care medicine, and improvements in the management of perioperative complications.

In what follows, we describe the operative techniques we employ in the management of both benign and malignant pancreatic disease, including pancreaticoduodenectomy (the Whipple procedure), distal pancreatectomy (open and laparoscopic), longitudinal pancreaticojjunostomy (the Puestow procedure), enteric drainage of pancreatic pseudocysts (open and laparoscopic), and palliative bypass for unresectable periampullary cancer.

Preoperative Evaluation

A number of different imaging options are available to help determine the appropriate surgical approach to management of pancreatic disease [see 5:9 *Tumors of the Pancreas, Biliary Tract, and Liver*]. These options include both noninvasive modalities (e.g., transabdominal ultrasonography, computed tomography, and magnetic resonance imaging) and invasive modalities (e.g., endoscopic retrograde cholangiopancreatography [ERCP] and endoscopic ultrasonography [EUS]).

Transabdominal ultrasonography can identify changes associated with chronic pancreatitis, biliary and pancreatic duct dilation, and the presence of pseudocysts. In the setting of malignant disease, it may demonstrate dilated intrahepatic and extrahepatic bile ducts, liver metastases, pancreatic masses, ascites, and enlarged peripancreatic lymph nodes. A malignancy of the pancreas typically appears as a hypoechoic mass; ultrasonography reveals a pancreatic mass in 60% to 70% of pancreatic cancer patients.

Currently, helical (spiral) CT is the preferred noninvasive imaging test for pancreatic disease, having largely supplanted ultrasonography in this context. Helical CT can delineate the anatomy of the pancreas and the surrounding organs in considerable detail, and it can easily define pancreatic calcifications, inflammation, necrosis, and masses. Pancreatic cancer usually appears as an area of pancreatic enlargement with a localized hypodense lesion. A triple-phase intravenous contrast study is ideal for the assessment of pancreatic lesions. Thin cuts are obtained through the pancreas and the liver during both the arterial phase and the venous phase after the injection of I.V. contrast material. Besides being used to determine the primary tumor size, CT is used to look for and evaluate invasion into local structures or metastatic disease.

In general, MRI has no significant advantages over CT: its signal-to-noise ratio is low, it is prone to motion artifacts, it does not opacify the bowel, and it has low spatial resolution. Nevertheless, magnetic resonance cholangiopancreatography (MRCP) can be quite useful for defining the anatomy and pathology of the bile ducts and the pancreatic duct noninvasively. It can be especially useful in cases where the ampulla of Vater is not accessible (as in patients who have previously undergone Roux-en-Y or Billroth II reconstructions).

ERCP allows direct imaging of the pancreatic and bile ducts and is the gold standard for diagnosing chronic pancreatitis. It also allows therapeutic stenting of biliary and pancreatic duct strictures. The sensitivity of ERCP for the diagnosis of pancreatic cancer approaches 90%. The presence of a long, irregular stricture in an otherwise normal pancreatic duct is highly suggestive of a pancreatic malignancy. Often, the pancreatic duct is obstructed with no distal filling.

EUS, though newer than the aforementioned modalities, has begun to play an important role in the evaluation of pancreatic diseases. It is a semi-invasive test that can be performed with a very low rate of complications (< 0.1%). EUS can diagnose the most common causes of extrahepatic biliary obstruction (e.g., choledocholithiasis and pancreaticobiliary malignancies) with a degree of accuracy equaling or exceeding that of direct cholangiography or ERCP, and it is the most sensitive modality for the diagnosis of pancreatic carcinoma. The particular strengths of EUS in the diagnosis of pancreatic cancer are (1) that it can clarify small (< 2 cm) lesions when CT findings are questionable or negative, (2) that it can detect malignant lymphadenopathy, and (3) that it can guide fine-needle aspiration (FNA) for definitive diagnosis and staging. On average, EUS without FNA is 85% accurate for T stage disease and 70% accurate for N stage disease. The combination of EUS and FNA is 93% sensitive and 100% specific for T stage disease and 88% accurate for N stage disease.⁴

Pylorus-Preserving Pancreaticoduodenectomy (Whipple Procedure)

Surgical resection of a periampullary carcinoma can be accomplished by means of either a pylorus-preserving pancreaticoduodenectomy (PPPD) or the classic Whipple resection (including an antrectomy). Multiple randomized trials have failed to show any significant differences between the two in terms of either relative ease of performance or short- or long-term outcome (including survival). The choice between them is usually made on the basis of individual surgeons' preferences (unless there is obvious tumor encroachment on the first portion of the duodenum). In the ensuing technical description, we focus primarily on the pylorus-preserving modification but also refer to certain important components of the classic Whipple resection.

OPERATIVE PLANNING

Operative management of periampullary cancer is carried out in two phases. First, the resectability of the tumor is assessed; then, if the tumor is resectable, a pancreaticoduodenectomy is performed and gastrointestinal continuity restored. Selective use of staging laparoscopy should be considered for patients at high risk for occult metastatic disease, such as patients with large primary tumors; patients with lesions in the neck, body, or tail of the pancreas; patients with equivocal radiographic findings suggestive of occult distant metastatic disease (e.g., low-volume ascites, CT findings indicating possible carcinomatosis, and small hypodense regions in the hepatic parenchyma indicating possible hepatic metastases that are not amenable to percutaneous biopsy); and patients with clinical and laboratory findings

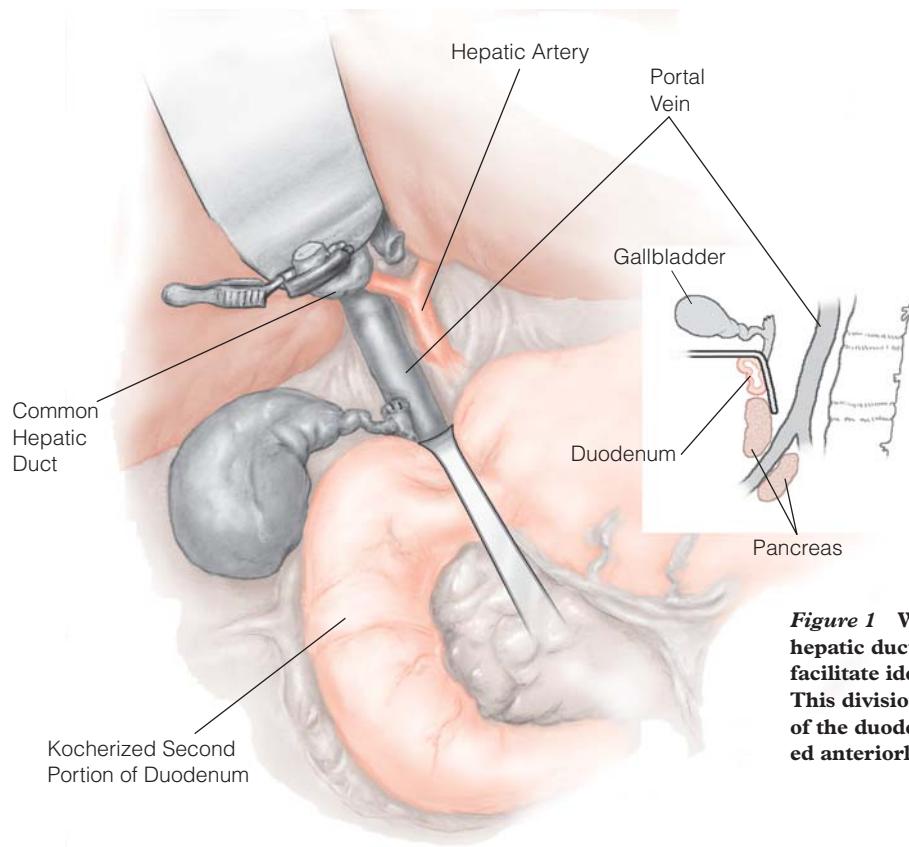

Figure 1 Whipple procedure. The common hepatic duct is divided at an early stage to facilitate identification of the portal vein. This division also untethers the first portion of the duodenum and allows it to be retracted anteriorly.

suggesting more advanced disease (e.g., marked hypoalbuminemia or weight loss, significant increases in the CA 19-9 level, and severe back or abdominal pain).

OPERATIVE TECHNIQUE

The peritoneal cavity is entered through an upper midline incision or a bilateral subcostal incision. The liver, the omentum, and the peritoneal surfaces are inspected and palpated. Biopsy is performed on suspicious lesions, and specimens are submitted for frozen-section analysis. Regional lymph nodes are examined for evidence of tumor involvement. The presence of tumor in the periaortic lymph nodes of the celiac axis indicates that the tumor has extended beyond the limits of normal resection; however, the presence of tumor in lymph nodes that normally would be incorporated within the resection specimen does not constitute a contraindication to resection.

Once distant metastases have been excluded, the resectability of the primary tumor is assessed. Various local factors may preclude pancreaticoduodenal resection, including retroperitoneal extension of the tumor to involve the inferior vena cava or the aorta and direct involvement or encasement of the superior mesenteric artery (SMA), the superior mesenteric vein (SMV), or the portal vein. Often, the determination of resectability is made on the basis of a careful review of the preoperative imaging (CT plus EUS) in conjunction with operative exploration.

Operative assessment of resectability begins with a Kocher maneuver and mobilization of the duodenum and the head of the pancreas from the underlying inferior vena cava and aorta. When the duodenum and head of the pancreas have been mobilized sufficiently, a hand is placed under the duodenum and the head of the pancreas to palpate the tumor mass and determine its relation to the SMA. Inability to identify a plane of normal tissue between the mass and the arterial pulsation indicates that the tumor directly involves the SMA, which means that complete tumor resection is not possible.

The final operative step for determining resectability involves dissection of the SMV and the portal vein to rule out tumor invasion. Identification of the portal vein is greatly simplified if the common hepatic duct is divided early in the dissection.⁵ Once the hepatic duct has been divided, the anterior surface of the portal vein is easily and quickly identified [see Figure 1]. The lymph node tissue lateral to the hepatic duct and the portal vein should be dissected off the structures to be included in the surgical specimen. It must be remembered that important variations in the hepatic arterial anatomy, including a replaced right hepatic artery, may be encountered during this dissection. If the appropriate plane is found along the anterior surface of the portal vein, it should be easy to pass the index finger of the left hand on top of the vessel posterior to the first portion of the duodenum and the neck of the pancreas (because there usually are no veins joining the anterior surface of the portal vein). If this maneuver proves difficult, the gastroduodenal artery should be identified where it comes off the common hepatic artery. Once adequate dissection has been carried out, the artery should first be clamped with a nonoccluding vascular clamp, then, if the hepatic artery pulse is preserved, it should be divided and ligated with 2-0 silk ties. (The initial clamping of the gastroduodenal artery with a vascular clamp is done to confirm that the arterial supply to the liver will not be interrupted should either variations in hepatic arterial anatomy or important collateral circulation be present in the face of celiac artery stenosis.) After the artery has been divided and ligated, an additional ligature of 3-0 polypropylene should be placed on the proximal stump. Division of the gastroduodenal artery unroofs part of the tunnel through which the index finger is slipped, thereby greatly facilitating the separation of the portal vein from the posterior aspect of the first portion of the duodenum and the neck of the pancreas.

Once the anterior surface of the portal vein has been dissected posterior to the neck of the pancreas, the next step is to identify the SMV and dissect its anterior surface. This is most easily accomplished by

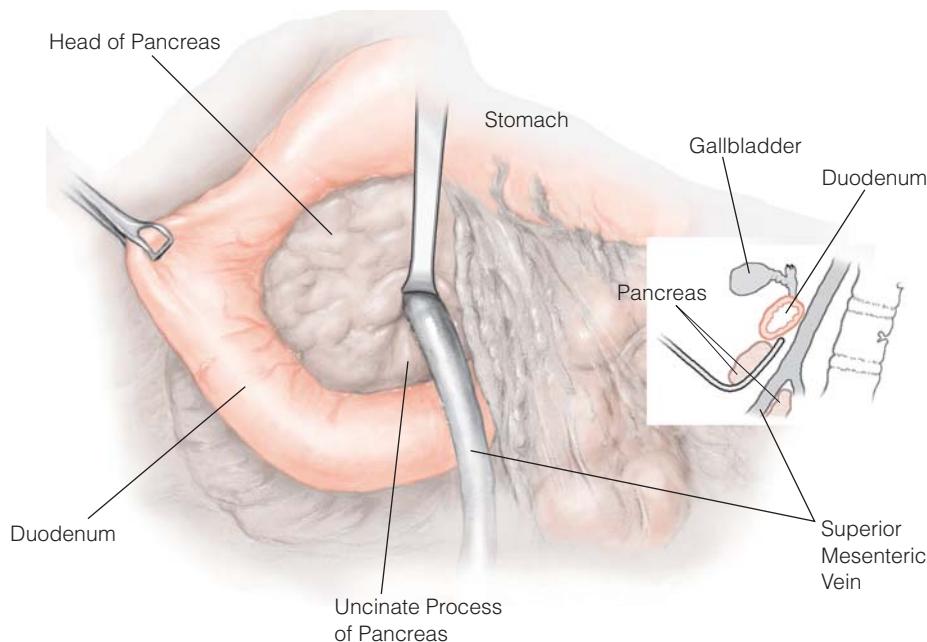

Figure 2 Whipple procedure.
Kocherization of the duodenum is continued along the third portion until the superior mesenteric vein is reached. This vein can then be easily cleaned up to its connection with the portal vein.

extending the Kocher maneuver past the second portion of the duodenum to include the third and fourth portions. During this extensive kocherization, the first structure encountered anterior to the third portion of the duodenum is the SMV [see Figure 2]. The anterior surface of the vein can then be cleaned rapidly and dissected under direct vision by retracting the neck of the pancreas anteriorly. This dissection

is continued until it connects to the portal vein dissection from above. If this maneuver can be completed without evidence of SMV or portal vein involvement, the tumor can generally be considered resectable. It is still possible, however, for an uncinate tumor to involve the right lateral surface and the undersurface of the SMV, and this possibility should be carefully evaluated.

If the neck of the pancreas can be successfully dissected off of the anterior and lateral surfaces of the portal vein and the SMV, most experienced pancreatic surgeons will proceed with pancreaticoduodenectomy without obtaining a tissue diagnosis. In defining the diagnosis of malignancy, an intraoperative biopsy is less conclusive than the combination of the clinical presentation, the results of preoperative CT scanning and cholangiography, and the operative finding of a palpable mass in the head of the pancreas.

In a PPPD,⁶ the duodenum is first mobilized and divided approximately 2 cm distal to the pylorus with a gastrointestinal anastomosis (GIA) stapler. The posterior surface of the proximal first portion of the duodenum is dissected until the lesser sac is entered. At this point, the soft tissue attachments from the inferior border of the duodenum to the inferior border of the pancreas are divided. The right gastroepiploic vessels, which can be sizable, are clamped, divided, and ligated. In a similar fashion, the soft tissue areolar attachments found superiorly are divided with the electrocautery. Care must be taken to identify and preserve the right gastric artery, which comes off the common hepatic artery and actually joins the foregut along the proximal part of the first portion of the duodenum.

In a classic Whipple procedure, an antrectomy is performed. The right gastroepiploic arcade and the right gastric vessels are divided to permit mobilization of the antrum. The stomach is then divided with a GIA stapler, usually at the level of the incisura. At this point, if the gastroduodenal artery was not divided earlier, it is identified, divided, and ligated as described (see above). During this step, particular care must be taken to ensure that the lumen of the common hepatic artery is not encroached on by one of the proximal ties.

The neck of the pancreas is then divided with the electrocautery [see Figure 3], with care taken not to injure the underlying SMV and portal vein. These veins are mobilized away from the uncinate process of the pancreas; the dissection should continue until the SMV, clearly palpable with the index finger of the left hand, is visualized. If a

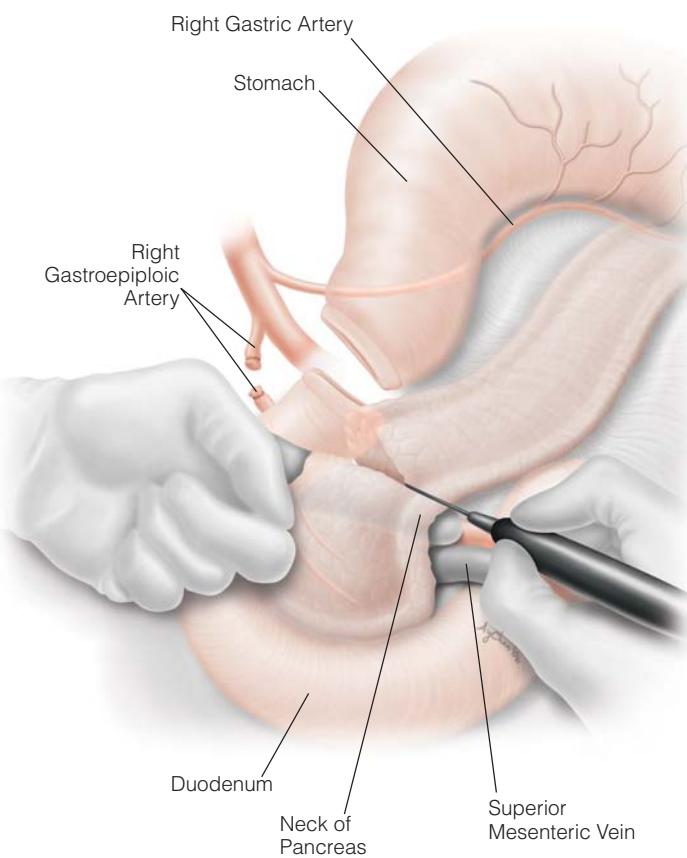

Figure 3 Whipple procedure. Transection of the neck of the pancreas with electrocautery.

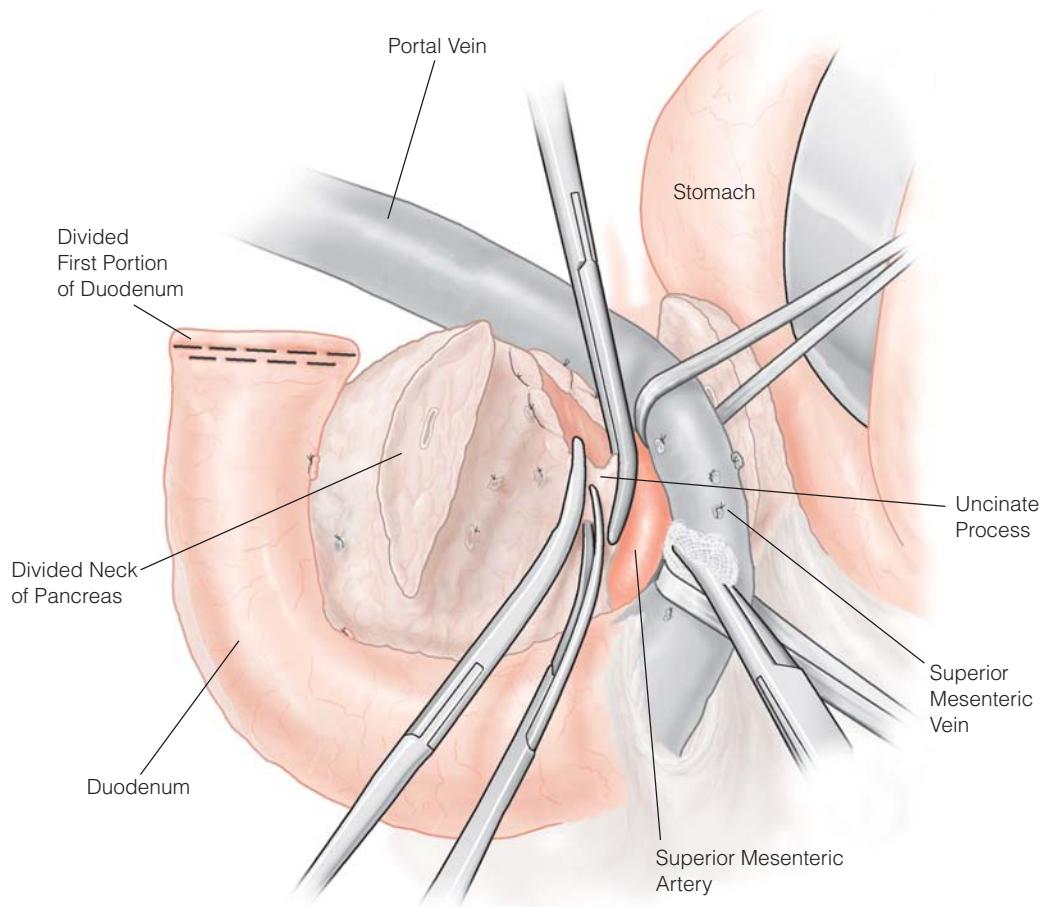

Figure 4 Whipple procedure. The uncinate process is divided flush with the superior mesenteric artery.

replaced right hepatic artery is present, its origin from the SMA will be encountered at this point and must be preserved. The uncinate process is divided between clamps flush with the SMA [see Figure 4], then ligated with 2-0 silk ties; alternatively, either a vessel-sealing system (e.g., LigaSure; Valleylab, Boulder, Colorado) or an ultrasonic shears may be used. The SMA is completely exposed during this dissection, which proceeds from cephalad to caudad. As a rule, there are two large veins joining the SMV inferiorly that must be dissected free, doubly ligated, and divided.

Once the uncinate process has been completely divided, the specimen is attached only by the third portion of the duodenum. At this point, the upper abdomen is copiously irrigated with an antibiotic solution and packed. The transverse colon, along with the greater omentum, is reflected cephalad. The proximal jejunum and the ligament of Treitz, along with the fourth portion of the duodenum, are dissected free, and the dissection is continued until it meets the right-side upper abdominal dissection. At a convenient point where there is a wide vascular arcade, the proximal jejunum is divided with a GIA

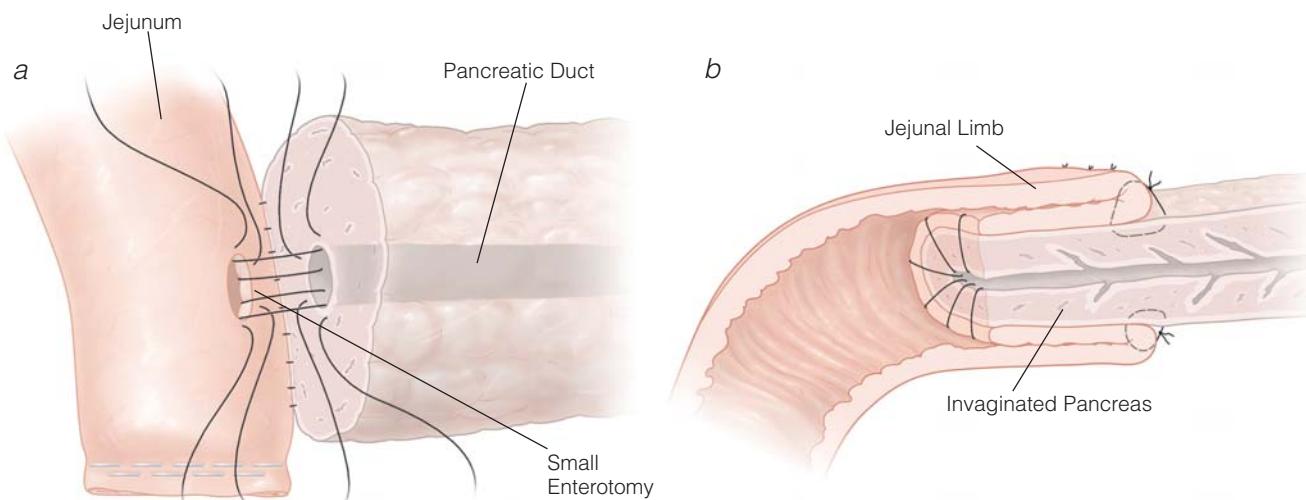

Figure 5 Whipple procedure. (a) An end-to-side mucosa-to-mucosa pancreaticojejunostomy is done in two layers with an outer layer of interrupted 3-0 silk sutures and an inner layer of interrupted 5-0 absorbable synthetic sutures. (b) Alternatively, the end of the pancreas can be invaginated into the end of the jejunum for approximately 2 cm. The anastomosis is done with an outer interrupted layer of 3-0 silk and an inner continuous layer of 3-0 absorbable synthetic suture material.

stapler approximately 10 to 12 cm from the ligament of Treitz. The proximal jejunum is then grasped with a Babcock clamp and retracted cephalad. The mesentery to the proximal jejunum is divided between clamps and ligated with 2-0 silk (or divided with a vessel-sealing device such as the LigaSure).

When division of the mesentery is complete, the specimen is free and can be removed from the operative field. The bile duct, the pancreatic neck, and the uncinate margins should be tagged with sutures and sent for frozen-section analysis. The bed of the tumor should be carefully inspected for hemostasis and its margins marked with ligating clips (e.g., LigaClip; Ethicon Endo-Surgery, Inc., Cincinnati, Ohio) to facilitate postoperative radiation therapy.

There are several technical options for restoring GI continuity after a pancreaticoduodenal resection. Our preferred technique is to bring the end of the divided jejunum through the transverse mesocolon to the right of the middle colic vessels in a retrocolic fashion and to perform an end-to-side pancreaticojejunostomy. A row of interrupted 3-0 silk Lembert sutures is placed between the side of the jejunum and the posterior capsule of the end of the pancreas. A small enterotomy, matching the size of the pancreatic duct, is made in the jejunum, and an inner layer of interrupted 5-0 absorbable monofilament sutures is placed to create a duct-to-mucosa anastomosis [see Figure 5a]. Meticulous stitch placement is crucial, and many surgeons use some degree of magnification to complete the anastomosis in small ducts. Often, a short segment of a pediatric feeding tube is placed across the anastomosis to be used as a temporary indwelling stent. The anastomosis is completed with an outer layer of 3-0 silk Lembert sutures placed between the anterior pancreatic capsule and the jejunum. A popular alternative to this duct-to-mucosa technique is to create an enterotomy approximately the same size as the pancreatic neck and to place an inner continuous layer of 3-0 absorbable synthetic suture material circumferentially around the entire gland. The neck is then invaginated 1 to 2 cm into the lumen of the bowel, and an outer interrupted layer of 3-0 silk is placed to complete the anastomosis [see Figure 5b].

The biliary-enteric anastomosis is performed 6 to 10 cm distal to the pancreaticojejunostomy. An end-to-side hepaticojejunostomy is fashioned with a single interrupted layer of 4-0 absorbable synthetic suture material [see Figure 6]. Generally, there is no need for a T tube or a stent.

Approximately 15 cm distal to the biliary-enteric anastomosis, an end-to-side duodenojejunostomy is performed with an inner continuous layer of 3-0 absorbable synthetic suture material and an outer interrupted layer of 3-0 silk [see Figure 7]. Some experienced pancreatic surgeons prefer to perform the duodenojejunostomy further distally in an antecolic position, in the belief that doing so reduces the incidence of early postoperative delayed gastric emptying. If an antrectomy was performed, the medial half of the gastric staple line is reinforced with interrupted 3-0 silk seromuscular Lembert sutures. The gastrojejunal anastomosis is completed to the lateral (greater curvature) aspect of the staple line as a two-layer Hofmeister-style anastomosis.

The abdomen is copiously irrigated with an antibiotic solution. The jejunal loop is tacked to the rent in the transverse mesocolon with interrupted 3-0 silk sutures. The defect in the retroperitoneum previously occupied by the fourth portion of the duodenum is closed with a continuous 2-0 silk suture. One or two closed suction Silastic drains are placed in the vicinity of the hepaticojejunostomy and the pancreaticojejunostomy and brought out through a stab wound in the right upper quadrant. The abdomen is closed in a standard fashion.

Distal Pancreatectomy with Splenectomy

Distal pancreatic resection is performed for a variety of conditions, including inflammatory processes, benign tumors and cysts, and pan-

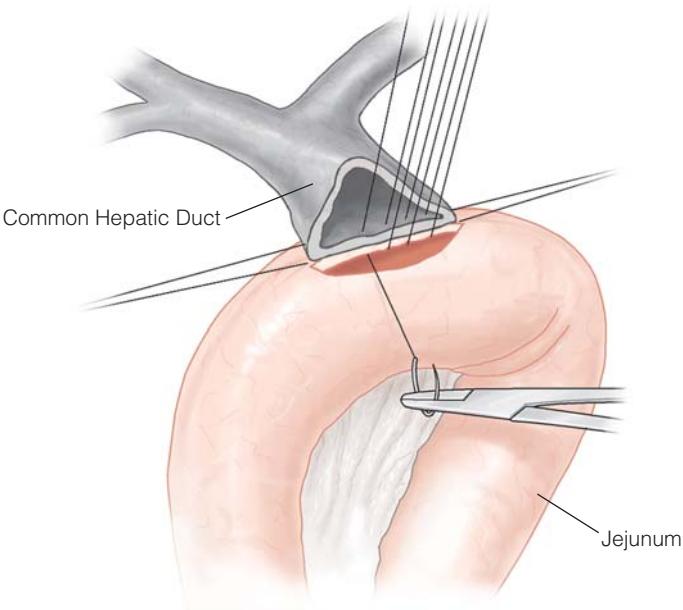

Figure 6 Whipple procedure. The common hepatic duct is anastomosed to the jejunum in an end-to-side fashion with a single layer of 4-0 interrupted absorbable synthetic sutures.

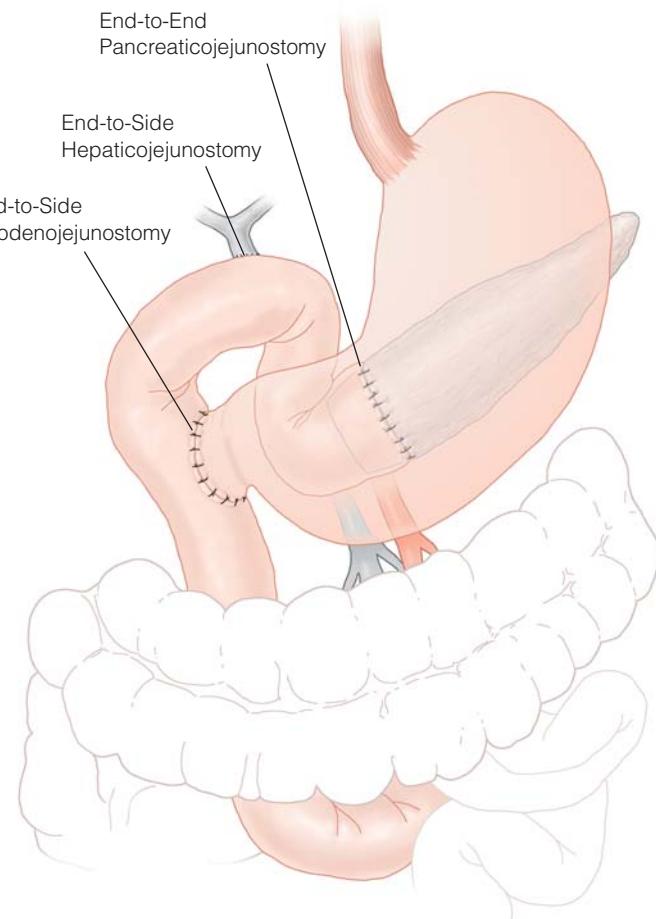

Figure 7 Whipple procedure. After the end-to-end pancreaticojejunostomy and the end-to-side hepaticojejunostomy, the duodenum is anastomosed to the jejunum in an end-to-side fashion with an inner continuous layer of 3-0 absorbable suture material and an outer interrupted layer of 3-0 silk.

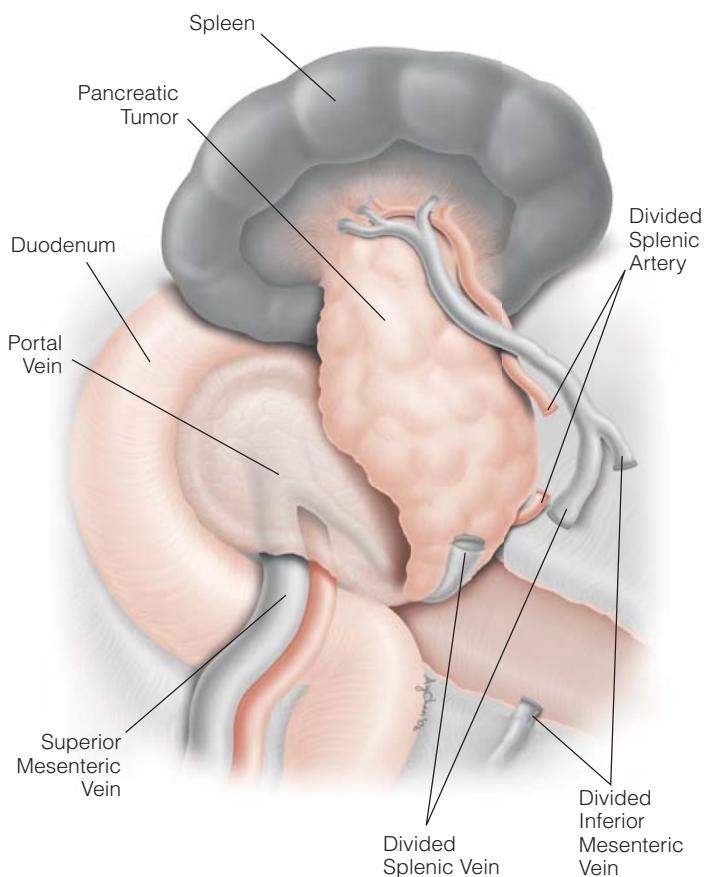

Figure 8 Distal pancreatectomy. The splenic vein is divided just distal to its junction with the inferior mesenteric vein, then dissected away from the posterior surface of the pancreas from the point of division up to the point where it joins the superior mesenteric vein to form the portal vein.

creatic malignancies. The following discussion focuses on distal pancreatectomy for malignant disease, but the basic technical principles of distal pancreatectomy for benign disease are much the same.

OPERATIVE TECHNIQUE

The peritoneal cavity is usually entered through a left subcostal incision that extends to the right of midline. In thin patients, an upper midline incision may be used instead. Upon entry into the abdomen, a careful exploration is performed to confirm the absence of disseminated disease.

The lesser sac is entered by dividing the gastrocolic omentum. Generally, this is best done by separating the greater omentum off the transverse colon and leaving it attached to the greater curvature of the stomach. Once the lesser sac has been entered, the posterior wall of the stomach is separated from the pancreas with sharp and blunt dissection to expose the body and tail of the pancreas. The duodenum is kocherized, and the head and the uncinate process of the pancreas are palpated and visualized; the entire gland can then be inspected and palpated. Intraoperative ultrasonography may be employed for further delineation of the tumor's relation to the surrounding vascular structures.

Once the pancreas has been exposed, the celiac axis and the superior mesenteric vessels are identified and assessed to determine whether the tumor is resectable. The splenic artery is identified where it comes off the celiac axis, and a vessel loop is placed around it; in this way, the vessel is controlled at an early stage of the procedure and can be promptly ligated if bleeding should occur. A patient with a

thrombosed splenic vein may have left-side portal hypertension and multiple collateral vessels leading from the spleen to the stomach via the short gastric vessels. With such a patient, it is usually preferable to ligate and divide the splenic artery early in the procedure.

The spleen is retracted toward the midline with the left hand; it should be compressed medially toward the spine rather than retracted anteriorly. It is then mobilized out of the retroperitoneum with the electrocautery. The retroperitoneum usually consists of loose areolar tissue that is easily mobilized. The omental attachments anterior to the hilum of the spleen are divided between Kelly clamps and ligated with 2-0 silk. The line of division is easily determined if the omentum has previously been completely taken off the transverse colon. As the division extends up toward and then along the greater curvature of the stomach, the vasa brevia are encountered and are doubly clamped, divided, and ligated. The splenic flexure of the colon is carefully dissected away from the inferior pole of the spleen, and the peritoneal attachments that make up the splenocolic ligament are divided.

The tail and the body of the pancreas are further mobilized out of the retroperitoneum by retracting the spleen and the pancreatic tail medially. In the course of this mobilization, care must be taken not to injure the left adrenal gland, which often occupies a fairly superficial position in the retroperitoneum, anterior and medial to the superior pole of the left kidney; care must also be taken not to carry the dissection too deep and thereby risk injuring the kidney or the renal vessels. The splenic vein is easily identified in the middle portion of the posterior aspect of the pancreas. The inferior mesenteric vein (IMV), which joins the splenic vein at the middle of the body of the pancreas, is identified in the retroperitoneum just lateral to the ligament of Treitz and can be divided at this point.

Further mobilization of the pancreas to the midline exposes the splenic artery where it takes off from the celiac axis. As noted (see

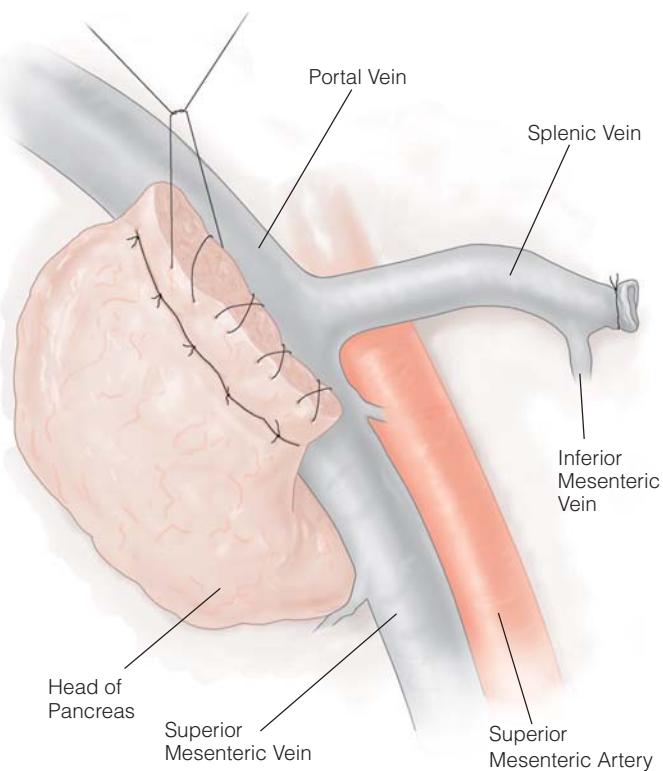

Figure 9 Distal pancreatectomy. A row of overlapping horizontal mattress sutures is placed in the neck of the pancreas just proximal to where it is to be divided, the neck is divided with the electrocautery, and a row of figure-eight sutures of 3-0 absorbable synthetic suture material is placed over the end of the pancreas.

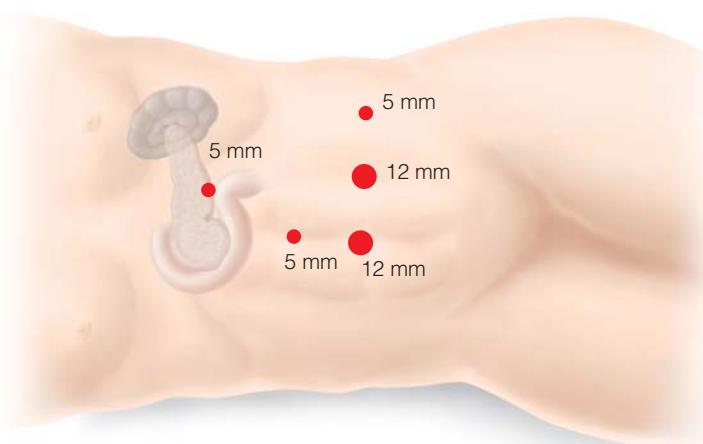

Figure 10 Laparoscopic distal pancreatectomy. Shown is the placement of ports for distal pancreatectomy.

above), this artery will already have been isolated with a vessel loop. The splenic artery is triply clamped, divided, and triply ligated with 2-0 silk and a 4-0 polypropylene suture near its point of origin.

The SMV can then be identified. A plane is developed by dissecting between the anterior surface of the SMV and the neck of the pancreas; a Penrose drain may be looped around the neck to facilitate exposure. With larger pancreatic cancers, tumor extension into the retroperitoneum may involve the splenic vein. Dividing the pancreatic neck with the electrocautery at this point may facilitate dissection of the splenic vein–portal vein confluence under direct vision. The splenic vein is clamped, divided (without compromising the portal vein–SMV complex), and ligated with 0 silk ties and a 4-0 polypropylene suture on the proximal stump [see Figure 8]. If there is a pancreatic tumor arising from the proximal body of the gland, the splenic vein may be ligated flush with the SMV. At this location, it is best to oversew the vein with a continuous 3-0 polypropylene suture so as not to compromise the portal vein–SMV complex.

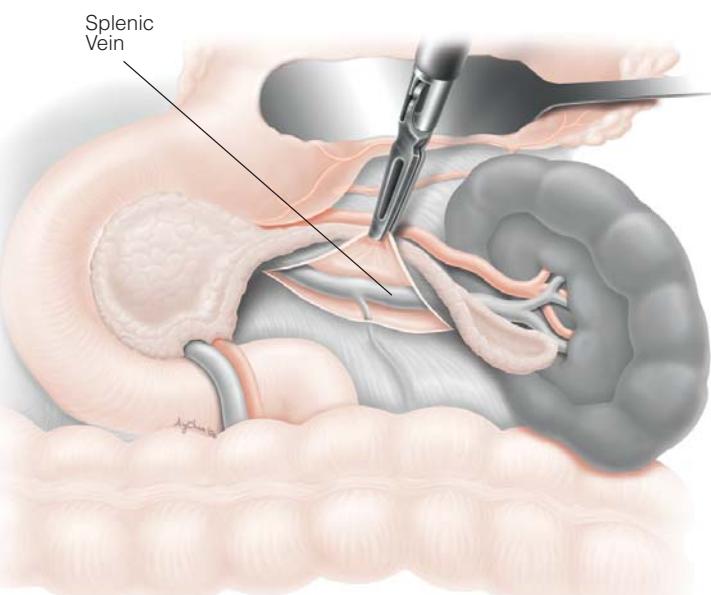

Figure 11 Laparoscopic distal pancreatectomy. Once the pancreatic body has been mobilized from the retroperitoneum, the splenic vein can be identified.

The portal vein and the SMV are carefully dissected away from the undersurface of the neck of the pancreas. Stay sutures of 2-0 silk are placed at the superior and inferior edges of the pancreas proximal to the site of transection, and the neck of the pancreas is divided with the electrocautery (or, alternatively, with a transverse anastomosis [TA] or GIA stapler). The operative specimen should be sent for frozen-section evaluation to ensure a negative microscopic margin.

A row of figure-eight sutures of 3-0 absorbable synthetic suture material is placed over the end of the pancreas [see Figure 9]. Using large needles that have been straightened makes this task simple even if the head-neck junction through which the needles are passed is thickened. If the pancreatic duct can be identified, it should be separately oversewn with a figure-eight or mattress suture of 5-0 absorbable synthetic suture material. The resection bed should be marked with titanium clips to guide postoperative radiation therapy if necessary.

The abdomen is copiously irrigated with an antibiotic solution. The pancreatic remnant is drained with a closed suction Silastic drain brought out through a stab wound in the left upper quadrant. There is no need to drain the splenic bed. The abdomen is then closed in a standard fashion.

Laparoscopic Distal Pancreatectomy with or without Splenectomy

Selected patients may benefit from a laparoscopic spleen-preserving distal pancreatectomy (SPDP) or a laparoscopic distal pancreatectomy with splenectomy. Conditions that are potentially amenable to treatment with a laparoscopic distal pancreatectomy include benign or premalignant cystic neoplasms, islet cell tumors of the pancreas, chronic pancreatitis with symptomatic ductal obstruction, and pancreatic pseudocysts confined to the distal body and tail of the pancreas.

OPERATIVE TECHNIQUE

The patient can be placed either supine in a low lithotomy position or in a semilateral position with the left side up. For lesions in the distal body or tail of the pancreas, we prefer the semilateral position; for lesions closer to the neck of the pancreas, we prefer the low lithotomy position. Five ports are placed [see Figure 10], and a 10 mm 30° laparoscope is used. As in all pancreatic procedures, the peritoneal surfaces, the omentum, the mesentery, and the viscera should all be carefully inspected to rule out metastatic disease. Intraoperative ultrasonography may be employed to evaluate the liver and locate the lesion in the pancreas.

The body and tail of the pancreas are exposed by opening the lesser sac. The gastrocolic omentum is divided and widely mobilized with an ultrasonic scalpel (e.g., Harmonic Scalpel; Ethicon Endo-Surgery, Inc., Cincinnati, Ohio), with care taken to stay outside the gastroepiploic vessels. A retractor is advanced into the lesser sac through the subxiphoid port and used to elevate the stomach anteromedially. The splenocolic ligament is divided, and the splenic flexure of the colon is reflected inferiorly.

After these maneuvers, the inferior pancreatic margin should be exposed. The peritoneum is then incised along the inferior pancreatic border, and the pancreatic body is separated from the retroperitoneum by means of sharp and blunt dissection along its inferior border. Laparoscopic ultrasonography and direct visual inspection, combined with the findings from preoperative imaging, may be employed to determine the extent of the dissection. Initially, the dissection should be directed so that it is medial to the pancreatic lesion. The pancreatic body is elevated by means of blunt and sharp dissection, after which the splenic vein should be easily identifiable [see Figure 11]. Care must be exercised to prevent inadvertent injury to this vessel. Once the splenic vein has been identified, a careful circumferential dissection around the splenic vein is performed with a right-angle

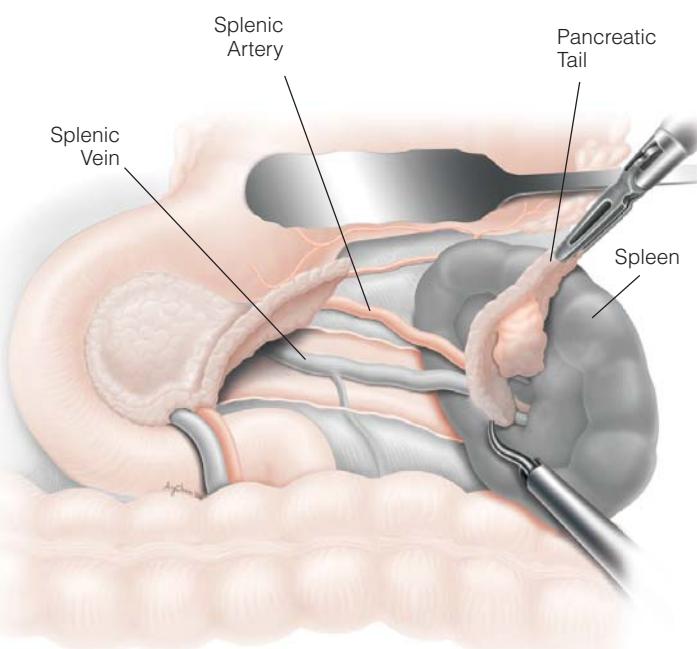

Figure 12 Laparoscopic distal pancreatectomy. After having been transected, the distal portion of the pancreas is dissected away from the splenic vessels in a medial-to-lateral direction. The pancreatic branches of the splenic vessels are divided sequentially as they are encountered.

clamp, and a vessel loop is placed around the vein. This dissection helps identify the splenic artery as well, which also is controlled with a vessel loop. These precautionary measures allow quick control of bleeding should a vascular tear occur later in the procedure.

Once the pancreatic body has been adequately mobilized from the splenic vessels, the pancreatic parenchyma is divided with the ultrasonic scalpel. Alternatively, an endoscopic stapler can be placed across the body of the pancreas, sparing the main splenic vessels. Once the proximal pancreatic tissue is divided, the specimen is grasped and gently retracted anteriorly to allow further dissection of the vessels. The dissection proceeds toward the splenic hilum in a medial-to-lateral direction. The pancreatic branches of the splenic vein are sequentially identified, dissected free with laparoscopic Metzenbaum scissors, and divided with the ultrasonic scalpel [see Figure 12]. The branches of the splenic artery, which runs just superior to the vein, are treated similarly. Special care must be taken as the dissection approaches the hilum of the spleen.

At the completion of an SPDP, the specimen is placed and removed in a standard endoscopic retrieval device (e.g., Endo Catch; United States Surgical, Norwalk, Connecticut). The pancreatic remnant is then oversewn with a series of interrupted absorbable horizontal mattress sutures. A single round Jackson Pratt drain is placed near the pancreatic transection line and brought out through one of the 5 mm lateral ports.

An alternative approach to SPDP involves dividing the splenic vessels proximally and distally while preserving the short gastric and left gastroepiploic vessels to maintain splenic perfusion [see Figure 13]. The initial steps of this technique are essentially the same as those already described (see above), up to the point where the pancreas is divided. In the alternative approach to SPDP, after pancreatic transection, the splenic artery and vein are divided with an endovascular stapler. The left portion of the pancreas is lifted up and mobilized posteriorly along with the splenic artery and vein, and the vessels are again divided as they emerge from the pancreatic tail to enter the hilum of

the spleen. The spleen is then supplied solely by the short gastric vessels and the left gastroepiploic vessels.

If an en bloc distal pancreatectomy with splenectomy is performed, the splenic artery and vein are divided after the pancreas is transected. The distal pancreas is dissected free in a medial-to-lateral direction. The short gastric vessels are divided with the ultrasonic scalpel, with care taken not to injure the stomach wall. The retroperitoneal attachments of the spleen and the tail of the pancreas are divided with the ultrasonic scalpel. The specimen is then placed in a specimen retrieval bag and extracted from a port site that has been enlarged to a size of 3 to 6 cm. To facilitate extraction of the specimen, the spleen may be morcellated within the bag [see 5:25 *Splenectomy*].

Laparoscopic Pancreatic Enucleation

Laparoscopic techniques have now been applied to the enucleation of benign neuroendocrine tumors of the pancreas. This approach is indicated for tumors in the body and tail of the pancreas that, on pre-operative imaging, appear not to involve the pancreatic duct. Patients are positioned and trocars placed in much the same way as for laparoscopic distal pancreatectomy [see Laparoscopic Distal Pancreatectomy with and without Splenectomy, Operative Technique, *above*].

The body and the tail of the pancreas are widely exposed by entering the lesser sac through the gastrocolic omentum. Intraoperative ultrasonography is extremely useful for identifying the tumor and for further delineating its relation to the splenic vessels and the pancreatic duct. Once identified, the lesion is dissected out of the pancreatic parenchyma with the ultrasonic shears and the electrocautery. The specimen is placed in a specimen retrieval bag and removed. The enucleation bed is then inspected for hemostasis, and a closed suction drain is placed to control any pancreatic leakage that may develop.

Longitudinal Pancreaticojunostomy (Puestow Procedure)

OPERATIVE TECHNIQUE

The abdomen is entered through an upper midline incision. The lesser sac is entered by removing the greater omentum from the transverse colon along virtually its entire length, thereby exposing the entire tail, body, neck, and head of the pancreas. The pancreas often appears markedly fibrotic and scarred. The posterior wall of the stomach may be adherent to a portion of the body of the pancreas as a result of multiple episodes of inflammation; if it is adherent, it is easily dissected free. The duodenum is kocherized, and the head and the uncinate process of the pancreas are palpated from both an anterior and a posterior direction. In many cases, the pancreatic duct is markedly dilated and can actually be palpated through the anterior surface in the middle portion of the body of the pancreas. The rest of the abdomen is explored to check for the presence of other pathologic conditions. To confirm the position of the dilated pancreatic duct, a 20-gauge needle on a 10 ml syringe is used to aspirate the duct. Intraoperative ultrasonography can be quite helpful for identifying the dilated pancreatic duct. Once pancreatic juice is obtained, the syringe is removed from the needle hub, with the needle left in place.

The pancreatic duct is entered by dividing the pancreatic parenchyma with the electrocautery on either side of the needle. A large right-angle clamp is then inserted, and the duct is filleted open with the electrocautery both proximally and distally [see Figure 14]. Small pancreatic ductal concretions are carefully removed. At least 6 cm of the duct must be opened to yield a good chance of long-term success. Ideally, if the duct is dilated all the way out to the tail, it can be filleted open virtually to the tip of the pancreas. In the proximal direction,

the duct can easily be opened as far as the neck of the pancreas. Beyond this point, however, the duct passes posteriorly and inferiorly into the head of the pancreas; because the head can be very thick, opening up the duct any further can be difficult.

A Bakes dilator is carefully passed proximally through the open pancreatic duct, down through the pancreatic duct in the unopened head, through the ampulla of Vater, and into the duodenum. If a Bakes dilator cannot be passed into the duodenum, some surgeons elect to open the duodenum and perform a sphincteroplasty [see 5:22 Procedures for Benign and Malignant Biliary Tract Disease], so that by working both from within the duodenum and from within the open pancreatic duct, they can ensure the patency of the entire pancreatic duct.

A Roux-en-Y jejunal loop approximately 60 cm long is constructed. The most proximal loop of jejunum in which there is a good vascular arcade is selected. A 2 cm segment of this loop is cleaned and divided with a GIA stapler. The small bowel mesentery is divided between clamps down through the arcade vessel and is ligated with 3-0 silk. The end of the distal jejunum is oversewn with a layer of 3-0 silk Lembert sutures. A 60 cm length is then measured. Alimentary tract continuity is reestablished by means of an end-to-side jejunoojunostomy, in which the most proximal portion of the divided jejunum is anastomosed to the side of the Roux-en-Y jejunal loop 60 cm distally with an inner continuous layer of 3-0 absorbable synthetic suture material and an outer interrupted layer of 3-0 silk. The defect in the small bowel mesentery is closed with a continuous 4-0 silk suture.

The Roux-en-Y jejunal loop is brought up into the lesser sac in a retrocolic position through a small rent in the transverse mesocolon. A side-to-side pancreaticojejunostomy is performed in two layers. Before the Roux loop is opened, an outer interrupted layer of 3-0 silk is placed between the jejunal loop and the pancreatotomy, passing through the capsule of the pancreas and out through the opened pancreatic parenchyma along the inferior border of the pancreas. When this layer is complete, an enterotomy approximately 2 mm from the jejunal suture line is made along the entire length of this line. Starting at the distal pancreatic tail, an inner continuous layer of 3-0 absorb-

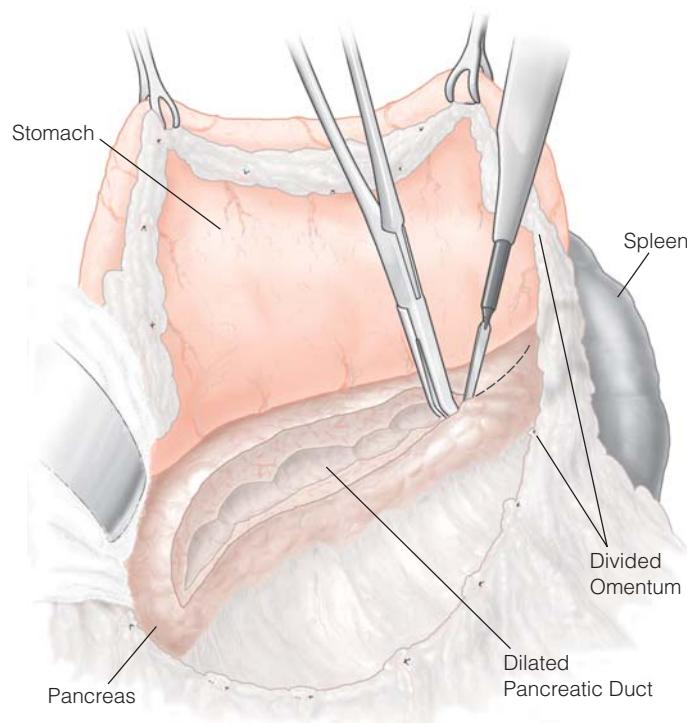

Figure 14 Puestow procedure. The dilated pancreatic duct is filleted open with the electrocautery both proximally and distally. At least 6 cm of the duct should be opened.

able synthetic suture material is placed in an over-and-over locking fashion through the entire wall of the jejunum and the entire divided surface of the pancreas and into the duct [see Figure 15]. The inner layer of the superior suture line is placed in an over-and-over fashion without locking, again with a continuous 3-0 absorbable synthetic suture. The outer layer of the superior suture line consists of interrupted 3-0 silk sutures placed in a Lembert fashion.

When the pancreatic duct is dilated to a diameter of 1 cm or greater, a two-layer anastomosis is possible and is in fact preferred. When the diameter of the duct is between 5 mm and 1 cm, however, a two-layer anastomosis is generally difficult, and a one-layer anastomosis is preferred. A single layer of interrupted 3-0 silk sutures is placed so that the knots are tied on the outside. This is easily accomplished with the superior suture line. With the inferior suture line, which is placed first, the suture passes from outside inward on the pancreas and then from inside outward on the jejunum. In a single-layer side-to-side pancreaticojejunostomy, the jejunotomy must be performed before any sutures are placed.

The procedure is completed by tacking the Roux-en-Y jejunal loop to the rent in the transverse mesocolon with interrupted 3-0 silk sutures. The pancreaticojejunostomy is drained with closed suction Silastic drains that are placed on either side of the anastomosis and brought out through separate stab wounds in the left upper quadrant. The abdomen is copiously irrigated with an antibiotic solution and closed in a standard fashion.

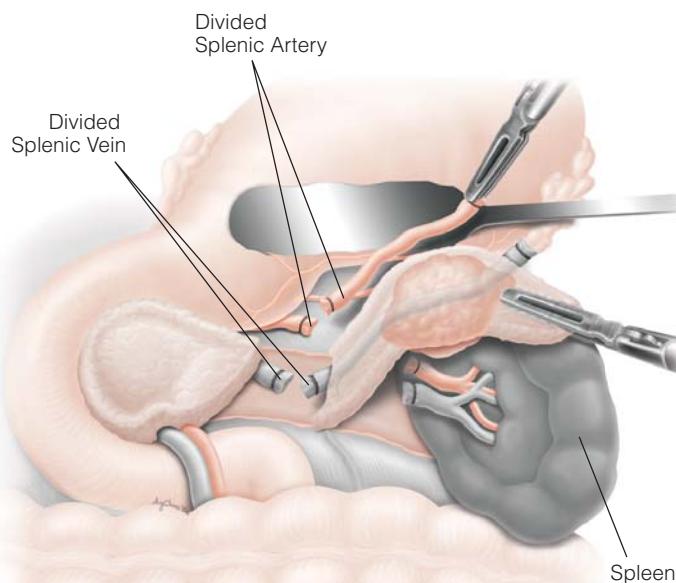

Figure 13 Laparoscopic distal pancreatectomy. In an alternative approach to spleen-preserving distal pancreatectomy, the splenic artery and the splenic vein are divided, and the viability of the spleen is maintained by preserving the short gastric and left gastroepiploic vessels.

Drainage of Pancreatic Pseudocyst

OPERATIVE TECHNIQUE

Drainage into Roux-en-Y Jejunal Loop

The peritoneal cavity is entered through a midline incision, and the abdomen is explored. Typically, a substantial mass that is cystic and

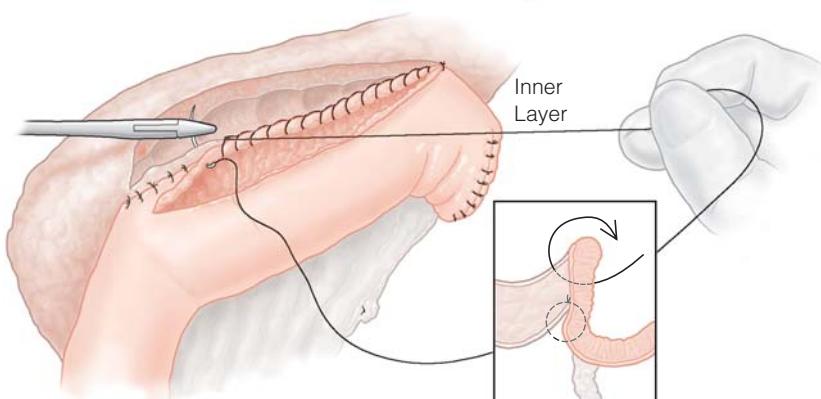

Figure 15 Puestow procedure. When the diameter of the dilated pancreatic duct is 1 cm or wider, a side-to-side pancreaticojejunostomy should be done in two layers. Once an outer layer of interrupted 3-0 silk sutures is placed between the jejunal loop and the pancreatotomy, an enterotomy is made along the entire length of the jejunal suture line, and an inner layer consisting of a continuous 3-0 absorbable synthetic suture is placed.

easily ballotable is palpable posterior to the stomach. The duodenum and the head of the pancreas are kocherized so that the head may be palpated both anteriorly and posteriorly. The physical characteristics of chronic pancreatitis are usually present. The body and the tail of the pancreas are palpated as well; the pancreas is usually fibrotic, firm, and somewhat enlarged. The rest of the abdomen is explored to check for the presence of other pathologic conditions.

At this point, the size and configuration of the cyst are compared with the size and configuration on the preoperative CT scan. If the CT scan shows a unilocular solitary cyst and if, at the time of laparotomy, there appears to be a mass that coincides exactly with what is seen on the CT scan, there is no need to enter the lesser sac. The lesion can be

drained into a Roux-en-Y jejunal loop through the transverse mesocolon, and the lesser sac need not be explored. Most pseudocysts are formed by anterior disruptions of the main pancreatic duct. When pancreatic secretions leak out into the lesser sac, the body walls off the leak through its inflammatory response. The transverse mesocolon becomes adherent to the posterior wall of the stomach, which in turn becomes adherent to other adjacent structures in and around the retroperitoneum, and the leak is sealed off. Thus, the transverse mesocolon is usually the inferior and most dependent portion of the pseudocyst, and this site is the ideal location for drainage [see Figure 16].

The transverse colon is retracted cephalad, and the cyst is easily visualized and palpated through the transverse mesocolon. The loca-

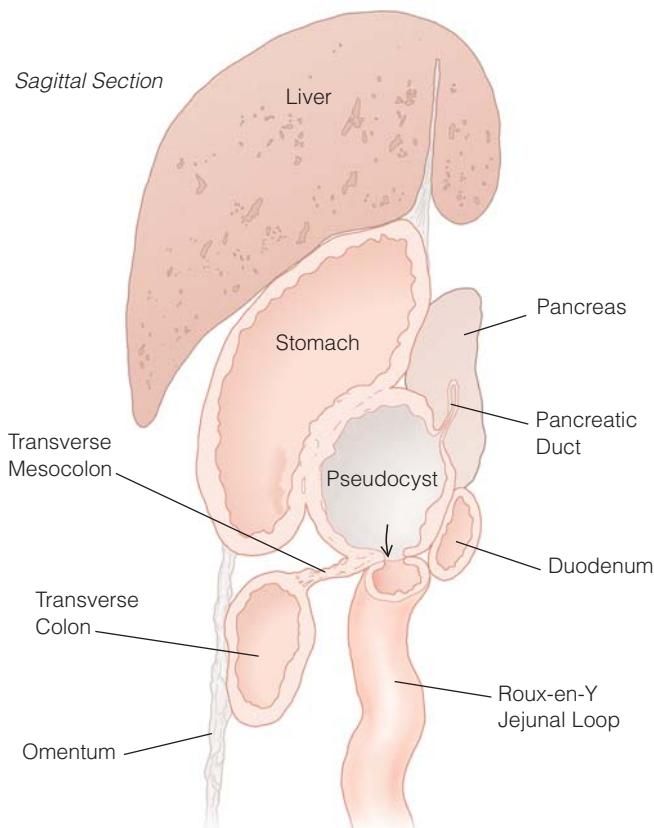

Figure 16 Drainage of pancreatic pseudocyst into Roux-en-Y jejunal loop. The transverse mesocolon is usually the most inferior and dependent part of a pancreatic pseudocyst; thus, drainage through the transverse mesocolon into a Roux loop is usually the ideal approach.

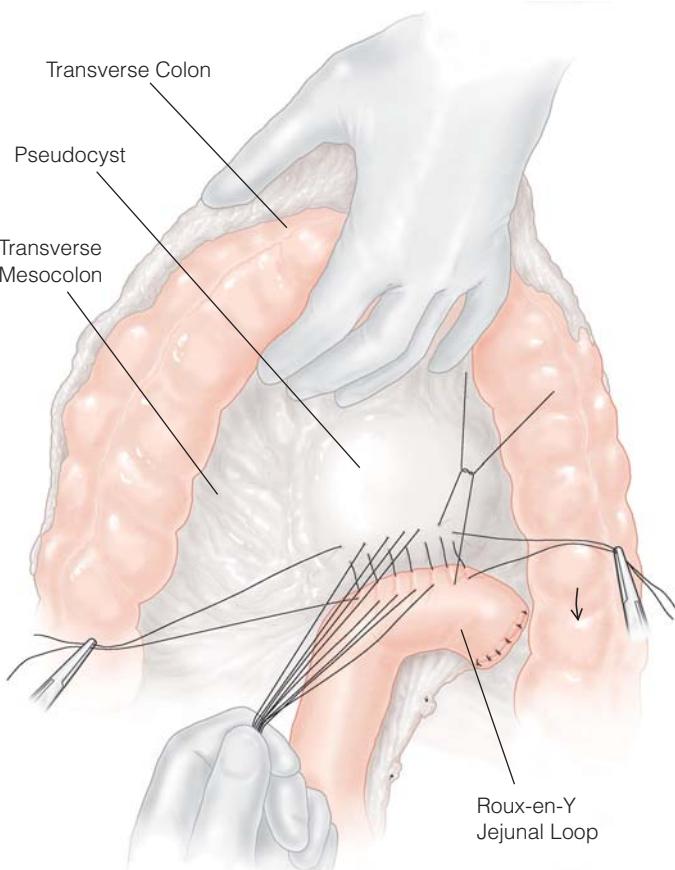

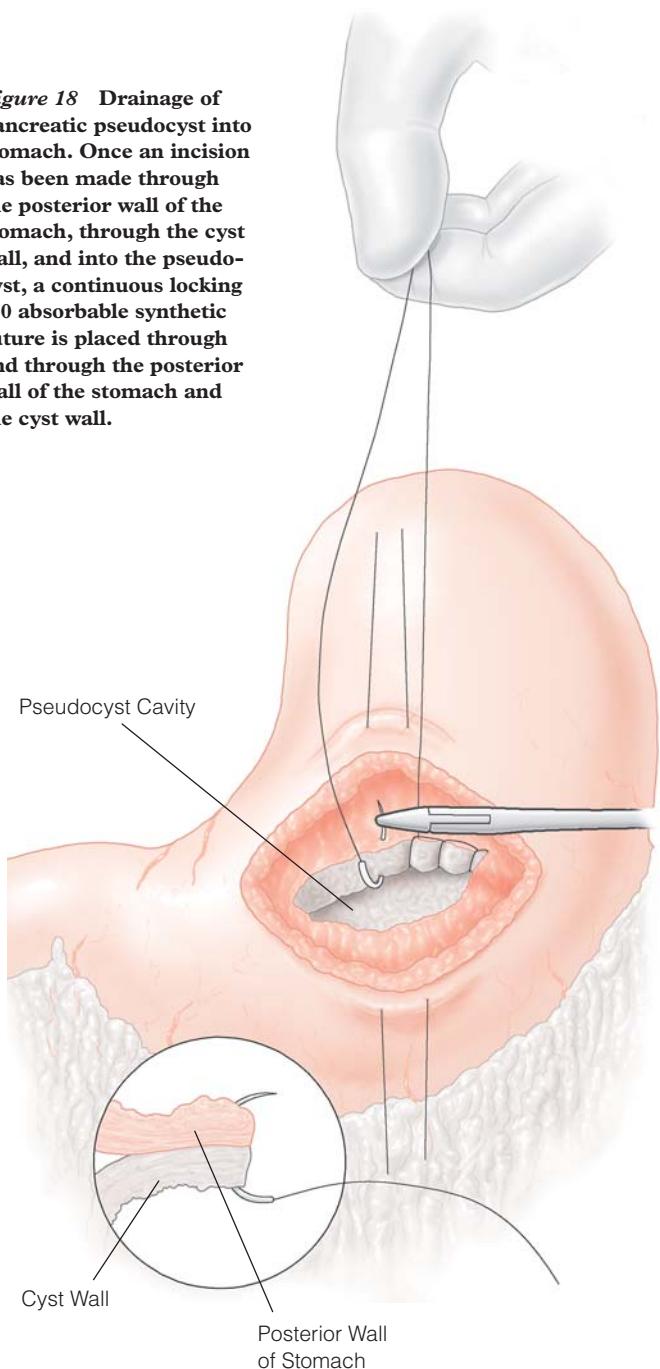

Figure 17 Drainage of pancreatic pseudocyst into Roux-en-Y jejunal loop. The outer posterior layer of the side-to-side cystojejunostomy comprises a series of 3-0 silk sutures placed through and through the jejunal loop and the transverse mesocolon.

Figure 18 Drainage of pancreatic pseudocyst into stomach. Once an incision has been made through the posterior wall of the stomach, through the cyst wall, and into the pseudocyst, a continuous locking 3-0 absorbable synthetic suture is placed through and through the posterior wall of the stomach and the cyst wall.

tion of the cyst is confirmed by aspirating pancreatic juice through the transverse mesocolon with a 10 ml syringe and a 20-gauge needle. The middle colic vessels must be carefully identified and avoided. A 60 cm long Roux-en-Y jejunal loop is constructed. The proximal jejunum is divided with a GIA stapler at the first convenient arcade. The small bowel mesentery is divided down through the arcade. The distal end of the jejunum is inverted with an interrupted layer of 3-0 silk Lembert sutures.

Alimentary tract continuity is reestablished by means of an end-to-side jejunojejunostomy, in which the proximal jejunum is anastomosed to the side of the Roux-en-Y jejunal loop 60 cm from the inverted end. This anastomosis is performed with an inner continuous layer of 3-0 absorbable synthetic suture material and an outer interrupted layer of 3-0 silk. The rent in the small bowel mesentery is closed with a continuous 3-0 silk suture.

A side-to-side cystojejunostomy is performed with an outer interrupted layer of 3-0 silk and an inner continuous layer of 3-0 absorbable synthetic suture material. The posterior outer layer of the anastomosis consists of a series of 3-0 silk sutures passed through and through the jejunal loop and through and through the transverse mesocolon (which is the inferior wall of the pseudocyst) [see Figure 17]. The suture line should be approximately 2.5 to 5 cm long. After the posterior layer has been secured, a cystotomy is performed with the electrocautery. An ellipse of cyst wall is removed and sent for frozen-section examination. No matter how clear it seems to be that the lesion is a pseudocyst, a specimen from the cyst wall should always be sent for frozen-section examination. Some cystic lesions of the pancreas are cystic neoplasms, which must be resected rather than drained. If no epithelial lining is found on frozen-section examination, it is safe to assume that the lesion is not a cystic neoplasm but a pancreatic pseudocyst and to proceed accordingly.

A parallel enterotomy is made in the jejunum. An inner continuous layer of 3-0 absorbable synthetic suture material is placed inferiorly in a locking fashion, then brought around superiorly in a Connell stitch. An outer interrupted layer of 3-0 silk is placed superiorly. With the cyst decompressed, a sizable lumen should be easily palpable in the anastomosis between the cyst and the jejunal loop.

A closed suction Silastic drain is left near the anastomosis and brought out through a stab wound in the left upper quadrant. The

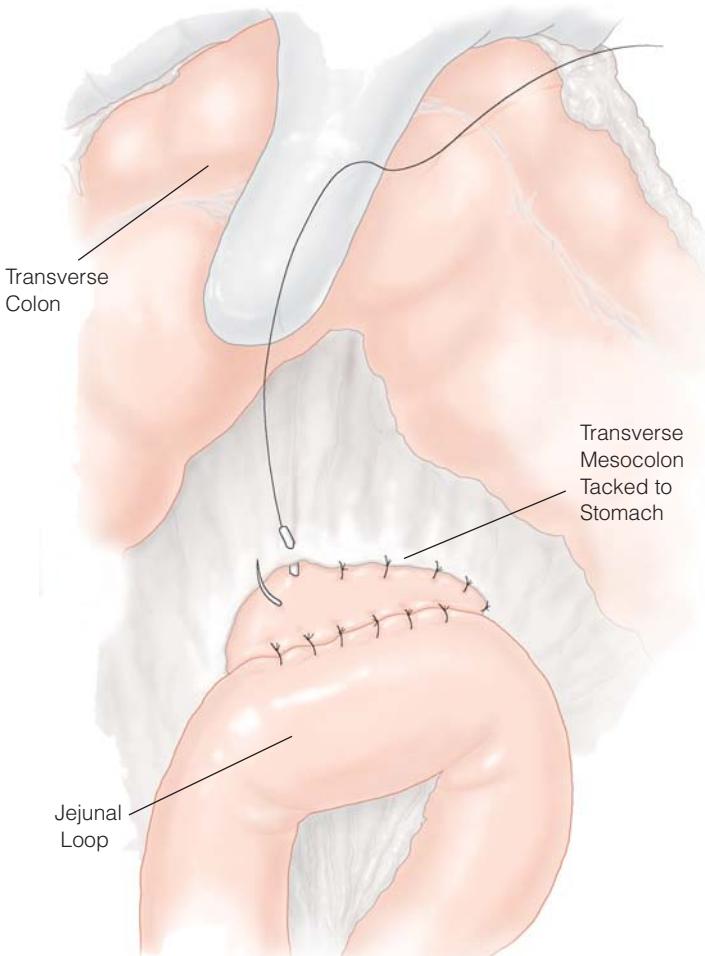

Figure 19 Palliative double bypass for unresectable pancreatic cancer. Once the retrocolic gastrojejunostomy is complete, the anastomosis is tacked to the rent in the transverse mesocolon on the gastric side with interrupted 3-0 silk sutures.

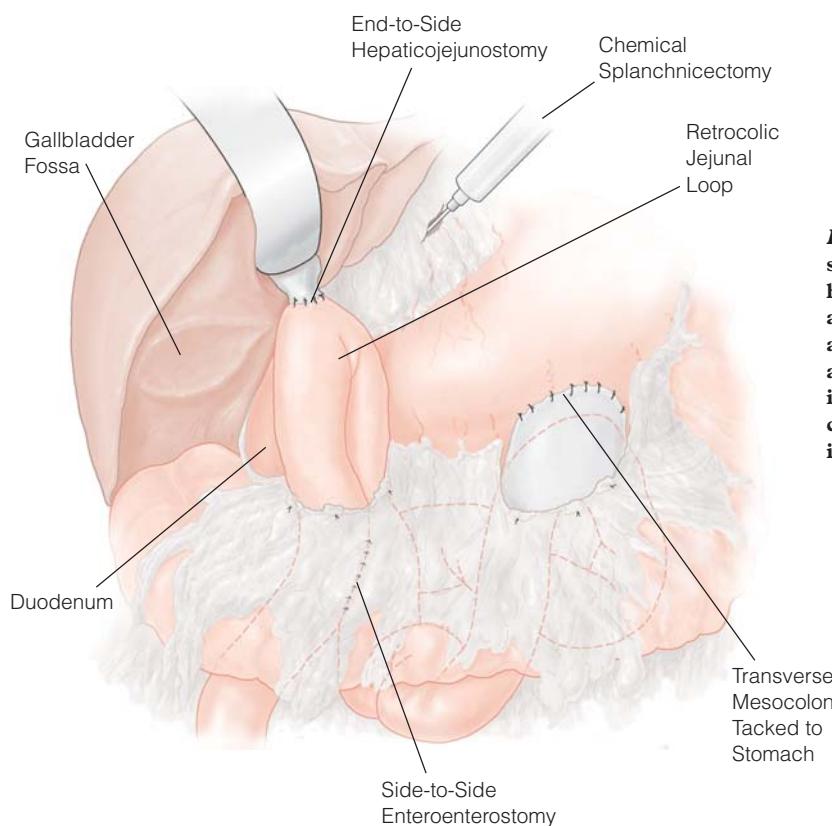

Figure 20 Palliative double bypass for unresectable pancreatic cancer. An end-to-side hepaticojejunostomy is performed, followed by a side-to-side jeunojejunostomy between the afferent loop leading to the biliary anastomosis and the efferent loop leading from it. An opening is made in the lesser omentum, and a chemical splanchicectomy is performed by injecting alcohol into the celiac plexus.

abdomen is copiously irrigated with an antibiotic solution and closed in a standard fashion.

Drainage into Stomach

The peritoneal cavity is entered through an upper midline incision, and the abdomen is explored. Typically, a pseudocyst that is not amenable to drainage through the transverse mesocolon presents as a mass that is cystic and is palpable through the anterior wall of the stomach and the lesser omentum in the upper abdomen; such a mass generally is not palpable through the root of the transverse mesocolon with the transverse mesocolon reflected cephalad and thus is not easily drained into a Roux-en-Y jejunal loop. The duodenum and the head of the pancreas are kocherized, and the head of the pancreas is palpated. Signs of chronic pancreatitis are invariably present. The rest of the abdomen is explored to check for the presence of other pathologic conditions.

Stay sutures of 3-0 silk are placed in the anterior wall of the body of the stomach. A transverse gastrotomy is made with the electrocautery. The cyst wall is easily palpable through the posterior wall of the stomach. The location of the cyst is confirmed by aspirating pancreatic juice through the back wall of the stomach with a 10 ml syringe and a 20-gauge needle. The mass palpated at the time of operation is compared with the cyst as it appears on the preoperative CT scan. If the CT scan shows a solitary unilocular cyst that corresponds to the palpable mass identified at the time of laparotomy, it is safe to conclude that the cyst is solitary and can be drained effectively into the stomach.

A transverse incision is made with the electrocautery through the posterior wall of the stomach, through the cyst wall, and into the pseudocyst. It is often desirable to leave the 20-gauge needle in place and to perform the posterior wall gastrotomy on either side of the needle. An ellipse of cyst wall is sent for frozen-section examination. Again, this step is mandatory, no matter how obvious it seems that the lesion is an inflammatory cyst. A continuous locking suture of 3-0

absorbable synthetic material is placed through and through the posterior wall of the stomach and the anterior wall of the cyst [see Figure 18]. This step may or may not actually be important for achieving long-term patency of the opening between the cyst and the posterior wall of the stomach, but it does ensure good hemostasis. The anterior gastrotomy is closed with an inner continuous layer of 3-0 absorbable synthetic suture material in a Connell stitch and an outer interrupted layer of 3-0 silk. The abdomen is closed in a standard fashion.

Laparoscopic Drainage of Pancreatic Pseudocysts

Five distinct laparoscopic approaches have been employed for the drainage of pancreatic pseudocysts: (1) transgastric cystogastrostomy, (2) intragastric cystogastrostomy, (3) minilaparoscopic intragastric cystogastrostomy, (4) cystogastrostomy via the lesser sac approach, and (5) Roux-en-Y cystojejunostomy.

In a laparoscopic transgastric cystogastrostomy, an anterior gastrotomy is created, and the electrocautery is used to open the cyst wall through the posterior wall of the stomach. A cystogastrostomy is then created; it may be either stapled (with an endoscopic stapler) or hand-sewn (with intracorporeal sutures).

In an intragastric cystogastrostomy, trocars are inserted percutaneously through the abdominal wall and directly into the gastric lumen under simultaneous laparoscopic and gastroscopic guidance. A cystogastrostomy is then created by means of electrocauterization and sharp dissection. The technique for a minilaparoscopic intragastric cystogastrostomy is essentially the same, except that 2 mm intragastric ports are used to reduce the invasiveness of the procedure and minimize the trauma to the anterior gastric wall.

When the anatomy is favorable, laparoscopic cystogastrostomy via the lesser sac approach is the preferred technique for minimally invasive pseudocyst drainage. The advantages of this technique are (1) that it does not require an anterior gastrotomy and (2) that it ensures a large

anastomosis that is not dependent on the adherence of the cyst to the posterior gastric wall. Because the entire anastomosis is either stapled or sutured, the risk of bleeding is minimized. In this procedure, a window is created in the gastrocolic omentum, through which the lesser sac is entered. The stomach is elevated, and a cystotomy is made adjacent to a posterior gastric wall gastrotomy. A cystogastrostomy is then created with an endoscopic stapler, and the opening is sutured closed.

For cysts that are large or are not in direct contact with the posterior wall of the stomach, a laparoscopic Roux-en-Y cystojejunostomy may be performed instead. The omentum and the transverse colon are retracted cephalad. Often, the pseudocyst is then visible through the transverse mesocolon. Laparoscopic ultrasonography may also be used to help identify the location of the cyst. The jejunum is divided approximately 30 cm distal to the ligament of Treitz to create a Roux limb. The pseudocyst is opened through the transverse mesocolon with the ultrasonic scalpel. A small enterotomy is made in the Roux limb, and a stapled cystojejunostomy is created. The cystoenterostomy is then closed with a continuous suture. The procedure is completed by performing a jejunojejunostomy at least 30 cm distal to the cystojejunostomy.

Palliative Bypass for Unresectable Periampullary Cancer

The peritoneal cavity is entered through an upper midline incision, and the abdomen is examined for evidence of liver metastases, serosal spread, carcinomatosis, involvement of regional lymph nodes, and invasion of major vascular structures. Once the tumor has been shown to be unresectable and histologic confirmation of malignancy has been received, a palliative double bypass procedure is begun, in which the duodenum is bypassed with a retrocolic gastrojejunostomy and the distally obstructed biliary tree is bypassed with a hepaticojejunostomy. A chemical splanchnicectomy is also performed to reduce pain.

Approximately 4 cm of the most dependent portion of the greater curvature of the stomach is cleaned by doubly clamping, dividing, and ligating attachments of the greater omentum. Once this is accomplished, a small rent is made in the transverse mesocolon, and a proximal loop of jejunum is brought up through this rent and anastomosed in an isoperistaltic fashion to the dependent wall of the stomach. The anastomosis is performed with an outer interrupted layer of 3-0 silk and an inner continuous layer of 3-0 absorbable synthetic suture material.

In the past, palliative duodenal bypasses for pancreatic cancer were frequently performed by carrying out an anterior antecolic gastrojejunostomy. Delayed gastric emptying proved to be a common occurrence with this approach. Fortunately, this complication can be virtually eliminated by performing a posterior gastroenterostomy. Once the posterior gastroenterostomy is complete, the anastomosis is tacked to the rent in the transverse mesocolon on the gastric side with interrupted 3-0 silk sutures to prevent the afferent and efferent jejunal limbs from herniating up through the transverse mesocolon [see Figure 19].

The gallbladder is mobilized out of the liver bed in a retrograde fashion and placed on traction to facilitate identification of the common hepatic duct. Once identified, the common hepatic duct is divided just proximal to the cystic duct. The gallbladder is removed, and the distal biliary segment is oversewn with a continuous 3-0 polypropylene suture. The jejunum is divided approximately 30 cm distal to the gastrojejunostomy, and a Roux-en-Y limb is brought up into the right upper quadrant through a second opening in the transverse mesocolon. An end-to-side hepaticojejunostomy is performed with a single layer of interrupted 4-0 absorbable synthetic sutures [see Figure 20]. An end-to-side jejunojejunostomy is then performed 60 cm downstream to restore enteric continuity and complete the Roux-en-Y. This anastomosis is performed with an inner continuous layer of 3-0 absorbable synthetic suture material and an outer interrupted layer of 3-0 silk. The Roux limb is tacked to the opening in the transverse mesocolon to prevent herniation.

The lesser omentum is divided, and a chemical splanchnicectomy is performed by injecting 20 ml of 50% alcohol into the celiac plexus on each side of the aorta at the level of the celiac axis. The level of the celiac axis is easily determined by palpating the thrill that is invariably present in the common hepatic artery as it comes off the celiac axis.

A closed suction Silastic drain may be left posterior to the area of the hepaticojejunostomy and brought out through a stab wound in the right upper quadrant. If tissue confirmation of the presence of adenocarcinoma of the head of the pancreas was not obtained preoperatively, it should be obtained during the operation. As a rule, this is most easily accomplished by performing a transduodenal needle biopsy (e.g., with a Tru-Cut needle; Cardinal Health, Dublin, Ohio). The abdomen is irrigated with an antibiotic solution and closed in a standard fashion.

25 SPLENECTOMY

Eric C. Poulin, M.D., M.Sc., F.A.C.S., F.R.C.S.C., Christopher M. Schlachta, M.D., F.A.C.S., and Joseph Mamazza, M.D., F.R.C.S.C.

Medicine is not an exact science, and nowhere is this observation more appropriate than in the operating room when a spleen is being removed.¹

The first reported splenectomy in the Western world was performed by Zacarello in 1549, though the veracity of his operative description has been questioned. Between this initial report and the 1800s, very few cases were recorded. The first reported splenectomy in North America was performed by O'Brien in 1816. The patient was in the act of committing a rape when his victim plunged a large knife into his left side. As in this case, most early splenectomies were done in patients who had undergone penetrating trauma; often, the spleen was protruding from the wound and the surgeon proceeded with en masse ligation. The first elective splenectomy was performed by Quittenbaum in 1826 for sequelae of portal hypertension, and soon afterward, Wells performed one of the first splenectomies using general anesthesia; both patients died. In 1866, Bryant was the first to attempt splenectomy in a patient with leukemia. Over the following 15 years, 14 splenectomies were attempted as therapy for leukemia; none of the patients survived. In a 1908 review of 49 similar cases, Johnston reported a mortality of 87.7%.² These dismal results led to the abandonment of splenectomy for leukemia. In 1916, Kaznelson, of Prague, was the first to report good results from splenectomy in patients with thrombocytopenic purpura.

As the 20th century progressed, splenectomy became more common in direct proportion to the increase in the use of the automobile. The eventual recognition of the syndrome known as overwhelming postsplenectomy infection (OPSI) made splenic conservation an important consideration. Partial splenectomy had initially been described by the French surgeon Péan in the 19th century. This procedure received little further study until almost 100 years later, when the Brazilian surgeon Campos Cristo reevaluated Péan's technique in his report of eight trauma patients treated with partial splenectomy.³ Simpson's report on 16 children admitted for splenic trauma to the Hospital for Sick Children in Toronto between 1948 and 1955 was instrumental in establishing the validity of nonoperative treatment of splenic trauma [see 7:6 *Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm*.⁴]

In late 1991 and early 1992, four groups working independently—Delâitre in Paris, Carroll in Los Angeles, Cushieri in the United Kingdom, and our group in Canada—published the first reports of laparoscopic splenectomy in patients with hematologic disorders.⁵⁻⁷ Since then, the development of operative techniques for partial laparoscopic splenectomy has tested the limits of minimally invasive surgery and encouraged clinical research into methods of simplifying the execution of the operation.^{8,9} The adoption of laparoscopic splenectomy has led to a gradual decrease in the indications for open splenectomy; however, both procedures are still essential components of spleen surgery.

Anatomic Considerations

Most anatomy texts suggest that the splenic artery is constant in its course and branches; however, as the classic essay by

Michels made clear, each spleen has its own peculiar pattern of terminal artery branches.¹⁰

SPLENIC ARTERY

The celiac axis is the largest but shortest branch of the abdominal aorta: it is only 15 to 20 mm long. The celiac axis arises above the body of the pancreas and, in 82% of specimens, divides into three primary branches: the left gastric artery, which is the first branch, and the hepatic and splenic arteries, which derive from a common stem. In rare instances, the splenic artery originates directly from the aorta; even less often, a second splenic artery arises from the celiac axis. There are numerous other possible variations, in which the splenic artery may originate from the aorta, the superior mesenteric artery, the middle colic artery, the left gastric artery, the left hepatic artery, or the accessory right hepatic artery. As a rule, however, the splenic artery arises from the celiac axis to the right of the midline, which means that the aorta must be crossed to reach the spleen and that selective angiography is likely to be difficult at times. The splenic artery can take a very tortuous course, particularly in patients who are elderly or who have a longer artery.

In his study of 100 cadaver spleens,¹⁰ Michels divided splenic arterial geography into two types, distributed and magistral (or bundled) [see Figure 1]. In the distributed type, found in 70% of dissections, the splenic trunk is short, and six to 12 long branches enter the spleen over approximately 75% of its medial surface. The branches originate between 3 and 13 cm from the hilum [see Figure 1a]. In the bundled type, found in the remaining 30% of dissections, there is a long main splenic artery that divides near the hilum into three or four large, short terminal branches that enter the spleen over only 25% to 35% of its medial surface. These short splenic branches originate, on average, 3.5 cm from the spleen, and they reach the center of the organ as a compact bundle [see Figure 1b]. Early identification of the type of splenic blood supply present can help the surgeon estimate how difficult a particular splenectomy is likely to be. Operation on a spleen with a distributed vascular anatomy usually involves dissection of more blood vessels; however, the vessels, being spread over a wider area of the splenic hilum, are relatively easy to deal with. Operation on a spleen with a bundled-type blood supply typically involves dissection of fewer vessels; however, because the hilum is narrower and more compact, dissection and separation of the vessels are more difficult.

BRANCHES OF SPLENIC ARTERY

The splenic branches vary so markedly in length, size, and origin that no two spleens have the same anatomy. Outside the spleen, the arteries also frequently form transverse anastomoses with each other that, like most collaterals, arise at a 90° angle to the vessels involved [see Figure 1].¹¹ As a consequence, attempts to occlude a branch of the splenic artery by means of clips or embolization, if carried out proximal to such an anastomosis, may fail to devascularize the corresponding splenic segment. Before the splenic trunk divides, it usually gives off a few slender branch-

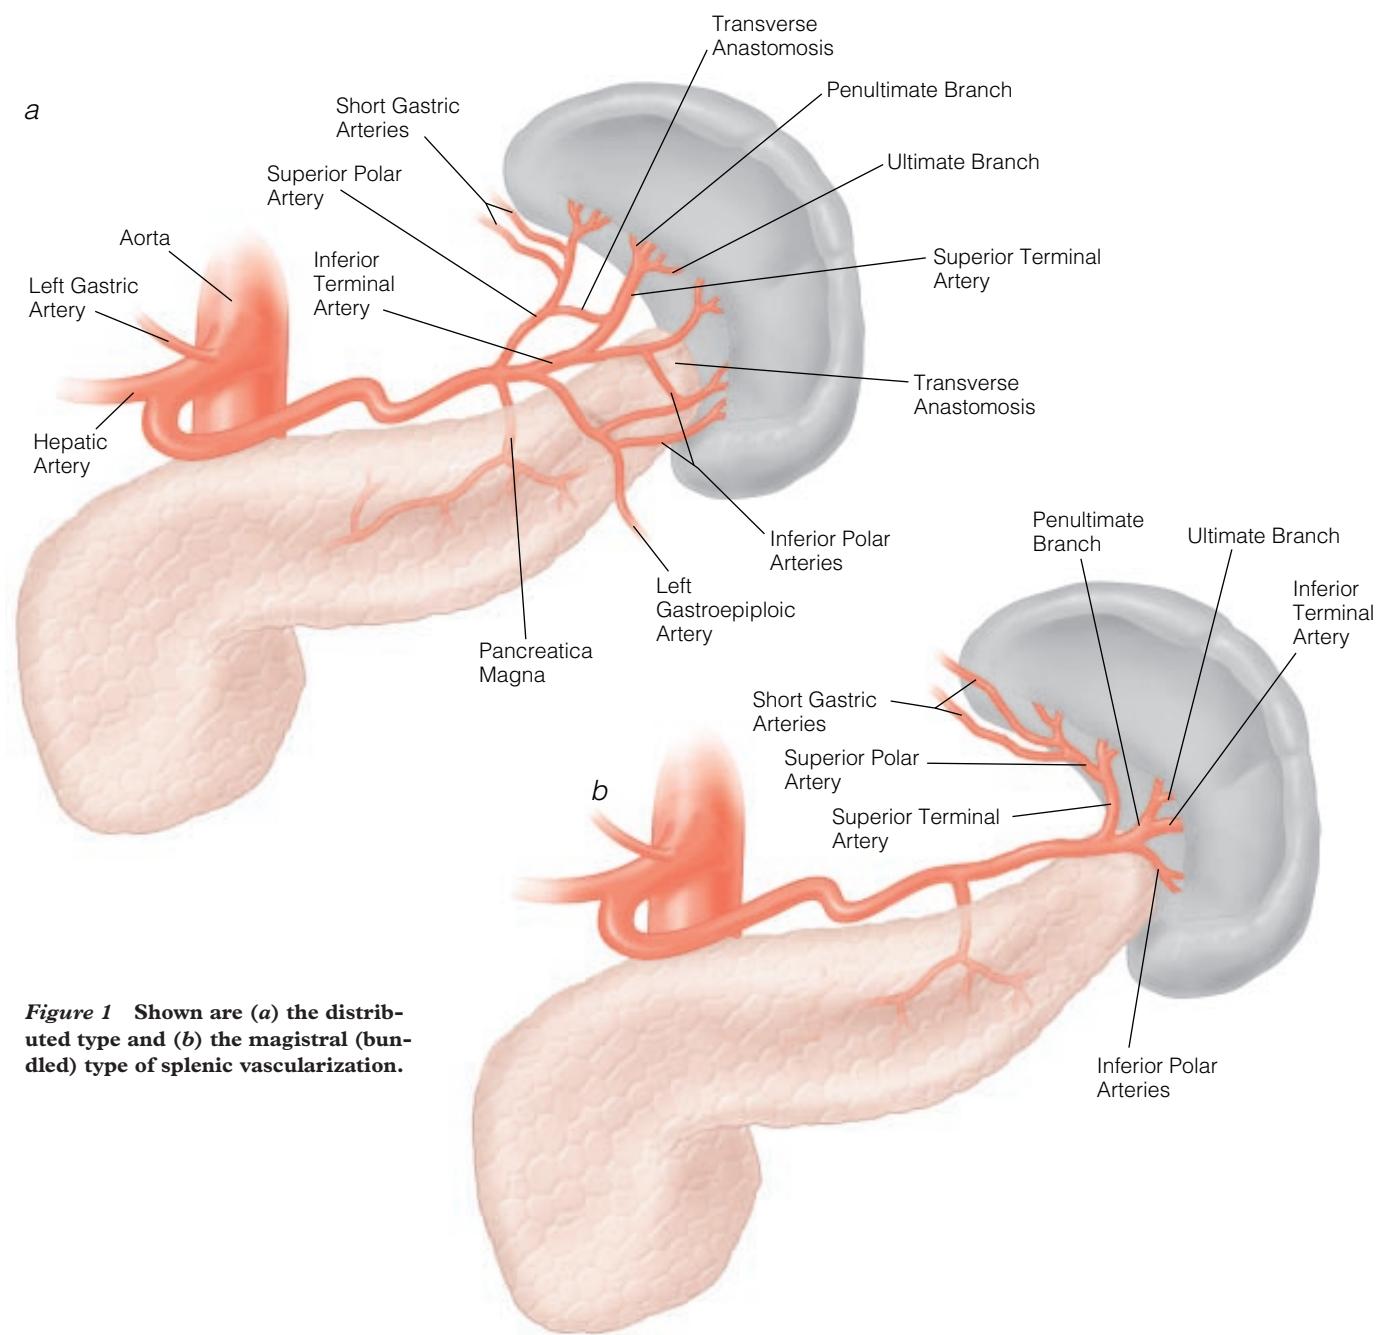

Figure 1 Shown are (a) the distributed type and (b) the magistral (bundled) type of splenic vascularization.

es to the tail of the pancreas. The most important of these is called the *Pancreatica magna* (a vessel familiar to vascular radiologists); occlusion of this branch with embolic material has been reported to result in pancreatitis. Next, the splenic artery divides into two to six first and second terminal branches, and these branches undergo two further levels of division into two to 12 penultimate and ultimate branches. Segmental and subsegmental division can occur either outside or inside the spleen. The number of arteries entering the spleen ranges from six to 36. The size of the spleen does not determine the number of arteries entering it; however, the presence of notches and tubercles usually correlates well with a higher number of entering arteries.

A reasonable general scheme of splenic artery branches might include as many as seven principal branches at various division levels and in various anatomic arrangements: (1) the superior

terminal artery, (2) the inferior terminal artery, (3) the medial terminal artery, (4) the short gastric arteries, (5) the left gastroepiploic artery, (6) the inferior polar artery, and (7) the superior polar artery [see Figure 2]. Veins are usually located behind the corresponding arteries, except at the ultimate level of division, where they may be either anterior or posterior.

First Terminal Division Branches

A classic study from 1917 found that 72% of specimens had three terminal branches (superior polar, superior terminal, and inferior terminal) and 28% had two¹²; the medial terminal artery was observed in only 20% of cases. When the superior terminal artery is excessively large, the inferior terminal is rudimentary, with an added blood supply often coming from the left gastroepiploic and polar vessels.

Second Terminal Division Branches

Superior polar artery The superior polar artery is present in 65% of patients. It usually arises from the main splenic trunk (75% of cases) or the superior terminal artery (20% of cases), but on occasion, it may originate from the inferior terminal artery or separately from the celiac axis (thus providing the spleen with a double splenic artery). In most instances, the superior polar artery gives rise to one or two short gastric branches; rarely, it gives rise to the left inferior phrenic and pancreatic rami. The presence and size of this artery appear to be correlated with tubercle formation, in that it is more prominent in spleens with large tubercles. The superior polar artery is frequently very long and slender and thus easily torn during splenectomy; accordingly, it was suggested in 1928 that ligation of splenic branches be started from the inferior pole of the spleen.¹³

Inferior polar artery The inferior polar artery is present in 82% of cases. As many as five collateral branches may arise from the splenic trunk, the inferior terminal artery, or, as noted, the left gastroepiploic artery. Inferior polar branches may have multiple origins, and they tend to be of smaller caliber than the superior polar artery.

Left gastroepiploic artery The left gastroepiploic artery, the most varied of the splenic branches, courses along the left side of the greater curvature in the anterior layer of the greater omentum. In 72% of cases, it arises from the splenic trunk several centimeters from its primary terminal division, and in 22% of cases, it originates from the inferior terminal artery or its branches; however, it may also originate from the middle of the splenic trunk or from the superior terminal artery. Characteristically, the left gastroepiploic artery gives off inferior polar arteries, which vary in number (ranging from one to five), size, and length. Typically, these branches are addressed first during laparoscopic splenectomy. When they are small, they can usually be controlled with the electrocautery.

Collaterals

Short gastric arteries As many as six short gastric arteries may arise from the fundus of the stomach, but as a rule, only the one to three that open into the superior polar artery must be ligated during laparoscopic splenectomy [see Figure 1].

SUSPENSORY LIGAMENTS OF SPLEEN AND TAIL OF PANCREAS

Duplications of the peritoneum form the many suspensory ligaments of the spleen [see Figure 3]. Medially and posteriorly, the splenorenal ligament contains the tail of the pancreas and the splenic vessels. Anteriorly, the gastrosplenic ligament contains the short gastric and gastroepiploic arteries. In the lateral approach to laparoscopic splenectomy [see Operative Technique, below], the splenorenal and gastrosplenic ligaments are easily distinguished, and dissection of the anatomic structures they contain is relatively simple. In the anterior approach, these two ligaments lie on top of each other, and to separate them correctly and safely requires considerable experience with splenic anatomy.

The phrenicocolic ligament courses laterally from the diaphragm to the splenic flexure of the colon; its upper portion is called the phrenicosplenic ligament. The attachment of the lower pole on the internal side is called the splenocolic ligament. Between these two structures, a horizontal shelf of areolar tissue, known as the sustentaculum lienis, is formed on which the inferior pole of the spleen rests. The sustentaculum lienis is often molded into a sac that opens cephalad and acts as a support for the lower pole. This structure, often overlooked during open procedures, is readily visible through a laparoscope. The phrenicocolic ligament, the splenocolic ligament, and the sustentaculum lienis are usually avascular, except in patients who have portal hypertension or myeloid metaplasia.

A 1937 study found that the tail of the pancreas was in direct contact with the spleen in 30% of cadavers.¹⁴ A subsequent report confirmed this finding and added that in 73% of patients, the distance between the two structures was no more than 1 cm.¹⁵ Care must be exercised to avoid damage with the electrocautery during

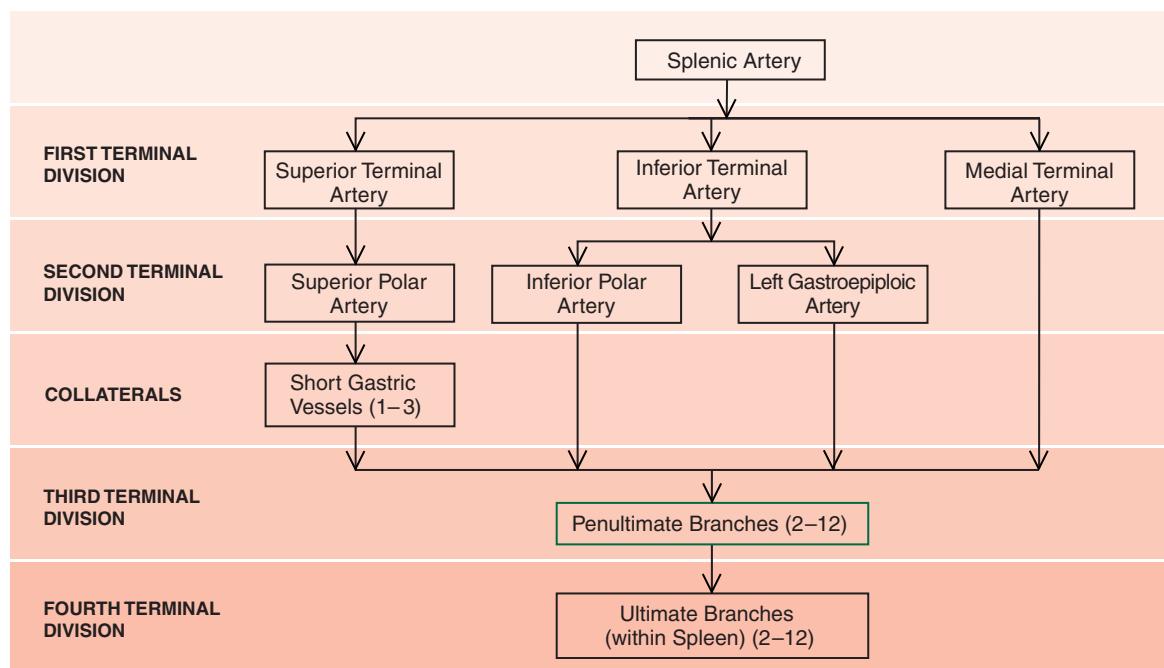

Figure 2 Outlined is a general scheme of the levels of division of the splenic artery branches.

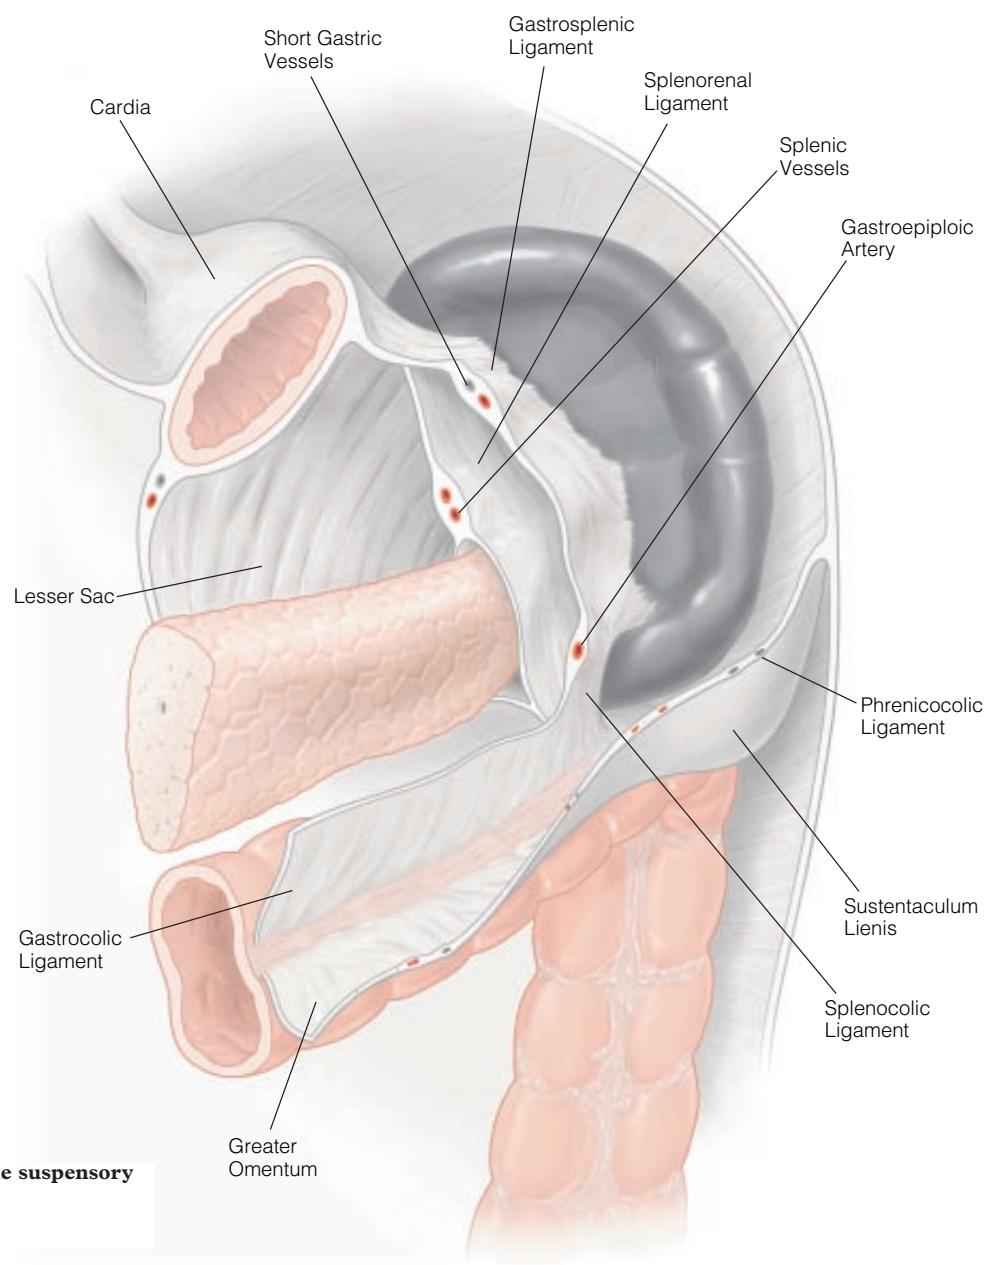

Figure 3 Depicted are the suspensory ligaments of the spleen.

dissection as well as damage with the linear stapler in the course of en masse ligation of the splenic hilum (a maneuver more easily performed via the lateral approach to laparoscopic splenectomy).

Laparoscopic Splenectomy

PREOPERATIVE EVALUATION

Currently, we consider all patients evaluated for elective splenectomy to be potential candidates for laparoscopic splenectomy. Contraindications to a laparoscopic approach include severe portal hypertension, uncorrectable coagulopathy, severe ascites, and most traumatic injuries to the spleen. Extreme splenomegaly remains a relative contraindication as well. Because most patients scheduled for laparoscopic splenectomy have hematologic disorders, they undergo the same hematologic preparation that patients scheduled for open surgery do—namely, steroids and γ -globulins (when required). Ultrasonography is performed to determine the

size of the spleen. Spleen size is expressed in terms of the maximum interpole length (i.e., the length of the line joining the two organ poles) and is generally classified into three categories: (1) normal spleen size (< 11 cm), (2) moderate splenomegaly (11 to 20 cm), and (3) severe splenomegaly (> 20 cm).¹⁶ Because extremely large spleens present special technical problems that test the current limits of laparoscopic surgery, we make use of a fourth category for spleens longer than 30 cm or heavier than 3 kg, which we call megaspleens [see Table 1]. The ultrasonographer is also asked to try to identify any accessory spleens that may be present. Computed tomography is done when there is doubt about the exactness of the ultrasonographic measurement; such measurement is sometimes inaccurate at the upper pole and with spleens longer than 16 cm.

Patients receive thorough counseling about the consequences of the asplenic state. Polyvalent pneumococcal vaccine is administered at least 2 weeks before operation in all cases; preoperative vaccination against *Haemophilus influenzae* and meningococci is also

advisable. Heparin prophylaxis for thrombophlebitis is administered according to standard guidelines, provided that there is no hematologic contraindication [see **6.6 Venous Thromboembolism**]. Nonsteroidal anti-inflammatory drugs (NSAIDs) are often given orally before operation to minimize postoperative pain; however, on empirical grounds, NSAIDs are not used when heparin prophylaxis is employed. Platelets are rarely, if ever, required when laparoscopic splenectomy is performed for idiopathic (immune) thrombocytopenic purpura (ITP).

OPERATIVE PLANNING

Laparoscopic splenectomy presents special problems, such as the necessity of dealing with a fragile and richly vascularized organ that is situated close to the stomach, the colon, and the pancreas and the difficulty of devising an extraction strategy that is compatible with proper histologic confirmation of the pathologic process while maintaining the advantages of minimal access surgery. For successful performance of laparoscopic splenectomy, a detailed knowledge of both splenic anatomy and potential complications is essential. The operative strategy is largely determined by the anatomic features, which, as noted [see Anatomic Considerations, above], may vary considerably from patient to patient.¹⁷

OPERATIVE TECHNIQUE

Lateral Approach

This approach was first described in connection with laparoscopic adrenalectomy and is currently used for most laparoscopic splenectomies.¹⁸ At present, the only indication for the anterior approach to laparoscopic splenectomy is the presence of massive splenomegaly or a megaspleen. Typically, this alternative approach is taken when a spleen reaches or exceeds 23 cm in length or 3 kg in weight.

Step 1: placement of trocars The patient is placed in the right lateral decubitus position, much as he or she would be for

Table 1 Classification of Spleens According to Spleen Length*

Spleen Class	Spleen Length
Normal-size spleen	7–11 cm
Moderate splenomegaly	12–20 cm
Massive splenomegaly	21–30 cm
Megaspleen	> 30 cm

*Spleen length is defined as interpole length, measured along a straight line connecting the two poles.

a left-side posterolateral thoracotomy. The operating table is flexed and the kidney bolster raised to increase the distance between the lower rib and the iliac crest. Usually, four 12 mm trocars are used around the costal margin so that the camera, the clip applier, and the linear stapler can be interchanged with maximum flexibility [see *Figure 4*]. The trocars must be far enough apart to permit good working angles. Some advantage may be gained from tilting the patient slightly backward; this step gives the operating team more freedom in moving the instruments placed along the left costal margins, especially during lifting movements, when it is easy for instrument handles to touch the operating table. For the same reason, it is also advisable to place the anterior or abdominal side of the patient closer to the edge of the operating table.

A local anesthetic is infiltrated into the skin at the midpoint of the anterior costal margin, and a 12 mm incision is made. The first trocar is inserted under direct vision, and a symmetrical 15 mm Hg pneumoperitoneum is created. The locations of the remaining trocars are determined by considering the anatomic configuration in relation to the size of the spleen to be excised. In most cases, the fourth posterior trocar cannot be inserted until the splenic flexure of the colon has been mobilized. Accordingly, the procedure is usually started with three trocars in place.

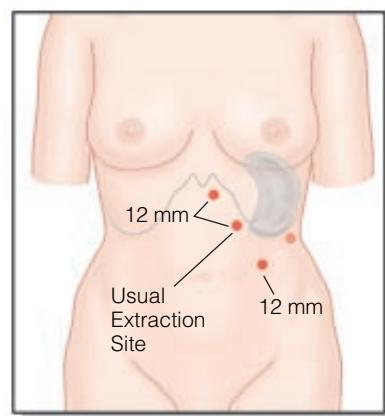

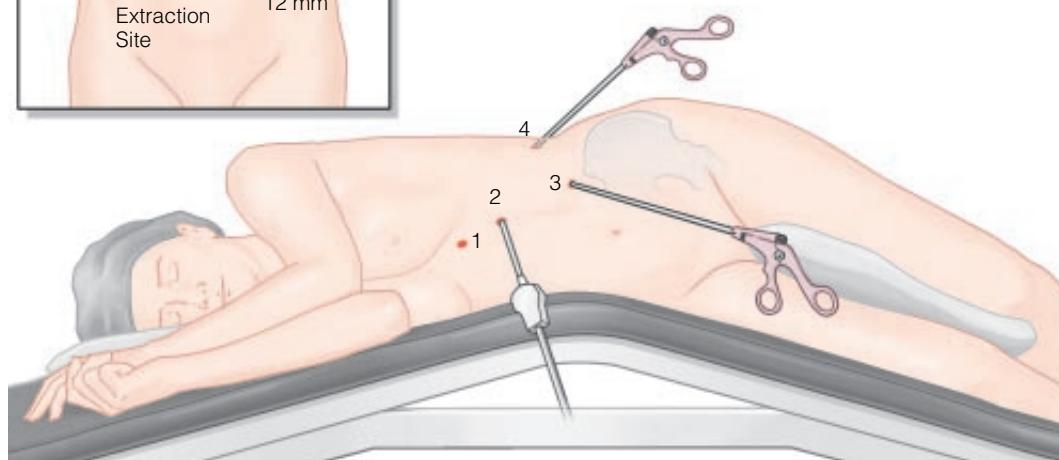

Figure 4 Laparoscopic splenectomy: lateral approach. Shown is standard trocar placement. Four trocars are used. In most cases, the procedure is begun without the posterior trocar in place.

Troubleshooting. After years of using the Veress needle, we now prefer the open method of inserting the first trocar. It is true that use of the Veress needle is for the most part safe; however, the small number of catastrophic complications that occur with blind methods of first trocar insertion are more and more difficult to justify. Admittedly, these complications are infrequent, and thus, it is unlikely that even a large randomized trial would be able to show any significant differences between various methods of first trocar insertion. Nevertheless, even though complications occur with the open method of first trocar insertion as well, they are very uncommon and tend to be limited to trauma to the intestine or the omental blood vessels; they do not have the same serious consequences as the major vessel injury that may arise from blind trocar insertion.

Trocars placements differing from the ones we describe may be considered. More experienced surgeons (or those simply wishing to make the procedure easier) may choose to replace one or two 12 mm trocars with 5 mm trocars [see Figure 5a]. The procedure can also be performed with only three trocars. In leaner patients, one of the trocars can be inserted into the umbilicus to gain a cosmetic advantage. The advent of needlescopic techniques has made it possible to replace some of the 5 and 12 mm trocars with 3 mm trocars. The ultimate (i.e., least invasive) technique, usually reserved for lean patients with ITP and normal-size spleens, involves one 12 mm trocar placed in the umbilicus and two 3 mm trocars placed subcostally [see Figure 5b]. This approach requires two different camera-laparoscope setups, so that a 3 mm laparoscope can be interchanged with a 10 mm laparoscope as necessary to permit application of clips or staplers through the umbilical incision once the dissection is completed. The specimen is then retrieved through the umbilicus. Because the use of 3 mm laparoscopes is accompanied by a decrease in available intra-abdominal light and focal width, a meticulously bloodless field and sophisticated surgical judgment are critical for successful performance of needlescopic splenectomy.

Step 2: search for and retrieval of accessory spleens The camera is inserted, and the stomach is retracted medially to expose the spleen. Then a fairly standard sequence is followed. A thorough search is then made for accessory spleens. To maximize retrieval, all known locations of accessory spleens should be care-

fully explored [see Figure 6]. Any accessory spleens found should be removed immediately; they are considerably harder to locate once the spleen is removed and the field is stained with blood.

Troubleshooting. It is especially important to retrieve accessory spleens from patients with ITP, in whom the presence of overlooked accessory spleens has been associated with recurrence of the disease. Remedial operation for excision of missed accessory spleens has been reported to bring remission of recurrent disease; such operation can be performed laparoscopically. The overall retrieval rate for accessory spleens should fall between 15% and 30%.

Splenic activity has been demonstrated after open and laparoscopic splenectomy for trauma and hematologic disorders^{19,20}; accordingly, it is advisable to wash out and recover all splenic fragments resulting from intraoperative trauma at the end of the procedure. This step is particularly important for patients with ITP, in whom intraoperative trauma to the spleen is thought to contribute to postoperative scan-detectable splenic activity. As of this writing, we have recovered accessory spleens in 33% of ITP cases treated laparoscopically.

Step 3: control of vessels at lower pole, demonstration of “splenic tent,” and incision of phrenicocolic ligament The splenic flexure is partially mobilized by incising the splenocolic ligament, the lower part of the phrenicocolic ligament, and the suspensaculum lienis. The incision is carried slightly into the left side of the gastrocolic ligament. This step affords access to the gastrosplenic ligament, which can then be readily separated from the splenorenal ligament to create what looks like a tent. This maneuver cannot be accomplished in all cases, but when it can be done, it simplifies the procedure considerably. The walls of this so-called splenic tent are made of the gastrosplenic ligament on the left and the splenorenal ligament on the right, and the floor is made up of the stomach. In fact, this maneuver opens the lesser sac in its lateral portion (a point that is better demonstrated with gentle upward retraction of the splenic tip) [see Figure 7].

The branches of the left gastroepiploic artery are controlled with the electrocautery or with clips, depending on the size of the branches. The avascular portion of the gastrosplenic ligament, situated between the gastroepiploic artery and the short gastric ves-

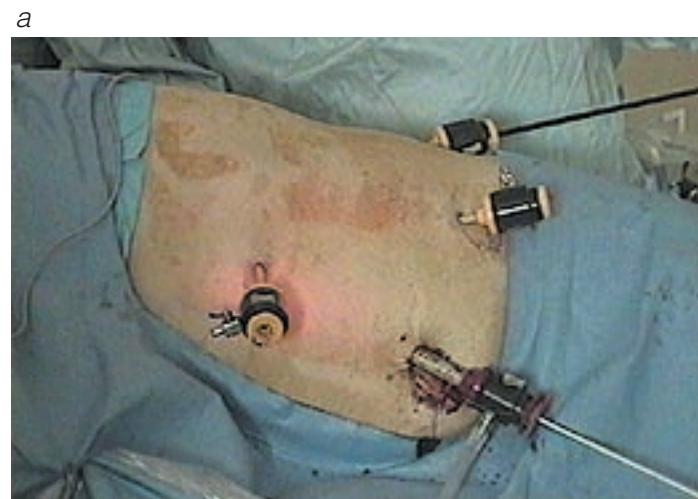

Figure 5 Laparoscopic splenectomy: lateral approach. Shown are alternative trocar placements. (a) In some patients (e.g., thin patients with normal-size spleens), a 12 mm trocar may be placed in the umbilicus to gain a cosmetic advantage, and most of the other trocars may be downsized to 5 mm. (b) In the needlescopic approach, only three trocars are placed: a 12 mm trocar in the umbilicus and two 3 mm subcostal trocars. Two camera-laparoscope setups (3 and 10 mm) are required.

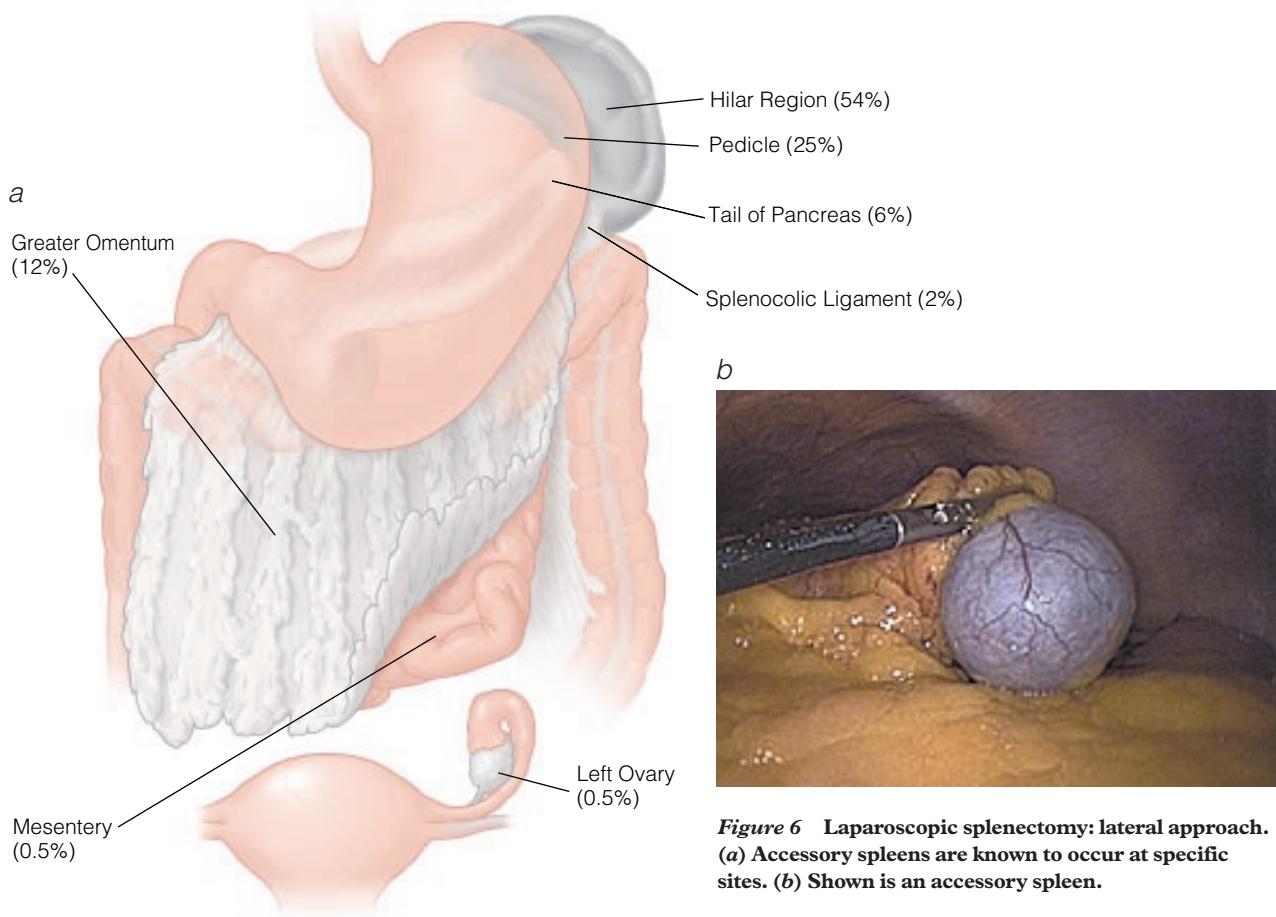

Figure 6 Laparoscopic splenectomy: lateral approach. (a) Accessory spleens are known to occur at specific sites. (b) Shown is an accessory spleen.

sels, is then incised sufficiently to expose the hilar structures in the splenorenal ligament. To accomplish this, the lower pole is gently elevated; in this position, the spleen almost retracts itself as it naturally falls toward the left lobe of the liver. At this point, the surgeon can usually assess the geography of the hilum and determine the degree of difficulty of the operation. The fourth trocar, if needed, is then placed posteriorly under direct vision, with care taken to avoid the left kidney. Caution must also be exercised in placing the trocars situated immediately anterior and posterior to the iliac crest. The iliac crest can impede movement and hinder upward mobilization of structures if the trocars are placed over it rather than in front of or behind it [see Figure 8].

Finally, the phrenicocolic ligament is incised all the way to the left crus of the diaphragm, either with a monopolar electrocautery with an L hook or with scissors. A small portion of the ligament is left to keep the spleen suspended and facilitate subsequent bagging. The phrenicocolic ligament is avascular except in patients with portal hypertension or myeloproliferative disorders (e.g., myeloid metaplasia). Leaving 1 to 2 cm of ligament all along the spleen side facilitates retraction and handling of the spleen with instruments.

Troubleshooting. Remarkably few instruments are needed for laparoscopic splenectomy: most of the operation is done with three reusable instruments. A dolphin-nose 5 mm atraumatic grasper is used to elevate and hold the spleen. It is also used to separate tissue planes and vessels with blunt dissection because its atraumatic tip is easily insinuated between tissue planes. A gently curved 5 mm fine-tip dissector (Crile or Maryland) and a 10 mm 90° right-angle dissector are the only other tools required for cost-efficient dissection.

When a powered instrument is called for, we use a monopolar electrocautery with an L hook or a gently curved scissors. Alternatively, an ultrasonic dissector or a tissue-welding device may be used, albeit at a much higher cost.

Step 4: dealing with splenic hilum and tailoring operative strategy to anatomy It is advisable to base one's operative strategy on the specific splenic anatomy. If a distributed anatomy

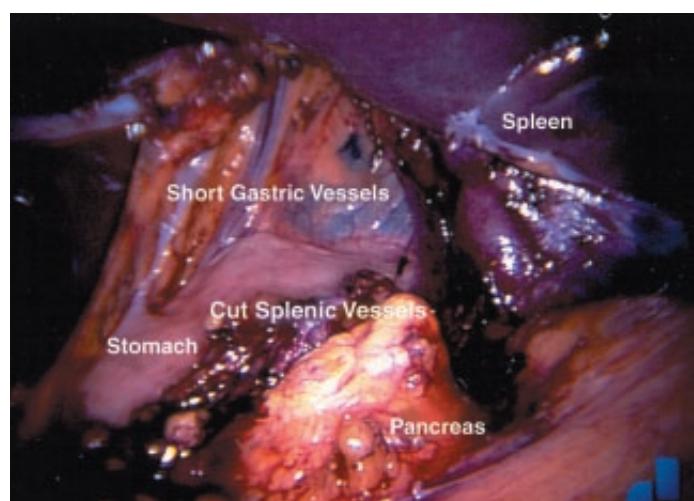

Figure 7 Laparoscopic splenectomy: lateral approach. The so-called splenic tent is formed by the gastrosplenic and splenorenal ligaments laterally and the stomach below.

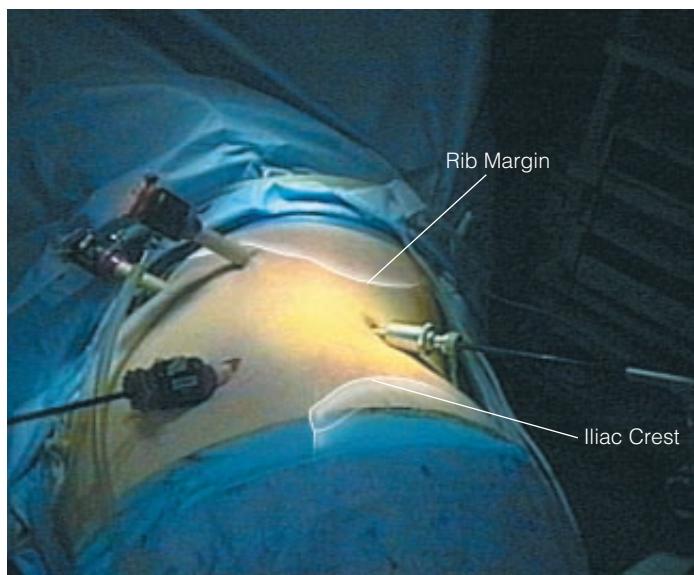

Figure 8 Laparoscopic splenectomy; lateral approach. Shown is the recommended trocar placement around the iliac crest.

is present, the splenic branches are usually dissected and clipped. This is not only the least costly approach but also the simplest, in that the vessels are spread over a wider area of the splenic hilum and are easier to dissect and separate [see Figure 9].

A bundled anatomy lends itself more to a single use of the linear stapler, provided that the tail of the pancreas is identified and dissected away when required. When possible, a window is created above the hilar pedicle in the splenorenal ligament so that all structures can be included within the markings of the linear stapler under direct vision [see Figure 10]. The angles provided by the various trocars make this maneuver much easier via the lateral approach than via the anterior approach. Dissection continues with individual dissection and clipping of the short gastric vessels; occasionally, these vessels can also be taken en masse with the linear stapler. So far, we have not used sutures in this setting, except once to control a short gastric vessel that was too short to be clipped safely. This portion of the operation is performed while the spleen is hanging from the upper portion of the phrenicocolic ligament, which has not yet been entirely cut.

Troubleshooting. It is at this point in the procedure that experience in designing the operative strategy pays off in reduced operating time. Because of the many variations in size, shape, vascular patterns, and relations to adjacent organs, spleens are almost as individual as fingerprints. Accordingly, an experienced spleen surgeon learns to keep an open mind with regard to operative strategy and must be able to call on a wide range of skills to facilitate the procedure.

The surgeon should start by looking at the internal surface of the spleen. If the splenic vessels cover more than 75% of the internal surface (as is the case in 70% of patients), a distributed anatomy is present. With a distributed vascular anatomy, the vessels tend to be easier to dissect and isolate and thus can be readily (and cost-effectively) controlled with clips. On the other hand, if the splenic vessels entering the spleen cover only 25% to 35% of the inner surface of the hilum (30% of patients), the pattern is bundled. With a bundled vascular anatomy, the vessels, being fewer and closer together, can usually be controlled with a single application of the vascular stapler across the hilum, provided that the tail of the pancreas can be protected.

Step 5: extraction of spleen A medium-size or large heavy-duty plastic freezer bag, of the sort commercially available in grocery stores, is used to bag the spleen. This bag is sterilized and folded, then introduced into the abdominal cavity through one of the 12 mm trocars [see Figure 11]. The bag is unfolded and the spleen slipped inside to prevent splenosis during the subsequent manipulations. Grasping forceps are used to hold the two rigid edges of the bag and to effect partial closure. Bagging is facilitated by preserving the upper portion of the phrenicocolic ligament. After final section of the phrenicocolic ligament and any diaphragmatic adhesions present, extraction is performed through one of the anterior port sites. Extraction through a posterior site is more difficult because of the thickness of the muscle mass; usually, the incision must be opened, and more muscle must be fulgurated than is desirable.

The subcostal or umbilical incision through which extraction is to take place is extended slightly. A grasping forceps is inserted through the extraction incision to hold the edges of the bag inside the abdomen. Gentle traction on the bag from outside brings the spleen close to the peritoneal surface of the umbilical incision and then out of the wound [see Figure 12]. Specimen retrieval bags

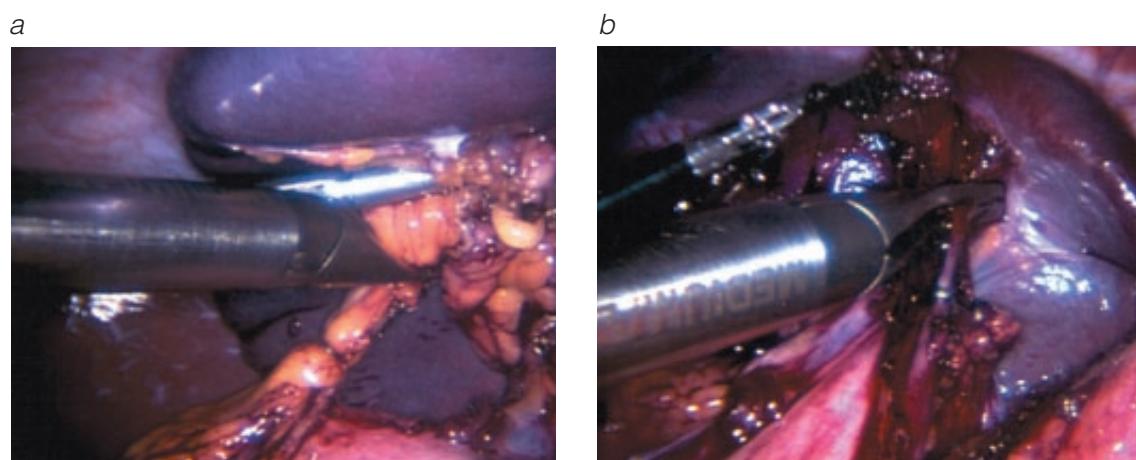

Figure 9 Laparoscopic splenectomy; lateral approach. (a, b) Clipping is well suited to controlling short gastric or gastroepiploic vessels. It is also appropriate for distributed-type splenic vasculatures, in which more splenic vessels are spread over a wider area of the hilum.

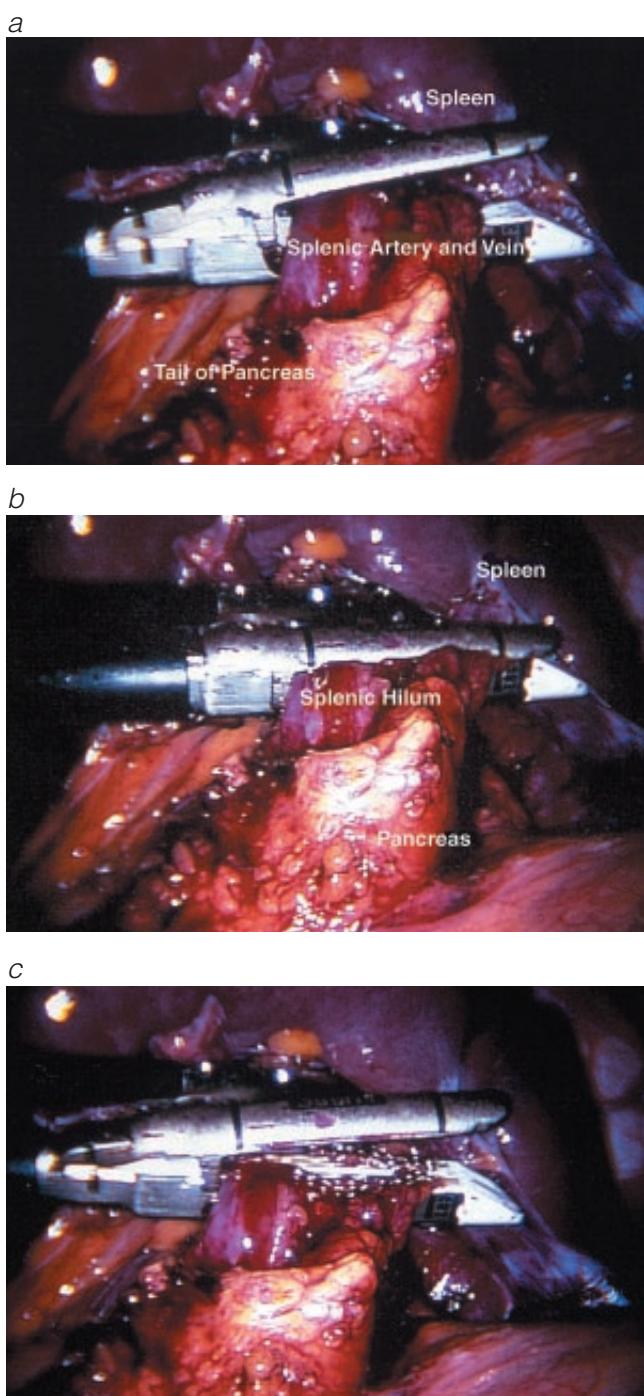

Figure 10 Laparoscopic splenectomy: lateral approach. (a through c) Stapling is particularly well suited to the compact hilum found in the magistral-type distribution of splenic vessels. As shown, all of the vascular structures are within the stapler markers, and the tail of the pancreas is well protected.

have been developed that can accommodate a normal-size spleen and thus make bagging much easier, but they are costly.

A biopsy specimen of a size suitable for pathologic identification is obtained by incising the splenic tip. The spleen is then fragmented with finger fracture, and the resulting blood is suctioned. The remaining stromal tissue of the spleen is then extracted through the small incision, hemostasis is again verified, and all trocars are removed. No drains are used. The incisions are closed with absorbable sutures and paper strips.

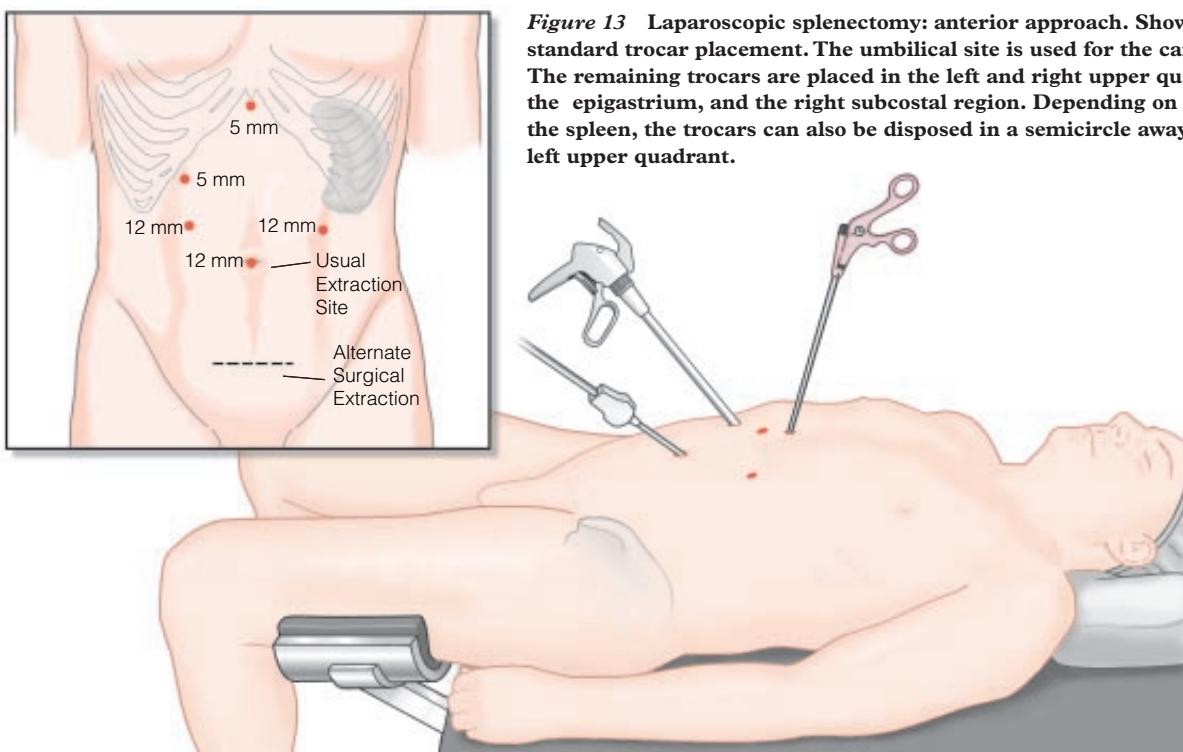

Figure 11 Laparoscopic splenectomy: lateral approach. Illustrated is the introduction of a sterile freezer bag for specimen extraction via the pull method. A toothed grasper is passed across the abdomen between two trocars and brought out through the 12 mm umbilical trocar site. This grasper is used to pull the extraction bag back into the abdomen.

Troubleshooting. The freezer bags can be more easily introduced into the abdomen if they are pulled in rather than pushed in [see Figure 11]. This may be accomplished by bringing out a 5 mm toothed grasper through the introduction trocar from another properly angled trocar, grasping the specimen bag, and pulling the bag back down through the trocar. A laparoscopic hernia mesh introducer may also be used.

Slipping the spleen into a freezer bag is also an acquired skill that takes some time to master. It is an important skill that is useful in many other instances where specimen retrieval is needed (e.g., in procedures involving the gallbladder, the appendix, the adrenal glands, or the colon). In addition, it is highly cost-effective, in that these commercially available bags cost only a few cents each. Admittedly, laparoscopic retrieval bags are easier to use, but their substantially higher cost can become a factor in a busy min-

Figure 12 Laparoscopic splenectomy: lateral approach. Shown is the position of the specimen bag before finger fragmentation or pulp suction.

imally invasive surgery unit. We use a powerful suction machine (-70 mm Hg) and a custom-made sharp beveled 10 mm cannula to suction splenic tissue from the plastic retrieval bag.

Anterior Approach

The anterior approach is seldom used nowadays; however, it remains the preferable approach in some patients with massive splenomegaly (21 to 30 cm long) and all patients with mega-spleens (> 30 cm or > 3 kg) with the aid of hand-assisted devices [see Special Considerations, Hand-Assisted Laparoscopic Splenectomy, below]. Very large spleens are extremely heavy and difficult to manipulate with laparoscopic instruments, and it is complicated to lift them so as to gain access to the phrenicocolic ligament posteriorly. The anterior approach can also be considered if another procedure (e.g., cholecystectomy) is being contemplated; alternatively, in this situation, the lateral approach can be used, and the patient can be repositioned for the secondary procedure.

Step 1: placement of trocars Under general anesthesia, the patient is placed in a modified lithotomy position to allow the surgeon to operate between the patient's legs and to allow the assistants to stand on each side of the patient. The procedure is performed through five trocars in the upper abdomen [see Figure 13], with the patient in a steep Fowler position with left-side elevation. A 12 mm trocar is introduced through an umbilical incision, and a 10 mm laparoscope (0° or 30°) is connected to a video system. A 12 mm trocar is placed in each upper quadrant, and two 5 mm trocars are inserted close to the rib margin on the left and right sides of the abdomen. Alternatively, trocars can be deployed in a semicircle away from the left upper quadrant. Trocar sites are carefully selected to optimize working angles. The 12 mm ports are used to allow introduction of clip appliers, staplers, or the laparoscope from a variety of angles as needed.

Troubleshooting. With increasing experience, we find that we prefer to do as many laparoscopic splenectomies as possible via

Figure 13 Laparoscopic splenectomy: anterior approach. Shown is standard trocar placement. The umbilical site is used for the camera. The remaining trocars are placed in the left and right upper quadrants, the epigastrium, and the right subcostal region. Depending on the size of the spleen, the trocars can also be disposed in a semicircle away from the left upper quadrant.

the lateral approach because it is so much easier, even with spleens that are longer than 20 cm and are readily palpable. The decision is arbitrarily made on the basis of estimated available working space. If the spleen comes too close to the iliac crest or the midline, the anterior approach should be taken instead.

Step 2: isolation of lower pole and control of blood supply The left hepatic lobe is retracted, and the stomach is retracted medially to expose the spleen. Accessory spleens are searched for, and the phrenicocolic ligament, the splenocolic ligament, and the sustentaculum lienis are incised near the lower pole with an electrocautery and a hook probe or with scissors. Vascular adhesions—frequently found on the medial side of the spleen—are cauterized. The gastrocolic ligament is carefully dissected close to the spleen, and the left gastroepiploic vessels are ligated one by one with metallic clips or, if small, simply cauterized. The upper and lower poles of the spleen are gently lifted with one or both palpators (placed through the 5 mm ports) to expose the splenic hilum and the tail of the pancreas within the splenorenal ligament, thereby facilitating individual dissection and clipping of all the branches of the splenic artery and vein close to the spleen. The short gastric vessels are then identified and ligated with clips or, occasionally, with staples. No sutures are used. Alternatively, the splenic artery itself can be isolated and clipped within the lesser sac before extensive dissection of the lower pole and suspensory ligaments.

Because of the segmental and terminal distribution of splenic arteries, it is easy to determine the devascularized portions of the spleen: these segments exhibit a characteristic grayish color, whereas the vascularized segments retain a pinkish hue. When the organ is completely isolated, it is left in its natural cavity, and hemostasis is verified.

Troubleshooting. If one elects first to clip the splenic artery within the lesser sac, there are a few precautions that must be taken. First, the clipping must be done distal to the pancreatica magna to prevent

pancreatic injury. Second, one must make sure that the splenic artery proper is clipped, not one of its branches (e.g., the superior terminal branch). This is an easy mistake to commit with the distributed type of splenic vasculature [see *Figure 1*] because the splenic artery itself is short and the branches can take off very early. Third, one must always keep in mind the possibility of an anastomotic branch between the major splenic branches, as described by Testut.¹¹ Should a major terminal branch be clipped rather than the splenic artery proper, there will be no spleen ischemia if such an anastomosis is present [see *Figure 1*].

Yet another challenge posed by the anterior approach is that if bleeding occurs, the blood tends to pool in the area of the hilum and obscure vision even more, whereas in the lateral approach, the blood tends to flow away from the operative field. One quickly learns that there is a steep price to pay for cutting corners during the dissection. The dissection must be meticulous, especially behind branches of the splenic vein.

Step 3: extraction of spleen Given that the anterior approach is now used only in cases of massive splenomegaly or megaspleen, bagging can be problematic. The largest commercially available freezer bag we have seen measures 27 by 28 cm, and the largest spleen we have been able to bag in one of them was 24 cm long. Furthermore, an accessory extraction incision is often required; a Pfannenstiel incision gives better cosmetic results, but a left lower quadrant incision can also be used. Hand-assisted devices are used with increasing frequency in laparoscopic removal of large spleens [see Special Considerations, Hand-Assisted Laparoscopic Splenectomy, below].

If the spleen cannot be bagged, it may be fragmented in the pelvis before extraction, provided that the abdomen is copiously washed and cleaned of any residual spleen fragments before closure to prevent splenosis. Most patients with large spleens have hematologic malignancies; thus, residual splenic activity is not as crucial an issue in these patients as it would be in others.

Laparoscopic Partial Splenectomy

Concern regarding the risk of OPSI has encouraged the practice of preserving splenic tissue and function whenever possible. For this reason, partial splenectomy has occasionally been indicated for treatment of benign tumors of the spleen and for excision of cystic lesions.²¹ Its use has been described in connection with the management of type I Gaucher disease, cholesterly ester storage disease, chronic myelogenous leukemia, and thalassemia major, as well as with the staging of Hodgkin disease.^{22,23} Partial splenectomy has also been an option in the management of splenic trauma when the patient's condition is stable enough to permit the meticulous dissection required for the operation.^{24,25}

Like standard laparoscopic splenectomy, laparoscopic partial splenectomy is performed with the patient in the right lateral decubitus position. Trocar placement is similar as well. The splenocolic ligament and the lower part of the phrenicocolic ligament are incised to permit mobilization of the lower pole of the spleen. If the lower portion of the spleen is to be excised, branches of the gastroepiploic vessels supplying the lower pole are dissected and clipped close to the parenchyma. An appropriate number of penultimate branches of the inferior polar artery are then taken in such a way as to create a clear line of demarcation between normal spleen and devascularized spleen. This process is continued until the desired number of splenic segments are devascularized.

Next, a standard monopolar electrocautery is used to score the

splenic capsule circumferentially, with care taken to ensure that a 5 mm rim of devascularized splenic tissue remains *in situ*; this is the most important technical point for this procedure [see *Figure 14*]. The incision is then carried into the splenic pulp. Atraumatic intestinal graspers are also used to fracture the splenic pulp in a bloodless fashion. The laparoscopic L hook and scissors provide excellent hemostatic control.

Once the spleen has been allowed to demarcate, resection is remarkably bloodless, provided that the 5 mm rim of ischemic tissue is left in place. Complete control of the splenic artery is not required before splenic separation, because division occurs in an ischemic segment of spleen.⁹ The feasibility of leaving portions of ischemic spleen *in situ* has been demonstrated in a large prospective, randomized trial involving partial splenic embolization as primary treatment of hematologic disorders.²⁶

If the superior pole is to be removed, the phrenicocolic ligament must be incised almost entirely so that the spleen can be easily mobilized and the proper exposure achieved. The short gastric branches are taken first, along with the desired number of superior or polar artery branches.

Laparoscopic partial splenectomy can be performed either with or without the aid of selective preoperative arterial embolization (see below). Radiologists are capable of cannulating the desired segmental splenic arterial branch and embolizing the segment that is to be resected. We have removed the superior pole in a patient with a class IV isolated splenic injury sustained while skiing⁸; laparoscopic partial splenectomy was made possible largely by the accuracy of selective arterial embolization, which permitted control of the bleeding and allowed laparoscopy to be performed in unhurried conditions.²⁷

Preoperative Splenic Artery Embolization

Preoperative splenic artery embolization is used as an adjuvant in a few patients to make laparoscopic splenectomy possible and to reduce blood loss. Although it is now infrequently used, it remains a useful tool in the armamentarium of spleen surgeons.

Generally speaking, the technique involves embolization of the spleen with coils placed proximally in the splenic artery and absorbable gelatin sponges and small coils placed distally in each splenic arterial branch (the double embolization technique), with care taken to spare vessels supplying the tail of the pancreas [see *Figure 15*].

The procedure is ended when it is estimated radiologically that 80% or more of the splenic tissue has been successfully embolized. In most cases, successful embolization is achieved with both proximal and distal emboli; in a minority of cases, it is achieved with proximal emboli alone or with distal emboli alone.²⁸

Troubleshooting Preoperative splenic artery embolization is safe, provided that two main principles are adhered to. First, embolization must be done distal to the pancreatica magna to avoid damaging the pancreas. Second, neither microspheres nor absorbable gelatin powder should be used, because particles of this small size may migrate to unintended target organ capillaries and cause tissue necrosis; only coils and absorbable gelatin sponge fragments should be used.

POSTOPERATIVE CARE

Postoperative care for patients who have undergone laparoscopic splenectomy is usually simple. The nasogastric tube inserted after induction of general anesthesia is removed either in the recovery room, once stomach emptying has been verified, or the

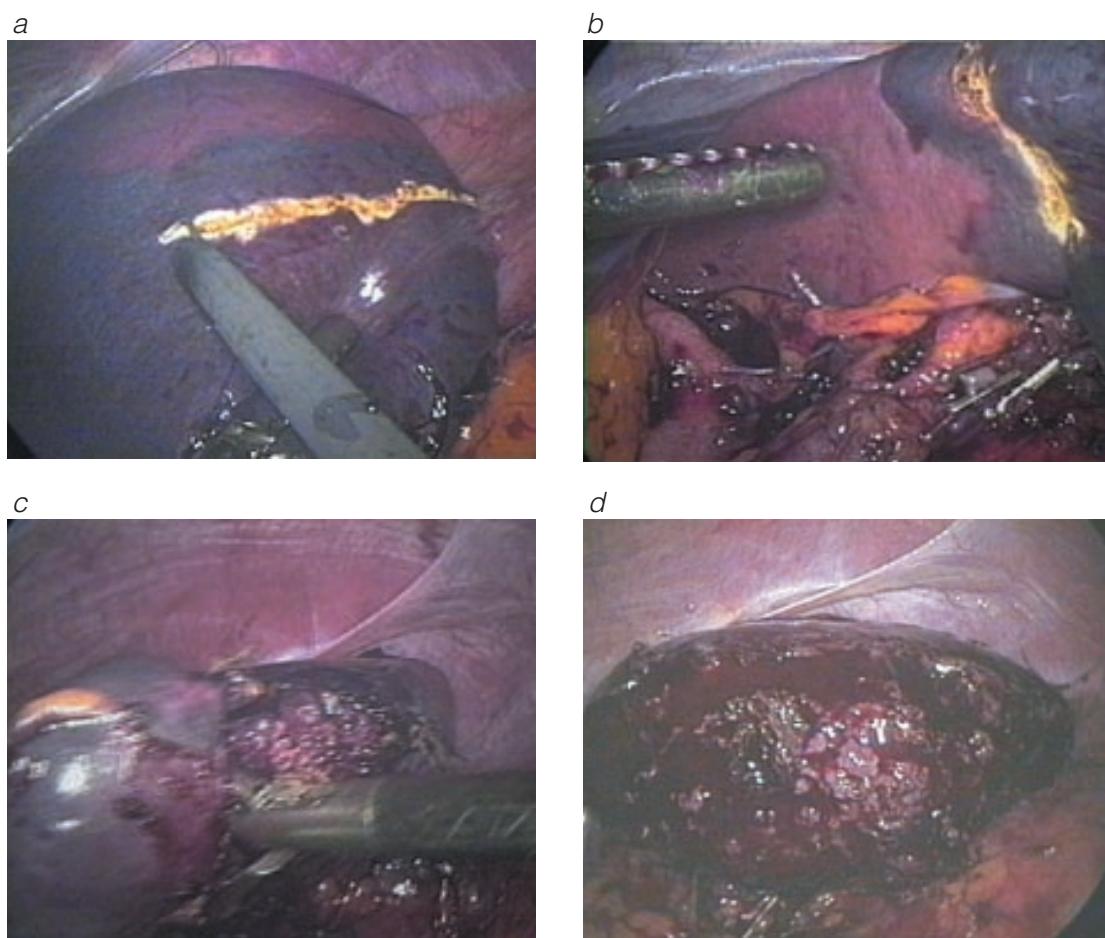

Figure 14 Laparoscopic splenectomy: partial splenectomy. (a, b) The splenic capsule is scored with the monopolar cautery, and a 5 mm margin of devitalized tissue is left. (c) The splenic pulp is fractured with an atraumatic grasper. The electrocautery with the L hook is also used to control parenchymal bleeding. (d) Shown is the cut surface of the spleen after transection. The operative field remains remarkably dry.

next morning, depending on the duration and the degree of technical difficulty of the procedure. The urinary catheter is usually removed before the patient leaves the recovery room. The patient is allowed to drink clear fluids on the morning after the operation; when clear fluids are well tolerated, the patient is allowed to proceed to a diet of his or her choice.

If the patient has no history of ulcer or dyspepsia, one naproxen sodium tablet (500 mg) is given with sips of water on the morning before operation. Meperidine injections (1 mg/kg) are administered during the first night, followed by oral acetaminophen (1 g every 6 hours). If pain is not well controlled, coanalgesia with an NSAID is added; this combination produces the best results. Because of its side effects (i.e., nausea, vomiting, abdominal fullness, and constipation), codeine is currently avoided if at all possible. When naproxen sodium is used, prophylactic doses of subcutaneous heparin are avoided on empirical grounds, especially if the platelet count is low or platelet function is abnormal.

Patients receiving I.V. cortisone are given oral steroids on postoperative day 1 after an overlap I.V. injection; thereafter, steroids are gradually tapered. Patients are allowed to shower 12 hours after surgery and are advised to keep the paper strips covering the trocar incisions in place for 7 to 10 days. No drains are used. No limitations are imposed on physical activity, and patients are allowed to tailor their activities to their degree of asthenia or discomfort.

COMPLICATIONS

Postoperative complications directly related to splenectomy include intraoperative and postoperative hemorrhage; left lower lobe atelectasis and pneumonia; left pleural effusion; subphrenic

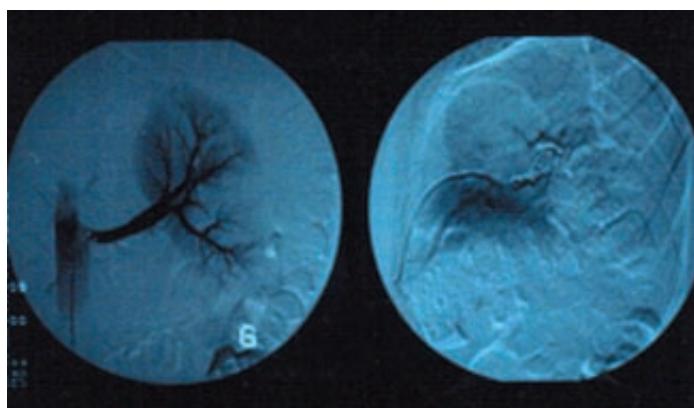

Figure 15 Laparoscopic splenectomy: splenic artery embolization. Shown are splenic angiograms of a patient with thrombotic thrombocytopenic purpura before (left) and after (right) splenic artery embolization with 3, 5, and 7 cm coils and absorbable gelatin sponge fragments.

collection; iatrogenic pancreatic, gastric, and colonic injury; and venous thrombosis.²⁴⁻³¹

Successful laparoscopic splenectomy depends to a large extent on proper preparation. Recognition of anatomic elements and their arrangement is paramount. As with other laparoscopic procedures, the keys are avoiding complications and minimizing technical misadventures. Vascular structures should be cleanly isolated and dissected from surrounding fat; they then can usually be controlled with two clips proximally and distally. Staplers should be used with care and should not be applied blindly. The stapler tip should be clearly seen to be free of tissue before it is closed; otherwise, hemorrhage from partial section of a major splenic branch might occur after the instrument is released. Blind application of the stapler may also result in damage to the tail of the pancreas, which often lies in close proximity to the inner surface of the spleen. If both clips and a linear stapler are used, it is vital to prevent interposition of clips in the staple line, which will cause the stapler to misfire and possibly to jam.

Improper use of the electrocautery during the procedure can cause iatrogenic injury to the stomach, the colon, or the pancreas. In a smoke-filled environment, where controlling vessels is difficult and time consuming, blind fulguration of fat in the hilum can lead to bleeding. Structures close to the lower pole in the gastrocolic ligament can be approached more aggressively, but not those in the hilum. To prevent arcing and spot necrosis, which may result in delayed perforation and sepsis, the instrument should be activated only in proximity to the target organ.

The assistants also play an important role in preventing complications. All instruments, including those handled by assistants, should be moved under direct vision. Especially in the anterior approach, retraction of the liver and stomach and elevation of the spleen require constant concentration if lacerations and subsequent hemorrhage or perforation are to be avoided.

SPECIAL CONSIDERATIONS

Extraction of Specimens

Spleens removed via the anterior approach are extracted through the umbilical trocar site after finger fragmentation in a plastic bag. It is rarely necessary to enlarge the umbilical incision to more than 2 or 3 cm. When the lateral approach is used, extraction is more easily performed through one of the ports situated anteriorly. This extraction site also requires little or no enlargement. On occasion, for a spleen longer than 20 cm, a 7.5 to 10 cm Pfannenstiel incision is made, and the operator's forearm is introduced into the abdomen to deliver the spleen into the pelvis for extraction in large fragments under direct vision.³² The abdomen is copiously irrigated before closure.

Special mention should be made of extraction of the splenic specimen from patients with malignant disease. If lymphoma or Hodgkin disease is suspected, neither preoperative splenic artery embolization nor finger fragmentation in a plastic bag should be performed, for fear of making the histologic diagnosis difficult. Extraction of intact spleens through a small left subcostal or median incision has also been employed when preservation of tissue architecture is required. Alternatively, a port site may be slightly enlarged, and a knife or a Mayo scissors may be used to furnish the pathologist with intact specimen pieces of various sizes. The various techniques of fragmentation and extraction of splenic tissue during laparoscopic splenectomy should be discussed and agreed on with the pathologist ahead of time to ensure that proper pathologic diagnoses are not compromised by either necrotic

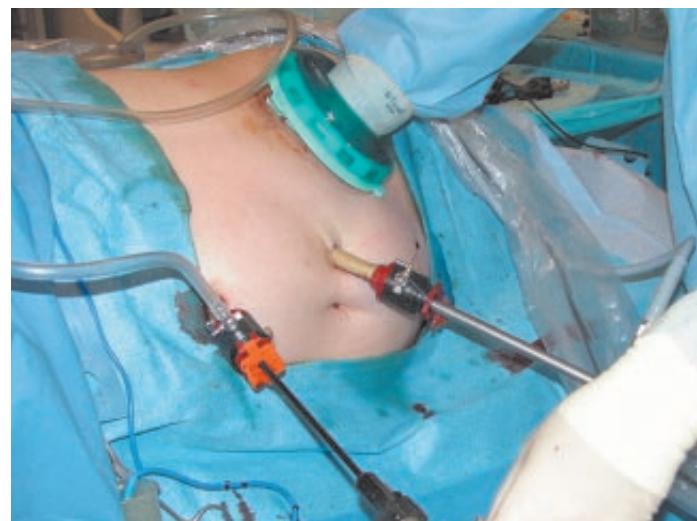

Figure 16 Laparoscopic splenectomy: hand-assisted. Shown is the use of a hand port in the left lower quadrant to facilitate laparoscopic splenectomy in a patient with a large spleen.

tissue (in the case of preoperative splenic artery embolization) or altered tissue architecture (in the case of finger fragmentation), especially if malignancy is suspected but not proved. In practice, however, we have found that the diagnosis is made preoperatively in more than 90% of patients with benign and malignant hematologic disease; hence, the issue rarely arises.

Hand-Assisted Laparoscopic Splenectomy

The term hand-assisted laparoscopic surgery refers to laparoscopic procedures performed with the aid of a plastic device inserted in a 7.5 to 10 cm wound. This plastic hand port consists of a sealed cuff that enables a hand to be inserted into and withdrawn from the abdomen without loss of pneumoperitoneum during the operation; in this way, the surgeon regains some of the tactile feedback lost in conventional laparoscopic surgery [see Figure 16]. A number of different models have been developed, some of them quite expensive. Most use either an inflatable sleeve clipped to an O-ring, a spiral inflatable valve, or a flap valve to maintain pneumoperitoneum.

The optimal placement of the incision for a hand-assisted laparoscopic splenectomy remains a subject of debate: recommended locations have included the upper midline, the right upper quadrant, the left iliac fossa, and, for very large spleens, the Pfannenstiel position. Whether the surgeon is left-handed or right-handed plays a role; most surgeons agree that the nondominant hand should be used in the device.

There are obvious advantages and drawbacks to hand-assisted laparoscopic splenectomy. The most apparent disadvantage is the cosmetic cost of a longer abdominal incision (except when a Pfannenstiel incision is employed). More generally, the use of a longer incision would seem to be at odds with the current trend toward developing surgical techniques that reduce surgical trauma as much as possible. Nevertheless, comparative studies of splenectomy in patients with large spleens (> 700 g) seem to indicate that for the most part, the hand-assisted approach yields outcomes similar to those of conventional laparoscopic splenectomy.³³

Although the precise role of hand-assisted laparoscopic splenectomy remains to be defined, it is likely that this technique will find a place in the surgical management of patients with large spleens. In addition, the hand-assisted approach may be a valuable aid for

*71% required accessory incision because of spleen size.

surgeons who have not yet completed the learning curve for conventional laparoscopic splenectomy. Finally, this technique may render preoperative splenic embolization unnecessary for most very large spleens.

OUTCOME EVALUATION

No randomized, prospective trials comparing open splenectomy with laparoscopic splenectomy have yet been conducted. At present, such trials are unlikely to be held, for a variety of reasons. For one thing, randomization is difficult with procedures that are still in evolution. At one end of the spectrum, laparoscopic splenectomy is done for patients with ITP, who usually are relatively healthy and have normal-size spleens. In many of these patients, needlescopic instruments (< 3 mm) can be used in conjunction with a single 12 mm port site in the umbilicus. This approach permits hospital discharge within 24 hours of operation in a significant number of cases. At the other end of the spectrum, laparoscopic splenectomy is done for patients with myeloid metaplasia and spleens longer than 30 cm. In this setting, a laparoscopic approach poses formidable challenges, and the optimal technique and its justification remain to be determined. The window of opportunity for randomized comparative trials may have been lost.

Large case series and nonrandomized comparative trials, however, have consistently reported better outcomes from laparoscopic splenectomy than from open splenectomy.³⁴⁻⁴¹ For example, in one set of 528 patients [see Table 2],³⁶⁻³⁹ the rate of postoperative pneumonia was 1.1% (6/528), and no subphrenic abscesses occurred as postoperative complications. Many surgeons who have completed the learning curve associated with the procedure feel that there is still room for improvement regarding complication rates and length of stay for patients with ITP and other relatively benign conditions necessitating laparoscopic splenectomy. The more serious conditions and the mortality seen in conjunction with the procedure tend to occur in patients with advanced hematologic malignancies or megasplines. In such cases, most of the adverse results are related to the disease state rather than to the operation, and it remains to be seen whether laparoscopic splenectomy will have a positive effect on outcome.

One of the great attractions of minimally invasive surgery has been the prospect of significant cost reductions. At this point in the development of laparoscopic splenectomy, however, we are reluctant to place too much trust in premature cost analyses that do not take into account the “work in progress” nature of minimally invasive surgery. Most surgeons can now perform most

laparoscopic splenectomies with simplified trays of reusable instruments. Our basic laparoscopic tray contains a few instruments and two sizes of reusable clip appliers with inexpensive clips. As noted [see Operative Technique, above], clips are used for distributed-type spleens, and single-use linear staplers are mostly used for magistral-type spleens. To reduce costs, ultrasonic dissectors are rarely used. In addition, the use of commercially available freezer bags instead of laparoscopic retrieval bags further reduces the cost of specimen extraction. Finally, even if intraoperative costs are higher with laparoscopic splenectomy, our experience is that the increase is offset by reductions in postoperative stay.

We, like most authorities, believe that as a surgeon gains experience with laparoscopic splenectomy, operating time tends to fall until it approaches that of open splenectomy. We also concur with the numerous authors who have suggested that once laparoscopic splenectomy is mastered, use of blood products tends to decrease substantially.

Open Splenectomy

PREOPERATIVE EVALUATION

With the growing acceptance of laparoscopic splenectomy, the indications for open splenectomy have essentially been reduced to (1) elective removal of megasplines and (2) treatment of splenic trauma when conservative treatment either is not indicated or has failed. In rare cases, open splenectomy may be done for iatrogenic injuries incurred during left upper quadrant surgical procedures.

Preoperative evaluation for elective open splenectomy is similar to that for laparoscopic splenectomy [see Laparoscopic Splenectomy, Preoperative Evaluation, above]. Preoperative evaluation of trauma patients is covered in more detail elsewhere [see 7:1 Initial Management of Life-Threatening Trauma]. Essentially, a coagulogram and blood typing and crossmatching are required. A preoperative CT scan will have established the size of the spleen, the grade of the splenic injury, the presence of other injuries (if any), and, in elective cases, the location and configuration of any masses or cysts.

OPERATIVE PLANNING

Most surgeons would agree that the lessons learned from successful performance of minimally invasive procedures have had a positive

impact on the refinement of the corresponding open procedures. The principles of careful appreciation of fine anatomic details (as described for laparoscopic splenectomy) and maximal reduction of tissue trauma from retractors or excessive tissue handling should be incorporated into the planning of open splenectomy.

Total versus Partial Splenectomy

As a consequence of the recognition that splenectomy renders patients susceptible to a lifelong risk of OPSI, it is now routine practice to attempt splenic conservation. Accordingly, saving normally functioning splenic parenchyma has become the most important goal in the management of splenic injuries. In some 50% of adults (and over 80% of children), this goal can be achieved by means of nonoperative treatment. In approximately 20% of adults, splenorrhaphy and partial splenectomy are possible; splenectomy is indicated in the remainder. Partial splenectomy is also favored on occasion when excision of splenic tissue is required for the treatment of other elective conditions.

For the sake of brevity, we describe the surgical technique for total splenectomy and partial splenectomy concurrently, noting differences only where significant.

OPERATIVE TECHNIQUE

Step 1: Incision

The patient is supine, in a reverse Tredelenburg position with a 15° tilt to the right. For maximal exposure, a midline incision is made, starting on the left side of the xiphoid process [see Figure 17]. The incision is extended below the umbilicus for a variable distance, depending on circumstances such as the size of the patient, the surgical situation (traumatic versus nontraumatic), the possibility of associated injury, and the size of the spleen. Occasionally, a left subcostal incision may be used for nontraumatic indications in patients with normal-size spleens. This incision may be extended onto the right side to form a chevron incision if necessary; however, this may impede the search for accessory spleens. Some surgeons have per-

formed splenectomy via a thoracoabdominal approach, but most have abandoned this approach. Appropriate retraction of the left lobe of the liver and the abdominal wall is achieved with the help of surgical assistants placed on each side of the table or the use of self-retaining retractors.

Troubleshooting In trauma cases, the anesthetist should always be informed when the peritoneum is opened; release of a tense hemoperitoneum can precipitate hypotension with the loss of tamponade.

Step 2: Evacuation of Blood and Packing of the Abdomen

In trauma cases, gross blood and clots are evacuated manually with large laparotomy sponges. All quadrants of the abdomen are then packed with laparotomy pads. Standard suction equipment is not very useful for evacuating large quantities of blood from the abdomen.

Step 3: Control of Splenic Artery

Once other major injuries are excluded, the first decision to be made is whether to control the splenic artery first or to mobilize the spleen to the midline. This decision is dictated by the urgency of the clinical situation, the spleen size, and the presence of underlying disease.

If the decision is made to control the splenic artery first, the main splenic trunk is identified above the pancreas via an approach that leads to the lesser sac either through the gastrocolic ligament or through the avascular plane of the greater omentum above the distal transverse colon. Once dissected, the artery is controlled with a vascular loop. The main artery can also be accessed and dissected posteriorly after the spleen is mobilized [see Figure 18].

Troubleshooting One advantage of dissecting the splenic artery in the lesser sac (as opposed to the hilum) is that the splenic vein is rarely damaged, being located under the pancreas and away from the artery. Good proximal control of the splenic blood supply facilitates the performance of the more complex variations of partial splenectomy or total splenectomy for megasplenes.

Step 4: Mobilization of Spleen

If the decision is made to mobilize the spleen first, as in most trauma cases, mobilization should be carried out in a carefully planned manner; it is all too easy to compound splenic injury with ill-advised maneuvers that obligate the surgeon to perform a total splenectomy.

Gastric decompression is ensured with a properly placed nasogastric tube. The spleen is then retracted anteromedially with the left hand, with care taken to confirm proper retraction of the left abdominal wall. The phrenicocolic ligament is thereby placed on stretch, and the ligament insertion on the lateral abdominal wall serves as countertraction. The phrenicocolic ligament is then incised from the bottom up with either long scissors or the 45°-angle tip of a monopolar cautery [see Figure 19]. Efforts should be made to leave 2 cm of ligament on the spleen side and to avoid capsular injury. If the surgeon cannot put a finger behind the ligament, an assistant should elevate the ligament between the jaws of a right-angle clamp. The incision of the phrenicocolic ligament is then extended to the left crus of the diaphragm. Except in patients with portal hypertension or myeloproliferative disorders, this ligament is avascular. The left lateral portion of the gastrocolic ligament (the greater omentum) is also dissected away from the splenic flexure of the colon to facilitate mobilization of the spleen.

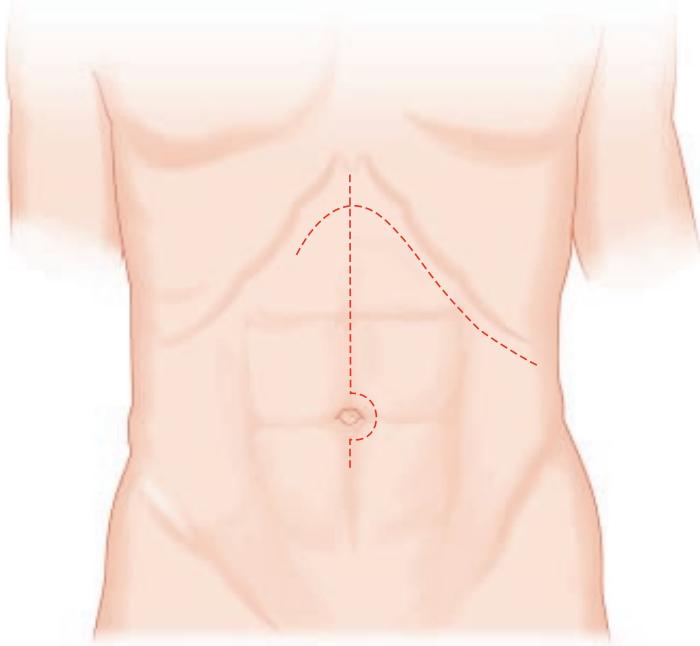

Figure 17 Open splenectomy. Shown are midline and left subcostal incisions.

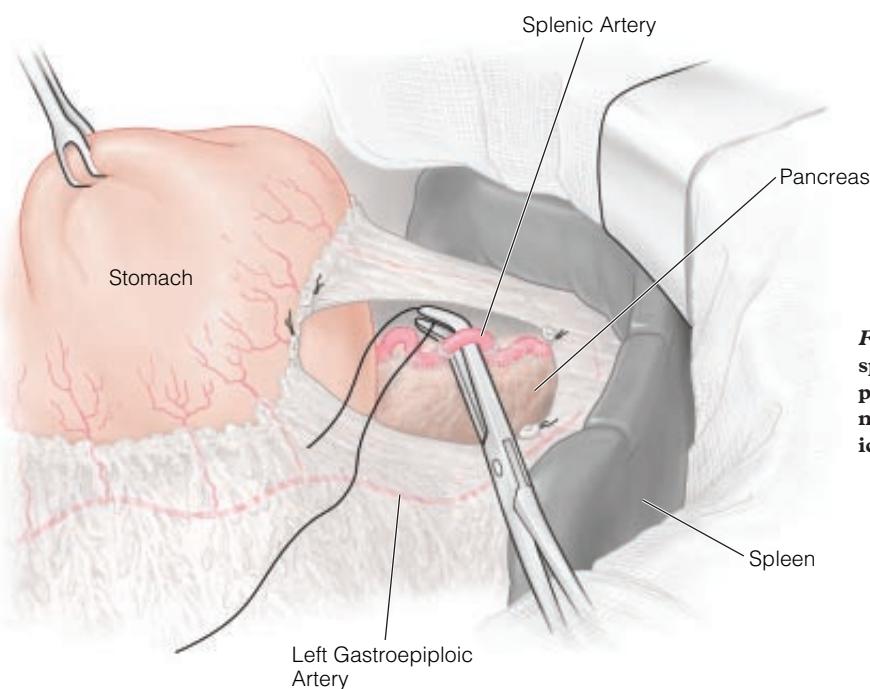

Figure 18 Open splenectomy. The splenic artery is controlled above the pancreas in the lesser sac. The artery must be ligated distal to the pancreatic magna artery.

At this point, the splenocolic ligament and the sustentaculum lienis are left alone.

After complete division of the phrenicocolic ligament, a plane is developed between the pancreas and the retroperitoneal structures with gentle blunt finger dissection. The spleen can then be delivered to the midline, where the splenectomy can be planned in an unhurried manner [see Figure 20]. Continuing splenic bleeding during this maneuver can be controlled with manual compression of the organ. The splenic pedicle may also be gently compressed between the thumb and the index finger at this stage. Laparotomy sponges are placed in the left subphrenic space.

Troubleshooting When performing elective resections of very large spleens, experienced spleen surgeons use a few tricks to simplify the procedure. In most patients with megasplines, the suspensory ligaments have been stretched over time, allowing the surgeon much more leeway in mobilizing or turning the spleen. This greater leeway allows the surgeon to rotate the spleen from the lower pole so as to deliver it transversely into the incision. Thus, the presence of a large spleen does not always necessitate the creation of a long xiphopubic incision, because a transversely placed spleen can be extracted into the abdominal wall through a shorter incision.

Step 5a (Total Splenectomy): Planning of Resection

To devise the appropriate operative strategy, the surgeon performing open total splenectomy must address the same anatomic issues that he or she would if performing laparoscopic total splenectomy—for example, the nature of the splenic blood supply (distributed or bundled) and the distance between the tip of the pancreas and the splenic hilum. The anatomy must be appreciated before the operative strategy can be defined.

Once the spleen has been delivered into the abdominal wall, various techniques may be employed to control the blood supply. The classic approach is to serially clamp, ligate, or suture-ligate the

vessels between curved clamps, starting from the lower pole. Alternatively, the vessels may be controlled with clips.

Troubleshooting We frequently use laparoscopic clip applicators to achieve vascular control in open splenectomy. The long, slender design of these devices is particularly useful in obese patients, in whom it is often difficult to achieve complete mobilization of the spleen without causing additional splenic trauma. With laparoscopic clip applicators, vessels can be safely controlled inside the abdomen. Locking plastic clips may also be used.

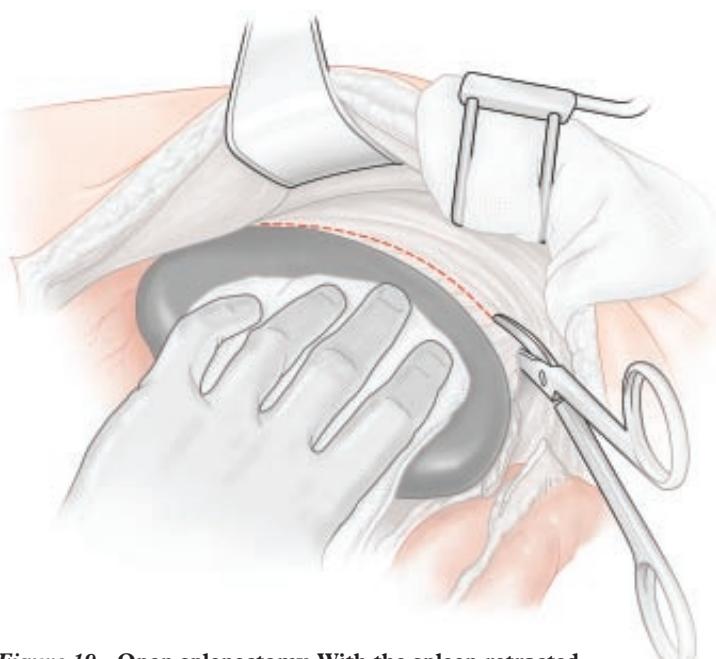

Figure 19 Open splenectomy. With the spleen retracted medially, the phrenicocolic ligament is incised.

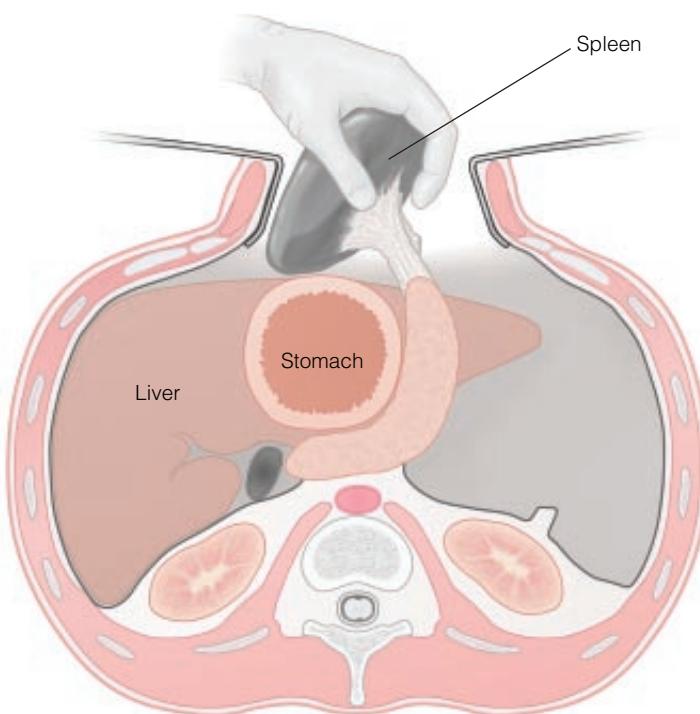

Figure 20 Open splenectomy. The spleen is delivered to the midline by means of blunt and sharp dissection of the areolar plane between the kidney and the pancreas.

Moreover, provided that the same precautions are taken as in laparoscopic splenectomy, a linear stapler with a vascular cartridge may be used to control the hilum in one step once the gastroepiploic branches have been controlled.

Step 5b (Partial Splenectomy): Planning of Resection

Once the spleen is appropriately placed for full evaluation and adequate hemostasis is ensured, planning for partial splenectomy can start. In trauma cases, such planning is guided by the extent of the injury, and in elective cases, it is guided by the nature of the underlying pathologic condition [see Table 3].

In most cases, as noted, the spleen can be divided into independent lobes or segments, each with its own terminal blood supply. The superior pole is supplied by the short gastric vessels, and the lower pole is supplied by branches of the gastroepiploic artery, which are known to form anastomoses with the inferior polar artery. In addition, most patients, possible variations notwithstanding, have two or three major vessels entering the hilum. Thus, there are usually four or five discrete regions or lobes that may be removed, individually or in combination, in a partial splenectomy. It should be kept in mind that the vessels supplying the spleen lie in different supportive ligaments. The vessels supplying the superior pole (the short gastrics) and the inferior pole (the gastroepiploic branches) rest in the gastrosplenic ligament, whereas the splenic branches proper lie in the splenorenal ligament along with the tail of the pancreas.

Step 6 (Partial Splenectomy): Exposure of Entire Hilum and Ligation of Appropriate Arteries

The entire hilum of the spleen is then exposed close to the parenchyma. The gastrosplenic ligament and the splenorenal ligament must be separated, with care taken to preserve the blood supply to both poles of the spleen. There is a fairly avascular area

of the gastrosplenic ligament, between the short gastric vessels supplying the superior pole and the gastroepiploic branches supplying the lower pole, that must be opened; once this is done, a complete view of the entire splenic blood supply is available. The surgeon can then determine whether partial splenectomy is feasible and how many lobes he or she can resect while still leaving enough spleen tissue behind for adequate splenic function. Any number of segmental resections are possible. If the surgeon is unsure of the extent of the necessary resection, an accurate assessment can be made by temporarily compressing the splenic arterial branches.

Selected arterial branches are then carefully dissected as close to the spleen parenchyma as possible, with the understanding that the veins are situated posteriorly in close proximity. The vessels may be doubly ligated, transfixed, or clipped. If clips are used, care is taken not to dislodge them with inappropriate manipulations. Once the arterial blood supply is controlled, the affected area of the spleen will rapidly become visibly demarcated. If the devitalized area of the spleen corresponds to the intended resection, a similar technique is applied to the venous side. Access to the venous side can also be achieved from the posterior aspect of the spleen. When this approach is followed, it is helpful to identify the tail of the pancreas if possible to avoid inadvertent damage: the tail of the pancreas touches the hilum of the spleen in 30% of cases and lies within 1 cm of the hilum in 70%.

Step 7 (Partial Splenectomy): Incision of Splenic Capsule and Partial Resection of Spleen

The capsule of the spleen is incised circumferentially with a scalpel or a monopolar cautery, and a 5 mm rim of devitalized tissue is left in situ. The splenic fragments may be transected with a scalpel, scissors, a monopolar cautery, or a combination thereof. Various techniques have been used to control residual bleeding, including use of a monopolar cautery on spray current; use of a cutaneous ultrasonic surgical aspirator; use of an argon beam

Table 3 Indications and Contraindications for Partial Splenectomy

Indications

Selected grade II–IV splenic injuries with the following:

- Hemodynamic stability
- No evidence of other intra-abdominal organ injury
- No associated head injury
- No coagulopathy
- CT confirmation of isolated splenic injury

Selective elective indications

- Resection of nonparasitic cysts
- Hamartomas and other benign splenic tumors
- Inflammatory pseudotumor of the spleen
- Type I Gaucher disease
- Cholesteryl ester storage disease
- Chronic myelogenous leukemia
- Thalassemia major
- Spherocytosis
- Staging of Hodgkin disease in children

Absolute/relative contraindications in trauma

- Inadequate exposure
- Inability to mobilize spleen and tail of pancreas to midline
- Inability to leave > 25% of splenic mass for complete splenic function

coagulator; suture compression, with or without Teflon pledges; and omental pedicle packing. One low-tech way of dealing with residual hemostatic requirements is to employ the hollow part of a Poole suction device to aspirate blood while employing a coagulating monopolar current on the suction tip. In some cases, wrapping the splenic remnant in an absorbable polyglycolic mesh is useful. Our experience suggests that when enough residual devitalized tissue (i.e., at least 5 mm) is left behind circumferentially, good hemostasis is easily achieved, typically requiring nothing more than simple measures and topical agents. No drains are used unless the tail of the pancreas has been damaged, in which case a closed-suction drain is placed.

POSTOPERATIVE CARE

The principles of postoperative care are essentially the same for open splenectomy as for laparoscopic splenectomy [see Laparoscopic Splenectomy, Postoperative Care, *above*], though most authors agree that the pace of aftercare is slower with the former.

It should be kept in mind that acute postoperative gastric distension occurs more frequently in children and may necessitate more prolonged gastric decompression.

COMPLICATIONS

The complications seen after open splenectomy are the same as those seen after its laparoscopic counterpart [*see Laparoscopic Splenectomy, Complications, above*]. Hemorrhagic complications may necessitate transfusion, reoperation, or both.

Although the rate of serious postoperative infection after splenic surgery is generally considered to be 8%, it is thought to be lower in patients undergoing splenorrhaphy or partial splenectomy. The lower rate is probably attributable to the presence of less severe underlying injuries, rather than to the preservation of splenic tissue. Infectious complications usually manifest themselves between postoperative days 5 and 10 and are typically diagnosed by means of physical examination, chest x-ray, ultrasonography, and CT.

26 ADRENALECTOMY

Abdelrahman A. Nimeri, M.D., and L. Michael Brunt, M.D., F.A.C.S.

The surgical approach to the adrenals has evolved substantially over the past decade with the development and refinement of techniques for performing laparoscopic adrenalectomy. At present, the majority of adrenal tumors are removed laparoscopically because minimally invasive approaches result in reduced pain, faster recovery, and fewer complications and because the rate of adrenal malignancy is low. Nevertheless, open adrenalectomy still has a role in the management of selected patients with large or malignant tumors. With both open adrenalectomy and laparoscopic adrenalectomy, several different surgical approaches to the adrenals are possible [see Operative Planning, Choice of Procedure, below]. Regardless of the particular approach followed, the keys to successful adrenalectomy are the same: proper patient selection for operation, a solid understanding of adrenal pathophysiology, and a thorough knowledge of adrenal anatomy.

Anatomic Considerations

The adrenal glands are retroperitoneal organs that lie along the superomedial aspects of the two kidneys [see Figure 1]. Each gland

comprises two discrete anatomic and functional units: the adrenal cortex, which is the site for synthesis and secretion of cortisol, aldosterone, and adrenal androgens; and the medulla, which is derived from the neural crest and is the site for synthesis of the catecholamines epinephrine and norepinephrine. A normal adrenal gland typically weighs between 4 and 6 g and measures approximately 4 to 5 cm by 2 to 3 cm by 0.5 to 1 cm. The right adrenal is relatively pyramidal in shape, whereas the left is somewhat flattened and is more closely applied to the kidney. Grossly, the adrenals may be distinguished from the surrounding retroperitoneal fat by their golden-orange color, which is a result of the high intracellular lipid content. The glands have a fibrous capsule but are relatively fragile and can be easily cracked or fragmented with surgical manipulation.

RIGHT ADRENAL

Anteriorly, the right adrenal is partially covered by the liver and the right triangular ligament. The gland abuts the inferior vena cava (IVC) medially and may, in part, lie posterior to the lateral aspect of the vena cava. Inferiorly, the adrenal sits just above the

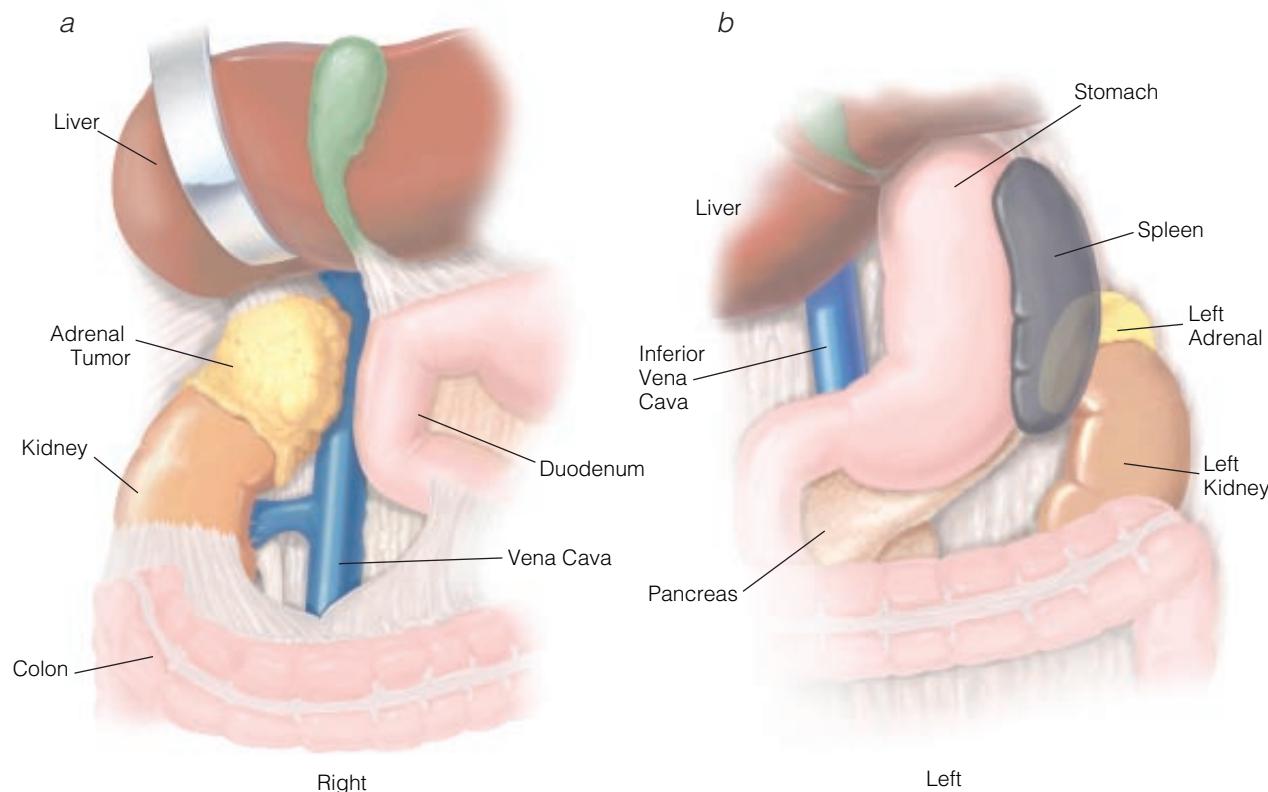

Figure 1 Depicted is the relation of the adrenal glands to adjacent structures. (IVC—inferior vena cava)

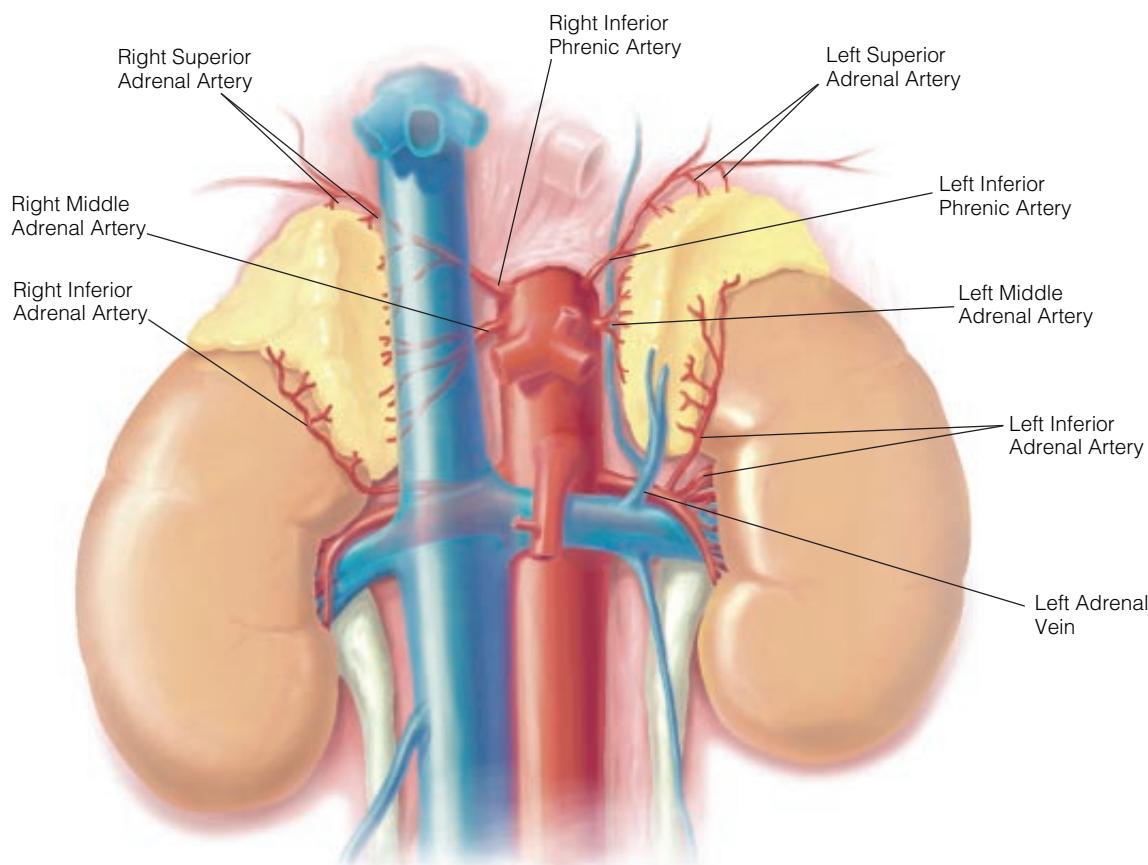

Figure 2 Depicted is the adrenal blood supply. Multiple adrenal arteries are present; a single central adrenal vein drains into the IVC on the right side and the renal vein on the left side.

upper pole of the kidney. The diaphragm forms the posterior and lateral boundaries of the gland.

The blood supply of the right adrenal is derived from branches of the inferior phrenic artery, the right renal artery, and the aorta [see Figure 2]. Typically, multiple small branches enter the gland along its superior, medial, and inferior aspects. Arterial branches from the aorta generally course posterior to the vena cava before entering the adrenal. Each adrenal is drained by a single central vein. On the right, this vein is short (1 to 1.5 cm long), runs transversely, and joins the lateral aspect of the inferior vena cava. In some cases, a more superiorly located accessory adrenal vein may enter either the IVC or one of the hepatic veins. Control of the adrenal vein is the most critical aspect of right adrenalectomy, in that the short course of this vessel makes it susceptible to tearing or avulsion from the IVC.

LEFT ADRENAL

The spleen and tail of the pancreas overlie the anterior and medial borders of the left adrenal. The inferolateral aspect of the gland lies over the superomedial aspect of the left kidney, to which it is more closely applied than the right adrenal is to the right kidney. The inferior aspect of the adrenal is in close proximity to the renal vessels, especially the renal vein. As on the right side, the posterior aspect of the adrenal rests on the diaphragm.

The arterial blood supply of the left adrenal is similar to that of the right adrenal [see Figure 2]. The left adrenal vein is longer than the right adrenal vein and runs somewhat obliquely from the inferomedial aspect of the gland to enter the left renal vein. The inferior phrenic vein courses in a superior-to-inferior direction just

medial to the adrenal and usually joins the left adrenal vein cephalad to its junction with the renal vein.

Preoperative Evaluation

INDICATIONS FOR OPERATION

The main indications for adrenalectomy are well established [see Table 1]. Any adrenal lesion that either is hypersecretory for one of

Table 1 Indications for Adrenalectomy

Aldosteronoma
Cushing syndrome
Cortisol-producing adenoma
Primary adrenal hyperplasia
Failed treatment of ACTH-dependent Cushing syndrome
Pheochromocytoma
Sporadic or familial
Malignant pheochromocytoma
Nonfunctioning incidental lesion
≥ 4–5 cm or atypical radiologic appearance
Adrenal metastasis
Solitary, unilateral in the absence of extra-adrenal cancer
Adrenal cortical carcinoma
Adrenal sarcoma
Adrenal myelolipomas (only if symptomatic or enlarging)
Miscellaneous other lesions (atypical cysts, ganglioneuromas)

the adrenal hormones or appears to be malignant or possibly malignant should be removed. In selected cases, it may be appropriate to remove adrenal metastases if they are solitary and if there is no evidence of extra-adrenal metastatic disease. Nonfunctioning adrenal lesions that appear to be benign on the basis of their size (< 4 cm) and their appearance on computed tomography or magnetic resonance imaging need not be removed unless they enlarge during follow-up. Adrenal myelolipomas and cysts usually can be diagnosed radiographically and should not be removed unless they cause symptoms.

Most of the conditions for which adrenalectomy is indicated are amenable to a laparoscopic approach. However, the role of laparoscopy in patients with large adrenal tumors (> 6 to 8 cm) or potentially malignant primary adrenal lesions remains controversial. In the presence of a locally invasive tumor, a laparoscopic approach is contraindicated because of the need to perform en bloc resection of the tumor and any adjacent involved structures.

COMMON ADRENAL TUMORS

A brief review of the pertinent clinical and biochemical features of the various hypersecretory adrenal tumors [see Table 2] will facilitate evaluation of adrenal lesions (including adrenal incidentalomas) and planning for adrenal surgery.

Aldosteronoma

Primary hyperaldosteronism is the most common form of secondary hypertension, and aldosterone-producing adenoma is the most common hypersecretory adrenal tumor. The prevalence of this diagnosis is much higher than was previously thought,^{1,2} reaching levels as high as 12% of hypertensive individuals in some series.¹ The classic finding in primary hyperaldosteronism is hypertension in conjunction with hypokalemia, but many patients have a normal or low-normal serum potassium level. Therefore, any patient who becomes hypertensive at an early age or who has

malignant or difficult-to-control hypertension should be screened for this diagnosis. Screening consists of measuring plasma aldosterone concentration (PAC) and plasma renin activity (PRA). A PAC-to-PRA ratio higher than 20 to 30, in conjunction with a plasma aldosterone concentration higher than 15 ng/dl, is suggestive of the diagnosis and should be confirmed by measuring 24-hour urine aldosterone levels while the patient is on a high-sodium diet.² A 24-hour urine aldosterone level higher than 12 µg/24 hr in this setting is confirmatory.

Because 25% or more of cases of primary hyperaldosteronism may be idiopathic as a result of bilateral adrenal hyperplasia and should therefore be managed medically and not surgically, the next step should be imaging with thin-section (3 mm cuts) CT or MRI. The finding of a discrete unilateral adenoma larger than 1 cm on CT in conjunction with a normal contralateral adrenal is sufficient localization to allow the surgeon to proceed with adrenalectomy. If CT shows bilateral nodules, bilateral normal adrenals, or a unilateral nodule smaller than 1 cm, then adrenal vein sampling for aldosterone and cortisol should be done to determine whether a unilateral gradient of increased aldosterone production exists.³

Cortisol-Producing Adenoma

Approximately 20% of cases of Cushing syndrome are related to increased production of cortisol by an adrenal cortical tumor. Adrenal Cushing syndrome is most commonly attributable to adenoma but may also result from adrenal cortical carcinoma or primary adrenal hyperplasia. The classic features of full-blown Cushing syndrome are usually obvious and include centripetal obesity, moon facies, hypertension, purple skin striae, proximal muscle weakness, osteopenia, and amenorrhea. Not all patients present with advanced clinical signs, however, and the high prevalence of hypertension and obesity in the general population necessitates liberal use of diagnostic testing.

Table 2 Clinical and Diagnostic Features of Common Adrenal Tumors

Adrenal Tumor	Clinical Presentation	Biochemical Testing	Preferred Method of Imaging/Localization
Aldosteronoma	Hypertension ± hypokalemia	Elevated PAC with suppressed PRA (PAC:PRA > 20–30) Urine aldosterone > 12 µg/24 hr Urine potassium > 30 mEq/24 hr	Thin-section (3 mm) adrenal CT Adrenal vein sampling
Cortisol-producing adenoma (Cushing syndrome)	Centripetal obesity, moon facies, hypertension, purple skin striae, osteopenia, plethora, amenorrhea	Elevated 24-hr urinary free cortisol Nonsuppressing low-dose dexamethasone test Decreased plasma ACTH	Abdominal CT
Pheochromocytoma	Severe episodic hypertension or hypertension with spells of tachycardia, headache, anxiety, and diaphoresis	Elevated plasma fractionated metanephrenes or urinary catecholamines and metabolites	MRI (T_2 -weighted sequences showing bright-appearing adrenal lesion) ^{123}I -MIBG scan or Octreoscan if MRI is negative or if malignant or extra-adrenal tumor is suspected
Adrenal cortical carcinoma	Cushing syndrome, virilizing features, local pain or mass	24-hr urinary free cortisol and metabolites Plasma DHEA-sulfate	CT of chest/abdomen/pelvis
Adrenal metastasis	None (often seen on follow-up imaging) or local pain	Plasma fractionated metanephrenes and low-dose DM test to exclude functioning lesion FNA biopsy only if unresectable	Abdominal CT, PET imaging to evaluate for extra-adrenal metastatic disease
Myelolipoma	None; occasionally local pain	None if radiographic appearance is unequivocal for myelolipoma	Presence of macroscopic fat on CT or MRI

ACTH—adrenocorticotropic hormone DHEA—dehydroepiandrosterone DM—dexamethasone FNA—fine-needle aspiration MIBG—meta-iodylbenzylguanidine PAC—plasma aldosterone concentration PET—positron emission tomography PRA—plasma renin activity

Figure 3 Laparoscopic adrenalectomy: transabdominal approach. The patient is placed in a lateral decubitus position with the affected side up (here, right lateral decubitus for left adrenalectomy).

Suspected Cushing syndrome should be evaluated initially by measuring 24-hour urinary free cortisol levels or by administering a single low-dose dexamethasone test. If plasma cortisol does not fall to a level below 3 to 5 µg/dl the morning after administration of 1 mg of dexamethasone at 11 P.M., Cushing syndrome is a strong possibility and further testing is required. Once the diagnosis of hypercortisolism is established, plasma levels of adrenocorticotrophic hormone (ACTH) should be measured to differentiate ACTH-dependent (resulting from increased ACTH production by a pituitary tumor or an ectopic source) from ACTH-independent (primary adrenal) causative conditions. The plasma ACTH level should be in the low-normal or suppressed range in patients with primary adrenal tumors, whereas it is normal or elevated in patients with ACTH-dependent Cushing syndrome. Imaging should then be carried out with CT (or MRI) to localize the adrenal tumor.

Pheochromocytoma

Pheochromocytoma should be suspected in any patient who experiences either severe episodic hypertension or hypertension that is associated with spells of tachycardia, headache, anxiety, and diaphoresis. Biochemical evaluation consists of measuring urinary concentrations of catecholamines and metabolites (e.g., metanephrine and normetanephrine), plasma concentrations of fractionated metanephries, or both. MRI is our preferred imaging modality for suspected pheochromocytomas because of the typical bright appearance these tumors exhibit on T₂-weighted imaging sequences. Occasionally, radionuclide imaging with iodine-123-metiodylbenzylguanidine (¹²³I-MIBG) or octreotide scintigraphy is necessary to localize an extra-adrenal pheochromocytoma.

Adrenocortical Carcinoma

Adrenocortical carcinomas are rare, with an incidence of approximately one per 1.5 to 2.0 million in the general population. These tumors are typically large (> 6 to 8 cm) at diagnosis, and most patients have advanced (stage III or IV) disease at presentation. Consequently, patients often have a mass or complain of abdominal or back pain. A significant percentage of patients with adrenocortical carcinoma present with evidence of hormone overproduction in the form of Cushing syndrome or virilizing features. Complete surgical resection offers the only chance for cure; thus,

the role of laparoscopic adrenalectomy in the treatment of adrenocortical carcinoma remains controversial [see Troubleshooting, Large Tumors, *below*].

Adrenal Incidentaloma

Adrenal incidentalomas are the adrenal lesions most frequently referred to surgeons and are seen on 1% to 5% of all abdominal CT scans.⁴ Practical, current recommendations for evaluation and management of patients with incidentally discovered adrenal lesions are available.⁵ The most common adrenal incidentaloma is a nonfunctioning cortical adenoma for which adrenalectomy is not usually required. All patients with adrenal incidentalomas should be screened for hypercortisolism by administering an overnight low-dose dexamethasone test and for pheochromocytoma by measuring plasma concentrations of fractionated metanephries or urine levels of catecholamines and metanephries. Patients who are hypertensive or hypokalemic should also undergo testing for hyperaldosteronism with measurement of plasma aldosterone and renin levels. Some patients with adrenal incidentalomas are found to have subclinical Cushing syndrome with evidence of autonomous corticoid steroid production, as demonstrated by lack of suppressibility with a dexamethasone test and by low plasma ACTH levels.⁶ These patients do not exhibit the classic features of Cushing syndrome but do have a high incidence of hypertension, diabetes, and osteoporosis. Adrenalectomy is generally indicated if the operative risk is suitably low. Supplemental corticosteroids should be given before, during, and after operation because contralateral adrenal function is often suppressed and adrenal insufficiency may ensue.

The nonfunctioning adrenal lesion should also be assessed for malignant potential on the basis of its size and appearance on diagnostic imaging. Cortical adenomas typically have low attenuation values (< 10 Hounsfield units) on unenhanced CT imaging and show loss of signal intensity on MRI chemical-shift imaging sequences. Needle biopsy is not useful in differentiating benign from malignant primary adrenal lesions and is rarely indicated. Adrenal biopsy should never be done unless a pheochromocytoma has first been excluded biochemically. Most experts recommend removing any nonfunctioning adrenal lesion larger than 4 to 5 cm unless the radiographic appearance of the lesion is diagnostic of a cyst or myelolipoma. Smaller tumors should be followed with imaging at 4 and 12 months after the initial presentation.

Operative Planning

PREPARATION FOR OPERATION

Preoperative preparation of the patient for adrenalectomy entails control of hypertension and correction of any electrolyte imbalances. Patients with a pheochromocytoma should receive 7 to 10 days of alpha-adrenergic blockade with phenoxybenzamine to minimize any exacerbation of hypertension during the operation. The usual starting dosage is 10 mg twice daily, which is increased by 10 to 20 mg/day until the hypertension and tachycardia are controlled and the patient is mildly orthostatic. Patients with Cushing syndrome or subclinical Cushing syndrome should receive perioperative dosages of stress steroids. Mechanical bowel preparation is not routinely employed.

CHOICE OF PROCEDURE

The retroperitoneal location of the adrenals renders them accessible via either transabdominal or retroperitoneal approaches. The choice of surgical approach in any given patient depends

on a number of factors, including the nature of the underlying adrenal pathology, the size of the tumor, the patient's body habitus, and the experience of the operating surgeon. For the vast majority of adrenal lesions, laparoscopic adrenalectomy is preferred. Most centers favor the transabdominal lateral approach to laparoscopic adrenalectomy,⁷ which has the advantages of a large working space, familiar anatomic landmarks, and widespread success. Some centers, however, prefer a retroperitoneal endoscopic approach.^{8,9} The advantages of this technique are that the peritoneal cavity is not entered, there is no need to retract overlying organs, and the incidence of postoperative ileus may be lower. The disadvantages are that the retroperitoneal approach employs a smaller working space, is more difficult to learn with fewer anatomic landmarks for orientation, and is usually restricted to tumors smaller than 5 cm.

The only absolute contraindications to laparoscopic adrenalectomy are local tumor invasion and the presence of regional lymphadenopathy. A large tumor (> 8 to 10 cm), a suspected primary adrenal malignancy, and a history of previous nephrectomy, splenectomy, or liver resection on the side of the lesion to be removed are all indicators that a case is likely to be more difficult and should be considered relative contraindications to a laparoscopic approach in all but the most experienced hands. Portal hypertension is also a contraindication to a laparoscopic approach because of the dilated collateral vessels in the retroperitoneum.

Options for open adrenalectomy include transabdominal, flank, posterior retroperitoneal, and thoracoabdominal approaches. The lateral flank approach and the posterior retroperitoneal approach have been replaced by laparoscopic approaches and are now rarely used. A posterior retroperitoneal adrenalectomy is done through a hockey-stick incision in the back, with subperiosteal resection of the 12th rib. This approach has low morbidity and yields adequate exposure of the adrenal gland, but the visual field is often limited, and there is a high incidence of residual incisional complaints. The current consensus is that open posterior retroperitoneal adrenalectomy is indicated only in patients who require bilateral adrenalectomy but are not candidates for laparoscopic adrenalectomy. Most large or malignant adrenal tumors that necessitate an open approach can be removed via an anterior abdominal incision, usually a unilateral or bilateral subcostal incision (with subxiphoid extension if necessary); a thoracoabdominal incision is rarely needed.

Operative Technique

LAPAROSCOPIC ADRENALECTOMY

Transabdominal Approach

Patient positioning A gel-padded bean-bag mattress is placed on the operating table before the patient enters the room. The patient is placed in the supine position, general anesthesia is induced, and sequential compression stockings are placed. A urinary catheter is inserted for monitoring of urine output, and the stomach is decompressed with an orogastric tube. Invasive monitoring is not usually necessary unless the patient has a vasoactive pheochromocytoma, in which case an arterial line is routinely placed.

Next, the patient is moved into a lateral decubitus position with the affected side up [see Figure 3]. A soft roll is placed underneath the chest wall to protect the axilla. The bean-bag mattress is molded around the patient and the legs are wrapped in a foam pad to minimize all pressure points. The patient is secured to the operating table with tape placed across the padded lower extremities and a safety strap across the pelvis. The operating table is then flexed at the waist. The combination of the lateral position, the flexed operating table, and the reverse Trendelenburg position facilitates placement of the laparoscopic ports and provides optimal access to the superior retroperitoneum.

Equipment Our preferred instrumentation for laparoscopic adrenalectomy is as follows [see Table 3]. An angled (30°) laparoscope, preferably 5 mm in diameter, is used to optimize viewing angles. One 10/12 mm port is employed to allow insertion of a clip applier and extraction of the specimen; the other ports can all be 5 mm if a 5 mm laparoscope is employed. The principal instruments needed for dissection and hemostasis are atraumatic graspers, an L-hook electrocautery, and a medium-large clip applier. An ultrasonic coagulator is not essential for a right adrenalectomy, but it may facilitate mobilization of the splenic ligaments and dissection of the adrenal from the retroperitoneal fat during a left adrenalectomy. An endovascular stapler should be available for a right adrenalectomy because it will occasionally be needed to divide the right adrenal vein. Other essential items are a suction-irrigation device and an impermeable specimen retrieval bag.

Initial access and placement of trocars Because the patient is in a lateral position, initial access to the peritoneal cavity is usually achieved in a closed fashion with a Veress needle. After insufflation to a pressure of 15 mm Hg, a 5 mm direct-view trocar is placed to afford direct visualization of the peritoneal cavity. An open insertion technique may be used instead, but this approach requires a larger incision and is hindered somewhat by the bulky overlapping muscle layers in the subcostal region. Open insertion at the umbilicus is an option in some patients.

The initial access site is generally at or somewhat medial to the anterior axillary line about two fingerbreadths below the costal margin [see Figure 4]. Subsequent ports should be placed at least 5 cm apart to allow freedom of movement externally. The most dorsal port should be approximately at the posterior axillary line. It is helpful to outline the anterior and posterior axillary lines with a marker before the patient is prepared to ensure that the ports are positioned properly. Whereas four ports are required for a right adrenalectomy, a left adrenalectomy can be done with either three or four ports, depending on the surgeon's preference and experience. On the left side, the splenic flexure of the colon usually must be mobilized before the fourth port (the most dorsal one) can be inserted.

Figure 4 Laparoscopic adrenalectomy: transabdominal approach. Shown is the recommended port site placement for laparoscopic adrenalectomy (here, left adrenalectomy). Dashed lines indicate the costal margin and the anterior and posterior axillary lines.

Right adrenalectomy *Step 1: exposure of right adrenal gland and vein.* The key to exposure of the right adrenal gland is extensive division of the right triangular ligament of the liver. This maneuver should be continued until the liver can be easily elevated and retracted medially and both the right adrenal and the IVC are visible. A retractor is then inserted through the most medial port to hold the right lobe of the liver up and away from the operative site.

Next, the plane between the medial border of the adrenal and the lateral aspect of the IVC is developed. An L-hook cautery is used for gentle elevation and division of the peritoneum and the small arterial branches here [see Figure 5]. The adrenal is pushed laterally with an atraumatic grasper to apply traction to the dissection site; however, the gland itself should not be grasped, because it is fragile and the capsule and adrenal parenchyma are easily fractured. At all times, it is imperative to know where the lateral border of the IVC is, both to ensure that the dissection is extra-adrenal and to avoid injuring the IVC. The right adrenal vein should come into view as the medial border is dissected.

Step 2: isolation, clipping, and division of right adrenal vein. The right adrenal vein is first exposed by gentle blunt spreading, and a right-angle dissector is then used to isolate enough of the vein's length to permit clip placement [see Figure 6]. A medium-large clip is usually sufficient for securing the vein, though sometimes it is necessary to use larger clips or even an endovascular stapler. (We use an endovascular stapler primarily in cases in which the tumor is located in the medial area of the adrenal and the vein must be taken along with a portion of the IVC junction.) Usually, two clips are placed on the IVC side and one or two on the adrenal side, depending on the length of vein available. Meticulous hemostasis throughout the dissection is important: even minimal bleeding will stain the tissue planes and make the dissection more difficult and potentially treacherous.

Step 3: mobilization and detachment of specimen. Once the adrenal vein is divided, dissection is continued superiorly and inferiorly with the L-hook cautery. The numerous small arteries that enter the gland at its superior, medial, and inferior margins can be

safely cauterized, but larger branches may have to be clipped. Superiorly, as the adrenal is mobilized, the musculature of the posterior diaphragm is exposed and serves as a marker of the proper plane for the posterior dissection. Inferiorly, the dissection should stay close to the margin of the adrenal so as not to injure branches of the renal hilar vessels. The inferior dissection then proceeds in a medial-to-lateral direction as the gland is elevated off the superior pole of the right kidney. The remaining attachments to the back muscles and the retroperitoneal fat are relatively avascular and can be divided with the electrocautery.

Once the specimen has been detached, it is placed in an impermeable bag. The retroperitoneum is then irrigated and inspected for hemostasis and for secure placement of the clips on the IVC.

Step 4: extraction of specimen. The fascial opening at the 10/12 mm port site is enlarged somewhat, and the specimen bag is removed through this site. For larger tumors, a remote extraction site (e.g., the umbilicus or the suprapubic region) may be a preferable alternative. Large pheochromocytomas may be morcellated within the entrapment bag and removed piecemeal, but ideally, cortical tumors and metastatic lesions should be extracted intact to permit full pathologic examination.

Left adrenalectomy *Step 1: exposure of left adrenal gland and vein.* The splenic flexure of the colon is mobilized. The lateral attachments of the flexure are divided to allow placement of the fourth port (if needed), and the colon is then released from the

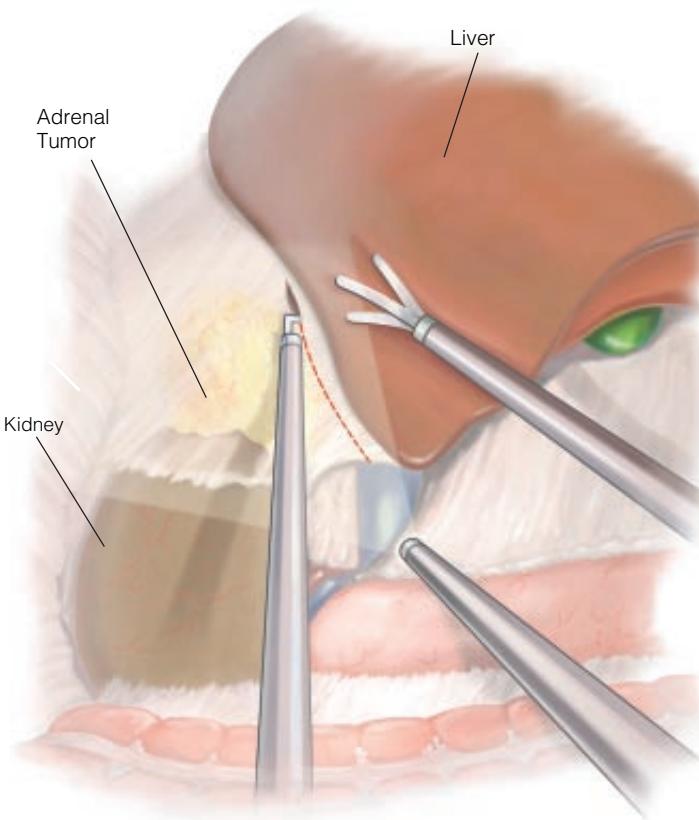

Figure 5 Laparoscopic right adrenalectomy: transabdominal approach. Depicted is the anatomic exposure for right adrenalectomy. The liver is retracted medially, and the right triangular ligament of the liver is divided with an L-hook electrocautery.

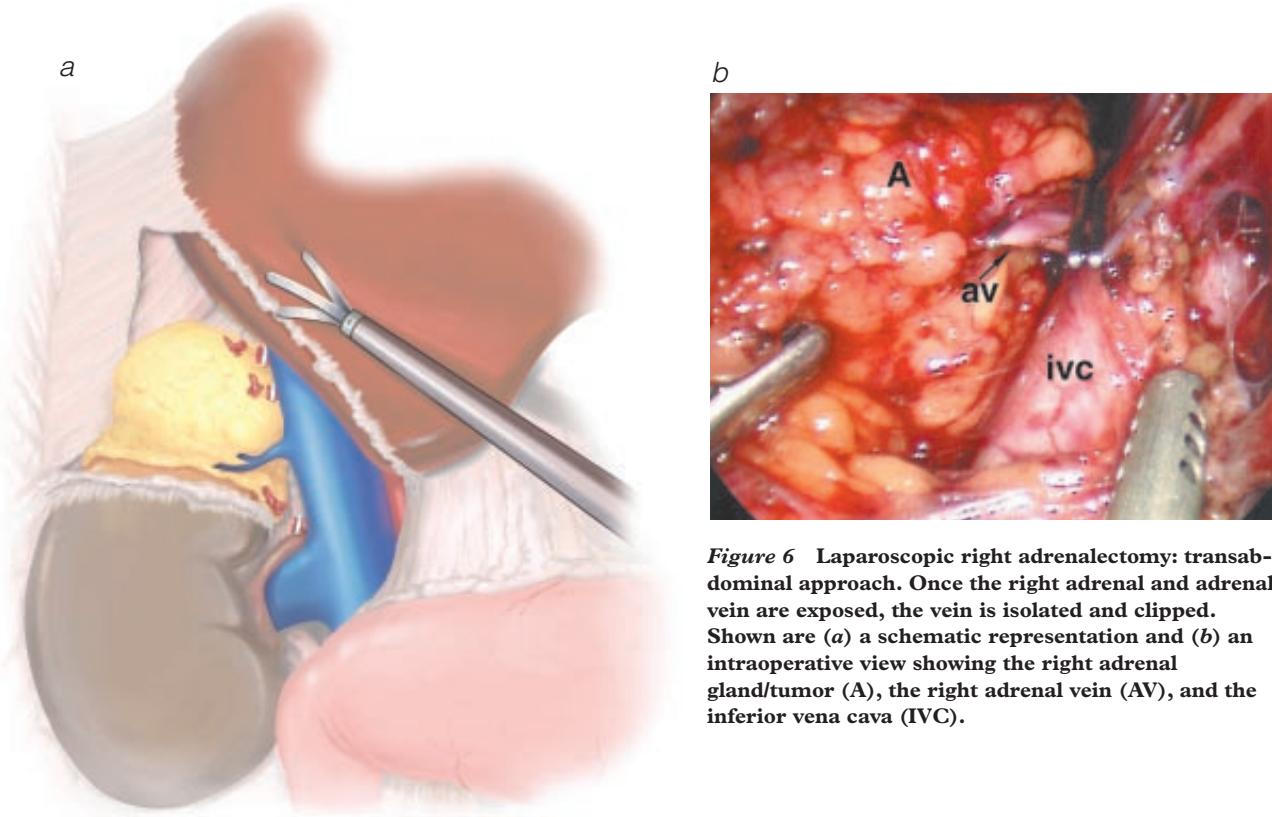

Figure 6 Laparoscopic right adrenalectomy: transabdominal approach. Once the right adrenal and adrenal vein are exposed, the vein is isolated and clipped. Shown are (a) a schematic representation and (b) an intraoperative view showing the right adrenal gland/tumor (A), the right adrenal vein (AV), and the inferior vena cava (IVC).

inferior pole of the spleen and away from the left kidney. Next, the splenorenal ligament is incised from the inferior pole of the spleen to the diaphragm to allow full medial rotation of the spleen and provide access to the left retroperitoneum [see Figure 7]. It is important not to dissect lateral to the kidney; doing so will cause the kidney to tilt forward and will interfere with exposure. Once the spleen is completely mobilized, it should fall medially, with minimal or no retraction needed to keep it out of the operative field. Division of the ligaments can be accomplished more quickly and with less bleeding if an ultrasonic coagulator is used.

At this point in the dissection, the tail of the pancreas should be visible, along with the splenic artery and vein. The plane between the pancreas and the left kidney is then developed. The adrenal is located on the superomedial aspect of the kidney just cephalad to the tail of the pancreas and should be visible at this point unless there is a great deal of retroperitoneal fat (as is often the case in patients with Cushing syndrome). If the adrenal gland is not readily visible, laparoscopic ultrasonography should be employed to help locate it and to delineate the surrounding anatomy, particularly the upper kidney and the renal hilar vessels. If the dissection starts too low, the renal hilar vessels or the ureter could be injured.

Once the adrenal is visualized, the medial and lateral borders are usually defined by means of dissection with the hook cautery and division of areolar attachments and small vessels. The dissection is then continued inferiorly to locate the adrenal vein as it exits the inferomedial border of the gland [see Figure 8]. The inferior border of the adrenal often sits adjacent to the left renal vein, from which it can be separated by means of gentle blunt dissection and judicious use of the electrocautery.

Step 2: isolation, clipping, and division of left adrenal vein. Once the adrenal vein has been visualized, it is isolated, doubly clipped, and divided. Because the adrenal vein is usually joined by the inferior phrenic vein cephalad to its junction with the renal vein, it is

often necessary to clip the inferior phrenic vein again as the dissection proceeds more proximally.

Step 3: mobilization and detachment of specimen. Once the left adrenal vein has been securely clipped and divided, the dissection is continued cephalad along both the lateral and the medial borders of the gland. Because of the surrounding retroperitoneal fat, it is advisable to use the ultrasonic coagulator for this part of the left-side dissection. Because the left adrenal is more flattened out on the superomedial aspect of the left kidney than the right adrenal is on the right kidney, more of the kidney will be exposed during dissection in a left adrenalectomy than in a right adrenalectomy. Finally, the posterior and superior attachments to the diaphragm and the retroperitoneal fat are divided.

Step 4: extraction of specimen. Once the gland is free, the retroperitoneum is inspected and the specimen extracted as in a right adrenalectomy. If there is any possibility that the pancreatic parenchyma may have been violated, a closed suction drain is left in place.

Retroperitoneal Approach

Retroperitoneal endoscopic adrenalectomy can be carried out with the patient in either a lateral or a prone position. In general, this technique is more challenging to learn than transabdominal adrenalectomy, the working space is more cramped, and it is easier for surgeons to become disoriented unless they have experience working in the retroperitoneum. On the other hand, the retroperitoneal approach allows surgeons to avoid having to reposition patients for bilateral adrenalectomy (if the prone position is used), and it may simplify access in patients who have previously undergone extensive upper abdominal procedures.

Initial access is usually achieved through open insertion of a 12 mm port into the retroperitoneum either (1) just lateral or inferi-

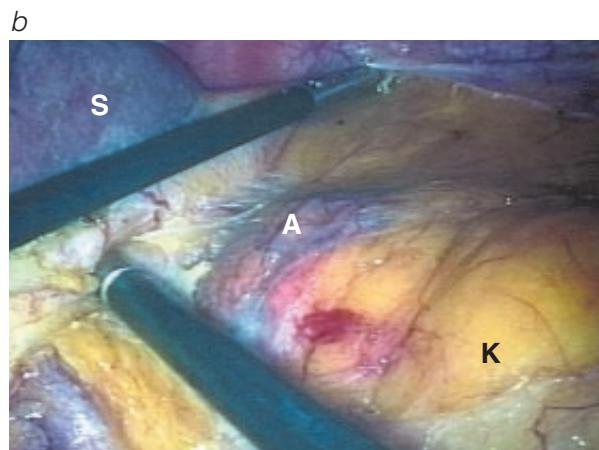

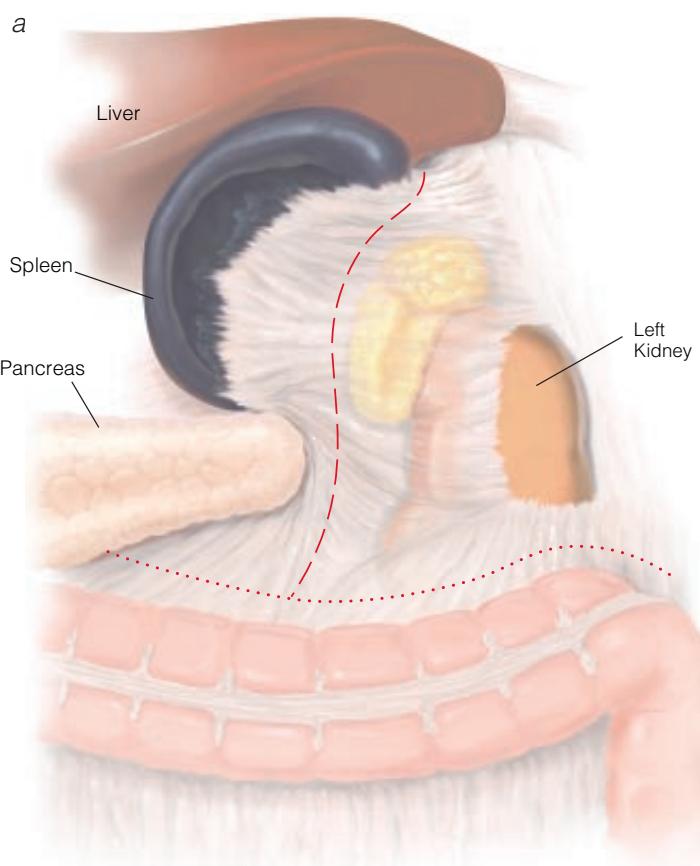

Figure 7 Laparoscopic left adrenalectomy: transabdominal approach. Depicted is the anatomic exposure for left adrenalectomy. (a) The splenic flexure of the colon is divided first (dotted line), and the splenorenal ligament is then divided (dashed line). (b) Shown is an intraoperative view. (S—spleen; A—adrenal; K—kidney)

or to the tip of the 12th rib (for the prone position) or (2) in the midaxillary line about 3 cm above the iliac crest (for the lateral position). A potential advantage of the lateral approach is that it can be converted to a transperitoneal approach if difficulty is encountered.

Once the retroperitoneum is entered, a balloon device is deployed to create an initial working space, which is further developed by means of CO₂ insufflation and blunt dissection. The second and third ports are then placed [see Figure 9]. The principles of dissection are the same as in a transabdominal adrenalectomy [see Transabdominal Approach, *above*]. Laparoscopic ultrasonography may be useful for defining the upper portion of the kidney and the adrenal gland and tumor.

OPEN ADRENALECTOMY

Of the four approaches to open adrenalectomy [see Operative Planning, Choice of Procedure, *above*], the anterior transabdominal approach is the preferred method for any tumors that are too large to be removed laparoscopically and for all invasive adrenal malignancies. The incision most commonly used is an extended unilateral or bilateral subcostal incision, though a midline incision is also an option [see Figure 10]. The extended subcostal incision yields exposure of both adrenal glands, as well as the rest of the peritoneal cavity. If necessary, it may be extended superiorly in the midline to the xiphoid to provide better upper abdominal exposure for full mobilization of the liver and access to the hepatic veins and the vena cava. The exposure obtained with this incision is sufficient for all but the most extensive adrenal malignancies. If the tumor involves the vena cava, the incision may be extended into a median sternotomy to provide access to the superior vena cava and the heart. The classic thoracoabdominal incision, which extends from the abdomen up through the seventh or eighth inter-

costal space and through the diaphragm, provides excellent exposure but is associated with increased incision-related morbidity and is rarely used.

Much of the exposure and dissection is the same as in a laparoscopic adrenalectomy; however, because open adrenalectomy is often employed for removal of particularly large tumors, some additional maneuvers may be necessary to achieve adequate exposure and vascular control. For example, it may be helpful to elevate the flank with a roll or a bean-bag mattress and then flex the operating table to open up the space between the costal margin and the iliac crest. Once the abdomen is entered, exploration is carried out for the presence of metastatic disease.

Exposure of the adrenal on the right side is achieved by dividing the right triangular ligament of the liver, as in the laparoscopic approach. The hepatic flexure of the colon is also reflected inferiorly. With large tumors, a Kocher maneuver should be performed to afford better exposure of the vena cava and the renal vessels. The remainder of the dissection proceeds in much the same manner as in a laparoscopic right adrenalectomy. For suspected adrenal malignancies, a wide resection should be carried out, with removal of periadrenal fat and lymphatic tissue and any suspicious lymph nodes. For tumors that appear to involve the vena cava, vascular control of both the IVC proximal and distal to the tumor and the renal veins should be achieved before the lesion is removed.

Open left adrenalectomy entails mobilization of the splenic flexure of the colon and division of the splenorenal ligament. The spleen, the tail of pancreas, and the stomach are reflected medially en bloc to expose the left kidney and the left adrenal. The left adrenal vein is ligated with clips or silk ties near its junction with the renal vein. The remainder of the dissection proceeds as in a laparoscopic left adrenalectomy. For left-side primary adrenal

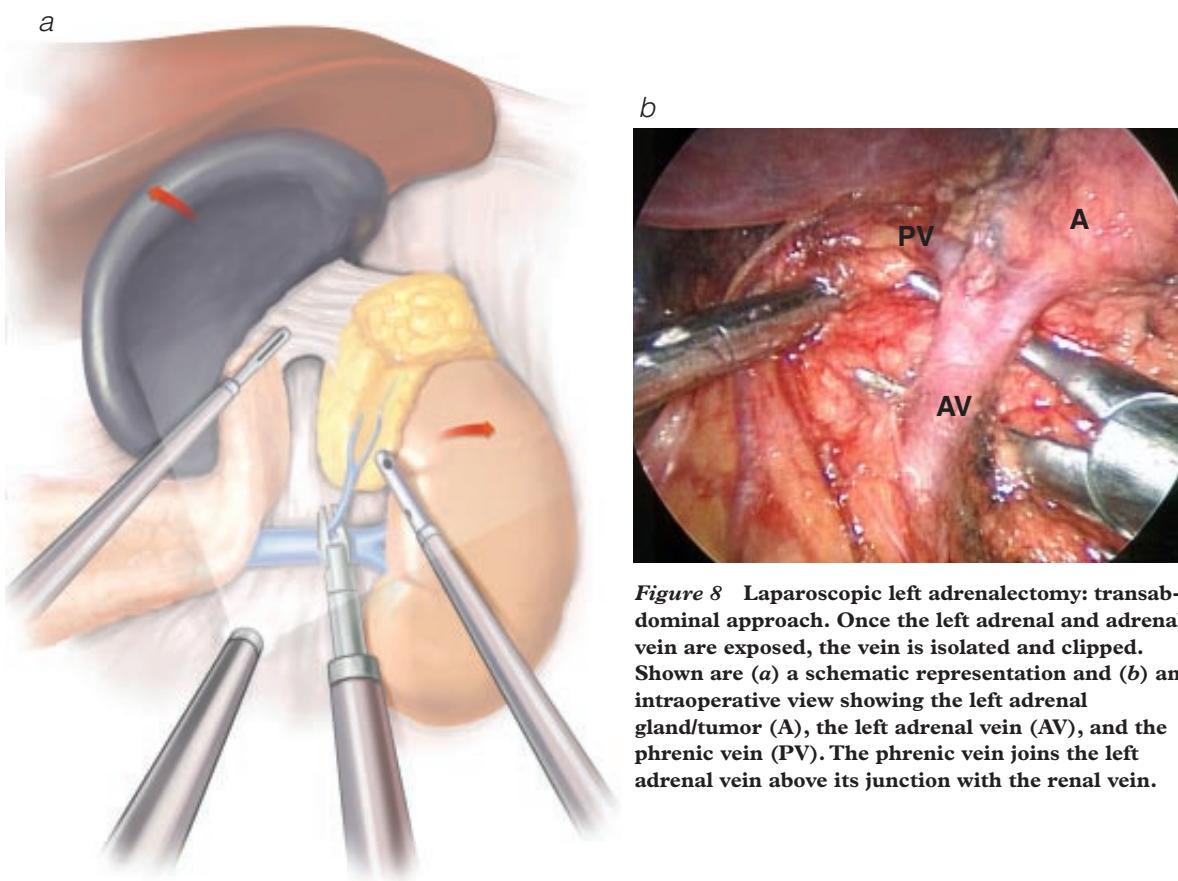

Figure 8 Laparoscopic left adrenalectomy: transabdominal approach. Once the left adrenal and adrenal vein are exposed, the vein is isolated and clipped. Shown are (a) a schematic representation and (b) an intraoperative view showing the left adrenal gland/tumor (A), the left adrenal vein (AV), and the phrenic vein (PV). The phrenic vein joins the left adrenal vein above its junction with the renal vein.

malignancies, periaortic lymphatic vessels and lymph nodes should be removed along with the specimen. If a large left-side tumor is invading adjacent structures, removal may require en bloc resection of the spleen, the distal pancreas, and the kidney.

Troubleshooting

INABILITY TO LOCATE ADRENAL

The adrenal is usually not difficult to find on the right side, where it should be visible once the right hemiliver has been mobilized. Important landmarks on that side are the IVC, which is medial to the adrenal, and the kidney, which is inferior to the adrenal. Once these structures have been identified, the location of the adrenal should be apparent. In contrast, the adrenal can be difficult to find on the left side, especially if the tumor is small or the patient is obese. To locate the left adrenal, the splenorenal ligament should be fully divided, and then the plane between the kidney and the tail of the pancreas should be developed, with the tail of the pancreas rotated medially. As dissection proceeds superiorly, the adrenal can be visually distinguished from the retroperitoneal fat by its golden-orange appearance. If the adrenal is not yet visualized at this point, laparoscopic ultrasonography should be used to verify the locations of the superior pole of the left kidney and the renal vessels. Ultrasonography should also be able to image the adrenal gland and tumor within the retroperitoneal fat [see Figure 11].

BLEEDING

The best means of managing bleeding problems during adrenalectomy is prevention. Important measures for minimizing bleed-

ing risk include obtaining good exposure of the operative field and employing meticulous dissection and gentle handling of the adrenal and surrounding structures. When bleeding does occur, it may be from the adrenal veins, the adrenal gland itself, the IVC, the renal veins, the liver, the pancreas, the spleen, or the kidney. For bleeding during laparoscopic adrenalectomy, the first maneuver should be to tamponade the bleeding site with anatraumatic instrument. If this maneuver is successful, dissection should be directed away from the bleeding site for a while, until better exposure of the area can be obtained. Major hemorrhage from the IVC or the renal veins that is not immediately controlled should be managed by prompt conversion to open adrenalectomy (see below). Lesser bleeding may also be an indication for conversion to open adrenalectomy if it obscures the tissue planes and thereby increases the risk of inadvertent entry into the adrenal gland or tumor.

CONVERSION TO OPEN ADRENALECTOMY

Conversion to open adrenalectomy may sometimes be necessary because of bleeding, failure to progress with the dissection, or a locally invasive tumor. If the patient is in the lateral decubitus position, conversion may be accomplished by means of a subcostal incision extended into the flank. With the patient on a bean-bag mattress, the operating table can be rotated out of the straight lateral plane so that the patient comes to occupy more of a hemilateral position. If the procedure is a bilateral adrenalectomy, then either a bilateral subcostal incision or a midline incision may be employed after the patient has first been returned to more of a supine position. For this reason, it is important to extend the initial preparation and draping past the midline of the abdomen. Alternatively, if the conversion is not being done on an urgent

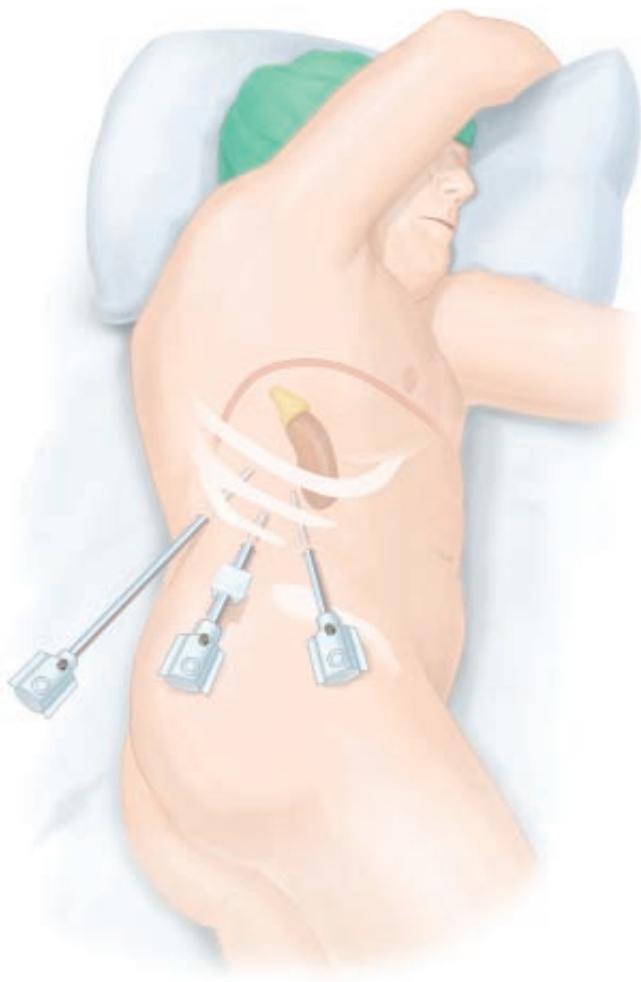

Figure 9 Laparoscopic left adrenalectomy: retroperitoneal endoscopic approach. Shown is the recommended port site placement.

basis because of bleeding, the port sites may be closed, and the patient may then be moved into the supine position, reprepared, and redraped.

An option that may be considered before conversion to an open procedure is the use of a hand access port. A hand-assisted technique may be particularly useful for larger, noninvasive tumors that are harder to manipulate with laparoscopic instruments. The location of the incision for the hand port may vary according to the patient's body habitus; generally, however, an ipsilateral subcostal location medial to the working ports allows adequate hand access while preserving visualization through the more lateral ports.

LARGE TUMORS

Large adrenal tumors (> 6 to 8 cm) are more difficult to remove than smaller ones because they are bulkier and more vascular and because they are harder to manipulate and retract. Accordingly, the dissection should stay extra-adrenal, and care must be exercised during manipulation to avoid entering the tumor. Although surgeons have not yet had a great deal of experience with hand-assisted laparoscopic adrenalectomy, it appears that this approach may be useful for exposure and retraction of large tumors and may facilitate extraction of large specimens. Laparoscopic ultrasonography should also be employed to verify that the tumor is well circumscribed and noninvasive. Surgeons who attempt to remove large adrenal tumors laparoscopically should be highly experienced in laparoscopic adrenalectomy techniques.

For large invasive adrenal malignancies, an open approach, involving a generous bilateral subcostal incision, is indicated, and the chest should be prepared in case a thoracoabdominal or median sternotomy extension proves necessary. The important principles are to obtain wide exposure of the operative field and to control all major vessels that may be involved before removing the tumor.

OBESE PATIENTS

Obese patients present a particular challenge during adrenalectomy, for several reasons: initial access is more difficult; retraction and exposure are more challenging; and the copious amount of retroperitoneal fat makes it difficult to identify the adrenal and to clearly define the margins of the gland within the retroperitoneum. Our practice is to attempt to gain initial access to the peritoneal cavity by using a closed Veress needle technique. Because resting intra-abdominal pressure may be higher in obese patients, especially if they are in the lateral position, it may be necessary to increase the CO_2 pressure to 20 mm Hg temporarily until the first trocar is inserted. If it proves difficult to establish pneumoperitoneum with the Veress needle technique, the initial trocar should be placed at the umbilicus by means of an open insertion technique. The subcostal and flank ports are then inserted in the usual locations under direct vision.

On the right side, the presence of a bulky, fatty liver should be anticipated, and the locations of the port sites should be adjusted accordingly by placing them somewhat more caudad. Ample time should be taken to mobilize the liver fully so that the adrenal and the IVC can be safely accessed. On the left, the ports may be placed in the standard locations. The splenic flexure should be

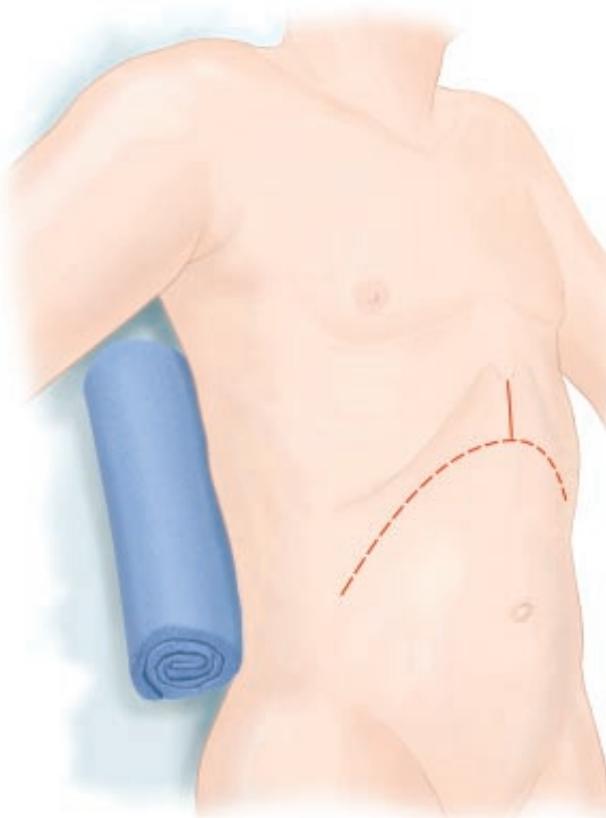

Figure 10 Open adrenalectomy. The procedure is generally done through a unilateral or bilateral subcostal incision. For better exposure for large adrenal malignancies, the incision may be extended cephalad in the midline.

Figure 11 If the left adrenal proves difficult to find, laparoscopic ultrasonography may be employed to locate the gland and the lesion within the retroperitoneal fat. This laparoscopic ultrasonogram shows an enlarged left adrenal gland secondary to metastatic squamous cell carcinoma of the lung.

fully mobilized, as should the spleen and the tail of the pancreas. Laparoscopic ultrasonography is often needed to locate the gland in the retroperitoneal fat. In addition, use of an ultrasonic coagulator may facilitate division of the retroperitoneal fat.

Postoperative Care

After a laparoscopic adrenalectomy, most patients are admitted to a regular nursing unit, though some patients with pheochromocytomas will need to undergo a short stay in the intensive care unit for invasive monitoring. Patients are started on clear liquids on postoperative day 1, and the diet is advanced as tolerated. The urinary catheter is usually removed on postoperative day 1. Intravenous analgesia is switched to oral analgesia as soon as the patient can tolerate oral feeding. A complete blood count is obtained on postoperative day 1 in all patients, and electrolyte levels are monitored in patients with aldosteromas and hypercortisolism. Patients with Cushing syndrome should be given stress doses of steroids perioperatively and should be discharged on a maintenance prednisone dosage of 10 to 15 mg/day in divided doses. These patients should be advised that it may take 6 to 12 months or longer for the contralateral adrenal to recover to the point where prednisone can be discontinued. Patients undergoing bilateral adrenalectomy will need lifelong replacement therapy with a glucocorticoid (e.g., prednisone) and a mineralocorticoid (e.g., fludrocortisone acetate, 0.1 mg/day).

Postoperative management of hypertensive medications depends on the pathology of the underlying adrenal lesion. In patients with aldosteromas, spironolactone is stopped immediately after adrenalectomy, and the other antihypertensive agents are usually continued while blood pressure is monitored closely on an outpatient basis; further medication reductions are made as clinically warranted. In most patients with Cushing syndrome, antihypertensive medications are continued, whereas in most patients with pheochromocytomas, they are not. In both sets of patients, however, close outpatient monitoring of blood pressure should be carried

out in the early postoperative period. Adrenalectomy can have a dramatic impact on hypertensive control and can lead to hypotension if medications are not appropriately adjusted.

In most routine cases, patients can be discharged within 24 hours after a laparoscopic adrenalectomy, though some patients will have to stay longer for blood pressure monitoring, for adjustment of steroid replacement therapy, or for resumption of a regular diet. After an open adrenalectomy, resumption of an oral diet takes longer, and postoperative hospital stays of 4 to 5 days are more typical.

After discharge, patients are seen in the clinic within 2 to 3 weeks for a wound check, blood pressure evaluation, and a review of antihypertensive medications. In patients who underwent adrenalectomy for an aldosteroma, electrolyte levels and the creatinine concentration should be checked. In patients who underwent adrenalectomy for pheochromocytoma, yearly clinical and biochemical follow-up is indicated, with measurement of either plasma levels of fractionated metanephrenes or urine levels of catecholamines and metanephrenes. In selected patients on steroid replacement therapy who are proving difficult to wean from prednisone, an ACTH stimulation test may be necessary to assess the responsiveness of the pituitary-adrenal axis.

Complications

It appears that laparoscopic adrenalectomy has a major advantage over open adrenalectomy in terms of the incidence of postoperative complications. In a meta-analysis of 98 adrenalectomy series reported between 1980 and 2000, the overall complication rate was 10.9% with laparoscopic procedures and 25.2% with open procedures.¹⁰ This difference between the complication rates was primarily attributable to the occurrence of fewer wound, pulmonary, and infectious complications in the laparoscopic series. The most common complication of laparoscopic adrenalectomy is bleeding, which was reported in 4.7% of patients from the series reviewed in the meta-analysis. Bleeding is also the most common reason for conversion to open adrenalectomy; however, major bleeding that leads to transfusion is relatively uncommon. The risk of bleeding can be minimized by obtaining meticulous hemostasis, taking care not to grasp the adrenal gland, and handling tissue gently. If bleeding does occur, the prudent course of action is to maintain pressure on the bleeding source while obtaining better exposure or even starting the dissection in another area, rather than to resort to indiscriminate use of clips or electrocautery. The surgeon must be prepared to convert rapidly to an open procedure should major hemorrhage occur.

Other potential complications of adrenalectomy (either laparoscopic or open) include injury to the tail of the pancreas (with resultant pancreatic leakage or pancreatitis), injury to the diaphragm, and pneumothorax. Wound infections are uncommon with laparoscopic adrenalectomy. Trocar site hernias are infrequent as well, provided that the fascia is closed at all port sites that are 10 mm or larger. Deep vein thrombosis occurs in 0.8% of cases, pulmonary embolism in 0.5%.¹⁰ Pneumatic compression stockings should be used perioperatively to minimize the risk of venous thromboembolism. Renovascular hypertension from injury to the renal artery has also been reported.^{11,12} The operative mortality associated with laparoscopic adrenalectomy is about 0.3%.

Several cases of local or regional tumor recurrence have been reported after laparoscopic adrenalectomy. In most of these cases, the tumors removed were either suspected or unsuspected adrenal malignancies, and the extensive nature of the recurrences was probably related to aggressive tumor biology rather than to the

minimally invasive surgical technique. In some of the cases, however, the pattern of recurrence, characterized by the development of multiple intraperitoneal or port site metastases, suggested that laparoscopic dissection and pneumoperitoneum might have contributed to tumor spread.¹³⁻¹⁶ One group treated three patients for recurrent pheochromocytomatosis that developed after laparoscopic adrenalectomy.¹⁷ These patients were found to have multiple small tumor nodules in the adrenalectomy bed during open reoperation after removal of apparently benign pheochromocytomas. Fragmentation of the tumor and excessive tumor manipulation during the laparoscopic dissection were considered the probable mechanisms of tumor recurrence.

These reports highlight the need for caution in approaching large, malignant, or potentially malignant adrenal tumors. Surgeons who attempt a laparoscopic approach in this setting should be highly experienced in laparoscopic adrenalectomy techniques, and the tumor should be well circumscribed and not locally invasive. The use of a hand port may be a valuable adjunct to resection in these cases. Regardless of the specific surgical approach followed, wide excision of the lesion along with the surrounding periadrenal fat is crucial for minimizing recurrence rates in this population.

Outcome Evaluation

The safety and efficacy of laparoscopic adrenalectomy for the removal of small, benign adrenal tumors have been clearly estab-

lished. Rates of conversion to open adrenalectomy in high-volume centers have ranged from 3% to 13%, and operating times have averaged 2 to 3 hours.^{9,11,18-23} Most patients are now discharged from the hospital within 24 to 48 hours after operation. Although no prospective, randomized trial comparing laparoscopic with open adrenalectomy has been carried out, several retrospective studies have consistently shown that the laparoscopic approach is associated with decreased pain, a shorter hospital stay, and a faster recovery.²⁴⁻²⁷ Complication rates have also been low, and overall, complications appear to be less common than with open adrenalectomy.¹⁰

The results of a laparoscopic approach in patients with large (> 6 cm) adrenal tumors or malignant primary or metastatic adrenal lesions have been reviewed²⁸; generally, the conversion rates for large or malignant tumors have been higher than those reported in other laparoscopic adrenalectomy series. Overall, tumor recurrence rates after laparoscopic adrenalectomy have been low.²⁹⁻³³ In one series, however, local or regional tumor recurrence developed in three of five patients with adrenocortical carcinomas that were treated laparoscopically.³⁴ Other groups have also published anecdotal reports of local tumor recurrences after resection of unsuspected adrenal carcinomas.¹³⁻¹⁶ Whether these recurrences were related primarily to the surgical technique employed or to the underlying tumor biology is unclear. It would appear, therefore, that in most cases, primary adrenal malignancies are best approached in an open fashion unless the tumor is small and well circumscribed and the surgeon is highly experienced.

27 OPEN HERNIA REPAIR

Robert J. Fitzgibbons, Jr., M.D., F.A.C.S., Alan T. Richards, M.D., F.A.C.S., and Thomas H. Quinn, Ph.D.

Herniorrhaphy is one of the most commonly performed operations in all of surgery. Worldwide, some 20 million groin hernia repairs are accomplished each year.¹ In the United States, over 1,000,000 herniorrhaphies are performed each year, of which 750,000 are for inguinal hernias, 166,000 for umbilical hernias, 97,000 for incisional hernias, 25,000 for femoral hernias, and 76,000 for miscellaneous hernias.² The significance of these large numbers is that small variations in practice patterns can have huge socioeconomic implications. Operations that might seem unimportant because they account for only a small percentage of herniorrhaphies actually are important in that they account for a large absolute number of procedures. Accordingly, though this chapter is necessarily selective, focusing on the most pertinent of the abdominal wall and groin herniorrhaphies being performed today, it addresses a wide variety of operative approaches to hernia repair.

Epidemiology of Hernia

Approximately 75% of all abdominal wall hernias occur in the groin. Inguinal hernias are more common on the right than on the left and are seven times more likely in males than in females. Indirect inguinal hernias are twice as common as direct hernias. Femoral hernias are much less common than either, accounting for fewer than 10% of all groin hernias; however, 40% of femoral hernias present as emergencies, with incarceration or strangulation, and mortality is higher for emergency repair than for elective repair. Femoral hernias are more common in older patients and in those who have previously undergone inguinal hernia repair. Females are at higher risk than males, by a factor of 4 to 1.³

The prevalence of abdominal wall hernias is difficult to determine, as illustrated by the wide range of published figures in the literature. The major reasons for this difficulty are (1) the lack of standardization in how inguinal and ventral hernias are defined, (2) the inconsistency of the data sources used (which include self-reporting by patients, audits of routine physical examinations, and insurance company databases, among others), and (3) the subjectivity of physical examination, even when done by trained surgeons. Prevalence was reported in a United States Health, Education and Welfare study conducted by interview in 1960 for hernia [see Figure 1].⁴ Given that a number of persons must have had hernias without knowing it, it can be assumed that these figures underestimate the actual prevalence. Nevertheless, they provide a rough idea of the scope of the hernia problem.

Modern data concerning the risk of major complications from untreated abdominal wall hernias are scarce. Typically, surgeons are taught that all hernias, even if asymptomatic, should be repaired at diagnosis to prevent strangulation or bowel obstruction and that herniorrhaphy becomes more difficult the longer repair is delayed. As a result, it is hard to find a whole patient population in which at least some of the members do not undergo routine hernia repair regardless of symptoms. This state of affairs makes accurate estimates of the natural history of hernia impossible.

Examination of obscure data from the 1800s and some unique data from South America suggests that both the risk of complications from an untreated hernia and the operative mortality

from managing them have been overstated.⁵ At the same time, it is becoming clear that abdominal wall herniorrhaphy is associated with a higher morbidity than was previously appreciated. Currently, numerous patients either choose or are counseled by their primary care physicians not to undergo herniorrhaphy if the hernia is not "bothering them too much." A better understanding of the natural history therefore becomes particularly important for identifying patient subgroups who might be at greater risk for complications.

Classification of Hernia Types

Numerous classification schemes for groin hernias have been devised, usually bearing the name of the responsible investigator or investigators (e.g., Casten, Lichtenstein, Gilbert, Robbins and Rutkow, Bendavid, Nyhus, and Schumpelick). The variety of classifications in current use indicates that the perfect system has yet to be developed.⁶ The main problem in developing a single classification scheme suitable for wide application is that it is impossible to eliminate subjective measurements and thus impossible to ensure consistency from observer to observer. The advent of laparoscopic herniorrhaphy has further complicated the issue in that some of the measurements needed cannot be obtained via a laparoscopic approach. At present, the Nyhus system enjoys the greatest degree of acceptance [see Table 1].

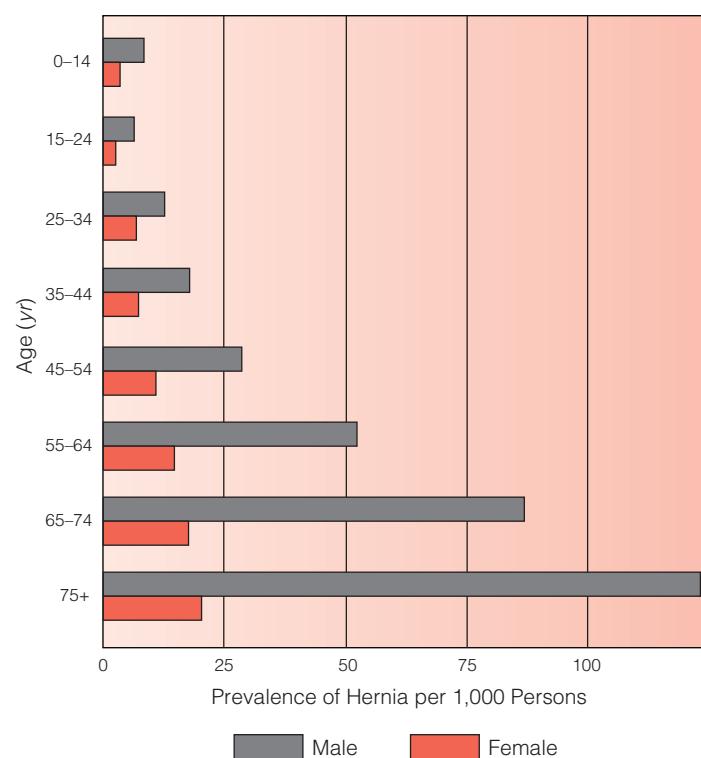

Figure 1 Illustrated is the prevalence of abdominal wall hernia in the United States per 1,000 population, by age and sex.⁴

Table 1 Nyhus Classification System for Groin Hernias

Type	Description
1	Indirect hernia with normal internal abdominal ring. This type is typically seen in infants, children, and small adults.
2	Indirect hernia in which internal ring is enlarged without impingement on the floor of the inguinal canal. Hernia does not extend to the scrotum.
3A	Direct hernia. Size is not taken into account.
3B	Indirect hernia that has enlarged enough to encroach upon the posterior inguinal wall. Indirect sliding or scrotal hernias are usually placed in this category because they are commonly associated with extension to direct space. This type also includes pantaloan hernias.
3C	Femoral hernia.
4	Recurrent hernia. Modifiers A, B, C, and D are sometimes added to type 4, corresponding to indirect, direct, femoral, and mixed, respectively.

Categorization of ventral abdominal wall hernias is not as critical as categorization of inguinal hernias, because there are so many different types of ventral hernias; however, Zollinger has proposed a classification scheme for these hernias that is frequently used [see Table 2]. Of the ventral hernias, incisional hernias are common enough to warrant their own discrete classification system. The scheme most often used for categorizing incisional hernias [see Table 3] represents the results of a 1998 consensus conference held in conjunction with the European Hernia Society's annual congress.⁷ This system is important in that it affords investigators a reliable means of comparing results between one procedure and another or between one center and another.

Table 2 Zollinger Classification System for Ventral Abdominal Wall Hernias

Type	Examples
Congenital	Omphalocele Gastroschisis Umbilical (infant)
Acquired	Midline Diastasis recti Epigastric Umbilical (adult, acquired, paraumbilical) Median Supravesical (anterior, posterior, lateral) Paramedian Spigelian Interparietal
Incisional	Midline Paramedian Transverse Special operative sites
Traumatic	Penetrating, autopenetrating* Blunt Focal, minimal injury Moderate injury Extensive force or shear Destructive

*Penetration from host tissue such as bone.

Abdominal Wall Anatomy

The skin of the lower anterior abdominal wall is innervated by anterior and lateral cutaneous branches of the ventral rami of the seventh through 12th intercostal nerves and by the ventral rami of the first and second lumbar nerves. These nerves course between the lateral flat muscles of the abdominal wall and enter the skin through the subcutaneous tissue.

The first layers encountered beneath the skin are Camper's and Scarpa's fasciae in the subcutaneous tissue. The only significance of these layers is that when sufficiently developed, they can be reapproximated to provide another layer between a repaired inguinal floor and the outside. The major blood vessels of this superficial fatty layer are the superficial inferior and superior epigastric vessels, the intercostal vessels, and the superficial circumflex iliac vessels (which are branches of the femoral vessels).

The external oblique muscle is the most superficial of the great flat muscles of the abdominal wall [see Figure 2]. This muscle arises from the posterior aspects of the lower eight ribs and interdigitates with both the serratus anterior and the latissimus dorsi at its origin. The posterior portion of the external oblique muscle is oriented vertically and inserts on the crest of the ilium. The anterior portion of the muscle courses inferiorly and obliquely toward the midline and the pubis. The muscle fibers themselves are of no interest to the inguinal hernia surgeon until they give way to form its aponeurosis, which occurs well above the inguinal region. The obliquely arranged anterior inferior fibers of the aponeurosis of the external oblique muscle fold back on themselves to form the inguinal ligament, which attaches laterally to the anterior superior iliac spine. In most persons, the medial insertion of the inguinal ligament is dual: one portion of the ligament inserts on the pubic tubercle and the pubic bone, whereas the other portion is fan-shaped and spans the distance between the inguinal ligament proper and the pecten line of the pubis. This fan-shaped portion of the inguinal ligament is called the lacunar ligament. It blends laterally with Cooper's ligament (or, to be anatomically correct, the pecten ligament). The more medial fibers of the aponeurosis of the external oblique muscle divide into a medial crus and a lateral crus to form the external or superficial inguinal ring, through which the spermatic cord (or the round ligament) and branches of the ilioinguinal and genitofemoral nerves pass. The rest of the medial fibers insert into the linea alba after contributing to the anterior portion of the rectus sheath.

Beneath the external oblique muscle is the internal abdominal oblique muscle. The fibers of the internal abdominal oblique muscle fan out following the shape of the iliac crest, so that the superior fibers course obliquely upward toward the distal ends of the lower three or four ribs while the lower fibers orient themselves inferomedially toward the pubis to run parallel to the external oblique aponeurotic fibers. These fibers arch over the round ligament or the spermatic cord, forming the superficial part of the internal (deep) inguinal ring.

Beneath the internal oblique muscle is the transversus abdominis. This muscle arises from the inguinal ligament, the inner side of the iliac crest, the endoabdominal fascia, and the lower six costal cartilages and ribs, where it interdigitates with the lateral diaphragmatic fibers. The medial aponeurotic fibers of the transversus abdominis contribute to the rectus sheath and insert on the pecten ossis pubis and the crest of the pubis, forming the falx inguinale. Infrequently, these fibers are joined by a portion of the internal oblique aponeurosis; only when this occurs is a true conjoined tendon formed.⁸

Aponeurotic fibers of the transversus abdominis also form the structure known as the aponeurotic arch. It is theorized that con-

Table 3 Classification System for Incisional Hernias

Parameter	Categories

*Difficult to measure consistently.

traction of the transversus abdominis causes the arch to move downward toward the inguinal ligament, thereby constituting a form of shutter mechanism that reinforces the weakest area of the groin when intra-abdominal pressure is raised. The area beneath the arch varies. Many authorities believe that a high arch, resulting in a larger area from which the transversus abdominis is by definition absent, is a predisposing factor for a direct inguinal hernia. The transverse aponeurotic arch is also important because the term is used by many authors to describe the medial structure that is sewn to the inguinal ligament in many of the older inguinal hernia repairs.

The rectus abdominis forms the central anchoring muscle mass of the anterior abdomen. It arises from the fifth through seventh costal cartilages and inserts on the pubic symphysis and the pubic crest. It is innervated by the seventh through 12th intercostal nerves, which laterally pierce the aponeurotic sheath of the muscle. The semilunar line is the slight depression in the aponeurotic fibers coursing toward the muscle. In a minority of persons, the small pyramidalis muscle accompanies the rectus abdominis at its insertion. This muscle arises from the pubic symphysis. It lies within the rectus sheath and tapers to attach to the linea alba, which represents the conjunction of the two rectus sheaths and is the major site of insertion for three aponeuroses from all three lateral muscle layers. The line of Douglas (i.e., the arcuate line of the rectus sheath) is formed at a variable distance between the umbilicus and the inguinal space because the fasciae of the large flat muscles of the abdominal wall contribute their aponeuroses to the anterior surface of the muscle, leaving only transversalis (or transverse) fascia to cover the posterior surface of the rectus abdominis.

The innervation of the anterior wall muscles is multifaceted. The seventh through 12th intercostal nerves and the first and second lumbar nerves provide most of the innervation of the lateral muscles, as well as of the rectus abdominis and the overlying skin.

The nerves pass anteriorly in a plane between the internal oblique muscle and the transversus abdominis, eventually piercing the lateral aspect of the rectus sheath to innervate the muscle therein. The external oblique muscle receives branches of the intercostal nerves, which penetrate the internal oblique muscle to reach it. The anterior ends of the nerves form part of the cutaneous innervation of the abdominal wall. The first lumbar nerve divides into the ilioinguinal nerve and the iliohypogastric nerve [see Figure 3]. These important nerves lie in the space between the internal oblique muscle and the external oblique aponeurosis. They may divide within the psoas major or between the internal oblique muscle and the transversus abdominis. The ilioinguinal nerve may communicate with the iliohypogastric nerve before innervating the internal oblique muscle. The ilioinguinal nerve then passes through the external inguinal ring to run parallel to the spermatic cord, while the iliohypogastric nerve pierces the external oblique muscle to innervate the skin above the pubis. The cremaster muscle fibers, which are derived from the internal oblique muscle, are innervated by the genitofemoral nerve. There can be considerable variability and overlap.

The blood supply of the lateral muscles of the anterior wall comes primarily from the lower three or four intercostal arteries, the deep circumflex iliac artery, and the lumbar arteries. The rectus abdominis has a complicated blood supply that derives from the superior epigastric artery (a terminal branch of the internal thoracic [internal mammary] artery), the inferior epigastric artery (a branch of the external iliac artery), and the lower intercostal arteries. The lower intercostal arteries enter the sides of the muscle after traveling between the oblique muscles; the superior and

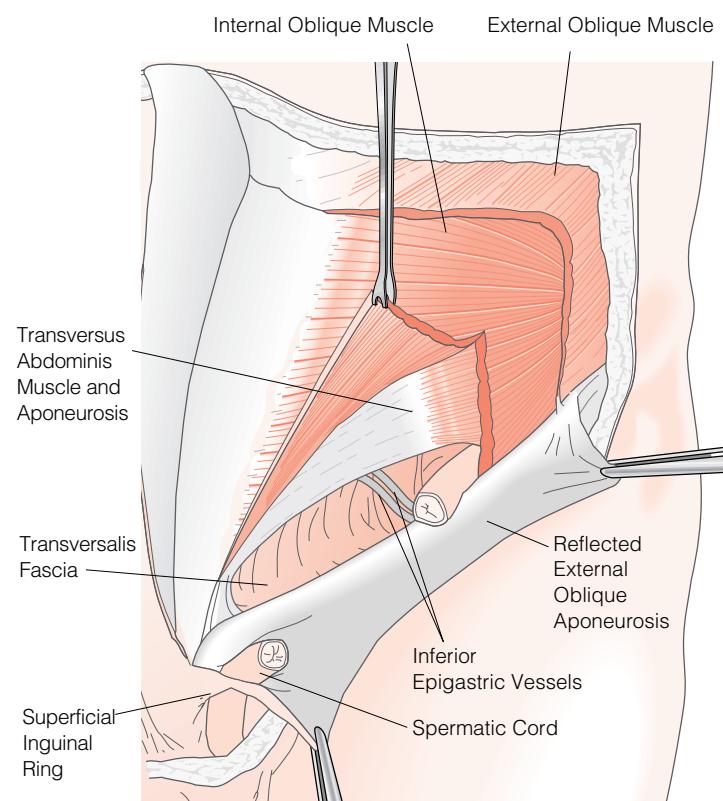

Figure 2 Depicted is the relationship of the great flat muscles of the abdominal wall to the groin.

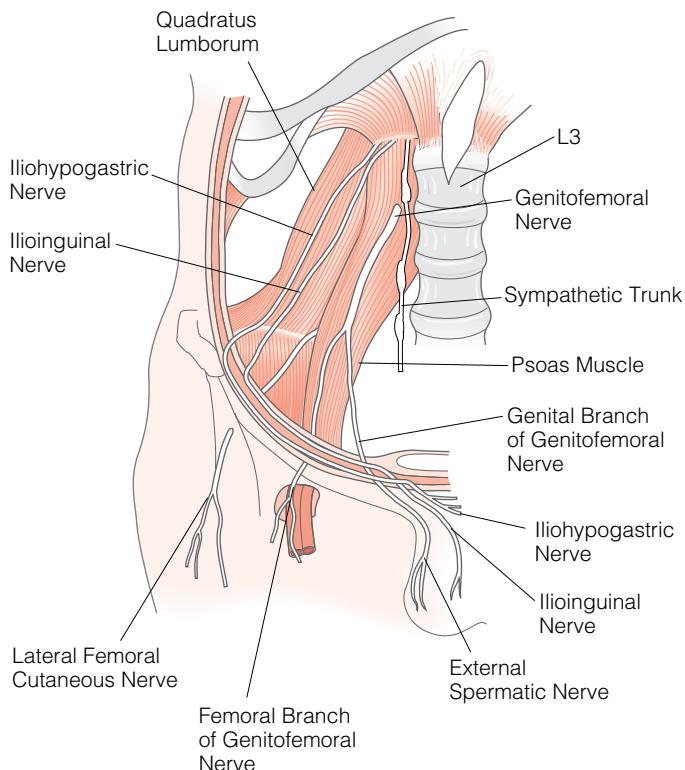

Figure 3 Shown are the important nerves of the lower abdominal wall.

the inferior epigastric arteries enter the rectus sheath and anastomose near the umbilicus.

The endoabdominal fascia is the deep fascia covering the internal surface of the transversus abdominis, the iliocostalis, the psoas major and minor, the obturator internus, and portions of the periosteum. It is a continuous sheet that extends throughout the extraperitoneal space and is sometimes referred to as the wallpaper of the abdominal cavity. Commonly, the endoabdominal fascia is subclassified according to the muscle being covered (e.g., iliac fascia or obturator fascia).

The transversalis fascia is particularly important for inguinal hernia repair because it forms anatomic landmarks known as analogues or derivatives. The most significant of these analogues for hernia surgeons are the ilipectineal arch, the iliopubic tract, the crura of the deep inguinal ring, and Cooper's ligament (i.e., the pecten ligament). The superior and inferior crura form a "monk's hood"-shaped sling around the deep inguinal ring. This sling has functional significance, in that as the crura of the ring are pulled upward and laterally by the contraction of the transversus abdominis, a valvular action is generated that helps preclude indirect hernia formation. The iliopubic tract is the thickened band of the transversalis fascia that courses parallel to the more superficially located inguinal ligament. It is attached to the iliac crest laterally and inserts on the pubic tubercle medially. The insertion curves inferolaterally for 1 to 2 cm along the pecten line of the pubis to blend with Cooper's ligament, ending at about the midportion of the superior pubic ramus. Cooper's ligament is actually a condensation of the periosteum and is not a true analogue of the transversalis fascia.

Hesselbach's inguinal triangle is the site of direct inguinal hernias. As viewed from the anterior aspect, the inguinal ligament forms the base of the triangle, the edge of the rectus abdominis

forms the medial border, and the inferior epigastric vessels form the superolateral border. (It should be noted, however, that Hesselbach actually described Cooper's ligament as the base.)

Below the iliopubic tract are the critical anatomic elements from which a femoral hernia may develop. The ilipectineal arch separates the vascular compartment that contains the femoral vessels from the neuromuscular compartment that contains the iliopsoas muscle, the femoral nerve, and the lateral femoral cutaneous nerve. The vascular compartment is invested by the femoral sheath, which has three subcompartments: (1) the lateral, containing the femoral artery and the femoral branch of the genitofemoral nerve; (2) the middle, containing the femoral vein; and (3) the medial, which is the cone-shaped cul-de-sac known as the femoral canal. The femoral canal is normally a 1 to 2 cm blind pouch that begins at the femoral ring and extends to the level of the fossa ovalis. The femoral ring is bordered by the superior pubic ramus inferiorly, the femoral vein laterally, and the iliopubic tract (with its curved insertion onto the pubic ramus) anteriorly and medially. The femoral canal normally contains preperitoneal fat, connective tissue, and lymph nodes (including Cloquet's node at the femoral ring), which collectively make up the femoral pad. This pad acts as a cushion for the femoral vein, allowing expansion such as might occur during a Valsalva maneuver, and serves as a plug to prevent abdominal contents from entering the thigh. A femoral hernia exists when the blind end of the femoral canal becomes an opening (the femoral orifice) through which a peritoneal sac can protrude.

Between the transversalis fascia and the peritoneum is the preperitoneal space. In the midline behind the pubis, this space is known as the space of Retzius; laterally, it is referred to as the space of Bogros. The preperitoneal space is of particular importance for surgeons because many of the inguinal hernia repairs (see below) are performed in this area. The inferior epigastric vessels, the deep inferior epigastric vein, the iliopubic vein, the rectus vein, the retropubic vein, the communicating rectus-epigastric vein, the internal spermatic vessels, and the vas deferens are all encountered in this space.⁹

Inguinal Herniorrhaphy: Choice of Procedure

The major indication for a surgeon to choose any one inguinal hernia repair over another is personal experience with a particular operation. Thus, in theory, any patient can be considered a candidate for any of these procedures. Some general guidelines are useful, however. The overriding consideration should be the need to tailor the operation to the patient's particular hernia. For example, a simple Marcy repair would be completely adequate for a pediatric patient with a Nyhus type 1 hernia but not for an elderly patient who has an indirect hernia in conjunction with extensive destruction of the inguinal floor. The conventional anterior prosthetic repairs are particularly useful in high-risk patients because they can easily be performed with local anesthesia. On the other hand, giant prosthetic reinforcement of the visceral sac (GPRVS), especially when bilateral, necessitates general or regional anesthesia and thus is best for patients with bilateral direct or recurrent hernias or, perhaps, for patients with connective tissue disorders that appear to be associated with their hernia. If surgery has previously been done in either the anterior or the preperitoneal space, the surgeon should choose a procedure that uses the undissected space. If local or systemic infection is present, a nonprosthetic repair is usually considered preferable, though the newer biologic prosthesis now being evaluated may eventually change this view. Uncorrected coagulopathy is a contraindication to elective repair.

Inguinal Herniorrhaphy: Conventional Anterior Nonprosthetic Repairs

ANESTHESIA

Local anesthesia is entirely adequate, especially when combined with I.V. infusion of a rapid-acting, short-lasting, amnesic, and anxiolytic agent such as propofol. This is the approach most commonly employed in specialty hernia clinics. In general practice, general anesthesia is preferred. This approach is reasonable in fit patients but is associated with a higher incidence of postoperative urinary retention.¹⁰ If general anesthesia is used, a local anesthetic should be given at the end of the procedure as an adjuvant to reduce immediate postoperative pain. Spinal or epidural anesthesia can also be used but is less popular.

OPERATIVE TECHNIQUE

The various anterior nonprosthetic herniorrhaphies have a number of initial technical steps in common; they differ primarily with respect to the specific details of the actual repair.

Step 1: Administration of Local Anesthetic

Generally, we use a solution containing 50 ml of 0.5% lidocaine with epinephrine and 50 ml of 0.25% bupivacaine with epinephrine; the epinephrine is optional and may be omitted in patients who have a history of coronary artery disease. In an adult of normal size, 70 ml of this solution is injected before preparation and draping: 10 ml is placed medial to the anterior superior iliac spine to block the ilioinguinal nerve, and the other 60 ml is used as a field block along the orientation of the eventual incision in the subcutaneous and deeper tissues. Care is taken to ensure that some of the material is injected into the areas of the pubic tubercle and Cooper's ligament, which are easily identified by tactile sensation (except in very obese patients). Intradermal injection is unnecessary because by the time the surgeon is scrubbed and the patient draped, anesthesia is complete. The remaining 30 ml is reserved for discretionary use during the procedure. With this technique, endotracheal intubation is avoided and the patient can be aroused from sedation periodically to perform Valsalva maneuvers to test the repair.

Step 2: Initial Incision

Traditionally, the skin is opened by making an oblique incision between the anterior superior iliac spine and the pubic tubercle. For cosmetic reasons, however, many surgeons now prefer a more horizontal skin incision placed in the natural skin lines. In either case, the incision is deepened through Scarpa's and Camper's fasciae and the subcutaneous tissue to expose the external oblique aponeurosis. The external oblique aponeurosis is then opened through the external inguinal ring.

Step 3: Mobilization of Cord Structures

The superior flap of the external oblique fascia is dissected away from the anterior rectus sheath medially and the internal oblique muscle laterally. The iliohypogastric nerve is identified at this time; it can be either left in situ or freed from the surrounding tissue and isolated from the operative field by passing a hemostat under the nerve and grasping the upper flap of the external oblique aponeurosis. Routine division of the iliohypogastric nerve along with the ilioinguinal nerve is practiced by some surgeons but is not advised by most. The cord structures are then bluntly dissected away from the inferior flap of the external oblique aponeurosis to expose the shelving edge of the inguinal ligament and the iliopubic tract. The cord structures are lifted en masse

with the fingers of one hand at the pubic tubercle so that the index finger can be passed underneath to meet the ipsilateral thumb or the fingers of the other hand. Mobilization of the cord structures is completed by means of blunt dissection, and a Penrose drain is placed around them so that they can be retracted during the procedure.

Step 4: Division of Cremaster Muscle

Complete division of the cremaster muscle has been common practice, especially with indirect hernias. The purposes of this practice are to facilitate identification of the sac and to lengthen the cord for better visualization of the inguinal floor. Almost always, however, adequate exposure can be obtained by opening the muscle longitudinally, which reduces the chances of damage to the cord and prevents testicular descent. Accordingly, the latter approach should be considered best practice unless there are extenuating circumstances.

Step 5: High Ligation of Sac

The term high ligation of the sac is used frequently in discussing hernia repair; its historical significance has ingrained it in the descriptions of most of the older operations. For our purposes in this chapter, high ligation of the sac should be considered equivalent to reduction of the sac into the preperitoneal space without excision. The two methods work equally well and are highly effective. Some surgeons believe that sac inversion results in less pain (because the richly innervated peritoneum is not incised) and may be less likely to cause adhesive complications. To date, however, no randomized trials have been done to determine whether this is so.¹¹ Sac eversion in lieu of excision does protect intra-abdominal viscera in cases of unrecognized incarcerated sac contents or sliding hernia.

Step 6: Management of Inguinal Scrotal Hernial Sacs

Some surgeons consider complete excision of all indirect inguinal hernial sacs important. The downside of this practice is that the incidence of ischemic orchitis from excessive trauma to the cord rises substantially. The logical sequela of ischemic orchitis is testicular atrophy, though this presumed relationship has not been conclusively proved. In our view, it is better to divide an indirect inguinal hernial sac in the midportion of the inguinal canal once it is clear that the hernia is not sliding and no abdominal contents are present. The distal sac is not removed, but its anterior wall is opened as far distally as is convenient. Contrary to the opinion commonly voiced in the urologic literature, this approach does not result in excessive postoperative hydrocele formation.

Step 7: Repair of Inguinal Floor

Methods of repairing the inguinal floor differ significantly among the various repairs and thus are described separately [see Details of Specific Repairs, below].

Step 8: Relaxing Incision

A relaxing incision is made through the anterior rectus sheath and down to the rectus abdominis, extending superiorly from the pubic tubercle for a variable distance, as determined by the degree of tension present. Some surgeons prefer to "hockey-stick" the incision laterally at the superior end. The posterior rectus sheath is strong enough to prevent future incisional herniation. This relaxing incision works because as the anterior rectus sheath separates, the various components of the abdominal wall are displaced laterally and inferiorly.

Step 9: Closure

Closure of the external oblique fascia serves to reconstruct the superficial (external) ring. The external ring must be loose enough to prevent strangulation of the cord structures yet tight enough to ensure that an inexperienced examiner will not confuse a dilated ring with a recurrence. A dilated external ring is sometimes referred to as an industrial hernia, because over the years it has occasionally been a problem during preemployment physical examinations. Scarpa's fascia and the skin are closed to complete the operation.

Details of Specific Repairs

Marcy repair The Marcy repair is the simplest nonprosthetic repair performed today. Its main indication is for treatment of Nyhus type 1 hernias (i.e., indirect inguinal hernias in which the internal ring is normal). It is appropriate for children and young adults in whom there is concern about the long-term effects of prosthetic material. The essential features of the Marcy repair are high ligation of the sac and narrowing of the internal ring. Displacing the cord structures laterally allows the placement of sutures through the muscular and fascial layers [see Figure 4].

Bassini repair Edoardo Bassini (1844–1924) is considered the father of modern inguinal hernia surgery. By combining high ligation of a hernial sac with reconstruction of the inguinal floor and taking advantage of the developing disciplines of antisepsis and anesthesia, he was able to reduce morbidity and mortality substantially. Before Bassini's achievements, elective herniorrhaphy was almost never recommended, because the results were so bad. Bassini's operation, known as the radical cure, became the gold standard for inguinal hernia repair for most of the 20th century.

The initial steps in the procedure are essentially as already described (see above). Bassini felt that the incision in the external oblique aponeurosis should be as superior as possible while still allowing the superficial external ring to be opened,¹² so that the

reapproximation suture line created later in the operation would not be directly over the suture line of the inguinal floor reconstruction. Whether this technical point is significant is debatable. Bassini also felt that lengthwise division of the cremaster muscle followed by resection was important for ensuring that an indirect hernial sac could not be missed and for achieving adequate exposure of the inguinal floor.

After performing the initial dissection and the reduction or ligation of the sac, Bassini began the reconstruction of the inguinal floor by opening the transversalis fascia from the internal inguinal ring to the pubic tubercle, thereby exposing the preperitoneal fat, which was bluntly dissected away from the undersurface of the superior flap of the transversalis fascia [see Figure 5a]. This step allowed him to properly prepare the deepest structure in his famous “triple layer” (comprising the transversalis fascia, the transversus abdominis, and the internal oblique muscle).

The first stitch in Bassini's repair includes the triple layer superiorly and the periosteum of the medial side of the pubic tubercle, along with the rectus sheath. In current practice, however, most surgeons try to avoid the periosteum of the pubic tubercle so as to decrease the incidence of osteitis pubis. The repair is then continued laterally, and the triple layer is secured to the reflected inguinal ligament (Poupart's ligament) with nonabsorbable sutures. The sutures are continued until the internal ring is closed on its medial side [see Figure 5b]. A relaxing incision was not part of Bassini's original description but now is commonly added.

Concerns about injuries to neurovascular structures in the preperitoneal space as well as to the bladder led many surgeons, especially in North America, to abandon the opening of the transversalis fascia. The unfortunate consequence of this decision is that the proper development of the triple layer is severely compromised. In lieu of opening the floor, a forceps (e.g., an Allis clamp) is used to grasp tissue blindly in the hope of including the transversalis fascia and the transversus abdominis. The layer is then sutured, along with the internal oblique muscle, to the reflected inguinal ligament as in the classic Bassini repair. The structure grasped in this modified procedure is sometimes referred to as the conjoined tendon, but this is not correct because of the variability in what is actually grasped in the clamp. This imprecise “good stuff to good stuff” approach almost certainly accounts for the inferior results achieved with the Bassini procedure in the United States.

Maloney darn The Maloney darn gets its name from the way in which a long nylon suture is repeatedly passed between the tissues to create a weave that one might consider similar to a mesh. After initial preparation of the groin (see above), a continuous nylon suture is used to oppose the transversus abdominis, the rectus abdominis, the internal oblique muscle, and the transversalis fascia medially to Poupart's ligament laterally. The suture is continued into the muscle around the cord and is woven in and out to form a reinforcement around the cord. On the lateral side of the cord, it is sutured to the inguinal ligament and tied. The darn is a second layer. The sutures are placed either parallel or in a criss-cross fashion and are plicated well into the inguinal ligament below. The darn must be carried well over the medial edge of the inguinal canal. Once the darn is complete, the external oblique muscle is closed over the cord structures. The Maloney darn can be considered a forerunner of the mesh repairs, in that the purpose of the darn is to provide a scaffold for tissue ingrowth.¹³

Shouldice repair Steps 1 through 6 are performed essentially as previously described (see above). Particular importance

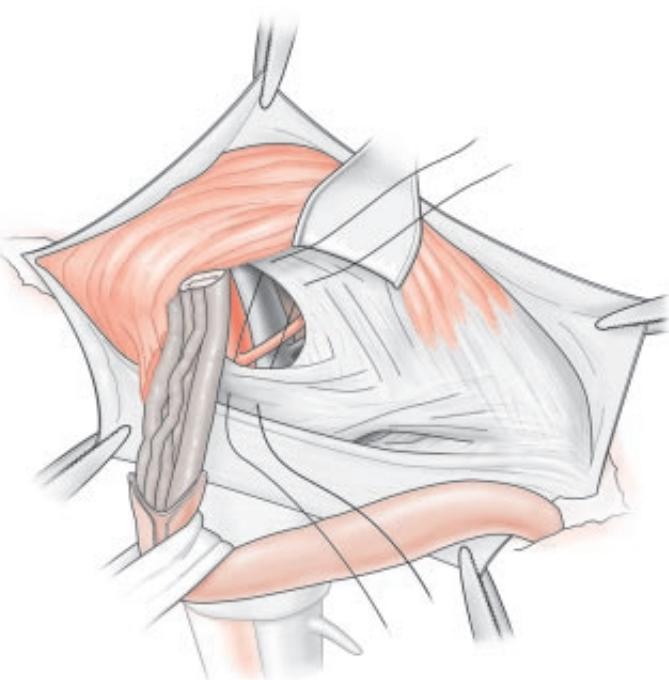

Figure 4 Inguinal herniorrhaphy: Marcy repair. The deep inguinal ring is narrowed medially with several sutures that approximate the transverse aponeurotic arch to the iliopubic tract.

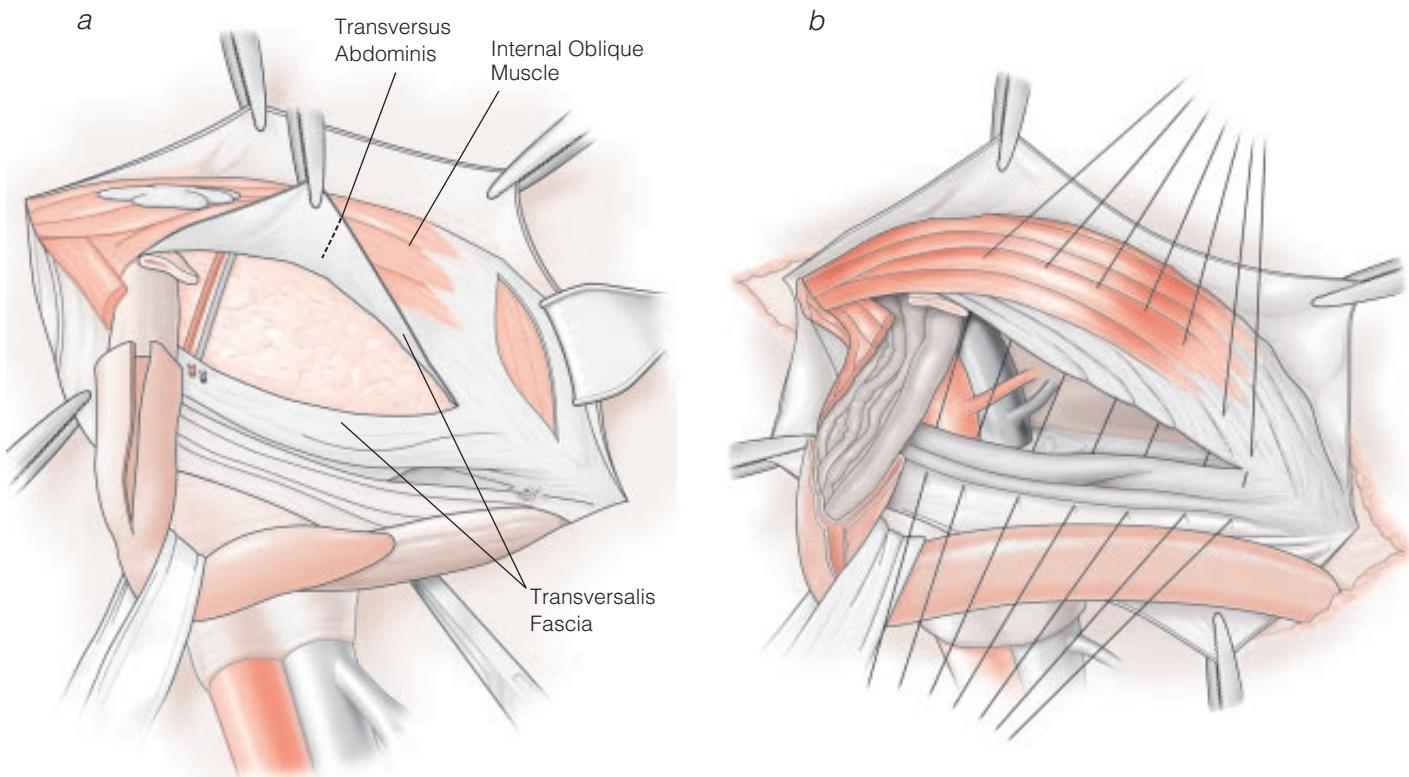

Figure 5 Inguinal herniorrhaphy: Bassini repair. (a) The transverse fascia has been opened and the preperitoneal fat stripped away to prepare the deepest structure in Bassini's triple layer (comprising the transverse fascia, the transversus abdominis, and the internal oblique muscle). (b) The triple layer superiorly is approximated to the inguinal ligament, beginning medially at the pubic tubercle and extending laterally until the deep inguinal ring is sufficiently narrowed.

is placed on freeing of the cord from its surrounding adhesions, resection of the cremaster muscle, high dissection of the hernial sac, and division of the transversalis fascia during the initial steps of the procedure.¹⁴ A continuous nonabsorbable suture (typically of monofilament steel wire) is used to repair the floor. The Shouldice surgeons believe that a continuous suture distributes tension evenly and prevents potential defects between interrupted sutures that could lead to recurrence.

The repair is started at the pubic tubercle by approximating the iliopubic tract laterally to the undersurface of the lateral edge of the rectus abdominis [see Figure 6a]. The suture is continued laterally, approximating the iliopubic tract to the medial flap, which is made up of the transversalis fascia, the internal oblique muscle, and the transversus abdominis. Eventually, four suture lines are developed from the medial flap. The continuous suture is extended to the internal ring, where the lateral stump of the cremaster muscle is picked up to form a new internal ring. Next, the direction of the suture is reversed back toward the pubic tubercle, approximating the medial edges of the internal oblique muscle and the transversus abdominis to Poupart's ligament, and the wire is tied to itself and then to the first knot [see Figure 6b]. Thus, two suture lines are formed by the first suture.

A second wire suture is started near the internal ring, approximating the internal oblique muscle and the transversus abdominis to a band of external oblique aponeurosis superficial and parallel to Poupart's ligament—in effect, creating a second, artificial Poupart's ligament. This third suture line ends at the pubic crest. The suture is then reversed, and a fourth suture line is constructed in a similar manner, superficial to the third line. At the

Shouldice clinic, the cribriform fascia is always incised in the thigh, parallel to the inguinal ligament, to make the inner side of the lower flap of the external oblique aponeurosis available for these multiple layers. In general practice, however, this step is commonly omitted.

The results at the Shouldice clinic have been truly outstanding and continue to be so today. For a time, the Shouldice repair was the gold standard against which all newer procedures were compared. The major criticism of this operation is that it is difficult to teach because surgeons have problems understanding what is really being sewn to what. Unless one is specifically trained at the Shouldice clinic and has the opportunity to work with the surgeons there, one may find it hard to identify the various layers in the medial flap reliably and reproducibly—a step that is crucial for developing the multiple suture lines. To compound the difficulty, modifications developed outside the Shouldice clinic have given rise to different versions of the procedure. For example, some surgeons use three continuous layers instead of four for reconstruction of the inguinal floor.

McVay Cooper's ligament repair This operation is similar to the Bassini repair, except that it uses Cooper's ligament instead of the inguinal ligament for the medial portion of the repair. Interrupted sutures are placed from the pubic tubercle laterally along Cooper's ligament, progressively narrowing the femoral ring; this constitutes the most common application of the repair—namely, treatment of a femoral hernia [see Figure 7]. The last stitch in Cooper's ligament is known as a transition stitch and includes the inguinal ligament. This stitch has two purposes: (1) to com-

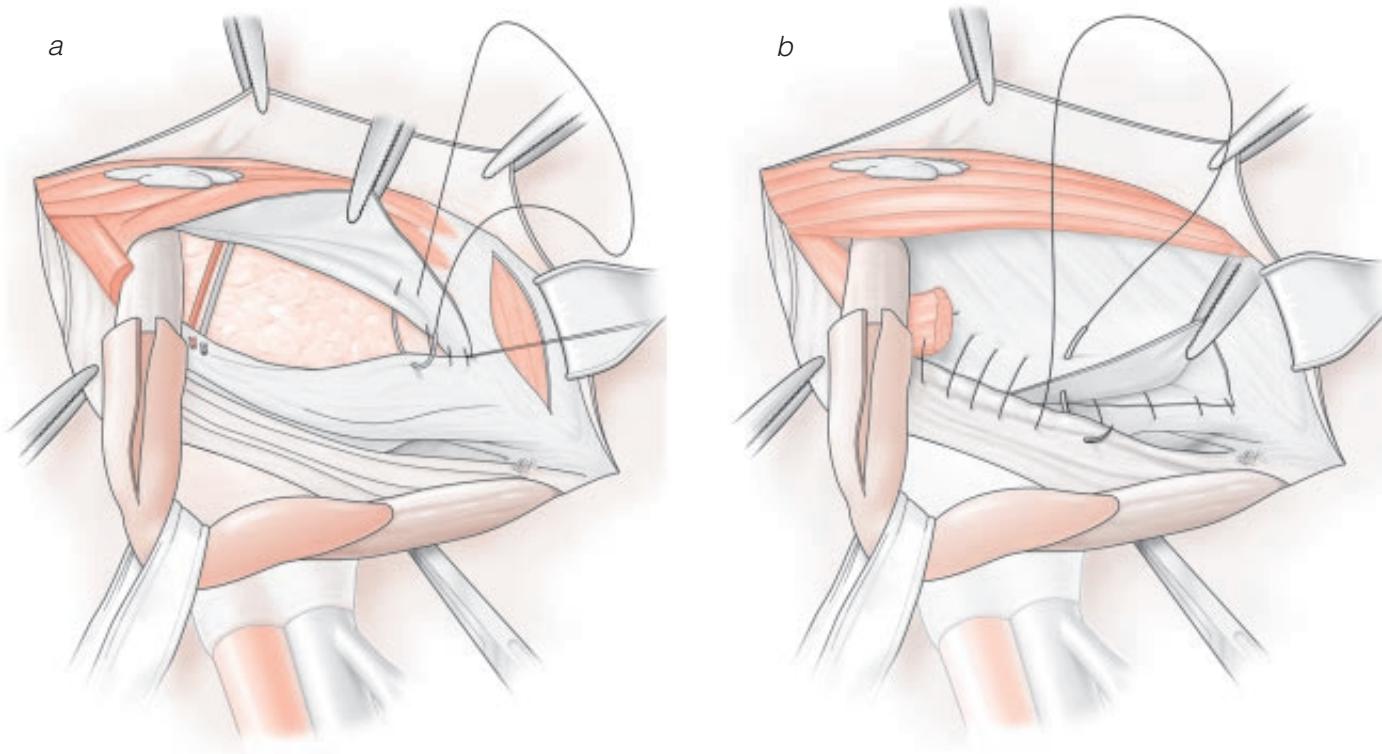

Figure 6 Inguinal herniorrhaphy: Shouldice repair. (a) The first suture line starts at the pubic tubercle by approximating the iliopubic tract laterally to the undersurface of the lateral edge of the rectus abdominis. The suture is continued laterally, approximating the iliopubic tract to the medial flap (made up of the transversalis fascia, the internal oblique muscle, and the transversus abdominis). (b) The second suture line begins after the stump of the divided cremaster muscle has been picked up. The direction of the suture is reversed back toward the pubic tubercle, approximating the medial edges of the internal oblique muscle and the transversus abdominis to Poupart's ligament. Two more suture lines will be constructed by approximating the internal oblique muscle and the transversus abdominis to a band of the inferior flap of the external oblique aponeurosis superficial and parallel to Poupart's ligament—in effect, creating a second and a third artificial Poupart's ligament.

plete the narrowing of the femoral ring by approximating the inguinal ligament to Cooper's ligament, as well as to the medial tissue, and (2) to provide a smooth transition to the inguinal ligament over the femoral vessel so that the repair can be continued laterally (as in a Bassini repair). Given the considerable tension required to bridge such a large distance, a relaxing incision should always be used. In the view of many authorities, this tension results in more pain than is noted with other herniorrhaphies and predisposes to recurrence. For this reason, the McVay repair is rarely chosen today, except in patients with a femoral hernia or patients with a specific contraindication to mesh repair.

Subinguinal femoral hernia repair Femoral hernias in females can easily be approached via a groin incision with dissection into the fossa ovalis beneath the inguinal ligament without the external oblique fascia being opened. The defect can be either closed with sutures or bridged with a mesh plug prosthesis [see *Figure 8*]. Larger femoral hernias in females and all femoral hernias in males are better treated with a McVay Cooper's ligament repair.

Pediatric hernia repair Children and young adults commonly present with an indirect sac only, with no discernible destruction of the inguinal floor. An extensive repair is not indicated: nearly all such patients are cured with sac ligation or eversion alone. A Marcy repair is the most extensive procedure that should be considered in this population.

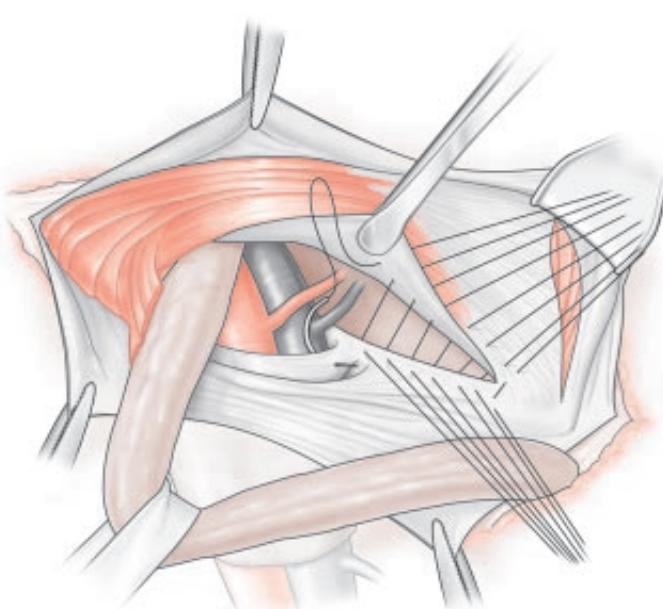

Figure 7 Inguinal herniorrhaphy: McVay Cooper's ligament repair. The lateral stitch is the transition stitch to the femoral sheath and the inguinal ligament.

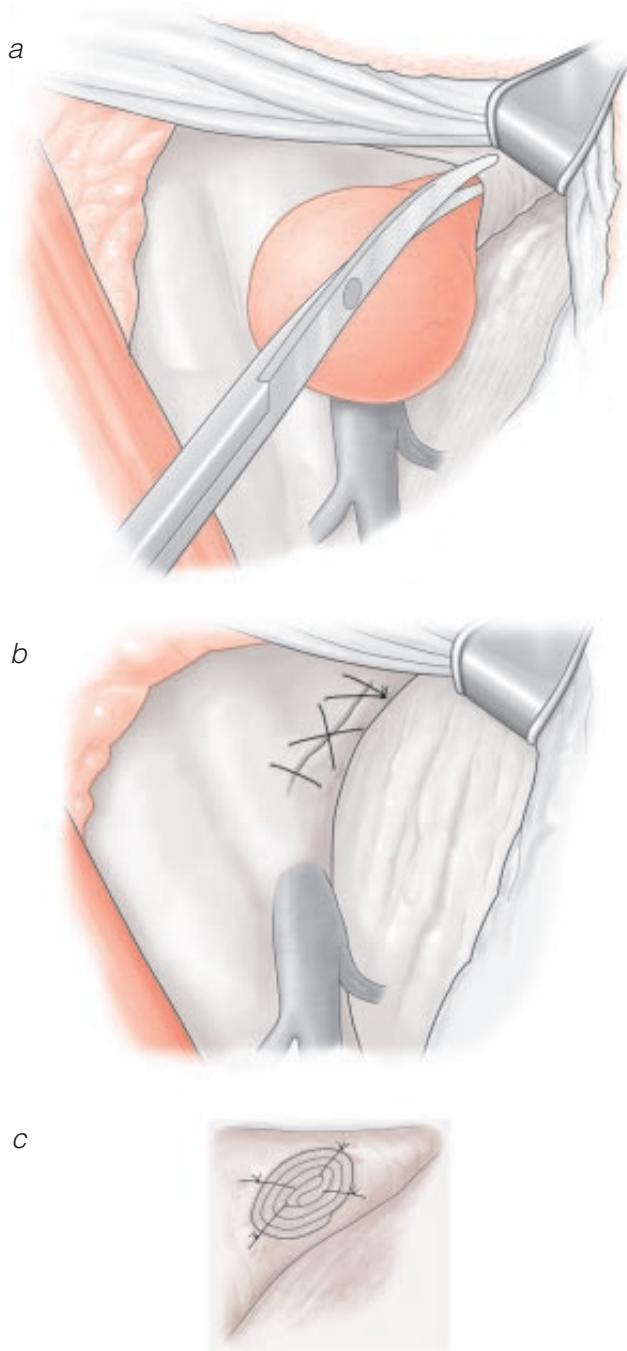

Figure 8 Inguinal herniorrhaphy: femoral hernia repair in females. The femoral canal is opened by dividing the inguinal ligament, the lacunar ligament, or both to facilitate reduction of the contents of the hernia. (a) The repair is then accomplished with either a continuous suture (b) or a mesh plug (c).

Inguinal Herniorrhaphy: Conventional Anterior Prosthetic Repairs

LICHTENSTEIN REPAIR

Steps 1 through 6

The first six steps of a Lichtenstein repair are very similar to the first six steps of a conventional anterior nonprosthetic repair [see *Inguinal Herniorrhaphy: Conventional Anterior Nonprosthetic Repairs, above*], but there are certain technical points that are worthy of emphasis. The external oblique aponeurosis is generously freed from the underlying anterior rectus sheath and internal

oblique muscle and aponeurosis in an avascular plane from a point at least 2 cm medial to the pubic tubercle to the anterior superior iliac spine laterally. Blunt dissection is continued in this avascular plane from the area lateral to the internal ring to the pubic tubercle along the shelving edge of the inguinal ligament and the iliopubic tract. As a continuation of this same motion, the cord with its cremaster covering is swept off the pubic tubercle and separated from the inguinal floor. Besides mobilizing the cord, these maneuvers create a large space beneath the external oblique aponeurosis that can eventually be used for prosthesis placement. The ilioinguinal nerve, the external spermatic vessels, and the genital branch of the genitofemoral nerve all remain with the cord structures.

For indirect hernias, the cremaster muscle is incised longitudinally, and the sac is dissected free and reduced into the preperitoneal space. Theoretically, this operation could be criticized on the grounds that if the inguinal floor is not opened, an occult femoral hernia might be overlooked. To date, however, an excessive incidence of missed femoral hernias has not been reported. In addition, it is possible to evaluate the femoral ring via the space of Bogros through a small opening in the canal floor.

Direct hernias are separated from the cord and other surrounding structures and reduced back into the preperitoneal space. Dividing the superficial layers of the neck of the sac circumferentially—which, in effect, opens the inguinal floor—usually facilitates reduction and helps maintain it while the prosthesis is being placed. This opening in the inguinal floor also allows the surgeon to palpate for a femoral hernia. Sutures can be used to maintain reduction of the sac, but they have no real strength in this setting; their main purpose is to allow the repair to proceed without being hindered by continual extrusion of the sac into the field, especially when the patient strains.

Step 7: Placement of Prosthesis

A mesh prosthesis is positioned over the inguinal floor. For an adult, the prosthesis should be at least 15×8 cm. The medial end is rounded to correspond to the patient's particular anatomy and secured to the anterior rectus sheath at least 2 cm medial to the pubic tubercle. A continuous suture of either nonabsorbable or long-lasting absorbable material should be used. Wide overlap of the pubic tubercle is important to prevent the pubic tubercle recurrences all too commonly seen with other operations. The suture is continued laterally in a locking fashion, securing the prosthesis to either side of the pubic tubercle (not into it) and then to the shelving edge of the inguinal ligament. The suture is tied at the internal ring.

Step 8: Creation of Shutter Valve

A slit is made at the lateral end of the mesh in such a way as to create two tails, a wider one (approximately two thirds of the total width) above and a narrower one below. The tails are positioned around the cord structures and placed beneath the external oblique aponeurosis laterally to about the anterior superior iliac spine, with the upper tail placed on top of the lower. A single interrupted suture is placed to secure the lower edge of the superior tail to the lower edge of the inferior tail—in effect, creating a shutter valve. This step is considered crucial for preventing the indirect recurrences occasionally seen when the tails are simply reapproximated. The same suture incorporates the shelving edge of the inguinal ligament so as to create a domelike buckling effect over the direct space, thereby ensuring that there is no tension, especially when the patient assumes an upright position. The Lichtenstein group has now developed a customized prosthesis

with a built-in domelike configuration, which, in their view, makes suturing the approximated tails to the inguinal ligament unnecessary.

Step 9: Securing of Prosthesis

A few interrupted sutures are placed to attach the superior and medial aspects of the prosthesis to the underlying internal oblique muscle and rectus fascia [see Figure 9]. On occasion, the iliohypogastric nerve, which courses on top of the internal oblique muscle, penetrates the medial flap of the external oblique aponeurosis. In this situation, the prosthesis should be slit to accommodate the nerve. The prosthesis can be trimmed in situ, but care should be taken to maintain enough laxity to allow for the difference between the supine and the upright positions, as well as for possible shrinkage of the mesh.

Step 10: Repair of Femoral Hernia

If a femoral hernia is present, the posterior surface of the mesh is sutured to Cooper's ligament after the inferior edge has been attached to the inguinal ligament, thereby closing the femoral canal.

Step 11: Closure

Closure is accomplished in the same manner as in a conventional anterior nonprosthetic repair.

PLUG-AND-PATCH REPAIR

The mesh plug technique was first developed by Gilbert and subsequently modified by Rutkow and Robbins, Millikan, and others [see Figure 10].¹⁵⁻¹⁷ The groin is entered via a standard

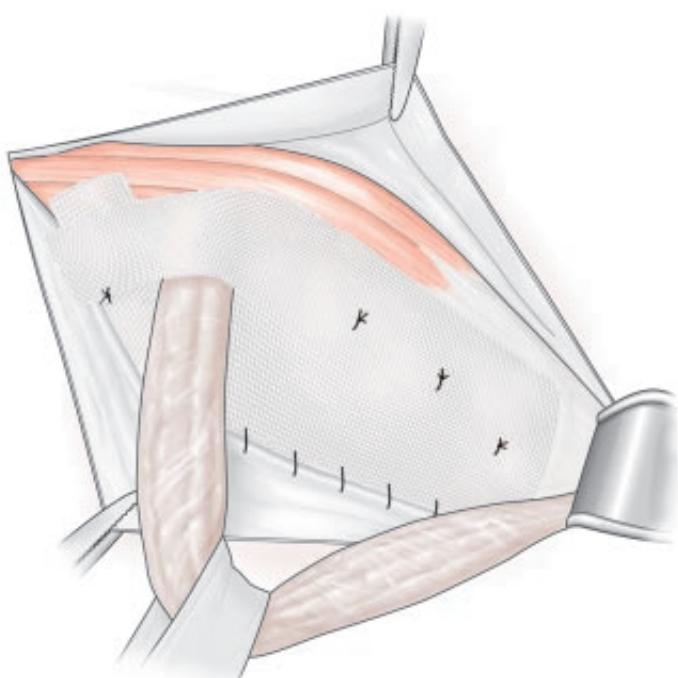

Figure 9 Inguinal herniorrhaphy: Lichtenstein repair. A mesh prosthesis is positioned over the inguinal floor and secured to the rectus sheath with a continuous suture. A slit is made in the mesh to accommodate the cord structures, and the two tails are secured to each other and to the shelving edge of the inguinal ligament with a single interrupted suture. The superior and medial aspects of the prosthesis are secured to the internal oblique muscle and the rectus fascia with a few interrupted sutures.

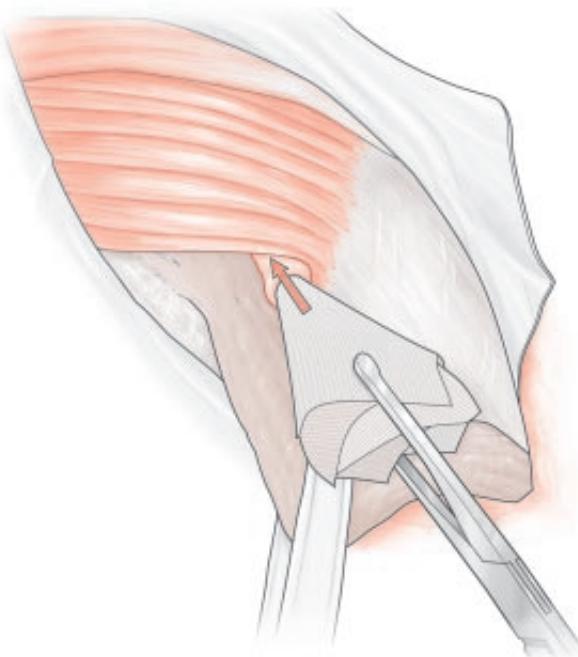

Figure 10 Inguinal herniorrhaphy: Gilbert repair. Depicted is the mesh plug technique for repair of an inguinal hernia. A flat sheet of polypropylene mesh is rolled up like a cigarette or formed into a cone (as shown here), inserted into the defect, and secured to either the internal ring (for an indirect hernia) or the neck of the defect (for a direct hernia) with interrupted sutures. Pre-fabricated mesh plugs are now available.

anterior approach. The hernial sac is dissected away from surrounding structures and reduced into the preperitoneal space. A flat sheet of polypropylene mesh is rolled up like a cigarette, tied, inserted in the defect, and secured with interrupted sutures to either the internal ring (for an indirect hernia) or the neck of the defect (for a direct hernia).

A prefabricated prosthesis that has the configuration of a flower is commercially available and is recommended by Rutkow and Robbins. This prosthesis is tailored to each patient's particular anatomy by removing some of the "petals" to avoid unnecessary bulk. Many surgeons consider this step important for preventing erosion into surrounding structures (e.g., the bladder); indeed, such complications have been reported, albeit rarely.

Millikan further modified the procedure by recommending that the inside petals be sewn to the ring of the defect. For an indirect hernia, the inside petals are sewn to the internal oblique portion of the internal ring, which forces the outside of the prosthesis underneath the inner side of the defect and makes it act like a preperitoneal underlay. For direct hernias, the inside petals are sewn to Cooper's ligament and the shelving edge of the inguinal ligament is sewn to the conjoined tendon, which, again, forces the outside of the prosthesis to act as an underlay.

The patch portion of the procedure is optional and involves placing a flat piece of polypropylene in the conventional inguinal space so that it widely overlaps the plug, much as in a Lichtenstein repair. The difference with a plug-and-patch repair is that only one or two sutures—or even, perhaps, no sutures—are used to secure the flat prosthesis to the underlying inguinal floor. Some surgeons, however, place so many sutures that they have in effect performed a Lichtenstein operation on top of the plug—a procedure sometimes referred to as a "plugstenstein."

To the credit of its proponents, the plug-and-patch repair, in all

of its varieties, has been skillfully presented and has rapidly taken a significant share of the overall inguinal hernia market. It is not only fast but also extremely easy to teach, which has made it popular in both private and academic centers.

Inguinal Herniorrhaphy: Preperitoneal Nonprosthetic Repairs

A key technical issue in a preperitoneal hernia repair is how the surgeon chooses to enter the preperitoneal space. In fact, within this general class of repair, the method of entry into this space constitutes the major difference between the various procedures.

Many approaches to the preperitoneal space have been described. For example, the space can be entered either anteriorly or posteriorly. If an anterior technique is to be used, the initial steps of the operation are similar to those of a conventional anterior herniorrhaphy. If a posterior technique is to be used, any of several incisions (lower midline, paramedian, or Pfannenstiel) will allow an extraperitoneal dissection. The preperitoneal space can also be entered transabdominally. This is useful when the patient is undergoing a laparotomy for some other condition and the hernia is to be repaired incidentally. Of course, the transabdominal preperitoneal laparoscopic repairs described elsewhere [see 5:28 *Laparoscopic Hernia Repair*], by definition, enter the preperitoneal space from the abdomen.

Reed credits Annandale as being the first surgeon to describe the anterior method of gaining access to the preperitoneal space.¹⁸ Bassini's operation, as classically performed, is technically an anterior preperitoneal operation, but it is never discussed in this group, because in the American variant of the procedure, the preperitoneal space is not entered. Cheatle suggested the posterior approach to the preperitoneal space for repair of an inguinal hernia but used a laparotomy to do it.¹⁹ Cheatle and Henry subsequently modified the operation so as to render it entirely extraperitoneal (the so-called Cheatle-Henry approach), which made the procedure more acceptable to surgeons.²⁰

The preperitoneal nonprosthetic method remained popular into the second half of the 20th century, championed by proponents such as Nyhus and Condon, who emphasized the importance of the iliopubic tract as the inferior border in primary closures of direct or indirect hernia defects.²¹ Today, however, these operations are of little more than historical significance, because it is now universally agreed that better results are obtained in this space when a prosthesis is used. Indeed, after 1975, Nyhus and Condon began routinely placing a 6 × 14 cm piece of polypropylene mesh to buttress the primary repair in all patients with recurrent hernias.²² When contraindications to a prosthesis are present [see Table 4], most surgeons would opt for a conventional anterior herniorrhaphy (e.g., a Bassini or Shouldice repair) rather than a preperitoneal nonprosthetic herniorrhaphy.

Inguinal Herniorrhaphy: Preperitoneal Prosthetic Repairs

The most important step in any preperitoneal prosthetic repair is the placement of a large prosthesis in the preperitoneal space on the abdominal side of the defect in the transversalis fascia. The theoretical advantage of this measure is that whereas in a conventional repair abdominal pressure might contribute to recurrence, in a preperitoneal repair, the abdominal pressure would actually help fix the mesh material against the abdominal wall, thereby adding strength to the repair. The hernia defect itself may or may not be closed, depending on the preference of the surgeon. The strength of the repair depends on the prosthesis rather

Table 4 Contraindications to Use of Prosthesis for Herniorrhaphy

Local infection ^{*52}	Allergy
Systemic infection	Patient preference

*The newer biological prostheses made of human cadaver skin or of submucosa from porcine small intestine may be acceptable.

than on closure of the defect; however, such closure may decrease the seroma formation that inevitably occurs at the site of the undisturbed residual sac. Although these seromas almost always are self-limited and disappear with time, they can be confused with recurrences by both patients and referring physicians. Accordingly, some surgeons prefer to take every step possible to prevent them.

ANTERIOR APPROACH

Read-Rives Repair

The initial part of a Read-Rives repair, including the opening of the inguinal floor, is much like that of a classic Bassini repair. The inferior epigastric vessels are identified and the preperitoneal space completely dissected. The spermatic cord is parietalized by separating the ductus deferens from the spermatic vessels. A 12 × 16 cm piece of mesh is positioned in the preperitoneal space deep to the inferior epigastric vessels and secured with three sutures placed in the pubic tubercle, in Cooper's ligament, and in the psoas muscle laterally. The transversalis fascia is closed over the prosthesis and the cord structures replaced. The rest of the closure is accomplished much as in a conventional anterior prosthetic repair.

POSTERIOR APPROACH

Stoppa-Rignault-Wantz Repair (Giant Prosthetic Reinforcement of Visceral Sac)

GPRVS has its roots in the important contribution that Henri Fruchaud made to herniology. In describing the myopectineal orifice that bears his name [see Figure 11], Fruchaud, who was Stoppa's mentor, popularized a different approach to the etiology of inguinal hernias.²³ Instead of subdividing hernias into direct, indirect, and femoral and then examining their specific causes, he emphasized that the common cause of all inguinal hernias was the failure of the transversalis fascia to retain the peritoneum. This concept led Stoppa to develop GPRVS, which reestablishes the integrity of the peritoneal sac by inserting a large permanent prosthesis that entirely replaces the transversalis fascia over the myopectineal orifice of Fruchaud with wide overlapping of surrounding tissue. With GPRVS, the exact type of hernia present (direct, indirect, or femoral) is unimportant, because the abdominal wall defect is not addressed.

Step 1: skin incision A lower midline, inguinal, or Pfannenstiel incision can be used, depending on the surgeon's preference. The inguinal incision is placed 2 to 3 cm below the level of the anterior superior iliac spine but above the internal ring; it is begun at the midline and extended laterally for 8 to 9 cm.²⁴

Step 2: preperitoneal dissection The fascia overlying the space of Retzius is opened without violation of the peritoneum. A combination of blunt and sharp dissection is continued later-

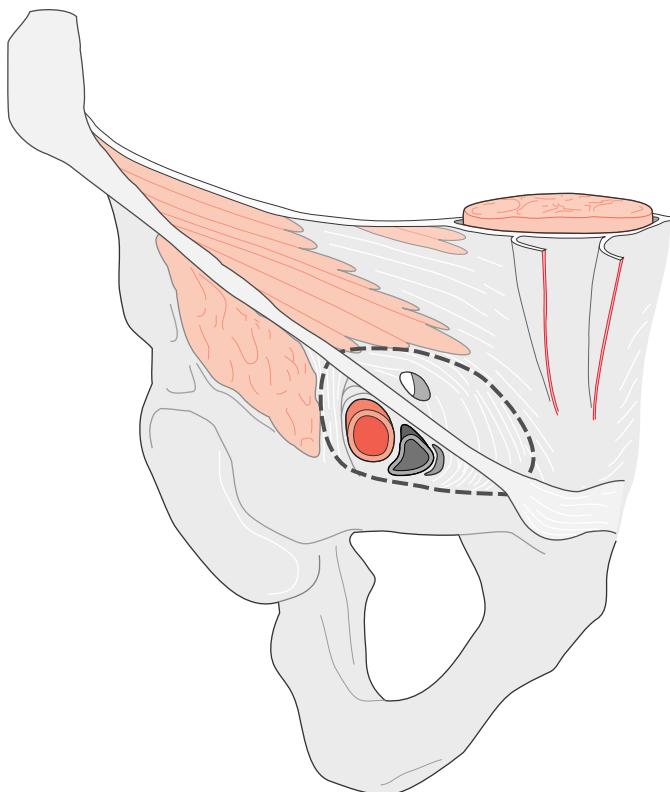

Figure 11 Inguinal herniorrhaphy. Depicted is the myopectineal orifice of Fruchaud. The area is bounded superiorly by the internal oblique muscle and the transversus abdominis, medially by the rectus muscle and sheath, laterally by the iliopsoas muscle, and inferiorly by Cooper's ligament. Critical anatomic landmarks (e.g., the inguinal ligament, the spermatic cord, and the femoral vessels) are contained within this structure.

ally posterior to the rectus abdominis and the inferior epigastric vessels. The preperitoneal space is completely dissected to a point lateral to the anterior superior iliac spine [see Figure 12]. The symphysis pubis, Cooper's ligament, and the iliopubic tract are identified. Inferiorly, the peritoneum is generously dissected away from the vas deferens and the internal spermatic vessels to create a large pocket, which will eventually accommodate a prosthesis without the possibility of rollup. In the inguinal approach, the anterior rectus sheath and the oblique muscles are incised for the length of the skin incision. The lower flaps of these structures are retracted inferiorly toward the pubis. The transversalis fascia is incised along the lateral edge of the rectus abdominis, and the preperitoneal space is entered; dissection then proceeds as previously indicated.

Step 3: management of hernial sac Direct hernial sacs are reduced during the course of the preperitoneal dissection. Care must be taken to stay in the plane between the peritoneum and the transversalis fascia, allowing the latter structure to retract into the hernia defect toward the skin. The transversalis fascia can be thin, and if it is inadvertently opened and incorporated with the peritoneal sac during reduction, a needless and bloody dissection of the abdominal wall is the result.

Indirect sacs are more difficult to deal with than direct sacs are, in that they often adhere to the cord structures. Trauma to the cord must be minimized to prevent damage to the vas deferens or the testicular blood supply. Small sacs should be mobilized from

the cord structures and reduced back into the peritoneal cavity. Large sacs may be difficult to mobilize from the cord without undue trauma if an attempt is made to remove the sac in its entirety. Accordingly, large sacs should be divided, with the distal portion left in situ and the proximal portion dissected away from the cord structures. Division of the sac is most easily accomplished by opening the sac on the side opposite the cord structures. A finger is placed in the sac to facilitate its separation from the cord. Downward traction is then placed on the cord structures to reduce any excessive fatty tissue (so-called lipoma of the cord) back into the preperitoneal space. This step prevents the “pseudorecurrences” that may occur if the abnormality palpated during the preoperative physical examination was not a hernia but a lipoma of the cord.

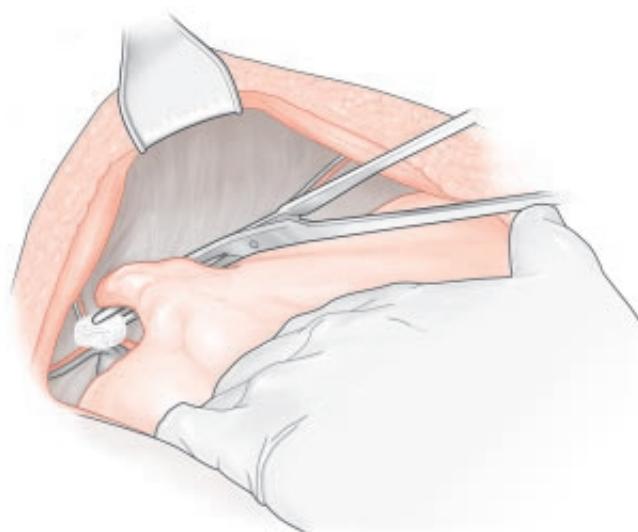

Figure 12 Inguinal herniorrhaphy: preperitoneal repair. The preperitoneal space is widely dissected from the pubic tubercle to the anterior superior iliac spine. Shown here is isolation of an indirect hernial sac.

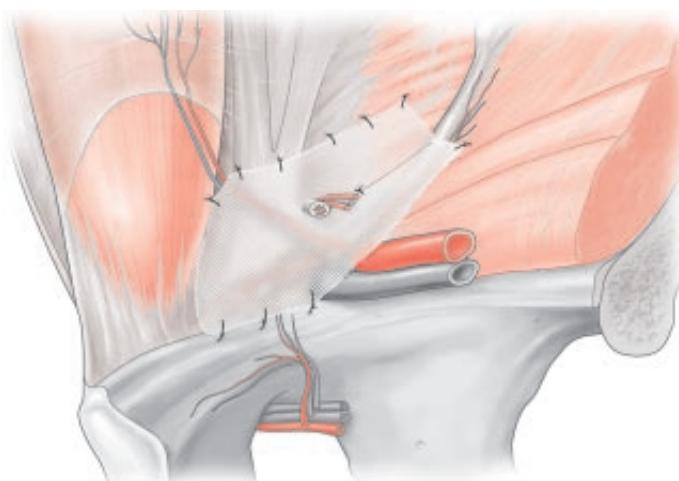

Figure 13 Inguinal herniorrhaphy: preperitoneal repair. Illustrated is the placement of a mesh prosthesis in the preperitoneal space. The prosthesis is sewn to Cooper's ligament inferiorly and to the transverse fascia well above the hernia defect anteriorly, in the fashion described by Nyhus.

Step 4: management of abdominal wall defect It is this step that varies most from one author to another. In Nyhus's approach, the defect is formally repaired, and only then is a tailored mesh prosthesis sutured to Cooper's ligament and the transversalis fascia for reinforcement [see Figure 13]. In Rignault's approach, the defect is loosely closed to prevent an unsightly early postoperative bulge.²⁵ In Stoppa's and Wantz's approaches, the defect is usually left alone, but the transversalis fascia in the defect is occasionally plicated by suturing it to Cooper's ligament to prevent the bulge caused by a seroma in the undisturbed sac.

Step 5: parietalization of spermatic cord The term parietalization of the spermatic cord, popularized by Stoppa, refers to a thorough dissection of the cord aimed at providing sufficient length to permit lateral movement of the structure [see Figure 14]. In Stoppa's view, this step is essential, in that it allows a prosthesis to be placed without having to be split laterally to accommodate the cord structures; the keyhole defect created when the prosthesis is split has been linked with recurrences. In Rignault's view, on the other hand, creation of a keyhole defect in the mesh to encircle the spermatic cord is preferable, the rationale being that this gives the prosthesis enough security to allow the surgeon to dispense with fixation sutures or tacks. Minimizing fixation in this area is important because of the numerous anatomic elements in the preperitoneal space that can be inadvertently damaged during suture placement.

Step 6: placement of prosthesis Dacron mesh, being more pliable than polypropylene, conforms well to the preperitoneal space and is therefore considered particularly suitable for GPRVS.

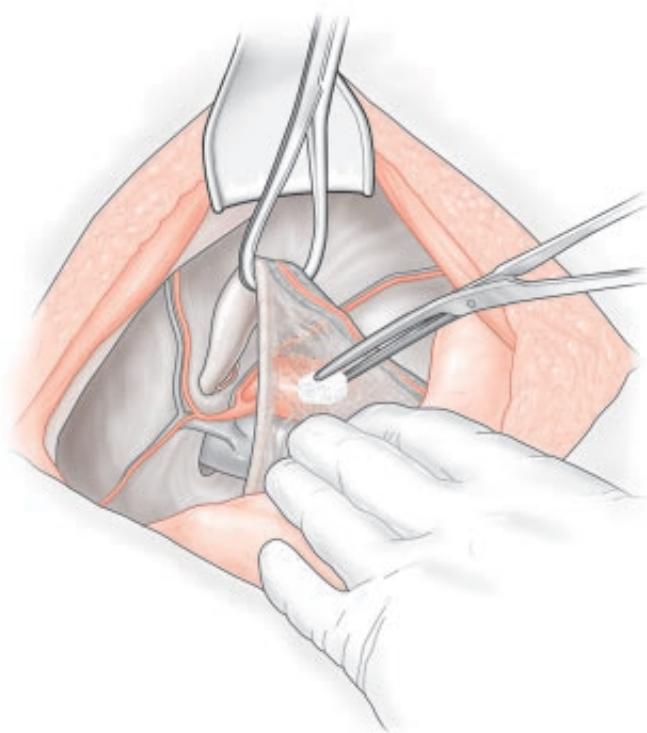

Figure 14 Inguinal herniorrhaphy: preperitoneal repair. Illustrated is the parietalization of the spermatic cord. The spermatic vessels and the vas deferens are mobilized so that they move laterally. This step is carried out so that the surgeon can place a large prosthesis that widely overlaps the myopectineal orifice without having to slit the prosthesis to accommodate the cord structures.

Stoppa's technique is most often associated with a single large prosthesis for bilateral hernias. The prosthesis is cut in the shape of a chevron [see Figure 15a], and eight clamps are positioned strategically around the prosthesis to facilitate placement into the preperitoneal space [see Figure 15b].

Unilateral repairs require a prosthesis that is approximately 15 × 12 cm but is cut so that the bottom edge is wider than the top edge and the lateral side is longer than the medial side. In Wantz's technique, three absorbable sutures are used to attach the superior border of the prosthesis to the anterior abdominal wall well above the defect [see Figure 16]. The sutures are placed from medial to lateral near the linea alba, the semilunar line, and the anterior superior iliac spine. A Reverdin suture needle facilitates this task. Three long clamps are then placed on each corner and the middle of the prosthesis of the inferior flap. The medial clamp is placed into the space of Retzius and held by an assistant. The middle clamp is positioned so that the mesh covers the pubic ramus, the obturator fossa, and the iliac vessels and is also held by the assistant. The lateral clamp is placed into the iliac fossa to cover the parietalized cord structures and the iliopsoas muscle. Care must be taken to prevent the prosthesis from rolling up as the clamps are removed.

Step 7: closure of the wound The surgical wound is closed along anatomic guidelines once the surgeon is assured that there has been no displacement or rollup of the prosthesis.

KUGEL AND UGAHARY REPAIRS

The Kugel and Ugahary repairs were developed to compete with laparoscopic repairs. They require only a small (2 to 3 cm) skin incision placed 2 to 3 cm above the internal ring.^{26,27} In Kugel's operation, the incision is oriented obliquely, with one third of the incision lateral to a point halfway between the anterior or superior iliac spine and the pubic tubercle and the remaining two thirds medial to this point. The incision is deepened through the external oblique fascia, and the internal oblique muscle is bluntly spread apart. The transversalis fascia is opened vertically for a distance of about 3 cm, but the internal ring is not violated. The preperitoneal space is entered and a blunt dissection performed. The inferior epigastric vessels are identified to confirm that the dissection is being done in the correct plane. These vessels should be left adherent to the overlying transversalis fascia and retracted medially and anteriorly. The iliac vessels, Cooper's ligament, the pubic bone, and the hernia defect are identified by palpation. Most hernial sacs are simply reduced; the exceptions are large indirect sacs, which must sometimes be divided, with the distal sac left in situ and the proximal sac closed. To prevent recurrences, the cord structures are thoroughly parietalized to allow adequate posterior dissection.

The key to Kugel's procedure is a specially designed 8 × 12 cm prosthesis made of two pieces of polypropylene with a single extruded monofilament fiber located near its edge. The construction of the prosthesis allows it to be deformed so that it can fit through the small incision; once inserted, it springs open to regain its normal shape, providing a wide overlap of the myopectineal orifice. The prosthesis also has a slit on its anterior surface, through which the surgeon places a finger to facilitate positioning.

Ugahary's operation is similar to Kugel's, but it does not require a special prosthesis. In what is known as the gridiron technique, the preperitoneal space is prepared through a 3 cm incision, much as in a Kugel repair. The space is held open with a narrow Langenbeck retractor and two ribbon retractors. A 10 × 15 cm piece of polypropylene mesh is rolled onto a long forceps

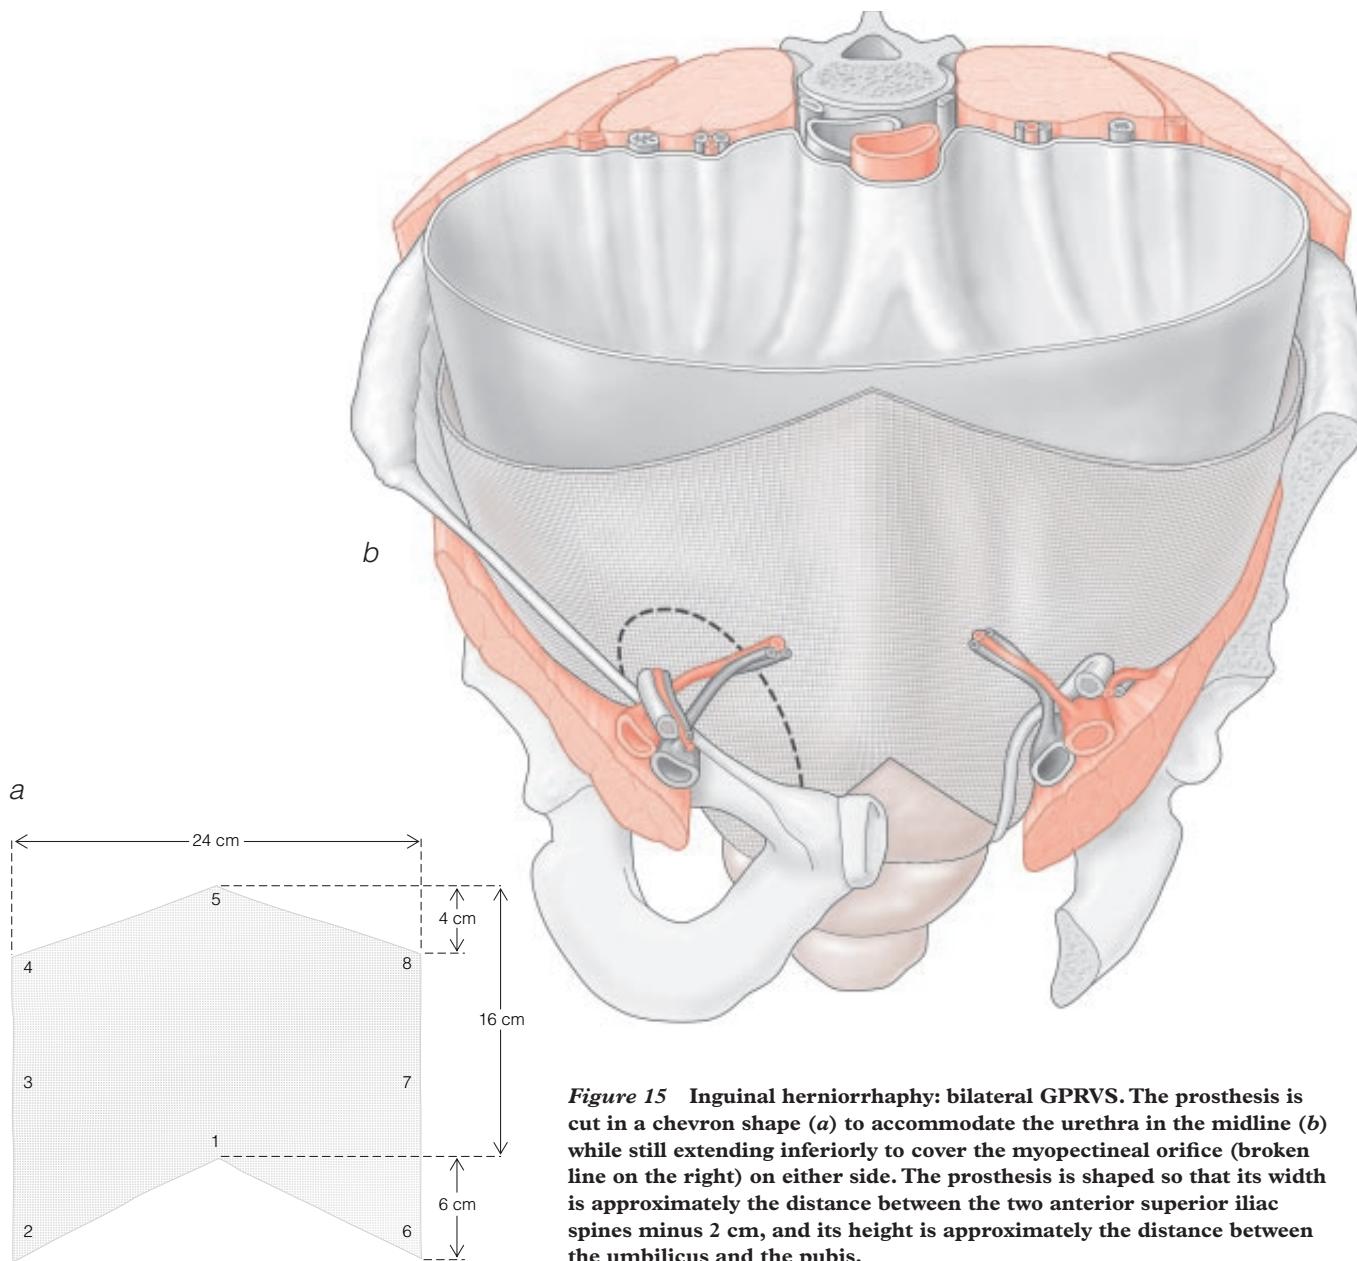

Figure 15 Inguinal herniorrhaphy: bilateral GPRVS. The prosthesis is cut in a chevron shape (*a*) to accommodate the urethra in the midline (*b*) while still extending inferiorly to cover the myopectineal orifice (broken line on the right) on either side. The prosthesis is shaped so that its width is approximately the distance between the two anterior superior iliac spines minus 2 cm, and its height is approximately the distance between the umbilicus and the pubis.

after the edges have been rounded and sutures placed to correspond to various anatomic landmarks. The forceps with the rolled-up mesh on it is introduced into the preperitoneal space, and the mesh is unrolled with the help of clamps and specific movements of the ribbon retractors.

Both operations have been very successful in some hands and have important proponents. However, because they are essentially blind repairs, considerable experience with them is required before the surgeon can be confident in his or her ability to place the patch properly.

COMBINED ANTERIOR-POSTERIOR APPROACH

Bilayer Prosthetic Repair

The bilayer prosthetic repair involves the use of a dumbbell-shaped prosthesis consisting of two flat pieces of polypropylene mesh connected by a cylinder of the same material. The purpose of this design is to allow the surgeon to take advantage of the pre-

sumed benefits of both anterior and posterior approaches by placing prosthetic material in both the preperitoneal space and the extraperitoneal space.

The initial steps are identical to those of a Lichtenstein repair. Once the conventional anterior space has been prepared, the preperitoneal space is entered through the hernia defect. Indirect hernias are reduced, and a gauze sponge is used to develop the preperitoneal space through the internal ring. For direct hernias, the transversalis fascia is opened, and the space between this structure and the peritoneum is developed with a gauze sponge. The deep layer of the prosthesis is deployed in the preperitoneal space, overlapping the direct and indirect spaces and Cooper's ligament. The superficial layer of the device occupies the conventional anterior space, much as in a Lichtenstein repair. It is slit laterally or centrally to accommodate the cord structures and then affixed to the area of the pubic tubercle, the middle of the inguinal ligament, and the internal oblique muscle with three or four interrupted sutures.

Inguinal Herniorrhaphy: Complications

POSTHERNIORRHAPHY GROIN PAIN

It is generally recognized that inguinal herniorrhaphy results in greater morbidity than was previously appreciated. Now that modern hernioplasty techniques have reduced recurrence rates to a minimum, chronic postoperative groin pain syndromes have emerged as the major complication facing inguinal hernia surgeons. In a crit-

ical review of inguinal herniorrhaphy studies between 1987 and 2000, the incidence of some degree of long-term groin pain after surgery was as high as 53% at 1 year (range, 0% to 53%).²⁸ In the absence of a standard raw database, it was somewhat difficult to extrapolate from these data, but the best estimate was that moderate to severe pain occurred in about 10% of patients and some degree of restriction of activity in about 25%.

Various postherniorrhaphy groin pain syndromes may develop,

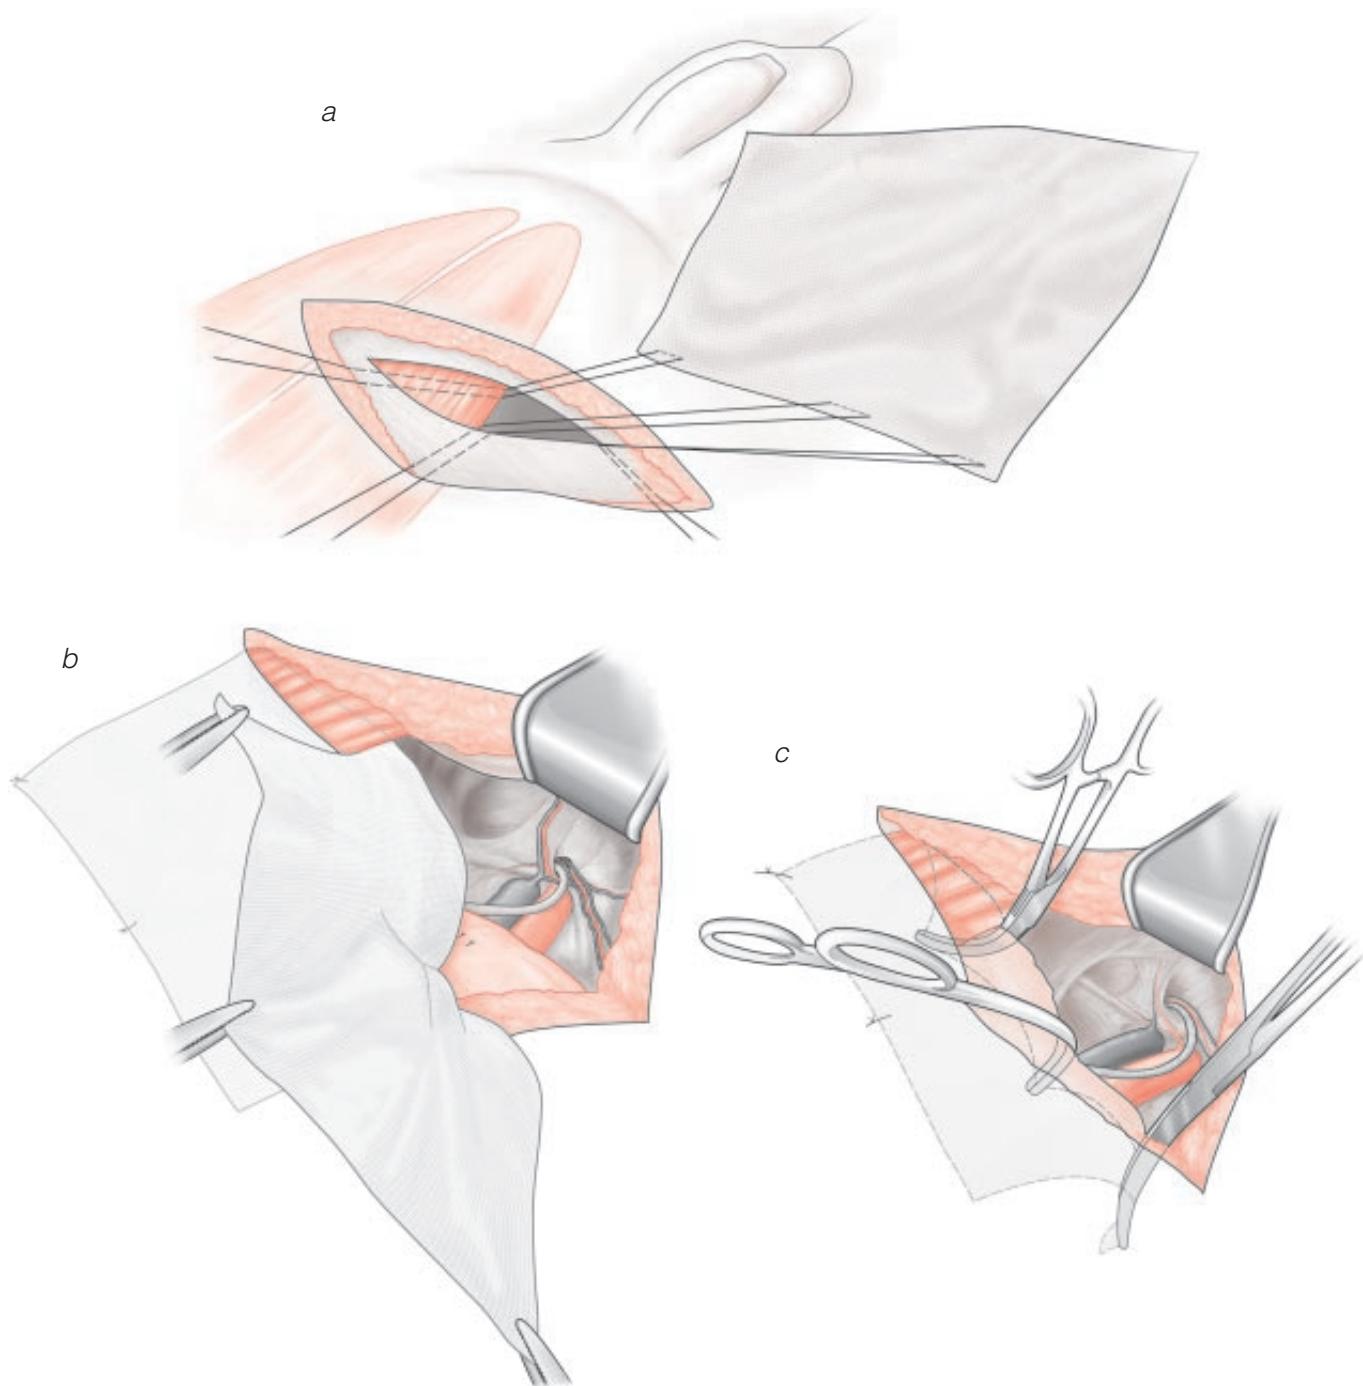

Figure 16 Inguinal herniorrhaphy: unilateral GPRVS (Wantz technique). The prosthesis is cut so that the inferior edge is wider than the superior edge by 2 to 4 cm and the lateral side is longer than the medial side. The width at the superior edge is approximately the distance between the umbilicus and the anterior superior iliac spine minus 1 cm, and the height is approximately 14 cm. Anteriorly, three sutures are placed—near the linea alba, near the semilunar line, and near the anterior superior iliac spine—from medial to lateral to fix the superior border (a). Three long clamps on the inferior edge (b) are used to implant the prosthesis deep into the preperitoneal space (c) with the peritoneal sac retracted cranially.

usually as a consequence of scarring, reaction to prosthetic material, or incorporation of a nerve in staples or suture material during the repair. Chronic postoperative groin pain occurs without regard to the type of repair performed. It can be classified into three general types, as follows:

1. Somatic (nociceptive) pain, the most common form, includes ongoing preoperative pathologic states that were the real causes of patients' pain preoperatively, usually related to ligament or muscle injury; new ligament or muscle injury caused by the operation; scar tissue; osteitis pubis; and reaction to prosthetic material.
2. Neuropathic pain is related to direct nerve damage. Accurate diagnosis is important because if the cause of pain is incorporation of a nerve in staples or sutures, effective surgical treatment is available. The nerves usually involved are the ilioinguinal nerve, the iliohypogastric nerve, the genital and femoral branches of the genitofemoral nerve, and the lateral cutaneous nerve of the thigh. The first two nerves are especially likely to be injured during a conventional herniorrhaphy, whereas the latter two are more likely to be damaged during a preperitoneal herniorrhaphy. Femoral nerve injury, fortunately, is extremely rare and is usually the result of a gross technical misadventure. Neuropathy is generally signaled by pain or paresthesia in the injured nerve's distribution; however, there is significant overlap in the distributions of these nerves, and as a result, it is frequently difficult to determine exactly which nerve is damaged.
3. Visceral pain is related to specific visceral functions; common examples are pain with urination and the dysejaculation syndrome.

Perhaps the most important single issue in dealing with postherniorrhaphy pain is whether the current pain is the same as or different from the pain that brought the hernia to the attention of the physician in the first place. If the latter is the case, efforts must be made to determine which of the numerous potential causative conditions is responsible. Computed tomography, ultrasonography, herniography, laparoscopy, and magnetic resonance imaging all are of diagnostic value in this setting. Of these, MRI has emerged as the most useful because of its ability to differentiate between muscle tears, osteitis pubis, bursitis, and stress fracture. A strain of the adductor muscle complex (comprising the adductor longus, the adductor brevis, the adductor magnus, and the gracilis) is a commonly overlooked cause of pain.

Treatment is difficult and often fails entirely. The difficulty is compounded when workers' compensation issues cloud the picture. The first possibility that must be ruled out is a recurrent hernia. As a rule, all three types of pain are best treated initially with reassurance and conservative treatment (e.g., anti-inflammatory medications and local nerve blocks); frequently, the complaint resolves spontaneously. The only exception to this rule might be the patient who complains of severe pain immediately (i.e., in the recovery room), who might be best treated with immediate reexploration before scar tissue develops. Otherwise, we scrupulously avoid reexploration in the first year after the procedure to allow for the possibility of spontaneous resolution. When groin exploration is required, neurectomy and neuroma excision, adhesiolysis, muscle or tendon repair, and foreign-body removal are all possibilities. The results are often less than satisfying.

ISCHEMIC ORCHITIS AND TESTICULAR ATROPHY

Orchitis or atrophy may result if the testicular blood supply is compromised during herniorrhaphy. Orchitis is defined as postoperative inflammation of the testicle occurring within the first 2

postoperative days. Patients experience painful enlargement and hardening of the testicle, usually associated with a low-grade fever; the pain is severe and may last several weeks. Ischemic orchitis is most likely attributable to thrombosis of the veins draining the testicle, caused by dissection of the spermatic cord. It may progress over a period of months and eventually result in testicular atrophy. This latter development is not inevitable, however. In fact, the occurrence of testicular atrophy is quite unpredictable, in that most patients with this condition have no history of any testicular problems associated with the index herniorrhaphy. Overall, the vast majority of patients who experience testicular problems as an immediate complication of herniorrhaphy go on to recover without atrophy. Bendavid, in a study of the incidence of testicular atrophy at the Shoultice Hospital, found that this complication occurred in only 19 (0.036%) of 52,583 primary inguinal hernia repairs and in only 33 (0.46%) of 7,169 recurrent inguinal hernia repairs.²⁹

HEMORRHAGE

Postherniorrhaphy bleeding—usually the result of delayed bleeding from the cremasteric artery, the internal spermatic artery, or branches of the inferior epigastric vessels—can produce a wound or scrotal hematoma. Injuries to the deep circumflex artery, the corona mortis, or the external iliac vessels may result in a large retroperitoneal hematoma.

OSTEITIS PUBIS

Osteitis pubis has diminished in frequency since surgeons began to realize the importance of not placing sutures through the periosteum. In laparoscopic repairs, staples are used to attach the mesh to Cooper's ligament, which may cause osteitis in some cases.

PROSTHESIS-RELATED COMPLICATIONS

The increasingly liberal use of prosthetic material in conventional herniorrhaphy and the routine use of such material in laparoscopic herniorrhaphy make the discussion of complications related directly to foreign material a timely one. Tissue response, which is variable from person to person, can be so intense that the prosthetic material is deformed by contraction. Erosion can result in intestinal obstruction or fistulization, especially if there is physical contact between intestine and prosthesis.^{30,31} Erosion into the cord structures has also been reported.³²

INFECTION

The prostheses used for inguinal herniorrhaphies, unlike those used for ventral herniorrhaphies, rarely become infected. The reasons why the groin is apparently a protected area are unclear. When infections do occur in the groin, they can occasionally be successfully treated with drainage and prolonged antibiotic therapy; more often, however, the prosthesis must be removed. Rejection of the prosthesis because of an allergic response is possible but extremely rare. What patients call rejection in their histories is usually the result of infection.

Incisional Herniorrhaphy

Incisional hernias occur as a complication of previous surgery. They may be caused by poor surgical technique, rough handling of tissues, use of rapidly degraded absorbable suture materials for closing the abdomen, closure of the abdomen under tension, and infection (with or without clinical wound dehiscence).³³ Male sex, advanced age, morbid obesity, abdominal distention, cigarette smoking, pulmonary disease, and hypoalbuminemia have all been

incriminated as associated predisposing conditions, but the exact nature of these associations has never been studied in well-controlled trials. Most authorities believe that the best way of preventing incisional hernias is to close abdominal wounds with continuous nonabsorbable monofilament sutures. This is a contentious issue among surgeons, because some feel that the new longer-lasting absorbable sutures are just as good and are less likely to cause suture sinus formation, which is reported in as many as 9% of patients whose abdomens are closed with a nonabsorbable suture.³⁴

In 2000, a systematic review and meta-analysis of randomized controlled trials was published that used the MEDLINE and Cochrane Library databases in an effort to determine which suture material and technique best reduced the risk of incisional hernia.³⁵ The incidence of incisional hernia was significantly lower when nonabsorbable sutures were used in a continuous closure; however, the incidence of suture sinus formation and that of wound pain were significantly higher. The incidence of wound dehiscence or wound infection was not affected by suture material or closure method. Subgroup analyses of individual sutures showed no significant difference in incisional hernia rates between polydioxanone and polypropylene; however, rates were noticeably higher with polyglactin. The authors concluded that surgical practice in this area depended far more on tradition than on high-quality level I scientific evidence.

Continuous suturing is faster, and there has never been convincing evidence that it is inferior to interrupted fascial closure; accordingly, it is favored by most surgeons. In a continuous closure, stitches should be placed 1 cm away from the edge and 1 cm apart from each other. To prevent excessive tension, the length of the suture should be four times the length of the wound.³⁶ The abdominal wall may be closed with a mass technique, whereby the peritoneum and the anterior and posterior muscle sheaths are fused as a single layer.³⁷ Alternatively, a multilayered approach may be considered.

The incidence of incisional herniation depends on how the condition is defined. The best definition is any abdominal wall gap, with or without a bulge, that is perceptible on clinical examination or imaging by 1 year after the index operation. If a visible bulge is made part of the definition, the incidence will be underestimated. In the literature, the incidence of incisional herniation after a midline laparotomy ranges from 3% to 20% and doubles if the index operation was associated with infection.

Herniation is most common after midline and transverse incisions but is also well documented after paramedian, subcostal, appendectomy (gridiron), and Pfannenstiel incisions.³⁸ A 1995 analysis of 11 publications addressing ventral hernia incidence after various types of incisions found the risk to be 10.5%, 7.5%, and 2.5% for midline, transverse, and paramedian incisions, respectively.³⁴ Upper midline incisions are most likely to lead to ventral hernia formation; transverse and oblique incisions are the least likely. Muscle-splitting incisions probably are associated with a lower incidence of herniation, but they restrict access to the abdominal cavity. Males and females are at roughly equal risk, but early evisceration is more common in males. Most cases are detected within 1 year of surgery, and the basic cause is thought to be separation of aponeurotic edges in the early postoperative period. Incarceration and strangulation occur with significant frequency, and recurrence rates after operative repair approach 50%.

OPERATIVE TECHNIQUE

Simple Nonprosthetic Repair

Simple nonprosthetic repair of an incisional hernia is reserved for only the least complicated defects, because in large series of

unselected patients, the recurrence rate ranges from 25% to 55%.⁷ If there is a solitary defect 3 cm or less in diameter, primary closure with nonabsorbable suture material is appropriate. Some surgeons perform a simple edge approximation after flaps are developed on either side of the defect. Others use a Mayo "vest-over-pants" repair. Various advancement and darn procedures have also been described.

A more substantial repair for these defects was popularized by Ramirez.³⁹ In this operation, known as the component separation technique, fascial planes are incised between muscle groups, so that, in effect, the abdominal wall is lengthened by allowing the muscle to separate on either side of a defect. The hernia can then be repaired primarily with less tension on the repair. This procedure is especially useful at contaminated hernia sites.

A similar procedure is the keel operation of Maingot, which was popular in the middle of the 20th century. The anterior rectus sheath is incised longitudinally, and the medial edge is allowed to rotate behind the rectus abdominis. This, in effect, lengthens the posterior rectus sheath, allowing it to be closed under less tension. The lateral edges of the incised rectus sheath on each side are then approximated to each other.

Onlay Prosthetic Repair

In this technique, a prosthetic onlay is placed over any of a wide variety of simple repairs. Large series of selected patients have documented acceptable results with onlay prosthetic repair, but most surgeons feel that this technique offers little advantage over the simple repair that the prosthesis overlies.⁷

Prosthetic Bridging Repair

Prosthetic bridging repair became popular in the 1990s, in keeping with the tension-free concept for inguinal herniorrhaphy. The basic principle underlying this technique is that for a prosthetic repair to be effective, the defect should be bridged. Although this repair is theoretically attractive, it has not been nearly as successful for incisional hernias as for inguinal hernias. The recurrence rate is especially high in obese patients.

When a hernia defect is bridged with a mesh prosthesis, every attempt should be made to isolate the material from the intra-abdominal viscera to prevent erosion and subsequent fistula formation or adhesive bowel obstruction. This can be accomplished by means of a peritoneal flap constructed from the peritoneal sac or omentum. When contact with intra-abdominal organs cannot be avoided, expanded polytetrafluoroethylene (e-PTFE) should be strongly considered for the prosthesis. Most authorities feel that complications are less likely with e-PTFE, though this has not been unequivocally shown to be the case.

Combined Fascial and Mesh Closure

The issue of contact between the intra-abdominal viscera and the prosthesis has been further addressed by techniques that combine features of the component separation technique with the tension-free concept. The posterior fascia is closed primarily, but the anterior fascia is allowed to remain open, so that there is no tension at all. The anterior fascia is then bridged with a prosthesis.

Sublay Prosthetic Repair

Sublay prosthetic repair, sometimes referred to as the retro-muscular approach, is characterized by the placement of a large prosthesis in the space between the abdominal muscles and the peritoneum [see Figure 17]. It was popularized by Velamenta, Stoppa, and Wantz and is particularly suitable for large and multiply recurrent hernias when most of the abdominal wall must be

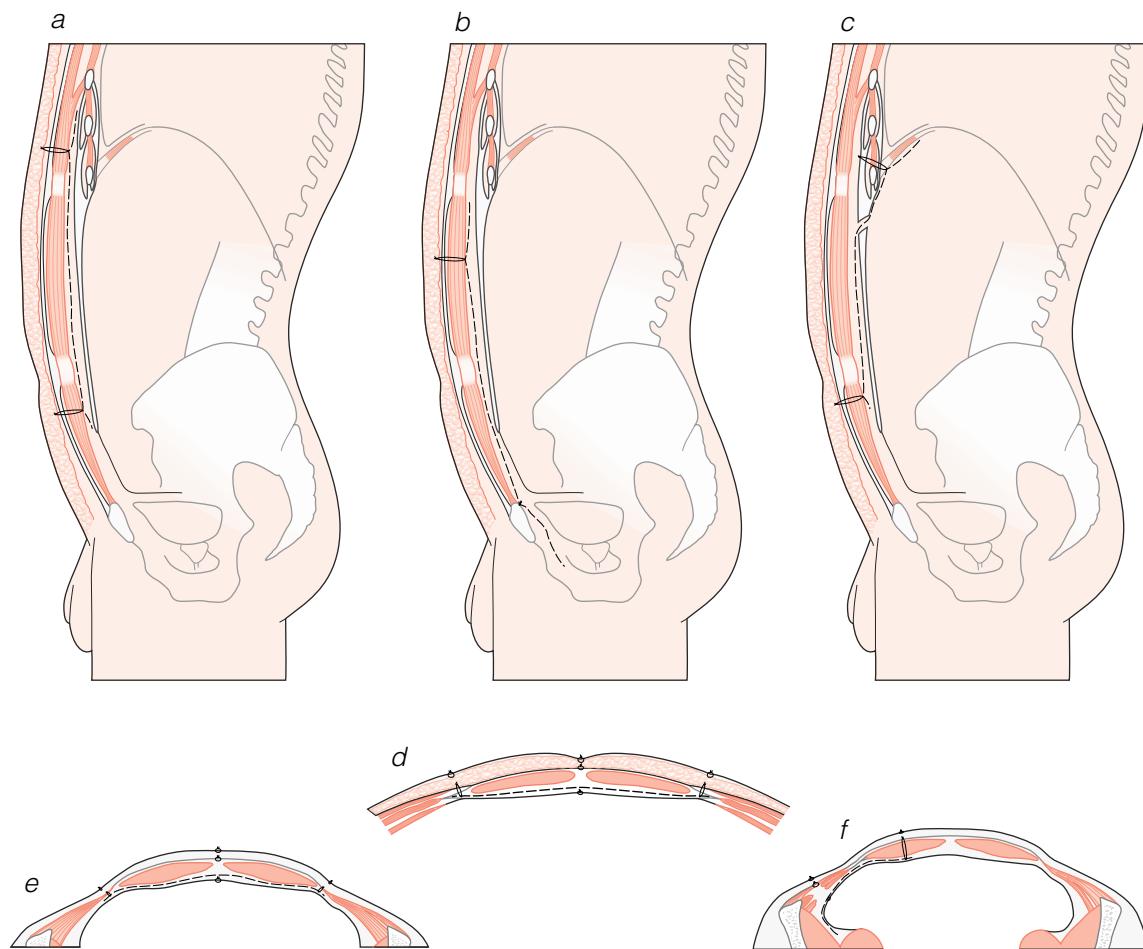

Figure 17 Incisional herniorrhaphy: sublay prosthetic repair. The lateral views show sites of prosthesis implantation (broken lines) and suture fixation for incisional hernias in (a) the upper midline, (b) the lower midline, and (c) the subcostal region. The cross-sectional views show the same things for incisional hernias in (d) the upper midline, (e) the lower midline, and (f) the right lower quadrant (after appendectomy).

reconstructed.⁴⁰⁻⁴² It is considered the most effective conventional incisional hernia repair and therefore the one against which other procedures must be measured.

The posterior rectus sheath is opened on each edge of the hernia defect and dissected away from the undersurface of the recti for a distance of 10 to 15 cm. The posterior rectus sheaths are then approximated to each other primarily. A large mesh prosthesis (composed of e-PTFE if the approximation of the posterior rectus sheath is inadequate) is then placed in this space outside the repaired posterior sheath but beneath the recti. The mesh is secured in this position with several sutures that are placed with a suture passer through small stab incisions at the periphery of the prosthesis and tied in the subcutaneous tissue above the fascia. The laparoscopic incisional herniorrhaphy discussed elsewhere [see 5:28 Laparoscopic Hernia Repair] was designed with the principles of this operation in mind.

COMPLICATIONS

Although prosthesis-related infection is rare with prosthetic inguinal herniorrhaphies, it remains a major problem with prosthetic incisional herniorrhaphies. It occurs in about 5% of repairs and can delay healing for prolonged periods. Risk factors for prosthesis infection include preexisting infection or ulceration of the skin overlying the hernia, obesity, incarcerated or obstructed

bowel within the hernia, and perforation of the bowel during hernia repair. Seromas are common, especially when a large prosthesis is required or there has been extensive flap dissection of the subcutaneous layer from the fascia. Untreated seromas commonly become infected secondarily. Suction drains can be useful but are likely to result in prosthesis infection if left in place too long. Strategies for preventing and managing seromas are largely based on empiricism and personal opinion; objective data are virtually nonexistent. It is not always necessary to remove the mesh prosthesis if infection develops. A trial of local wound care after opening the incision and debriding the infected area is warranted. As noted, some authorities believe that e-PTFE is less prone to infection. Nevertheless, once infection is established, e-PTFE prostheses (unlike mesh prostheses) usually have to be removed.

A dilemma arises when a patient has a large incisional hernia and the wound is contaminated either by skin infection or by injury to the bowel during mobilization. In this situation, a non-absorbable mesh would have a significant chance of becoming infected, and an enterocutaneous fistula could complicate matters further. For these situations, an absorbable mesh made of polyglycolic acid is recommended to prevent evisceration. Granulation tissue forms over the mesh, making skin grafting possible. The mesh itself is absorbed in about 3 weeks, leaving no permanent foreign body to serve as a persistent focus of infection.

Unfortunately, however, recurrence of the incisional hernia is inevitable. The biologic prosthesis now being evaluated for inguinal herniorrhaphy has also been employed in this situation, but the results are as yet unknown.

Several other factors might contribute to the poor results of incisional hernia repair, including preexisting comorbid conditions for which the patient underwent the original operation, cancer-related debilitation, morbid obesity, the use of steroids, and chemotherapy.

Repair of Other Abdominal Wall Hernias

PERUMBILICAL HERNIA

Gastroschisis

Gastroschisis is seen in fetuses and neonates. The typical presentation is a defect in the abdominal wall to the right of the umbilicus through which the intestines protrude. There is no associated sac. Usually, only the small bowel and the large bowel are eviscerated; however, the stomach, the liver, and the genitourinary system may be involved. Because the bowel is exposed to amniotic fluid, the maternal serum α -fetoprotein (AFP) level tends to be elevated, and the bowel may become thickened and dilated as a result. Bowel complications (e.g., malrotation and segmental atresia) are present in approximately 15% of cases of gastroschisis; however, other anomalies are uncommon. Gastroschisis occurs sporadically and is not associated with chromosome abnormalities, though some familial occurrences are reported.

After the presence of gastroschisis is confirmed, serial ultrasonographic follow-up is indicated for measurement of fetal growth and evaluation of bowel status. Counseling of a couple expecting a baby with gastroschisis should include assessment of the prognosis, description of the surgical and medical support the newborn is likely to need, and discussion with both the neonatologist and the pediatric surgeon.

Omphalocele (Exomphalos)

Omphalocele also is seen in fetuses and neonates. In this condition, a midline defect of the abdominal wall results in herniation of the bowel and intra-abdominal contents into the umbilical cord; the coverings of the hernia are therefore the coverings of the umbilical cord. The defect may be categorized according to whether the liver is present in the omphalocele sac. If the liver is present in the sac, the omphalocele is extracorporeal; if not, the omphalocele is intracorporeal. Omphalocele differs from gastroschisis in that the bowel contents are contained in a membrane, and thus, maternal serum AFP levels generally are not elevated. Often, ascites develops within the omphalocele sac.

Amniocentesis is indicated when an omphalocele is identified in a fetus, because approximately 30% of fetuses with an omphalocele have a chromosome abnormality. The most common such abnormalities are trisomies 18, 13, and 21; Turner syndrome (45, X); and triploidy. Beckwith-Wiedemann syndrome may also be associated with omphalocele. Approximately 67% to 88% of fetuses with an omphalocele have other anomalies as well. These associated anomalies often determine the prognosis.

Umbilical and Paraumbilical Hernia

An umbilical hernia is the result of improper healing of an umbilical scar, which leads to a fascial defect that is covered by skin. If the defect is to one side, it is called a paraumbilical hernia; this variant is more common in adults. The vast majority of

umbilical hernias presenting in children are congenital, whereas 90% of those diagnosed in adults are acquired. These hernias are eight times more common in black children than in white ones. The onset of umbilical or paraumbilical hernia in older patients is usually sudden, and the defect tends to be relatively small. In these patients, it is important to look for an underlying cause of increased intra-abdominal pressure (e.g., ascites or an intra-abdominal tumor).

The differential diagnosis of an umbilical hernia should include so-called caput medusae, a condition in which varicosities extend radially from the umbilicus as a consequence of portal hypertension. These varicosities look like varicose veins, exhibit a bluish discoloration, and fill when the patient strains. Another condition to be considered is the so-called Sister Mary Joseph node, which is a metastatic deposit of intra-abdominal cancer at the umbilicus. The cancer cells reach this area via lymphatic vessels in the falciform ligament. A hard nodule is palpable at the umbilicus, and biopsy verifies its cancerous nature. Other periumbilical masses that might be confused with an umbilical hernia are umbilical granulomas, omphalomesenteric duct remnant cysts, and urachal cysts.

Management of umbilical hernias is conservative in children younger than 2 years. A large proportion of these defects heal spontaneously. Consequently, the usual practice is to observe the hernia until the child has reached 2 years of age, by which point about 80% of defects will have healed. Umbilical hernias persisting after the age of 2 years probably will not heal spontaneously and therefore must be treated surgically. The customary recommendation is to repair the hernia by the time the child reaches 5 years of age, so that he or she is not subjected to psychological trauma when participating in normal school sports activities.

In young patients, compression of the hernia with a bandage or a coin is commonly attempted. This practice probably has no real effect but has gained acceptance by parents; the high rate of spontaneous closure fuels the perception (or misperception) of efficacy. In patients who do require surgery—namely, children older than 2 years and adults—the repair used depends on the size of the hernia. Most of the defects are small and can therefore be closed by simple suturing. Alternatively, the Mayo technique may be used. A subumbilical semilunar incision is made, the hernial sac is opened, the contents of the sac are reduced into the abdomen, and the sac is excised. An overlapping or waist-coating technique is then employed, in which the upper edge of the linea alba is placed so as to overlap the lower and fixed in place with a nonabsorbable mattress suture. This technique is controversial: some surgeons argue that the overlapping layers serve only to increase the tension on the repair, thus inviting recurrence.

For larger hernias, particularly those in adults, a popular approach is to dissect the sac away from the undersurface of the skin of the umbilicus and reduce it into the preperitoneal space. The fascial defect is then bridged with a prosthesis without fear of contact with the intra-abdominal viscera. The prosthesis is sutured circumferentially to the defect; alternatively, it can be sutured to the undersurface of the posterior rectus sheath and the linea alba above the peritoneal closure. If the peritoneum cannot be kept intact beneath the defect, omentum should be tacked to the peritoneum circumferentially to isolate the abdominal viscera from the prosthesis at least to some degree.

EPIGASTRIC HERNIA

Epigastric hernias occur through a defect in the linea alba. In most patients with these hernias, as well as those with umbilical

hernias, only a single decussation of the fibers of the linea alba is present, as opposed to the triple decussation seen in most persons; this abnormality is the cause of the defect in the midline.

The reported incidence of epigastric hernia ranges from less than 1% to as high as 5%. They are two to three times more common in men than in women, and 20% of them are multiple. Most defects are less than 1 cm long and contain only incarcerated preperitoneal fat, with no peritoneal sac. For this reason, they generally cannot be visualized laparoscopically. The usual complaint is a painful nodule in the upper midline. As a rule, reduction of the preperitoneal fat and simple closure of the defect resolves the complaint. Given the relatively high recurrence rate (up to 10%), however, some surgeons prefer to place a postage stamp-sized piece of prosthetic material in the preperitoneal space to reinforce the repair. Others bridge the defect by suturing the prosthesis circumferentially. Some authorities recommend exposure of the entire linea alba because of the incidence of multicentricity. We believe that this practice leads to unnecessary morbidity. Instead, we make a small incision with the patient under local anesthesia and explain to him or her that additional repairs may be required later.

Left untreated, an epigastric hernia can become large enough to develop a peritoneal sac into which intra-abdominal contents can protrude. Usually, however, the sac is wide, and serious complications are infrequent.

DIASTASIS RECTI

In diastasis recti, the two recti abdominis are separated quite widely, and the linea alba area is stretched and protrudes like a fin. Although the protrusion is easily reducible and almost never produces complications, many patients find it unsightly and request treatment. Surgical therapy would involve removing a strip of the weakened linea alba and reapproximating it; however, this approach could result in tension, which in turn might lead to recurrence. The alternative would be a mesh repair.

PARASTOMAL HERNIA

Parastomal hernia is one of the most common complications of stoma formation. Its incidence is much higher than is generally appreciated. There is good evidence to suggest that more than 50% of patients will eventually be found to have a paracolostomy hernia if followed for longer than 5 years.⁴³ The rate of herniation with small bowel stomas is also discouraging, though less so than that with colostomies. The results of parastomal hernia repair are particularly dismal, with recurrence being the rule rather than the exception.

Some parastomal hernias can be accounted for by poor site selection or technical errors (e.g., making the fascial opening too large or placing a stoma in an incision), but the overall incidence is too high to be explained by these causes alone. Placement of the stoma lateral to the rectus sheath is widely touted as a cause of parastomal hernia, but this claim is not universally accepted. Obesity, malnutrition, advanced age, collagen abnormalities, postoperative sepsis, abdominal distention, constipation, obstructive uropathy, steroid use, and chronic lung disease are also contributing factors.^{44,45}

Newer techniques for stoma construction (e.g., extraperitoneal tunneling) have had little impact on the incidence of parastomal hernia. Fortunately, patients tolerate these hernias well, and life-threatening complications (e.g., bowel obstruction or strangulation) are rare. Routine repair, therefore, is not recommended; repair is appropriate only when there is an absolute or relative indication [see Table 5]. If repair is considered, patients

must be informed that there is a significant chance that the hernia will recur.

Three general types of parastomal hernia repairs are currently performed: (1) fascial repair, (2) stomal relocation, and (3) prosthetic repair. Fascial repair involves local exploration around the stoma site, with primary closure of the defect. This approach should be considered of historical interest only because the results are so miserable. Stomal relocation yields much better results and is considered the procedure of choice by many surgeons. This approach is especially appropriate for patients who have other stoma problems (e.g., skin excoriation or suboptimal stoma construction). The use of a prosthesis with stomal relocation is not generally recommended because of the inherent danger of contamination. In the past few years, the popularity of stomal relocation has waned because of the realization that many patients who undergo this procedure ultimately end up with three hernias instead of one: incisional hernias develop in the old stoma site and the laparotomy incision, while a paracolostomy hernia develops at the new site.

Prosthetic repair appears to be the most promising approach, but it is necessary to accept the complications inherent in the placement of a foreign body. The stoma exit site must be isolated from the surgical field to lower the risk of prosthesis-related infection. The prosthesis can be placed extraperitoneally by making a hockey-stick incision around the stoma, taking care to ensure that the incision is outside the periphery of the stoma appliance. Once the subcutaneous tissue is divided, dissection proceeds along the fascia until the sac is identified and removed. The defect is then closed and an overlying prosthesis buttress sutured in place. Alternatively, the fascial defect is bridged with the prosthesis for a “tension-free” repair.

The extraperitoneal prosthetic approach seems logical but can be very technically demanding, in that it is sometimes difficult to define the entire extent of the hernia defect. Moreover, the considerable undermining involved can lead to seroma formation and eventual infection. As an alternative, an intra-abdominal prosthetic approach has also been described that is theoretically attractive because it avoids the local complications of the extraperitoneal operation and incorporates the mechanical advantage gained by placing the prosthesis on the peritoneal side of the abdominal wall.^{46,47} Intra-abdominal pressure then serves to fuse the prosthetic material to the abdominal wall rather than being a factor in recurrence. Either e-PTFE or polypropylene mesh can be used. The detractors of the intra-abdominal approach argue that the risk of complications (e.g., adhesive bowel obstruction and fistula formation resulting from the intra-abdominal placement of the prosthesis) outweighs the advantages. The intra-abdominal approach is particularly well suited for laparoscopic repair, and several techniques have been described.^{48,49}

SPIGELIAN HERNIA

The Flemish anatomist Adriaan van der Spieghel was the first to describe the semilunar line, which defines the lower limit of the posterior rectus sheath. A spigelian hernia protrudes through an area of weakness just lateral to the rectus sheath and just below this line.⁵⁰ The hernia usually is interparietal and rarely penetrates the external oblique fascia; consequently, it can be difficult to appreciate. Spigelian hernias are unusual, with fewer than 750 cases described in the literature to date; however, given that they are so easily diagnosed laparoscopically, it is possible that the incidence will increase. These hernias tend to occur more often in elderly female patients. It is difficult to explain precisely why

Table 5 Indications for Repair of Parastomal Hernia

Absolute indications	Obstruction Incarceration with strangulation
Relative indications	Incarceration Prolapse Stenosis Intractable dermatitis Difficulty with appliance management Large size Cosmesis Pain

spigelian hernias develop; there is no area of weakness in the abdominal wall caused by the passage of blood vessels through the abdominal wall in this position. Undoubtedly, childbirth and various other events that stretch the abdominal wall contribute to their development.

Spigelian hernias are usually small (about 1 to 2 cm in diameter), though large ones (up to 14 cm in diameter) have been described. Omentum, small bowel, or large bowel may enter the sac. Incarceration and strangulation are common complications. The usual clinical presentation is a lower abdominal swelling just lateral to the lateral border of the rectus abdominis. In many cases, however, pain and tenderness are the only signs. Plain x-rays may show a bowel shadow in this area, and of course, CT scanning visualizes the defect and the hernia well.

The standard treatment for a spigelian hernia is operative repair. A transverse incision is centered over the mass. The external oblique aponeurosis is split to reveal the protrusion. If there is a large sac, it is divided and sutured. The aponeurotic defect is triangular, with the base located at or near the lateral border of the rectus abdominis. The defect is closed by joining the separated transversus abdominis and internal oblique muscle layers. Recurrence is uncommon.

SUPRAVESICAL HERNIA

Supravesical hernias develop anterior to the urinary bladder as a consequence of failure of the integrity of the transversus abdominis and the transversalis fascia, both of which insert into Cooper's ligament.⁵¹ The preperitoneal space is continuous with the retropubic space of Retzius, and the hernial sac protrudes into this area. The sac is directed laterally and emerges at the lateral border of the rectus abdominis in the inguinal region, the femoral region, or the obturator region. It also may be associated with an inguinal hernia, a femoral hernia, or an obturator hernia. Treatment of a supravesical hernia involves prompt recognition of the defect at the time of groin exploration and appropriate reinforcement of the area of the defect.

A variant of this hernia, known as an internal supravesical hernia, may also arise. Internal supravesical hernias are classified according to whether they cross in front of, beside, or behind the bladder. Bowel symptoms predominate in patients with these defects, and urinary tract symptoms develop in as many as 30%. Treatment is surgical and is accomplished transperitoneally via a low midline incision. The sac can usually be reduced without difficulty; the neck of the sac should be divided and closed.

INTERPARIETAL HERNIA

With an interparietal hernia, the hernial sac lies between the

layers of the abdominal wall. It may be either preperitoneal (between the peritoneum and the transversalis fascia) or interstitial (between the muscle layers of the abdominal wall). Most interparietal hernias are of the latter type and occur in the groin; accordingly, they are designated inguinal interstitial hernias. When the sac passes behind the inguinal ligament in the region of the femoral ring, the resulting defect is known as an inguinocrural hernia.

The cause of interparietal hernias appears to be related to congenital abnormalities (e.g., maldescent of the testis, congenital pouches, absence of the cremaster muscle, and absence of the external abdominal ring). Diagnosis is difficult because there is no obvious swelling of the abdominal wall unless the hernia is large. In many cases, pain is the only symptom; therefore, it is not unusual for patients to present with intestinal obstruction secondary to incarceration. CT, ultrasonography, and laparoscopy can facilitate the diagnosis. Not infrequently, the correct diagnosis is made only at operation. Treatment starts by addressing the intestinal obstruction that is so often the presenting symptom. The defect itself is then repaired in accordance with the same principles followed in inguinal or incisional herniorrhaphy.

RICHTER'S HERNIA

In a Richter's hernia, part of the bowel wall herniates through the defect and may become ischemic and gangrenous, but intestinal obstruction does not occur. The overlying skin may be discolored. The herniated bowel wall is exposed by opening the sac, and the neck of the sac is enlarged to allow delivery of the bowel into the wound. The gangrenous patch is excised and the bowel wall reconstituted. The hernia is then repaired.

LUMBAR HERNIA

The lumbar region is the area bounded inferiorly by the iliac crest, superiorly by the 12th rib, posteriorly by the erector spinae group of muscles, and anteriorly by the posterior border of the external oblique muscle as it extends from the 12th rib to the iliac crest. There are three varieties of lumbar hernia:

1. The superior lumbar hernia of Grynfelt. In this variety, the defect is in a space between the latissimus dorsi, the serratus posterior inferior, and the posterior border of the internal oblique muscle.
2. The inferior lumbar hernia of Petit. Here, the defect is in the space bounded by the latissimus dorsi posteriorly, the iliac crest inferiorly, and the posterior border of the external oblique muscle anteriorly.
3. Secondary lumbar hernia. This hernia develops as a result of trauma—mostly surgical (e.g., renal surgery)—or infection. In the past, it was encountered relatively frequently as a consequence of spinal tuberculosis with paraspinal abscesses; however, it is less common today. Surgical repair is discouraged because the natural history is more consistent with that of a diastasis recti than that of a true hernia. Denervation appears to play a significant role in the pathogenesis. In other words, this "hernia" really reflects a weakness in the abdominal wall more than it does a dangerous hernia defect. Therefore, appropriate repair is commonly followed by gradual evagination, which is perceived by the patient as a recurrence.

Lumbar hernias should be repaired if they are large or symptomatic. A prosthesis or a tissue flap of some kind is usually required for a successful repair. A rotation flap of fascia lata can be used for inferior lumbar hernias.

28 LAPAROSCOPIC HERNIA REPAIR

Liane S. Feldman, M.D., F.A.C.S., Marvin J. Wexler, M.D., F.A.C.S., and Shannon A. Fraser, M.D.

Since its first description in 1990,¹ laparoscopic inguinal herniorrhaphy has shown a great deal of promise; however, concurrently with its development, open anterior herniorrhaphy has evolved into a tension-free, mesh repair that is easily performed with the patient under local anesthesia and that is also associated with rapid recovery and low recurrence rates [see 5:27 *Open Hernia Repair*.^{2,3}] Thus, the key question about laparoscopic inguinal hernia repair at present is whether it provides a significant advantage over the tension-free open repair now in use.

The two most common techniques for laparoscopic inguinal hernia repair involve the insertion of mesh into the preperitoneal space; one makes use of a transabdominal preperitoneal (TAPP) approach, the other a totally extraperitoneal (TEP) approach. Both approaches would appear to offer potential advantages, such as reduced post-operative pain, shortened recovery, quicker and more accurate assessment and repair of bilateral groin hernias simultaneously, and, in the case of recurrent hernia, avoidance of previously dissected and technically difficult scarred areas. In practice, however, the advantages are not invariably realized; a laparoscopic approach is not always minimally invasive, and various disadvantages accrue from the current requirement for general anesthesia, the need to traverse the abdominal cavity in the TAPP technique, and the increase in operating room time and costs.⁴

Meticulous attention to surgical technique is essential. Because surgeons may be unfamiliar with inguinal anatomy as viewed from inside the abdomen and because the potential for complication necessitating laparotomy is increased with the laparoscopic approach, surgeons must be proficient in laparoscopic techniques and must have a precise knowledge of anatomic relations in the region of the groin as seen from the peritoneal surface.

Since the late 1990s, laparoscopic video techniques have also been increasingly applied to the repair of incisional hernias.⁵⁻⁹ Laparoscopic repair of large incisional hernias resembles open repair in that mesh is inserted to cover the defect in the abdominal wall fascia [see 5:27 *Open Hernia Repair*]. A laparoscopic approach is theoretically attractive because an open approach usually necessitates a large incision as well as extensive and tedious wide dissection to expose the abdominal wall defect, resulting in considerable postoperative pain and a risk of wound complications—problems that a laparoscopic approach to the defect from within might minimize.

It may be many more years before the true safety and efficacy of laparoscopic herniorrhaphy can be determined and the correct indications for its use established. In the meantime, every repair performed should be subjected to careful classification, documentation, and quality-of-life assessment. Surgeons should not perform laparoscopic herniorrhaphy simply because it is relatively new or potentially economical; they should perform it only when convinced that it is anatomically and physiologically correct and logical.

In what follows, we discuss laparoscopic repair of both inguinal and incisional hernias. In addition to describing current operative techniques, we address inguinal surgical anatomy, preoperative planning, and complications. Finally, we review selected trials

measuring the results of laparoscopic repair against those of open repair and comparing the outcomes of TAPP repair with those of TEP repair.

Laparoscopic Inguinal Hernia Repair

ANATOMIC CONSIDERATIONS

To most surgeons, inguinal anatomy as viewed through the laparoscope appears unfamiliar. This is particularly true for the TEP approach, in which the preperitoneal space must be developed. The surgical perspective on the pelvic anatomy from the intraperitoneal view has been elegantly described by Skandalakis and coworkers¹⁰ and has been elegantly demonstrated in cadaver dissections by Spaw and colleagues,¹¹ whose work forms the basis of the descriptions we present in this chapter. Excellent descriptions of the preperitoneal space by Wantz¹² and Condon¹³ are also worthy of review.

During laparoscopic herniorrhaphy, a number of structures that are usually visible during open herniorrhaphy (e.g. the inguinal ligament, the pubic tubercle, the lacunar ligament, and the ilioinguinal and iliohypogastric nerves) are not seen initially. Conversely, a number of structures that are visible only after significant dissection in the open approach are easily viewed through the laparoscope [see *Figure 1*]. Identification of the iliopubic tract, Cooper's ligament, and the transversus abdominis arch is mandatory to ensure proper coverage by the prosthetic material used in the repair.

During a TAPP repair, four important landmarks should be seen at initial laparoscopic inspection of the inguinal region [see *Figure 2*]: the spermatic vessels, the obliterated umbilical artery (also referred to as the medial umbilical ligament or the bladder ligament), the inferior epigastric vessels (also referred to as the lateral umbilical ligament), and the external iliac vessels. During a TEP repair, once the preperitoneal space has been established, the first easily identified landmarks are Cooper's ligament and the inferior epigastric vessels; identification of these structures is helpful in guiding early dissection.

Spermatic Vessels

The testicular artery and vein descend from the retroperitoneum, travel directly over and slightly lateral to the external iliac artery, and enter the internal spermatic ring posteriorly. These vessels are covered only by the peritoneum and are usually well visualized as flat structures in the abdominal cavity that assume a cordlike appearance when joined by the vas deferens immediately before entering the internal spermatic ring. If no hernia is present, a mere dimple will be seen [see *Figure 2*]. In the TAPP approach, an indirect hernia, if present, will be immediately apparent and will have an obvious opening. In the TEP approach, the indirect sac will be seen later, after dissection of the tissue on the anterior abdominal wall. The vas deferens is best identified where it joins the spermatic vessels. From there, the vas can be traced back medially as it courses over the

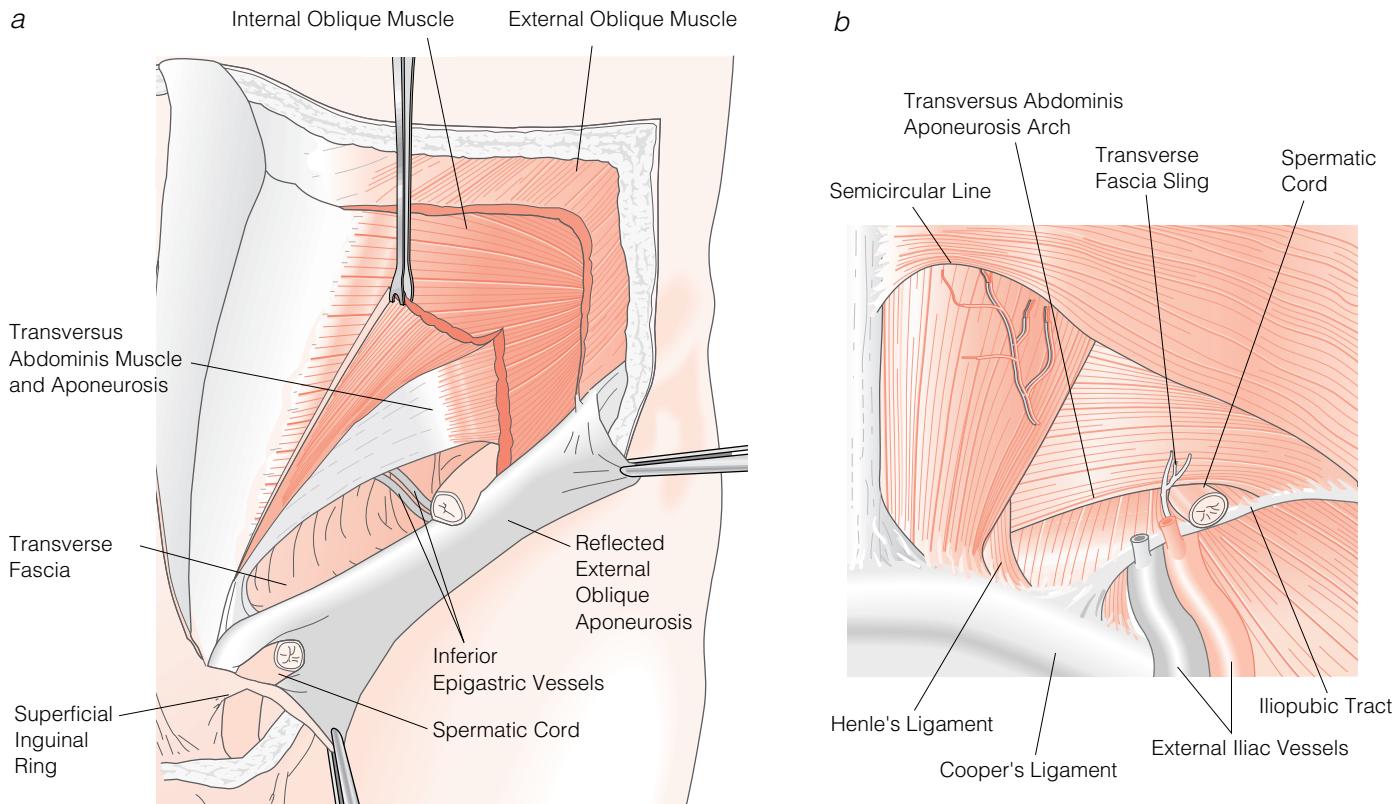

Figure 1 Laparoscopic inguinal hernia repair. Shown are (a) the anatomy of the left groin region as seen from the traditional anterior approach to herniorrhaphy and (b) the anatomy of the right groin from the posterior, or peritoneal, approach. The inguinal canal floor is covered by transverse fascia alone, and a large space separates the transversus abdominis aponeurosis from the inguinal ligament (a). A preperitoneal view of the groin region shows the distance between the transversus abdominis tendon and Cooper's ligament, the iliopubic tract, and the inguinal ligament (b).

pelvic brim and falls into the pelvis and behind the bladder. There is a small artery that runs with the vas deferens and is not well seen or known. It is white and cordlike in appearance and can usually be seen just beneath the peritoneum.

Obliterated Umbilical Artery

The obliterated umbilical artery is an unfamiliar but sometimes prominent structure that is seen in the TAPP approach. It courses along the anterior abdominal wall toward the umbilicus, often with an apparent mesentery. It is most prominent in the region of the medial inguinal space. This ligament is most readily identified when the umbilical laparoscope is directed toward the pelvic midline, where the ligament's bilateral structure is best seen as it is oriented toward the umbilicus. Medial retraction of this structure is usually necessary for full exposure of the medial aspect of the inguinal canal.

Inferior Epigastric Vessels

The inferior epigastric artery and vein lie in the medial aspect of the internal inguinal ring and ascend the inferior surface of the rectus abdominis. In the TAPP approach, these vessels may be difficult to visualize, particularly in obese patients. They are best identified by locating the internal inguinal ring at the junction of the vas deferens and the testicular artery and vein. At this location, the vessels exit the medial margin of the internal ring. However, they can quickly fade from view as they travel superiorly and medially along the anterior abdominal wall. In the TEP approach, early identification of the inferior epigastric vessels helps guide lateral dissection

and identification of the internal ring [see Figure 3]. However, dissection in the incorrect plane when the preperitoneal space is initially established may strip these vessels off the abdominal wall.

External Iliac Vessels

The lateral spermatic vessels and the medial vas deferens merge at the internal inguinal ring and enter the inguinal canal, where they form the apex of the so-called triangle of doom [see Figure 4a, *insert*]. Beneath this triangle lie the external iliac artery and the external iliac vein. More laterally, the femoral nerve can be found. The external iliac vessels are often difficult to visualize, though in an elderly patient, a calcified pulsating artery may be prominent. Extreme care must be taken not to dissect within the triangle of doom, because such dissection can result in serious bleeding.

Cooper's Ligament

Cooper's ligament is a condensation of the transversalis fascia and the periosteum of the superior pubic ramus lateral to the pubic tubercle. It can be seen only in the preperitoneal space and is the first landmark that should be identified during a TEP repair. In the initial stages of a TAPP repair, with the peritoneum intact, it is often easier to palpate the ligament than to see it, but once the ligament has been identified and cleaned, its glistening white fibers are apparent. Care must be taken during dissection to avoid the tiny branches of the obturator vein that often run along the ligament's surface. The iliopubic tract inserts into the superior ramus of the pubis just lateral to Cooper's ligament, blending into it.

Internal Inguinal Ring

In the TAPP approach, the internal inguinal ring is normally identified by a slight indentation of the peritoneum at the junction of the vas deferens and the spermatic vessels. When an indirect hernia is present, however, a true ring or opening is easily identified, and by rotating a 30° laparoscope, the surgeon can look directly into the hernial sac or insert the laparoscope into the sac, which often allows the external inguinal ring to be identified more medially. An indirect hernial sac lies anterior and lateral to the spermatic cord at this level, as opposed to the familiar medial cord position seen in the classic exterior groin approach to open herniorrhaphy. The medial border of the internal inguinal ring is formed by the transversalis fascia and the inferior epigastric vessels. The inferior border is formed by the iliopubic tract, a distinct structure that is the internal counterpart of the inguinal ligament. Anteriorly, the internal inguinal ring is bordered by the transversus abdominis arch, which passes laterally over the internal ring and forms a very well defined visible edge. The layers of the abdominal wall constituting the lateral border of the internal inguinal ring appear the same as when viewed from the exterior approach, and this border, like all margins of the internal inguinal ring, is visible only when an indirect hernia is present.

Iliopubic Tract

The iliopubic tract originates laterally from the anterior superior spine of the ilium and courses medially, forming the inferior margin of the internal inguinal ring and the roof of the femoral canal before inserting medially into the superior pubic ramus. This tract is formed by the condensation of the transversalis fascia with the most inferior portion of the transversus abdominis muscle and aponeurosis, and it is usually sturdy along its entire course. All inguinal hernia defects lie above the iliopubic tract, either anterior or superior to it. Conversely, femoral hernias occur below the tract, either posterior or inferior to it. Fibers of the iliopubic tract extend into Cooper's ligament medially, where they become the medial margin of the femoral canal. The iliopubic tract is frequently confused with the inguinal ligament. This ligament, though nearby, is part of the superficial musculocutaneous layer, which is not seen laparoscopically, whereas the iliopubic tract is part of the deep layer.

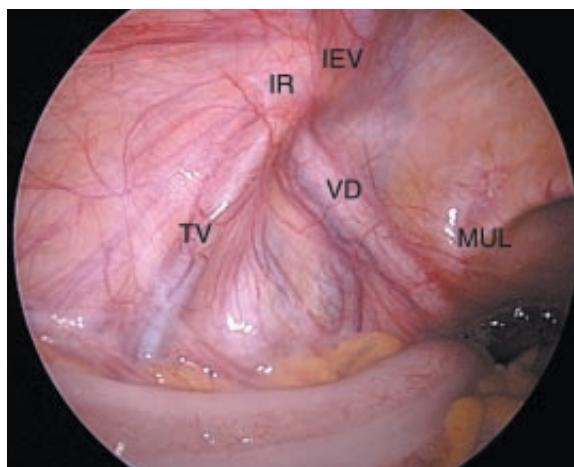

Figure 2 Laparoscopic inguinal hernia repair. Shown is a laparoscopic view of the anatomy of the left groin with the peritoneum intact in a patient without a hernia. (IEV—inferior epigastric vessels; IR—internal ring; MUL—medial umbilical ligament; TV—testicular vessels; VD—vas deferens)

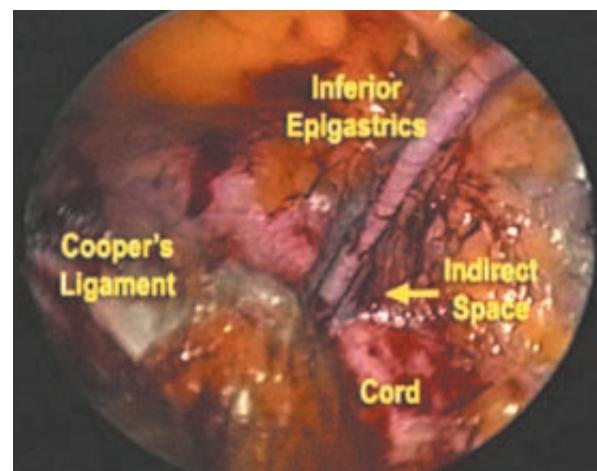

Figure 3 Laparoscopic inguinal hernia repair: TEP approach. The significant anatomic landmarks are identified at the internal ring: the inferior epigastric vessels, Cooper's ligament, and the spermatic vessels and cord, as well as the potential indirect space seen lateral to the cord structures.

Femoral Canal

The femoral canal is seen only in the presence of a femoral hernia in the most medial aspect of the femoral triangle. The anterior and medial borders are formed by the iliopubic tract, the posterior or border is formed by the pectineal fascia, and the lateral border is formed by the femoral sheath and vein.

Trapezoid of Disaster

Another area worthy of careful attention is the so-called trapezoid of disaster, containing the genitofemoral, ilioinguinal, iliohypogastric, and lateral cutaneous nerves of the thigh, which innervate the spermatic cord, the testicle, the scrotum, and the upper and lateral thigh, respectively. A detailed knowledge of the anatomic courses of the nerves and careful avoidance of these structures during dissection are essential [see Figure 4].

Genitofemoral nerve The genitofemoral nerve arises from the first and second lumbar nerves; pierces the psoas muscle and fascia at its medial border opposite L3 or L4; descends under the peritoneum, on the psoas major; and divides into a medial genital and a lateral femoral branch. The femoral branch descends lateral to the external iliac artery and spermatic cord, passing posteroinferior to the iliopubic tract and into the femoral sheath to supply the skin over the femoral triangle. The genital branch crosses the lower end of the external iliac artery and enters the inguinal canal through the internal inguinal ring with the testicular vessels. This branch supplies the coverings of the spermatic cord down to the skin of the scrotum. The genitofemoral nerve is the most visible of the cutaneous nerves and is sometimes confused with the testicular vessels if the latter are not well appreciated in their more medial position.

Ilioinguinal and iliohypogastric nerves When dissected from the anterior position, the ilioinguinal and iliohypogastric nerves lie between the external oblique and the internal oblique muscles above the internal inguinal ring and descend with the spermatic cord. In the abdomen, the ilioinguinal and iliohypogastric nerves arise from the 12th thoracic and first lumbar nerve roots, are more laterally located, and run subperitoneally, emerging from the lateral psoas border to pierce the transversus abdominis near the iliac crest, then piercing and coursing between the

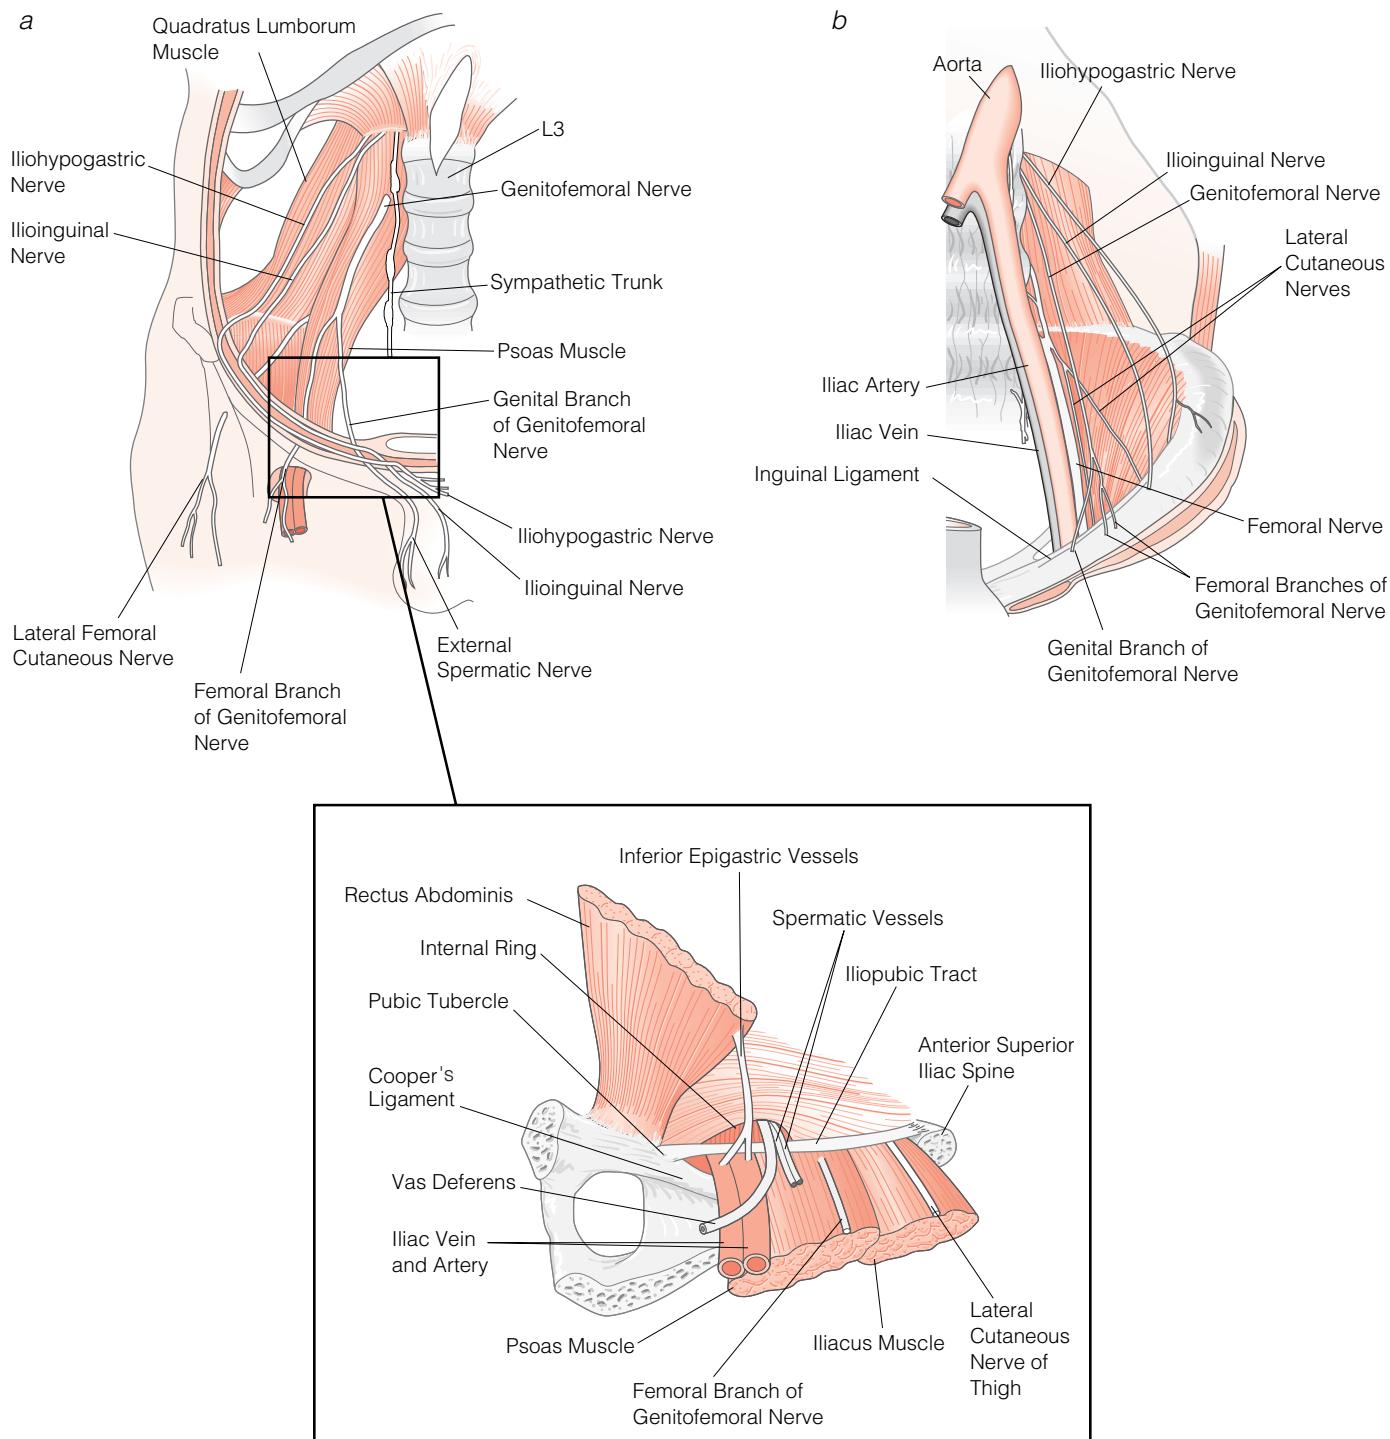

Figure 4 Laparoscopic inguinal hernia repair. Shown are the courses of the genitofemoral and ilioinguinal nerves of the right groin (*a*) and of the left groin (*b*). Inset shows the preperitoneal anatomy of the right groin, as seen by the laparoscopic surgeon.

internal oblique and the external oblique muscles close to the internal inguinal ring. Aberrant branches sometimes descend with the genital nerve. The ilioinguinal nerve supplies a small cutaneous area near the external genitals.

Lateral cutaneous nerve of thigh Supplying the front and lateral aspect of the thigh, the lateral cutaneous nerve of the thigh arises from the second and third lumbar nerves and emerges at the lateral border of the psoas. There, it descends deep to the peri-

toneum on the iliac muscle and only comes to lie in a superficial position 3 cm below the anterosuperior iliac spine.

PREOPERATIVE EVALUATION

History and Physical Examination

Preoperative assessment is necessary to determine whether a patient is a suitable candidate for laparoscopic herniorrhaphy. A careful surgical history, including both previous hernia repairs and

other procedures (particularly those involving the lower abdomen), should be elicited. A cardiovascular history should also be obtained and risk factors for general anesthesia determined.

Physical examination should confirm the presence of an inguinal hernia. If the patient reports a history of a bulge but no hernia is felt on physical examination, an occult hernia may be presumed. Ultrasonography may be helpful for distinguishing an incarcerated groin hernia from other causes of inguinal swelling (e.g., lymphadenopathy or venous varix).

Selection of Patients

Indications With the evolution of the open anterior approach to tension-free prosthetic mesh repair, determining which patients will benefit significantly from laparoscopic herniorrhaphy has become increasingly important. In 2003, the Cochrane Database of Systemic Reviews⁴ published an update to its original 2000 report on laparoscopic versus open techniques for hernia repair, which indicated that whereas laparoscopic repairs (TAPP and TEP) generally took longer and had a higher rate of more serious complications (bowel, bladder, and vascular injuries) than open repairs, they also were associated with shorter recovery times and a lower incidence of persistent pain and numbness.¹⁴ Reduced hernia recurrence was related to the use of mesh rather than to operative technique. The overall risk of recurrence with the laparoscopic approach may be related to the surgeon's level of experience.¹⁵ We believe that patients are best served when a surgeon has several approaches at his or her command that can be applied to and, if necessary, modified for individual circumstances.

Currently, we treat primary unilateral hernias with an open anterior mesh repair, preferably with the patient under local or regional anesthesia; possible exceptions include manual laborers and athletes who desire a rapid return to vigorous physical activity. We generally reserve laparoscopic inguinal herniorrhaphy for the following clinical situations:

1. Recurrent hernia after previous anterior repair. In such cases, a laparoscopic approach allows the surgeon to avoid the scar tissue and distorted anatomy present in the anterior abdominal wall by performing the repair through uninvolved tissue, thereby potentially reducing the risk of damage to the vas deferens or the testicular vessels. This is especially true when mesh has previously been placed anteriorly.
2. Bilateral hernias or a unilateral hernia when the presence of a contralateral hernia is strongly suspected. In such cases, a laparoscopic approach allows the surgeon to repair the two hernias simultaneously (and perhaps more rapidly) without having to make additional incisions.
3. Repair of an inguinal hernia concurrent with another laparoscopic procedure, provided that there is no contamination of the peritoneal cavity.

The choice of laparoscopic technique depends on the patient's history and on the type of hernia present. In general, we favor TEP repair for most patients because it does not involve entry into the abdominal cavity. The TEP approach reduces the risk of complications affecting intra-abdominal structures, theoretically decreases the risk of adhesions, maintains an intact peritoneal layer between the mesh and the intra-abdominal contents, and allows the mesh to be placed without the use of fixation. However, it has a steeper learning curve than TAPP does, and it may not be feasible in patients who have undergone lower abdominal procedures.

Contraindications We do not treat acutely incarcerated hernias laparoscopically. In patients to whom general anesthesia may

pose an increased risk, we prefer open anterior repair using local or regional anesthesia. In infants and young children with indirect hernias, for whom repair of the posterior canal wall is unnecessary, we recommend high ligation of the sac via the anterior approach.

Previous lower abdominal surgery, though not an absolute contraindication, may make laparoscopic dissection difficult. In particular, with respect to TEP repair, previous lower abdominal wall incisions may make it impossible to safely separate the peritoneum from the abdominal parietes for entry into the extraperitoneal plane, and conversion to a TAPP repair or an open repair may be required. Previous surgery in the retropubic space of Retzius, as in prostatic procedures, is a relative contraindication that is associated with an increased risk of bladder injury¹⁶ and other complications.¹⁷ Similarly, previous pelvic irradiation may preclude safe dissection of the peritoneum from the abdominal wall.¹⁸

OPERATIVE PLANNING

Preparation

General anesthesia is administered routinely. Prophylactic antibiotics are unnecessary.¹⁹ The patient is instructed to void before surgery, which renders bladder catheterization unnecessary.

Patient Positioning

The patient is placed in the supine position with both arms tucked against the sides. The anesthesia screen is placed as far toward the head of the table as possible to allow the surgeon a wide range of mobility with the laparoscope. The skin is prepared and draped so as to allow exposure of the entire lower abdomen, the genital region, and the upper thighs because manipulation of the hernial sac and the scrotum may be necessary. After the laparoscope has been introduced, the patient is placed in a deep Trendelenburg position so that the viscera will fall away from the inguinal areas. Further bowel manipulation is rarely necessary, except to reduce hernial contents. Rotation of the table to elevate the side of the hernia can provide additional exposure, if necessary. A single video monitor is placed at the foot of the bed, directly facing the patient's head.

The surgeon usually begins the repair while standing on the side contralateral to the defect; the assistant surgeon stands opposite the surgeon, and the nurse stands on the ipsilateral side [see Figure 5]. A two-handed operating technique provides a distinct technical advantage.

Equipment

Because inguinal hernias occur in the anterior abdominal wall, visualization through the umbilicus requires that the laparoscope be angled close to the horizontal plane. The view is paralleled anteriorly by the surface of the lower abdominal wall, which may make visualization with a 0° laparoscope difficult. In addition, an indirect hernia is a three-dimensional tubular defect that can be well visualized in its entirety only with an angled lens. For these reasons, we recommend routine use of an oblique, forward-viewing 30° or 45° laparoscope. Excellent laparoscopes are currently available in 10 mm and 5 mm sizes. For the TAPP repair, one 10/12 mm and two 5 mm trocars are used. The dissection is performed with a dissector and scissors, to which an electrocautery may be attached. For mesh fixation, we currently use a spiral tacker (e.g., TACKER; U.S. Surgical Inc., Norwalk, Connecticut).

In a TEP repair, besides the equipment needed for a TAPP repair, a balloon-tipped blunt trocar is used to gain access to the preperitoneal space. We usually develop the preperitoneal space with a balloon system [see Operative Technique, Totally Extraperitoneal (TEP) Repair].

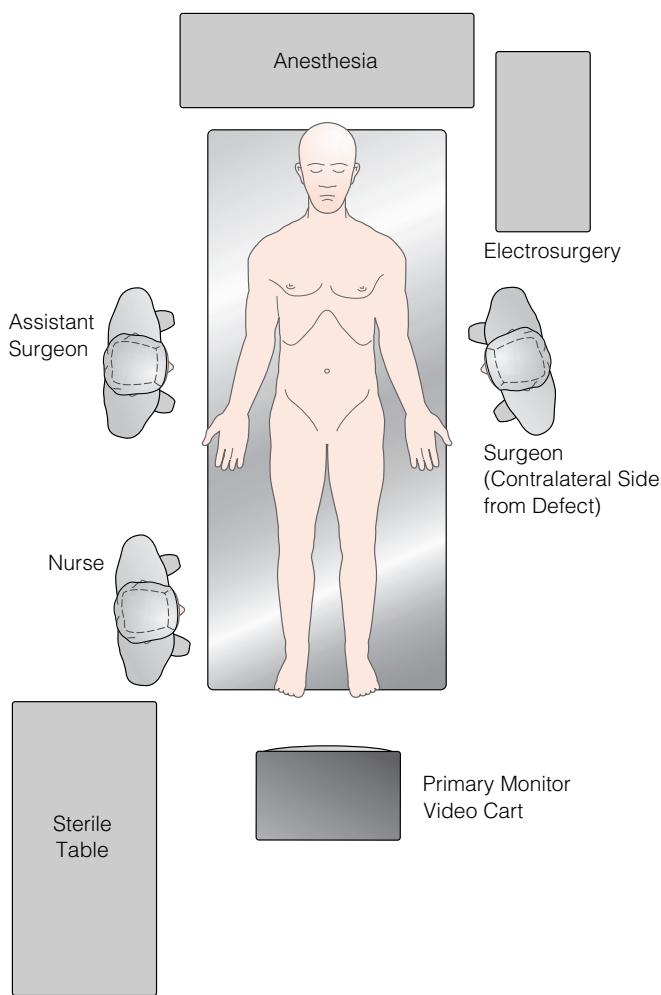

Figure 5 Laparoscopic inguinal hernia repair. Shown is one of several possible OR setups. The surgeon stands on the side contralateral to the defect, with a nurse on the ipsilateral side. The assistant surgeon stands opposite the surgeon. This positioning may vary, depending on the surgeon's preference and handedness, the visibility of the defect, and the type of defect present, as well as on the prominence of the medial umbilical ligament and the need for its retraction

toneal Repair, below], but this can also be done with blunt dissection if the surgeon prefers. Two additional 5 mm trocars are placed. The dissection is performed with two blunt-tipped dissectors.

OPERATIVE TECHNIQUE

Totally Extraperitoneal Repair

The extra-abdominal preperitoneal approach to laparoscopic hernia repair, developed by McKernan,^{20,21} attempts to duplicate the open preperitoneal repair described by Stoppa²²⁻²⁴ and Wantz.^{12,25} In a TEP repair, the trocars are placed preperitoneally in a space created between the fascia and the peritoneum. Ideally, the dissection remains in the extra-abdominal plane at all times, and the peritoneum is never penetrated.

Step 1: creation of preperitoneal space With the patient in the Trendelenburg position, the anterior rectus fascia is opened through a 1 cm infraumbilical transverse incision placed slightly toward the side of the hernia, which helps prevent inadvertent opening of the peritoneum. An index finger is inserted on the medial aspect of the exposed rectus abdominis and slid over the posterior rectus sheath. In this plane, a preperitoneal tunnel between the recti abdominis and the peritoneum is created in the midline by inserting a Kelly forceps (with the tips up) and performing gentle blunt dissection to the level of the symphysis pubis. A blunt 10/12 mm trocar is then secured in the preperitoneal space with fascial stay sutures.

A 30° or 45° operating laparoscope is inserted into the trocar for visualization of the development of the correct plane while insufflation of the preperitoneal space is begun, with the recti abdominis seen anteriorly and the peritoneum posteriorly. Maximal inflation pressure is 10 to 12 mm Hg to prevent disruption of the peritoneum or development of extensive subcutaneous emphysema. Blunt gentle dissection with the laparoscope is employed to develop the space sufficiently to allow placement of additional trocars.

An alternative approach to dissection of the preperitoneal space—one that is especially helpful early in a surgeon's experience—is to employ a preperitoneal distention balloon system (e.g., PDB; U.S. Surgical Inc., Norwalk, Connecticut). This system consists of a trocar with an inflatable balloon at its tip, which is used to develop the preperitoneal space by atraumatically separating the peritoneum from the abdominal wall. The balloon is

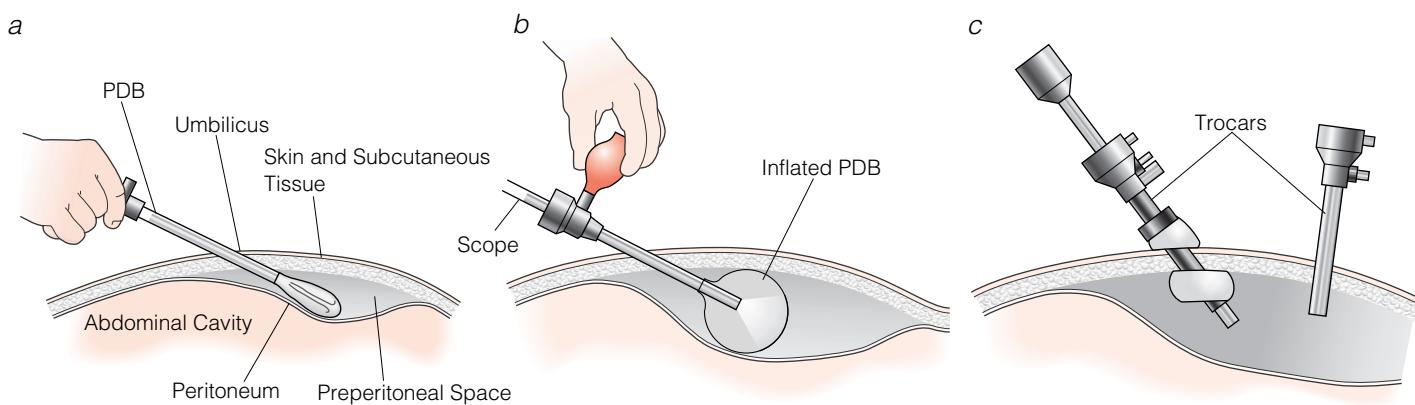

Figure 6 Laparoscopic inguinal hernia repair: TEP approach. Shown is the preperitoneal distention balloon (PDB) system. The PDB is introduced into the preperitoneal space (a). As it is tunneled inferiorly toward the pubis, the PDB is inflated under laparoscopic vision (b). Once the preperitoneal space is created, the PDB is removed and replaced with a blunt-tip trocar. The preperitoneal space is insufflated under low pressure, additional trocars are placed, and the repair is completed (c).

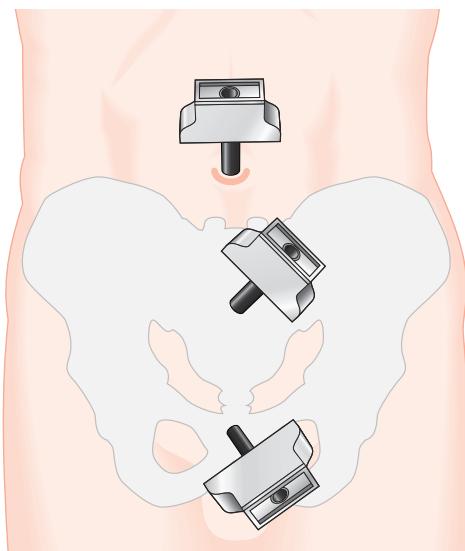

Figure 7 Laparoscopic inguinal hernia repair: TEP approach. Shown is standard trocar placement for TEP repair. As in TAPP repair, three trocar sites are used. One trocar is placed in the umbilicus; the second is placed in the midline, midway between the umbilicus and the pubis; and the third is placed above the pubic arch. The trocars should not penetrate the peritoneum.

inserted into the preperitoneal space below the umbilicus by means of an open Hasson technique and is tunneled inferiorly toward the pubis until the bone is felt with the tip of the balloon trocar. With the laparoscope in the trocar, the preperitoneal working space is developed by gradual inflation of the balloon to a volume of 1 L; the transparency of the balloon permits constant laparoscopic visualization throughout the distention process. Once the working space is created, the PDB is removed and replaced with a blunt sealing trocar. S-retractors are used to elevate the rectus and help ensure correct positioning of the trocar above the posterior fascia. The preperitoneal space is then reinsufflated to a pressure of 10 to 12 mm Hg [see Figure 6].

Step 2: trocar placement After the peritoneum is dissected away from the rectus abdominis, a midline 5 mm trocar is inserted under direct vision three fingerbreadths below the infraumbilical port. A second 5 mm trocar is then inserted another three fingerbreadths below the first 5 mm trocar. Placement of the working trocars away from the pubis facilitates mesh placement, in that the bottom port is not covered by the top of the mesh and thereby rendered nonfunctional [see Figure 7]. Care must be taken not to penetrate the peritoneum during trocar placement. If the peritoneum is penetrated, the resulting pneumoperitoneum can reduce the already limited working space. If the working space is compromised to the point where the repair cannot continue (which is not always the case), the surgeon can either try to repair the rent with a suture or place a Veress needle in the upper abdominal peritoneal cavity. If such maneuvers are unsuccessful, the loss of working space may necessitate conversion to a TAPP approach.

Step 3: dissection of hernial sac Wide dissection of the preperitoneal space is then undertaken with blunt graspers in a two-handed technique by bluntly dividing the avascular areolar tissue between the peritoneum and the abdominal wall [see Figure 8]. The pubis, Cooper's ligament, and the inferior epigastric vessels are located first and used to orient the dissection. If

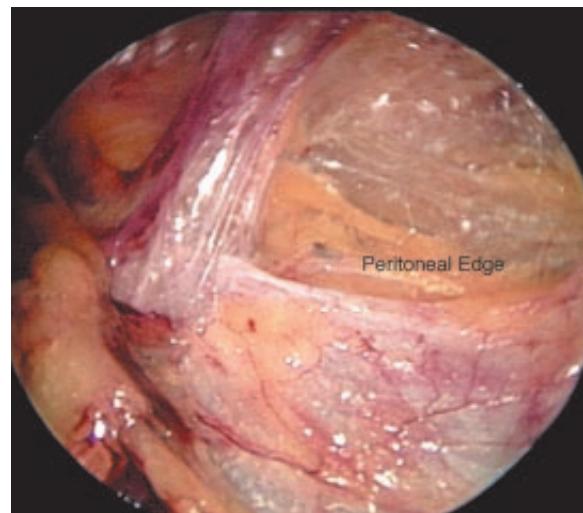

Figure 8 Laparoscopic inguinal hernia repair: TEP approach. The edge of the peritoneum is identified lateral to the internal ring and is dissected cephalad off the abdominal wall.

a direct hernia is present medial to the inferior epigastric vessels, it will often be reduced by the balloon dissector [see Figure 9]. If not, the sac and the preperitoneal contents are carefully dissected away from the fascial defect and swept cephalad as far as possible. Gentle traction is applied to expose and dissect away the attachment of the peritoneum to the transversalis fascia [see Figure 10].

The indirect space is then exposed by sweeping off the tissue lateral to the inferior epigastric vessels until the peritoneum is found. If a lipoma of the cord is present, it will be lateral to and covering the peritoneum and should be dissected out of the internal ring in a cephalad direction to prevent it from displacing the mesh.¹⁸ If there is no indirect hernia, the peritoneum will be found cephalad to the internal ring. To ensure secure mesh placement, the peritoneum is bluntly dissected off the cord structures and placed as far cephalad as possible.

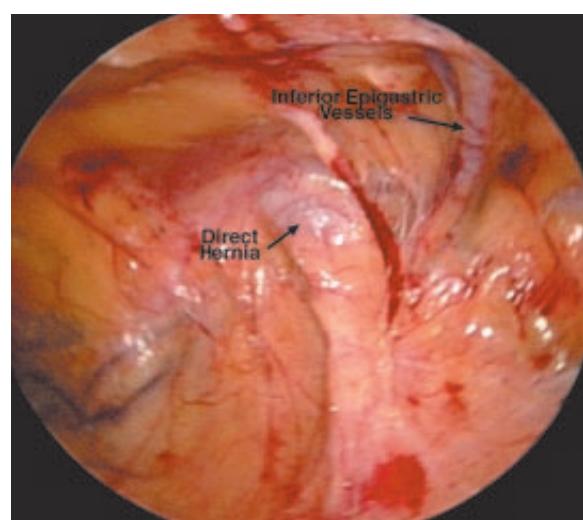

Figure 9 Laparoscopic inguinal hernia repair: TEP approach. Shown is a right-side direct hernia, with the inferior epigastric vessels lateral to the defect, as visualized after initial gas insufflation and before dissection of preperitoneal fat.

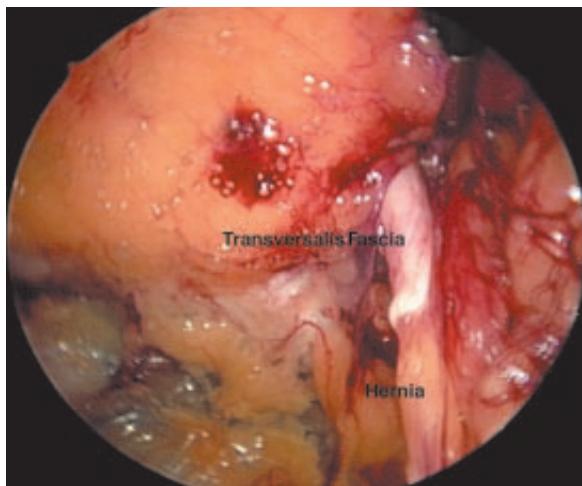

Figure 10 Laparoscopic inguinal hernia repair: TEP approach. The transversalis fascia is seen adherent to the hernial sac. The sac must be separated from the fascia and dissected cephalad to the level of the umbilicus.

If an indirect hernia is present, the sac will be lateral and anterior to the cord structures. A small indirect hernial sac is bluntly dissected off the spermatic cord with a hand-over-hand technique and reduced until an area sufficient for mesh placement is created [see Figure 11]. To prevent early recurrence, all attachments of the peritoneum should be dissected cephalad to where the inferior edge of the mesh will be. If a large indirect sac is not easily reduced from the scrotum, it may be transected in its superolateral edge, dissected off the cord structures, and closed with an endoscopic ligating loop. The distal sac is then left in place and not ligated.

Unlike a TAPP repair, in which any indirect hernia present is readily apparent at first inspection, a TEP repair always requires that the space lateral to the inferior epigastric vessels be dissected to make sure that there is no indirect component. This dissection should be done even if a direct or femoral hernia is identified. The medial border of dissection is the iliac vein or its overlying fat, and the lateral border of dissection is the psoas muscle. Superiorly, dissection should reach the level of the umbilicus.

Step 4: placement of mesh As a rule, we use a large (10.8 × 16 cm) piece of polypropylene mesh shaped to the contours of the inguinal region. A number of different products can also be used for this purpose, including various forms of polypropylene and several types of polyester. A marking suture is placed at the superior edge of the mesh on the concave side, which is to be apposed to the peritoneum. The mesh is wrapped around a grasper in a tubular fashion, then inserted through the umbilical trocar into the preperitoneal space. Once in the preperitoneal space, the mesh is manipulated to cover the pubic tubercle, the internal ring, Cooper's ligament, the femoral canal, and the rectus abdominis superiorly [see Figure 12]. Tacks or sutures are not usually needed for fixation, but if they are used, they should be placed into Cooper's ligament and the anterior abdominal wall; to prevent nerve injury, no tacks should be placed inferior to the iliopubic tract lateral to the internal ring. Some surgeons believe that with direct hernias, there is a risk that the mesh may migrate into a large defect. Accordingly, they place several tacks into Cooper's ligament to prevent this occurrence. For bilateral hernias, two identical repairs are done, and two mesh patches are used.

Step 5: closure The operative site is inspected for hemostasis. The trocars are removed under direct vision. The insufflated CO₂ is slowly released so that the mesh may be visualized as the preperitoneal fat and contents collapse back onto the mesh. The fascia at trocar sites 10 mm or larger is closed with 2-0 polydioxanone sutures, and the skin is closed with subcuticular sutures.

Transabdominal Preperitoneal Repair

Step 1: placement of trocars Pneumoperitoneum is established through a small infraumbilical incision. We generally prefer an open technique, in which a blunt-tipped 12 mm trocar is inserted into the peritoneal cavity under direct vision. CO₂ is then insufflated into the abdomen to a pressure of 12 to 15 mm Hg. The angled laparoscope is introduced, and both inguinal areas are inspected. Two 5 mm ports are placed, one at the lateral border of each rectus abdominis at the level of the umbilicus, to allow placement of the camera and the instruments [see Figure 13]. The 5 mm lateral ports may be replaced with 10 mm ports if only a 10 mm laparoscope is available.

Step 2: identification of anatomic landmarks The four key anatomic landmarks mentioned earlier [see Laparoscopic Inguinal Hernia Repair, Anatomic Considerations, above]—the spermatic vessels, the obliterated umbilical artery (medial umbilical ligament), the inferior epigastric vessels (lateral umbilical ligament), and the external iliac vessels—are identified on each side.

In the presence of an indirect hernia, the internal inguinal ring is easily identified by the presence of a discrete hole lateral to the junction of the vas deferens, the testicular vessels, and the inferior epigastric vessels. Identification of a direct hernia can be more difficult. Sometimes, a direct hernia appears as a complete circle or hole; at other times, it appears as a cleft, medial to the vas deferens–vascular junction; and at still other times, it is completely hidden by preperitoneal fat and the bladder and umbilical ligaments. Visualization can be particularly difficult in obese patients, who may have considerable lipomatous tissue between the peritoneum and the transversalis fascia, or in patients whose hernia consists of a weakness and bulging of the entire inguinal floor rather than a distinct sac. For adequate definition of this type of hernia and deeper anatomic structures, the peritoneum must be opened, a peritoneal flap developed, and the underlying fatty layer dissected.²⁶ Direct hernial defects are often situated

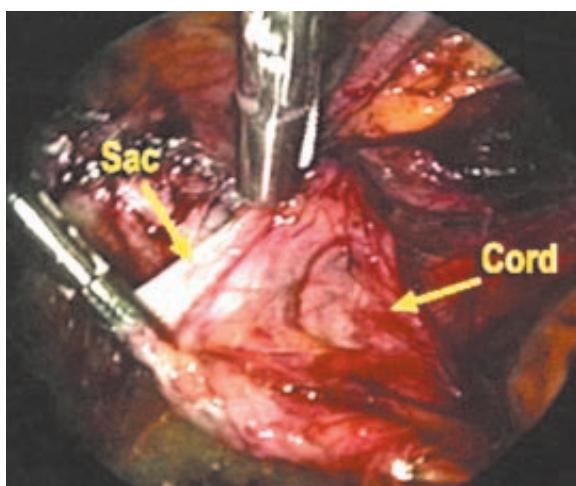

Figure 11 Laparoscopic inguinal hernia repair: TEP approach. Shown is an indirect hernial sac retracted laterally, with cord structures visualized medially.

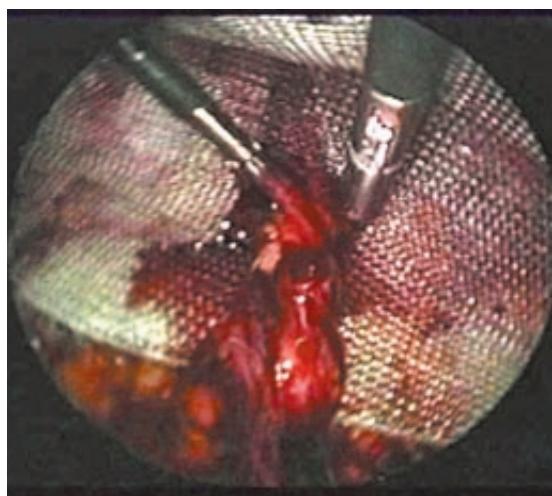

Figure 12 Laparoscopic inguinal hernia repair: TEP approach. The mesh is oriented so as to cover the indirect, direct, and femoral spaces (inguinal floor). The dissected hernial sac is placed over the top of the mesh to reduce the risk that the sac will slide underneath the mesh and cause a recurrence of the hernia.

medial to the ipsilateral umbilical ligament, and retraction or even division of this structure is sometimes necessary. Division of this structure has no negative sequelae; however, the surgeon should be aware that the obliterated umbilical artery may still be patent and that use of the electrocautery or clips may be necessary. Traction on the ipsilateral testicle can demonstrate the vas deferens when visualization is obscured by overlying fat or pressure from the pneumoperitoneum.

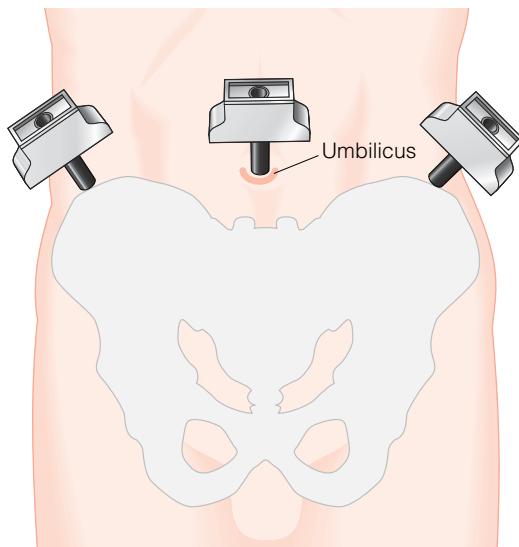

Figure 13 Laparoscopic inguinal hernia repair: TAPP approach. Shown is standard trocar placement for TAPP repair. Usually, three trocar sites are used. The laparoscope is inserted through the umbilical trocar, and two additional trocars are placed in the right and the left midabdomen. To ensure that the first trocar is not placed too close to the surgical field, the first trocar should be placed either in the umbilicus or immediately above it. The two lateral trocars should be placed lateral to the rectus sheath to prevent bleeding and postoperative muscle spasms. At least one trocar must be 10/12 mm to allow insertion of the mesh.

Step 3: creation of peritoneal flap The curved scissors or the hook cautery is used to create a peritoneal flap by making a transverse incision along the peritoneum, beginning 2 cm above the upper border of the internal inguinal ring and extending medially above the pubic tubercle and laterally 5 cm beyond the internal inguinal ring [see Figure 14]. Extreme care must be taken to avoid the inferior epigastric vessels. Bleeding from these vessels can usually be controlled by cauterization, but application of hemostatic clips may be necessary on occasion. Another solution is to pass percutaneously placed sutures above and below the bleeding point while applying pressure to the bleeding vessel so as not to obscure the field of vision. If the monopolar cautery is used to create the peritoneal flap, the entire uninsulated portion of the instrument must be visible at all times to ensure that inadvertent bowel injury does not occur.

The incised peritoneum is grasped along with the attached preperitoneal fat and the peritoneal sac and is dissected cephalad with blunt and sharp instruments to create a lower peritoneal flap [see Figure 15]. Dissection must stay close to the abdominal wall. A significant amount of preperitoneal fat may be encountered, and this should remain with the peritoneal flap so that the abdominal wall is cleared. When the correct preperitoneal plane is entered, dissection is almost bloodless and is easily carried out.

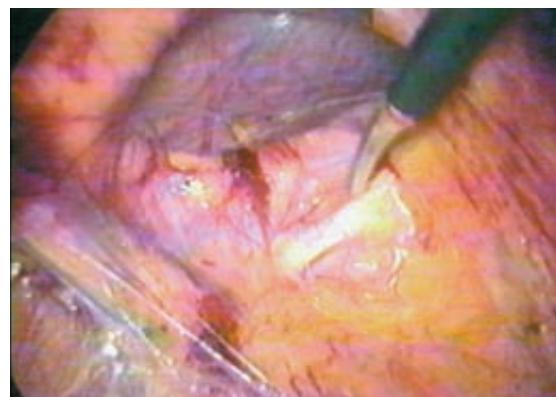

Figure 14 Laparoscopic inguinal hernia repair: TAPP approach. Shown is dissection of a left direct inguinal hernia. The hernial sac is inverted and the peritoneum incised superior to the sac.

Figure 15 Laparoscopic inguinal hernia repair: TAPP approach. A flap of peritoneum is dissected downward, revealing a hernial defect and the inferior epigastric vessels (arrow) on the left side.

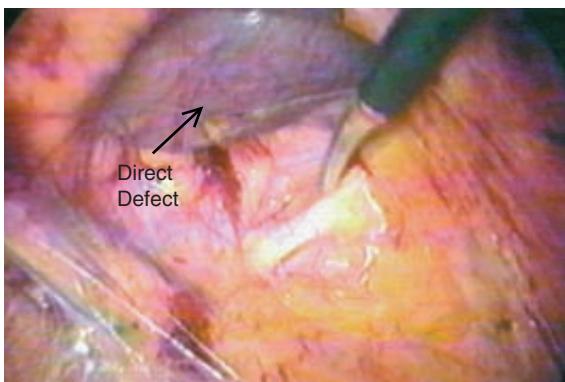

Figure 16 Laparoscopic inguinal hernia repair: TAPP approach. Dissection of the preperitoneal space on the left side allows identification of the anatomic landmarks. The dissector points to the iliopubic tract inferior to the direct hernial defect.

Step 4: dissection of hernial sac The hernial sac, if present, is removed from Hesselbach's triangle or the spermatic cord and surrounding muscle through inward traction, countertraction, and blunt dissection with progressive inversion of the sac until the musculofascial boundary of the internal inguinal ring and the key deep anatomic structures are identified. In most cases, the hernial sac can be slowly drawn away from the transversalis fascia or the spermatic cord. The sac is grasped at its apex and pulled inward, thus being reduced by inversion. The indirect sac may be visualized more easily if it is grasped and retracted medially; this step facilitates its dissection away from the cord structures.

Spermatic cord lipomas usually lie posterolaterally and are extensions of preperitoneal fat. In the presence of an indirect defect, such lipomas should be dissected off the cord along with the peritoneal flap to lie cephalad to the internal inguinal ring and the subsequent repair so that prolapse through the ring can be prevented.

A large indirect hernial sac can be divided at the internal ring if it cannot be readily dissected away from the cord structures. This step may prevent the type of cord injury that can result from extensive dissection of a large indirect sac. Division of a large indirect sac is best accomplished by opening the sac on the side opposite the spermatic cord, then completing the division from the inside.¹⁶

Step 5: reidentification and exposure of landmarks Once the peritoneal flap has been created, the key anatomic landmarks mentioned earlier [see Laparoscopic Inguinal Hernia Repair, Anatomic Considerations, *above*] must be reidentified and exposed so that neurovascular structures can be protected from injury and the tissues required for reliable mesh fixation can be located. The pubic tubercle is often more easily felt than seen. Cooper's ligament is initially felt and subsequently seen along the pectenial prominence of the superior pubic ramus as dissection continues laterally and fatty tissue is swept off to expose the glistening white structure. Care must be taken to avoid the numerous small veins that often run on the surface of the ligament, as well as to avoid the occasional aberrant obturator artery. The iliopubic tract is initially identified at the inferior margin of the internal inguinal ring, with the spermatic cord above, and is then followed in both a medial and a lateral direction. Minimal dissection is carried out inferior to the iliopubic tract so as not to injure the genital femoral nerve, the femoral nerve, and the lateral cutaneous nerve of the thigh [see Figure 16].

Step 6: placement of mesh A 10 × 6 cm sheet of polypropylene mesh is rolled into a tubular shape and introduced into the abdomen through the 10/12 mm umbilical trocar. Prolene is preferable to Marlex in this application because it is less dense, conforms more easily to the posterior inguinal wall, and has larger pores, which facilitate visualization and subsequent securing with staples or tacks. The inherent elasticity and resiliency of Prolene mesh allow it to unroll easily while maintaining its form. The mesh is used to cover the direct space (Hesselbach's triangle), the indirect space, and the femoral ring areas (i.e., the entire inguinal floor). We do not make a slit in the mesh for the cord.

It is our practice with the TAPP technique to tack the mesh to prevent any migration. We use an endoscopic multifire spiral tacker to secure the mesh, beginning medially and proceeding laterally. The upper margin is first tacked to the rectus abdominis and the transversus abdominis fascia and arch, with care taken to stay 1 to 2 cm above the level of the internal inguinal ring and to avoid the inferior epigastric vessels, up to a point several centimeters lateral to the internal inguinal ring or the indirect hernial defect. Extending mesh fixation to the anterior iliac spine is neither necessary nor desirable. A two-handed technique is recommended for tack placement: one hand is on the tacker, and the other is on the abdominal wall, applying external pressure to place the wall against the tacker. The tacker itself is frequently pushed against the tissues and used as a spreader and palpator. However, it must not be forced too deeply into the abdominal wall superolateral to the spermatic cord; doing so might lead to inadvertent entrapment of the sensory nerves. The tacker can be moved from the left to the right port, depending on which position more readily allows placement of the staples perpendicular to the mesh and the abdominal wall.

Once the superior margin is fixed, fixation of the inferior margin is accomplished, beginning at the pubic tubercle and moving laterally along Cooper's ligament. The mesh is lifted frequently to ensure adequate visualization of the spermatic cord. Care is taken to avoid the adjacent external iliac vessels, which lie inferiorly. Lateral to the cord structures, all tacks are placed superior to the iliopubic tract to prevent subsequent neuralgias involving the lateral cutaneous nerve of the thigh or the branches of the genitofemoral nerve. If the surgeon can palpate the tacker through the abdominal wall with the non-dominant hand, the tacker is above the iliopubic tract. The mesh should lie flat at the end of the procedure.

Step 7: closure of peritoneum The peritoneal flap, including the redundant inverted hernial sac, is placed over the mesh, and the peritoneum is reapproximated with the tacker [see Figure 17]. Reduction of the intra-abdominal pressure to 8 mm Hg, coupled with external abdominal wall pressure, facilitates a tension-free reapproximation. Alternatively, the peritoneum may be sutured over the mesh, but in most surgeons' hands, this closure takes longer.

Step 8: closure of fascia and skin The peritoneal repair is inspected to ensure that there are no major gaps that might result in exposure of the mesh and subsequent formation of adhesions. The trocars are then removed under direct vision, and the pneumoperitoneum is released. The fascia at the 10/12 mm port sites is closed with 2-0 polydioxanone sutures to prevent incisional hernias. The skin is closed with 4-0 absorbable subcuticular sutures.

POSTOPERATIVE CARE

Patients are observed in the recovery room until they are able to ambulate unassisted and to void; if they are unable to void at

the time of discharge, in-and-out catheterization is performed. Patients are advised to resume their usual activities as they see fit; driving a car is permitted when pain is minimal. Outpatient prescriptions for acetaminophen, naproxen, and oxycodone are given, and follow-up visits in the surgical clinic are scheduled for postoperative day 7 to 14. Patients who live alone, have had intraoperative complications, have significant nausea or vomiting, or experience unexplained or inordinate pain are admitted overnight.

DISADVANTAGES AND COMPLICATIONS

Disadvantages

Need for general anesthesia The need for pneumoperitoneum and thus for general anesthesia in laparoscopic herniorrhaphy is sometimes considered a major disadvantage. Nausea, dizziness, and headache are more common in the recovery room after TAPP repair than after Lichtenstein repair.²⁷ It is not necessarily true, however, that local or regional anesthesia is safer than general anesthesia.²⁸ Anesthesiology studies critically appraising anesthetic techniques for hernia surgery have shown the choice of general anesthesia over local or regional anesthesia to be safe and, in many cases, advantageous, particularly in patients who are in poor health. Furthermore, TEP repair has been successfully done with patients under epidural and local anesthesia.^{14,29,30}

Lower cost-effectiveness A study comparing costs at North American teaching hospitals found that TEP repair cost US\$852 more than Lichtenstein repair; however, this study could not quantify the cost savings arising from faster recuperation and earlier reentry into the workforce.³¹ Some studies have demonstrated economic savings with the use of a laparoscopic approach, in the form of fewer days of work missed and reduced worker's compensation costs.^{32,33} Operating costs can also be reduced by avoiding the use of disposable instruments.³⁴ In addition, operating time has been shown to decrease as the surgeon's experience with the procedure increases.^{15,35,36}

Complications

Most randomized trials comparing laparoscopic repair with open mesh repair have found the overall complication rate to be comparable between groups.^{14,15} In general, however, the rate of serious perioperative complications, though still low, is increased with the laparoscopic approach.¹⁵

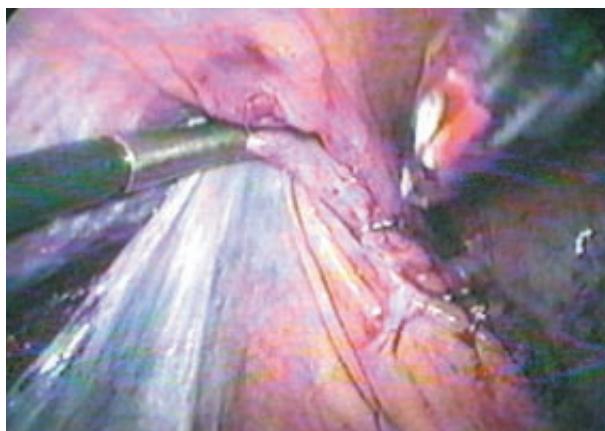

Figure 17 Laparoscopic inguinal hernia repair: TAPP approach. The peritoneum is stapled over the mesh.

Complications of access to peritoneal cavity A TAPP repair exposes the patient to several potentially serious risks related to the choice of the transabdominal route. Trocar injuries to the bowel, the bladder, and the vascular structures can occur during the creation of the initial pneumoperitoneum or the subsequent insertion of the trocars.^{14,37} Visceral injury rates reported for the laparoscopic approach, though quite low, are still about 10 times those reported for the open approach.¹⁴ Another complication related to trocar placement is incisional hernia,¹⁴ which can lead to postoperative bowel obstruction^{14,15,38}; however, this complication can be minimized by using 5 mm trocars and a 5 mm laparoscope instead of the larger 10/12 mm instruments.

Complications of dissection Injuries occurring during dissection are often linked to inexperience with laparoscopic inguinal anatomy. If serious enough, they can necessitate laparotomy. Fortunately, such conversion is rare (< 3%).¹⁴ The most common vascular injuries occurring during laparoscopic inguinal herniorrhaphy are those involving the inferior epigastric vessels and the spermatic vessels.¹⁴ The external iliac, circumflex iliac, profunda, and obturator vessels are also at risk. A previous lower abdominal operation is a risk factor.¹⁶ The source of any abnormal bleeding during the procedure must be quickly identified. All vessels in the groin can be ligated except the external iliac vessels, which must be repaired.¹⁶

Injuries to the urinary tract may also occur. Four bladder injuries necessitating repair were documented in a collected series of 762 laparoscopic repairs by different surgical groups.^{37,39,40} Bladder injuries are most likely to occur when the space of Retzius has been previously dissected (e.g., in a prostatectomy). Renal and ureteral injuries identified intraoperatively should be repaired immediately. Often, however, these injuries are not apparent until the postoperative period, when they present as lower abdominal pain, renal failure, ascites, dysuria, or hematuria—all of which should be investigated promptly. Although indwelling catheter drainage may constitute sufficient treatment of a missed retroperitoneal bladder injury, intraperitoneal injuries are best treated by direct repair via either laparoscopy or laparotomy.

Complications related to mesh Complications related to the use of mesh include infection, migration, adhesion formation, and erosion into intraperitoneal organs. Such complications usually become apparent weeks to years after the initial repair, presenting as abscess, fistula, or small bowel obstruction.

Mesh infection is very rare. In the 2003 Cochrane review of antibiotic prophylaxis for nonmesh hernia repairs,¹⁹ the overall infection rate was 4.69% in the control group and 3.08% in the treatment group. Thus, to prevent one infection in 30 days, 50 patients would have to be treated, and these patients would then be at risk for antibiotic-associated complications. Laparoscopic repairs were excluded from this review; however, in a meta-analysis comparing postoperative complications after laparoscopic inguinal hernia repair with those after open repair, superficial infection was less frequent in the laparoscopic groups.¹⁴ Deep mesh infection was rare in both groups. Mesh infection usually responds to conservative treatment with antibiotics and drainage. On rare occasions, the mesh must be removed; this may be accomplished via an external approach. It is noteworthy that removal of the mesh does not always lead to recurrence of the hernia, a finding that may be attributable to the resulting fibrosis.⁴¹

Mesh migration may lead to hernia recurrence. In a TAPP repair, appropriate stapling of the mesh should reduce this possibility. In a TEP repair, stapling does not appear to be necessary to prevent migration.^{35,42}

The risk that adhesions to the mesh will form is augmented if the mesh is left exposed to the bowel. The long-term durability and effectiveness of the sometimes flimsy peritoneal coverage employed in the TAPP approach have been questioned. Even in the TEP approach, small tears in the peritoneum may expose the bowel to the mesh.

Urinary complications Injuries to the urinary tract aside [see Complications of Dissection, *above*], urinary retention, urinary tract infection, and hematuria are the most common complications. Avoidance of bladder catheterization reduces the incidence of these complications, but urinary retention still occurs in 1.5% to 3% of patients.¹⁵ General anesthesia and the administration of large volumes of I.V. fluids may also predispose to retention.

Vas deferens and testicular complications Wantz⁴³ believed that the most common cause of postoperative testicular swelling, orchitis, and ischemic atrophy is surgical trauma to the testicular veins (i.e., venous congestion and subsequent thrombosis). Because spermatic cord dissection is minimized with the laparoscopic approach, the risk of groin and testicular complications resulting from injury to cord structures and adjacent nerves may be reduced.¹⁵

Most testicular complications, such as swelling, pain and epididymitis, are self-limited. Testicular pain occurs in about 1% of patients after laparoscopic repair,³³ an incidence comparable to that seen after open repair.^{15,44} A similar number of patients experience testicular atrophy,³⁷ for which there is no specific treatment.

The risk of injury to the vas deferens appears to be much the same in laparoscopic repair as in open repair.¹⁴ If fertility is an issue, the cut ends should be reapproximated if the injury is recognized intraoperatively.

Postoperative groin and thigh pain Unlike patients who undergo open anterior herniorrhaphy, in whom discomfort or numbness is usually localized to the operative area, patients who undergo laparoscopic repair occasionally describe unusual but specific symptoms of deep discomfort that are usually positional and are often of a transient, shooting nature suggestive of nerve irritation. The pain is frequently incited by stooping, twisting, or movements causing extension of the hip and can be shocklike. Although these symptoms can frequently be elicited in the early postoperative period, they are usually transient. If tacks or staples were used and neuralgia is present in the recovery room, prompt reexploration is the best approach.¹⁶

Persistent pain and burning sensations in the inguinal region, the upper medial thigh, or the spermatic cord and scrotal skin region occur when the genitofemoral nerve or the ilioinguinal nerve is stimulated, entrapped, or unintentionally injured. When these symptoms persist, they may result in severe morbidity.⁴⁵ A more worrisome symptom is lateral or central upper medial thigh numbness, which is reported in 1% to 2% of patients and often lasts several months or longer. Whether this numbness is related to staple entrapment, fibrous adhesions, cicatricial neuroma, or mesh irritation is unknown. Numbness and paresthesia of the lateral thigh are less frequent and are related to the involvement of fibers of the lateral cutaneous nerve. These problems can be prevented by paying careful attention to anatomic detail and technique.⁴⁶ Anatomic study, based on cadaveric dissections, suggests that both the genitofemoral nerve and the lateral cutaneous nerve of the thigh will be protected in all cases if no staples are placed further than 1.5 cm lateral to the edge of the internal ring.⁴⁷

A great deal of attention has rightly been focused on the risk of nerve injury with laparoscopic hernia repair, as well as on ways of preventing it. At the same time, it is important to note that pain and numbness, including thigh numbness, can also occur after open repair and may in fact be more common in that setting than was previously realized. In one study, persistent groin pain was present in 9.5% of patients after Lichtenstein repair versus 5.5% of patients after TAPP.⁴⁸ In the Cochrane meta-analysis, persistent pain and numbness 1 year after surgery were found to be significantly reduced with either TEP or TAPP repair.¹⁴ This finding was confirmed by a 2004 study that reported a 9.8% incidence of neuralgia or other pain at 2 years in patients who underwent laparoscopic repair, compared with a 14.3% incidence in open repair patients.¹⁵

Miscellaneous complications Laparoscopic repair apparently reduces the incidence of hematomas while increasing that of seromas.¹⁴ Lipomas of the spermatic cord, if left unreduced in patients with indirect hernias, may produce a persistent groin mass and a cough impulse that mimic recurrence, especially to an uninitiated examiner. These lipomas are always asymptomatic.

OUTCOME EVALUATION

Although there is a large body of literature on laparoscopic inguinal hernia repair—including a variety of randomized, controlled trials—the benefits of the laparoscopic approach have not yet been clearly defined or widely accepted. Given the low morbidity and relatively short recovery already associated with the conventional operation, demonstration of any significant differences between the open mesh and laparoscopic techniques requires large study samples. The previously cited meta-analysis done by the Cochrane collaboration addressed this question.¹⁴ Forty-one trials were included in this meta-analysis, ranging in size from 38 to 994 randomized patients. The duration of follow-up ranged from 6 weeks to 36 months. The results of the meta-analysis suggested that whereas operating times were longer and the risk of rare but serious complications higher in the laparoscopic groups, recovery was quicker and persistent pain and numbness less frequent. Recurrence rates did not differ significantly.

In addition, a large randomized, multicenter Veterans Affairs (VA) study published in 2004 compared open mesh repair with laparoscopic mesh repair (TEP, 90%; TAPP, 10%) in 2,164 patients.¹⁵ Patients with previous mesh repairs were excluded. In this study, the laparoscopic approach was associated with a higher risk of complications and, in contrast to the findings of the meta-analysis, a higher overall recurrence rate at 2 years after operation. Pain was reduced and recovery time shortened in the laparoscopic group.

Thus, there remains a degree of controversy regarding the ideal approach to and outcome for inguinal hernia repair. Accordingly, we will briefly review the salient outcomes of a number of studies that compare laparoscopic inguinal herniorrhaphy with open mesh repair.

Laparoscopic Repair versus Open Mesh Repair

Operating time The Cochrane meta-analysis suggested that overall, the average operating time was 15 minutes longer with the laparoscopic approach; however, for bilateral hernias, laparoscopic repair required no more time than open repair.¹⁴ The surgeon's level of experience with laparoscopic technique was not explicitly stated in all of these studies, which made it difficult to assess the impact of this variable on operating time. It has been shown that with more experience and greater specialization, the differences in operating time between laparoscopic and open repair tend to decrease and become clinically unimportant.^{35,49}

Recovery time The most significant short-term outcome measure after hernia repair is recovery time, defined as the time required for the patient to return to normal activities. One of the most frequently cited benefits of laparoscopic herniorrhaphy is the patient's rapid return to unrestricted activity, including work. The Cochrane meta-analysis revealed that recovery time was significantly shorter after laparoscopic repair than after open mesh repair.¹⁴ In a cost comparison between TEP repair and Lichtenstein repair, recovery time was 15 days after the former, compared with 34 days after the latter.³¹ In the 2004 VA study, laparoscopic repair patients returned to their normal activities 1 day earlier.¹⁵

Postoperative pain After laparoscopic repair, most patients experience minimal immediate postoperative pain and have little or no need for analgesics after postoperative day 1. Patients are able to perform some exercises better after laparoscopic repair than after Lichtenstein repair.⁴⁸ That patients experience less postoperative pain after laparoscopic repair than after open mesh repair has been reported in several randomized studies.^{27,32,40,44,50,51} In the Cochrane meta-analysis, persistent pain and numbness 1 year after surgery was significantly less after either TEP or TAPP repair than after open repair.¹⁴ In a 2003 report describing a 5-year follow-up of 400 patients treated with either Lichtenstein open mesh repair or TAPP repair, the incidence of permanent paresthesia and groin pain was lower with the TAPP approach.⁵² Moreover, all of the patients with pain and paresthesia significant enough to affect their daily lives were in the open repair group. A later study that evaluated postoperative neuralgia in 400 patients who underwent either TAPP repair or Lichtenstein repair reported similar findings.⁴⁸

Quality of life The studies that have assessed quality of life immediately after hernia repair have tended to favor the laparoscopic approach, albeit marginally. Using the SF-36 (a widely accepted general health-related quality-of-life questionnaire), one group found that at 1 month, greater improvements from baseline were apparent in the laparoscopic group in every dimension except general health; however, by 3 months, the differences between the two groups were no longer significant.²⁷ Another group also found no differences in any SF-36 domains at 3 months after operation.³⁷ Yet another study, however, using the Sickness Impact Profile, found some benefit to the laparoscopic approach.⁵³ In contrast, no postoperative differences in SF-36 domains were found in the VA study.¹⁵

Bilateral hernias Laparoscopy allows simultaneous exploration of the abdominal cavity (TAPP) and diagnosis and treatment of bilateral groin hernias, as well as coexisting femoral hernias (which are often unrecognized preoperatively), potentially without added risk or disability. Bilateral hernias accounted for 9% of the hernias reviewed in the Cochrane database.¹⁴ Operating time was longer in the laparoscopic groups than in the open groups; however, recovery time, the incidence of persistent numbness, and the risk of wound infection were significantly reduced in the former. These results are consistent with those of a prospective, randomized, controlled trial from 2003 that compared TAPP repair with open mesh repair for bilateral and recurrent hernias.⁵⁴ In this study, TAPP repair not only was less painful and led to an earlier return to work but also was associated with a shorter operating time. Further prospective, randomized trials designed to compare simultaneous bilateral open tension-free repair with bilateral TEP laparoscopic repair should be undertaken.

Recurrent hernias Approximately 10% of patients undergoing hernia repair present with recurrent inguinal hernia.⁵⁴ Patients with recurrent hernias may potentially derive greater benefits from a laparoscopic approach through an undisturbed plane of dissection, rather than a second groin exploration via an open technique, dissecting through scar tissue and potentially causing significant tissue trauma. This is especially true when mesh was used for the previous open repair.

Open mesh repair has been associated with long-term recurrence rates of 1% or less, even when not performed by hernia specialists.^{2,55} If the laparoscopic approach is to be a viable alternative to open repair, it should have comparable results. With respect to short-term results, prospective, randomized trials suggest that hernia recurrence rates are comparable in laparoscopic repair and open mesh repair groups.¹⁴ However, the Cochrane meta-analysis found that reductions in hernia recurrence were effected primarily by the use of mesh rather than by any specific placement technique.¹⁴ This finding is consistent with the Cochrane meta-analysis of open mesh inguinal hernia repair versus open nonmesh repair, which indicated that tension-free mesh repair led to a significant reduction in hernia recurrence.³ In a 5-year follow-up study from 2004, the recurrence rate after laparoscopic mesh repair still was not significantly different from that after open mesh repair.³⁴ In the VA study, the hernia recurrence rate at 2 years was higher in the laparoscopic group (10%) than in the open mesh repair group (4%) for primary, unilateral hernias.¹⁵ In both groups, the recurrence rates were higher than generally expected. However, these rates were found to be affected by the surgeon's level of experience: those who had performed more than 250 laparoscopic repairs reported a recurrence rate of 5%.

Most reported recurrences after laparoscopic herniorrhaphy come at an early stage in the surgeon's experience with these procedures and arise soon after operation.⁵⁶ The majority can be attributed to (1) inadequate preperitoneal dissection; (2) use of an inadequately sized patch, which may migrate or fail to support the entire inguinal area, including direct, indirect, and femoral spaces; or (3) staple failure with TAPP repair.

Transabdominal Preperitoneal Repair (TAPP) versus Totally Extraperitoneal Repair (TEP)

The TAPP approach is easier to learn and perform than the TEP approach, and even experienced laparoscopic hernia surgeons report more technical difficulties with the latter.^{15,57} Nonetheless, there is a growing body of literature to suggest that TEP repair, by avoiding entry into the peritoneal cavity, has significant advantages over TAPP repair.⁴ In particular, the TEP approach should reduce the risk of trocar site hernias, small bowel injury and obstruction, and intraperitoneal adhesions to the mesh. In a study that included 426 patients, TAPP repairs were performed in 339 and TEP repairs in 87, and the patients were followed for a mean of 23 and 7 months, respectively.⁵⁸ Time off work was shorter after TEP. A total of 15 major complications were noted, including one death, two bowel obstructions, one severe neuralgia, three trocar site hernias, one epigastric artery hemorrhage, and seven recurrences. With the exception of the epigastric artery hemorrhage, all of these complications occurred in the TAPP group. It is possible, however, that these results can be partly explained by the learning curve, in that the TAPP repairs were all done before the TEP repairs. That six TAPP recurrences occurred in the first 31 cases, whereas only one occurred in the subsequent 395 cases, lends support to this possibility.

In a study comparing 733 TAPP repairs with 382 TEP repairs, 11 major complications occurred in the TAPP group (two recur-

rences, six trocar site hernias, one small bowel obstruction, and two small bowel injuries), whereas only one recurrence and no intraperitoneal complications occurred in the TEP group.⁵⁹ Seven TEP procedures were converted to TAPP procedures. Time off work was equal in the two groups but was prolonged in patients receiving compensation. As in the study cited above,⁵⁸ the TAPP patients were followed longer than the TEP patients, and the TAPP cases occupied the first part of the learning curve. To avoid this type of selection bias would require a randomized study.

Not all surgeons are convinced that TEP repair is the laparoscopic procedure of choice. A 1998 study compared 108 TAPP repairs with 100 TEP repairs.⁵⁷ Although the TEP repairs were done only by surgeons who were already familiar with TAPP repair, many of the surgeons still encountered technical difficulties and problems with landmark identification. Overall, complications did not occur significantly more frequently in either group, but they seemed more severe in the TAPP group: four trocar site hernias, one bladder injury, and six seromas were noted in the TAPP group, compared with one cellulitis and six seromas in the TEP group. The authors concluded that because TAPP repair is easier and does not increase complications significantly, it is an “adequate” procedure. The sample size may have been too small to permit detection of small differences in complication rates.

Regardless of any individual preference for one technique or the other, laparoscopic hernia surgeons ideally should be capable of performing both TEP and TAPP well. For example, a planned TEP repair may have to be converted to a TAPP repair, or a TAPP approach may be required if the surgeon is doing another intra-peritoneal diagnostic or therapeutic procedure.

Laparoscopic Incisional Hernia Repair

Incisional hernias develop in approximately 2% to 11% of patients undergoing laparotomy.^{60,61} It has been estimated that 90,000 ventral hernia repairs are done in the United States every year.⁵ When prosthetic mesh is not used, repair of large incisional hernias is associated with recurrence rates as high as 63% after 10 years, compared with 32% when mesh is used.⁶² In addition to these high recurrence rates, even with the use of mesh, open incisional hernia repair may be associated with significant complications and a substantial hospital stay.

Initially described in 1992,⁹ laparoscopic repair of incisional hernias has evolved from an investigational procedure to one that can safely and successfully be used to repair ventral hernias. Taking a laparoscopic approach allows the surgeon to minimize abdominal wall incisions, avoid extensive flap dissection and muscle mobilization, and eliminate the need for drains in proximity to the mesh, thereby potentially achieving reductions in pain, recovery time, and duration of hospitalization, as well as lower rates of surgical site infection (SSI).^{8,63,64} In addition, the improved visualization of the abdominal wall associated with the laparoscopic view may result in better definition of the defect, the discovery of unrecognized hernia sites, and improved adhesiolysis. Improved visualization permits more precise and accurate placement and tailoring of the mesh, as is suggested by the reduced recurrence rates (9% to 12%) reported up to 5 years after laparoscopic incisional herniorrhaphy.⁶⁴⁻⁶⁶

PREOPERATIVE EVALUATION

Selection of Patients

Laparoscopic incisional hernia repair may be considered for any ventral hernia in which mesh will be used for the repair. This cat-

egory includes virtually all incisional hernias, in that even small ($< 10 \text{ cm}^2$) defects are known to carry a significant risk of recurrence.⁶² Both upper abdominal and lower abdominal incisions are amenable to a laparoscopic approach, although hernias at the extremes of the abdominal wall—abutting the pubis, the xiphoid, or the costal margins—pose a technical challenge for effective mesh fixation. The so-called Swiss cheese hernia, which comprises multiple small defects, is particularly well suited to this approach; open repair would necessitate a large incision for access to the multiple fascial defects, and small defects might not be appreciated. Incarcerated hernias can also be approached laparoscopically; however, the suspected presence of compromised bowel is a contraindication. An abdomen that has undergone multiple operations and contains dense adhesions presents a challenge in terms of both access to the abdominal cavity and access to the hernia site. If the surgeon cannot obtain safe access to the peritoneal cavity for insufflation, a laparoscopic approach is contraindicated.

Contraindications Laparoscopic incisional herniorrhaphy is contraindicated in patients with suspected strangulated bowel or loss of domain. Hernias in which the fascial edges extend lateral to

Table 2 Devices Used for Mesh Fixation in Incisional Hernia Repair

Onux Medical	Salute	Wire loop deployment

the midclavicular line may make trocar placement lateral to the defect impossible. Defects in close proximity to the bony margins of the abdomen, especially those near the xiphoid, pose significant challenges for mesh fixation, though this is also true with open incisional herniorrhaphy. Patients who have undergone multiple previous operations, with or without mesh, may have dense adhesions. Patients in whom polypropylene mesh has previously been placed in an intra-abdominal position may have dense adhesions to the underlying viscera. Whether such patients are approached laparoscopically should be determined by the surgeon's expertise.

OPERATIVE PLANNING

Preparation

The procedure is performed with the patient under general anesthesia. Mechanical bowel preparation is not routinely used; however, it may be considered if incarcerated colon is suspected. If the defect is in the lower abdomen, a three-way Foley catheter is placed in the bladder. Sequential compression stockings are applied. Patients are routinely given heparin, 5,000 U subcutaneously, and prophylactic antibiotics.⁶⁷

Positioning

The patient is placed in the supine position with both arms tucked. If the hernia is in the midline, the surgeon can stand on either side of the patient, with the monitor directly opposite. If the hernia extends significantly to one side, initial trocar placement is done on the opposite side. Initially, the assistant stands on the same side as the surgeon; however, he or she may later have to move to the opposite side to help with dissection and stapling. A second monitor on the opposite side of the table is useful. If the defect is subcostal, the surgeon may prefer to operate from between the patient's legs, with a monitor at the head of the bed.

Equipment

As the wide variety of mesh materials currently available suggests, there is no one ideal mesh. Meshes may be divided into two categories: (1) polymeric meshes and (2) meshes made of specially prepared connective tissue (animal or human) [see Table 1]. The polymeric meshes are biocompatible materials made of either polypropylene, polyester, expanded polytetrafluoroethylene (ePTFE), or laminates of these. Most ePTFE meshes are engineered so that one side is porous to encourage tissue ingrowth and the other is smooth to resist adhesion formation. They may also be coated with an adhesion-resisting absorbable material.

Because laparoscopic incisional hernia repair leaves the mesh exposed to the intraperitoneal cavity, concerns have been expressed about the risk of adhesion formation and fistulization if polypropylene mesh is used. Polytetrafluoroethylene (PTFE) mesh has been demonstrated to have a reduced propensity for adhesion formation.

Additional special equipment used for incisional hernia repair includes a suture passer, a 5 mm spiral tacker (or other tacking device), and 2-0 monofilament sutures. Several tacking devices and suture placement devices have been developed to facilitate mesh fixation [see Table 2]. All work in essentially the same manner. A Keith or similar needle may also be used. Atraumatic bowel instruments are required to manipulate the bowel if lysis of adhesions is needed.

OPERATIVE TECHNIQUE

In essence, the repair consists of the intraperitoneal placement of a large piece of mesh so that it overlaps the defect in the fascia

Figure 18 Laparoscopic incisional hernia repair. Shown is an external view of incisional hernia trocar site placement. Open insertion of a blunt 10/12 mm trocar at the left lateral midabdomen site is performed, with subsequent placement under direct vision of two 5 mm trocars above and below the initial trocar.

and the abdominal wall. The defect is not closed. The mesh is anchored with a minimum of four subcutaneously tied transfascial sutures placed at the four corners and is further secured between the sutures with intraperitoneally placed tacks and additional sutures as needed.

Step 1: placement of trocars Because of the probability of extensive intra-abdominal adhesions, we begin with open insertion of a blunt 12 mm trocar. Although open insertion necessitates an often tedious dissection through several layers of the abdominal wall, it has the advantage of allowing early diagnosis and repair of any iatrogenic bowel injury. Nevertheless, good results have also been reported with insertion of a Veress needle, usually in the left upper quadrant (where adhesions are presumed to be minimal). Ultimately, trocar position is determined by the location of the hernia. For midline hernias, we usually begin on the left side of the patient and insert the first trocar lateral to the edges of the defect, about midway between the costal margin and the iliac crest.

CO₂ is then insufflated to a pressure of 12 to 15 mm Hg, and a 5 mm 30° scope is inserted. As in laparoscopic inguinal hernia repair, an angled scope is essential because dissection and repair are done on the undersurface of the anterior abdominal wall, which cannot be adequately visualized with a 0° scope. The hernial defect is visually identified, and two additional 5 mm trocars are placed on the same side under direct vision, with their precise placement dependent on the size and contours of the defect and on the locations of any adhesions. If possible, these trocars are placed superior and inferior to the initial trocar, as far laterally as possible, with care taken to ensure that the downward movement of the instruments is not limited by the iliac crest or the thigh. Lateral placement is necessary to optimize exposure of the abdominal wall [see Figure 18].

Step 2: exposure of hernial defect The edges of the hernial defect are exposed by reducing the contents of the hernia into the abdominal cavity. All adhesions from bowel or omentum to the abdominal wall in the vicinity of the defect and along the full length of the previous incision should be divided. Complete adhesiolysis of abdominal wall adhesions facilitates the identification of

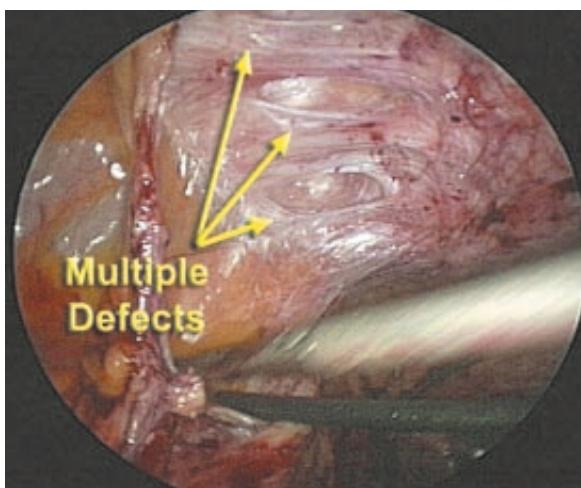

Figure 19 Laparoscopic incisional hernia repair. Multiple small hernial defects (so-called Swiss cheese hernia) may be seen.

Swiss cheese defects [see *Figure 19*]. Starting in the upper abdomen may be easier, in that bowel adhesions are less likely to be encountered. External pressure may also help reduce hernial contents and facilitate identification of the hernial sac. Placing the patient head down or head up and rotating the table will also aid in exposure.

If dense adhesions are present, it is preferable to divide the sac or the fascia, so as not to risk bowel injury [see *Figure 20*]. Sharp dissection with scissors is recommended to prevent thermal injury to the bowel, which may not be immediately recognized. If incarcerated bowel cannot be reduced with laparoscopic techniques, an incision is made over the area of concern, and the bowel is freed under direct vision. Once this incision is closed, laparoscopic mesh placement can proceed, and there may be no need for full conversion to an open operation. Strategies for avoidance and treatment of bowel injury are discussed in more detail elsewhere [see Complications, Bowel Injury, below].

Step 3: selection of mesh The contours of the hernial defect are marked as accurately as possible on the exterior abdominal wall; the edges may be delineated with a combination of palpation and visualization. All Swiss cheese defects are marked. The defect is measured after pneumoperitoneum is released to ensure

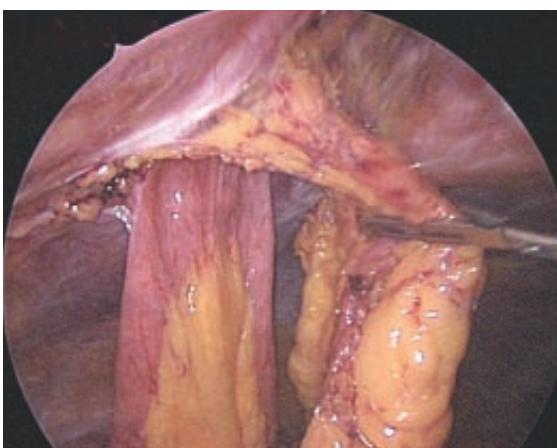

Figure 20 Laparoscopic incisional hernia repair. Shown is dissection of incarcerated small bowel and omentum from an incisional hernia.

that its size is not overestimated [*see Figure 21*]. Ideally, the prosthesis should overlap the defect by at least 3 cm on all sides. Coverage of all of the defects with a single sheet of mesh is preferred, but more than one sheet may be needed, depending on the locations of the defects and the size of the patient. The mesh sheet is laid on the abdominal wall in a position that approximates its eventual intra-abdominal position, and its four corners and those of its representation on the abdominal wall are numbered clockwise from 1 through 4 for later orientation [*see Figure 22*]. A mark is made on the inner side of the mesh sheet so that the surgeon can easily determine which side is to face the peritoneum once the mesh is inserted into the peritoneal cavity. If a dual-sided mesh is being used, the smooth side must be the one facing the bowel. A 2-0 monofilament suture is tied in each corner of the mesh, and both ends of each suture are left about 15 cm long.

The mesh swatch is rolled as tightly as possible around a grasping forceps and introduced into the peritoneal cavity. Small swatches can be inserted through a 12 mm trocar; for larger pieces, we remove a large trocar and insert the mesh directly into the abdomen. The trocar is then repositioned and insufflation of CO₂ recommenced.

Step 4: fixation of mesh Once the mesh swatch has been introduced into the abdomen, it is unfurled and spread out, with the previously placed corner sutures facing the fascia and oriented so that the four numbered corners are aligned with the numbers marked on the abdominal wall. Small skin incisions are then made with a No. 11 blade. Through each of these incisions, a suture passer is inserted to grasp one tail of the previously placed anchoring suture and pull it out through the abdominal wall, then reintroduced through the incision at a slightly different angle to pull out the second tail. This is done for each of the four anchoring sutures, and the mesh is unfurled under appropriate tension (with care taken to avoid excessive tension and stretching). Initially, the corner sutures are held with hemostats and not tied; some adjustment to achieve optimal positioning of the mesh is often required, especially early in the surgeon's experience.

Once the mesh is in a satisfactory position, each suture is tied and buried in the subcutaneous tissue to anchor the mesh swatch to the fascia and maintain its proper orientation [*see Figure 23*]. With large defects, it is usually necessary to place one or more additional 5 mm trocars contralateral to the initial ports to aid in mesh fixation. A tacker is then employed to tack the mesh circumferentially at 1 cm intervals along its edge. A two-handed technique is used, in which the second hand applies external pressure to the abdominal wall to ensure that the tacks obtain the best possible purchase on the mesh and the abdominal wall [*see Figure 24*]. Care should be taken to place the tacks flush because they can cause bowel injury if left protruding.⁶⁸ Additional sutures are then passed at 5 cm intervals directly through the mesh with either the suture passer and a free suture or a suture on a Keith needle. Sutures should be tied taut but not tight, so as not to cause necrosis of the intervening tissue.

Step 5: closure The pneumoperitoneum is released. The fascia at any trocar site 10 mm in diameter or larger is closed. Careful closure of the site used for open insertion of the first trocar is mandatory to prevent trocar site hernia. The skin is then closed with subcuticular sutures.

POSTOPERATIVE CARE

The Foley catheter is removed at the end of the procedure. Unless adhesiolysis was minimal, patients are admitted to the hos-

Figure 21 Laparoscopic incisional hernia repair. The contours of the incisional hernial defect are marked on the abdomen, as measured after gas insufflation has been released (here, 8 × 7 cm). Ideally, the mesh should overlap the defect by 3 cm on all sides, meaning that it should be at least 14 × 13 cm.

Figure 22 Laparoscopic incisional hernia repair. Shown is an external view of the orientation of a two-sided mesh swatch overlying the marked hernial defect. The sites of suture placement are numbered.

pital. Oral intake is begun immediately. Patients are discharged when oral intake is tolerated and pain is controlled with oral medication. Patients are informed that fluid will accumulate at the hernia site and are asked to report any fever or redness. Finally, patients are instructed to resume all regular activities as soon as they feel capable.

SPECIAL SITUATIONS

Suprapubic Hernia

For hernial defects that extend to the pubic bone, a three-way Foley catheter is inserted. After adhesiolysis, the patient is placed in the Trendelenburg position, and the bladder is distended with methylene blue in saline. The bladder is dissected off the pubic bone until Cooper's ligament is reached. The mesh is then placed so that it extends behind the bladder and is tacked to the pubic bone, to Cooper's ligament, or to both.

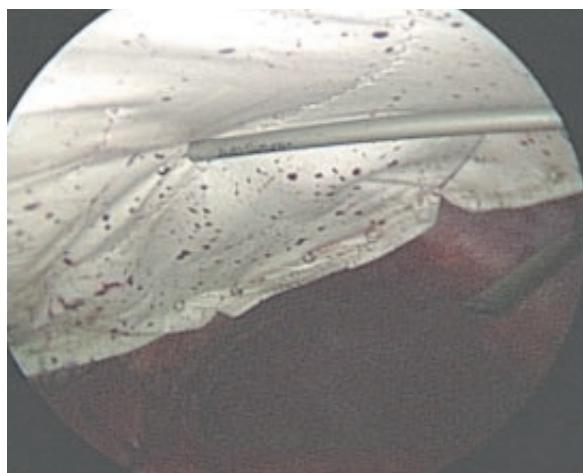

Figure 23 Laparoscopic incisional hernia repair. Shown is an internal view of a two-layer mesh covering the hernial defect and fixed to the abdominal wall with sutures and spiral tacks.

Subxiphoid or Subcostal Hernia

A hernia in which there is no fascia between the hernia and the ribs or the xiphoid (e.g., a poststernotomy hernia) poses significant challenges for fixation. Because of the risk of intrathoracic injury, the mesh is not tacked to the diaphragm. Although some surgeons perform mesh fixation to the ribs, this measure is often associated with significant postoperative pain and morbidity. In these situations, we take down the falciform ligament and lay the mesh along the diaphragm above the liver, placing tacks and sutures up to but not above the level of the costal margin. Taking down the falciform ligament may be a helpful step for all upper abdominal wall hernia repairs. The recurrence rates for subxiphoid and subcostal hernias are higher than those for hernias at other locations.⁶⁹

Parastomal Hernias

As many as 50% of stomas are complicated by parastomal hernia formation,⁷⁰⁻⁷² and 10% to 15% will require operative intervention for obstruction, pain, difficulty with stoma care, or unsatisfactory cosmesis. Three methods of repair have been described:

Figure 24 Laparoscopic incisional hernia repair. Shown is two-handed tacking.

primary fascial repair, repair with mesh, and stoma relocation [see 5:27 *Open Hernia Repair*]. Repair via a laparoscopic approach that uses ePTFE mesh has shown promising short-term results.^{72,73} The technique that currently seems to be the most successful is the one described by LeBlanc and Bellanger.⁷³ Rather than lateralizing the intestine (as in the technique described by Sugarbaker⁷⁴), this method centralizes the intestine in the mesh by cutting an appropriately sized hole in the middle of the mesh sheet, along with a slit to allow it to be placed around the intestine. This step is repeated on a second piece of mesh, but with the slit oriented to the opposite side. The mesh is fixed with sutures and tacks in such a way that it overlaps the defect by at least 3 cm (more commonly, 5 cm) on all sides, as in other ventral hernia repairs. This method appears to minimize the risk of mesh prolapse and bowel herniation alongside the stoma. The authors reported no recurrences within their 3- to 11-month follow-up period and no morbidity. In contrast, a subsequent study reported recurrences within 12 months in five of nine patients who underwent a variation of this repair, in which a slit in the mesh (instead of a central defect) was created and only one mesh sheet (instead of two) was used to cover the defect.⁷¹

Laparoscopic parastomal hernia repair appears to be a viable alternative to laparotomy or stoma relocation, but long-term multicenter evaluation is necessary for full assessment of this technique's value in this setting.

COMPLICATIONS

Overall, fewer complications are reported after laparoscopic incisional herniorrhaphy than after open mesh repair.^{8,63,75-77} There are, however, several specific complications that are of particular relevance in laparoscopic procedures (see below).

Bowel Injury

A missed bowel injury is a potentially lethal complication. The overall incidence of bowel injury does not differ significantly between open repair and laparoscopic repair and is generally low with either approach (1% to 5% when serosal injuries are included). It should be noted, however, that pneumoperitoneum may hinder the recognition of bowel injury at the time of operation. There have also been several reports of late bowel perforation secondary to thermal injury with laparoscopic repair.^{65,76-79} One study reported two bowel injuries that were not discovered until sepsis developed; these late discoveries resulted in multiple operations, removal of the mesh, prolonged hospital stay, and, in one patient, death. The incidence of bowel injury is likely to be higher with less experienced surgeons⁸⁰ and in patients who require extensive adhesiolysis. In one series describing a surgeon's first 100 cases, four of six inadvertent enterotomies were made in the first 25 cases.⁸¹

To reduce the risk of bowel injury, we strongly discourage the use of electrocauterization and ultrasonic dissection. The visualization afforded by the pneumoperitoneum, which helps place adhesions between the abdominal wall and the bowel under tension, and the magnification afforded by the laparoscope facilitate identification of the least vascularized planes. As far as possible, we avoid grasping the bowel itself, preferring simply to push it or to grasp the adhesions themselves to provide countertraction. External pressure on the hernia may also help. Larger vessels in the omentum or adhesions are controlled with clips. Some degree of oozing from the dissected areas is tolerated; such oozing almost always settles down without specific hemostatic measures.

As noted, if dense adhesions are present, it is preferable to divide the sac or the fascia rather than risk injury to bowel. In the

case of densely adherent polypropylene mesh, it may be better to excise it from the abdominal wall rather than attempt to separate it from the serosa of the bowel. If there is reason to suspect that bowel injury may have occurred, immediate and thorough inspection should be carried out; if this is not done, it may be difficult or impossible to find the exact site of injury later, once the bowel has been released after being freed of its attachments. If an injury to the bowel is recognized, the extent of the injury and the surgeon's level of comfort with laparoscopic suture repair will determine the best approach. If there is no or minimal spillage of bowel contents, the injury may be treated with either laparoscopic repair or open repair; the latter usually can be carried out through a several centimeter counterincision over the injured area. Whether a mesh prosthesis will be placed depends on the degree of contamination. If there has been minimal or no contamination, any small open incision is closed, and laparoscopic lysis of adhesions and mesh placement can continue. If the contamination is more significant, adhesiolysis is completed, but the patient is brought back for mesh placement at another date. More significant bowel injuries may necessitate conversion to open repair.

Chronic Pain

In about 5% of patients, the transfascial fixation sutures used to secure the mesh cause pain that lasts more than 2 months. In most cases, postoperative pain decreases over time; if it does not, injection of local anesthetic into the area around the painful suture may be helpful.⁸²

Seroma

Seroma formation is one of the most commonly reported complications: it occurs immediately after operation in virtually all patients, to some extent.^{65,80,83} Patients sometimes mistake a tense seroma for recurring incisional hernia, but appropriate preoperative discussion should provide them with significant reassurance on this point. Seroma formation seems not to be related to particular mesh types or to the use of drains.⁸⁰ Virtually all seromas resolve spontaneously over a period of weeks to months, with fewer than 5% persisting for more than 8 weeks.⁶⁴ They are rarely clinically significant. Aspiration may increase the risk of mesh infection.⁸⁴

Infection

Overall wound complication rates have been shown to be lower with laparoscopic incisional herniorrhaphy than with open repair.^{65,79,80,85} In particular, SSIs appear to be reduced with the laparoscopic approach.^{65,79,80,85} SSI rates for open incisional repair range from 5% to 20%,^{63,79,80,83} whereas those for laparoscopic repair range from 1% to 8%.^{5,65,72,79} Mesh infection extensive enough to necessitate mesh removal is rare (incidence ~1%); however, SSI after laparoscopic repair, especially when PTFE is used, more frequently results in seeding of the mesh.^{65,80} Because this type of mesh does not become well incorporated, antibiotic treatment alone is ineffective.⁸⁰

OUTCOME EVALUATION

Several studies have demonstrated improvements in outcome measures—such as decreased postoperative pain, shorter length of stay, earlier return to work,⁸⁶ and reduced blood loss—with the laparoscopic approach to incisional hernia repair.^{5,8,63,64,76,84,87-89} The only randomized trial published to date compared 30 laparoscopic incisional hernia repairs with 30 open repairs.⁶ The mean operating time was significantly shorter in the laparoscopic group (87 minutes versus 111.5 minutes), as was the postop-

erative length of stay (2.2 days versus 9.1 days). Another study compared 56 prospective laparoscopic incisional hernia repairs with 49 open incisional hernia repairs assessed through retrospective chart review.⁸ The laparoscopic and open groups were comparable in terms of patient characteristics and hernia size. Although the mean operating time was longer in the laparoscopic group (95.4 minutes versus 78.5 minutes), the postoperative length of stay was significantly shorter after laparoscopic repair (3.4 days versus 6.5 days). In contrast, some studies have found the operating time to be 30 to 40 minutes shorter with laparoscopic repair.^{63,76}

The recurrence rate—the primary long-term outcome measure of interest—is reported to be reduced after laparoscopic repair. In studies comparing laparoscopic and open incisional hernia repair with mesh, the recurrence rates after the laparoscopic repairs ranged from 0% to 11%, whereas those after the open repairs ranged from 5% to 35%.^{6,8,78,86,88} In expert hands, recurrence rates are low after laparoscopic repair. For example, in a multicenter series of 850 laparoscopic incisional hernia repairs, mostly followed prospectively, the recurrence rate after a mean follow-up period of 20 months was 4.7%.⁷⁷ One group found no recurrences in the laparoscopic group and two in the open group after a minimum follow-up period of 18 months.⁷⁶ Another group, however, reported a recurrence rate of 18%,⁹⁰ which approached that

reported after open mesh repair. Recurrence has been associated with lack of suture fixation, prostheses that overlap the defect by less than 2 to 3 cm, postoperative complications, and previous repairs.^{64,65,77,91}

The surgeon's level of experience plays a significant role in patient outcome, as demonstrated by a group that compared the outcomes for their first 100 laparoscopic incisional hernia repair patients with those for their second 100.⁸⁴ Recurrence rates after a mean follow-up period of 36 months dropped from 9% in the first 100 patients to 4% in the second 100. In addition, the second set of patients were an average of 9 years older, had a higher percentage of recurrent hernias, and exhibited more comorbidities, yet despite these added challenges, operating time was not lengthened, length of stay was similarly short, and the complication rate was no different. Another group reported similar findings for their laparoscopic incisional hernia repair learning curve.⁹² Operating times and complication rates in the first 32 patients were comparable to those in the second 32; however, bowel injuries were more common in the first 32.

Although the results of large randomized trials are not available yet, the evidence to date suggests that the laparoscopic approach to the repair of large incisional hernias is highly promising. The laparoscopic approach seems to be safe and compares favorably with the open operation in terms of complication and recurrence rates.

29 INTESTINAL ANASTOMOSIS

Julian Britton, M.S., F.R.C.S.

Intestinal obstruction, peritonitis from a perforated bowel, abdominal trauma, and disease of the bowel are common surgical problems throughout the world. These problems usually must be treated operatively; hence, it is frequently necessary to join two sections of bowel together. Unlike joining two areas of skin, where there is a powerful evolutionary incentive to achieve rapid healing, joining two segments of bowel so as to restore intestinal function without leakage of intestinal contents is not easy. Over time, the basic principles crucial for obtaining successful results have been defined [see Table 1]. Accurate approximation of the bowel without tension and with a good blood supply to both of the structures being joined are obviously fundamental. Surgical technique is equally important: between two given surgeons, rates of anastomotic breakdown can vary by as much as a factor of 60.¹

Failure of an anastomosis with leakage of intestinal contents is still, regrettably, a common surgical experience. Reported failure rates range from 1.5%² to 2.2%,³ depending on what type of anastomosis was performed and whether the operation was an elective or an emergency procedure. A leaking anastomosis greatly increases the morbidity and mortality associated with the operation: it can double the length of the hospital stay and increase the mortality as much as 10-fold.⁴ Dehiscence, when it occurs, has been associated with one fifth to one third of all postoperative deaths in patients who underwent an intestinal anastomosis.⁵

Unfortunately, anastomotic dehiscence can occur even in ideal circumstances. This unwelcome fact has stimulated a great deal of debate regarding the reliability of various methods and approaches. With the aim of clarifying the debate, I will address certain fundamental technical issues in the performance of an intestinal anastomosis and attempt to summarize what is known about how these issues relate to the reliability of the various anastomotic techniques in current use. I will then outline operative approaches to performing three common intestinal anastomoses in somewhat greater detail [see Operative Techniques for Selected Anastomoses, below].

Intestinal Anastomotic Healing

Most of the strength of the bowel wall resides in the submucosa;⁶ however, for the purpose of suturing bowel segments together, it is important to keep in mind that the serosa (i.e., the visceral peritoneum) holds sutures better than either the longitudinal or the circular muscle layer [see Figure 1]. The absence of a peritoneal layer makes suturing of the thoracic esophagus and the rectum below the peritoneal reflection technically more difficult than suturing the intraperitoneal segments of the intestine. In addition, the stomach and the small bowel possess a richer blood supply than the esophagus and the large bowel and consequently tend to heal more readily.

The process of intestinal anastomotic healing mimics that of wound healing elsewhere in the body in that it can be arbitrarily

divided into an acute inflammatory (lag) phase, a proliferative phase, and, finally, a remodeling or maturation phase. The strongest component of the bowel wall, the submucosa, owes most of its strength to the collagenous connective tissue it contains. Collagen is thus the single most important molecule for determining intestinal strength, which makes its metabolism of particular interest for understanding anastomotic healing.

Collagen is secreted from fibroblasts in a monomeric form called tropocollagen; this is a large, stiff molecule that can be visualized by electron microscopy. Collagen itself can be divided into subtypes on the basis of compositional differences (i.e., different combinations of α_1 and α_2 chains). Type I collagen predominates in mature organisms; type II is found primarily in cartilage; and type III is associated with type I in remodeling tissue and in elastic tissues such as the aorta, the esophagus, and the uterus. Synthesis of collagen is an intracellular process that occurs on polysomes. A critical stage in collagen formation is the hydroxylation of proline to produce hydroxyproline; this process is believed to be important for maintaining the three-dimensional triple-helix conformation of mature collagen, which gives the molecule its structural strength. The amount of collagen found in a tissue is indirectly determined by measuring the amount of hydroxyproline, though no significant statistical correlation between hydroxyproline content and objective measurements of anastomotic strength has ever been demonstrated.⁷ Vitamin C deficiency results in impaired hydroxylation of proline and the accumulation of proline-rich, hydroxyproline-poor molecules in intracellular vacuoles.

The degree of fiber and fibril cross-linking relates to the maturity of the collagen and is probably important in determining the overall strength of the scar tissue. Of equal importance is the orientation of the fibers and their weave. The bursting pressure of anastomoses has often been used to gauge the strength of the healing process. This pressure has been found to increase rapidly in the early postoperative period, reaching 60% of the strength of the surrounding bowel by 3 to 4 days and 100% by 1 week.^{8,9}

Collagen synthesis is a dynamic process that depends on the balance between synthesis and collagenolysis. Degradation of mature collagen begins in the first 24 hours and predominates for

Table 1 Principles of Successful Intestinal Anastomosis

- Well-nourished patient with no systemic illness
- No fecal contamination, either within the gut or in the surrounding peritoneal cavity
- Adequate exposure and access
- Well-vascularized tissues
- Absence of tension at the anastomosis
- Meticulous technique

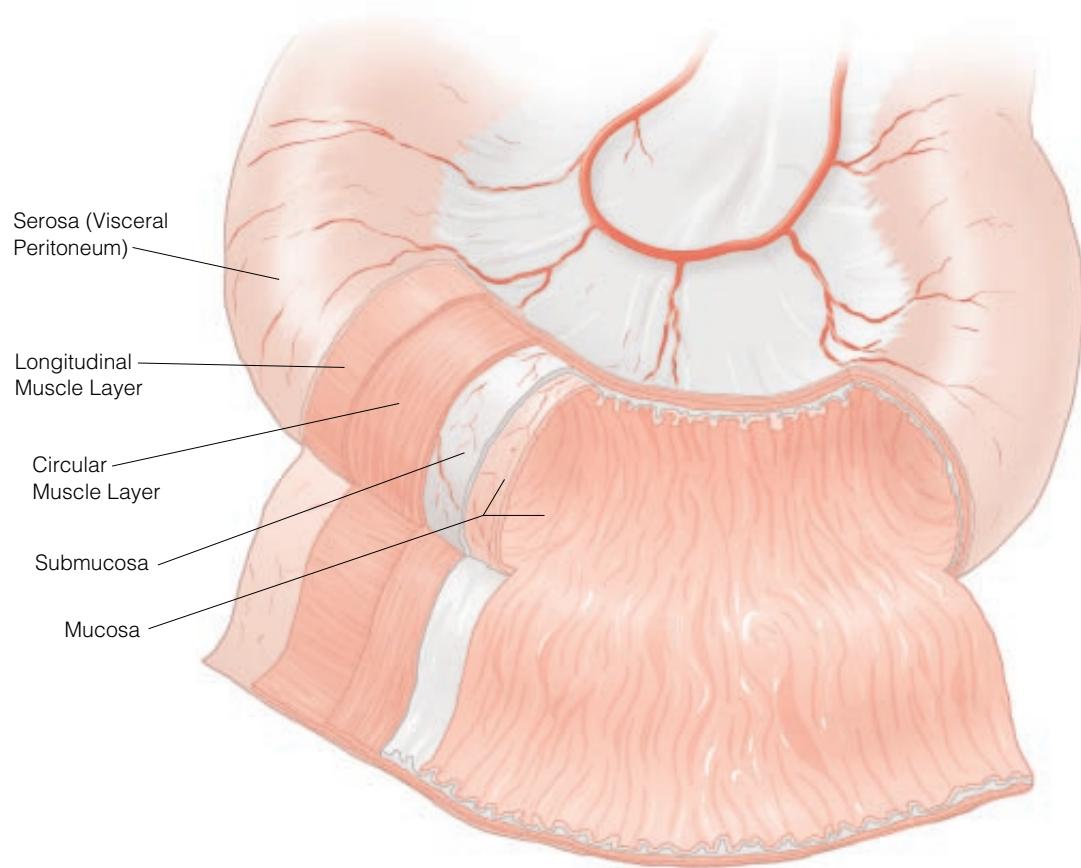

Figure 1 Shown are the tissue layers of the jejunum. Most of the bowel wall's strength is provided by the submucosa.

the first 4 days. By 1 week, collagen synthesis is the dominant force, particularly proximal to the anastomosis. After 5 to 6 weeks, there is no significant increase in the amount of collagen in a healing wound or anastomosis, though turnover and thus synthesis are extensive. The strength of the scar continues to increase for many months after injury. Local infection increases collagenase activity and reduces levels of circulating collagenase inhibitors.^{10,11}

Collagen synthetic capacity is relatively uniform throughout the large bowel but less so in the small intestine: synthesis is significantly higher in the proximal and distal small intestine than in the midjejunum. Overall collagen synthetic capacity is somewhat less in the small intestine. Although no significant difference has been found between the strength of ileal anastomoses and that of colonic anastomoses at 4 days, colonic collagen formation is much greater in the first 48 hours.¹² It is noteworthy that the synthetic response is not restricted to the anastomotic site but appears to be generalized to a significant extent.¹³

Various attempts have been made to improve the healing of intestinal anastomoses. A 2002 animal study concluded that locally applied charged particles improved the healing of colonic anastomoses.¹⁴

Technical Options for Fashioning Anastomoses

Sewing bowel segments together with various suture materials, ranging from catgut to stainless steel wire, has been a standard surgical technique for more than 150 years. Staplers, though first developed early in the 20th century, only began to have a significant impact on GI surgery within the past three decades. Staplers certainly

appeal to the technically minded, and most studies suggest that they save a small amount of operating time¹⁵; however, they remain relatively expensive, and it is still unclear whether the results are any better than can be achieved with suturing. Accordingly, it is worthwhile to examine the technical aspects of the two approaches to bowel anastomosis and to compare their respective merits.

SUTURING: TECHNICAL ISSUES

Choice of Suture Material

Sutures act as foreign bodies in the anastomosis and thus produce an inflammatory reaction.⁷ One study that examined the relative efficiency of absorbable and nonabsorbable material concluded that the strength of the anastomosis, expressed as a percentage of normal tissue strength, was essentially the same regardless of the type of suture used. Other studies that examined the amount of inflammation induced at the anastomosis by various types of sutures found that polypropylene (Prolene), catgut, and polyglycolic acid (Dexon) were equivalent in this regard.^{16,17} Silk, however, produced a significantly greater cellular reaction at the anastomosis, and the reaction persisted for as long as 6 weeks.¹⁷ A 1975 study reported on a series of 41 patients who underwent low anterior resection involving a primary side-to-end colorectal anastomosis with 5-0 stainless steel wire.¹⁸ The investigators considered this material ideal because of its strength and relative inertness within the tissues, and they supported their claims with a relatively low clinical leakage rate (7.3%).

The ideal suture material—one that causes minimal inflammation and tissue reaction while providing maximum strength during the lag phase of wound healing—is yet to be discovered.

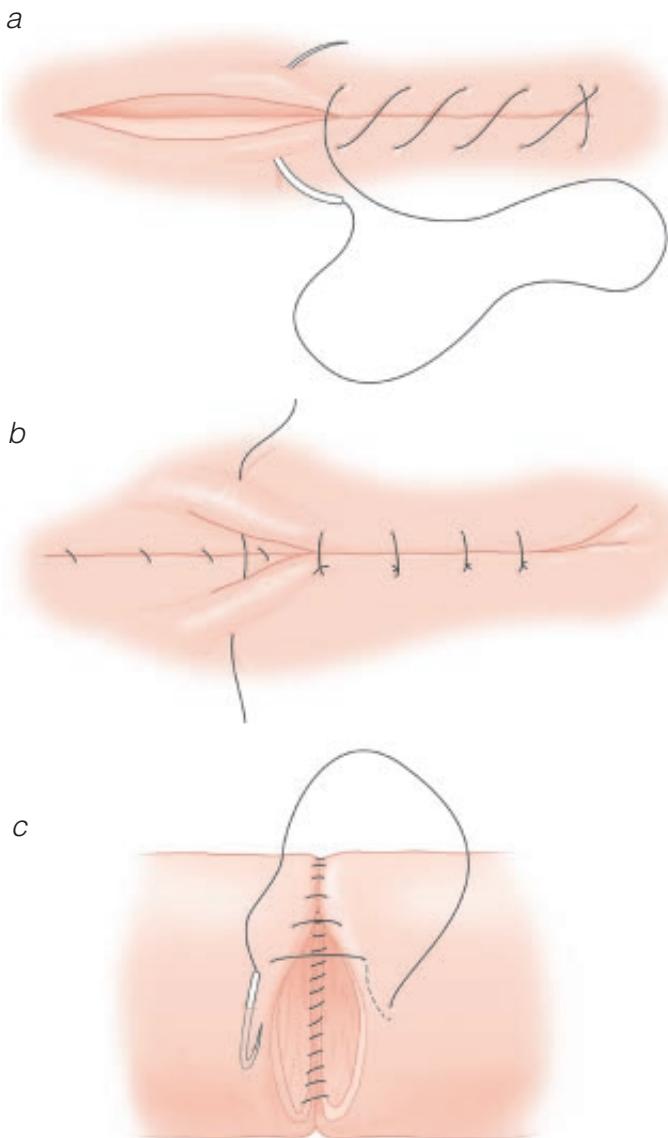

Figure 2 Shown are stitches commonly used in fashioning intestinal anastomoses: (a) the continuous over-and-over suture, (b) the interrupted Lembert suture, and (c) the Connell suture.

Clearly, however, monofilament and coated braided sutures represent an advance beyond silk and other multifilament materials.

Continuous versus Interrupted Sutures

Both continuous and interrupted sutures are commonly used in fashioning intestinal anastomoses [see Figure 2]. No randomized trials have addressed the question of whether interrupted sutures have a significant advantage over continuous sutures in a single-layer anastomosis; however, retrospective reviews have not revealed any such advantage.¹⁹⁻²¹ Animal studies, on the other hand, indicated that perianastomotic tissue oxygen tension was significantly less with continuous sutures than with interrupted sutures.²² This finding was correlated with an increased anastomotic complication rate and impaired collagen synthesis and healing with continuous sutures in a rat model.²³

Single-Layer versus Double-Layer Anastomoses

Double-layer anastomoses were described in the literature before single-layer ones. All such anastomoses are of essentially

similar construction, consisting of an inner layer of continuous or interrupted absorbable sutures and an outer layer of interrupted absorbable or nonabsorbable sutures [see Figure 3]. Traditionally, double-layer anastomoses have been considered more secure; however, for some time, single-layer anastomoses have been performed in difficult locations (e.g., low in the pelvis or high in the chest) or in difficult circumstances (e.g., in a patient who is unstable or has multiple intra-abdominal injuries) with good results. Moreover, work from the 1980s suggests that the single-layer technique has significant inherent advantages.²³⁻²⁶

Double-layer anastomoses were long believed to be essential for safe healing; however, subsequent pathologic analysis of these anastomoses revealed microscopic areas of necrosis and sloughing of the tissues incorporated in the inner layer as a result of strangulation.²⁷ Animal studies confirmed that single-layer anastomoses take less time to create,²⁸ cause less narrowing of the intestinal lumen,²⁴⁻²⁹ foster more rapid vascularization²³ and mucosal healing, and increase the strength of the anastomosis (as measured by the bursting pressure) in the first few postoperative days.²⁸ Nonetheless, although clinical studies have fairly consistently demonstrated that single-layer anastomoses are associated with

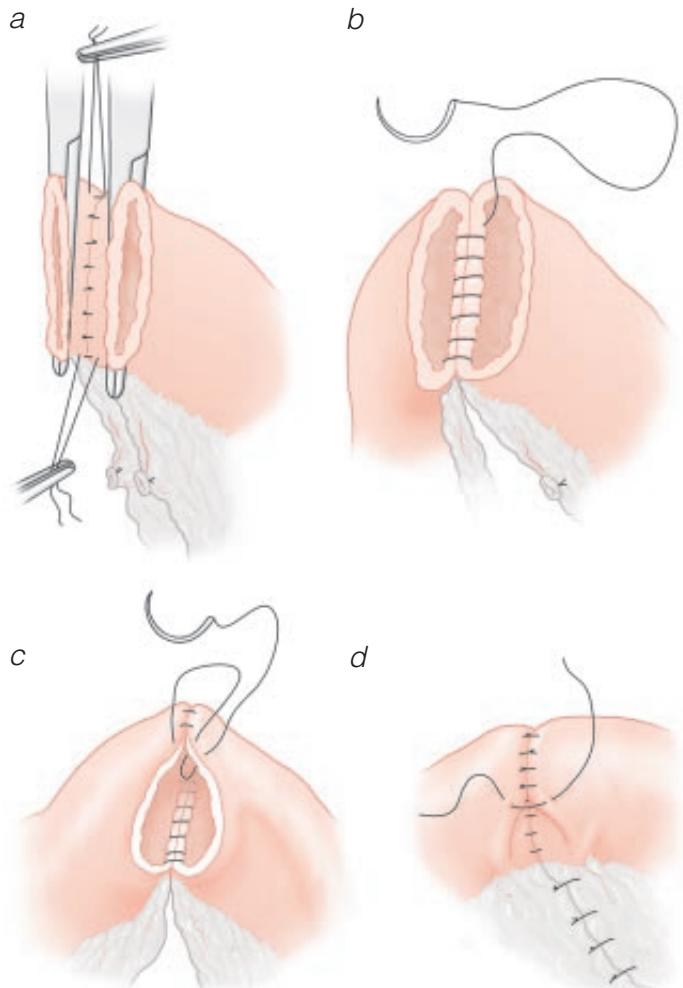

Figure 3 Double-layer end-to-end anastomosis. (a) Interrupted Lembert stitches are used to form the posterior outer layer. (b) A full-thickness continuous over-and-over stitch is used to form the posterior inner layer. (c) A Connell stitch is used to form the anterior inner layer. (d) Interrupted Lembert stitches are used to form the anterior outer layer.

improved postoperative return to normal bowel function (as measured by bowel sounds, passage of flatus, and return to oral intake),^{30,31} nonrandomized studies of anastomotic leakage rates have not shown any differences between single- and double-layer anastomoses in this regard.³²⁻³⁴

Some authors still favor double-layer anastomoses when the tissues are very edematous or friable, are under minimal tension, or lie in highly vascular areas (e.g., the stomach). There are no data to indicate that this practice yields superior results.

STAPLING: TECHNICAL ISSUES

Choice of Stapler

Surgical stapling devices were first introduced in 1908 by Hültl; however, they did not gain popularity at that time and for some time afterward because the early instruments were cumbersome and unreliable. The development of reliable, disposable instruments over the past 25 years has changed surgical practice dra-

matically. With modern devices, technical failures are rarer, the staple lines are of more consistent quality, and anastomoses in difficult locations are easier to construct.

Three different types of stapler are commonly used for fashioning intestinal anastomoses. The transverse anastomosis (TA) stapler is the simplest of these. This device places two staggered rows of B-shaped staples across the bowel but does not cut it: the bowel must then be divided in a separate step. The gastrointestinal anastomosis (GIA) stapler places two double staggered rows of staples and simultaneously cuts between the double rows. The circular, or end-to-end anastomosis (EEA), stapler places a double row of staples in a circle and then cuts out the tissue within the circle of staples with a built-in cylindrical knife. All of these staplers are available in a range of lengths or diameters. Staplers may be used to create functional or true anatomic end-to-end anastomoses as well as side-to-side anastomoses. The original staplers were all designed for use in open procedures, but there are now a number of instruments (mostly of the GIA type) available for use in laparo-

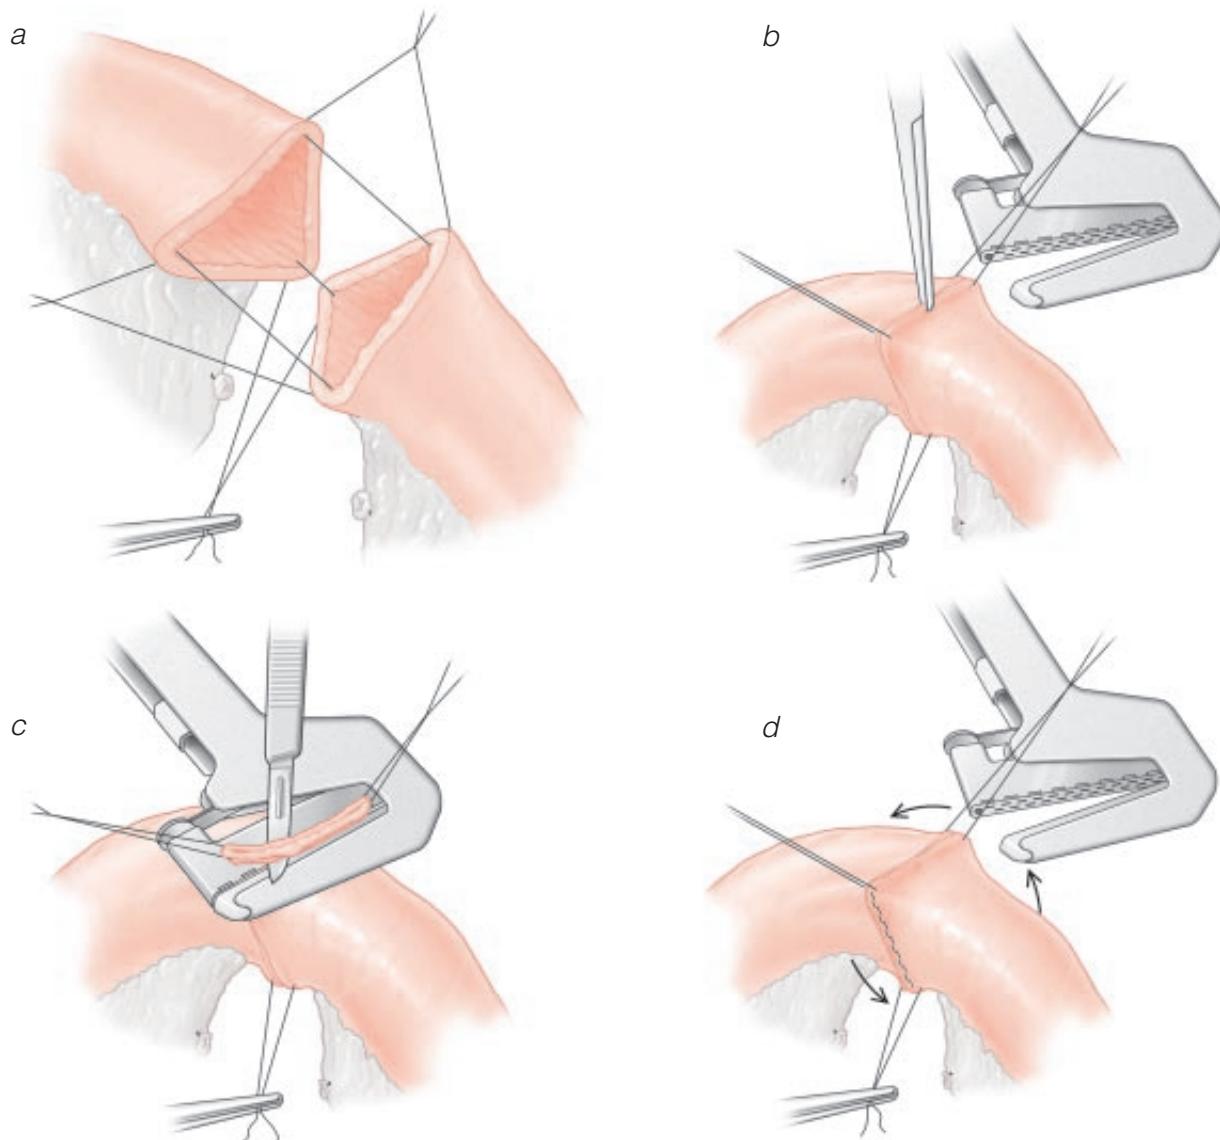

Figure 4 End-to-end anastomosis with linear noncutting stapler. (a) The bowel ends are triangulated with three traction sutures. (b) A noncutting linear stapler (TA) is placed between two of the sutures. (c) The stapler is closed and the excess tissue excised. (d) The bowel is rotated, and steps b and c are repeated twice more to close the remaining two sides of the triangle.

scopic procedures. The staples themselves are all made of titanium, which causes little tissue reaction. They are not magnetic and do not cause subsequent difficulties with MRI scanning.

In a functional end-to-end anastomosis, two cut ends of bowel (either open or stapled closed) are placed side by side with their blind ends beside each other. If the bowel ends are closed, an enterotomy must be made in each loop of bowel to allow insertion of the stapler. A cutting linear (GIA) stapler is then used to fuse the two bowel walls into a single septum with two double staggered rows of staples and to create a lumen between the two bowel segments by dividing this septum between the rows. A noncutting linear (TA) stapler is then used to close the defect at the apex of the anastomosis where the GIA stapler was inserted. An alternative, and cheaper, method of closing the defect is to use a continuous suture. The cut and stapled edges of the bowel should be inspected for adequacy of hemostasis before the apex is closed. Some authors suggest cauterizing these edges to ensure hemostasis³⁵; however, given that electrical current may be conducted along the metallic staple line to the rest of the bowel, it is probably easier and safer simply to underpin bleeding vessels with a fine absorbable suture. It is also important to offset the two inverted staple lines before closing the apex.³⁶

True anatomic end-to-end stapled anastomoses may be fashioned with a linear stapler by triangulating the two cut ends and then firing the stapler three times in intersecting vectors to achieve complete closure [see *Figure 4*]. The potential drawback of this approach is that the staple lines are all everted. It is often easier to join two cut ends of bowel with an EEA stapler, which creates a directly apposed, inverted, stapled end-to-end anastomosis. However, circular staplers can be more difficult to use at times because of the need to invert a complete circle of full-thickness bowel wall. In addition—at least at locations other than the anus—they typically require closure of an adjacent enterotomy.

Staple Height

TA and GIA staplers are available with a variety of inserts containing several different types of staples. These inserts vary with respect to width, the height (or depth) of the closed staple, and the distance between the staples in the rows. They are designed for use in specific tissues, and it is important to choose the correct stapler insert for a given application. In particular, inserts designed for closing blood vessels should not be used on the bowel, and vice versa. With TA and EEA staplers, it is possible to vary the depth of the closed staples by altering the distance between the staples and the anvil as the instrument is closed. The safe range of closure is usually indicated by a colored or shaded area on the shaft of the instrument. Thus, if full closure would cause excessive crushing of the intervening tissues, the stapler need not be closed to its maximum extent.

A 1987 comparison of anastomotic techniques that used blood flow to the divided tissues as a measure of outcome found that the best blood flow to the healing site was provided by stapled anastomoses in which the staple height was adjusted to the thickness of the bowel wall.³⁷ The next best blood flow was provided by double-layer stapled and sutured anastomoses, followed by double-layer sutured anastomoses and tightly stapled anastomoses, in that order.

Single-Stapled versus Double-Stapled Anastomoses

To accomplish many of these anastomoses, intersecting staple lines are created. Initially, some concern was expressed about the security of these areas and about the ability of the blade in the cutting staplers to divide a double staggered row of staples. Animal studies, however, demonstrated that even though nearly all (> 90%) of the staple lines that were subsequently transected by a

second staple line contained bent or cut staples, the integrity of the anastomosis was not compromised in any way, nor was healing adversely affected.^{38,39}

HAND-SEWN VERSUS STAPLED ANASTOMOSES

Stapled anastomoses are said to heal by primary intention, whereas sutured anastomoses are said to heal by secondary intention, though further experimentation is needed to confirm this distinction.⁴⁰ Titanium staples are ideal for tissue apposition at anastomotic sites because they provoke only a minimal inflammatory response and provide immediate strength to the cut surfaces during the weakest phase of healing. Initially, tissue eversion at the stapled anastomosis was a major concern, given that everted hand-sewn anastomoses had previously been shown to be inferior to inverted ones; however, the greater support and improved blood supply to the healing tissues associated with stapling tend to counteract the negative effects of eversion. In fact, one study found that bursting strength for canine colonic end-to-end anastomoses was six times greater when the procedure was performed with an EEA stapler than when it was done with interrupted Dacron sutures.⁴¹ Another study demonstrated a significantly reduced radiographic anastomotic leakage rate with staples applied by an EEA stapler as opposed to a double layer of sutures.⁴² Various prospective, randomized trials have demonstrated no differences in clinical and subclinical leakage rates, length of hospital stay, or overall morbidity.^{15,39,43-46} Even when the anastomosis had to heal under adverse conditions (e.g., carcinomatosis, malnutrition, previous chemotherapy or radiation therapy, bowel obstruction, anemia, or leukopenia), no significant differences were apparent between stapled and hand-sewn anastomoses. Stapling did, however, shorten operating time, especially for low pelvic anastomoses.

Cancer recurrence rates at the site of the anastomosis have been reported to be higher or lower depending on the technique used. Certainly, suture materials engender a more pronounced cellular proliferative response than titanium staples do, particularly with full-thickness sutures as opposed to seromuscular ones,⁴⁷ and malignant cells have been shown to adhere to suture materials.⁴⁸ Two studies suggested that stapling anastomoses after resection for cancer reduces anastomotic recurrence by 40% and cancer-specific mortality by 50%.^{47,49}

UNUSUAL TECHNIQUES

In 1892, Murphy introduced his button, which consisted of a two-part metal stud that was designed to hold the bowel edges in apposition without suturing until adhesion had occurred.⁵⁰ Thereafter, the stud was voided via the rectum. Several modifications of this technique have been described since then, primarily focusing on the composition of the rings or stents. In particular, dissolvable poly-glycolic acid systems have been developed. These so-called biofragmentable anastomotic rings leave a gap of 1.5, 2.0, or 2.5 mm between the bowel ends to prevent ischemia of the anastomotic line.

The use of adhesive agents such as methyl-2-cyanoacrylate to approximate the divided ends of intestinal segments has been studied as well.⁵¹ There was only a moderate inflammatory response at the wound, which persisted for 2 to 3 weeks. Leakage rates were high, however, and many technical problems remained (e.g., how to stabilize the bowel edges while they underwent adhesion).

Fibrin glues have also been employed in this setting. Although these substances are not strong enough to hold two pieces of bowel in apposition, they have been used to coat a sutured bowel anastomosis in an effort to reduce the risk of anastomotic failure. So far, no controlled clinical trials have confirmed that this approach is worthwhile.

Factors Contributing to Failure of Anastomoses

TYPE AND LOCATION OF ANASTOMOSIS

As a rule, for any given technique, the location of the anastomosis seems not to influence the overall leakage rate. There are two exceptions to this general rule. First, low anterior rectal anastomoses are associated with leakage rates ranging from 4.5% to an incredible 70%.^{52,53} Second, esophageal anastomoses are associated with leakage rates of about 5%.⁵⁴

Animal studies demonstrated improved transmission of the intestinal migrating myoelectric complex across hand-sewn end-to-end anastomoses, compared with stapled or sewn side-to-side or end-to-side anastomoses or stapled functional end-to-end anastomoses.⁵⁵ This improvement may be significant for patients with diseases affecting small bowel motility, but in ordinary surgical practice, there is no difference between the two methods of anastomosis with respect to return of intestinal function.⁵⁶

PATIENT PREPARATION

Many intestinal anastomoses are constructed in an emergency setting. In this context, careful preoperative preparation, including adequate fluid resuscitation, is important and should be carried out to the extent possible. Elective patients should be as fit as is feasible, and any other active coexisting illnesses should be stabilized or controlled as well as possible. To maximize the chances that the anastomosis will heal uneventfully, patients should be well nourished and not anemic. Adequate preoperative antibiotic prophylaxis has been shown to reduce the risk of postoperative infection in all types of bowel surgery and must be given at the start of the operation [see 1:5 *Postoperative Pain*]. Some patients require additional steroids perioperatively [see 8:10 *Endocrine Problems*].

For elective operations on the colon, it is traditional to empty the bowel before surgery. Some studies, however, have suggested that mechanical bowel preparation may not be essential for successful healing.^{57,58} In one such study, a series of 72 patients underwent elective colonic anastomosis without any mechanical bowel preparation and with a single preoperative dose of I.V. antibiotics.⁵⁷ Anastomotic dehiscence was not observed, nor were any differences in wound infection rates (8.3%) or overall mortality (2.7%) noted in comparison with published reports of series of patients who underwent full bowel preparation. On the other hand, a 1989 study reported significantly increased anastomotic bursting pressure and reduced anastomotic dehiscence rates in dogs that underwent mechanical bowel cleansing before low anterior resection.⁵² This observation was further supported by a study showing that adding oral erythromycin and kanamycin to bowel preparation led to significantly increased bursting pressure at 7 days after operation.⁵⁹ In a number of published clinical series, inadequate bowel preparation increased the incidence of anastomotic complications.^{53,60} However, there are also several papers in which mechanical bowel preparation yielded no demonstrable benefit.⁶¹

Whatever the advantages or disadvantages of preoperative bowel preparation from a postoperative point of view, most surgeons would agree that it is much easier to operate on an empty bowel. Several methods of bowel preparation are in current use, including oral laxatives (e.g., magnesium sulfate and sodium picosulfate), enemas, washouts, and various combinations of these. It is advisable for patients to stop eating solid food 24 hours before the operation. The evidence that adding oral antibiotics is beneficial is inconclusive, but many trials have confirmed the benefits of one, two, or three doses of I.V. antibiotics over the perioperative period. Prophylaxis of thromboembolism [see 6:6 *Venous*

Thromboembolism] is mandatory in all patients scheduled to undergo intestinal anastomosis.

ASSOCIATED DISEASES AND SYSTEMIC FACTORS

Anemia, diabetes mellitus, previous irradiation or chemotherapy, malnutrition with hypoalbuminemia, and vitamin deficiencies are all associated with poor anastomotic healing. Some of these factors can be corrected preoperatively. Malnourished patients benefit from nutritional support delivered enterally or parenterally before and after operation [see 8:23 *Nutritional Support*]. Well-nourished patients appear not to derive similar benefits from such support.⁶²

Resections for Crohn disease appear to carry a significant risk of anastomotic dehiscence (12% in one prospective study) even when macroscopically normal margins are obtained.³ Strictureplasty has therefore become an attractive alternative to resectional management of Crohn disease even in the presence of moderately long strictures, diseased tissue, or sites of previous anastomoses.

The glucocorticoid response to injury may attenuate physiologic responses to other mediators whose combined effects could be deleterious to the organism.⁶³ In animal experiments, wound healing, as measured by bursting pressure of an ileal anastomosis 1 week after operation, was optimal at a plasma corticosterone level that maintained maximal nitrogen balance and corresponded to the mean corticosterone level of normal animals.⁶⁴ Both supranormal and subnormal cortisol levels resulted in significantly impaired wound healing, probably through different mechanisms. It is believed that slow protein turnover is responsible for delayed anastomotic healing in adrenalectomized animals,⁶⁵ whereas negative nitrogen metabolic balance is responsible for increased protein breakdown and delayed healing in animals with excess glucocorticoid activity.⁶⁴ Nonsteroidal anti-inflammatory drugs (NSAIDs) may help increase anastomotic bursting pressure by decreasing perianastomotic inflammation,^{66,67} but this effect has not been well studied.

Controversial Issues in Intestinal Anastomosis

INVERSION VERSUS EVERSTON

The question of the importance of inversion (as described by Lembert in the early 1800s) versus eversion of the anastomotic line has long been a controversial one. It has been argued that the traditional inverting methods ignore the basic principle of accurately opposing clean-cut tissues. In the late 19th century, Halsted proposed an interrupted extramucosal technique, which has since been assessed in retrospective¹ and prospective³ reviews and found to have a low leakage rate (1.3% to 6.0%) in a wide variety of circumstances. A 1969 study reported greater anastomotic strength, less luminal narrowing, and less edema and inflammation with everted small intestinal anastomoses in dogs.⁶⁷ Subsequent laboratory and clinical studies have not confirmed these findings and, in fact, have often yielded quite the opposite results: lower bursting pressure,⁶⁸ slower healing,⁶⁹ and more severe inflammation³¹ have all been associated with an everted suture line. Another argument in favor of inversion is an aesthetic one: an inverted anastomosis always looks neater.

NASOGASTRIC DECOMPRESSION

Routine nasogastric decompression in patients undergoing a procedure involving an intestinal anastomosis remains controversial. In retrospective⁷⁰ and prospective,⁷¹ randomized, controlled trials, routine use of a nasogastric tube conferred no significant advantage. In fact, there was a trend toward an increased inci-

dence of respiratory tract infections after routine gastric decompression.⁷² Nonetheless, one study found that nearly 20% of patients required insertion of a gastric tube in the early postoperative period.⁷¹ If the choice is made not to place a nasogastric tube routinely, it is important to remain alert to the potential for gastric dilatation, which can develop suddenly and without warning.

ABDOMINAL DRAINS

There has been a great deal of disagreement regarding the ability of abdominal drainage to “protect” an anastomosis. Even before World War I, the old dictum “when in doubt, drain” was called into question by Yates, who wrote that the peritoneal cavity could not be effectively drained because of adhesions and rapid sealing of the drain tract.⁷³ Six decades later, one study showed a dramatic increase in the incidence of anastomotic dehiscence (from 15% to 55%) after the placement of perianastomotic drains in dogs.⁷⁴ This increase was associated with a significant increase in mortality. A 1999 study of pelvic drainage after a rectal or anal anastomosis showed that prophylactic drainage did not improve outcome or reduce complications.⁷⁵ Yet another study reported the severe inflammatory reaction caused by drains at anastomoses.⁷⁶

These findings to the contrary, many surgeons elect to place an intra-abdominal drain to the pelvis after an anterior resection or a coloanal anastomosis because of the higher than usual risk that a fluid collection will develop. Drainage is rarely helpful, or indeed easy, after a gastric or small bowel anastomosis. Drains are indicated, however, after emergency operations for peritonitis or trauma in which it was necessary to close or anastomose damaged or inflamed bowel. Rectal tubes are commonly employed after subtotal colectomy for acute colitis and after two-stage pelvic pouch procedures.

Operative Techniques for Selected Anastomoses

In what follows, I outline the essential preliminary steps before a bowel anastomosis and then describe three generic operations involving the small and large bowel. These procedures illustrate many of the general principles previously discussed (see above).

PATIENT POSITIONING AND INCISION

Patients must be positioned on the operating table in a manner that is appropriate for the planned operation. Most abdominal operations are performed through a midline incision of adequate length with the patient supine. For pelvic procedures, the patient is placed in the lithotomy position to allow access to the abdomen and the anus; care must be taken to position the legs and feet in the stirrups correctly, without excessive flexion or abduction and with sufficient padding to prevent pressure ulceration, thrombosis, and neurapraxia. For esophageal procedures, the patient is positioned lying on the appropriate side, and the incision of choice is a lateral thoracotomy [see 4:4 *Open Esophageal Procedures*]. Occasionally, the patient must be shifted to a different position during the course of an operation.

Gravity can be useful for moving structures out of the way. Accordingly, it is often helpful to alter the axis of the operating table. For example, a 30° head down or Trendelenburg position facilitates pelvic operations.

EXPOSURE, MOBILIZATION, AND DISSECTION

The incision should be held open with a suitable retractor. In addition, sophisticated mechanical systems are available that attach to the operating table and can be positioned to expose the area of the surgeon’s attention, thereby reducing the need for surgical assistants. Constructing such systems and adjusting them for

specific patients takes some time and skill, but the effort is usually well rewarded. Adequate exposure of the operative field is an essential preliminary to any operation. Given that most intestinal operations are performed inside the body cavity, packing away structures that are not required for the procedure being done is an important skill. In a pelvic operation, for example, the small bowel should be packed into the upper abdomen and retained there with a suitable retractor; in an esophageal resection, the lung should be deflated and held well away.

In the absence of adhesions or tethering caused by disease, the small bowel is usually sufficiently mobile to allow the relevant segment to be brought out of the abdomen. Doing so makes the operation easier and allows the remainder of the bowel to be kept warm and tension free inside the abdominal cavity. Sometimes, the transverse colon and the sigmoid colon are mobile enough to be brought to the surface. More commonly, however, as with the other sections of the large bowel, the peritoneum must be divided along the lateral border of the colon and the retroperitoneal structures reflected posteriorly. Tension is rarely a problem during small bowel anastomosis, but for colonic or esophageal anastomoses, it is absolutely vital that the two ends of bowel to be joined lie together easily. For a large bowel anastomosis, this means that the splenic flexure or the hepatic flexure—or, sometimes, both—must be adequately mobilized.

Classically, the tissues around the bowel are divided with a scissor, whereas the mesentery is divided between clamps and tied with a suitable thread. Recognized tissue planes are separated by means of blunt dissection with either the fingers or a swab. Minor bleeding points are occluded with a coagulating electrocautery, though this approach is often relatively ineffective on mesenteric or omental vessels. The disadvantages of this dissection technique are that oozing from raw surfaces can be a nuisance and that the tissues beyond a tie are often bulky and leave dead tissue within the body that may act as a focus for infection and adhesions. Newer methods of dissection that make use of the ultrasonic scalpel or the bloodless bipolar electrocautery prevent these problems by coagulating a small section of tissue between the jaws of the instrument and simultaneously occluding all blood vessels up to a certain size within the tissues. Consequently, bleeding is reduced, fewer (or no) ties are needed, and only a small quantity of dead tissue results at each point. Becoming skilled in the use of these instruments often takes a little time, but the time is well spent, in that it is now possible to perform an intestinal resection without resort to a single tie.

BOWEL RESECTION

The precise techniques involved in resecting specific bowel segments will not be discussed in great detail here. (Colonic resection, for example, is described elsewhere [see 5:34 *Laparoscopic Colectomy*.]) The following discussion outlines only the general principles.

Preparation

The segment of bowel to be removed must be isolated with an adequate resection margin. To this end, all surrounding adhesions are divided. Next, the mesentery is divided. The key consideration in this step is to preserve the blood supply to the two remaining ends of bowel while still achieving adequate excision of the diseased bowel. This is more easily accomplished in the small bowel than in the large bowel, thanks to the ample blood supply of the former; even so, transillumination of the mesentery and careful division of the vascular arcade are vital. In the colon, the surrounding fat and the appendices epiploicae should be cleared from the remaining bowel ends so that subsequent suture placement is straightforward.

Care should be taken to avoid two common problems. First, ties placed close to the bowel can bunch tissues excessively and thereby cause angulation or distortion of the free edge of the intestine, which can make the anastomosis difficult and threaten the blood supply. Second, because mesenteric vessels are usually tied very close to their ends, the arteries sometimes slip back beyond the ties. Such slippage results in a hematoma within the leaves of the mesentery, which can itself threaten the viability of the bowel. Generally, the bleeding vessel can be secured with a fine stitch; sometimes, however, a limited further bowel resection is the only safe course of action. Both of these problems can be avoided by using the ultrasonic scalpel or the bipolar coagulating electrocautery.

Division of Bowel

If staplers are not available, the bowel segment to be removed is isolated between noncrushing clamps placed across the intestinal lumen some distance away from the resection margin so as to limit the amount of bowel contents that can escape into the wound. Crushing clamps are then placed on the specimen side of the diseased segment at the point of the resection, and the bowel is divided with a knife just proximal and distal to the clamps. Thus, the lumen of the diseased segment is never open within the abdominal wound. Even so, the contents of the bowel between the open ends and the noncrushing clamps can leak into the wound. To minimize this problem, it is usual to isolate the working area with abdominal packs, which are sometimes soaked in an antiseptic (e.g., povidone-iodine).

One advantage of using staplers for anastomosis is that in most instances, division of the bowel can be accomplished without opening the lumen. A linear cutting stapler (e.g., GIA) transects the bowel and seals the two cut ends simultaneously. Unfortunately, in the pelvis, it is usually necessary to employ an angulated non-cutting linear stapler (e.g., TA) so as to obtain as much length as possible distal to the lesion. The proximal rectum is then clamped with a crushing bowel clamp, and a long knife is used to transect the rectum above the staple line. Even so, there remains the potential for leakage of a small amount of fecal material, which must then be suctioned away.

SIMPLE BOWEL CLOSURE

There are many cases in which simple closure of a hole in the bowel is required, as with a perforated duodenal ulcer, a gunshot wound, or the inadvertent perforation of the small bowel during the division of dense peritoneal adhesions. Most surgeons close such holes with two layers of soluble suture material (e.g., 2-0 polyglycolic acid). My own preference is for an inner continuous layer inverted with outer seromuscular interrupted sutures, but there are many perfectly satisfactory alternatives.

Special mention should be made of the technique of strictureplasty, which is used for a number of benign small bowel strictures (especially those resulting from Crohn disease) as a means of avoiding small bowel resection and anastomoses. In this procedure, the bowel is opened longitudinally and closed transversely with a single layer of 2-0 polyglycolic acid sutures in a Connell stitch. Excellent functional results have been achieved with this technique despite its reputation for fistula formation, which is associated with Crohn disease.

SINGLE-LAYER SUTURED EXTRAMUCOSAL SIDE-TO-SIDE ENTEROENTEROSTOMY

A side-to-side anastomosis [see *Figure 5*] may be performed when no resection is done, as a bypass procedure (e.g., a gas-

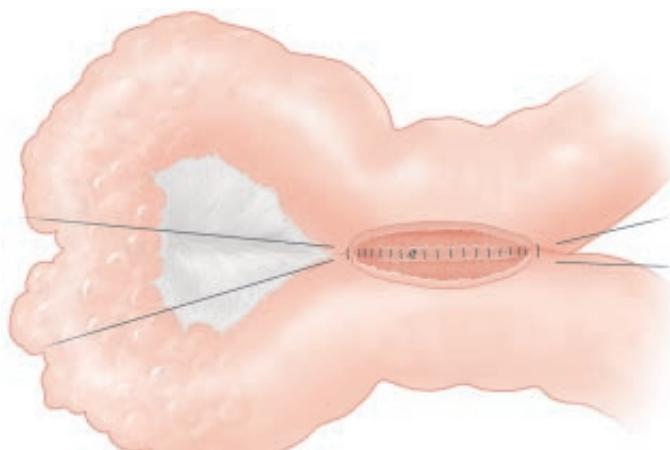

Figure 5 Single-layer sutured extramucosal side-to-side enterostomy. A full-length suture is started in the back wall and run through the seromuscular and submucosal layers in the direction of the surgeon; the corners of the enterotomy are approximated with a baseball stitch, and a single Connell stitch is used to invert the anterior layer. A second suture is started at the same spot on the posterior wall and run in the opposite direction, again through all layers except the mucosa; the corners of the enterotomies are approximated with a baseball stitch, and the suture is continued in either the Connell stitch or the over-and-over stitch to complete the anterior wall of the anastomosis.

troenterostomy); after a small bowel resection; when there is a discrepancy in the diameter of the two ends to be anastomosed (e.g., an ileocolic anastomosis after a right hemicolectomy); or when the anatomy is such that the most tension-free position for the anastomosis is with the two bowel segments parallel (as in a Finney strictureplasty).

Two stay sutures of 3-0 polyglycolic acid are placed approximately 8 cm apart on the inner aspect of the antimesenteric border. A 5 cm enterotomy is made on each loop with an electrocautery or a blade on the inner aspect of the antimesenteric border. If electrocautery is used, care must be taken not to injure the mucosa of the posterior wall during this maneuver; placement of a hemostat into the enterotomy to lift the anterior wall usually prevents this problem. Hemostasis of the cut edges is ensured, and the remaining enteric contents are gently suctioned out. A swab soaked in povidone-iodine may be used at this point to cleanse the lumen of the bowel in the perianastomotic region.

A full-length seromuscular and submucosal suture of 4-0 polyglycolic acid is placed and tied on the inside approximately 5 to 10 mm from the far end of the enterotomies. The stitch is not passed through the mucosa: to do so would add no strength to the anastomosis and would hinder epithelialization by rendering the tissue ischemic. A hemostat is placed on the short end of the tied suture, and the assistant applies continuous gentle tension to the long end of the suture. An over-and-over stitch is started in the direction of the surgeon; small bites are taken, and proper inversion of the suture line is ensured with each pass through tissue. When the proximal ends of the enterostomies are reached, this so-called baseball stitch is continued almost completely around to the anterior wall of the anastomosis. A single Connell stitch may be used to invert this anterior layer.

Another full-length seromuscular and submucosal suture of 4-0 polyglycolic acid is then inserted and tied at the same location in the posterior wall as the first. If the two sutures are placed close enough together, the short ends need not be tied together and may simply be cut off. The remainder of the posterior wall is sewn

away from the surgeon in the same manner as the portion already sewn, and the corners are approximated with the baseball stitch. The anterior wall is then completed with this second suture, either with the Connell stitch or with an over-and-over stitch with the assistant inverting the edges before applying tension to the previous stitch.

When the defect is completely closed, the two sutures are tied across the anastomotic line. The stay sutures are removed, and the anastomosis is carefully inspected. Often, there is no mesenteric defect to close in a side-to-side anastomosis, but if there is one, it should be approximated at this point with continuous or interrupted absorbable sutures, with care taken not to injure the vascular supply to the anastomosis.

DOUBLE-LAYER SUTURED END-TO-SIDE ENTEROCOLOSTOMY

In this procedure, the end of the ileum is joined to the side of the transverse colon [see Figure 6]. The distal colon is divided with a cutting stapler so that a blind end is left. Some surgeons underpin or bury this staple line, though this practice is probably unnecessary. The proximal cut end of the intestine is similarly closed either with staples after division with a cutting linear stapler or with a crushing bowel clamp. This proximal end is brought into apposition with the side of the distal bowel segment at a point no farther than 2.5 to 5 cm from the blind end of the distal segment; this proximity to the cut end is important for prevention of the blind loop syndrome.

Stay sutures of 3-0 polyglycolic acid are placed between the serosa of the proximal limb, about 10 to 15 mm from the clamp, and the serosa of the distal limb. Interrupted seromuscular sutures of 3-0 polyglycolic acid are then placed between these stay sutures, spaced about three to six to the centimeter. These stitch-

es may be tied sequentially or snipped and tied once they are all in place. It is crucial not to apply excessive tension, which could cut the seromuscular layer or render it ischemic. Suction is then readied. The staple line or crushed tissue on the proximal limb is cut off with a coagulating electrocautery or a knife; this maneuver opens the lumen of the proximal limb. All residual intestinal content is gently suctioned.

An enterotomy or colotomy is created on the distal limb opposite the open lumen of the proximal bowel. A full-thickness suture of 3-0 polyglycolic acid is inserted in the posterior wall at a point close to the far end of the enterotomy and run in an over-and-over stitch back toward the surgeon. The corner is rounded with the baseball stitch, and when the anterior wall is reached, the Connell stitch is used. A second full-length 3-0 suture is started at the same point on the posterior wall as the first, and the short ends of the two sutures are tied together and cut. This second suture is then run away from the surgeon to complete the posterior wall, and the anterior wall is completed with the Connell stitch. The two sutures are then tied across the anastomotic line.

A second series of interrupted seromuscular stitches is then placed anteriorly in the same fashion as the seromuscular stitches placed in the posterior wall. It is important not to narrow either lumen excessively by imbricating too much of the bowel wall into this second layer. The lumen of the anastomosis is palpated to confirm patency, and the mesenteric defect is closed if possible with either continuous or interrupted absorbable sutures.

DOUBLE-STAPLED END-TO-END COLOANAL ANASTOMOSIS

Resection of the distal sigmoid colon and the rectum is a common procedure. In the past, it often resulted in a permanent colostomy because of the technical difficulties associated with a hand-sewn

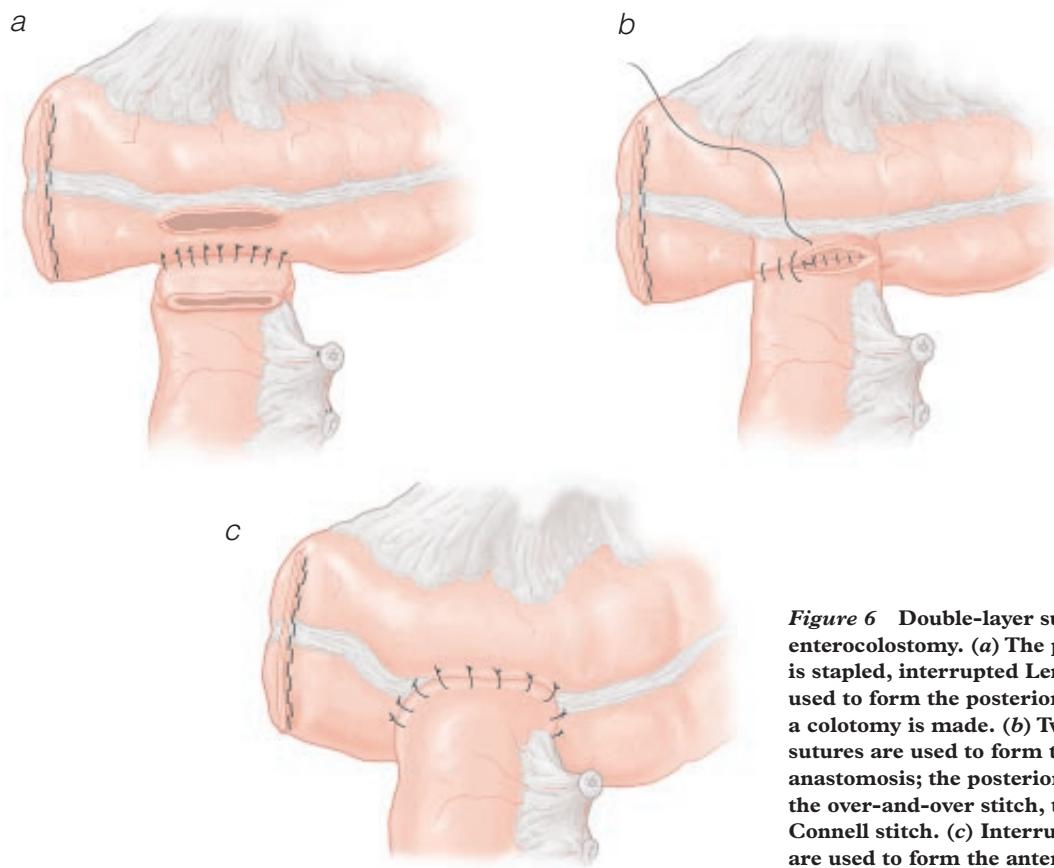

Figure 6 Double-layer sutured end-to-side enterocolostomy. (a) The proximal bowel end is stapled, interrupted Lembert stitches are used to form the posterior outer layer, and a colotomy is made. (b) Two continuous sutures are used to form the inner layer of the anastomosis; the posterior portion is done with the over-and-over stitch, the anterior with the Connell stitch. (c) Interrupted Lembert stitches are used to form the anterior outer layer.

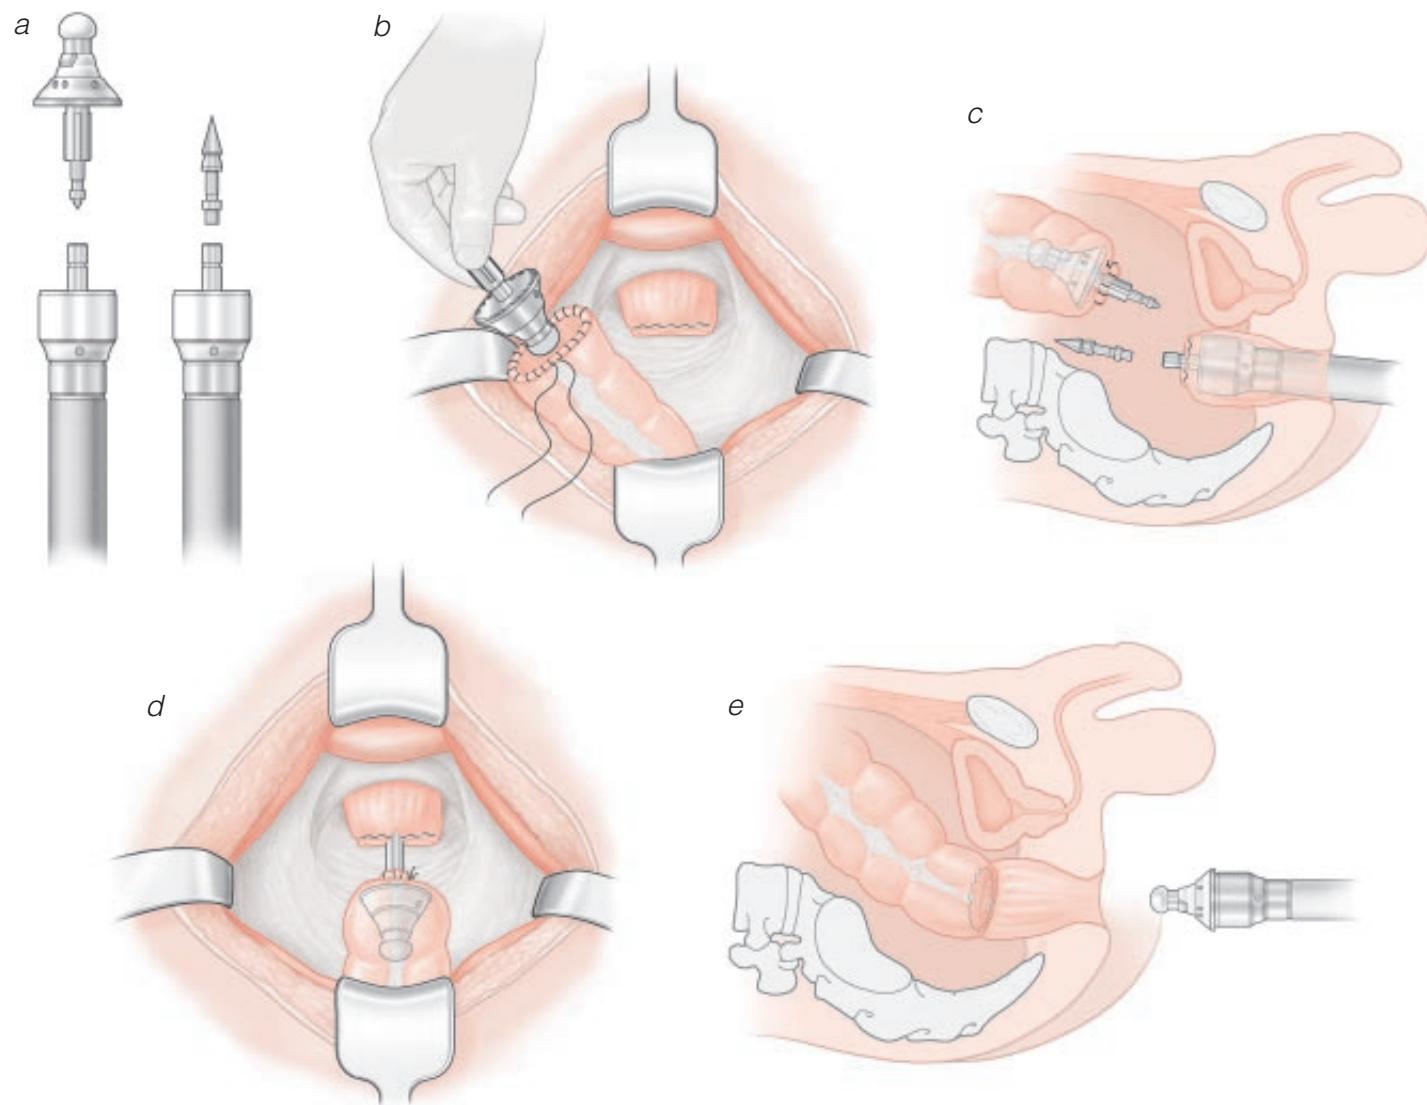

Figure 7 Double-stapled end-to-end coloanal anastomosis. (a) The C-EEA stapler comes with both a standard anvil (left) and a trocar attachment (right). (b) The rectal stump is closed with an angled linear noncutting stapler. A purse-string suture is placed around the colotomy, and the anvil of the stapler is placed in the open end and secured. (c) The stapler, with the sharp trocar attachment in place, is inserted into the anus, and the trocar is made to pierce the rectal stump at or near the staple line, after which the trocar is removed. (d) The anvil in the proximal colon is joined with the stapler in the rectal stump, and the two edges are slowly brought together. (e) The stapler is fired and then gently withdrawn.

anastomosis deep in the pelvis. The development of circular staplers reduced the technical difficulty of the operation and made possible anastomoses as far down as the anus [see Figure 7].

Proper preparation of the patient and the bowel is essential before resection of the rectum. The patient is placed in the lithotomy position with the head tilted down, and the small bowel is packed away in the upper abdomen. This positioning gives the surgeon the best access to the pelvis.

The splenic flexure and all of the distal large bowel are fully mobilized along with the rectum. The proximal resection margin is determined and cleared of serosal fat, and the bowel is divided either with a GIA stapler or between crushing bowel clamps. An angled TA stapler is fired across the distal rectal resection margin, and another bowel clamp is placed proximal to it. The rectum is divided with a long-handled knife, with care

taken to avoid plunging the blade into the pelvic sidewall, which could cause significant neurovascular damage. The specimen is removed and the stapler withdrawn. Adequate pelvic hemostasis is ensured.

Once the surgeon is satisfied that the bowel is sufficiently mobilized, a noncrushing bowel clamp is placed on the colon 10 to 15 cm proximal to the margin, and the crushing clamp is removed. At this stage, it is usual to create an 8 to 10 cm colonic J pouch; this measure typically yields a substantially improved functional outcome, especially in the early postoperative period in older patients.⁷⁷ A whip-stitch (or purse-string suture) of 2-0 polypropylene is placed around the colotomy, and the anvil from the appropriately sized curved EEA stapler is inserted into the open end and secured in place by tying the suture [see Figure 7]. The proximal bowel clamp is removed. The assistant—who may also, if desired,

gently wash out the rectal stump with a dilute povidone-iodine solution—performs a digital rectal examination.

The stapler, with its trocar attachment in place, is then inserted into the anus under the careful guidance of the surgeon. The pointed shaft is brought out through or adjacent to the linear staple line, and the sharp point is removed. The peg from the anvil in the proximal colon is snapped into the protruding shaft of the stapler, and the two edges are slowly brought together. The colonic mesentery must not be twisted, and the ends must come together without any tension whatsoever. The stapler is fired, and a distinctive crunching sound is heard. The anvil is then loosened the appropriate amount, and the entire mechanism is withdrawn through the anus. Finally, the proximal and distal rings of tissue, which remain on the stapler, are carefully inspected to confirm circumferential closure of the staple line.

The pelvis is then filled with body-temperature saline, and a Toomey or bladder syringe is used to insufflate the neorectum with air. The surgeon watches for bubbling in the pelvis as a sign of leakage from the anastomosis. If there is a leak, additional soluble sutures must be placed to close the defect and another air test performed. A rectal tube may then be inserted by the assistant or may be placed at the end of the procedure.

When the anastomosis is very low or there is some concern about healing, a drain may be placed in the pelvis behind the staple line; however, as noted [see Controversial Issues in Intestinal Anastomosis, above], this practice has not been shown to be beneficial and may in fact impair healing. Some surgeons prefer to protect the anastomosis with a temporary proximal defunctioning stoma. There is some evidence that such protection reduces the

risk of an anastomotic leak, but it is unclear whether a loop ileostomy or a loop colostomy is better for this purpose.⁷⁸⁻⁸²

Conclusion

A general note about the cosmetic aspect of these procedures is appropriate here. After any of these operations, a close visual inspection of the entire circumference of the anastomosis should be performed. As a rule, if the divided ends appear well apposed, then the anastomosis is probably sound.

Over the past 200 years, our understanding of how the bowel heals and how to perform intestinal anastomoses safely and effectively has improved considerably. This improvement is reflected in lower anastomotic leakage and dehiscence rates, lower operative morbidity, and lower mortality. Some would argue that much of the improved outcome is attributable to improved anesthesia, more potent antibiotics, and better postoperative monitoring and care. No doubt there is a good deal of truth to this argument. There is also no doubt, however, that one of the most significant determinants of outcome after procedures that include intestinal anastomosis is surgical technique. The central importance of meticulous technique means that constant practice and careful attention to detail are essential for all surgeons operating on the GI tract. In addition, it is important that academic surgeons in particular continue to research such issues as the best suture material or stapler for specific operations, the most suitable and best-tolerated type of bowel preparation, the mechanisms and variables involved in wound healing and collagen deposition, and the importance of local and systemic factors in determining overall outcome.

30 INTESTINAL STOMAS

J. Graham Williams, M.Ch., F.R.C.S.

Formation of an intestinal stoma is frequently a component of surgical intervention for diseases of the small bowel and the colon. The most common intestinal stomas are the ileostomies (end and loop) and the colostomies (end and loop); the less common stomas, such as cecostomy and appendicostomy, have limited applications and thus are not considered further in this chapter.

For optimal results, it is essential that stoma creation be considered an integral part of the surgical procedure, not merely an irritating and time-consuming addendum at the end of a long operation. Accordingly, the potential requirement for a stoma should be appropriately addressed in the planning of an intestinal procedure. A great effort should be made to counsel the patient before operation as to whether a stoma is likely to be needed, what stoma creation would involve, where the stoma would be situated, and whether the stoma is likely to be permanent or temporary.

Operative Planning

PREOPERATIVE COUNSELING

Ideally, as soon as surgical intervention that may involve a stoma is contemplated, the enterostomal nursing service should become involved—though this may not be possible in an emergency setting. Patients often have misconceptions about the effects stoma will have on their quality of life and consequently may experience considerable anxiety. Adequate preoperative counseling helps correct these misconceptions and reduce the attendant anxiety. Enough time should be set aside to allow the counselor to explore the patient's knowledge of the disease and understanding of why a stoma may be required. This process involves reviewing the planned operation, describing what the stoma will look like, and explaining how the stoma will function. Visual aids (e.g., videos, CD-ROMs, and booklets) can be very useful in this regard and should be freely available to patients and their families. As simple a measure as showing the patient a stoma appliance and attaching it to the abdominal wall before the procedure can be helpful in preparing the patient for a stoma. Many patients facing the prospect of stoma surgery also derive great benefit from meeting patients of similar age and background who have a stoma.

CHOICE OF PROCEDURE

A number of common indications for stoma formation have been identified [see Table 1]. These indications are usually associated with particular types of stoma, but the association is not always a simple or automatic one. In many situations, more than one option exists, and it can be difficult to select the best available option for a particular patient.

Loop Ileostomy versus Loop Colostomy

Defunctioning of a distal anastomosis after rectal excision and anastomosis may be achieved with either a loop ileostomy or a loop transverse colostomy. A number of nonrandomized studies¹⁻³ and randomized control trials⁴⁻⁷ have been performed in an effort to determine which of these two approaches is superior.

Both types of stoma effectively defunction the distal bowel; however, loop ileostomy appears to be associated with a lower incidence of complications related to stoma formation and closure, though it may also carry a higher risk of postoperative intestinal obstruction.⁶ The two types of stoma are comparable with respect to patient quality of life, and the degree of subsequent social restriction is influenced more by the number and type of complications than by the type of stoma formed.⁸

SELECTION OF STOMA SITE

A poorly sited stoma will cause considerable morbidity and adversely affect quality of life. For this reason, great emphasis should be placed on selecting the best site for the stoma on the abdominal wall. In many instances [see Table 1], it may not be possible to decide beforehand whether a colostomy or an ileostomy is to be performed. An example would be the case of a patient with a tumor in the lower rectum in which the surgeon's intention is to perform a restorative resection covered by a loop ileostomy. In such a case, the surgeon sometimes finds that restorative resection is not technically possible and elects to perform an abdominoperineal resection or a low Hartmann resection with an end colostomy instead.

A stoma should be brought out through a separate opening in the abdominal wall, not through the main incision: there is a high incidence of wound infection and incisional hernia formation if the main incision is used as a stoma site. In general, ileostomies are sited in the right iliac fossa, sigmoid colostomies (loop or end) in the left iliac fossa, and transverse loop colostomies in either the right or the left upper quadrant. These positions are preferred because they are conveniently close to the particular bowel segments to be used for creating the various stomas. At need, however—as when finding a suitable site proves difficult because of previous scars or deformity—both the ileum and the colon can be mobilized to provide sufficient length to reach most sites on the abdominal wall.

In selecting and marking a stoma site, the following key considerations should be taken into account:

1. A flat area of skin is required for adequate adhesion of the appliance.
2. The patient should be able to see the stoma.
3. Skin creases, folds, previous scars, and bony prominences should be avoided.
4. The stoma site should not be located at the beltline.
5. The site should be identified with the patient lying, sitting, and standing.
6. Preexisting disabilities should be taken into account.

According to received wisdom, the stoma should be brought out of the abdomen through the rectus abdominis, so that the emerging stoma will be supported and the incidence of parastomal hernia reduced. Several studies, however, have shown that this approach is not always ideal and that the optimum site for a stoma should be selected without regard to its position in relation to the rectus abdominis.⁹⁻¹¹ Once selected, the site is marked with an indelible pen or tattooed with India ink and a fine needle.

Table 1 Indications for Different Types of Intestinal Stomas

Disease	Presentation	Indication	Stoma Type	Intention
Colorectal cancer	Perforation Obstruction Rectal cancer	Defunctioning of bowel Relief of obstruction Low tumor (abdominoperineal resection) Defunctioning of low anastomosis	Loop or end colostomy Loop or end colostomy End colostomy Loop ileostomy or colostomy	Temporary, often permanent Temporary Permanent Temporary
Diverticular disease	Perforation Obstruction Elective resection for fistula	Resolution of sepsis; defunctioning of bowel Relief of obstruction Protection of anastomosis	Colostomy Loop or end colostomy Loop ileostomy or colostomy	Temporary, sometimes permanent Temporary, sometimes permanent Temporary
Ulcerative colitis	Acute colitis Chronic colitis	Defunctioning of bowel Eradication of disease Ileoanal pouch procedure	End ileostomy (after subtotal colectomy) End ileostomy (after panproctocolectomy) Loop ileostomy	Temporary or permanent Permanent Temporary
Crohn disease	Crohn colitis Small bowel disease Perianal disease Elective resection for septic complications	Defunctioning of bowel Defunctioning of bowel after excision Defunctioning of bowel Defunctioning of bowel Excision of disease Defunctioning of bowel	Loop or split ileostomy End ileostomy or colostomy Loop, end, or split ileostomy Loop or split ileostomy Ileostomy (after panproctocolectomy) Colostomy (after rectal excision) Loop or divided loop ileostomy	Temporary, sometimes permanent Temporary, often permanent Temporary, sometimes permanent Temporary, often permanent Permanent Temporary
Trauma	Colon injury Rectal injury	Defunctioning of bowel Defunctioning of bowel	Colostomy or loop ileostomy Colostomy	Temporary, sometimes permanent Temporary, sometimes permanent
Functional disorders	Fecal incontinence Sphincter repair	Defunctioning of anus Defunctioning of bowel	End colostomy Loop ileostomy or colostomy	Permanent Temporary

Operative Technique

GENERAL PRINCIPLES

Most abdominal stomas are formed at the end of an open operation performed to resect bowel, drain an infectious focus, or relieve obstruction. In this setting, a midline incision is generally the most appropriate choice for gaining access to the abdominal cavity because it leaves the areas to either side of the midline available for stoma placement. Other incisions may be used as well, but more careful operative planning will be required.

A defunctioning stoma can be created without opening the abdomen by making a trephine hole and using retractors and forceps to identify the relevant bowel loop from which the stoma will be formed. I generally avoid this approach, for two reasons. First, the trephine hole invariably ends up larger than is ideal, and the greater size leads to an increased risk of parastomal hernia. Second, it is often difficult to be sure that the correct bowel loop has been identified and the correct end opened as a stoma. These disadvantages can be overcome by taking a laparoscopic approach. One port is placed though the previously marked site. A tissue forceps is passed down this port and used to grasp and orient the relevant bowel segment. If necessary, the bowel can be mobilized by means of laparoscopic dissection. The colon is then divided with a linear stapler, and the proximal end is brought out through a small trephine hole made at the port site.

The fundamental concept in stoma formation is that a stoma is simply an anastomosis between a piece of bowel and the skin

of the abdominal wall. For this reason, the same basic principles that apply to intestinal anastomosis also apply to stoma formation—namely, maintaining an adequate blood supply to both sides of the anastomosis, ensuring that the anastomosis is performed without tension, and avoiding any preexisting infection. In accordance with these principles, the bowel segment used should have as much of its blood supply as possible preserved during mobilization, and mobilization should be sufficient to allow the bowel to be brought through the abdominal wall without tension and without occlusion of the blood supply at the fascial level by a too-small hole in the abdominal wall. If these criteria are not met, then either the bowel should be mobilized further or a new bowel segment should be selected. It is important to make the best possible technical choices at the time of initial stoma formation. If the correct principles are not followed at the beginning of the procedure, it is generally futile to hope that the situation will improve thereafter; the usual result is a poor stoma that requires surgical revision.

Creation of Stoma Aperture

It is wise to leave formation of the hole for the stoma until the end of the procedure because unforeseen events during the operation may necessitate a change in the type or the site of the stoma. A circular incision 2.5 cm in diameter is made at the marked site, and the skin is excised. The subcutaneous fat is parted with scissors and small retractors until the fascia of the abdominal wall is reached. The fat need not be excised: it supports the emerging stoma, and its absence would leave a potential dead space. A cruciate incision is made in the rectus sheath, initially no more than

2 cm in each direction. The muscle fibers of the underlying rectus abdominis are split in the direction of their fibers with an arterial clamp or the tips of heavy scissors. The small retractors are inserted deeper to keep the muscle fibers apart, and a small cruciate incision is made in the posterior rectus sheath with an electrocautery. A swab held against the peritoneum at the stoma site will protect the intra-abdominal organs and the assistant's fingers from being injured by the electrocautery point.

On occasion, the epigastric vessels, which lie between the rectus abdominis and the posterior sheath, are injured. Should this occur, the simplest way of dealing with the problem is to open the posterior sheath from inside the abdominal cavity and suture-ligate the bleeding point.

COLOSTOMY

End

The typical site for an end colostomy is the left iliac fossa, and either the sigmoid or the descending colon is used for the stoma. If the rectum has been excised, the inferior mesenteric vessels will have been divided, and the blood supply to the distal colon will come from the middle colic vessels via the marginal artery. It is not usually necessary to take down the splenic flexure to mobilize the colon adequately; however, if there is any concern regarding tension on the stoma, full splenic flexure mobilization should be performed. For a simple defunctioning end colostomy, only a few small vessels in the mesentery will have to be divided.

The colon is divided at the relevant site with either crushing clamps or a linear intestinal stapler. The adequacy of the vascular supply is checked by inspection. A nontraumatic bowel clamp or a Babcock tissue forceps is passed through the hole in the abdominal wall and used to grasp the closed-off end of the colon. Care is taken when drawing the colon through the abdominal wall to keep from twisting the colon and damaging the small vessels in the supporting mesentery. The end of the colon should sit 2 cm above the skin surface. To prevent wound contamination, the colostomy is constructed only after the skin incision has been fully closed and dressed. The closed-off end of the colon is excised with a sharp knife, and the colostomy is constructed with a small spout by evertting the bowel wall. The spout helps the patient position the stoma appliance but should not protrude more than 0.5 to 1 cm above the surface of the skin. The anastomosis is performed with interrupted absorbable sutures that take bites of the full thickness of the end of the colon and the subcuticular layer of the skin. Small bites are also taken of the seromuscular layer of the emerging colon at the level of the skin [see Figure 1].

This technique is sometimes modified by closing the lateral space between the abdominal wall and the colon with absorbable sutures in an effort to prevent internal herniation of the small bowel. An alternative approach is to tunnel the colostomy to the hole in the abdominal wall via an extraperitoneal route. This approach may prevent herniation and colostomy prolapse,⁹ but the stoma may be slow to function and difficult to mobilize if a reversal or revision operation is performed.

Loop

A loop colostomy is usually performed as a quick and temporary method of relieving acute colonic obstruction or to cover an anastomosis in the distal colon or rectum. Whenever possible, I avoid using loop colostomies, for the following reasons.

1. Because of the need to accommodate two pieces of bowel, a loop colostomy requires a larger hole in the abdominal wall

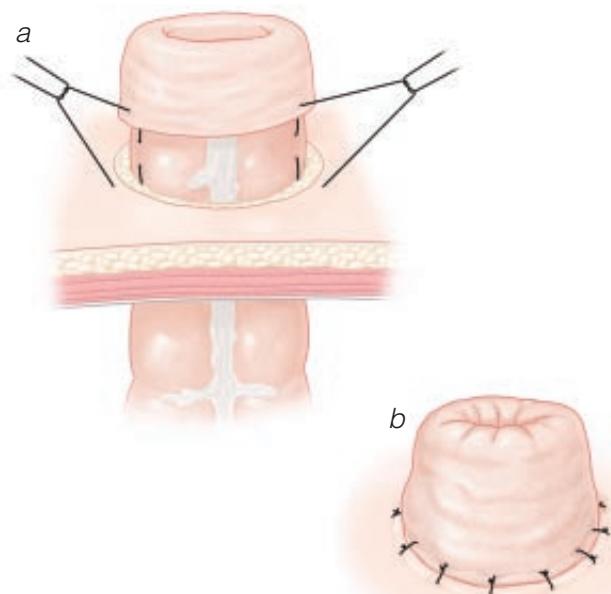

Figure 1 End colostomy. (a) The end of the colon sits 1 to 2 cm above skin level. Four absorbable sutures are placed, one in each quadrant of the stoma. Each suture takes a full-thickness bite of the end of the colon, a seromuscular bite of the emerging colon at skin level, and a subcutaneous bite of the edge of the skin opening. (b) The stoma is completed by filling in the gaps between the four quadrant sutures with interrupted sutures that take full-thickness bites of the end of the colon and subepidermal bites of the skin edge. The stoma should have a small (0.5 to 1 cm) lip, which facilitates accurate positioning of the colostomy bag.

- than an end colostomy does. This is a particular concern in emergency situations, where the colon may be greatly dilated.
2. The larger hole predisposes to formation of a parastomal hernia, which can be a problem if the stoma is not reversed.
 3. Loop colostomies are more prone to prolapse than end colostomies are, possibly as a consequence of parastomal hernia formation.
 4. The effluent from the transverse colon can be highly liquid, and the absence of a spout with loop colostomy may lead to difficulties with appliance leakage.
 5. When a loop colostomy is used to defunction a distal anastomosis, there is a theoretical risk of damage to the marginal artery, which may be the only vessel supplying the distal side of the anastomosis.

The usual site for a loop colostomy is either the right upper quadrant (using the proximal transverse colon) or the left iliac fossa (using the left colon). The colon segment that will be used to form the stoma is identified, and peritoneal attachments are divided to provide sufficient length to reach the desired site on the abdominal wall without tension. If the transverse colon is to be used, the omentum is removed. Care is taken not to damage the marginal artery, which, if occluded, may compromise vascular supply to the distal bowel.

A trephine hole is made at the marked site as described [see Operative Technique, General Principles, *above*]. The hole is usually larger than it would be in an end colostomy; the bowel loop to be brought out is often bulky, especially when the colon is obstructed. A small window is made in the mesentery immediately adjacent to the colon wall, and a Jacques catheter is passed through this aperture. The Jacques catheter is used as a handle by

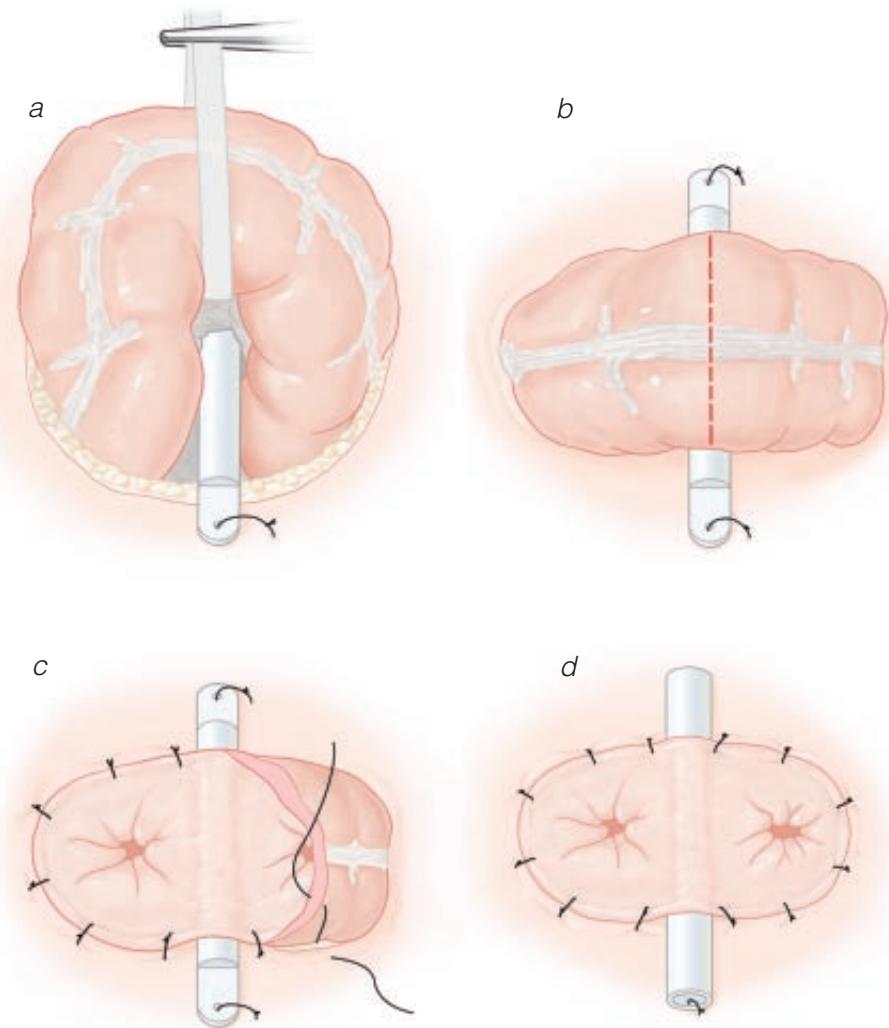

Figure 2 Loop colostomy. (a) A soft catheter or a length of nylon tape is passed through a small window made in the mesentery of the colon, and the prepared loop of colon is eased through the hole in the abdominal wall with the aid of the catheter. The catheter or tube is replaced by a supporting colostomy rod. (b) A transverse incision is made across the apex of the colon loop. (c) The cut edges of the colon are everted and sutured to the skin edge of the stoma hole with interrupted absorbable sutures that take full-thickness bites of the colon and subepidermal bites of the skin. (d) The rod is left in place for 5 days to support the loop stoma during the early phase of healing.

which the colon loop is drawn through the trephine hole in the abdominal wall, with care taken to maintain the orientation of the colon and avoid twisting [see Figure 2a]. The catheter is then replaced by a plastic or glass stoma rod, which supports the loop at the level of the skin.

The main incision is closed, and the stoma is matured. A transverse incision is made in the apex of the bowel loop [see Figure 2b], and the two edges are peeled back and sutured to the skin edge of the trephine hole to produce a double opening [see Figure 2c, d]. The bridge remains in place for 5 days, by which time the stoma is usually beginning to function properly. The rod can then be removed because by this point, the stoma is fixed in place and unable to retract into the abdominal cavity.

Double-Barrel

At one time, there was a vogue for creating a double-barrel colostomy to defunction the colon. Although the height of the vogue has passed, this type of stoma still has a place in the management of colorectal trauma. After resection of a damaged segment of the colon, the proximal and distal ends of the colon are tacked together along the antimesenteric surfaces with interrupted absorbable sutures. The resulting double end is then brought out through a trephine incision at the relevant site. The double-barrel configuration makes the colostomy easier to close: closure can be performed after mobilization by resection and a sutured anastomosis or via a double-stapled technique.

ILEOSTOMY

End

End ileostomy is most frequently performed after colectomy for inflammatory bowel disease. The most distal segment of the ileum is used (i.e., that immediately proximal to the ileocecal valve), the reason being that it is important to preserve intestinal length, both for nutritional reasons and to allow for the possibility that an ileoanal pouch may have to be fashioned in the future. In certain instances, it is necessary to create an end ileostomy from a more proximal segment of the ileum.

The terminal ileum is mobilized, a large avascular window is opened between the ileocolic vessels and the ileal branches of the superior mesenteric vessels, and the ileocolic vessels are divided where they branch from the superior mesenteric vessels. The terminal ileum is usually supplied by two arcades of vessels, which join the ileocolic vessels adjacent to the cecum. These arcades must be divided as close to the ileocolic vessels as possible to preserve the blood supply to the terminal ileum [see Figure 3]. The ileocecal fold (Treves's fold) is dissected away from the terminal ileum, which can then be divided flush with the ileocecal valve, either with a linear stapler or with a knife between bowel clamps.

The trephine incision is created at the previously marked site, and a Babcock tissue forceps is passed into the abdominal cavity and used to grasp the divided end of the ileum. The terminal ileum and the supporting mesentery are gently eased through the aperture, with the mesenteric surface oriented superiorly, until 5

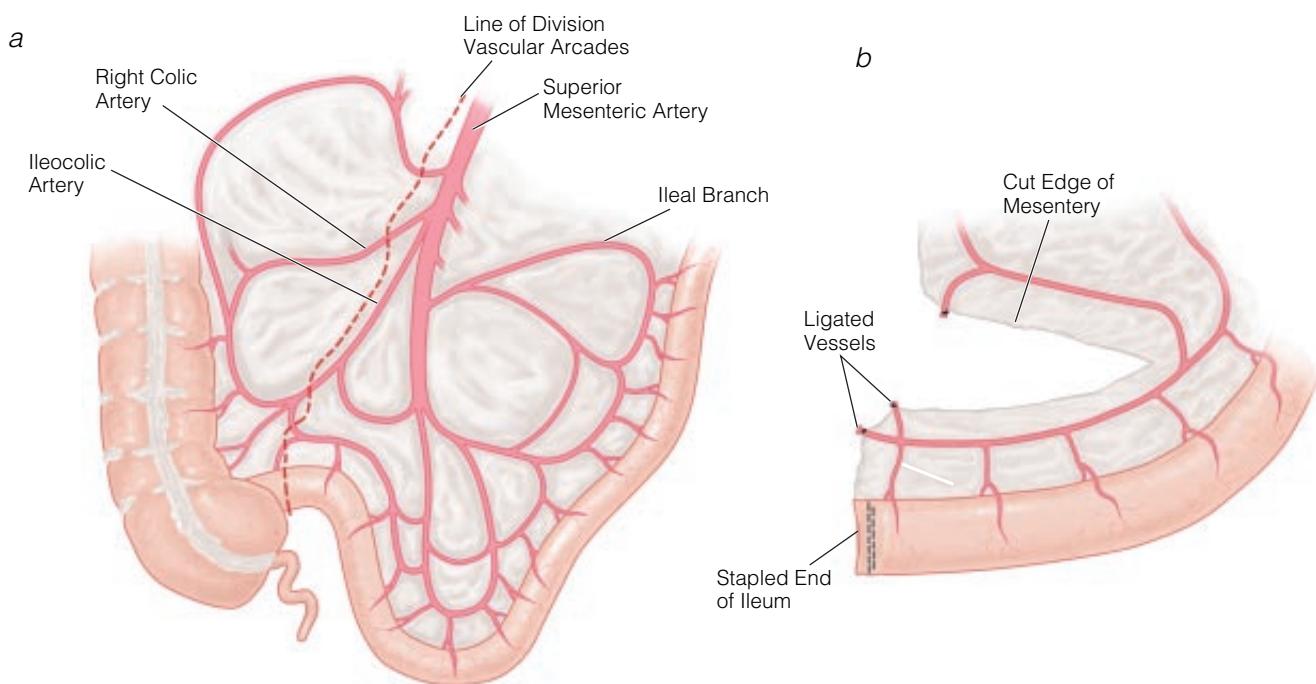

Figure 3 End ileostomy. Shown is preparation of the terminal ileum. (a) Care is taken when dividing the blood supply of the right colon to preserve the arcades supplying the terminal ileum. The line of division of the vessels and the mesentery is shown (dashed line). (b) The mesentery of the terminal ileum is divided so as to preserve the vascular arcade adjacent to the ileum. A segment of well-perfused ileum at least 10 cm long is created, which can be brought through the abdominal wall opening to provide sufficient ileum for creation of a stoma.

cm of ileum protrudes above the abdominal skin. The cut edge of the ileal mesentery is secured to the peritoneum of the back of the anterior abdominal wall, along the line of the lateral border of the rectus abdominis, with an absorbable suture. This measure helps stabilize the stoma and is thought to prevent stoma prolapse, volvulus, and internal herniation around the stoma.

The stapled end of the ileum is excised to produce a fresh bleeding end. The emerging ileum is then everted to yield a spout about 2.5 cm long. This is accomplished by placing a suture on either side of the mesentery and a third suture on the antimesenteric side, which lies inferiorly. The superior sutures take bites of the serosa of the emerging ileum, 5 cm from the cut end of the bowel, and the inferior suture includes a serosal bite 4 cm from the cut edge [see Figure 4]. When the sutures are tied, an everted spout is created that points downward into the ileostomy appliance.¹² The mucocutaneous anastomosis is then completed with a series of interrupted absorbable sutures.

Loop

A loop ileostomy is employed to rest the distal bowel or to protect an anastomosis. The ileal loop used should be as distal as possible while still maintaining adequate mobility; if there is any tension, a more proximal loop may be required. The technique of loop ileostomy formation is similar to that of loop colostomy formation. A Jacques catheter is used to draw the loop through the abdominal wall trephine hole, ideally with the proximal limb in the lower position [see Figure 5a]. Care is taken to distinguish the proximal and distal limbs of the loop and to keep from rotating the loop during its passage through the abdominal wall. A marking suture is useful for identifying the proximal side of the loop. A supporting rod may be used, but it is not necessary, and it can hinder the fitting of the stoma appliance.

The ileostomy is created by making a circumferential incision around 80% of the distal limb at the level of the skin, with the

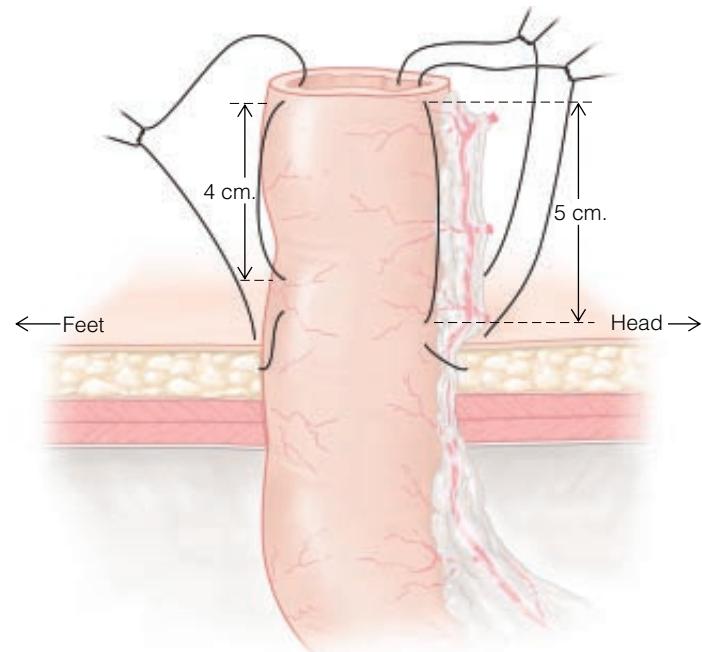

Figure 4 End ileostomy. The ileum having been brought through the abdominal wall, the ileostomy is created by evertting the end of the ileum. Three sutures are placed: one on the antimesenteric side and one to each side of the mesentery. Each suture takes a full-thickness bite of the cut edge of the ileum, a seromuscular bite of the emerging ileum at skin level, and a subepidermal bite of the skin edge. The spout is created when these sutures are tied. A nontoothed forceps or a Babcock tissue forceps is sometimes helpful for evertting the ileum. Gaps between the three sutures are filled in with further absorbable sutures, which include only the end of the ileum and the skin edge.

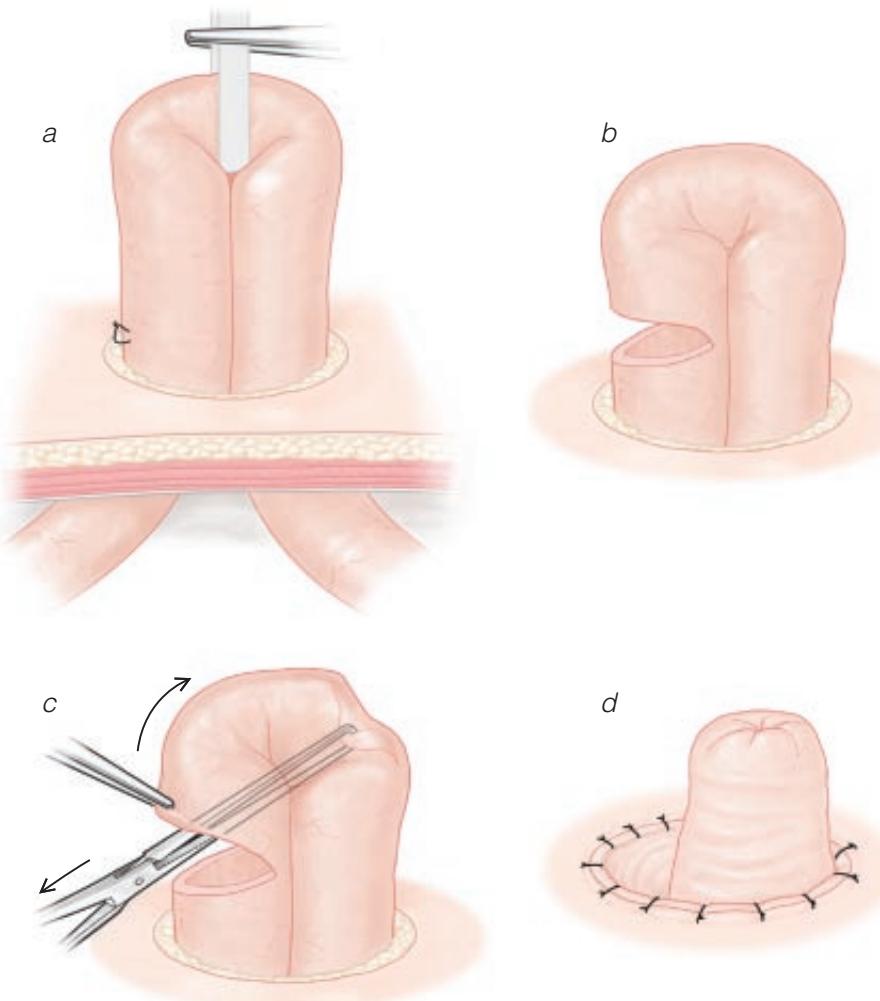

Figure 5 Loop ileostomy. (a) A soft catheter or a length of nylon tape is passed through a small window made in the mesentery of the ileum, and the ileal loop to be used for the stoma is eased through the hole in the abdominal wall and left protruding a few centimeters above skin level. A suture is placed to mark the distal limb. (b) A semilunar incision is made in the mesenteric border of the distal limb at skin level, extending around most of the circumference of the ileum. (c) A Babcock tissue forceps is inserted into the loop and used to grasp the wall of the proximal limb. The cut edge of the ileum is peeled back to evert the bowel wall and create a spout from the proximal limb of the loop. (d) The stoma is completed by placing interrupted absorbable sutures between the cut edge of the ileum and the subepidermal layer of the skin. A few of these sutures also take a seromuscular bite of the emerging ileum at skin level.

mesenteric side preserved [see Figure 5b]. The cut edge of the proximal limb is then everted to create a spout for the ileostomy [see Figure 5c]. A Babcock tissue forceps is sometimes used to apply gentle traction to the mucosal side of the proximal limb. The cut edge of the ileum is anastomosed to the skin with a series of interrupted subcuticular absorbable sutures. The distal limb is sutured flush with the skin. On the proximal side, several sutures take bites of the serosa of the emerging ileum at skin level. The corners of the incision in the ileum are drawn around the proximal limb of the ileostomy to accentuate the spout effect and create a thin, semilunar distal limb opening [see Figure 5d].

An alternative approach is to create a divided loop ileostomy, which some consider superior to a conventional loop stoma.¹³ The construction technique for this stoma is similar to that of its conventional counterpart. The distal limb of the ileostomy is divided with a linear cutting stapler after the loop is brought through the abdominal wall. The closed distal end is tacked to the side of the emerging spout of the proximal end below skin level, and the proximal end is fashioned into an everted spout as in a conventional end ileostomy. A divided loop ileostomy is slightly more difficult and expensive to construct than a conventional loop ileostomy, but it has the advantage of achieving complete defunctioning of the distal bowel (because there is no chance that the ileostomy contents will spill over).

Loop-End

A loop-end ileostomy can be useful in cases where the ileum and its supporting mesentery are grossly thickened and the sur-

geon is encountering difficulty in preparing a sufficient length of well-vascularized ileum for a conventional end ileostomy. In a loop-end ileostomy, the ileum is prepared as in a conventional end ileostomy, but the vascular arcades are left undisturbed. A small window is made in the mesentery 5 to 10 cm proximal to the closed end of the ileum, and a nylon tape or a Jacques catheter is used to draw this distal ileal loop through the abdominal wall. The stapled closed end of the ileum lies just within the abdominal cavity. The ileostomy is then constructed in essentially the same manner as a conventional loop ileostomy.

Split

A split ileostomy is created by bringing out the two cut bowel ends at different sites. The proximal end is usually terminal ileum, but the distal end may be either ileum or colon, depending on the indication for stoma formation. This procedure forms a mucous fistula, and only a small stoma appliance is usually required. The distal end can be either included in the closure of the abdominal wound or brought out through a separate trephine hole on the opposite side of the abdomen from the ileostomy. The advantage of a split ileostomy is that it completely defunctions the bowel without the risk of intra-abdominal leakage from a closed distal stump. The disadvantage is that it is more difficult to close: closure usually necessitates reopening of the main incision.

Continent

A continent ileostomy involves formation of a reservoir and placement of a nonreturn nipple valve, which is emptied regular-

ly via a catheter, so that the patient need wear only a small cap appliance. The surgical technique is demanding and beyond the scope of this chapter; it is described more fully elsewhere.¹⁴

STOMA CLOSURE

Loop Ileostomy

Closure of a loop ileostomy is usually a simple local procedure that does not require the main incision to be opened. The operation is easier to perform if a period of at least 12 weeks is allowed to elapse between formation of the stoma and closure so that there is time for edema and inflammatory adhesions to settle. Dissection is facilitated by injecting epinephrine (1:100,000 solution) into the subcutaneous plane around the stoma.

An incision is made in the peristomal skin 2 mm from the mucocutaneous junction [see Figure 6a]. The incision is deepened into the subcutaneous fat until the serosa of the emerging bowel appears. Sharp dissection is continued circumferentially in this plane, dividing the fine adhesions between the bowel and its mesentery and the subcutaneous fat [see Figure 6b]. Blunt dissection should be avoided because it can easily lead to serosal tears. Some difficulty may be encountered at the fascial level, and care must be taken with the dissection if adhesions are particularly dense. Eventually, the peritoneal cavity is entered, and the remaining adhesions are identified with a finger and divided.

The emerging ileal loop is withdrawn from the abdominal cavity, and the mucocutaneous junction and the rim of skin are excised. The everted proximal end of the stoma is unfolded [see Figure 6c]; some sharp dissection is usually required to accomplish this. The freshened edges of the enterotomy are then

approximated with interrupted seromuscular absorbable sutures [see Figure 6d]. Sometimes, a limited ileal resection is required if the stoma site is in poor condition, and a conventional end-to-end anastomosis is performed to restore intestinal continuity. It is possible to close a loop ileostomy with a double-stapled technique; however, there does not appear to be much advantage in doing so. Two randomized trials and a nonrandomized study comparing suture closure with stapled closure yielded conflicting results with respect to complication rates,¹⁵⁻¹⁷ but both randomized trials reported that extra costs were incurred when staples were used. Once the enterotomy is closed, the loop of ileum is returned to the abdominal cavity, and the stoma site is closed with interrupted nonabsorbable sutures.

A divided loop ileostomy is closed in the same manner as described above. Care should be taken to identify the closed distal end and to fully mobilize both limbs of the ileum from the abdomen. The closed distal end is separated from the proximal limb, and the staple line is excised to yield a fresh end. The proximal end is unfolded and a simple end-to-end anastomosis is performed with interrupted sutures. There may be a significant size discrepancy between the two limbs. Again, a double-stapled technique may be employed as an alternative closure method.

Loop Colostomy

A loop colostomy is closed in much the same manner as a loop ileostomy after the emerging colon is mobilized away from the subcutaneous fat and the abdominal wall by means of sharp dissection. Transverse closure is achieved with interrupted absorbable sutures.

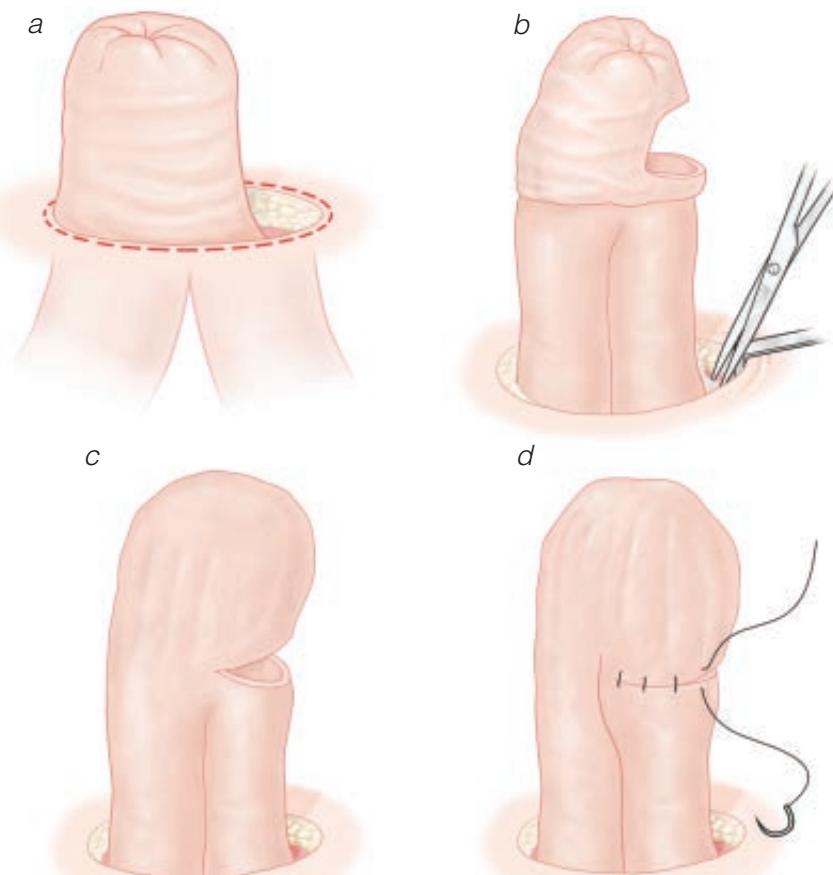

Figure 6 Stoma closure: loop ileostomy. (a) Epinephrine is infiltrated into the subcutaneous tissues around the ileostomy, and an incision is made through the full thickness of the skin 2 mm from the mucocutaneous junction. (b) The emerging ileum is mobilized by dividing adhesions between the bowel and the subcutaneous fat and the abdominal wall until the bowel is completely free. (c) The everted segment of ileum is reduced by a combination of sharp and blunt dissection, and the edge of the opening in the ileum is excised to leave fresh supple ileum for anastomosis. (d) The opening in the ileum is closed with a single layer of interrupted absorbable sutures that take bites of the seromuscular layers only. The ileal loop is then returned to the abdominal cavity, and the defect in the abdominal wall is closed with interrupted nonabsorbable sutures.

Postoperative Care

A clear stoma appliance is cut to the proper size and placed on the stoma before the patient leaves the operating room. A degree of edema is to be expected in the first week. In addition, the stoma may appear somewhat dusky; this is a sign that the aperture in the abdominal wall is the correct size. It often happens that the patient becomes alarmed at the initial appearance of the stoma and requires reassurance that the stoma will look better as time passes.

When the stoma starts to function, the clear appliance is changed for the chosen appliance, and the patient is instructed in how and when to empty the pouch. When confident with this aspect of stoma management, the patient is instructed in how to cut the plate to the correct size and how to change the stoma bag or flange (if he or she is using a two-piece appliance). An ileostomy works throughout the day, often showing an increase in activity after meals. The appliance will therefore require regular emptying, a task that some patients find inconvenient. A loop transverse colostomy may be as unpredictable as an ileostomy in this regard; however, a sigmoid colostomy may have a more predictable activity, similar to the frequency of normal bowel movements. Some patients find that quality of life is improved by irrigating the colostomy with water instilled via a special appliance. This procedure induces a full colonic clearout and allows the patient to wear a less obtrusive cap appliance for 24 to 48 hours, until irrigation is repeated.

Detailed discussion of stoma care is beyond the scope of this chapter. A key role is played by the enterostomal therapist, who is an important point of contact for the patient, providing advice, instruction, and emotional support in the postoperative period. Skin complications are common, and most can be managed by the enterostomal therapist. Many such complications result from contact between the peristomal skin and digestive enzymes; common causes include poor appliance fit and stoma retraction. Skin problems can usually be resolved by means of simple measures such as switching to a different appliance, using a convex flange, applying barrier cream, or filling dips in the peristomal skin with stoma paste. Given that surgical complications such as fistula formation and parastomal hernia may present as skin problems, it is important that the surgeon and the enterostomal therapist work closely together in addressing these problems.

Troubleshooting

Wound infection after stoma closure is common. Drainage of the incision with a small corrugated drain can help reduce the incidence of such infection. Some surgeons leave the stoma site open and allow it to heal by second intention.

Incisional hernia can develop in the stoma site, and its incidence is increased by wound infection in the postoperative period. Because the defect is relatively narrow, the hernia can lead to significant symptoms. Repair is usually necessary.

Breakdown of the anastomosis lying beneath the incision will lead to a fecal fistula, with discharge from the stoma site. If the fistula is simple and there is no distal obstruction, it is likely to heal spontaneously. Expert nursing is required to manage the fistula effluent while healing occurs to prevent damage to the surrounding skin.

If there is a complex inflammatory mass at the closure site, spontaneous healing is less likely. Laparotomy may be required, with resection of the stoma site and reanastomosis or further stoma formation, depending on the patient's condition.

Table 2 Incidence of Common Complications of Intestinal Stomas

Complication	Ileostomy Patients ¹⁸ (N = 150)	Colostomy Patients ⁴⁶ (N = 126)	Colostomy Patients ⁹ (N = 203)
	No. (%) [*]	No. (%) [†]	No. (%) [‡]

† Retrospective review of all patients who underwent end colostomy formation.

‡ All complications recorded at clinic review. Complication rate expressed as cumulative probability from life-table analysis.

Complications

Complications after stoma formation are frequent and varied [see Table 2] and can adversely affect quality of life. The complication rate has been reported to be about 25% after a colostomy formation and as high as 57% after an end ileostomy¹⁸ and 75% after a loop ileostomy.¹⁹ Cumulative complication rates at 20 years have reached 76% in patients undergoing ileostomy for ulcerative colitis and 56% in those undergoing ileostomy for Crohn disease.²⁰ As noted [see Postoperative Care, above], many complications can be successfully managed with enterostomal care.¹⁸ This is fortunate because the results of surgical correction are often unsatisfactory, with many patients requiring further surgical revision of their stomas.²¹

Careful assessment is warranted when a patient presents with stoma complications. Such complications may be interrelated or may have a different cause from what initial examination suggests. For example, skin damage may be a result of a poorly fitting appliance, but the poor fit may itself be caused by a parastomal hernia or a flush ileostomy. Furthermore, stoma complications may arise from renewed activity of the underlying disease (e.g., recrudescence of Crohn disease²¹⁻²³ or recurrence of cancer).

ISCHEMIA

Mild ischemia of the stoma is common in the early postoperative period but usually resolves within a few days. More profound ischemia can result in necrosis of all or part of the circumference of the bowel end used to form the stoma. Satisfactory healing of the stoma depends on an adequate blood supply. Problems with the blood supply are more common with end stomas than with loop stomas; likely causes include excessive division of mesenteric blood vessels, tension on the stoma from inadequate mobilization, and a too-narrow aperture through the abdominal wall that constricts the vessels at the fascial level. It is a good idea to prepare the relevant bowel segment for use in a stoma some time before the end of the operation so that any problems with the blood supply will be evident before the stoma is fashioned. An obviously ischemic stoma should be revised at

the time of operation. Such revision may include mobilization of a more proximal bowel segment.

Patchy necrosis that is confined to the mucosa can be managed expectantly and usually heals by second intention. Complete necrosis of an ileostomy is an indication for urgent revision. Necrosis of a colostomy may not necessitate revision if the segment is short. However, a fistula may form at the fascial level, or stenosis may develop as the necrotic segment heals.

STENOSIS

Stenosis of the stoma is a consequence of postoperative ischemia. Mild stenosis can be managed with simple dilatation and may not cause many symptoms, particularly if the effluent is liquid. Substantial stenosis of a colostomy can lead to subacute obstruction that must be managed with surgical revision. Sometimes, revision can be accomplished as a local procedure. A disk of skin that includes the stenosed stoma site is excised. The distal colon is mobilized and sutured to the new skin opening. In most instances, however, it is not possible to mobilize sufficient length with this approach, and laparotomy is required for adequate mobilization.

PROLAPSE

Prolapse may occur with any type of stoma but is most common with loop colostomy. Patients with loop colostomies usually have a degree of parastomal hernia, which allows adequate space for prolapse of the emerging bowel. Appearances are often alarming, and symptoms are usually related to difficulties with fitting an appliance or to leakage. The best treatment option is to close the stoma (if appropriate). Another option is to divide the loop stoma, thus creating an end colostomy, and then to return the closed distal end to the abdomen. Amputation of the prolapsed

stoma corrects the problem in the short term, but the prolapse often recurs quickly. Repairing a coexisting parastomal hernia can lower the risk of recurrence, but it involves a more extensive operation [see Parastomal Hernia, below]. Neither ensuring that the emerging stoma is brought through the rectus abdominis nor fixing the mesentery to the abdominal wall appears to prevent stoma prolapse.²⁰

RETRACTION

Stoma retraction is more of a concern with an ileostomy than with a colostomy because of the possibility of leakage from the appliance. Retraction generally results from poor adhesion between the serosal surfaces of the everted stoma but may also reflect the presence of a parastomal hernia. If the retracted ileostomy is fixed in position, laparotomy will probably be required to correct the problem, though it is worthwhile to attempt local mobilization of the stoma after incising the mucocutaneous junction. If the retracted ileostomy is mobile, the problem can be corrected by inserting a series of interrupted absorbable sutures through the full thickness of the everted stoma to fix the walls together. A similar effect can be obtained by pulling the retracted stoma upward with tissue forceps, then fixing the walls together with several firings of a noncutting linear stapler inserted into the ileostomy, with care taken to avoid the mesentery [see Figure 7].²⁴

PARASTOMAL HERNIA

Formation of an abdominal stoma necessarily involves creating a defect in the abdominal wall to accommodate the emerging bowel. Such defects may become enlarged as a result of tangential force applied to the edge of the opening, and this enlargement may lead to hernia formation. The tangential force is related to the radial force and the radius of the opening; in turn, the radial force is related to the intra-abdominal pressure and the radius of the abdominal cavity.²⁵ Consequently, tangential forces are greater in larger openings in obese patients, who are thus at greater risk for parastomal hernia. Patients undergoing emergency procedures in which dilated bowel is used to form a stoma are also likely to be at increased risk for hernia formation. Care must be taken to make an opening that is just large enough for the emerging bowel. An incision that admits only two fingers is appropriate for most elective indications.

Several authors have addressed the problem of enlargement of the stoma opening by reinforcing the opening with a prosthetic ring or a sheet of Marlex mesh.^{25,26} One randomized trial compared the incidence of parastomal hernia in patients undergoing conventional end colostomy with the incidence in patients undergoing colostomy with insertion of a partially absorbable lightweight mesh between the posterior rectus sheath and the rectus abdominis.²⁷ At 12 months, eight of the 18 patients with a conventional colostomy showed evidence of parastomal hernia formation, compared with none of the 16 with a mesh-reinforced colostomy.²⁷

There remains some controversy over the issue of where the stoma site should be located in relation to the rectus abdominis. Some authors claim that hernia formation is less frequent when the stoma emerges through the rectus abdominis²⁸⁻³⁰; however, other authors dispute this claim,⁹⁻¹¹ and a clinical and radiologic study of paraileostomy hernia found no differences in incidence between stomas brought out through the rectus abdominis and stomas brought out more laterally.³¹

The incidence of parastomal hernia formation varies widely among published studies [see Table 3]. This wide variation reflects both differences in length of follow-up and differences in the

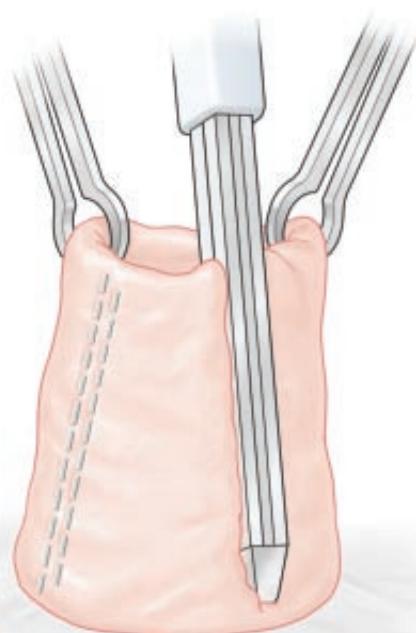

Figure 7 Illustrated is an alternative method of stabilizing a retracted ileostomy. The ileostomy is everted to its full extent with a Babcock tissue forceps. The site of the mesentery is identified. A noncutting linear stapler is inserted with the anvil in the stoma, with care taken to avoid the mesentery. The stapler is fired several times to fix the two walls of the ileum together.

* Details of method of follow-up not provided. †Prospective follow-up of patients undergoing stoma construction. ‡Retrospective study of patients undergoing stoma construction. §Figure represents cumulative rate, based on life-table analysis. ¶Incidence based on reoperation rate. ¶Patients presenting to a specialist stoma clinic. **Patients specifically reviewed for hernia formation.

methods used to identify parastomal hernias. Given that many hernias are small and asymptomatic, the true incidence of hernia formation may well be higher than the reported figures. It is generally accepted, however, that paracolostomy hernias are more common than paraileostomy hernias. It is unclear why this is so, but the reason is likely to involve the size of the opening in the abdominal wall.

Parastomal hernias are often asymptomatic, and in obese patients, they may not be apparent on clinical examination. Patients usually present with an unsightly bulge at the stoma site, but they may also have other symptoms, such as leakage around the stoma appliance, skin problems, or difficulty in irrigating a colostomy. Rarer presenting symptoms include intestinal obstruction and strangulation of the bowel loop within the hernia. Clinical examination usually suffices for making the diagnosis, particularly when performed with the patient standing. Small hernias in obese patients can be a challenge to diagnose; in this setting, computed tomographic scanning limited to the stoma area can be helpful.³¹

Surgical repair of a parastomal hernia often yields disappointing results and should be considered only if the patient's symptoms are troublesome. Many patients manage reasonably well by wearing a suitably adapted appliance and a support belt. When surgical repair is indicated, it follows one of three possible approaches:

1. Local repair. This approach to hernia repair is the simplest of the three but also the least successful.^{32–34} The stoma is mobilized, and the sac is identified and removed. The defect in the fascia of the abdominal wall is narrowed around the emerging bowel with a series of interrupted nonabsorbable sutures. The repair is completed by recreating the mucocutaneous anastomosis.
2. Repair with prosthetic mesh. Mesh repairs have become increasingly popular as different meshes have become available and as surgeons have become aware of the advantages of these materials in hernia surgery. The mesh can be inserted intra-abdominally,^{35,36} in the preperitoneal plane [see Figure 8],^{32,37} or in the subcutaneous plane.^{38,39} Regardless of where the mesh is inserted, the basic principle is the same—namely, to achieve and maintain a narrowing of the stoma site by surrounding the emerging bowel with a sheet of mesh in which a hole is cut to accommodate the stoma.
3. Stoma relocation. The stoma can be moved to a fresh site on the abdominal wall without reopening the main incision. The stoma is fully mobilized, and a new hole is made in the abdominal wall. A plane is developed between the peritoneum and the abdominal contents by means of blunt finger dissection between the existing stoma site and the new one. The mobilized stoma is then passed through the new hole.⁴⁰ If difficulties are encountered, a laparotomy will be required. An alter-

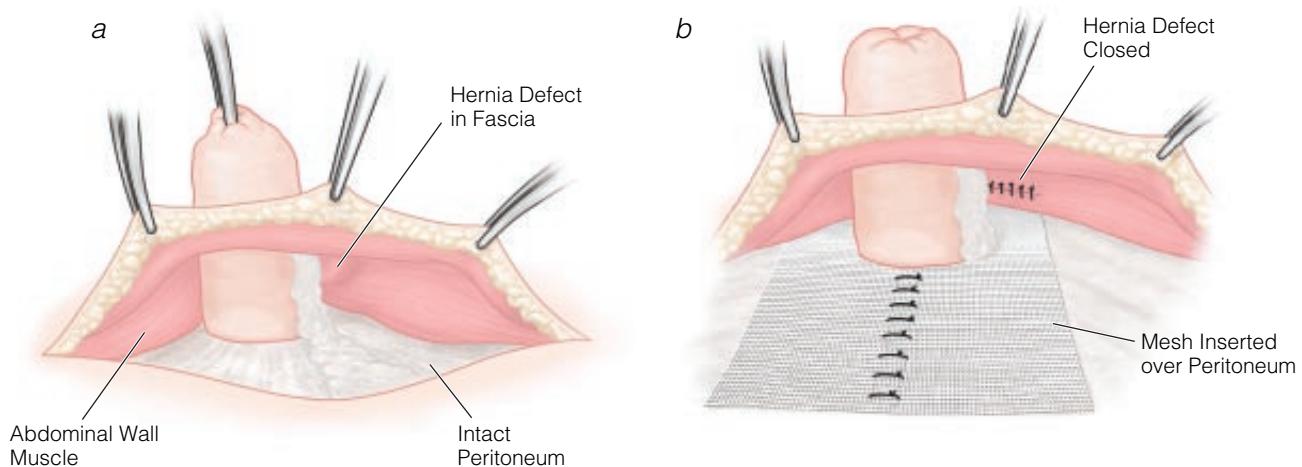

Figure 8 Depicted is preperitoneal mesh repair of parastomal hernia. (a) The midline incision is reopened without disturbing the stoma. The space between the peritoneum and the muscles of the abdominal wall is opened widely, with care taken not to damage the bowel as it emerges from the abdominal cavity. The contents of the hernia are returned to the abdominal cavity, and the defect in the peritoneum is repaired with absorbable sutures. (b) A piece of nonabsorbable mesh is cut to shape to cover the defect in the abdominal wall and to just accommodate the emerging bowel. The mesh swatch is placed round the bowel on the intact peritoneum, and the two tails of the swatch are sutured together so as to encircle the bowel. The defect in the muscle layer is closed with a few interrupted nonabsorbable sutures.

native approach is to reroute the stoma through a new fascial defect while maintaining the existing skin aperture. The original fascial defect is repaired with mesh.⁴¹

The best method of repair has not been established.⁴² Most published studies have included relatively few patients who were followed for a relatively short time. With longer follow-up, recurrence rates as high as 76% have been reported. Local repair is associated with the highest recurrence rate,⁴³ and stoma relocation carries an increased morbidity (from incisional hernia at the original stoma site).⁴⁴ Nor is mesh repair free of problems: intra-abdominal placement of mesh is associated with a significant risk of adhesions to the mesh and of small bowel obstruction.⁴⁵ The risk of mesh infection is highest when the mesh is placed in a superficial position through a parastomal incision.

At present, the best approach is to tailor repair to the individual patient's condition and situation. For more specific recommendations, randomized trials of the different methods of parastomal hernia repair will be required. There is a growing amount of evidence in favor of inserting prosthetic mesh at the time of stoma formation in an effort to reduce the incidence of this complication.

OBSTRUCTION

Conditions that may cause intestinal obstruction after stoma formation include stenosis of the stoma, parastomal hernia, post-operative adhesions, and recurrent disease (e.g., Crohn disease in the proximal ileum or recurrent cancer). Management depends on the cause of the obstruction. Retrograde contrast studies are useful for identifying the site and determining the likely cause of obstruction.

FISTULA

A fistula may form adjacent to a stoma as a consequence of inadvertent full-thickness placement of a suture through both walls of the stoma during formation, pressure necrosis at skin level from a tightly fitting stoma appliance, or recurrent disease, especially Crohn disease in the ileum proximal to the stoma. Surgical treatment usually involves laparotomy and reformation of the stoma at a new site.

OTHER COMPLICATIONS

Other, less common complications arising after stoma formation include bleeding, perforation, skin ulceration, and the development of cancer [see Table 4].

Table 4 Additional Complications Arising after Stoma Formation

Complication	Cause	Differential Diagnosis	Treatment
Bleeding	Trauma Inflammatory polyps	Portal hypertension Recurrent disease	Review of stoma appliance and technique
Perforation	Traumatic (irrigation) Recurrent disease	Stercoral (constipation)	Laparotomy and revision of stoma
Skin ulceration	Contact dermatitis	Pyoderma gangrenosum	Review of stoma appliance and technique
Cancer formation	Recurrence at stoma site De novo cancer formation	Inflammatory polyps	Resection

31 APPENDECTOMY

Hung S. Ho, M.D., F.A.C.S.

First depicted in anatomic drawings in 1492 by Leonardo da Vinci, the veriform appendix was described as an anatomic structure in 1521 by Jacopo Berengari da Carpi, a professor of human anatomy at Bologna. Appendicitis became recognized as a surgical disease when the Harvard University pathologist Reginald Heber Fitz read his analysis of 257 cases of perforating inflammation of the appendix and 209 cases of typhlitis or perityphlitis at the 1886 meeting of the Association of American Physicians. In this landmark report, Fitz correctly pointed out that the frequent abscesses in the right iliac fossa were often due to perforation of the veriform appendix, and he referred to the condition as appendicitis.¹ Among his classic observations of the disease was his emphasis on the “vital importance of early recognition” and its “eventual treatment by laparotomy.” It was not until 1894 that Charles McBurney first described the surgical incision that bears his name and the technique of appendectomy that was to become the gold standard for appendectomy throughout the 20th century and into the 21st.²

Although appendectomy has traditionally been done—and largely continues to be done—as an open procedure, there has been increasing interest in laparoscopic appendectomy since the beginning of the 1990s. At present, however, the only patients for whom laparoscopic appendectomy appears to offer significant advantages are women of childbearing age, obese patients, and patients with an unclear diagnosis [see Figure 1]. Accordingly, the gold standard for surgical treatment of acute appendicitis remains open appendectomy as described by McBurney. The occasional patient with chronic appendicitis should be electively treated with the laparoscopic approach.

Operative Technique

OPEN APPENDECTOMY

With the patient in the supine position, general anesthesia is induced and the abdomen is prepared and draped in a sterile fashion so as to expose the right lower quadrant. The skin incision is made in an oblique direction, crossing a line drawn between the anterior superior iliac spine and the umbilicus at nearly a right angle at a point about 2 to 3 cm from the iliac spine. This point, McBurney’s point, is approximately one third of the way from the iliac spine to the umbilicus [see Figure 2]. The subcutaneous fat and fascia are incised to expose the external oblique aponeurosis. A slightly shorter incision is made in this aponeurosis; first, a scalpel is used, and then, the incision is extended with scissors in the direction of the fibers of the muscle and its tendon in such a way that the fibers are separated but not cut.

The fibers of the internal oblique muscle and the transversus abdominis are separated with a blunt instrument at nearly a right angle to the incision on the external oblique aponeurosis. The parietal peritoneum is lifted up, with care taken not to include the underlying viscera, and is opened in a transverse fashion with a scalpel. This incision is then enlarged transversely with scissors. When greater exposure is required, the lateral edge of the rectus sheath is incised and the rectus abdominis

retracted medially without being divided [see Figure 3].

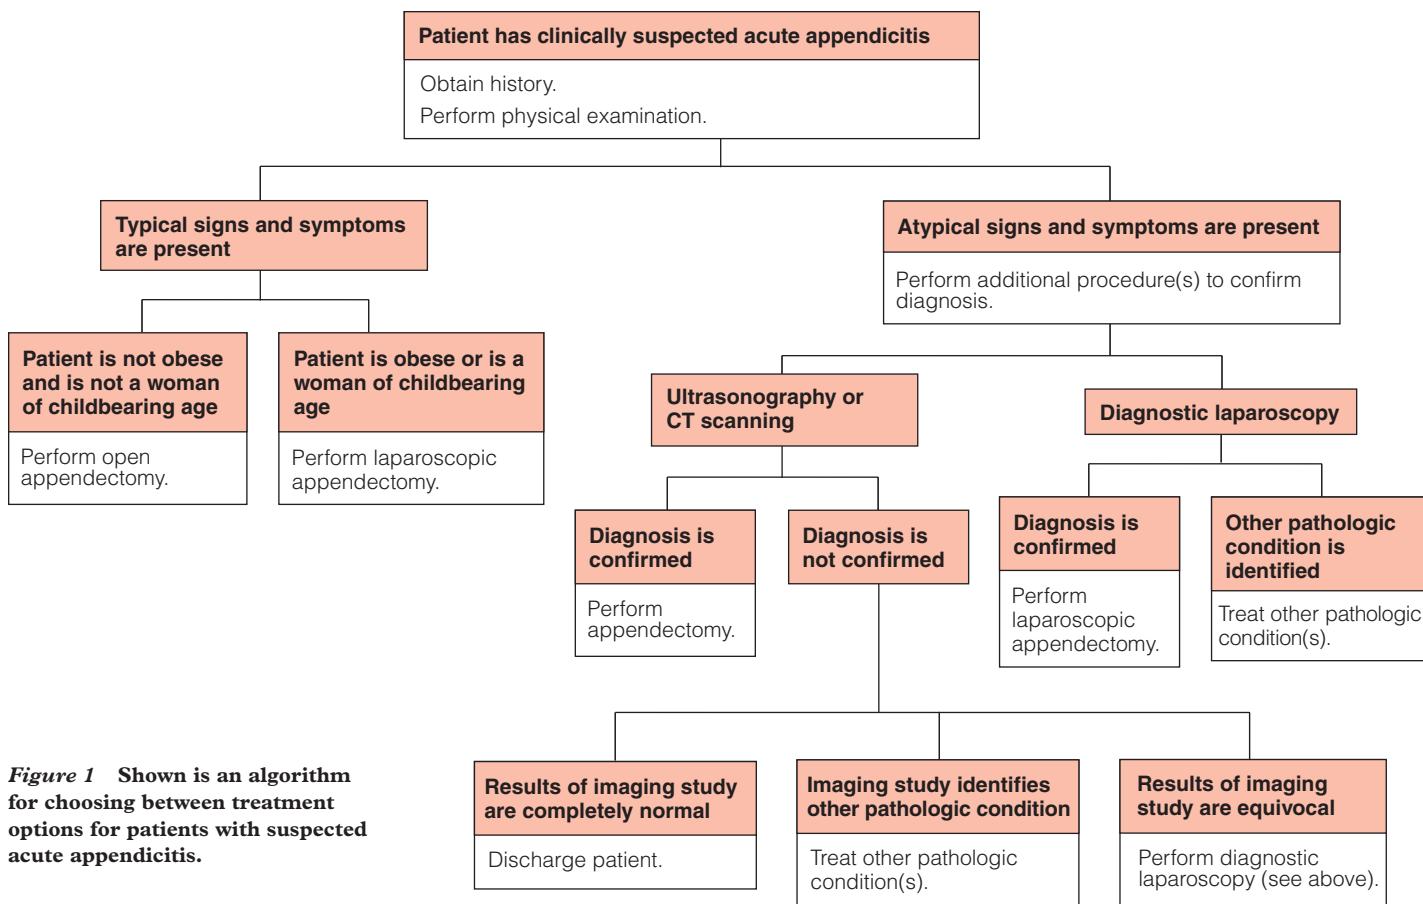

A foul smell or the presence of pus on entry into the peritoneum is an indication of advanced or perforating appendicitis. The free peritoneal fluid is collected for bacteriologic analysis. The appendix is located by following the cecal taeniae distally. The inflamed appendix usually feels firm and turgid. The appendix, together with the cecum, is delivered into the surgical incision and held with a Babcock tissue forceps. If this step proves difficult, the appendix can sometimes be swept into the field with the surgeon’s right index finger as gentle traction is maintained on the cecum with a small, moist gauze pad held in the left hand [see Figure 4]. Care should be taken at this point not to avulse the friable and possibly necrotic appendix. To deliver a retrocecal appendix, it may be necessary to mobilize the ascending colon partially by dividing the peritoneum on its lateral side, starting from the terminal ileum and proceeding toward the hepatic flexure.

The mesoappendix, containing the appendicular artery, is divided between clamps and ligated with 3-0 absorbable sutures [see Figure 5]. The appendix is held up with a Babcock tissue forceps, and its base is crushed with a straight mosquito arterial forceps. The mosquito forceps is then opened, moved up the appendix, and closed again. The base of the appendix is doubly ligated with 2-0 absorbable sutures at the point where it was crushed, so that a cuff of about 3 mm is left between the forceps and the tie.

The appendix is divided by running a scalpel along the underside of the forceps. The mucosa of the appendiceal stump is fulgurated with the electrocautery. The stump is not routinely invaginated into the cecum. In those rare cases in which the viability of the appendiceal base is in question, a 2-0 absorbable purse-string suture is placed in the cecum, and the stump is invaginated as the suture is tied; if this is done, palpation for a patent ileocecal valve is indicated. The operative field is then checked for hemostasis. In cases of perforating appendicitis, the right paracolic gutter and pelvis are irrigated and thoroughly aspirated to ensure that any collected pus or particulate material is removed.

The peritoneum is then closed with a continuous 3-0 absorbable suture. The fibers of the transversus abdominis and the internal oblique muscle fall together readily, and their closure can be completed with two interrupted 3-0 absorbable ligatures. The external oblique aponeurosis is closed from end to end with a continuous 2-0 absorbable suture. Scarpa’s fascia is approximated with interrupted 3-0 absorbable sutures, and the skin is closed with a continuous subcuticular 4-0 absorbable suture and reinforcing tapes (Steri-Strips).

If the wound has been grossly contaminated, the fascia and muscles are closed as described, but the skin is loosely approximated with Steri-Strips, which can easily be removed after the procedure if surgical site infection or abscess develops. An alternative approach is to leave the skin and the subcutaneous tissue open but dressed with sterile nonadherent material and then to perform delayed primary closure with Steri-Strips on postoperative day 4 or 5. A meta-analysis of 27 studies involving 2,532 patients with gangrenous or perforating appendicitis concluded that the risk of surgical site infection was no higher with primary closure than with delayed primary closure.³

LAPAROSCOPIC APPENDECTOMY

The patient is placed in the supine position, with both arms tucked along the sides, and general anesthesia is induced. Decompression with an orogastric tube should be routine, as should placement of a urinary Foley catheter and use of lower-extremity sequential compression devices. The surgeon should stand on the patient's left side, with the assistant (who operates the camera) near the patient's left shoulder [see Figure 6]. The monitors are placed on the opposite side of the operating table so that both the surgeon and the assistant can view the procedure at all times.

The abdomen is prepared and draped in a sterile fashion so as to expose the entire abdomen. A three-port approach is routinely used [see Figure 6]. All skin incisions along the midline are made vertically to allow a more cosmetically acceptable conversion to laparotomy, should this become necessary. The suprapubic port must be large enough to accommodate the laparoscopic stapler (usually 12 mm); the other two ports can be smaller (e.g., 5 or 10 mm). The ports are placed as far away from the operative field as possible to permit the application of a two-handed dissection technique. The use of a 30° angled scope facilitates operative viewing and dissection.

With the patient pharmacologically relaxed and in the Trendelenburg position, a Veress needle is inserted into the peritoneal cavity at the base of the umbilical ligament. Aspiration and the saline-drop test are performed to ensure that the tip of the needle is correctly positioned. Pneumoperitoneum is established by insufflating CO₂ to an intra-abdominal pressure of 14 mm Hg. The first port is placed at the infraumbilical skin incision, the laparoscope is inserted, and a complete diagnostic laparoscopy is

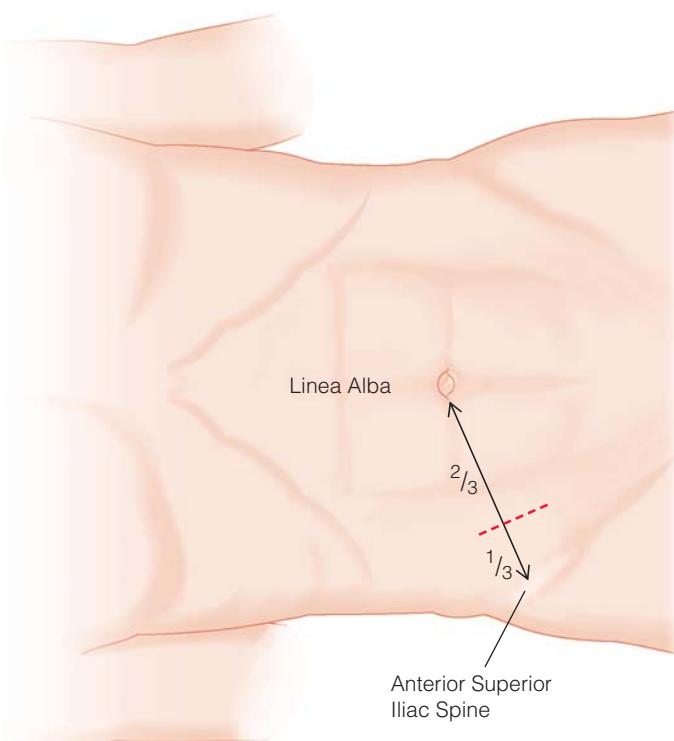

Figure 2 Open appendectomy. Shown are McBurney's point and McBurney's incision.

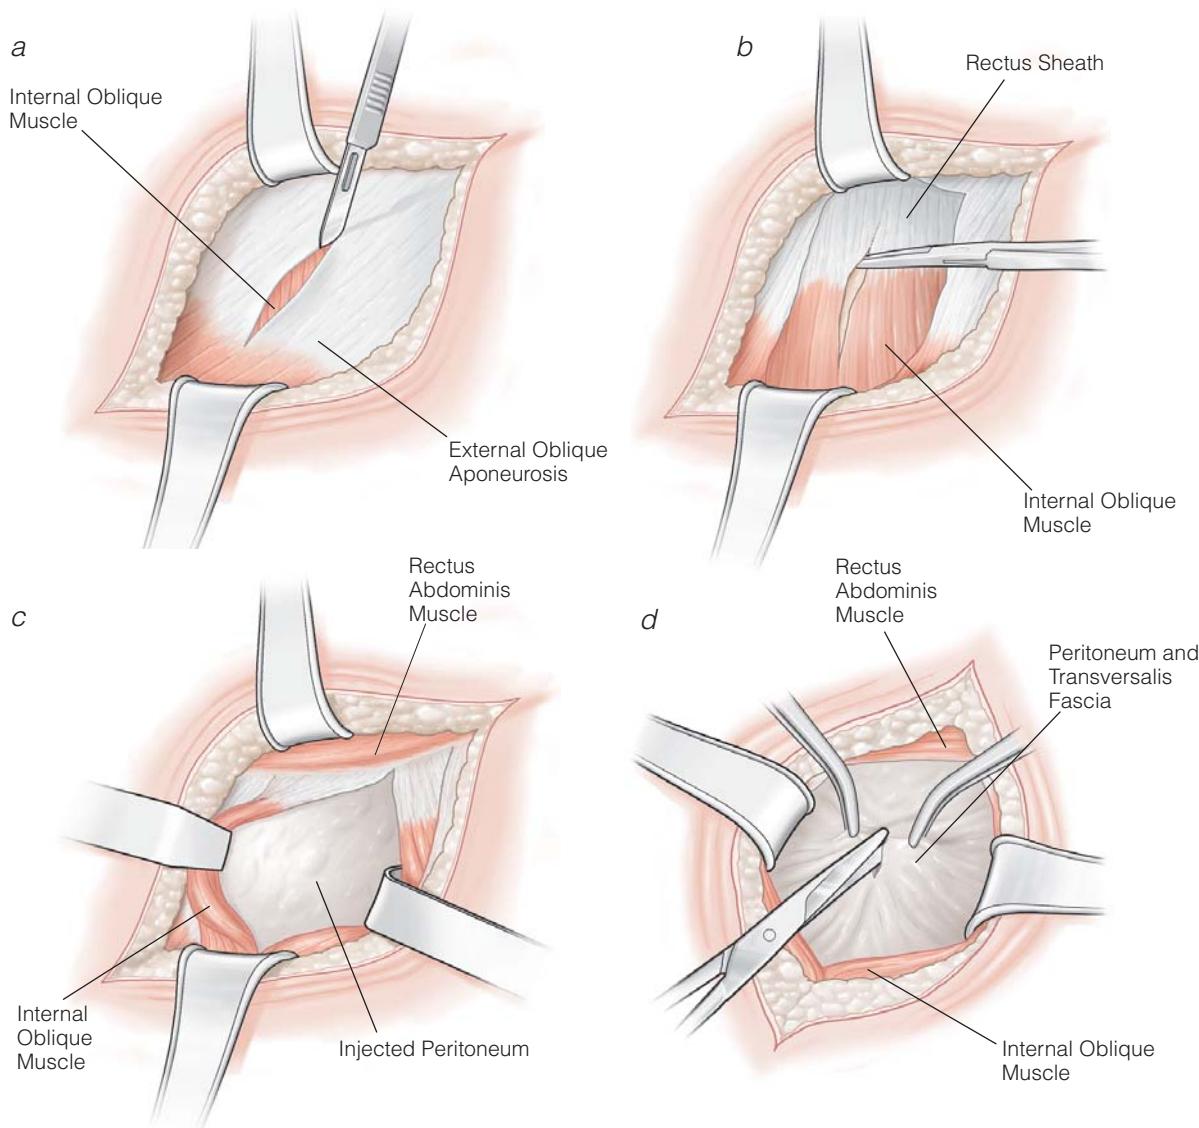

Figure 3 Open appendectomy. Depicted is exposure of the abdominal cavity. The external oblique aponeurosis is opened (a). The fibers of the internal oblique muscle are separated bluntly (b). The parietal peritoneum is exposed (c) and opened transversely (d).

performed. Once the diagnosis of acute appendicitis is confirmed by inspection, the two remaining ports are placed under direct vision. In many cases, however, the diagnosis cannot be confirmed without first placing the second and third ports and exposing the appendix. If purulent fluid is encountered, it should be carefully aspirated dry without irrigation to ensure that the infected fluid is not disseminated throughout the abdominal cavity.

The appendix is exposed and traced to its base on the cecum by using an atraumatic retracting forceps. In cases of retrocecal appendix or severe appendiceal inflammation, it is best first to mobilize the cecum completely by taking the lateral reflection of the peritoneum around the terminal ileum and up the ascending colon with an ultrasonic scalpel (e.g., the Harmonic Scalpel; Ethicon Endo-Surgery, Inc., Cincinnati, Ohio). Surrounding structures, such as the iliac and gonadal vessels and the ureter, should be clearly identified to minimize the risk of injury. Dissection of the appendix can then begin.

The tip of the appendix is grasped and retracted anteriorly toward the anterior abdominal wall and slightly toward the pelvis; the mesoappendix is thus exposed in a triangular fashion. A window between the base of the appendix and the blood supply is created with a curved dissecting forceps. The mesoappendix is divided either with hemostatic clips and scissors or with a laparoscopic gastrointestinal anastomosis (GIA) stapler loaded with a vascular cartridge [see Figure 7]. If a window on the mesoappendix cannot be safely created because of intense inflammation, antegrade dissection of the blood supply is necessary. The ultrasonic scalpel is a handy (albeit expensive) instrument for this purpose. Endoscopic hemostatic clips usually suffice to control the small branches of the appendicular artery during the course of this dissection.

The base of the appendix is then cleared circumferentially of any adipose or connective tissue and is divided with a laparoscopic GIA stapler loaded with an intestinal cartridge [see Figure 8]. To ensure an adequate closure away from the inflamed appendiceal wall, a

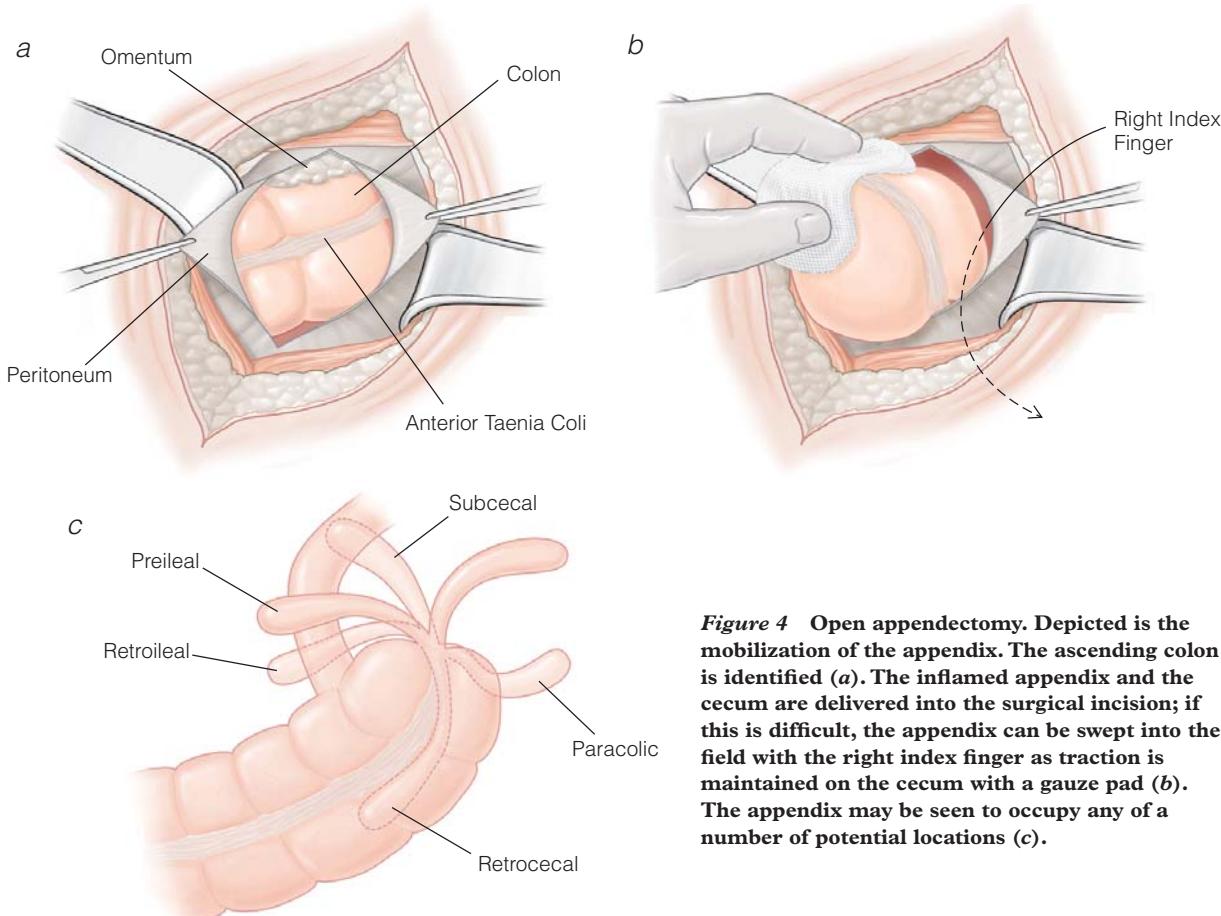

Figure 4 Open appendectomy. Depicted is the mobilization of the appendix. The ascending colon is identified (*a*). The inflamed appendix and the cecum are delivered into the surgical incision; if this is difficult, the appendix can be swept into the field with the right index finger with traction maintained on the cecum with a gauze pad (*b*). The appendix may be seen to occupy any of a number of potential locations (*c*).

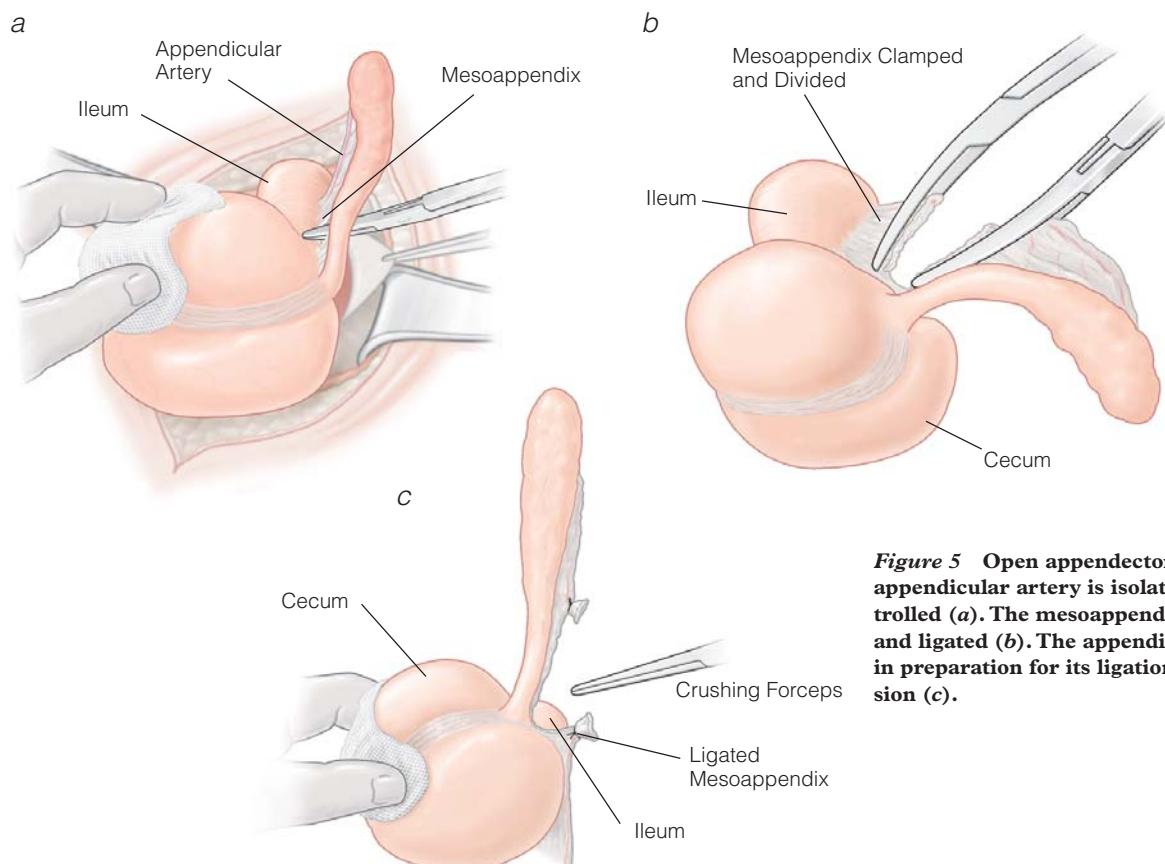

Figure 5 Open appendectomy. The appendicular artery is isolated and controlled (*a*). The mesoappendix is divided and ligated (*b*). The appendix is held up in preparation for its ligation and division (*c*).

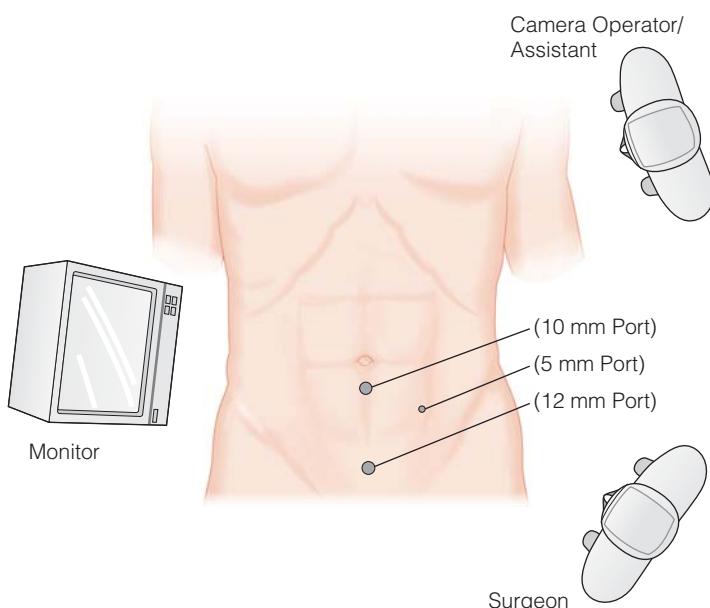

Figure 6 Laparoscopic appendectomy. Shown are the positioning and placement of the operative ports, as well as the recommended positions for the surgeon, the camera operator, and the video monitor.

small portion of the cecum may have to be included within the stapler. To ensure proper placement of the stapler and to prevent injury to the right ureter or the adjacent small bowel, the tips of the stapler must be clearly visualized before the instrument is closed. The use of an angled scope and an articulated rotating laparoscopic GIA stapler (e.g., Roticulator; AutoSuture, Norwalk, Connecticut) will facilitate this maneuver. A noninflamed or minimally inflamed appendix can be ligated with sutures, as described earlier [see Open Appendectomy, above]. The appendix is removed from the abdominal cavity, with care taken to avoid direct contact with the abdominal wall. A mildly inflamed appendix can be delivered through one of the larger ports; a severely inflamed appendix is often too big and hence should be delivered in a specimen retrieval bag [see Figure 9].

The operative field is irrigated and aspirated dry. Hemostasis is confirmed, and the cecum is inspected to ensure proper closure of the appendiceal stump. The ports are removed under direct vision, the absence of back-bleeding from the port sites is confirmed, and the abdomen is completely decompressed. All fascial defects larger than 5 mm are closed with 0 absorbable sutures. The skin incisions are reapproximated with a subcuticular 4-0 absorbable suture and reinforcing Steri-Strips.

Special Considerations

HISTOLOGICALLY NORMAL APPENDIX

Acute appendicitis is the most common cause of an acute surgical abdomen in the United States, and it remains one of the most challenging diagnoses to make in the emergency department. Although the use of advanced diagnostic imaging modalities (e.g., ultrasonography and computed tomography) has led to more accurate diagnosis of acute appendicitis in research settings, it has not been shown to reduce the rate of misdiagnosis of acute appendicitis in the general population.⁴

The incidence of histologically normal appendix in patients with clinical signs and symptoms of acute appendicitis ranges from

8% to 41%.⁵⁻¹⁴ Nonetheless, appendectomy relieves symptoms in the vast majority of these patients. When extensive sectioning is done on histologically normal specimens, it often happens that a focus of inflammation is found in only a few serial sections. This condition is known as focal appendicitis—so called because the polymorphonuclear infiltration is confined to a single focus, while the remaining appendix is devoid of any polymorphonuclear cells.¹⁵ It is not clear that all cases of acute appendicitis arise from this focal inflammation; however, such inflammatory foci may be

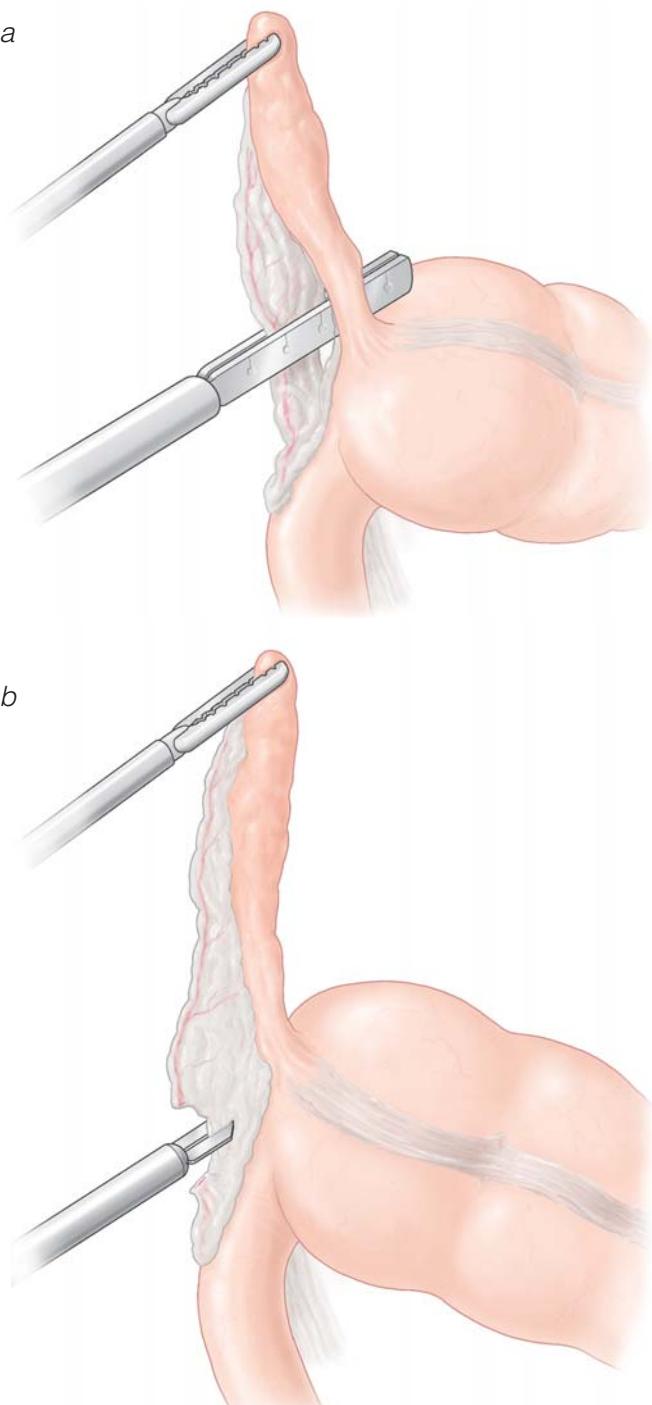

Figure 7 Laparoscopic appendectomy. The mesoappendix is divided either with a laparoscopic GIA stapler (a) or with hemostatic clips and scissors (b).

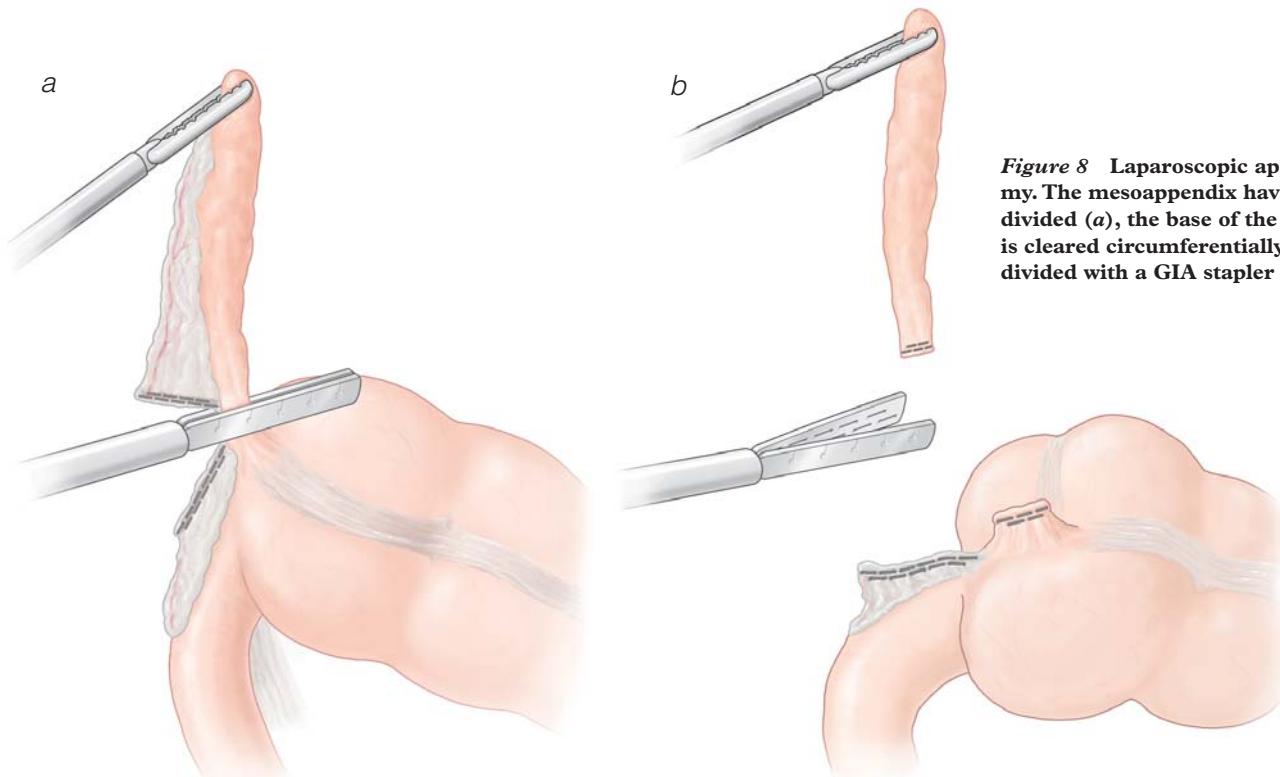

Figure 8 Laparoscopic appendectomy. The mesoappendix having been divided (a), the base of the appendix is cleared circumferentially and divided with a GIA stapler (b).

the earliest recognizable manifestations of appendicitis in some so-called negative appendectomies. Furthermore, a substantial proportion of histologically normal appendices removed from patients with clinical signs and symptoms of acute appendicitis exhibit significantly increased expression of tumor necrosis factor- α and interleukin-2 messenger RNA (a sensitive marker of inflammation in appendicitis) in germinal centers, the submucosa, and the lamina propria.¹⁶ Therefore, appendectomy is recommended in patients with clinically suspected acute appendicitis even when the appendix does not appear inflamed during exploration.¹⁷

Laparoscopic appendectomy has not been shown to reduce the incidence of negative exploration in patients with clinically suspected acute appendicitis [see Complications and Outcome Evaluation, Open versus Laparoscopic Appendectomy, below].

APPENDICEAL NEOPLASM

Neoplastic lesions of the appendix are found in as many as 5% of specimens obtained with routine appendectomy for acute appendicitis.¹⁸⁻²¹ Most are benign. Preoperative detection of such conditions is rare, and intraoperative diagnosis is made in fewer than 50% of cases. Appendectomy alone may be curative for appendiceal mucocele, localized pseudomyxoma peritonei, most appendiceal carcinoids, and other benign tumors. Definitive management of an appendiceal mass unexpectedly encountered during exploration for clinically suspected acute appendicitis depends on whether the tumor is carcinoid, its size and location, the presence or absence of metastatic disease, and histologic and immunohistochemical findings [see Figure 10].

Benign neoplasms of the appendix include mucosal hyperplasia or metaplasia, leiomyomas, neuromas, lipomas, angiomas, and other rare lesions. Appendiceal adenomas tend to be diffuse and to have a predominant villous character. Mucus-producing cystadenomas predispose to appendiceal mucocele, sometimes accompanied by localized pseudomyxoma peritonei. These lesions are

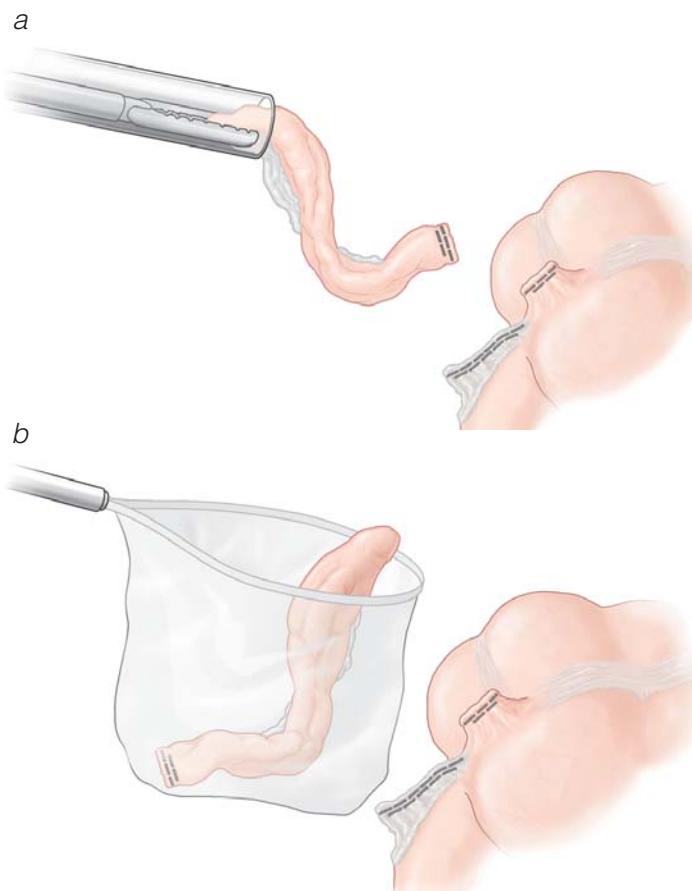

Figure 9 Laparoscopic appendectomy. The specimen is delivered either through one of the larger ports (a) or in a specimen retrieval bag (b).

rarely symptomatic and are often encountered incidentally during operation; however, they may also be clinically manifested as acute appendicitis, torsion, intussusception, ureteral obstruction, or another acute condition. If the base of the appendix is free of disease, appendectomy alone is sufficient treatment.

Malignant tumors of the appendix primarily consist of carcinoids and adenocarcinomas; all together, they account for 0.5% of all GI malignancies.²² The incidence of malignancy in the appendix is 1.35%.¹⁸ Metastasis to the appendix is rare. Carcinoids are substantially more common than adenocarcinomas in the appendix; as many as 80% of all appendiceal masses are carcinoid tumors. Overall, carcinoid tumors are found in 0.5% of all appendiceal specimens, and appendiceal carcinoid tumors account for 18.9% of all carcinoid lesions.²³ These tumors are predominantly of neural cellular origin and have a better prognosis than all other intestinal carcinoid tumors, which typically are of mucosal cellular origin. If the tumor is less than 2 cm in diameter, is located within the body or the tip of the appendix, and has not metastasized, appendectomy is the treatment of choice. If the lesion is at the base of the appendix, is larger than 2 cm in diameter, or has metastasized, right hemicolectomy [see 5:34 Segmental Colon Resection] is indicated. In addition, secondary right hemicolectomy is indicated if the tumor is invasive, if mucin production is noted, or if the tumor is found to be of mucosal cellular origin at final pathologic examination.^{24,25} Patients with metastatic appendiceal carcinoid tumors appear to have a far better prognosis than those with other types of metastatic cancers.²⁴ Therefore, hepatic debulking for symptomatic control is indicated and justified in cases of liver metastasis.

Primary adenocarcinoma of the appendix is rare, and as yet there is no firm consensus regarding prognosis, treatment of choice, and outcome.²⁶ Currently, the recommended treatment is right hemicolectomy: a 1993 study found that this approach resulted in an overall 5-year survival rate of 68%, compared with a rate of 20% when appendectomy alone was performed.²⁵ The prognosis is determined by the degree of tumor differentiation and by the histologic stage. As many as one third of these patients have a second primary neoplasm, which will be located within the GI tract about half the time.

Finally, nonepithelial appendiceal tumors, though extremely rare, occur as well. Such lesions include malignant and Burkitt lymphomas, smooth muscle tumors, granular cell tumors, ganglioneuromas, and Kaposi sarcoma.

INFLAMMATORY BOWEL DISEASE

The appendix is frequently involved in Crohn disease and ulcerative colitis (25% and 50% of cases, respectively), but isolated Crohn disease of the appendix is rare.²⁷⁻³⁰ When a histologically normal appendix is encountered in a patient with active Crohn disease, appendectomy should be performed because of the high risk of recurrent right lower quadrant pain, fever, and tenderness. Although isolated Crohn disease of the appendix may present as acute appendicitis, it is not clear that this condition will necessarily develop into a more extensive form of Crohn disease. Appendectomy is safe in such cases because fistulas almost never develop after appendectomy in patients with isolated involvement of the appendix.

GYNECOLOGIC CONDITIONS

It is clear that the presentation of right lower quadrant pain in a woman remains a challenge to the treating physician. Frequently, the causes can be identified by means of proper blood work or ultrasonography, but often they can be revealed only through sur-

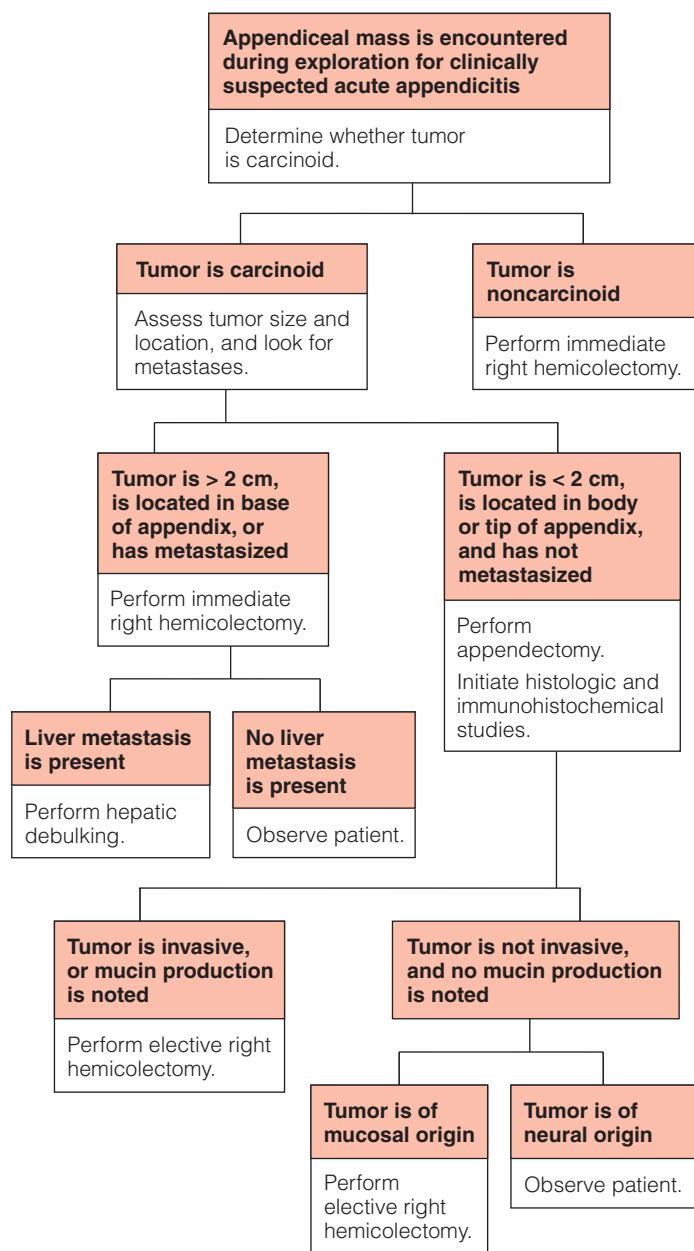

Figure 10 Shown is an algorithm for the management of an appendiceal mass encountered during exploration for clinically suspected acute appendicitis.

gical exploration. In such cases, diagnostic laparoscopy provides an excellent view of the pelvic organs, and it offers the potential for easy continuation on to laparoscopic treatment. Ovarian cysts found in premenopausal women include unilocular clear fluid cysts (e.g., follicular cysts and corpus luteum cysts), dermoid cysts, and endometrial cysts. They can be removed by making an incision on the ovary and separating the cyst from the ovarian cortex. Dermoid cysts should be removed in toto to prevent chemical peritonitis. Endometrial cysts are best evaporated with the laser: complete removal is very difficult and sometimes impossible. Torsion of the fallopian tube or the ovary can be reversed by gentle detorsion of the organ withatraumatic forceps. If there is no evidence of ischemia, no further therapy is indicated. If there is gangrene with no indication of recovery, resection is indicated. If the organ shows partial recovery within 10 minutes after the pedicle is untwisted, a

Table 1 Results of 31 Prospective, Randomized Trials Comparing Laparoscopic Appendectomy with Open Appendectomy³¹⁻⁶¹

Variable	Laparoscopic Appendectomy (N=2,194)		Open Appendectomy (N=2,158)	
	No.	Range	No.	Range
Negative appendix	314 (14.3%)	7.7%–36.0%	319 (14.8%)	0%–35.5%
Conversion to open procedure	223 (10.2%)	0%–23.9%	NA	NA
Surgical site infection	77 (3.5%)	0%–18.3%	144 (6.7%)	0%–17.3%
Intra-abdominal abscess	55 (2.5%)	0%–7.4%	24 (1.1%)	0%–4.6%
Days in hospital	2.7	1–4.9	3.2	1.2–5.3

second-look laparoscopy is indicated in 24 hours. Pelvic inflammatory disease should be treated on an individualized basis in accordance with the degree of inflammation, the patient's age and desire to have children, and the microbiologic findings.

Complications and Outcome Evaluation

OPEN VERSUS LAPAROSCOPIC APPENDECTOMY

To date, 31 reports of randomized, controlled trials comparing laparoscopic appendectomy with open appendectomy have been published as full manuscripts in English [see Table 1].³¹⁻⁶¹ These reports involved a total of 4,352 patients, of whom 2,194 underwent laparoscopic appendectomy and 2,158 underwent open appendectomy. The incidence of histologically normal appendix was similar in the two groups (14.3% with laparoscopic appendectomy versus 14.8% with open appendectomy). The conversion rate from laparoscopic appendectomy to open appendectomy was 10% (range, 0% to 23%). Laparoscopic appendectomy was associated with a lower incidence of postoperative wound infection than open appendectomy was (3.5% versus 6.7%), but it was also associated with a higher incidence of postoperative intra-abdominal abscess (2.5% versus 1.1%). The length of stay was slightly shorter after laparoscopic appendectomy (1 to 4.9 days; average, 2.7 days) than after open appendectomy (1.2 to 5.3 days; average, 3.2 days). Randomized, controlled trials carried out within the past 5 years have not led to any significant changes in the statistical picture.

In men and children with suspected acute appendicitis, laparoscopic appendectomy has no major advantage over open appendectomy.³⁷ In women of childbearing age and in equivocal cases, laparoscopy may be valuable as a diagnostic tool, but the practice of not removing a normal-looking appendix during exploration for right lower quadrant pain is controversial. Laparoscopic appendectomy appears to offer the potential benefit of less postoperative adhesion formation, but the evidence is inconclusive in the light of the short follow-up times reported in these trials, and the higher incidence of intra-abdominal abscess formation remains cause for concern. To date, unfortunately, there have been no studies designed specifically to address reduced adhesion formation as a primary end point.

Although laparoscopic appendectomy is being performed with increased frequency, it continues to be used selectively. The laparoscopic version of the procedure is at least as safe as the corresponding open procedure, but it is undeniably more time-consuming and more costly. Moreover, it remains questionable whether the benefits of laparoscopic appendectomy—reduced postoperative pain, earlier resumption of oral feeding, shortened hospital stay, quicker return to normal preoperative activities, and lower incidence of surgical site infection—outweigh the doubled incidence of postoperative intra-abdominal abscess formation. Further randomized clinical studies focusing on the efficacy of laparoscopic appendectomy as a diagnostic tool and on the incidence of postoperative intra-abdominal abscess and adhesion formation are needed, as are additional cost analyses.

32 PROCEDURES FOR DIVERTICULAR DISEASE

Jeffrey L. Cohen, M.D., F.A.C.S., F.A.S.C.R.S., and John P. Welch, M.D., F.A.C.S.

Preoperative Evaluation

The extent of the preoperative evaluation received by patients undergoing surgical treatment of diverticular disease is dictated predominantly by the urgency of the situation. Whereas patients with recurrent symptoms will undergo repeated assessments with myriad diagnostic tests before the decision is made to proceed with surgical intervention, patients with perforated diverticulitis may have only a chest x-ray documenting free air before they are taken to the operating room. Given the varied complications of diverticular disease and the numerous options for surgical treatment, we believe it is most convenient to divide the relevant operations into emergency procedures and elective procedures. Such a division facilitates discussion of technical issues, preoperative evaluation, and management of complications.

As noted, in the emergency setting, a demonstration of pneumoperitoneum may be the only workup performed. In fact, in most patients with perforated diverticulitis, pneumoperitoneum is the initial presentation.^{1,2} In patients who present with massive lower GI hemorrhage, angiographic demonstration of the bleeding site is known to reduce operative mortality, even if therapeutic superselective embolization is unsuccessful in controlling the bleeding.^{3,4} The other complication of diverticular disease that may necessitate an emergency operation is colonic obstruction. A careful history may reveal progressive obstructive symptoms, but if the patient presents with complete obstruction and cecal dilatation, urgent decompression is required. In this setting, retrograde administration of a water-soluble enema may be very helpful—at least for delineating the level of the obstruction, if not the specific cause.^{1,5} Communication with the radiologist should be maintained to prevent both overly forceful instillation of the contrast material and the use of barium, which may cause problems if the agent cannot be evacuated.

When surgical treatment of diverticular disease is to be performed in the elective setting, a detailed preoperative evaluation is imperative [see 5:12 *Diverticulitis*]. The key point here is that objective evidence of diverticulitis must be obtained at some point in the care of the patient. Too often, symptoms of irritable bowel syndrome are confused with those of diverticulitis, with the result that the patient carries an incorrect diagnosis.⁶⁻⁹ In the most common scenario, computed tomographic scanning is performed when a patient is experiencing left-side pain, possibly associated with fever, nausea, anorexia, or abdominal distention. A finding of pericolonic inflammation in an area of diverticulosis is the definitive radiographic presentation.^{10,11} Preoperative endoscopic evaluation of the colon, whenever feasible, is extremely valuable not only for confirming the presence of diverticulosis but also for ruling out inflammatory bowel disease or even a neoplastic lesion.

It is possible to expend a great deal of effort on trying to demonstrate a diverticular fistula. In many circumstances, however, this task proves difficult to accomplish. In our view, demon-

stration of a diverticular fistula should not be considered a mandatory precondition for operative treatment. A strong history of either a colovaginal or a colovesical fistula with suggestive findings on CT scans (e.g., air in the bladder or pericolonic inflammation contiguous with either the bladder or the vagina) constitutes a sufficient indication for surgical resection.^{12,13}

Operative Planning

In planning the operative approach to a patient with diverticular disease, the major decision is whether to perform a one-stage or a two-stage procedure. Traditionally, an emergency operation for perforation, obstruction, or massive bleeding includes a temporary stoma procedure to eliminate the risk of anastomotic leakage.^{14,15} The operation most commonly performed in this setting is the Hartmann procedure [*see Emergency Procedures, Hartmann Procedure, below*], named after Henri Hartmann, who first described the use of this operation to treat colon cancer in 1923.¹⁶ The obvious advantage of the Hartmann procedure is that it removes the inflammatory focus without putting the compromised patient at risk for anastomotic leakage. Unfortunately, to restore intestinal continuity after this procedure, it is necessary to perform a potentially difficult second operation; as many as one third of patients never undergo reversal of their colostomy.^{17,18}

Another therapeutic option is to perform a primary anastomosis with a diverting loop ileostomy instead of a colostomy. In this situation, the risk of anastomotic leakage with possible fecal peritonitis is still avoided, but only a relatively minor second procedure is necessary to reverse the ileostomy.¹⁹ Occasionally, it may be appropriate to perform on-table colonic lavage with a primary anastomosis. This approach is most useful in the setting of colonic obstruction secondary to a diverticular stricture in a patient who is otherwise hemodynamically stable but has a large fecal load proximal to the intended anastomosis.^{20,21}

Laparoscopic intestinal surgery has shown tremendous development of late, benefited both by significant technological improvements and by growing surgical experience with advanced laparoscopic procedures.^{22,23} Newer approaches (e.g., hand-assisted techniques) have markedly reduced the learning curve and shortened the operating time.^{24,25} Consequently, minimal access surgery is rapidly becoming the approach of choice in the management of uncomplicated diverticular disease.²⁶⁻²⁹

Emergency Procedures

Patient setup and positioning are similar for all emergency operations. The patient is placed in a modified lithotomy position to facilitate access to the rectum. Urinary drainage with a Foley catheter and temporary gastric decompression with a nasogastric tube are performed. When feasible, the stoma is marked by an enterostomal therapist before operation.

HARTMANN PROCEDURE

Step 1: Incision and Initial Exploration

A lower midline incision is made and extended above the umbilicus as necessary. The abdomen is thoroughly explored to confirm the diagnosis of diverticular disease and to wash out any gross fecal spillage. A self-retaining retractor (e.g., a Bookwalter retractor) is placed, with care taken to pad the abdominal wall.

Step 2: Mobilization and Division of Sigmoid Colon

The patient is placed in the Trendelenburg position, with the small bowel carefully retracted into the upper abdomen. The sigmoid colon is mobilized away from the lateral peritoneal attachments. Mobilization is continued into the pelvis lateral to the upper portion of the rectum.

Troubleshooting If a severe phlegmon is stuck to the pelvic sidewall, it may be helpful at some point in the mobilization to dissect cephalad from below the mass so as to isolate the area from above and below.

Step 3: Identification of Ureter

As the sigmoid colon is retracted medially, the ureter can usually be identified where it crosses over the bifurcation of the iliac vessels. The gonadal vessels are usually identified first; the ureter lies slightly medial and deep to them [see Figure 1].

Step 4: Division of Sigmoid Colon

The proximal sigmoid colon is divided through noninflamed tissue with a linear cutting stapler [see Figure 2a]. The sigmoid vessels are sequentially divided (with attention paid to their relation to the left ureter) up to the rectosigmoid junction, which is identified by the loss of the taeniae coli. The rectum is then transected through noninflamed tissue with a linear cutting stapler [see Figure 2b].

Troubleshooting The top of the rectal stump can be marked with a nonabsorbable suture to facilitate subsequent identification.

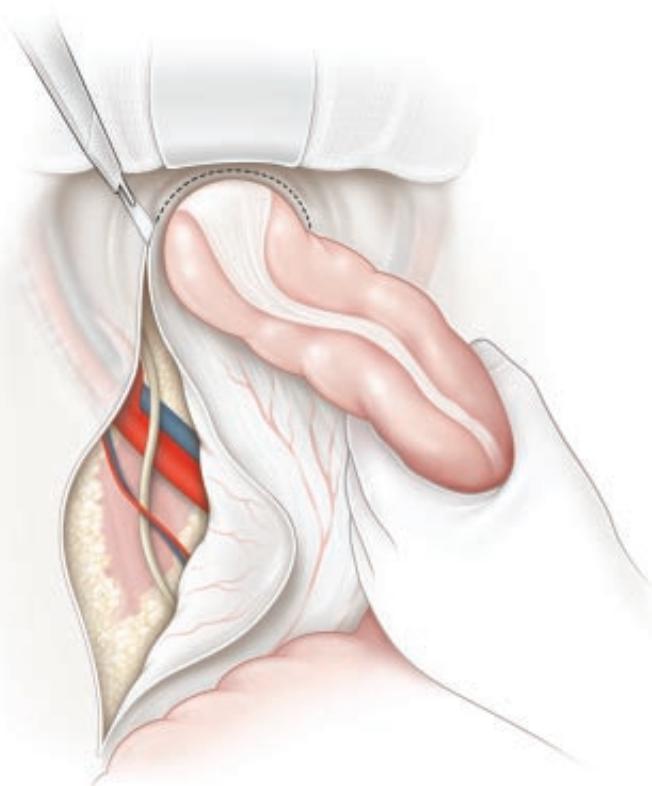

Figure 1 Hartmann procedure. Illustrated is the relation of the ureter to other structures in the left lower quadrant.

Step 5: Construction of Colostomy

The proximal colon is delivered through the previously marked stoma site in the left lower quadrant with a muscle-splitting incision in the rectus abdominis (with care taken not to twist it on its mesentery), and a colostomy is created [see 5:30 Intestinal Stomas].

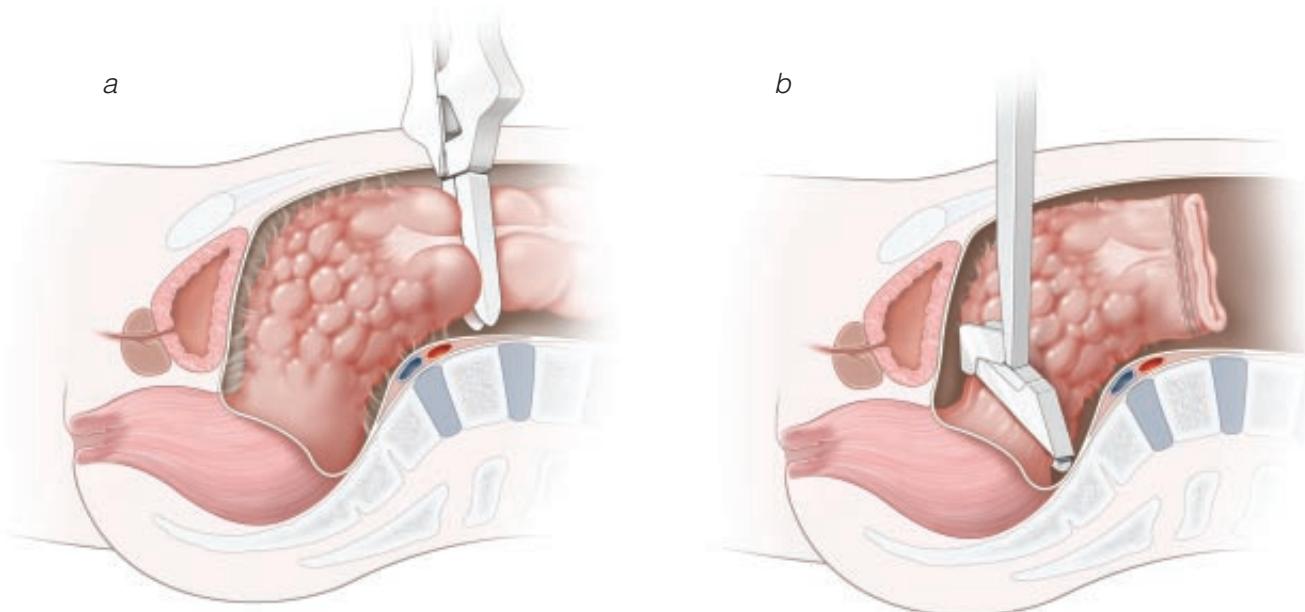

Figure 2 Hartmann procedure. (a) The colon is divided above the level of the inflammatory mass. (b) The rectum is divided below the inflammatory mass; division must be through normal tissue.

Step 5—Alternative (Primary Anastomosis with Diverting Ileostomy): Creation of Colorectal Anastomosis

As an alternative to a colostomy, the surgeon may elect to perform a primary colorectal anastomosis with a diverting ileostomy. (Such an anastomosis is described in more detail elsewhere [see 5:35 Procedures for Rectal Cancer].) The anvil of a circular stapler is positioned in the proximal colon, and a purse-string suture is placed around it. If there is any gaping of the tissue around the shaft of the anvil, a second suture may be added for reinforcement.

The stapler is inserted through the anus, with the shaft being brought out either through the anterior wall of the rectum or through the top of the rectal stump, adjacent to the staple line. The stapler is then engaged, with care taken to ensure that no extraneous tissue is caught between the body of the stapler and the anvil and that the proximal bowel is not twisted on its mesentery. The stapler is fired to create the anastomosis, and the integrity of the anastomosis is tested by occluding the proximal bowel and placing the anastomotic area under water while air is insufflated into the rectum via a rigid proctoscope.

Troubleshooting It is helpful to divide the mesentery where it is draped over the anvil. This measure diminishes the risk of bleeding from the circular staple line while also providing a greater length of colon for the anastomosis. If there is any question regarding possible tension on the anastomosis, the splenic flexure should be fully mobilized.

Step 6—Alternative (Primary Anastomosis with Diverting Ileostomy): Construction of Loop Ileostomy

A loop ileostomy is created in the right lower quadrant, using a muscle-splitting incision in the rectus abdominis [see 5:30 Intestinal Stomas]. Loop ileostomies can usually be designed to be diverting; however, stapling the distal end and leaving it at skin level will ensure complete diversion.

Troubleshooting If there is a column of stool between the ileostomy and the anastomosis, it should be washed out before the ileostomy is completed.

ON-TABLE COLONIC LAVAGE

Steps 1 through 4

Steps 1, 2, 3, and 4 of on-table colonic lavage are the same as the first four steps of the Hartmann procedure.

Step 5: Mobilization of Flexures

After the sigmoid resection, the hepatic flexure and the splenic flexure are carefully mobilized to facilitate the washout process.

Step 6: Placement of Tubing

Corrugated anesthesia tubing is placed in the colon proximal to the resected segment and secured in place with umbilical tape. The distal end of the tubing is passed off the operating table and is connected to a device that collects the effluent [see Figure 3].

Step 7: Construction of Appendicostomy

An appendicostomy is performed, a Foley catheter is placed, and a purse-string suture is tied around the tube with the balloon inflated. If the patient has previously undergone appendectomy, the terminal ileum is used instead.

Step 8: Irrigation of Colon

The colon is washed with an irrigant until the effluent is relatively clear. It may be necessary to manipulate the colon so as to initiate flushing of formed stool.

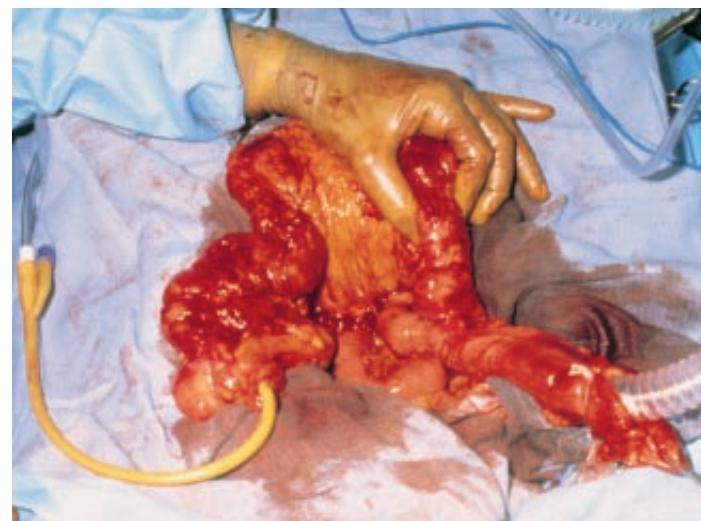

Figure 3 On-table colonic lavage. Shown is full mobilization of the colon, with corrugated anesthesia tubing secured in the colon and connected to a collection system. A Foley catheter is inserted through an appendicostomy into the base of the cecum.

Step 9: Excision of Appendix and Creation of Colorectal Anastomosis

A formal appendectomy is performed [see 5:31 Appendectomy]. The corrugated anesthesia tubing is removed from the colon, and a colorectal anastomosis is performed, usually with a circular stapler.

Elective Procedures

OPEN RESECTION

Open resection in the elective setting consists of steps 1 through 4 of the Hartmann procedure, followed by creation of a primary colorectal anastomosis and a diverting loop ileostomy (alternative steps 5 and 6) [see Emergency Procedures, Hartmann Procedure, above].

LAPAROSCOPIC RESECTION

The patient is placed in a low lithotomy position with minimal hip flexion. The right arm is well padded and tucked at the side because both surgeons will be operating from the right side of the table. Video monitors are placed on both sides of the table. It is beneficial to place the patient on a bean bag because a significant portion of the operation will be performed with the patient in extremes of positioning.

Step 1: Placement of Trocars

The first port is placed at a periumbilical location by means of an open Hasson approach, and a 30° laparoscope is inserted. After pneumoperitoneum is achieved, the other ports are placed under direct vision: 5 and 12 mm ports are placed in the right lower quadrant, and an optional 5 mm port may be placed in the midepigastrium [see Figure 4]. The midepigastric port facilitates mobilization of the left colon and is essential for mobilization of the splenic flexure.

Step 2: Mobilization of Sigmoid Colon

After the abdomen has been explored, the patient is placed in a steep Trendelenburg position, with the right side tilted down. This

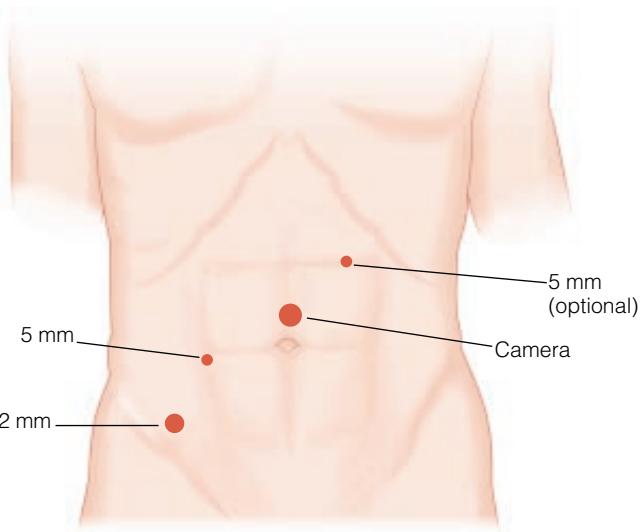

Figure 4 Laparoscopic sigmoid resection. Shown is recommended port placement. The midepigastric 5 mm port is essential for mobilization of the splenic flexure.

position allows gravity to retract the small bowel into the upper abdomen. The sigmoid colon is mobilized from its lateral peritoneal attachments, and the colon is thereby converted to a midline structure. Mobilization is extended superiorly along the descending colon and inferiorly to the pelvic cul-de-sac. The left ureter is then identified and swept laterally away from the base of the mesentery.

Alternative approach to colonic mobilization and division In place of the conventional approach (see above), a medial-to-lateral approach can be undertaken. In this approach, the

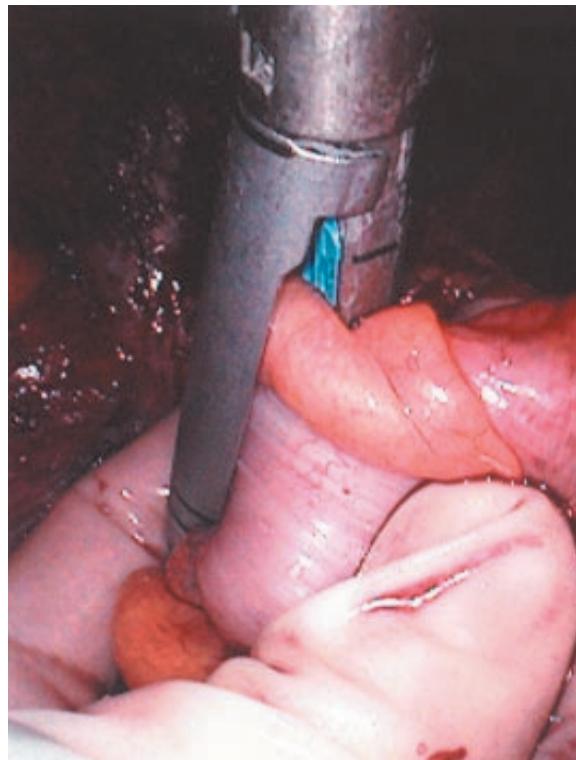

Figure 5 Laparoscopic sigmoid resection. Shown is division of the rectum with the endoscopic stapler.

initial dissection proceeds from the right side of the colon, mobilizing the superior rectal vessels from the sacral promontory. The left ureter is then visualized through the window thus created before the sigmoid mesentery is divided. Division of the sigmoid mesentery is performed in a proximal-to-distal direction, with the inferior mesenteric vessels generally divided first. Once the sigmoid mesentery has been completely divided, the bowel is transected with staplers at the rectosigmoid junction.

The advantage of the traditional approach is that surgeons are more familiar with it from corresponding open procedures. In our view, given the difficulty of mastering laparoscopic colon surgery, the medial-to-lateral approach to colonic mobilization only increases the steepness of the learning curve without affording any significant benefit.

Step 3: Division of Rectum and Sigmoid Mesentery

An incision is made in the peritoneum along the right side of the rectosigmoid mesentery and extended inferiorly to the pelvic cul-de-sac. A window is created between the upper rectum and its mesentery and enlarged to allow insertion of an endoscopic gastrointestinal anastomosis (GIA) stapler [see Figure 5]. The stapler is then fired once or twice to divide the rectosigmoid bowel. The mesentery of the sigmoid colon is sequentially divided with staplers, clips, an ultrasonic scalpel, or the LigaSure system (Valleylab, Boulder, Colorado).

Step 4: Exteriorization of Sigmoid Colon

Once the colon is mobilized and the blood supply divided, either a left lower quadrant muscle-splitting incision or a Pfannenstiel incision is made to exteriorize the bowel, which is then divided proximally. The anvil of a circular stapler is inserted in the proximal colon and secured with a purse-string suture. The bowel is then replaced into the abdomen, and the incision is closed.

Step 5: Creation of Colorectal Anastomosis

After pneumoperitoneum is recreated, the circular stapler is inserted transanally. The shaft is brought out either through the top of the rectal stump or through the anterior wall of the rectum [see Figure 6]; the former is preferred if bowel length is an issue. After the stapler is engaged but before it is fired, the proximal colon is inspected to confirm that it is not twisted. The stapler is

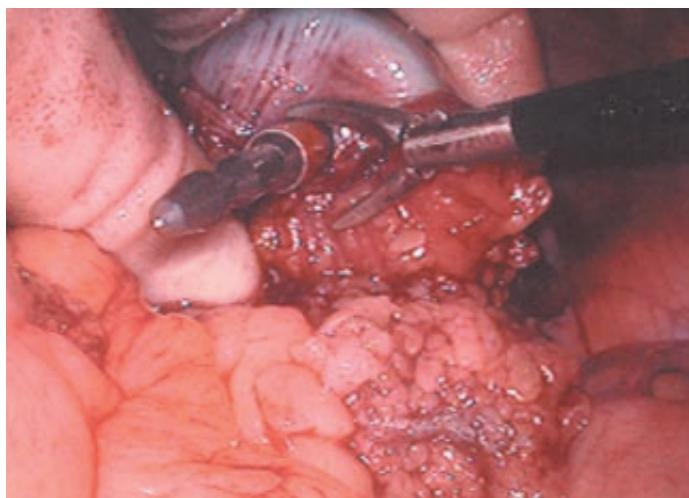

Figure 6 Laparoscopic sigmoid resection. The shaft of the circular stapler is guided through the top of the rectal stump by applying countertraction with a laparoscopic instrument.

then fired, and the anastomosis is then tested under water to confirm the absence of an air leak.

HAND-ASSISTED LAPAROSCOPIC RESECTION

Steps 1 and 2

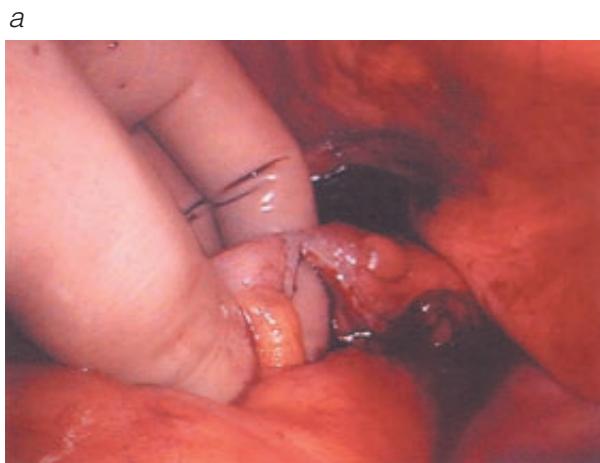

The first two steps of a hand-assisted laparoscopic resection are identical to steps 1 and 2 of a full laparoscopic resection.

Step 3: Placement of Hand Device

A 6 to 8 cm muscle-splitting incision is made in the left lower quadrant, and the hand device is placed [see Figure 7]. The surgeon's left hand is placed through this device into the abdomen.

Step 4: Division of Rectum and Sigmoid Mesentery

The surgeon's left hand is used to facilitate creation of a window between the rectum and the underlying mesentery. An endoscopic GIA stapler is safely guided through this window, and the bowel is divided [see Figure 8a]. The hand is then used to isolate segments of the mesentery for division [see Figure 8b], as well as to help control vessels that continue to bleed despite having been divided.

Steps 5 and 6

Steps 5 and 6 are identical to steps 4 and 5 of a full laparoscopic resection.

Troubleshooting Having the surgeon's hand in the pelvis greatly facilitates engagement of the circular stapler and makes its closure safer by protecting the surrounding structures [see Figure 9]. Furthermore, the presence of the hand in the pelvis not only assists in testing the anastomosis but also helps the surgeon better assess the degree of tension (if any) on the anastomosis. Given that the size of the hand port is similar to that of the extraction site in a full laparoscopic resection, we prefer the hand-assisted technique on the basis of its greater safety and its ability to restore a measure of tactile sense and proprioception to the surgeon.

LAPAROSCOPIC HARTMANN CLOSURE

Step 1: Placement of Trocars

A port is placed by means of the Hasson technique at an upper midline location, cephalad to the previous incision if possible. A 30° laparoscope is inserted through this port. After pneumoperitoneum is achieved, two 5 mm ports are placed in the right lower quadrant to facilitate dissection of pelvic and midline adhesions as necessary.

Step 2: Mobilization of Colostomy and Rectal Stump

All adhesions and attachments should be cleared away from the intra-abdominal portions of the colostomy [see Figure 10]. In addition, the top of the Hartmann pouch should be cleared of all adherent small bowel or adjacent structures. Occasionally, other ports may have to be placed to facilitate takedown of adhesions, especially those from the original midline incision. The colostomy is detached from the skin circumferentially. The anvil of a circular stapler is then placed in the proximal bowel after the exposed portion of the colostomy has been resected.

Step 3: Placement of Hand and Completion of Anastomosis

The colostomy site is enlarged slightly so that the surgeon's left hand can be placed in the abdomen. The stapler is engaged and fired while the surgeon's hand keeps any extraneous tissue away from the anastomotic area. The anastomosis is then tested by placing it under water and insufflating air via a proctoscope.

Troubleshooting It is often easier to bring out the shaft of

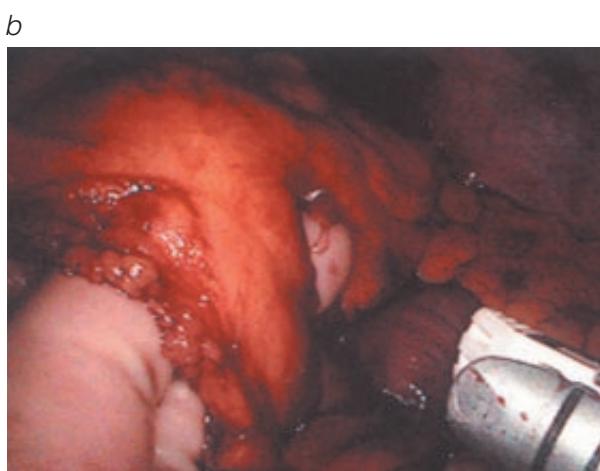

Figure 8 Hand-assisted laparoscopic resection. (a) Placement of the surgeon's hand intracorporeally facilitates division of the rectum. (b) The surgeon's hand isolates mesenteric vessels for subsequent division.

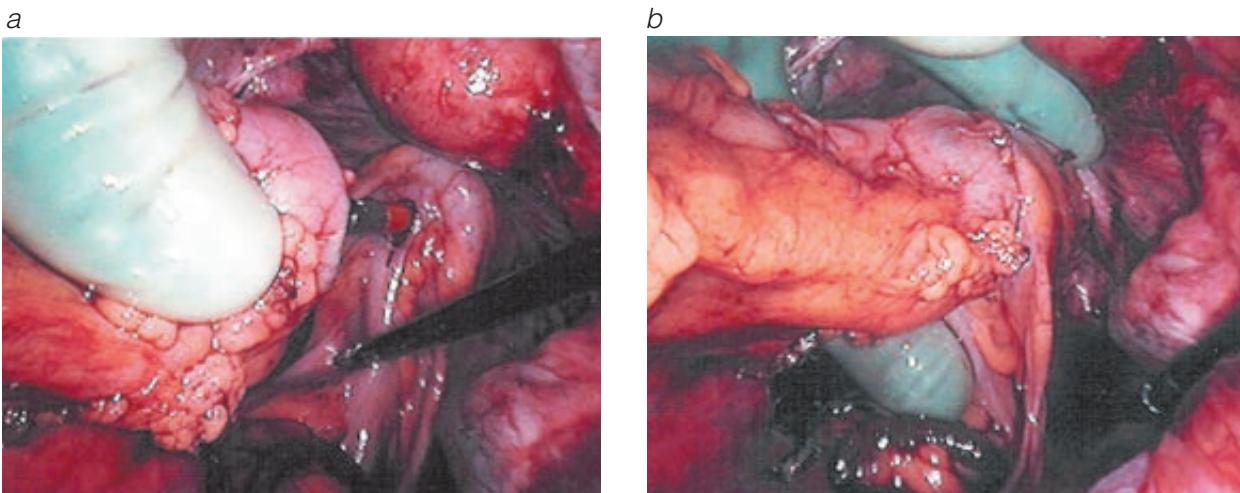

Figure 9 Hand-assisted laparoscopic resection. The surgeon's hand guides engagement of the circular stapler, protecting surrounding pelvic structures.

the stapler through the anterior wall of the rectum, especially if there has been a significant inflammatory response around the area of the Hartmann pouch.

Complications

Operative management of diverticular disease poses distinct challenges, the level of which is proportional to the degree of inflammation present and to the urgency of the procedure. Whereas many of the complications encountered are not specific to this setting but are common to all abdominal procedures, there are several that warrant particular attention in the context of surgical treatment of diverticular disease.

ANASTOMOTIC LEAKAGE

The most serious and potentially life-threatening complication of procedures for diverticular disease is the development of an anastomotic leak. Many factors contribute to the maintenance of anastomotic integrity, ranging from the surgeon's technical ability to the patient's comorbidities. Of these factors, however, the single most important one is probably the setting in which the operation is carried out. Patients undergoing emergency procedures are at four

times higher risk for anastomotic leakage than those undergoing elective procedures.^{30,31} Furthermore, mortality is 13% in patients presenting with purulent peritonitis and 43% in those presenting with feculent peritonitis; these figures suggest that performing an anastomosis in these settings is unwise.^{14,15,32,33}

As with any anastomosis, the long-established basic technical principles—using healthy, uninflamed tissue; ensuring an adequate blood supply; and avoiding tension on the anastomosis—should be strictly adhered to. If any of these principles cannot be followed, then either the patient should undergo proximal diversion or (preferably) the problem with the anastomosis should be corrected. For instance, in a situation where the sigmoid inflammatory process extends into the rectal mesentery, attempts should be made to resect below the level of the inflammation, even if the process is reaching well into the rectum itself. Another technical point worth mentioning involves preserving the superior rectal vessels, though no randomized, prospective study has yet been performed to determine whether this measure has any significant positive effect.

RECURRENT DISEASE

It is unusual for a recurrent diverticular fistula to develop after takedown with resection of the involved colon. Much more likely than the persistence of a diverticular fistula is the development of a recurrent colovesical or colovaginal fistula secondary to an anastomotic leak with drainage through the point of least resistance (i.e., the anastomosis).

There is some question as to whether a recurrence of diverticulitis after sigmoid resection is actually a complication of the procedure. Although it has been shown that resection of all diverticulum-bearing colon is not required for successful treatment of the disease process, it does appear that the location of any remaining diverticulosis influences the recurrence of the disease. Studies have demonstrated that if a sigmoid resection with a colorectal anastomosis is performed, the recurrence rate is 5%, whereas if the anastomosis is performed to the distal sigmoid colon, the recurrence rate rises to 12%.^{34,35} When recurrent diverticulitis develops, it is important to reexamine the histologic findings from the original operation to rule out the possibility that the patient was misdiagnosed. Occasionally, diverticulosis and Crohn disease coexist; recurrence of Crohn disease is much more common than recurrence of diverticulosis and, given a long enough follow-up period, is actually to be expected.

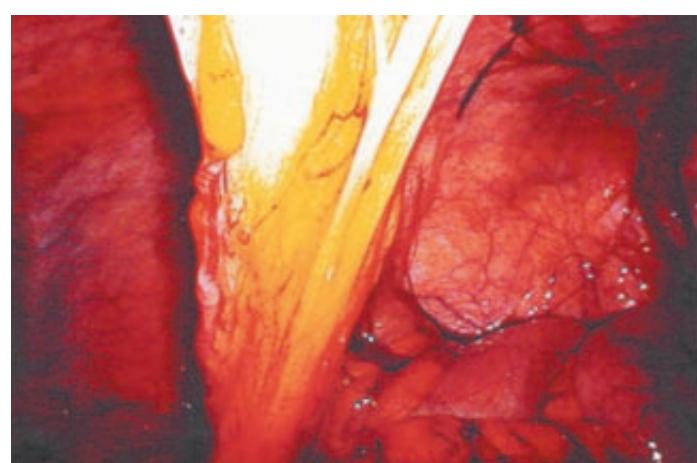

Figure 10 Laparoscopic Hartmann closure. Shown is a laparoscopic view of the colostomy after intra-abdominal adhesions have been divided.

URETERAL INJURY

Ureteral injuries occur in as many as 1% of patients undergoing diverticular resection.³⁶ Because of the inflammatory process associated with severe diverticular disease, it may be difficult to identify the ureter as it crosses the bifurcation of the iliac vessels; however, it is always possible to identify the ureter more proximally and then

follow it down to the inflamed area. If a difficult dissection is anticipated or if technical difficulties are encountered intraoperatively, ureteral stents may be placed. These stents do not prevent injuries from occurring, but they can facilitate early identification of developing problems. Ureteral injuries should always be repaired at the time of operation, in consultation with the urologist.

33 PROCEDURES FOR ULCERATIVE COLITIS

Robert R. Cima, M.D., F.A.C.S., F.A.S.C.R.S., Tonia Young-Fadok, M.D., M.S., F.A.C.S., F.A.S.C.R.S., and John H. Pemberton, M.D., F.A.C.S., F.A.S.C.R.S.

Chronic ulcerative colitis (CUC) is one of the two main categories of inflammatory bowel disease (Crohn disease being the other). CUC is characterized by contiguous inflammation of the mucosa, beginning in the rectum and progressing for variable distances proximally within the colon. Its cause is unknown. Patients typically experience intermittent exacerbations of the disease, which are notable for bloody diarrhea associated with urgency and tenesmus. In a minority of patients, the first episode of the disease is a fulminant presentation that may be fatal without prompt surgical intervention.

Medical therapy for CUC is aimed at controlling symptoms or managing the underlying inflammatory process; it does not cure either the intestinal or the extraintestinal manifestations of CUC. The intestinal manifestations of CUC and the associated risk of malignancy can, however, be effectively cured by surgical intervention, which involves removal of the entire large intestine. In what follows, we discuss the indications for surgical treatment of CUC and describe the surgical options.

Preoperative Evaluation

INDICATIONS FOR OPERATION

Surgical treatment of CUC is indicated in a variety of situations. The easiest classification scheme divides these indications into two broad categories: indications for emergency operation and indications for elective operation.

Emergency Operation

The main conditions calling for emergency operative treatment of CUC are fulminant colitis, toxic megacolon, and massive hemorrhage. In these situations, the primary surgical strategy is to remove the bulk of the diseased colon to allow the patient's medical condition to improve; an important secondary consideration is to perform an operation that will not preclude a future restorative procedure.

Fulminant colitis Although as a rule, CUC is a chronic disease that allows deliberate and coordinated care, approximately 10% of patients initially present with severe disease.¹ Fulminant colitis is characterized by the sudden onset of severe and frequent (> 10/day) bloody bowel movements, abdominal pain, dehydration, and anemia. Diagnostic criteria for fulminant colitis (originally described by Truelove and Witts in 1955) include the above signs and symptoms and at least two of the following: tachycardia, body temperature higher than 38.6° C (101.5° F), leukocytosis (> 10,500/mm³), and hypoalbuminemia.²

Patients with fulminant colitis are extremely ill and require rapid, aggressive medical therapy, including fluid resuscitation, correction of electrolyte abnormalities, and, in some cases, blood transfusions. A nihil per os (NPO) regimen is indicated. Naso-

gastric tube decompression may be required if colonic distention is a component of the presentation. If CUC is known to be present, high-dose intravenous steroid administration should be initiated, and stool cultures should be obtained. If no diagnosis of CUC has yet been made, endoscopic evaluation of the colon should be carried out expeditiously, with the aim not of assessing the entire colon but only of visualizing the rectal and distal colonic mucosa. If the results of the endoscopic examination are obviously consistent with CUC, the endoscope can be withdrawn; the remainder of the colon need not be evaluated.

If the patient is clinically stable, antibiotic therapy is not indicated. If, however, the patient is very ill or has a high fever or leukocytosis, administration of appropriate broad-spectrum antibiotics should be initiated after cultures are obtained. The patient should be observed closely for 24 to 48 hours while on maximal medical therapy. If there is no improvement or if the patient's condition deteriorates, surgical treatment is recommended. If there is evidence of peritonitis, hemodynamic instability, or perforation, the patient should be operated on immediately.

Toxic megacolon Toxic megacolon may be the initial presentation of ulcerative colitis or may represent a flare in a patient with long-standing disease. Either the entire colon or an isolated segment of the colon (usually the transverse or the left colon) is involved. Although a radiographic definition of toxic megacolon exists (i.e., greater than 5.5 cm dilatation of the transverse colon on a supine abdominal film), toxic megacolon is truly a clinical diagnosis.

Medical treatment of toxic megacolon is similar to that of fulminant colitis—namely, an NPO regimen, nasogastric tube decompression, correction of fluid deficits and electrolyte abnormalities, administration of high-dose steroids, and initiation of antibiotic therapy if there is fever or an elevated leukocyte count. Emergency surgical management is indicated if the patient's clinical or radiographic status worsens, if there is evidence of perforation, or if there is no improvement 24 to 36 hours after aggressive medical therapy is begun. Delaying the operation increases the risk of perforation, which raises mortality from less than 5% to nearly 30%.¹ Fortunately, fewer patients are now seen with severe complications of CUC than was once the case, primarily because of improved medical therapies and a general trend toward earlier surgical intervention for CUC.

Other surgical emergencies Colonic perforation without megacolon should raise concern that the actual diagnosis might be Crohn disease or that there might be another cause for the perforation (e.g., a gastric or duodenal ulcer related to steroid use). Whatever the cause of the perforation, there is no role for conservative therapy, and the patient should immediately undergo surgical exploration.

Hemorrhage severe enough to result in hemodynamic insta-

bility is an unusual complication of CUC. Decisions regarding intervention are made after consultation with the treating gastroenterologist. Initial treatment should consist of aggressive fluid and blood-product resuscitation. Any electrolyte or clotting deficiencies should be corrected. Upper GI endoscopy should be done to exclude the possibility that a gastric or duodenal ulcer is causing the bleeding. The timing of operation is determined by the clinical situation. If the patient is hemodynamically unstable even after effective resuscitation, emergency operation is indicated because medical therapy would take too long to decrease the mucosal inflammation responsible for the bleeding. If there is slow but continuing hemorrhage that does not cause hemodynamic instability or symptoms, high-dose steroid therapy may be tried for 48 to 72 hours before surgical intervention is considered.

Elective Operation

Given the chronic nature of CUC, the indications for elective operation may occur early in the course of a patient's disease or may arise after years of relatively mild disease. The major indications for elective surgical treatment of CUC are failure of medical management to control symptoms (intractability) and the presence of mucosal dysplasia, dysplasia-associated lesion or mass (DALM), or malignancy. Elective surgical treatment may also be indicated in patients with extraintestinal manifestations of CUC and children with growth retardation.

Intractable symptoms Intractability is a clinically defined condition that can occur in either the acute or the chronic state of CUC. In an acute flare, intractability refers to the inability to control a patient's symptoms with maximal medical therapy; in the chronic state, it refers to either the inability to taper steroids to a reasonable maintenance dose or the development of severe drug-related side effects.

In most cases, medical management of an acute CUC flare consists of I.V. steroid therapy for 5 to 10 days. If this approach does not bring about clinical improvement, elective operation is advisable. One study recommended I.V. or oral cyclosporine therapy for patients who are experiencing an acute flare of CUC that does not respond to I.V. steroid therapy³; however, a subsequent report involving a larger number of patients and a longer follow-up period showed that nearly 50% of all patients treated in this manner required colectomy within 1 year.⁴ During the treatment period for acute disease, it is important that the patient receive adequate nutritional support (often in the form of total parenteral nutrition). If the patient's nutritional status declines significantly, a three-stage procedure may be necessary to improve surgical outcome.⁵

Dysplasia or malignancy The development of malignancy in the setting of CUC has been well described. The risk of colon cancer in a CUC patient has been estimated to be anywhere from 2% at 20 years after onset of CUC to 43% at 35 years.⁶ A patient's individual risk level for colon cancer appears to increase when there is evidence of high-grade dysplasia on random colon biopsies or if there is a DALM. The presence of low-grade dysplasia on random biopsy is a more difficult clinical situation. Traditionally, most clinicians have recommended increases in the frequency of surveillance colonoscopies rather than surgery. There are, however, some preliminary reports suggesting that the presence of any degree of dysplasia not associated with a mass lesion should be viewed with a very high degree of suspicion and that surgery should be recommended⁷; this has

become our practice. In addition, any colonic stricture significant enough to cause obstructive symptoms, even if it appears benign on endoscopy, should be considered to be potentially harboring a malignancy and should be treated surgically.

When there is a suspected or known colonic or rectal malignancy, the surgical options should be driven by oncologic principles. In most patients, except for those with low rectal cancers or metastatic disease, total colectomy with ileal pouch-anal anastomosis (IPAA) is an acceptable surgical treatment modality. There is a particular concern regarding the performance of an IPAA in the setting of a rectal cancer, in that the required irradiation may severely compromise pouch function. Stage for stage, the prognosis for patients with malignancies who have CUC is generally similar to that of patients with malignancies who do not have CUC. CUC patients who have undergone surgical treatment, particularly with an IPAA procedure, tolerate chemotherapy as well as patients without CUC do.⁸⁻¹⁰ As a rule, if oncologic principles are not compromised, an IPAA procedure can be performed without any deleterious impact on oncologic outcome or long-term IPAA function.

Operative Planning

CHOICE OF PROCEDURE

Currently, there are two widely accepted surgical options for the treatment of CUC: total proctocolectomy with end (Brooke) ileostomy and total proctocolectomy with IPAA. A third option, total abdominal colectomy with ileorectal anastomosis, may be considered in highly select groups of patients—namely, those who have relatively mild disease and who have a contraindication to an ostomy (e.g., portal hypertension or ascites) and those in whom an ileal pouch procedure would be technically impossible and who refuse an ileostomy. Previously, a fourth option, proctocolectomy with construction of a continent ileostomy (or Kock pouch), was employed; however, this procedure was associated with such a high rate of pouch dysfunction (requiring surgical correction in the majority of patients) that it is no longer performed. For this reason, as well as because the IPAA procedure has yielded outstanding functional results, the continent ileostomy is now of historical interest only and thus will not be discussed further.

The choice of surgical procedure is individualized on the basis of the patient's underlying physical and medical condition, as well as of his or her social and psychological situation. At present, proctocolectomy with IPAA (first described in 1978^{11,12}) is the preferred operation for most patients because it removes the diseased colon while preserving fecal continence and nearly normal defecation through the anus. Construction of the ileal pouch is the key to the success of this operation: the pouch provides a fecal reservoir that is adequate to allow voluntary defecation, albeit at a higher (but still manageable) daily frequency than is seen in patients with an intact rectum. In almost all series, the majority of IPAA patients report good functional results and a high degree of satisfaction with quality of life, and these findings remain stable over time. The decision to proceed with operations other than IPAA is based on individual patient circumstances or on the presence of preexisting medical or physiologic conditions that are contraindications to this type of restorative procedure.

In patients who require emergency surgery or are in poor medical condition as a consequence of their underlying disease, a three-stage procedure is performed. Stage I consists of total abdominal colectomy with a Hartmann closure and an end

ileostomy. The majority of the diseased colon is removed, the patient's clinical condition is improved, and any immunosuppressive medications the patient has been receiving can be tapered. Once the patient has recovered and is clinically ready for another operation, stage II—entailing either a completion proctectomy with end ileostomy or an IPAA with diverting loop ileostomy—is carried out. If the latter alternative is chosen, the patient must subsequently undergo stage III, which involves reversal of the ileostomy.

The reason why a proctectomy is not performed in an emergency setting is that if the rectum is left in place, a restorative operation can be performed later without the dissection planes in the pelvis having been disturbed. In addition, emergency proctectomy is associated with a higher risk of bleeding and injury to the nerves of the pelvic floor, the bladder, and the genitalia. Usually, the small amount of diseased tissue left behind does not present a clinical problem.

Special Considerations in Patient Selection

Age Most CUC patients are relatively young and thus, unless there are unusual circumstances, should be offered proctocolectomy and IPAA. However, CUC is known to have a bimodal age distribution, and significant numbers of older CUC patients are being referred for surgical evaluation. Although many institutions have reported their long-term results with IPAA, few have regularly performed IPAA in elderly patients. In a Mayo Clinic survey of 1,386 patients who underwent IPAA, the median age at the time of operation was 32 years (range, 5 to 65 years)¹³; only 16% were older than 45 years, and none were older than 65 years. Functional outcomes—determined on the basis of nocturnal stool frequency, daytime and nocturnal incontinence, and need for constipating medications—were significantly worse in patients who were older than 45 years at the time of the IPAA.

Results such as those of this Mayo survey have often led gastroenterologists and surgeons not to recommend IPAA for elderly patients. Another study, however, came to somewhat different conclusions.¹⁴ The investigators evaluated their experience with IPAA patients from the age of 50 years to past the age of 70 years. Twenty-eight of 227 patients were older than 50 years when the IPAA was performed; of those 28, 10 were between 60 and 70 years of age and five were between 70 and 80. When the elderly patients were compared with younger patients with CUC, there were no significant differences between the groups with respect to the major complications (i.e., pelvic sepsis, pouch-related fistula, and anastomotic leakage); however, pouch-anal stenosis was significantly more common in the older patient group. In regard to functional outcome—determined on the basis of frequency of daytime and nighttime bowel movements, use of pads, and incontinence episodes—there were no significant differences. Overall, advanced age is not an absolute contraindication to IPAA. The data suggest that in healthy older patients with good sphincter tone, functional results may be comparable to those in younger patients.

Fertility and fecundity Given that most patients diagnosed with CUC are in their childbearing years, the possible impact of surgery on fertility is obviously an important consideration when surgical management is being discussed with a young woman. A number of studies have evaluated fertility and the course of subsequent pregnancy after surgical treatment of CUC.¹⁵⁻¹⁹ Patients who have undergone proctocolectomy with an end ileostomy or a Kock pouch can expect to have a normal pregnancy and delivery; the type of delivery chosen (vaginal or cesarean section) should

depend on obstetric issues. Although pregnancies and deliveries may be uneventful, patients often experience temporary stoma or Kock pouch dysfunction.¹⁷ Studies documented similar dysfunction in post-IPAA patients, who reported a slight increase in stool frequency, incontinence, and pad usage during pregnancy,^{19,20} though they returned to baseline pouch function after delivery. These studies noted a higher rate of cesarean sections in post-IPAA patients than was seen in other studies that reported on modes of fetal delivery in patients with Kock pouches and end ileostomies. It is unclear, however, whether this increase was due to uncertainty about how these patients would fare after vaginal deliveries, because fewer than 50% of these cesarean sections were performed for obstetric indications. Overall, there appeared to be no contraindication to vaginal delivery, though the authors suggested that women who have a scarred, stiff perineum might be best advised to avoid vaginal delivery.

Although various studies have examined the course of pregnancy and the development of complications after IPAA, the specific issue of fecundity (the ability to become pregnant) after IPAA has not been thoroughly investigated. One analysis of the rate of pregnancy after IPAA reported a significant reduction in postoperative fertility.¹⁸ In a subsequent study, the same authors examined young women with familial adenomatous polyposis and found that fecundity was significantly lower in those with an ileal pouch than in those with an iliorectal anastomosis.²¹ The basis of the decrease in fertility with IPAA is unknown, but it has been suggested that anatomic changes in the pelvis may contribute to the problem. Until further studies are done to confirm and clarify these findings, women considering undergoing IPAA should be informed of the possibility of decreased fertility.

TECHNICAL CONTROVERSIES

The two main controversies regarding the technical aspects of the IPAA procedure revolve around the choice of anastomotic technique and the question of whether a diverting ileostomy is needed.

Ultimately, the choice of anastomotic technique depends on the patient's clinical situation and the surgeon's preference. Currently, most authorities believe that the double-stapled technique is easier to perform than a mucosectomy with a handsewn anastomosis and yields superior functional results in terms of episodes of incontinence or soiling.^{22,23} Those surgeons who advocate the double-stapled pouch-anal anastomosis at the level of the pelvic floor believe that leaving 1.5 to 2.0 cm of anal mucosa proximal to the dentate line improves the functional result by enhancing anal canal sensation. Not all investigators have found this to be the case, however. In a prospective trial from the Mayo Clinic in which 41 patients with CUC were randomly selected to undergo either mucosectomy and handsewn IPAA or double-stapled IPAA, there was no significant difference between the groups with respect to functional outcome (determined on the basis of stool frequency or episodes of fecal incontinence) at 6 months after ileostomy closure.²⁴ However, the double-stapled IPAA group generally had higher resting sphincter pressures (as measured by manometry) and tended to experience less nocturnal incontinence. Although proponents of mucosectomy with a handsewn anastomosis believe that this operation removes all of the anal canal mucosa at risk, analyses of the fate of the anal canal mucosa after mucosectomy indicate that even after mucosectomy, islands of residual rectal mucosa remain.^{25,26} Taken as a whole, the evidence available at present suggests that double-stapled IPAA might yield slightly better functional results than handsewn IPAA.

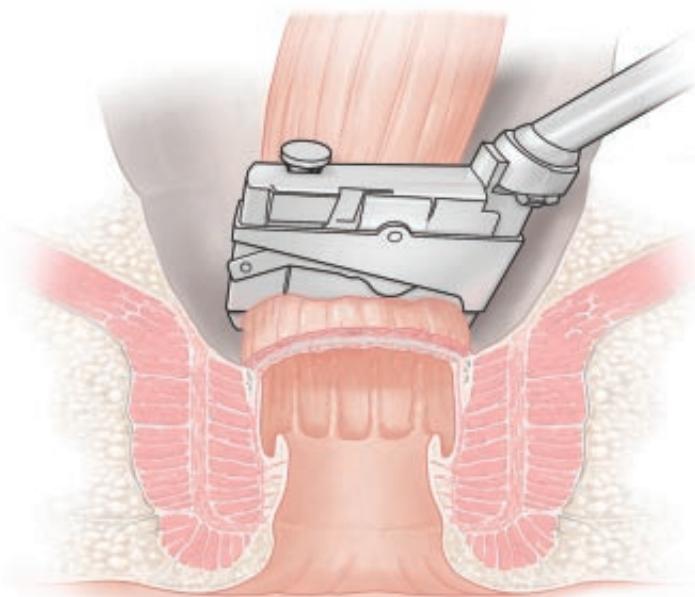

Figure 1 Open proctocolectomy and IPAA. Once the rectum has been dissected down to the level of the pelvic floor, it is divided with a stapler. The stapler is positioned 1 to 2 cm above the dentate line and fired. This positioning ensures that the final pouch-anal anastomosis is within the anal canal and not in the rectum.

The need for a temporary ileostomy has been questioned in several quarters. In most large series, the IPAA procedure has included a temporary ileostomy to divert the fecal stream from the pouch while the pouch staple line and the anastomosis heal.^{13,27-29} Proponents of this approach believe that the diverting ileostomy decreases the rate of pelvic sepsis, which is known to result in worse long-term functional results. Supporters of a one-stage procedure, on the other hand, believe that an IPAA can be performed without an increased risk of pelvic sepsis.³⁰⁻³⁵ In addition to avoiding an ileostomy, a one-stage procedure renders a second hospitalization and operation unnecessary, lowers the total cost, results in a shorter hospital stay, and perhaps even decreases the incidence of small bowel obstruction. In one large single-institution study, there were no differences in complication rate and functional outcome between patients who had not undergone diversion and those who had, nor was there any correlation between diversion and steroid use.²⁷ Others have reported similar findings.^{32,36} Although there might be no significant difference in the rate of complications without a diverting ileostomy, one study suggested that complications might be more severe in patients who lack a protecting ileostomy.³⁷ Our view is that in properly selected patients who are undergoing uncomplicated procedures performed by experienced surgeons, a one-stage IPAA might be appropriate. However, the surgeon and the patient care team must be vigilant for the early signs of pelvic sepsis, aggressively investigate any possibility of leakage from the pouch or the anastomosis, and intervene as needed.

Operative Technique

Since its introduction, proctocolectomy with IPAA has continued to evolve, especially with the application of new technologies such as laparoscopy.³⁷⁻³⁹ Conceptually, the operation can be divided into four phases: (1) removal of the intra-abdominal colon; (2) dissection and removal of the rectum, with the pelvic nerves and

the anal sphincter mechanism spared; (3) construction of an ileal reservoir (pouch); and (4) anastomosis of the ileal reservoir to the anal canal. The following descriptions illustrate the general open and laparoscopic approaches by which these phases are carried out at the Mayo Clinic.

OPEN PROCTOCOLECTOMY AND ILEAL POUCH-ANAL ANASTOMOSIS

A complete bowel preparation is performed on the evening before operation. After induction of anesthesia, the patient is placed in the modified lithotomy position, which allows easy access to both the abdomen and the perineum.

Step 1: Initial Incision and Exploration of Abdomen

The abdomen is entered through a midline vertical incision, and the abdomen is thoroughly explored to determine whether there are any technical or pathologic contraindications to the planned procedure.

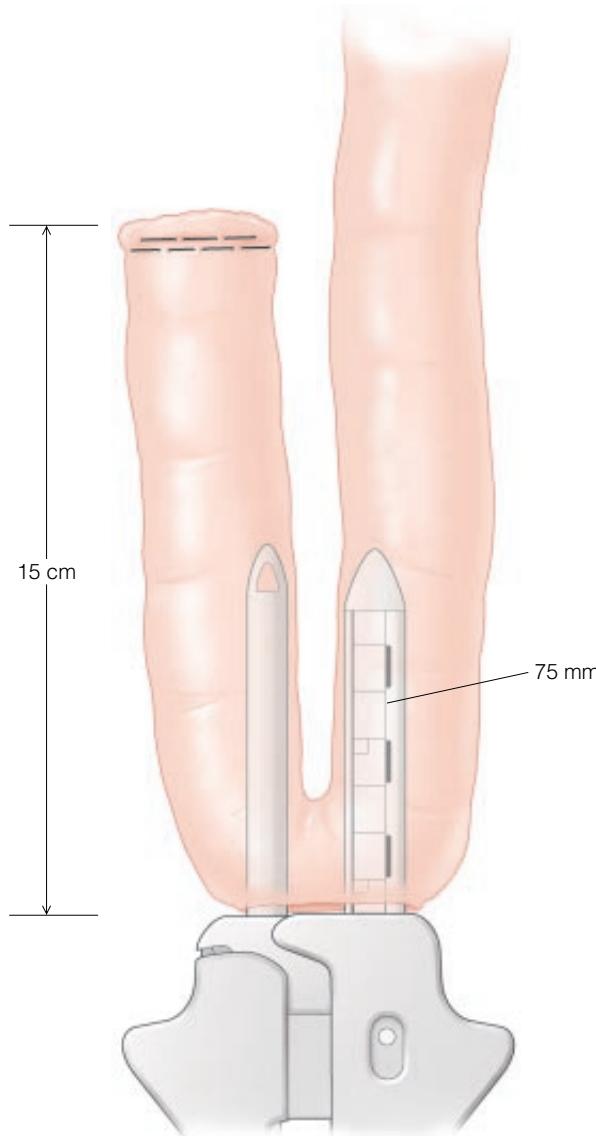

Figure 2 Open proctocolectomy and IPAA. The ileal pouch is constructed by dividing the common wall of the afferent and efferent limbs of the distal ileum by means of multiple firings of a linear cutting stapler.

Step 2: Mobilization and Division of Colon

The entire colon is mobilized away from its retroperitoneal attachments. The transverse colon is freed from the greater omentum, which is preserved if it is of good quality and quantity. Once the intra-abdominal colon has been mobilized, the terminal ileum is divided from the right colon adjacent to the ileocecal junction with a linear stapler. The mesentery is divided as close to the right colon as possible so as not to injure the ileocolic vessels supplying the terminal ileum. Once the right colon has been mobilized, the remainder of the colon is divided from its mesentery.

Step 3: Dissection and Division of Rectum

When the intra-abdominal colon has been fully mobilized and the mesentery has been divided, the patient is placed in a steep Trendelenburg position to facilitate the pelvic dissection of the rectum. The rectum is freed down to the pelvic floor. Great care is taken to avoid the pelvic nerves that lie in the interface between the mesorectum and the presacral fascia. The rectum is divided at the pelvic floor with a stapler [see Figure 1]. The colon and the rectum are then sent in their entirety for pathologic evaluation.

Step 4: Construction of Ileal Pouch

After the colon has been removed, the ileal reservoir is constructed. The small bowel mesentery is completely mobilized from the retroperitoneum up to the inferior border of the pancreas; this mobilization is crucial for ensuring that there is adequate small bowel length to allow the ileal pouch to reach the pelvic floor. To increase the length further, the visceral peritoneum should be scored along the right side of the superior mesenteric vessel.

Once the mesentery has been mobilized, the pouch is fashioned. Our practice is to use a J-shaped reservoir (J pouch) constructed from the last 30 to 35 cm of the terminal ileum. J pouches are simpler to construct, use less small bowel length, and are associated with fewer complications related to pouch-emptying problems than W or S pouches are. The ultimate reservoir capacity of the pouch should be approximately 400 ml. Construction is begun by folding the terminal ileum into a J shape. The hook of the J should be approximately 15 cm long. This efferent limb of the J is loosely secured to the afferent limb of the small bowel. The reservoir is then formed by firing a 75 mm linear cutting stapler twice from the apex of the pouch, thereby dividing the common wall between the two limbs of the pouch [see Figure 2].

Whether an adequate length of small bowel is available must be determined before the reservoir is constructed. To confirm that the pouch will reach the pelvic floor and the region of the anastomosis without tension, it should be possible to pull the apex of the pouch 3 to 5 cm below the upper aspect of the pubic symphysis. If, after full mesenteric mobilization and scoring of the visceral peritoneum, the pouch does not easily reach the pelvic floor, it may be necessary to divide either the ileocolic vessel or one of the proximal branches of the superior mesenteric vessels. When there is a concern that a J pouch will not reach the pelvic floor satisfactorily, an S or a W pouch may be constructed instead.

Step 5: Construction of Ileal Pouch-Anal Anastomosis

Before the pouch is brought down to the anus, one must verify that the small intestine from the ligament of Treitz to the ileal pouch is not twisted. At this point in the operation, there are, as noted [see Operative Planning, Technical Controversies, *above*], two options for performing the anastomosis. The first is to secure the pouch to the anal canal by means of a double-stapled technique. The head of an end-to-end anastomosis (EEA) stapler is

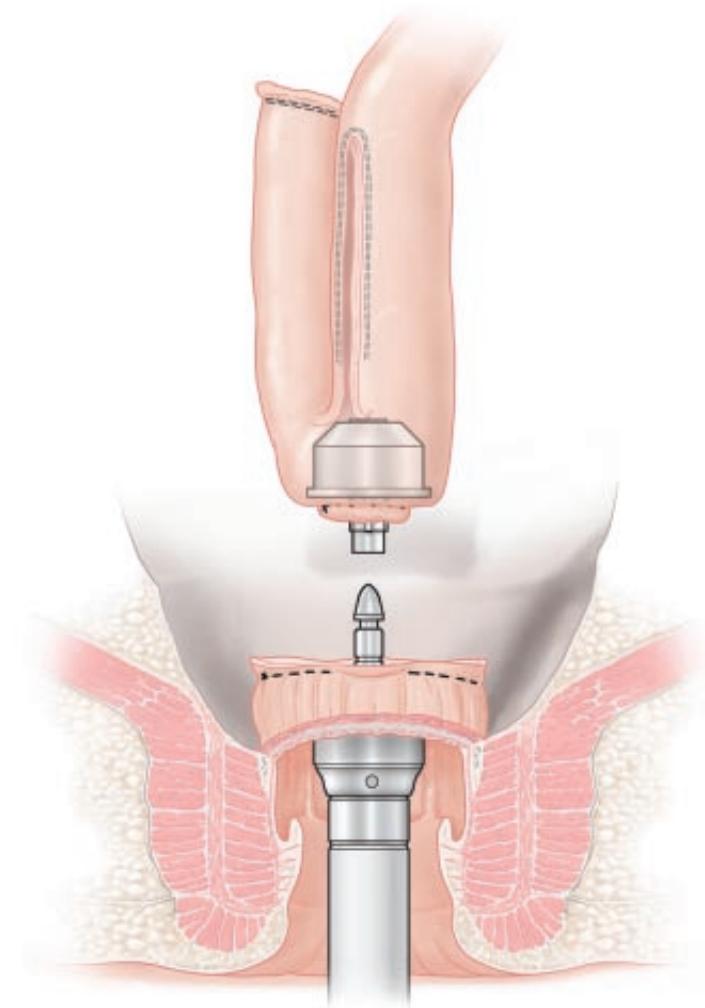

Figure 3 Open proctocolectomy and IPAA. After the pouch is constructed, the head of an EEA stapler is secured in the apex of the pouch and connected to the pin of the stapler, which was placed upward through the anus.

secured in the apex of the pouch with a purse-string suture [see Figure 3]. The stapler is then advanced into the anus, and the attachment pin is placed adjacent to the staple line marking the point where the rectum was divided at the level of the pelvic floor. The pouch is brought down into the pelvis, with proper orientation maintained, the head of the stapler is fitted onto the pin, and the stapler is fired to anastomose the pouch to the anus [see Figure 4].

The second option is to perform a mucosectomy of the anal canal and the lower rectal remnant. The dentate line area is exposed with the help of a self-retaining retractor. A dilute solution of epinephrine is injected into the submucosa to facilitate circumferential excision of the anal canal mucosa; the muscularis propria is left intact. The excision is extended proximally to the level of the stapled rectum. Once the staple line is reached, the full thickness of the rectal wall is divided, and the intact lower rectal remnant and the anal canal mucosa are removed. A long Babcock clamp is placed into the pelvis through the anal opening, and the apex of the pouch is drawn down to the level of the dentate line. A side-to-end handsewn anastomosis between the apex of the pouch and the dentate line is performed with absorbable interrupted sutures. Once the anastomosis is completed, one or two closed suction drains are placed behind the pouch and brought out of separate left abdominal stab wounds. In the majority of patients, a loop ileostomy is constructed in the right lower abdomen.

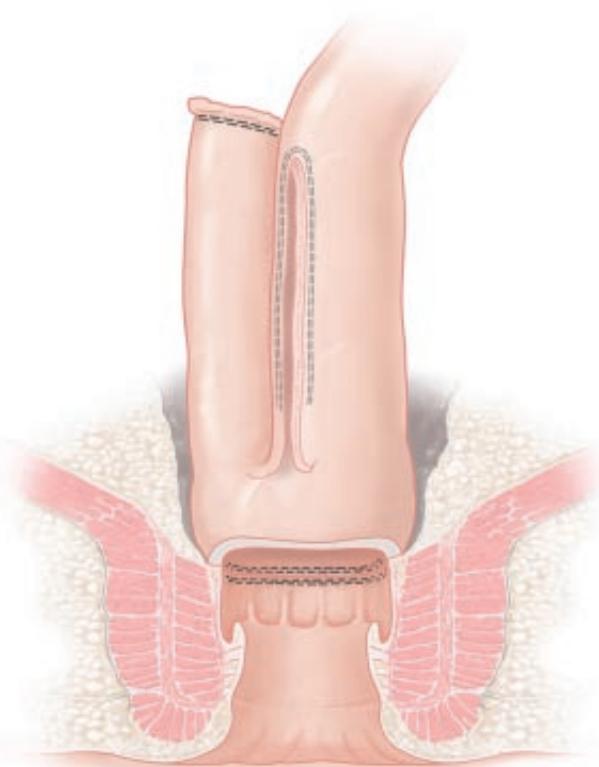

Figure 4 Open proctocolectomy and IPAA. Shown is the completed ileal J pouch with the circular stapled anastomosis within the anal canal, just above the dentate line.

Step 6: Later Reversal of Loop Ileostomy

Approximately 3 months after the original operation, a barium study through the anus is performed to determine whether the pouch has healed. If the reservoir and the anastomosis have healed completely, the loop ileostomy can be reversed during a second operation. Often, the ileostomy can be closed by mobilizing it through a small transverse biconvex incision around the stoma. The loop of ileum is then fully mobilized, and an end-to-end handsewn anastomosis or a stapled side-to-side functional end-to-end anastomosis can be done.

LAPAROSCOPIC PROCTOCOLECTOMY AND ILEAL POUCH-ANAL ANASTOMOSIS

Laparoscopic approaches to IPAA were developed to reduce the impact of the procedure on patients who are already physiologically stressed. Initial descriptions of laparoscopic IPAA, however, were not encouraging. In a comparison of five open cases with five laparoscopic cases, operating time was markedly longer in the laparoscopic group, as were hospital stay and the duration of postoperative ileus.⁴⁰ The study did, however, show that the procedure was feasible. The procedure described in the initial reports was complex, using seven incisions—five for the ports, a separate Pfannenstiel incision for rectal dissection, and another incision for the ileostomy. Other early series also reported very long operating times, in the range of 380 to 710 minutes,⁴¹⁻⁴³ as well as high complication rates.^{44,45} A 2000 study, however, documented benefits from a minimally invasive approach, with a reduction in hospital stay from 8 days to 7 days ($P = 0.02$), though operating times were still significantly longer than with open IPAA (330 minutes versus 225 minutes).⁴⁶

The technical issues surrounding laparoscopic IPAA have been addressed by developing a simplified version of the procedure, based on lessons learned from segmental procedures.⁴⁷ The sim-

plified operation differs from the original version in several key respects: only four ports are placed [see Figure 5], the right and the left colon are dissected in a lateral-to-medial direction, the rectum is mobilized intracorporeally, a 4 to 5 cm periumbilical incision is employed for specimen extraction, and the right lower quadrant port site is used for the ileostomy.

As work proceeds in different quadrants of the abdomen and the pelvis, the monitors are moved between the patient's shoulders and ankles, in line with the surgeon's field of view. An instrument stand is placed above the head, and a larger instrument table is placed behind the scrub nurse. The patient's arms are tucked adjacent to the body, and the thighs are kept level with the abdomen to prevent interference with the instruments placed in the lower ports. Because steep position changes are used, the patient is carefully secured (e.g., with padded straps or a bean bag). The bladder is decompressed with a urinary catheter, and the stomach is decompressed with an orogastric tube, which is removed at the end of the procedure. In general, the first assistant stands opposite the surgeon, and the camera-holder stands next to the surgeon.

Step 1: Placement of Trocars and Exploration of Abdomen

A 12 mm blunt port is placed above the umbilicus via cutdown; this port is used for a 30° laparoscope. After abdominal exploration, three additional trocars are placed so as to form a diamond shape with the first trocar [see Figure 5]. One 5 mm trocar is placed in the left lower quadrant, and another in the suprapubic midline. If a loop ileostomy is planned, an appropriate site in the right lower quadrant is marked before operation, and a 12 mm trocar is placed at this location. This trocar is used for passage of the stapler, and its site does not require closure, because it becomes the stoma site. A disk of skin and subcutaneous fat is excised from the planned stoma site before the trocar is placed directly through the fascia.

Step 2: Mobilization of Intra-abdominal Colon

Left colon The patient is placed in the Trendelenburg posi-

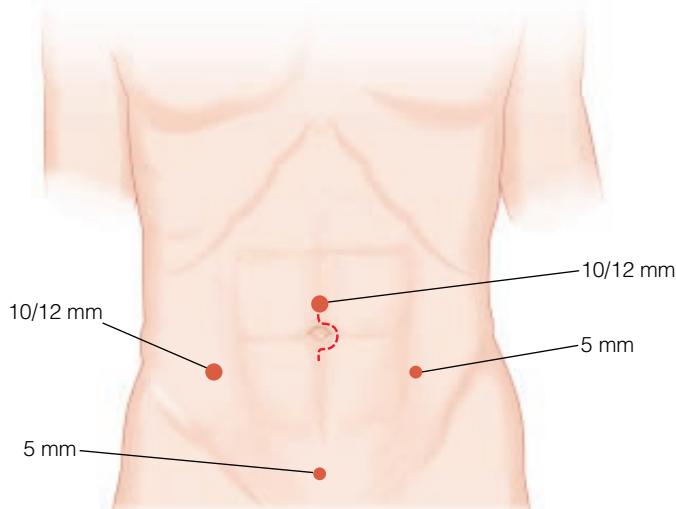

Figure 5 Laparoscopic proctocolectomy and IPAA. Four trocars are placed in a diamond-shaped pattern: a 12 mm trocar is placed supraumbilically for the camera, another 12 mm trocar is placed in the right lower quadrant, a 5 mm trocar is placed in the left lower quadrant, and another 5 mm trocar is placed above the pubis. A disk of skin and fat is excised for the ileostomy.

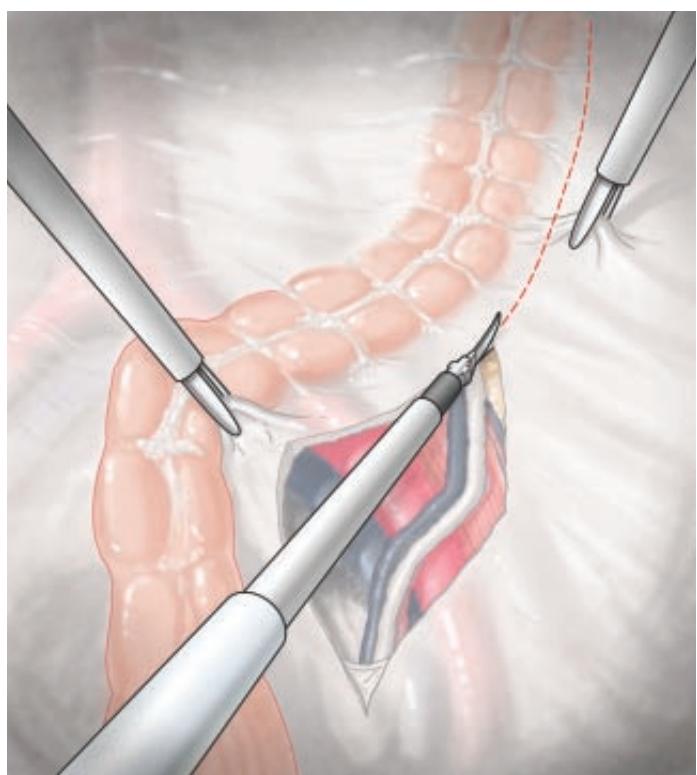

Figure 6 Laparoscopic proctocolectomy and IPAA. Illustrated is mobilization of the left colon. With the patient in the Trendelenburg position and the left side tilted up, the left lateral peritoneal reflection is opened and the left ureter identified. The descending colon and the sigmoid colon are mobilized medially.

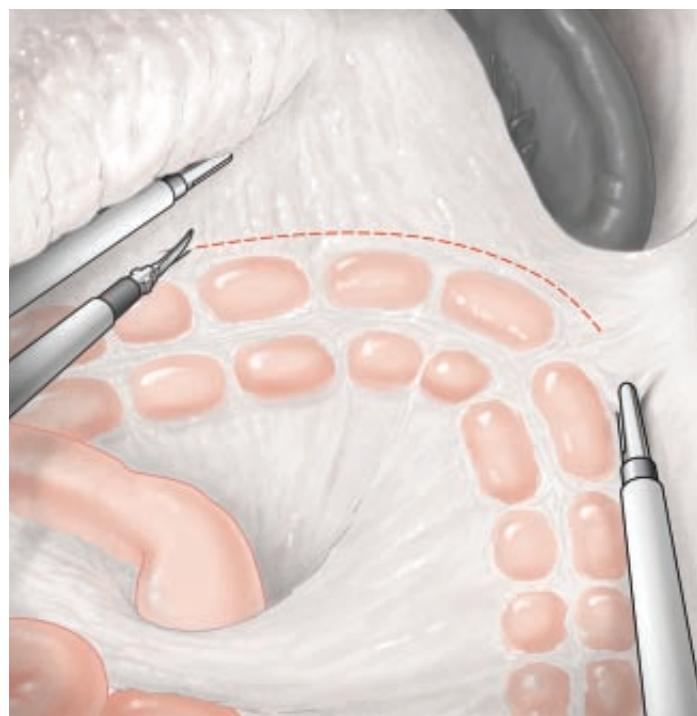

Figure 7 Laparoscopic proctocolectomy and IPAA. Illustrated is mobilization of the splenic flexure. With the patient in the reverse Trendelenburg position and the left side tilted up, the splenic flexure is mobilized off the retroperitoneum and the omentum dissected off the distal transverse colon.

tion, with the left side tilted up. Gravity moves the omentum and the small bowel away from the operative site. With the laparoscope in the supraumbilical port, the surgeon faces the left colon, using the suprapubic and left lower quadrant ports. The first assistant provides retraction via the right lower quadrant port. The left ureter is identified after the left lateral peritoneal reflection is opened, and the descending colon and the sigmoid colon are mobilized medially [see Figure 6].

Splenic flexure The patient is then placed in the reverse Trendelenburg position, with the left side still tilted up. The surgeon moves to a position between the legs. Mobilization of the splenic flexure requires a combination of lateral dissection off the retroperitoneum and dissection of the omentum off the distal transverse colon [see Figure 7]. The first assistant elevates the omentum, which is dissected away from the medial aspect of the splenic flexure sufficiently to allow the flexure to reach below the level of the umbilicus; this facilitates subsequent exteriorization [see Step 4, below].

Right colon The patient is returned to the Trendelenburg position, but with the right side tilted up. In slim patients, the right ureter is identified before the peritoneum is opened; in heavier patients, it is identified after the peritoneum has been opened. The correct retroperitoneal plane is entered by scoring the peritoneum around the base of the cecum and the terminal ileum. The ascending colon is mobilized medially after the right lateral peritoneal reflection is opened [see Figure 8]. Medially, the peritoneal attachments of the terminal ileum are divided up to the inferior border of the duodenum to ensure that the terminal ileum is sufficiently mobilized.

Hepatic flexure The patient is again placed in the reverse Trendelenburg position, but with the right side still tilted up. The attachments of the hepatic flexure are exposed. From the point where the previous dissection ended, the gastrocolic ligament is grasped immediately cephalad to the transverse colon and elevated. The duodenum is identified and protected as dissection proceeds medially [see Figure 9]. When the hepatic flexure can be brought down to the level of the umbilicus, it is sufficiently mobilized.⁴³

Step 3: Pelvic Dissection

The patient is once more moved into the Trendelenburg position, but tilted neither to the left nor to the right. The surgeon may stand on either the right or the left, in either case performing the dissection on the near side of the pelvis and exposing the planes for the assistant during dissection of the far side. The presacral space is entered by scoring the left pararectal peritoneum, and the plane is developed posteriorly and laterally. The right pararectal peritoneum is similarly scored, the presacral space is entered, and the plane is developed so as to join the previous dissection. Anteriorly, in male patients, care is taken to identify the seminal vesicles and the prostate. To obtain anterior exposure in female patients, the uterus is suspended either with two sutures passed through the abdominal wall or with a fan retractor (which would require an additional port). The rectum is circumferentially dissected down to the pelvic floor, where digital rectal examination confirms the level of the dissection [see Figure 10]. The rectum is transected at the pelvic floor with a laparoscopic articulated linear stapler introduced through the 12 mm right lower quadrant port. If mucosectomy is indicated, it is performed at this point.

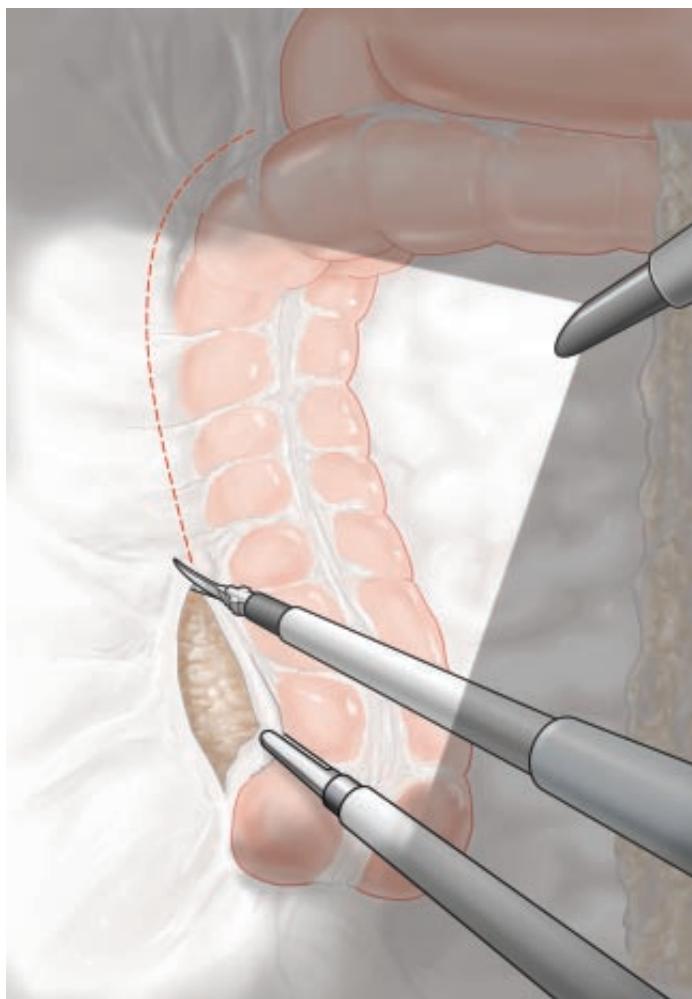

Figure 8 Laparoscopic proctocolectomy and IPAA. Illustrated is mobilization of the right colon. With the patient in the Trendelenburg position and the right side tilted up, the peritoneum around the cecum and the terminal ileum is scored to enter the correct retroperitoneal plane.

*Step 4: Exteriorization and Resection of Colon and Rectum;
Creation of Pouch*

The supraumbilical trocar incision is enlarged around the umbilicus to a length of 4 to 5 cm. The specimen is exteriorized from the terminal ileum to the transected distal rectum; the omentum may be preserved or removed with the specimen. The mesentery is divided and ligated; the ileocolic pedicle may be preserved if desired. In lean patients (body mass index [BMI] < 25), the mesenteric vessels are divided at their origin, but in heavier patients, the vessels must be divided closer to the colon. (This is not a critical consideration in the setting of benign disease.) Alternatively, the mesentery may be divided intracorporeally; however, the method we describe here is faster, safer (because bleeding is readily controlled), and cheaper (because multiple clips or stapler applications are unnecessary).

The terminal ileum is divided with a linear stapler. The small bowel is exteriorized to allow inspection for Crohn disease, then replaced into the abdomen, with care taken to maintain the correct orientation of the cut edge of the small bowel mesentery. A standard 15 cm J pouch is constructed, and the head of a circular stapler is secured in the apex of the pouch. The pouch is

returned to the abdomen, which is then irrigated. The midline incision is closed with interrupted sutures, two of which are used to secure the blunt port in the incision. Pneumoperitoneum is reestablished.

Step 5: Construction of Ileal Pouch–Anal Anastomosis

The circular stapler is inserted into the anus, and the spike is brought out adjacent to the staple line. The pouch mesentery is traced from the pouch to the duodenum to confirm correct orientation. The pouch and the anvil are then placed onto the handle of the stapler, which is approximated and fired. A drain is left adjacent to the pouch and brought out through the suprapubic port site.

To create an ileostomy, an appropriate point on the ileum is identified and brought up through the right lower quadrant trocar site after the anterior and posterior rectus fasciae have been incised in a cruciate fashion. The ileostomy is drawn through the site under direct vision to ensure correct orientation. The remaining trocars are removed, the sites are inspected for hemostasis, the skin incisions are closed, and the stoma is matured.

Postoperative Care

On postoperative day 1, clear liquids are started if the patient is not experiencing nausea and if the abdomen is not distended. A

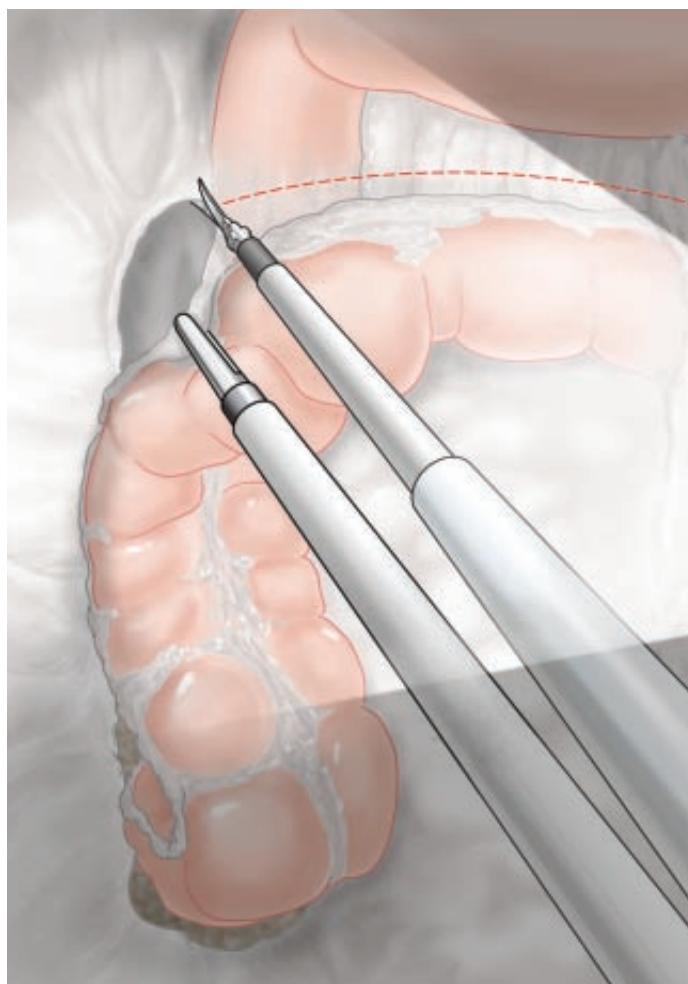

Figure 9 Laparoscopic proctocolectomy and IPAA. Illustrated is mobilization of the hepatic flexure. With the patient in the reverse Trendelenburg position and the right side tilted up, the gastrocolic ligament is elevated.

Figure 10 Laparoscopic proctocolectomy and IPAA. Illustrated is mobilization of the rectum. With the patient in the Trendelenburg position and the table tilted neither to the left nor to the right, the left pararectal peritoneum is scored and the presacral space entered.

low-fiber diet is instituted on the following day if clear liquids are tolerated. Communication with the enterostomal therapist is important: patients are often sufficiently comfortable on postoperative day 1 to be receptive to teaching, and some patients are ready for discharge by postoperative day 3.

Complications

Total proctocolectomy with IPAA is a technically demanding procedure: the patient commonly must endure two, and sometimes three, operations. A number of significant complications have been reported.⁴⁸⁻⁵² Of these, the most frequently encountered are small bowel obstruction, pouch leakage, pelvic abscess, anastomotic stricture, pouch fistula, and pouchitis.

The most common short-term and long-term complication after IPAA is small bowel obstruction. In a series of 1,310 patients who underwent an open IPAA at the Mayo Clinic, the incidence of this complication in the perioperative period was 15%,⁴⁸ and 24% of patients required early reoperation to resolve the obstruction. Other groups have reported similar incidences, albeit with generally lower rates of reoperation.^{27,50} The long-term incidence of small bowel obstruction is also relatively high: one review of the literature on late small bowel obstruction after IPAA reported incidences of 18% at 1 year, 27% at 5 years, and 31% at 10 years.⁵⁰ The majority of patients responded to conservative management, but the rate of operative treatment increased from 2.7% at 1 year to 7.5% at 10 years. The most common operative findings in patients who required exploration for relief of the obstruction were pelvic adhesions (32%) and adhesions to the ileostomy closure site (20%).

Pouch leakage and the associated pelvic sepsis are potentially devastating complications after IPAA. The reported incidence of

such complications ranges from 5% to 14%.^{36,48,53} In the Mayo Clinic study just cited (see above), sepsis occurred in 74 (6%) of 1,310 patients, 73 of whom had pelvic sepsis as the result of the pouch procedure.⁴⁸ The majority (63%) of these patients required operative intervention; the remainder were treated with either antibiotics or a combination of antibiotics and CT-guided drainage. In this series and others, the rate of pouch leaks and episodes of pelvic sepsis declined as experience with the procedure increased.

Another fairly common complication of IPAA procedures is the formation of an anastomotic stricture. In one study, 42 (37%) of the 114 patients who required reoperative treatment for pouch-related complications had symptomatic anastomotic strictures.⁵⁴ There is no clear correlation between stricture formation and the type of anastomosis performed. In many cases, anastomotic strictures can be treated with intermittent dilatation, which can often be performed by the patient after an initial operative dilatation.

Fistulas after IPAA procedures are extremely difficult to treat. Pouch-vaginal fistulas and, more rarely, pouch-perineal fistulas can occur either in the perioperative period or years later. An early pouch fistula is generally the result of a technical error or a complication of a pouch leak or pelvic abscess. A late pouch fistula raises the possibility of Crohn disease. Most fistulas are low and originate at the level of the anastomosis. They appear to occur equally frequently with handsewn anastomoses and with double-stapled anastomoses. The reported incidence of pouch-vaginal fistulas ranges from 4% to 12%.^{27,55-59}

The most important considerations in managing a postpouch fistula are to rule out Crohn disease and to initiate treatment by a surgeon experienced in treating these complications. Before any surgical treatment of a fistula, the patient should be examined under anesthesia and biopsies performed to rule out the presence of Crohn disease. The basic principles of management are (1) local control of any septic process and (2) repair of the fistula by interposing healthy tissue between the pouch and the vagina or the perineal opening. Pouch-vaginal fistulas have been repaired via transanal, transvaginal, transperineal, and transabdominal approaches, with rates of successful closure ranging from 10% to 78%^{55,56,58,59}; however, both these fistulas and pouch-perineal fistulas can often be successfully managed with simple interventions, such as seton fistulotomy.⁵⁵ Severely symptomatic patients may eventually require pouch diversion or complete pouch excision with end ileostomy.

Pouchitis is a late complication of IPAA. It is an acute inflammatory process of the pouch. In a minority (< 10%) of patients, however, pouchitis can become a chronic process. Chronic pouchitis may eventually lead to pouch failure that necessitates excision of the pouch; fortunately, this is a quite rare event. Pouchitis occurs more frequently in patients who have extraintestinal manifestations of CUC than in those who do not.⁶⁰ Measuring the exact incidence of pouchitis is difficult because of variations in presentation and differences in diagnostic criteria, but most series report figures between 12% and 50%.^{13,48,61} Pouchitis should be suspected in any patient who experiences abdominal cramps, increased stool frequency, watery or bloody diarrhea, and flulike symptoms. Although many patients are treated on clinical grounds alone, accurate diagnosis requires endoscopic visualization of the pouch, as well as histologic evaluation.

The exact cause of pouchitis is unclear, but the observation that antibiotic therapy (particularly with metronidazole) can successfully treat acute and chronic pouchitis lends support to the theoretical

ry that interaction between pouch bacteria levels and the mucosal immune system plays an important role in pathogenesis. In cases of chronic pouchitis, immunosuppressive agents may have to be added to achieve control of symptoms. Fewer than 8% of patients who undergo an IPAA procedure experience chronic severe pouchitis, and about half of these require pouch excision.^{13,60}

Outcome Evaluation

Perhaps surprisingly, given the complexity of the IPAA procedure and the often debilitated condition of the patients, quite similar functional results have been obtained by many different surgeons and many different institutions.^{13,27,30,31,36,48-50,61} Most patients report good to excellent pouch function. The most commonly used markers of pouch function are the number of diurnal and nocturnal bowel movements, the number of episodes of soiling, the number of episodes of incontinence, and the extent to which medications are required to control bowel activity. In the Mayo Clinic series of open IPAA patients cited earlier [see Operative Planning, Choice of Procedure, Special Considerations in Patient Selection, above], the average number of diurnal bowel movements at the time of discharge after closure of the ileostomy was six, and the average number of nocturnal bowel movements was one.^{13,48} Nearly 80% of patients had complete diurnal continence, whereas 19% had occasional episodes of incontinence and 2% had frequent episodes. Occasional nocturnal incontinence occurred in 49% of patients. Nearly 50% of patients were discharged on some type of medication to slow their bowels or provide dietary bulk. In patients who had had an ileal pouch for longer than 10 years, stool frequency and continence remained remarkably stable over time. When all patients were considered, however, episodes of incontinence increased slightly, with 73% of patients reporting complete continence at 10 years (a modest decrease from the initial 80%). Many groups have reported similarly stable functional results.⁶¹⁻⁶³

A number of studies have investigated patients' quality of life after surgical treatment of CUC. One group found that quality of life after IPAA is comparable to the norms for the general healthy population in the United States.⁶⁴ Others reported that quality-of-life measures yielded better results after an IPAA than after an end or continent ileostomy.⁶⁵⁻⁶⁷ These results do not, however, mean

that the IPAA is the treatment of choice for all CUC patients or that CUC patients who either request an end ileostomy or are unable to have an IPAA will necessarily have a poorer postoperative quality of life. Several reports have shown that quality of life improves after operation regardless of what procedure is performed, probably as a consequence of eradication of the underlying disease.⁶⁸⁻⁷⁰

It is generally accepted that avoiding an abdominal stoma improves a patient's body image, but it is unclear whether the route of bowel emptying (i.e., through a pouch or through a stoma) has any real effect on quality of life. A study in which patients were asked to place a monetary value on the disability they believe themselves to be experiencing as a result of their condition found no difference between ileostomy patients and IPAA patients.⁷¹ In fact, when patients were asked to rank the impact of altered bowel emptying on quality of life and disability, those with pelvic pouches considered altered bowel emptying a significantly worse problem than those with stomas did. These findings suggest, again, that the choice of operation for CUC must be individualized on the basis of various health and personal factors specific to each patient.

LAPAROSCOPIC IPAA

Laparoscopic proctocolectomy with IPAA has been performed in more than 70 CUC patients since the initial pilot study involving seven patients.⁷² The indications for operative intervention [see Preoperative Evaluation, Indications for Operation, above] are the same for the laparoscopic approach as for the open approach. In a case-matched series of 40 patients undergoing laparoscopic IPAA, each of whom was matched to two open IPAA patients (with disease, age, gender, BMI, and date of operation controlled for), the laparoscopic group experienced significant benefits with respect to time to clear liquid ingestion (1 versus 3 days; $P < 0.001$), time to resumption of regular diet (3 versus 4 days; $P < 0.001$), and time to restoration of bowel function (2 versus 3 days; $P < 0.001$).⁷³ The duration of narcotic use was shorter in the laparoscopic group ($P < 0.001$), and length of stay was reduced as well (4 versus 7 days; $P < 0.001$). Operating time was longer in the laparoscopic group (270 versus 192 minutes; $P < 0.001$), but it decreased as the surgeon gained experience with the procedure, reaching an average of 3 to 3.5 hours. Other authors are reporting similar advantages.^{39,74}

34 SEGMENTAL COLON RESECTION

Toyooki Sonoda, M.D., and Jeffrey W. Milsom, M.D., F.A.C.S.

Segmental (or partial) resections of the colon are commonly performed throughout the world to treat both benign and malignant disease. Benign conditions that may be treated with these procedures include polyps, inflammatory bowel disease, diverticulitis, hemorrhage, ischemia, trauma, and redundancy (e.g., volvulus, constipation, or rectal prolapse). However, malignant conditions, as a group, constitute the most common indication for colon resection. Adenocarcinoma is the neoplasm for which segmental colectomy is most commonly performed in most Western countries, but there are a number of other neoplasms (e.g., carcinoid tumor, lymphoma, leiomyoma, and leiomyosarcoma) for which such treatment may also be indicated. Detailed knowledge of the relevant surgical anatomy and a systematic approach to colonic mobilization are essential to the performance of a safe and oncologically sound segmental colectomy.

Operative Planning

BENIGN VERSUS MALIGNANT DISEASE

The differences between segmental colon resections done to treat benign disease and those done to treat malignancies are fundamentally important and may have a substantial effect on outcome. Accordingly, before specific techniques are described, it is worthwhile to review these differences, paying particular attention to the basic principles of and justifications for oncologic resections.

Resections for Benign Disease

For patients with benign colon disease, removal of the diseased portion of the bowel in such a way as to leave uninvolved, healthy, and well-vascularized margins should be sufficient treatment. When indicated, the proximal and distal ends are anastomosed to restore continuity of the bowel. In these benign cases, dissection of the mesentery should be performed where it is easiest and most convenient. To this end, the major named branches are usually divided in their midportions: if the mesentery is divided within a few centimeters of the bowel wall, many of the small mesenteric branches will have to be ligated, which is inconvenient and time-consuming [see Figure 1].

Modern electrosurgical devices, such as the LigaSure vessel sealing system (Valleylab, Boulder, Colorado), can reliably seal mesenteric vessels as large as 7 mm in diameter without the traditional clamping and tying, and they can reduce operating times during more extensive colon resections (whether laparoscopic or open). The LigaSure Atlas and the LigaSure V use bipolar current and have a built-in knife that allows the surgeon to seal and divide the vessel in a single maneuver.

Certain inflammatory conditions (e.g., Crohn disease and diverticulitis) may result in such severe pericolic inflammation and thickening that dissection of the mesentery close to the bowel wall may not be possible. In these cases, it may be necessary to perform a more radical mesenteric dissection in an area where the mesentery is softer. Severe inflammatory adhesions may cause the bowel

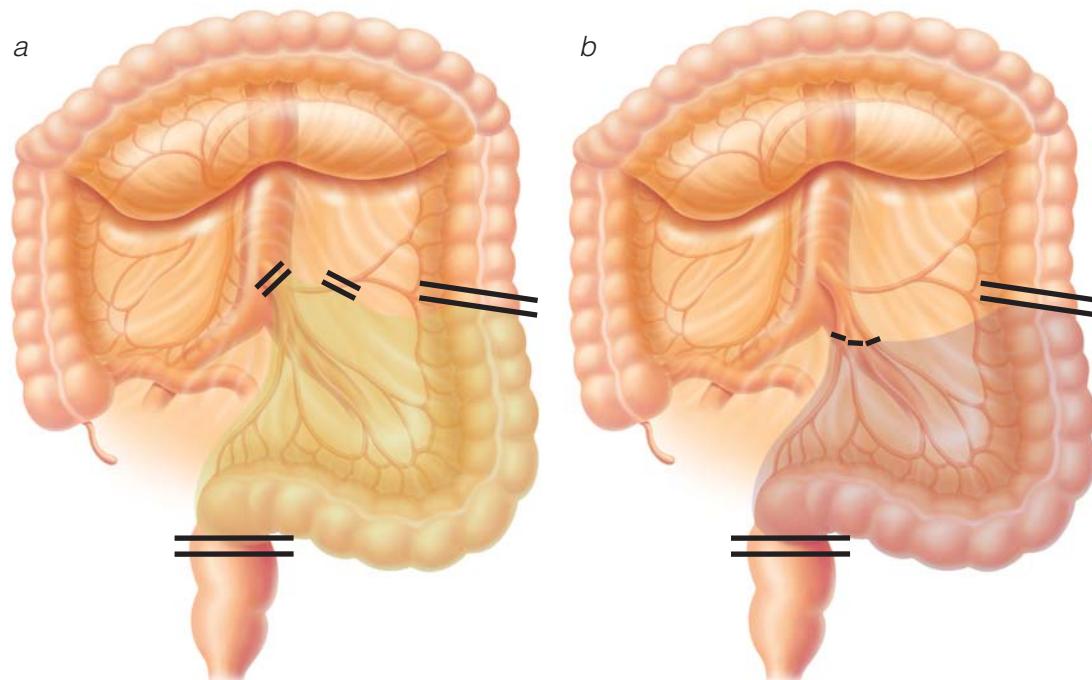

Figure 1 Illustrated is the difference between (a) malignant and (b) benign resections of the sigmoid colon.

to be stuck to the retroperitoneum, making the usual lateral mobilization of the colon nearly impossible. In these cases, early division of the mesentery (i.e., medial-to-lateral mobilization of the colon) may provide easier access to the proper plane of dissection, where the tissues are soft (i.e., in the retromesenteric plane anterior to Toldt's retroperitoneal fascia [see Figure 2]). This approach may help minimize the risk of injury to retroperitoneal organs (e.g., the ureter).

Resections for Malignant Disease

Colon resections for malignancy should include radical en bloc removal of the draining lymphovascular complex, with bowel margins wide enough to limit intraluminal and pericolic (lymphatic) recurrence. The drainage of the lymphatic system mirrors that of the vascular system. In the case of colon carcinomas, there are two possible directions for lymphatic drainage: (1) paraintestinal (along the intestine) and (2) central (along named mesenteric vessels). To prevent regional lymphatic recurrence, the major draining mesenteric vessel should be divided at the point of origin, together with the accompanying lymphatic network. If the tumor is equidistant from two named mesenteric vessels, both vessels should be ligated proximally.

Although, in most cases, intramural spreading of cancer should not exceed 2 cm,^{1,2} an oncologic resection of the abdominal colon should aim at achieving proximal and distal margins of at least 5 to 10 cm to ensure adequate procurement of the epicolic and pericolic lymph nodes.^{3,4} The two exceptions to this rule are in resection of rectal cancer, where a margin of 1 to 2 cm is accepted as part of a sphincter-saving operation, and in resection of a cecal carcinoma, where the ileum can be divided close to the ileocecal valve without compromising the oncologic outcome, provided that the lymphatic vessels along the ileocolic pedicle are removed. The ultimate length of the resected bowel segment is dictated by the lymphovascular resection. Large adenomatous polyps may harbor cancer, especially when they are villous, and resections for this indication should also include wide mesenteric clearance.

Oncologic principles There is increasing evidence that the quality of the operation done to treat colorectal carcinoma is directly correlated with the quality of the oncologic outcome. To date, the bulk of this evidence has come from studies of rectal carcinoma, but the correlation appears to hold true for colon cancer as well. In an excellent study carried out by the German Colon Cancer Study Group, the treating surgeon and the treating institution were found to be independent variables that affected both survival and locoregional recurrence after colon cancer resections.⁵

The concept that surgical technique may influence survival was first popularized in the 1960s. In a classic study (that has nonetheless been criticized for its uncontrolled methodology), Turnbull and associates retrospectively compared the outcomes of patients who underwent resections for malignancy that used the no-touch isolation technique with the outcomes of patients who underwent more traditional resections performed by other surgeons.⁶ The patients who underwent no-touch oncologic resections had a better 5-year survival. In the no-touch isolation technique, draining mesenteric vessels are ligated at their origin early in the dissection, and the bowel is divided proximal and distal to the lesion before the tumor is mobilized; as a result, the tumor is effectively isolated from intraluminal and hematogenous spillage during manipulation. This operative technique makes sense in the light of reports suggesting that malignant cells may be shed into the portal circu-

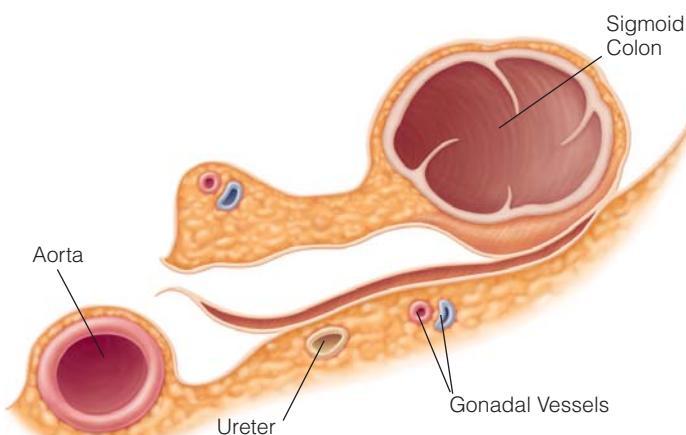

Figure 2 In patients with severe inflammatory conditions of the colon, early division of the mesentery provides access to the retromesenteric plane medially.

lation during colon cancer operations (though the evidence for this phenomenon is still inconclusive).⁷⁻⁹

To date, only one randomized, prospective trial has compared the no-touch isolation technique with conventional techniques for the curative treatment of colon cancer. In this trial, which involved 236 patients, there was no significant difference in 5-year survival between the no-touch group and the conventional group, though there was a trend toward better cancer-related survival in the former.¹⁰ Fewer liver metastases were observed in the no-touch group, and those that were observed seemed to develop later. This study was criticized on the grounds that the mean numbers of lymph nodes harvested were only 3.8 and 4.8 for conventional and no-touch operations, respectively, which raised questions about the quality of the oncologic resections. However, the authors pointed out that the study was designed to analyze only the effects of early lymphovascular isolation and that extensive lymphadenectomies were not performed.

Another randomized, prospective trial compared extended resections with segmental resections for treatment of carcinoma of the left colon. In this trial, 260 patients with cancer between the distal transverse colon and the rectosigmoid were randomly assigned to undergo either left hemicolectomy or segmental colectomy.¹¹ The lymphadenectomy done as part of the left hemicolectomy extended to the origin of the inferior mesenteric artery (IMA), whereas that done as part of the segmental colectomy was more limited, extending only to the region of the left colic artery (LCA). There was no difference in survival between the two groups, even when Dukes class C (TNM stage III) cancers were compared. Although a few retrospective studies have suggested that a more extensive lymphadenectomy improves survival, there remains some disagreement regarding whether true high ligation accomplishes this goal.¹²⁻¹⁴ Intuitively, it would seem that high ligation should affect survival only in patients who have malignant lymph node involvement up to—but not past—the origin of the draining vessel. However, an adequate lymphadenectomy is undoubtedly important for accurate staging, and the current recommendation is that at least 13 lymph nodes should be harvested to ensure a high degree of staging accuracy.¹⁵

Although the quality of the operation does appear to affect the oncologic outcome, routine use of no-touch isolation for curative treatment of colon cancer is not currently an evidence-based practice. We believe that the risk of locoregional recurrences can be minimized by maintaining the following principles:

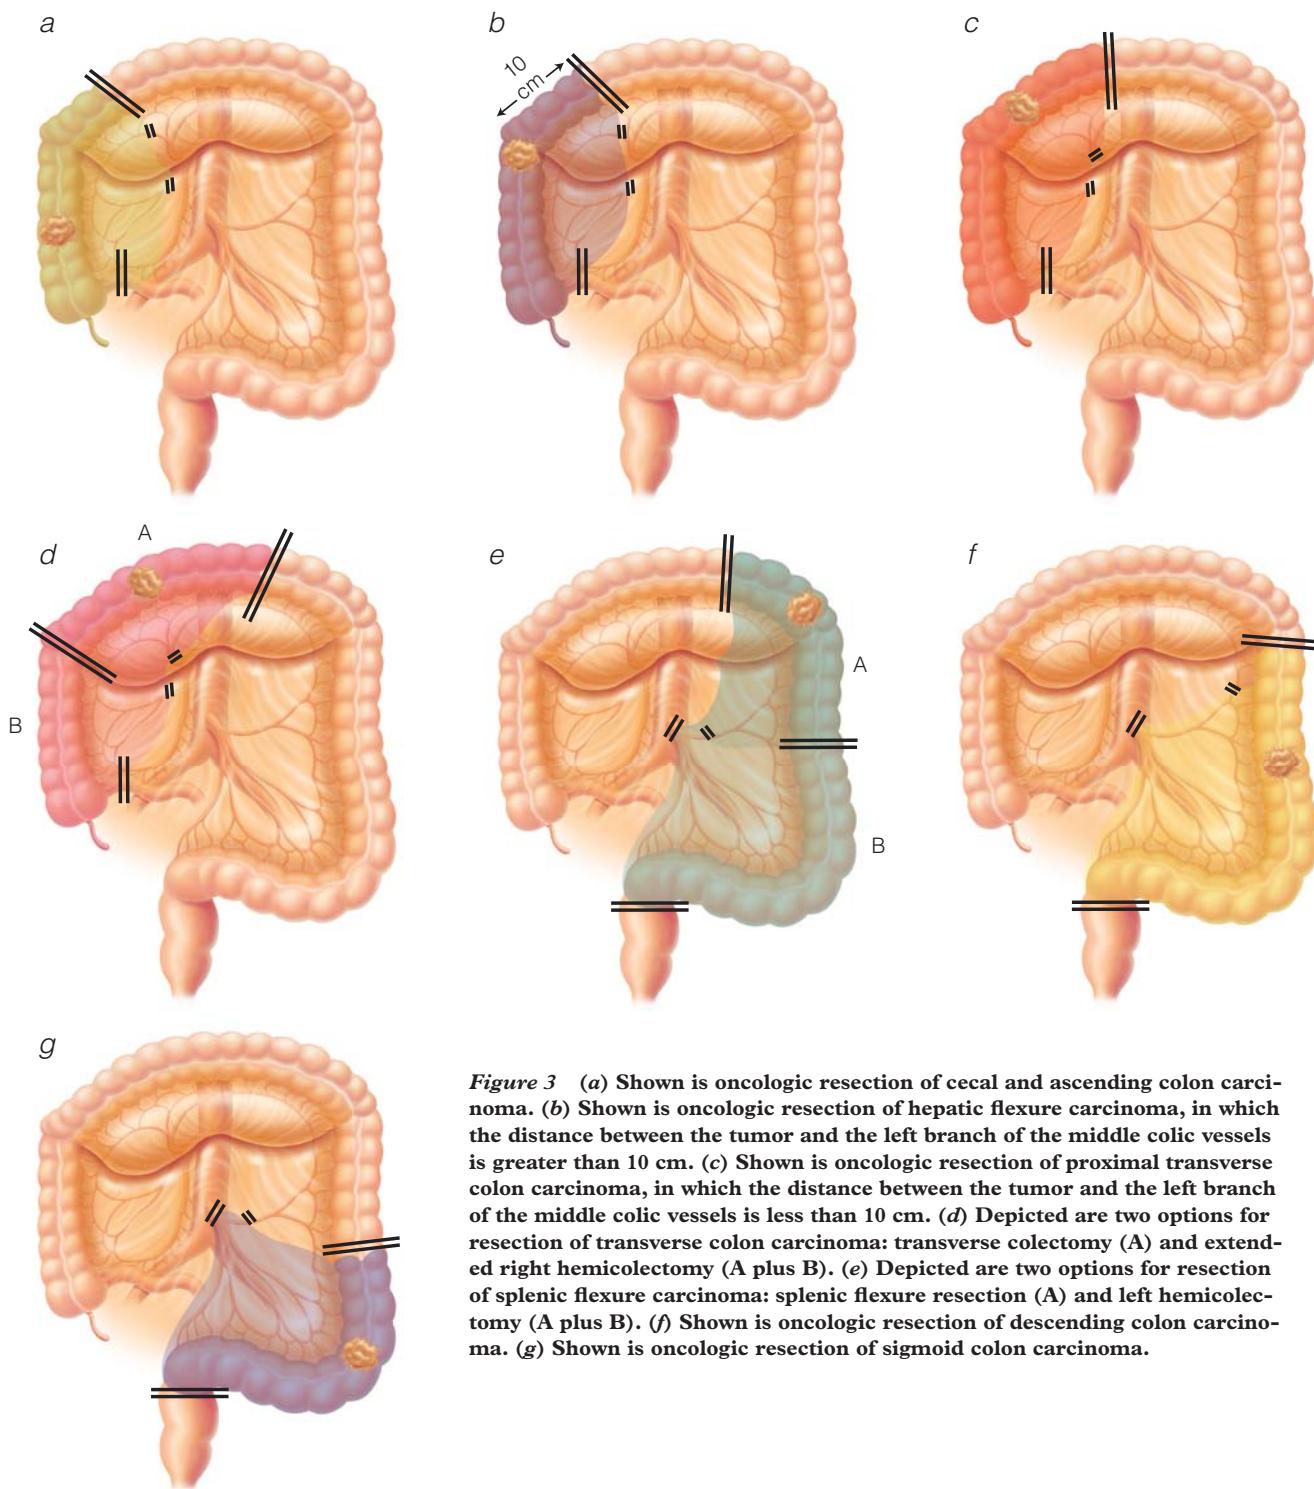

Figure 3 (a) Shown is oncologic resection of cecal and ascending colon carcinoma. (b) Shown is oncologic resection of hepatic flexure carcinoma, in which the distance between the tumor and the left branch of the middle colic vessels is greater than 10 cm. (c) Shown is oncologic resection of proximal transverse colon carcinoma, in which the distance between the tumor and the left branch of the middle colic vessels is less than 10 cm. (d) Depicted are two options for resection of transverse colon carcinoma: transverse colectomy (A) and extended right hemicolectomy (A plus B). (e) Depicted are two options for resection of splenic flexure carcinoma: splenic flexure resection (A) and left hemicolectomy (A plus B). (f) Shown is oncologic resection of descending colon carcinoma. (g) Shown is oncologic resection of sigmoid colon carcinoma.

1. Wide mesenteric clearance, including high ligation of all draining mesenteric vessels.
2. Minimization of trauma to the tumor during mobilization.
3. Adequate proximal and distal bowel margins.
4. Wide clearance of tumor in cases of contiguous organ invasion.
5. Complete and accurate intraoperative exploration.

It can be argued that the no-touch isolation technique is an important component of oncologic surgical principles. Certainly, this technique adds little to the difficulty of the operation and can be performed without causing additional morbidity. We continue to employ the no-touch technique in the resection of

colon carcinomas. Recommended resections of the abdominal colon for cancer depend on the location of the tumor [see Figure 3].

LAPAROSCOPIC VERSUS OPEN RESECTION

Laparoscopic surgical treatment of colorectal disease has been slow to gain acceptance, primarily because the techniques are difficult to master, the operations are longer, and the ileus response is still not eliminated after the procedure. At present, the overwhelming majority of colon resections in the United States are still being performed by conventional means.

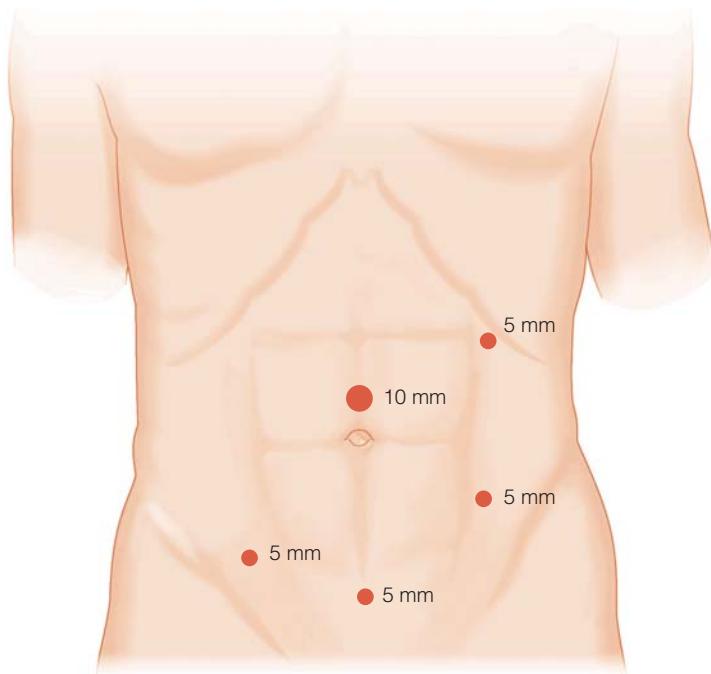

Figure 4 Laparoscopic right hemicolecotomy. Illustrated is recommended port placement.

A growing number of reports have described short-term benefits of laparoscopy in treating benign conditions of the colon (e.g., diverticulitis, Crohn disease, and ulcerative colitis). Controlled studies performed by experienced surgeons have found laparoscopy to have advantages over open resection in terms of resolution of ileus, duration of hospitalization, level of postoperative pain, recovery of pulmonary function, and complication rates.¹⁶⁻²⁰ Even some cost analyses favor laparoscopic colectomy over conventional surgery, finding that the higher costs of the surgical instruments and the potentially longer operating times are outweighed by the shorter duration of hospitalization.²¹⁻²⁴ There also appears to be a lower incidence of surgical site complications after laparoscopy than after open surgery, as well as a lower incidence of postoperative adhesions (and thus, possibly, of subsequent small bowel obstruction).^{25,26}

Fear of port-site recurrences initially kept laparoscopy from being widely accepted in the treatment of colorectal carcinoma, but several randomized, controlled studies reported that the wound recurrence rates with laparoscopic resections were no different from those with open resections.²⁷⁻³¹ Particularly significant were the long-awaited results of the randomized, prospective trial carried out by the Clinical Outcomes of Surgical Therapy (COST) Study Group, which found the oncologic outcomes of open and laparoscopic surgery to be similar after a median follow-up period of 4.4 years.³¹ Also noteworthy was a randomized, prospective trial from Barcelona, which reported that cancer-related survival was actually better after laparoscopic surgery for colon cancer than after open surgery.²⁹ Further randomized trials are under way in Europe and Australia. These studies have helped lift the virtual moratorium on laparoscopic treatment of colorectal cancer, but surgeons must be reminded that they must first gain adequate laparoscopic experience with benign conditions of the colon before attempting laparoscopy for malignant disease.

APPROACHES TO MOBILIZATION OF COLON

The development of laparoscopy has given prominence to the concept of medial-to-lateral mobilization of the colon, as opposed

to the lateral mobilization employed in most open colectomies. In all, there are four main approaches to mobilizing the colon. With the lateral approach, the lateral attachment of the colon is divided first, and the retromesenteric plane is then developed in a lateral-to-medial fashion. With the medial-to-lateral approach, the mesenteric vessels are isolated first, and the retromesenteric plane is then developed in an outward direction, with the lateral attachments of the colon left alone to suspend the colon during medial mobilization. With the inferior approach (as in right colectomy), the ileal attachment to the retroperitoneum is dissected initially in the direction of the duodenum. With the superior approach, the greater omentum and the transverse colon are dissected first.

It is quite possible—indeed, likely—that during the mobilization of a given colon segment, several or all of these approaches may be used sequentially. One approach may suit a particular patient better than another one does, and it is not uncommon for one approach to be abandoned in favor of another in the middle of the operation. Accordingly, it is important that surgeons achieve proficiency with all four approaches to mobilization. Provided that the proper dissection plane is entered, all four approaches will eventually converge.

Laparoscopic Right Hemicolecotomy

A right hemicolecotomy is performed to treat neoplasms of the cecum, the ascending colon, or the hepatic flexure. An extended right hemicolecotomy is usually performed to treat tumors located in the transverse colon, especially those to the right of the midline.

OPERATIVE TECHNIQUE

Step 1: Placement of Ports

The patient is placed in a modified lithotomy position. Four 5 mm ports and one 10 mm port are placed [see Figure 4]. The surgeon can stand either between the patient's legs or on the patient's left.

Step 2: Isolation of Ileocolic Pedicle

The patient is moved into the Trendelenburg position, with the right side tilted up. The greater omentum is raised above the transverse colon, and the transverse colon is retracted superiorly. The terminal ileum is allowed to drop inferiorly toward the pelvis, and the proximal small bowel loops are swept to the patient's left. The

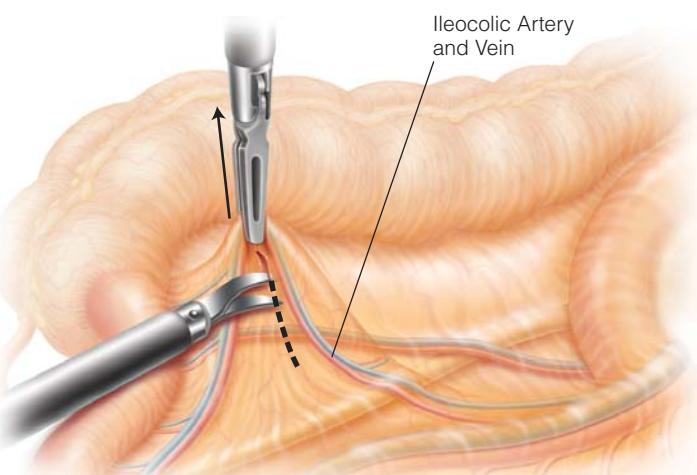

Figure 5 Laparoscopic right hemicolecotomy. The ileocolic pedicle is dissected in the direction of its origin and isolated.

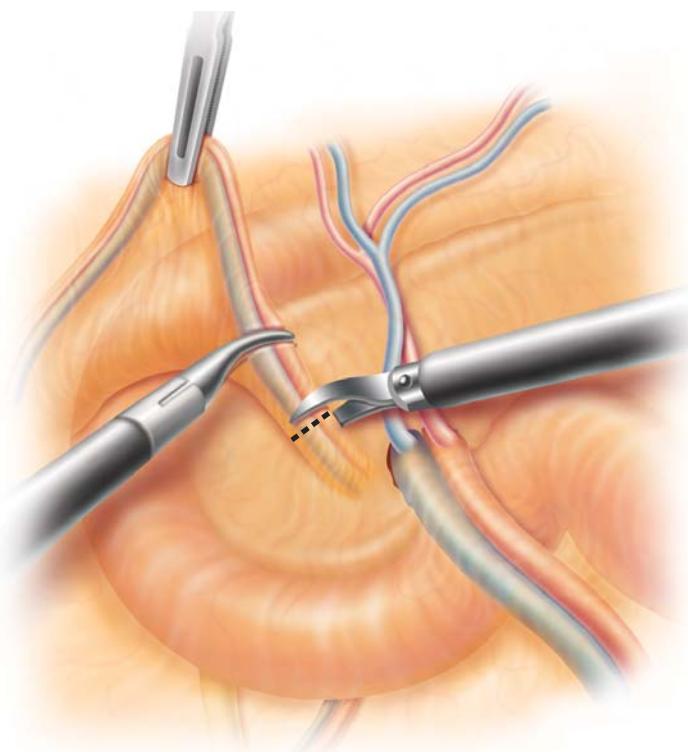

Figure 6 Laparoscopic right hemicolectomy. The right colic vein and the artery accompanying it to the hepatic flexure are isolated and divided.

duodenum is initially identified through the mesentery, just to the right of the superior mesenteric vessels at the angle between the transverse mesocolon and the right colonic mesentery. With anterolateral traction placed on the ileocecal junction, the ileocolic pedicle can be seen “bowstringing” through the mesentery, just inferior to the duodenum. Studies of arterial anatomy show that the ileocolic artery (ICA) is a constant structure and that, in almost

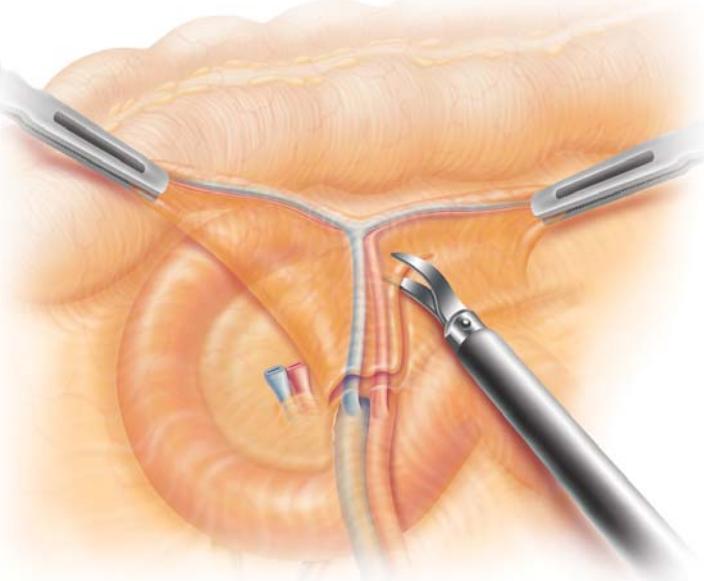

Figure 7 Laparoscopic right hemicolectomy. The main trunk of the middle colic artery is most easily accessed via a plane created to the left of the vessel.

90% of cases, the right colic artery (RCA) branches off from the ICA, not from the superior mesenteric artery (SMA). A window is made in the mesentery inferior and superior to the ileocolic pedicle, and the pedicle is dissected in the direction of its origin and ligated [see Figure 5]. Ligation can be accomplished by means of clips, vascular staplers, or the LigaSure Atlas; unless clips are used, the ICA and the ileocolic vein (ICV) can be ligated together.

Step 3: Dissection of Middle Colic Vessels

Next, the thin cut edge of the transverse mesocolon overlying the duodenum is grasped, and the duodenum is carefully swept down in a posterior direction. This measure initiates the medial-to-lateral mobilization of the transverse colon. The head of the pancreas is bluntly dissected, with care taken not to avulse the right colic vein or a branch of the inferior pancreaticoduodenal vein. A plane is gently developed to the right of the middle colic vessels. If this dissection proves difficult, the planned medial-to-lateral mobilization approach should be abandoned in favor of superior mobilization, and the omentum should be dissected off the transverse colon. In this way, access behind the middle colic artery (MCA) is facilitated.

The first vessel encountered to the right of the middle colic vessels is a venous branch to the right colic flexure. This branch converges with the right gastroepiploic vein (GEV) to form Henle’s gastrocolic trunk, which empties into the superior mesenteric vein (SMV). The right colic vein (RCV) should be divided proximally so as to spare the right GEV. In some cases, an artery accompanies the RCV to the hepatic flexure; if present, this artery should be divided proximally, together with the vein [see Figure 6]. The peritoneum overlying the middle colic vasculature is then opened from right to left, and the right branch of the MCA is isolated and divided at its origin, with care taken to preserve the left branch. The anatomy of the MCA is quite variable, and the classic pattern of a single trunk that bifurcates into right and left branches occurs in only 46% of cases. Instead, one, two, or even three vessels may arise from the SMA to supply the transverse colon.

In the case of an extended right hemicolectomy, the main trunk of the MCA should be divided at its takeoff from the SMA at the base of the pancreas. To this end, the peritoneum overlying the base of the middle colic vessels is opened from right to left, and a dissection plane is created to the left of the MCA [see Figure 7]. Access behind the middle colic vessels is best gained by proceeding from left to right, with the surgeon operating from the patient’s left side. The middle colic vessels are isolated and divided at the appropriate level. After ligation of the middle colic vessels, an area of the transverse colon is chosen as the distal transection line, and the transverse mesocolon is divided in the direction of the bowel wall.

Step 4: Medial-to-Lateral Mobilization of Right Colon

The transverse mesocolon is then lifted anteriorly, and blunt medial-to-lateral dissection of the colon is performed, extending the previous dissection plane above the duodenum to the patient’s right [see Figure 8]. Care should be taken to ensure that the dissection plane remains anterior to Toldt’s retroperitoneal fascia (the white line of Toldt). The dissection is extended underneath the hepatic flexure, then underneath the right colon and the cecum. The right ureter should remain safely underneath an intact retroperitoneal fascia.

Step 5: Inferior Mobilization of Ileum and Lateral Mobilization of Right Colon

Next, the terminal ileum is retracted out of the pelvis. With strong traction applied anteriorly and cephalad, the ileal attach-

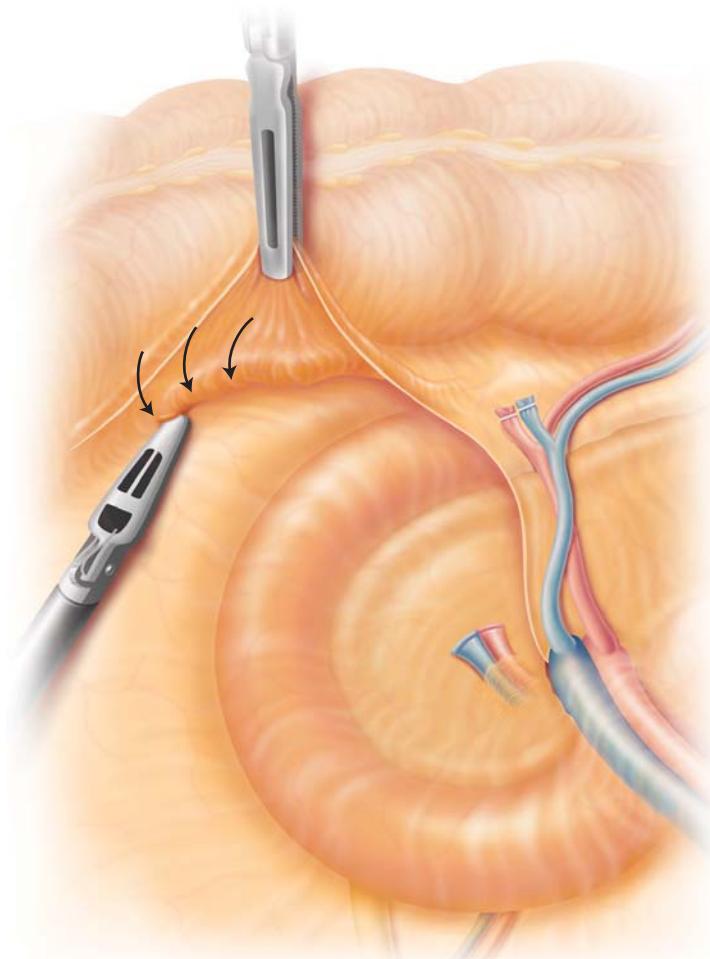

Figure 8 Laparoscopic right hemicolectomy. The right colon undergoes medial-to-lateral retromesenteric dissection, with the lateral attachments remaining untouched.

ment to the retroperitoneum is exposed and the peritoneum incised. If the medial dissection was adequate, this attachment will be thin; if not, the retroperitoneum may remain adherent to the cecum, in which case it will be necessary to identify the right ureter as it crosses over the right iliac vessels to ensure that it is not injured during mobilization. After the dissection has met the previous medial dissection plane, it is continued around the appendix and the cecum, and the lateral attachments of the right colon are taken down [see Figure 9]. Dissection of the hepatic flexure will become difficult with this approach. To resolve the difficulty, the patient is taken out of the Trendelenburg position, and the surgeon moves to the patient's left. The omentum is further dissected off the proximal transverse colon from left to right, and the takedown of the hepatic flexure is completed via this approach.

Step 6: Exteriorization, Resection, and Anastomosis

The appendix is grasped with a bowel clamp. A minilaparotomy is made, either as a midline extension of the umbilical port incision or in the epigastrium, depending on the transverse colon reach. It is usually about 5 cm long, but the size may be adjusted, depending on the size of the tumor. A wound protector is inserted to keep the surgical site from being contaminated by tumor. The mobilized right colon is then exteriorized.

Extracorporeally, the terminal ileum is cleaned and divided proximal to the ileocecal valve with a linear stapler. The ileal

mesentery is dissected from the divided ileum toward the cut edge of the ileocolic pedicle, and the ileal and accessory ileal branches are ligated. The marginal artery of the transverse colon is ligated, and the transverse colon is divided with a linear stapler 5 to 10 cm distal to the tumor to liberate the specimen.

As in the equivalent open procedure, the anastomosis is then created extracorporeally with either handsewn stitches or staples. The bowel is replaced into the abdomen, and the minilaparotomy is closed.

TROUBLESHOOTING

Injury to Superior Mesenteric Vessels

The SMV is fragile and is susceptible to sharp injury, as well as to avulsion injury at the origin of the ICV caused by aggressive blunt dissection. Accordingly, the area around this vessel must be dissected with particular care. To prevent sharp injury to the SMV, the peritoneum overlying the origin of the ileocolic pedicle should be dissected first; this measure should help clarify the vascular anatomy. During ligation of the ileocolic pedicle, a small stump should be left to prevent encroachment into the superior mesenteric vessels. If bleeding develops from the cut pedicle, an absorbable 2-0 tie can be placed around the stump with an Endoloop applicator (Ethicon Endo-Surgery, Somerville, New Jersey).

Injury to Inferior Pancreaticoduodenal Vein or Right Gastroepiploic Vein

The head of the pancreas is susceptible to significant venous bleeding, especially when a branch of the inferior pancreaticoduodenal vein is torn during aggressive blunt mobilization. The right GEV is also at risk for division or injury with proximal ligation of the RVC. Any blunt dissection at the pancreatic head must be performed gently. It should be kept in mind that the RCV converges with the right GEV at the head of the pancreas. To prevent injury to the right GEV, the transverse colon should be lifted anteriorly, and only the vein or veins traveling to the colon should be divided; any veins traveling underneath the colon toward the stomach should be spared.

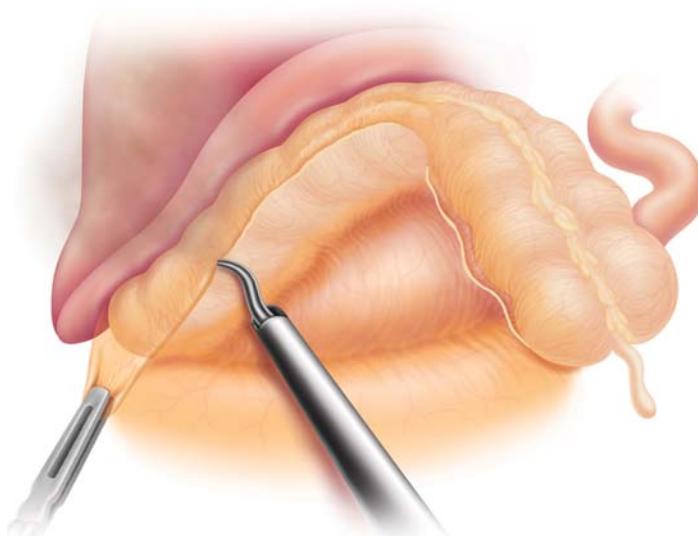

Figure 9 Laparoscopic right hemicolectomy. The right colon is mobilized laterally.

Injury to Duodenal Sweep

Because the origin of the ileocolic pedicle is always in close proximity to the duodenal sweep, the latter structure is at risk for injury during dissection of the former. Accordingly, during the mobilization and division of the ileocolic pedicle, the duodenum should be identified and bluntly swept away to ensure that it is not subjected to sharp injury or accidental cauterization.

Injury to Right Ureter

As a rule, in a properly performed laparoscopic right hemicolectomy, the ureter should remain underneath Toldt's retroperitoneal fascia, and thus, the surgeon should be able to complete the operation without seeing a skeletonized right ureter. However, injury to the right ureter remains a risk. If Toldt's fascia cannot be clearly visualized via a medial approach and the dissection plane is unclear during the isolation of the ileocolic pedicle, it is advisable to switch to an inferior approach and mobilize the ileum off the retroperitoneum, identifying the right ureter and tracing it toward the duodenum before dividing the pedicle. Right ureter injury most commonly occurs over the right iliac vessels during cecal mobilization; accordingly, care should be taken to make sure that the dissection plane is not too posterior.

Mobilization Posterior to Gerota's Fat

In some patients, Gerota's fat is fused to the posterior aspect of the right colon mesentery. When this is the case, there is a risk that Gerota's fat will be entered during either medial or lateral mobilization—or, worse, that dissection will take place posterior to the kidney during lateral mobilization. To minimize this risk, one must carefully look for Toldt's retroperitoneal fascia during both medial and lateral mobilization, then make sure to push down this fascia and remain anterior to it.

Twisting of Ileum during Anastomosis

During anastomosis, the terminal ileum (or, less commonly, the transverse colon) can be twisted 360° around its mesentery. The twisting tends to occur after division of the ileum, while the surgeon is concentrating on the transverse colon; often, it is not visible through a minilaparotomy and consequently goes unnoticed. To prevent this complication, two seromuscular stay sutures, one proximal and one distal, may be placed into the ileum after the right colon is exteriorized and the terminal ileum and the mesentery are divided. These stay sutures are clamped individually and are never crossed. Once the anastomosis has been created, a final look through the laparoscope can confirm that the mesenteric orientation is correct.

Open Right Hemicolectomy

The major elements of open right hemicolectomy are essentially the same as those of the corresponding laparoscopic procedure [see Laparoscopic Right Hemicolectomy, above]: (1) vascular isolation, (2) bowel division, (3) mobilization, and (4) anastomosis. The length of the resected specimen should be the same for the open version of the operation as for the laparoscopic version. In what follows, we describe the no-touch isolation technique, which is our preferred approach.

OPERATIVE TECHNIQUE

Step 1: Incision

Although the operation is technically feasible through either a transverse incision or a midline incision, we prefer to use a midline

incision. Superiorly, the incision should extend about two thirds of the distance between the umbilicus and the xiphoid; inferiorly, it should extend about one third of the distance between the umbilicus and the pubic symphysis. The abdomen is explored for metastatic disease, and an abdominal retractor is inserted. A simple retractor, such as a Balfour or Alexis wound retractor, will usually suffice, though some additional manual retraction may be necessary. Some surgeons prefer to use a Thompson or Omni retractor, either of which will be more cumbersome to set up than a Balfour or Alexis retractor but will allow a wider field of retraction.

Step 2: Division of Ileocolic Pedicle

The tumor is identified but is not extensively manipulated. The omentum and the transverse colon are retracted superiorly, and any obvious lymph node enlargement is addressed along the ileocolic and middle colic vessels, the right gastroepiploic vessels, and the superior mesenteric vessels. If malignant involvement is suspected, a central lymph node may be sampled and evaluated by frozen-section examination. The ileocolic pedicle is identified as in a laparoscopic right hemicolectomy. A mesenteric window is made superior and inferior to the ileocolic pedicle, and the pedicle is isolated between two fingers. Both the artery and the vein are dissected in the direction of their origin from the superior mesenteric vessels, and the pedicle is clamped, divided, and tied.

Step 3: Dissection of Middle Colic Vessels

Next, the duodenum and the head of the pancreas are gently mobilized posteriorly and are bluntly swept away from the posterior aspect of the transverse mesocolon to expose the right side of the middle colic vessels. A dissecting clamp is placed underneath the peritoneum at the superior aspect of the divided ileocolic pedicle, and the peritoneum is incised just to the right of the superior mesenteric vessels in the direction of the trunk of the middle colic vessels. The peritoneum is then further incised along the right side of the middle colic trunk past the bifurcation of the middle colic vessels. (Delineation of these vessels can be facilitated by transillumination of the transverse mesocolon from the superior aspect.)

The right branches of the middle colic vessels are then carefully isolated and divided at their origins; the left branches are spared. The dissection is extended back toward the pancreas, and the RCV is divided at its origin, with the right GEV spared [see Laparoscopic Right Hemicolectomy, above]. The transverse mesocolon is dissected outward toward the transverse colon wall, where the marginal artery is divided and tied. The omentum is dissected away from the right half of the transverse colon, and the transverse colon is transected with a linear cutting stapler (for a stapled anastomosis) or divided between clamps (for a handsewn anastomosis).

If, during any part of this dissection, the anatomy of the middle colic vessels is unclear, it is advisable to switch to a superior approach. In this approach, the omentum is dissected away from the right half of the transverse colon and the mesocolon, and the transverse colon is cleaned off and divided at the appropriate level. The transverse mesocolon is then dissected in a central direction. The marginal artery is divided, and the mesentery is divided with the electrocautery in the direction of the bifurcation of the middle colic vessels. At this point, the right branch of the middle colic system should be easily identifiable. After the right branch is divided, the RCV is identified and divided near the head of the pancreas—again, with the right GEV spared.

Step 4: Division of Ileum and Ileal Mesentery

Next, the terminal ileum is retracted forcefully out of the pelvis and dissected free of the retroperitoneal structures along Toldt's

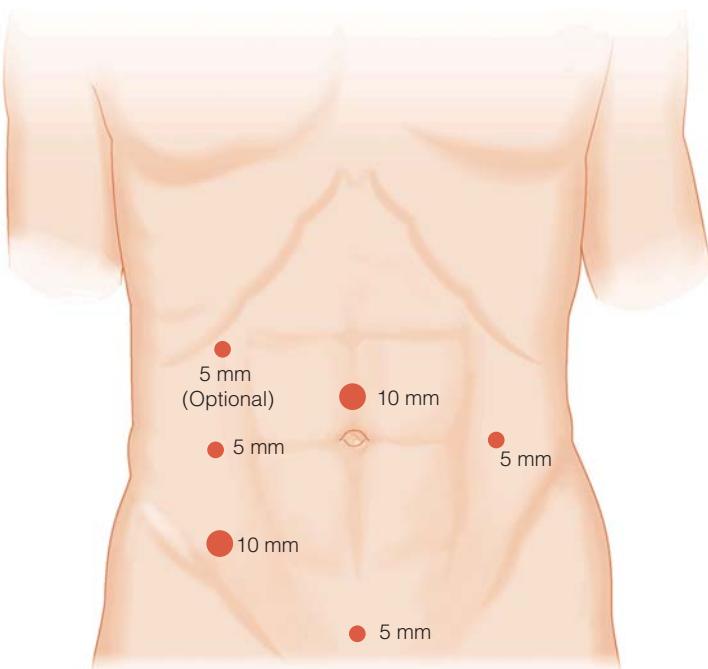

Figure 10 Laparoscopic sigmoid colectomy. Illustrated is recommended port placement.

retroperitoneal fascia. The terminal ileum is cleaned off and divided about 5 cm proximal to the ileocecal valve, either with a linear cutting stapler or between clamps. The ileal mesentery is then divided in the direction of the cut ileocolic pedicle. The marginal artery and the ileal and accessory ileal branches are divided. This step completes the isolation of the tumor before any manipulation of the cancer-bearing segment.

Step 5: Mobilization of Right Colon

The rest of the bowel mobilization is carried out via the lateral approach. With the ileocecal region retracted cephalad, the peritoneum is incised around the cecum along the white line of Toldt. A finger is passed through the peritoneal defect, and the cecum is retracted away from the retroperitoneum to facilitate this dissection. It is important that the dissection remain anterior to the right

ureter and the gonadal vessels. Dissection is continued around the cecum, and the right colon is mobilized along the white line of Toldt in the direction of the hepatic flexure. Some degree of fusion may be present between Toldt's retroperitoneal fascia and the mesentery, causing the mobilization to stray posterior to Gerota's fascia or even the right kidney; however, the correct dissection plane always remains anterior to the retroperitoneal fascia. A finger is passed underneath the peritoneal layers of the hepatic flexure, and the flexure is mobilized with the electrocautery.

As the right colon is peeled away from the retroperitoneal fascia, the duodenum is identified. The duodenal attachments to the mobilized right colon are divided to free the specimen.

Step 6: Anastomosis

The anastomosis between the ileum and the transverse colon can be created with any of several handsewn or stapled techniques (e.g., end-to-end, end-to-side, side-to-side, or functional end-to-end). Basic anastomotic techniques are discussed in greater detail elsewhere [see 5:29 *Intestinal Anastomosis*]. For present purposes, it is sufficient to note that all of the various approaches to intestinal anastomosis, if constructed well, should yield essentially equal results in terms of postoperative function and rate of leakage. Whichever approach is adopted, it is essential that the cut ends of the bowel be well perfused. If bowel perfusion is in doubt, one should check for bleeding from the cut bowel edge or assess the marginal artery for pulses or bleeding. The mesenteric window need not be closed after creation of the anastomosis, because it is usually large and a mesenteric hernia with incarceration is exceedingly rare.

Laparoscopic Sigmoid Colectomy

Step 1: Placement of Ports

The patient is placed in a modified lithotomy position. Three or four 5 mm ports, one 10 mm port, and one 12 mm port are placed [see Figure 10]. When addressing the left lower quadrant, the surgeon stands to the patient's right, with the assistant standing to the patient's left. When mobilizing the splenic flexure, the surgeon stands between the patient's legs, with the assistant standing to the patient's right.

Step 2: Isolation and Division of Inferior Mesenteric Vessels

The patient is moved into a steep Trendelenburg position, with the left side tilted up. With the medial-to-lateral approach to mobilization, the IMA is first approached medially. The sigmoid colon is retracted strongly out of the pelvis, and the sigmoid mesocolon is placed on anterolateral traction by the assistant. The initial dissection plane is just posterior to the IMA, where there is a clear avascular space, and the dissection is best begun at the sacral promontory. A wide peritoneal incision is made in the sigmoid mesentery [see Figure 11]. The right and left hypogastric nerves are swept away from the inferior mesenteric vessels in a posterior direction. The dissection plane is then extended laterally toward the abdominal wall, staying anterior to Toldt's retroperitoneal fascia. The left ureter must be identified before the next step is initiated; if it cannot be identified, it should be sought on the superior aspect of the LCA, or the approach should be changed to a lateral one. The IMA is isolated at its takeoff from the aorta and divided. The IMV is then isolated and divided proximally.

Next, Toldt's retroperitoneal fascia is bluntly swept away from the posterior aspect of the left colon mesentery in a medial-to-lateral direction as far as the lateral abdominal wall. If the dissection

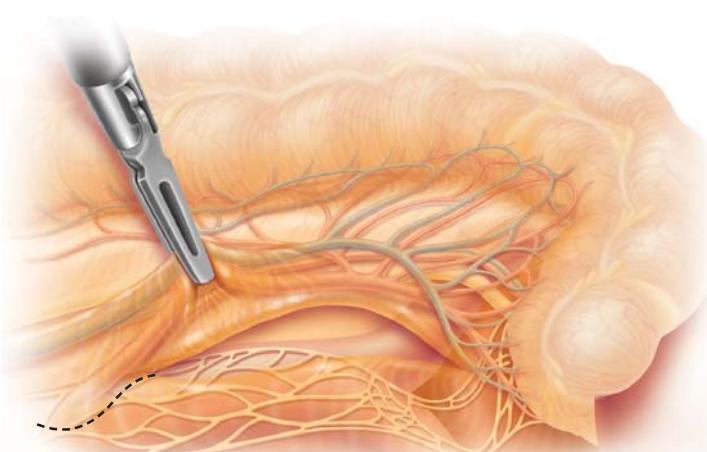

Figure 11 Laparoscopic sigmoid colectomy. A wide peritoneal window is created to provide access to the avascular plane posterior to the inferior mesenteric vessels.

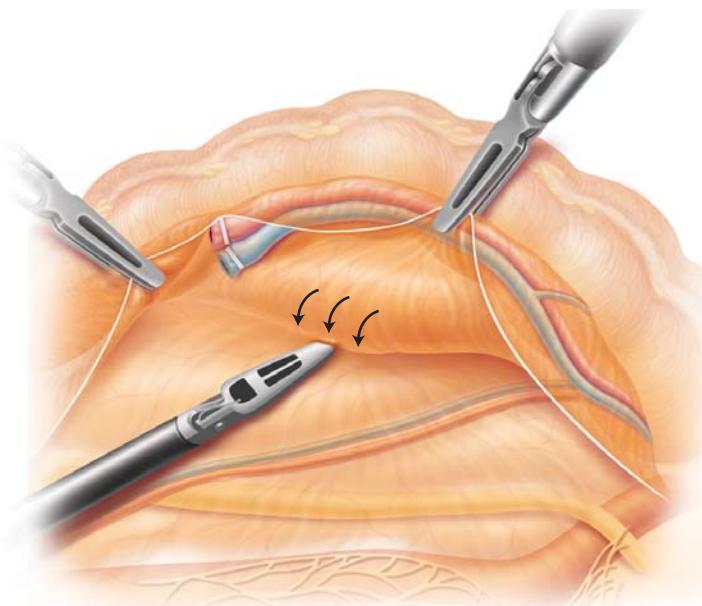

Figure 12 Laparoscopic sigmoid colectomy. In a medial-to-lateral retromesenteric dissection, the correct dissection plane is anterior to Toldt's retroperitoneal fascia.

is carried out in the correct plane, Gerota's fat will remain safely underneath Toldt's retroperitoneal fascia, as will the left ureter and the left gonadal vein [see Figure 12]. This retromesenteric dissection is then continued toward the upper pole of the kidney until it becomes difficult, at which point it is extended inferiorly toward the left psoas muscle and the iliac vessels.

Step 3: Lateral Mobilization of Left Colon and Takedown of Splenic Flexure

The sigmoid colon is retracted medially, and its attachment to the lateral abdominal wall is taken down. If the medial mobilization was adequately done underneath the sigmoid colon, the lateral attachment should be thin [see Figure 13]. The lateral ligament is divided cephalad, toward the splenic flexure. The attachments of the splenic flexure are complex; eventually, the splenocolic ligament, the so-called renocolic ligament (which is actually more a fusion of tissues than it is a ligament), and the omental attachments are mobilized. The inferior border of the pancreas has

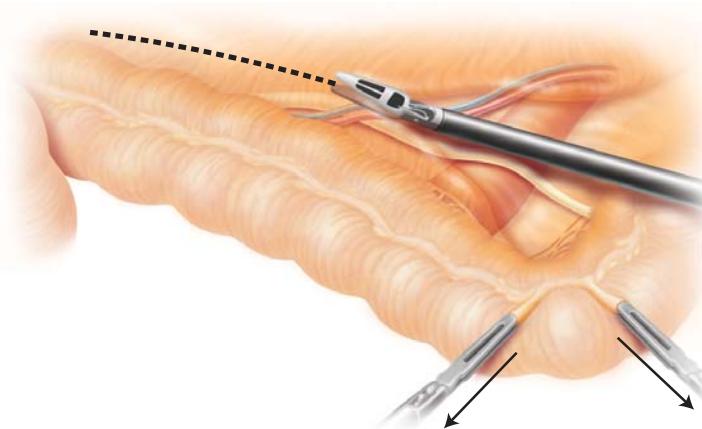

Figure 13 Laparoscopic sigmoid colectomy. The left colon is mobilized laterally.

attachments to the transverse mesocolon, and this area should be dissected carefully so as not to injure the pancreatic tail, which sometimes, at first viewing, is difficult to distinguish from omental fat. A LigaSure Atlas or an ultrasonic dissector works especially well for limiting blood loss during takedown of the splenic flexure. The greater omentum is dissected off the distal transverse colon from right to left, the lesser sac is entered, and mobilization is continued laterally until it meets the previous dissection, at which point the flexure is completely mobilized.

Step 4: Distal Division, Exteriorization, and Proximal Division of Sigmoid Colon

The mesentery of the rectosigmoid is then mobilized, and the line of distal transection is determined. The hypogastric nerves should be assessed again to confirm that they are not stuck to the mesentery. The upper mesorectum, including the superior hemorrhoidal vessels, is divided until the rectosigmoid wall is cleaned off. A laparoscopic linear stapler is inserted through the 12 mm port in the lower abdomen, and the rectosigmoid is divided. Division may require one or two firings and is facilitated by the use of an articulated rotating stapler. The cut end of the rectosigmoid is grasped with a bowel grasper placed through the right lower quadrant port.

A minilaparotomy is then created, either as an extension of the left lower quadrant port incision or as an extension of the umbilical port incision. As in a right hemicolectomy, the length of the minilaparotomy is tailored to the size of the tumor. A wound protector is inserted to prevent implantation of tumor cells, and the cut end of the specimen is exteriorized through the minilaparotomy [see Figure 14]. The sigmoid colon is brought out of the wound until at least 15 cm proximal to the tumor has been exteriorized. The colon is then divided so as to leave an adequate proximal margin, and the marginal artery is ligated at this level to liberate the specimen.

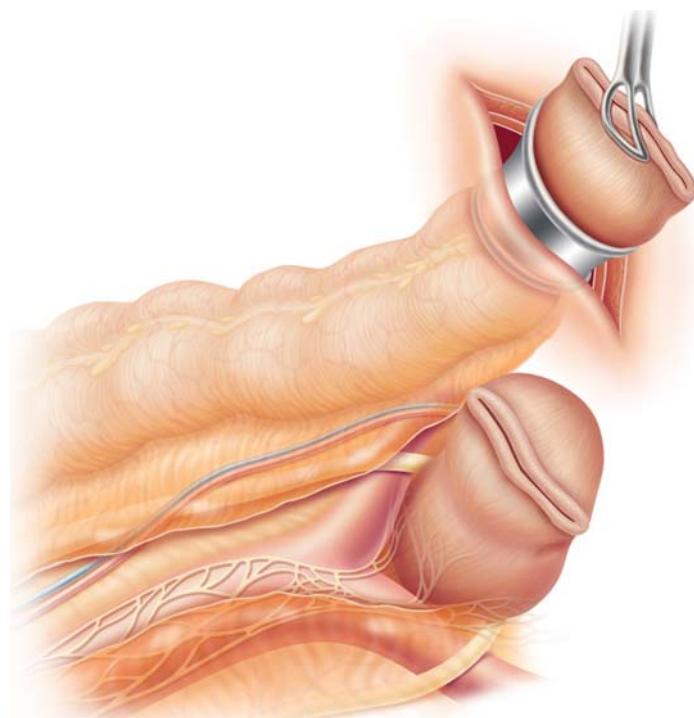

Figure 14 Laparoscopic sigmoid colectomy. After distal transection, the sigmoid colon is exteriorized.

Step 5: Anastomosis

Next, the colon is prepared for anastomosis. A purse-string suture is placed into the open mouth of the colon, and the center rod and the anvil of a circular end-to-end anastomosis (EEA) stapler are inserted. The colon is placed back into the abdomen, and the minilaparotomy is closed.

Pneumoperitoneum is reestablished, and under laparoscopic visualization, a stapled circular anastomosis is fashioned between the proximal cut end and the rectosigmoid stump. A leak test is performed by instilling normal saline into the pelvis, occluding the bowel proximal to the anastomosis, and injecting air through a rigid proctoscope or a flexible sigmoidoscope. A final exploration is performed to confirm that the small bowel has not migrated underneath the left colon mesentery.

TROUBLESHOOTING***Difficulty Identifying IMA***

Especially in obese patients, initial identification of the IMA can be difficult from the medial approach (with dissection either too posterior or too anterior), leading to a bloody and confusing mobilization. The problem can be minimized by first retracting the sigmoid colon strongly out of the pelvis, then retracting it anterolaterally. This action pulls the IMA pedicle anteriorly away from the surface of the aorta. The next step is to feel for the sacral promontory with laparoscopic instruments and start the dissection there; this site affords the easiest entry into the avascular plane posterior to the IMA. If the bony promontory cannot be palpated, the colon has not been adequately retracted. If the correct plane still cannot be identified, it is advisable to switch to the lateral approach.

Injury to Hypogastric Nerve Plexus

The right and left hypogastric nerves travel along the anterior surface of the aorta and over the aortic bifurcation, then spread out toward the pelvic sidewall. Branches of these nerves—and sometimes the main trunks—adhere to the posterior aspect of the inferior mesenteric pedicle and consequently may be transected when the IMA is divided. To keep this from occurring, these nerves must be visualized and swept away in a posterior direction. The initial mesenteric window should be made wide enough for adequate visualization. The surface of the aorta and its bifurcation should not be skeletonized.

Injury to Left Ureter

With the medial approach, it is easy to dissect too deeply, extending the plane underneath the left ureter and the left gonadal vein. Care should therefore be taken to search for Toldt's retroperitoneal fascia and stay anterior to it. Ideally, the left ureter should be identified before the IMA is ligated. If this is not possible, it is advisable to switch to the lateral approach and mobilize the sigmoid colon accordingly.

Tearing of Splenic Capsule during Splenic Flexure Mobilization

Avgulsion of the splenic capsule is usually caused by traction. The capsule is most vulnerable to injury when the colon is in close proximity to the spleen. The risk of splenic injury may be reduced by either (1) early (posterior) dissection of the renocolic ligament before lateral mobilization of the splenic flexure or (2) dissection of the flexure close to the colonic wall. The early separation of the left kidney from the left colonic mesentery (with the dissection plane remaining anterior to the retroperitoneal fascia) causes the flexure to drop down, which widens the distance between the colon and the spleen. During mobilization of the splenocolic liga-

ment and the greater omentum, it is important that the dissection not wander away from the colonic wall; if it does, the anatomy can become even more confusing.

Positive Anastomotic Leak Test

When a leak test yields positive results, the anastomosis must be repaired or revised. If the site of the bubbling from the anastomosis can be identified and is on the anterior aspect of the colon, sutures may be placed laparoscopically for repair, and the leak test should be repeated. If the site of the leak is hard to identify, the rectum distal to the anastomosis may be dissected and divided and the anastomosis refashioned; however, this can be a difficult procedure. In cases where laparoscopic repair is not feasible, a small laparotomy (either a Pfannenstiel incision or a low midline incision) may be made, and the problem may be addressed by means of open techniques.

Open Sigmoid Colectomy

The major elements of open sigmoid colectomy, like those of open right hemicolectomy, are similar to those of its laparoscopic counterpart [see Laparoscopic Sigmoid Colectomy, above]: (1) vascular isolation, (2) bowel division, (3) mobilization, and (4) anastomosis. The excellent visualization afforded by the laparoscope allows the use of the no-touch isolation technique for laparoscopic resection of left colon malignancies, but it is difficult to employ a true no-touch technique for open left colon resections. Because it is hard to ligate the IMA as the initial step, the sigmoid colon is usually mobilized via a lateral approach, which facilitates isolation and ligation of the inferior mesenteric vessels.

OPERATIVE TECHNIQUE***Step 1: Incision***

A midline incision is made from a point halfway between the xiphoid and the umbilicus down to the level of the pubis. The abdomen is explored, and a wound retractor is inserted.

Step 2: Mobilization of Sigmoid Colon

The sigmoid colon is strongly retracted in an anteromedial direction, and the white line of Toldt is incised to allow the sigmoid colon to be mobilized in a medial direction. With care taken not to dissect into the retroperitoneal structures, the dissection proceeds cephalad toward the splenic flexure along the line of fusion between the left colon and Toldt's retroperitoneal fascia, remaining anterior to the fascia at all times. The left gonadal vessels and the left ureter are identified and swept away from the sigmoid mesentery. Eventually, the undersurface of the IMV is identified in the midline. The left hypogastric nerve fibers are bluntly swept away in a posterior direction, and a finger is inserted underneath the inferior mesenteric vessels toward the patient's right. The sigmoid mesentery from the medial side is then opened widely, and the right hypogastric nerve fibers are preserved by sweeping them away from the IMA in a posterior direction.

Step 3: Division of Inferior Mesenteric Artery and Vein

The IMA is dissected in the direction of its takeoff from the aorta, isolated, and divided. If the IMA is not fully skeletonized, the left ureter should be checked to make sure that it has not been inadvertently clamped together with the IMA before transection of the vessel. The IMV, located just lateral to the IMA at this location, is isolated and divided in the direction of the inferior border of the pancreas. The mesenteric dissection is then continued back toward

the LCA, which is divided at its origin to preserve a secondary arcade that will perfuse the proximal aspect of the anastomosis.

Step 4: Mobilization of Left Colon and Splenic Flexure

The splenic flexure should be mobilized via an inferior rather than a lateral approach. With the sigmoid colon retracted anteriorly and superiorly, a broad white line is apparent, delineating the fusion of Toldt's retroperitoneal fascia with the left colon mesentery (i.e., the renocolic ligament). The retroperitoneal fascia overlying the left kidney is bluntly swept away from the posterior aspect of the left colonic mesentery toward the base of the pancreas. When the upper pole of the left kidney is reached, the colon is returned to its original position, and the splenic flexure is approached.

Early mobilization of the splenic flexure posteriorly allows the flexure to drop down, increasing the distance between it and the capsule of the spleen in most cases. A finger is inserted underneath the peritoneum overlying the splenic flexure, staying close to the colon wall, and this splenocolic ligament is divided with the electrocautery. Any omental attachments to the flexure that are present are divided close to the colonic wall until the dissection becomes difficult. Takedown of the splenic flexure is easiest when dissection is done from both the right and the left. The omentum is dissected away from the distal transverse colon in a right-to-left direction as the colon both distal to and proximal to the flexure is simultaneously retracted inferiorly (the so-called omega maneuver). The final attachments of the splenic flexure are taken down with the electrocautery.

Step 5: Proximal and Distal Division of Bowel

With the left colon fully mobilized, the proximal resection line is chosen, with care taken to ensure that the proximal margin is ade-

quate and that the remaining bowel will be able to reach down to the pelvis without undue tension. The left colon mesentery is divided from the cut edge of the LCA toward the bowel wall, and the marginal artery is divided. The bowel is transected between clamps.

Distally, the rectosigmoid colon and the mesentery are mobilized, and the hypogastric nerves are swept away from the specimen. The mesentery of the rectosigmoid is dissected, and the superior hemorrhoidal vessels are divided. The rectosigmoid wall is then cleaned off and divided either between clamps or with a linear stapler (for a double-stapled anastomosis) to liberate the specimen.

Step 6: Anastomosis

A colorectal anastomosis is created between the proximal and distal cut edges of the bowel. For a double-stapled anastomosis [see 5:29 *Intestinal Anastomosis*], a purse-string suture is placed into the open mouth of the proximal bowel, the center rod and the anvil of a circular EEA stapler are inserted, and the purse-string suture is tied. The body of the stapler is advanced into the rectal stump, and the spike is pushed through the rectal wall. Once the proximal bowel has been checked to confirm that it is not twisted, the stapler is engaged and fired. A leak test of the anastomosis is then performed by instilling saline into the pelvis and gently infusing air into the bowel with a rigid proctoscope or a flexible sigmoidoscope while occluding the bowel proximally.

The anastomosis can also be created by means of a handsewn technique or a single-stapled technique (in which purse-string sutures are placed in both the proximal bowel and the distal bowel); these alternatives are described in more detail elsewhere [see 5:29 *Intestinal Anastomosis*]. In many cases, handsewn and stapling techniques may be equally suitable; however, for anastomoses fashioned lower in the pelvis, staples should be favored over sutures.

35 PROCEDURES FOR RECTAL CANCER

David A. Rothenberger, M.D., F.A.C.S., and Rocco Ricciardi, M.D.

Rectal cancer is a common and lethal malignancy that is diagnosed in more than 42,000 persons in the United States each year.¹ In treating this condition, the goals are to cure or control the primary cancer, to maintain or restore bowel continuity with normal anal continence, to preserve sexual and bladder function, and to minimize other treatment-associated morbidity and mortality. A variety of rectal cancer treatment regimens are now available, spanning the spectrum from simple polypectomy to prolonged and potentially morbid multimodality regimens involving neoadjuvant chemoradiation therapy, radical extirpative surgery, and adjuvant chemotherapy.

Choosing the optimal therapy for rectal cancer is a complex process. Although physicians from different disciplines are often involved, it is the colorectal surgeon who generally directs the process of evaluation and treatment. As new knowledge has been acquired and new therapies and techniques have been developed, management of rectal cancer has changed dramatically. In this chapter, we examine the surgeon's unique and critical role in the preoperative decisions leading to choice of therapy, review the intraoperative decisions influencing the course of surgical therapy, and address key technical aspects of the operations performed to treat rectal cancer.

Preoperative Evaluation

Evaluation of the patient with rectal cancer includes the following: (1) visualization of the tumor and biopsy to determine the precise location of the lesion and confirm the diagnosis of adenocarcinoma; (2) accurate staging of the neoplasm by determining the extent of bowel wall penetration (T stage), the presence of metastases to local lymph nodes (N stage), and the presence of metastatic spread to distant sites (M stage); (3) colonoscopy to exclude synchronous lesions or other pathologic conditions of the colon; and (4) a thorough medical assessment to determine operative risk. A standardized workup facilitates staging and decision making.

HISTORY AND PHYSICAL EXAMINATION

A thorough history and a careful physical examination must be done to assess operative risk so that therapeutic options can be tailored to fit the comorbidities and desires of the patient. In modern series, mortality after radical resection of the rectum ranges from 2% to 6%,^{2,3} with the most common causes of death being myocardial infarction, pneumonia, venous thromboembolism (deep vein thrombosis and pulmonary embolism), anastomotic leakage, and stroke.⁴ Factors associated with increased mortality include impaired sensorium, low albumin level, elevated blood urea nitrogen concentration, and prolonged prothrombin time.³

The history focuses on gaining information that might alter the treatment plan or identify preexisting conditions worth addressing before an elective procedure. Essential information to be elicited includes a personal history of colorectal polyps or cancers; previous operations (especially those involving the digestive

or genitourinary organs); previous irradiation of the pelvis; baseline bowel and anal sphincter function; smoking status; use of alcohol or other drugs; medical comorbidities; and current medications. In particular, a family history suggestive of a hereditary cancer syndrome should be sought because such a history might call for additional diagnostic testing or affect the extent of bowel resection.

During the physical examination, the surgeon should be alert to the presence of liver enlargement, abdominal tenderness or masses, lymphadenopathy, and abdominal scars or ventral hernias from previous operations. The integrity and function of the anal sphincter are carefully assessed by means of digital rectal examination. A patient with preexisting fecal incontinence or sphincter injury may be best served by a local procedure or abdominoperineal resection (APR) rather than a well-intentioned but ill-conceived heroic effort to save the anal sphincter.

DETERMINATION OF EXTENT OF LOCAL DISEASE

Evaluation of the extent of the primary rectal cancer is essential for planning appropriate therapy. An easily palpable distal rectal malignancy that directly invades the anal sphincters usually is treated with APR. A large, fixed cancer that invades adjacent organs, the pelvic sidewalls, or the sacrum usually is treated with neoadjuvant chemoradiation followed by resection or palliative measures. A small, mobile, and readily accessible lesion may be amenable to local therapy.

Determination of the extent of local disease involves clinical examination, endoscopic assessment, and diagnostic imaging. Digital rectal examination, combined with proctoscopy, endorectal ultrasonography (ERUS), or magnetic resonance imaging, can determine the morphology of the lesion, the percentage of the rectal circumference involved, and the quadrants affected, as well as the degree of fixation, the adjacent organs invaded, and the presence of lymph nodes or extrarectal masses. The level of the lesion in relation to the anal sphincters is best assessed by means of digital rectal examination and ERUS or endorectal MRI. The distance of the lesion from the dentate line or the anal verge is assessed more accurately with rigid proctoscopy than with flexible endoscopy. Biopsy is required to confirm the suspected diagnosis of adenocarcinoma and to ascertain whether any unfavorable histologic features (e.g., mucin production, lymphovascular invasion, or signet cell histology) are present.

ERUS and MRI with endorectal coil are the two most useful methods of determining the T and N stages of rectal cancer. In a combined review of 1,966 patients evaluated with ERUS, staging accuracy averaged 88%.⁵ ERUS was highly (80% to 90%) accurate in predicting the extent of bowel wall involvement but was somewhat less (70% to 80%) accurate in identifying lymph node metastases.⁶ Currently, MRI with endorectal coil, though promising, is accurate in only 40% to 60% of cases; accordingly, it has not replaced ERUS for staging the extent of local disease.^{7,8} Newer MRI approaches that employ stronger magnets and do not require insertion of an endorectal coil may prove more accurate. ERUS

has the added advantage of offering a convenient and accurate means of performing image-directed biopsies of suspicious areas.

Pelvic computed tomographic scanning is not very accurate in determining the depth of bowel wall involvement or the presence of lymph node metastases: the highest accuracy reported for CT in this setting is approximately 76%,⁹ and most studies report much lower figures. Pelvic CT scanning is, however, useful for detecting extrarectal pelvic spread from rectal cancer. Presacral stranding, obliteration of normal landmarks lateral to the rectum, direct invasion of the sacrum or the pelvic sidewalls, invasion into the bladder or the vagina, and evidence of hydronephrosis are all signs of extensive pelvic disease.

SEARCH FOR DISTANT METASTASES

Evaluation of the patient with rectal cancer must also include a search for metastatic disease because the approach to the primary lesion may change if metastases are present. Few data are available on the utility of palliative rectal cancer surgery in the setting of metastatic disease; however, it is generally accepted that patients who present with asymptomatic or minimally symptomatic distant metastases but who have major local symptoms resulting from the primary rectal cancer may benefit from some form of palliative operation. As a rule, the least morbid procedure that will relieve the local symptoms is preferred. Often, the chosen procedure is palliative proctectomy, but sometimes, a less invasive local procedure (e.g., stenting) is an option. Patients who present with advanced and highly symptomatic distant metastases but who have an asymptomatic primary rectal cancer are usually best served by therapy directed toward the symptomatic metastases. The presence of extensive but minimally symptomatic metastases and a minimally symptomatic primary cancer of the rectum may mandate use of nonoperative, palliative treatment regimens.

Distant metastases arise most frequently in the liver and the lungs and are often asymptomatic; accordingly, routine evaluation for distant disease focuses on assessment of these two sites. If patients have specific symptoms suggestive of possible metastases to other organs or sites, additional imaging studies are ordered to explore this possibility. Chest x-ray and CT scanning are the modalities most commonly employed to identify pulmonary metastases; CT and MRI scanning are the ones most commonly employed to identify liver metastases. An alternative modality, positron emission tomography (PET), has proved highly (96%) sensitive in detecting the primary cancer but is of limited value in detecting local pelvic lymph node metastases.¹⁰ Some advocate using PET to detect other organ metastases or involvement of lymph nodes at distant sites. At present, however, there is little evidence to justify routine use of PET scanning in the workup of rectal cancer. Its major current uses are (1) to clarify equivocal findings on other scans and (2) to minimize the risk of missing a distant metastasis to an unusual site in a patient being considered for a highly morbid resection of an extensive primary or recurrent rectal cancer.

ASSESSMENT OF SYNCHRONOUS COLORECTAL NEOPLASMS

Total colonoscopy is recommended to exclude or remove synchronous lesions (e.g., polyps and other cancers). It is estimated that 5% to 10% of rectal cancer patients have synchronous cancers and 30% have additional adenomatous polyps. The significance of these other lesions is highlighted by a study of 98 patients with rectal cancers who underwent full colonoscopic surveillance before operation; in this study, surgical treatment was altered in 33% of cases.¹¹ If colonoscopy is incomplete, a double-

contrast barium enema or virtual colonoscopy with CT colography is a suitable alternative. If preoperative surveillance of the proximal colon is not possible, intraoperative or postoperative colonoscopy should be done.

Operative Planning

PRETREATMENT DECISIONS

In general, the surgeon is responsible for deciding what the intent of therapy will be (curative or palliative) and which treatment or treatments will be employed. To make these decisions, he or she must carefully consider the clinical staging information in the light of the anticipated operative technical challenges, the likely functional results, and the patient's level of operative risk, comorbidities, previous treatments, and specific needs.

Clinical staging is based on integration of information obtained from several sources, including clinical evaluation, imaging studies (e.g., ERUS, CT, MRI, and PET), colonoscopy, and histopathologic examination of the specimen obtained via biopsy or local excision. Because the information on which it is based is obtained before institution of definitive treatment, clinical staging is necessarily a less than perfect means of assessing the extent of disease. Nonetheless, it usually suffices to allow the surgeon to decide whether the intent of treatment will be curative or palliative and whether a local procedure, a radical procedure, or multimodality therapy will be indicated.

A history of previous cancer treatment may influence the choice of therapy, as may the presence of synchronous lesions, metastatic disease, extensive local spread, or unfavorable histopathology. Not infrequently, the ideal treatment is not feasible—either because of patient risk factors and comorbidities or because the patient refuses to accept the proposed treatment and its associated morbidity (e.g., a permanent colostomy)—and the treatment eventually chosen represents a compromise. The experienced surgeon can counsel the patient about therapeutic options, realistic expectations, and likely prognosis and obtain informed consent to proceed with a treatment protocol that is individualized to the specifics of a given case.

TREATMENT PROTOCOLS AND MULTIMODALITY THERAPY

Because treatment of rectal cancer is so highly individualized, it is difficult to be dogmatic about what constitutes optimal therapy. Nonetheless, there are certain generally accepted treatment guidelines for curative-intent treatment of rectal cancer, based primarily on pretreatment stage of disease, that are useful for the practicing surgeon [see Table 1].^{12,13} Curative-intent treatment of rectal cancer involves resection or ablation of all neoplastic tissue, which almost always necessitates surgical intervention, usually in the form of a radical resection. In highly select cases, local therapy may be indicated. Currently, multimodality therapy that combines operative treatment with perioperative chemoradiation is increasingly being employed to overcome the persistent problem of local recurrence.

Clinical trials designed to assess the efficacy of postoperative adjuvant pelvic irradiation in treating advanced cancers of the rectum demonstrated that appropriate doses of radiation can reduce local recurrence and even improve survival, especially when administered in conjunction with radiation-sensitizing chemotherapy and postoperative adjuvant chemotherapy.¹⁴⁻¹⁷ In the United States, most centers administer 45 to 54 Gy of radiation to the rectal cancer and the pelvis over a period of 4 to 6

Table 1 Rectal Neoplasms: Curative-Intent Therapy

Pretreatment Stage	Preferred Treatment	Acceptable Treatment
Stage 0 Tis N0 M0	Local therapy if technically feasible (excision is preferred to ablation for obtaining pathologic confirmation of T stage)	Radical resection (APR rarely indicated for Tis N0 M0 lesion) if local therapy is not feasible or safe
Stage I T1 N0 M0 (favorable features*) T1 N0 M0 (unfavorable features) T2 N0 M0	Local therapy ± chemoradiation for distal-third lesions or high-risk patients; radical resection for proximal lesions in good-risk patients Radical resection Radical resection (especially if unfavorable features are present and for proximal lesions in good-risk patients)	Radical resection Local therapy plus chemoradiation Local therapy plus chemoradiation
Stage II T3 N0 M0 T4 N0 M0	Preoperative chemoradiation, radical resection, and adjuvant chemotherapy Preoperative chemoradiation, radical resection with en bloc resection of involved organs, and adjuvant chemotherapy	Radical resection, postoperative chemoradiation, and adjuvant chemotherapy if pathologically appropriate (no adjuvant therapy if lesion is early T3 N0 M0) Radical resection, postoperative chemoradiation, and adjuvant chemotherapy
Stage III Tany N+ M0	Preoperative chemoradiation, radical resection, and adjuvant chemotherapy	Radical resection, postoperative chemoradiation, and adjuvant chemotherapy

*Lesions with favorable features are those that are exophytic, moderately or well differentiated, nonmucinous, non-signet cell, without lymphovascular invasion, extending around one quarter or less of the circumference of the rectum or no more than 3 cm in diameter, and located so that local therapy options are technically feasible and safe.

weeks. A 1990 National Institutes of Health consensus conference endorsed postoperative multimodality treatment of all stage II and III rectal cancers.¹⁸

Several researchers have assessed the use of preoperative neoadjuvant chemoradiation in treating advanced-stage rectal cancers.^{19,20} It was argued that because preoperative irradiation treats undisturbed, well-oxygenated rectal cancers, it should be more effective than postoperative irradiation, resulting in improved local control and better survival. In addition, it was argued that by decreasing the size of bulky rectal cancers, preoperative irradiation should increase the rate of curative resection and the rate of sphincter preservation.²¹ It was also thought that this neoadjuvant approach should diminish the incidence of the radiation injury seen after postoperative irradiation when small bowel is adherent to the pelvic operative site.²² Whereas centers in the United States tended to employ a prolonged course of irradiation both preoperatively and postoperatively, many European centers, especially in Scandinavia, preferred to use a protocol of preoperative short-course, high-dose, hypofractionation irradiation, which usually delivered 25 Gy over a period of 1 week.²³

There is now considerable evidence that chemoradiation can decrease local recurrence rates after radical procedures for rectal cancer and that it may improve survival and decrease the need for a permanent colostomy. To date, most studies have used 5-fluorouracil-based chemotherapy for radiation sensitization; studies using newer agents may be able to obtain further improvements in outcome.¹⁷ The success achieved by employing perioperative chemoradiation in conjunction with radical surgery has led to the use of perioperative chemoradiation with local excision in several centers. These promising results must be weighed against the short- and long-term morbidity associated with chemoradiation. At present, the main controversies in the selection of multimodality therapy for rectal cancer are (1) the tumor selection criteria, (2) the timing of therapy (preoperative or postoperative), (3) the dosing and course of radiation therapy, and (4) the use of chemoradiation in conjunction with local therapy. Discussion of these controversies and other issues surrounding the application of chemoradiation and adjuvant chemotherapy in the setting of rectal cancer is beyond the scope of this chapter.

PATHOLOGY-BASED STAGING AND POSTTREATMENT DECISIONS

Clinical staging that is based on pretreatment assessment must be distinguished from pathology-based staging that relies on information obtained by means of gross and microscopic examination of the resected rectal tumor and the surrounding mesorectum after radical excision. The classic pathology-based staging system developed by Dukes correlated patient survival with depth of rectal cancer invasion and local lymph node metastases.²⁴ Many modifications to the Dukes staging system were proposed, but it remained the most widely used system until 1987, when the American Joint Committee for Cancer Staging and End Results Reporting (now the American Joint Committee on Cancer [AJCC]) developed a new classification methodology that incorporated both relevant clinical information and pathology-based information.²⁵ The AJCC's proposed TNM classification system, which has been adopted by the International Union Against Cancer, is clinically useful, simple to use, and accepted worldwide [see Tables 2 and 3].

An important principle in managing patients with rectal cancer is to compare the pretreatment clinical stage with the final pathology-based stage to confirm the appropriateness of the proposed treatment protocol or to adjust therapy on the basis of new information. There is some evidence to indicate that patients who undergo radical procedures immediately after local excision of a tumor with unfavorable pathologic characteristics survive longer than those who undergo radical resection after a local recurrence.²⁶ The finding of a more advanced T stage after local therapy may induce the surgeon to proceed with radical resection or to add postoperative chemoradiation to the treatment protocol. The finding of a less advanced T stage after local therapy may induce the surgeon to recommend observation rather than risk the morbidity associated with planned chemoradiation. The presence of unsuspected multiple lymph node metastases in the mesorectum after radical resection of a T2 cancer may dictate use of postoperative chemoradiation. Whether a complete clinical response to neoadjuvant preoperative chemoradiation therapy for advanced-stage rectal cancer obviates radical resection is an issue that remains to be resolved.

Table 2 American Joint Committee on Cancer TNM Clinical Classification of Colorectal Cancer⁷⁶

Stage	Description*
Primary tumor (T)	Tis Carcinoma in situ
	T1 Invades submucosa
	T2 Invades muscularis propria
	T3 Invades serosa
	T4 Invades peritoneal cavity or adjacent organ through serosa
Regional lymph nodes (N)	NX Nodes cannot be assessed
	N0 No regional node metastases
	N1 1–3 positive nodes
	N2 4 or more positive nodes
Distant metastasis (M)	N3 Positive central nodes
	MX Cannot assess metastases
	M0 No distant metastases
	M1 Distant metastases present

*Suffix "m" is used to indicate primary tumors in a single site; prefix "y," to indicate cancers classified after pretreatment; prefix "r," to indicate tumors that have recurred; and prefix "a," to indicate staging at autopsy.

CHOICE OF PROCEDURE

Local Procedures

The benefits of local procedures for treatment of rectal cancer include minimal morbidity and mortality and rapid postoperative recovery. Such procedures allow preservation of genitourinary function and cause only minimal disturbance of anal continence. In some cases, local therapy is the only alternative to permanent colostomy. The major disadvantage of local procedures is that employing them inappropriately will result in high local recurrence rates and compromised survival. Local procedures may be used as curative-intent therapy for rectal cancer or as compromise therapy for patients who might not tolerate a radical procedure or who refuse a recommended radical resection (usually because of the potential for a permanent colostomy). Local therapy may also be used in select cases for palliation of symptomatic but incurable rectal cancers.

Curative-intent local therapy is usually restricted to treatment of highly favorable, accessible rectal cancers that do not invade the anal sphincter, are confined to the rectal wall, and are small enough to be totally removed or ablated. Any spread to local lymph nodes or distant sites is a contraindication to curative-intent local therapy. In theory, preoperative selection of such favorable T1–2 N0 M0 cancers for local treatment should result in minimal morbidity, excellent function, and long-term cancer-free survival.

Critics of local therapy note that on the basis of final pathology-based staging after radical resection, as many as 12% of patients with T1 cancers and 22% of those with T2 cancers have node-positive disease that would not have been treated by local procedures.^{27–32} These critics suggest that imaging studies cannot reliably distinguish node-negative from node-positive T1 and T2 rectal cancers and that treating all T1 and T2 rectal cancers with local therapy would result in dramatic increases in local recurrence rates and unacceptable decreases in survival rates. Thus, they argue that using local therapy as the only form of curative-intent treatment is inappropriate even for presumed early rectal cancer. Some authorities maintain that curative-intent local therapy should be employed only in conjunction with multimodality therapy, even for favorable T1 lesions.

Proponents of curative-intent local therapy suggest that it is possible to restrict such therapy to select T1 and T2 rectal cancers that do not have associated lymph node metastases. It is known that the incidence of lymph node metastases correlates most closely with the depth of rectal wall invasion and is especially high if the cancer extends through the wall. These proponents argue that preoperative staging with ERUS or MRI can differentiate intramural (T1–2) cancers from transmural (T3) cancers with a high degree of accuracy³³ and can distinguish most of the T1 and T2 cancers in which lymph node metastases are present. In addition, they note that poorly differentiated tumors recur three times more often than well-differentiated to moderately differentiated tumors³⁴ and that lymph node metastases are more common if preoperative biopsy reveals poor differentiation, lymphovascular invasion, mucin production, or signet cell histology. Accordingly, they recommend avoiding curative-intent local therapy if any of these unfavorable histologic characteristics are present, if imaging studies suggest involvement of lymph nodes, or if the cancer is transmural, arguing that occult lymph node metastases are rarely present if such stringent selection criteria are used. Furthermore, advocates of curative-intent local therapy suggest that close post-treatment follow-up will detect any local cancer development arising from occult nodal disease at a point where salvage therapy can still be instituted.

It was hoped that by using these strict criteria for initiating curative-intent local therapy, T1–2 N0 M0 lesions amenable to such therapy could be reliably identified. Unfortunately, this hope has not been realized [see Local Procedures, Operative Technique, Local Excision, below]. The poor outcomes reported after local excision of select T1 and T2 cancers of the rectum have prompted several centers (including our own) to limit the use of curative-intent local therapy by restricting it to favorable T1 tumors as staged by ERUS or MRI. Some surgeons recommend further subdividing T1 lesions on the basis of submucosal invasion and employing local therapy only for those lesions that extend into the superficial third or the middle third of the submucosa.^{35,36} Ideally, strictly limiting the indications for local therapy should retain the advantages (e.g., low morbidity) while minimizing the disadvantages (e.g., high local recurrence rates), but further studies are needed to determine whether this will be an effective strategy. Clearly, the key to more appropriate use of local therapy lies in finding better means of predicting the precise TNM stage and biologic behavior of rectal cancers before initiating therapy.

Table 3 American Joint Committee on Cancer Staging System for Colorectal Cancer⁷⁶

Stage	T	N	M
Stage 0	Tis	N0	M0
Stage I	T1, T2	N0	M0
Stage IIA	T3	N0	M0
Stage IIB	T4	N0	M0
Stage IIIA	T1, T2	N1	M0

Stage IIIC	Any T	N2	M0
Stage IV	Any T	Any N	M1

Radical Procedures

The majority of patients with operable rectal cancer require a radical proctectomy. The primary goal of radical resection is to remove the rectal cancer, the rectosigmoid mesentery, and the mesorectum with clear margins. Curative-intent radical resections may be classified on the basis of the final pathologic assessment as follows: R0 if all margins are clear, R1 if microscopic tumor is present at the margin, and R2 if gross disease is present.

For the first half of the 20th century, APR with permanent colostomy was accepted as the treatment of choice for most rectal cancers. Improvements in perioperative care, anesthesia, and surgical technique; the development of reliable bowel-stapling devices; and improved understanding of the extent and nature of the spread of rectal cancer led to reductions in operative and cancer-related mortality and made anal sphincter-sparing operations increasingly reliable and popular. Gradually, anterior resection with colorectal anastomosis became the preferred procedure for proximal rectal and midrectal cancers.

Radical extirpation, with or without colorectal anastomosis, remained the only treatment option for most rectal cancers until the last quarter of the 20th century, when multimodality therapy was proved to be effective. Currently, surgeons frequently combine chemoradiation with radical resection and increasingly perform restorative procedures even for distal rectal cancers. Despite these improvements, local recurrence and poor function continue to be major sources of morbidity and mortality after radical resection.

Local Procedures

Local procedures used to treat rectal cancer include polypectomy, excision, fulguration, and endocavitary radiation. Polypectomy and excision have the advantage of providing a biopsy specimen that can be examined to determine the depth of tumor invasion and thereby confirm or change the preoperative T stage. If microscopic examination of the specimen shows involvement of the circumferential or deep margins or if the pathologic T stage is more advanced than the preoperative clinical T stage, radical surgery or chemoradiation may be employed to improve local control. It is not clear whether this approach—excisional biopsy with subsequent additional therapy depending on final pathologic examination of the specimen—compromises survival in comparison with a more aggressive initial approach. Obviously, this approach is not feasible if local ablative techniques (e.g., endocavitary radiation or fulguration) are employed, because the primary lesion is destroyed and thus unavailable for pathologic study.

Endocavitary radiation has the distinct advantage of being performed in the outpatient setting with local anesthesia with sedation; however, it requires special equipment and expertise and is not widely available. Fulguration is now used primarily for palliation. Its main advantage is that it controls bleeding from incurable rectal cancers with minimal morbidity. None of the local therapy techniques include removal of the mesorectum; thus, lymph nodes are not assessed, and it is impossible for the pathologist to confirm or alter the preoperative N stage.

OPERATIVE TECHNIQUE

Polypectomy

Snare polypectomy is most often done during colonoscopic examination of the entire colon with the assumption that the rectal polyp is benign. Polyps larger than 1.0 cm, polypoid villous adenomas, and polyps with firm ulcerated areas are more likely to

harbor invasive cancer. With such lesions, it is occasionally helpful to use a large-diameter rigid proctoscope to facilitate snare polypectomy. The goal is to remove the polyp in one piece and provide the pathologist with a properly oriented specimen. If the endoscopist has any suspicion that the polyp may harbor a malignancy, the polypectomy site should be marked by means of submucosal injection and the precise level of the lesion recorded in the procedure note.

Benign-appearing sessile polyps of the rectum are generally best removed in one piece by means of transanal local submucosal or full-thickness operative excision rather than piecemeal by means of endoscopic snare excision. This approach provides the pathologist with a single specimen that can be properly oriented for histologic examination to assess the depth of tissue invasion. It also avoids the difficulties that arise when an unsuspected invasive cancer is identified microscopically but inability to orient the multiple pieces of tissue removed by piecemeal excision precludes accurate assessment of the T stage.

Snare polypectomy by itself is adequate for treating cancer arising in a rectal polyp if the lesion is noninvasive (i.e., confined to the mucosa) or if an invasive cancer is confined to the head, neck, or stalk of a pedunculated polyp and the margins are clear. If tumor is present within 2 mm of the margin or if the cancer extends into the submucosa of a pedunculated or sessile polyp, additional therapy is usually indicated. Various options are available for such therapy, including transanal excision of the rectal wall along with the base of the polyp (for accurate determination of the T stage), chemoradiation, and radical resection. The factors that determine whether local therapy is sufficient for cancers arising in a polyp or whether radical resection or adjuvant therapy is indicated are reviewed elsewhere.³⁷

Local Excision

The goal of local excision procedures is to perform a full-thickness resection of the primary rectal cancer with a 1.0 cm margin. Local excision is most often accomplished via an endoanal (transanal) approach under direct vision or by means of transanal endoscopic microsurgery (TEM). The endoanal approach is generally suitable for more distal tumors up to 10 cm from the anal verge, whereas TEM is appropriate for more proximal cancers.

Posterior approaches to excision are rarely necessary. Occasionally, it is helpful to expose the anorectum via a parasacral incision so as to facilitate local excision of a rectal cancer that is otherwise difficult to access. Currently, transsacral and transperineal approaches are infrequently used because of the significant associated morbidity (i.e., wound infections, bowel fistulas, and impaired continence). Tumors closer to the anal verge may involve the anal sphincter; such involvement is a contraindication to local excision unless the patient is unfit for a more aggressive option.

Endoanal local excision Because of its relative simplicity and excellent safety record, transanal excision is the most commonly performed local procedure [see Figure 1]. Full mechanical bowel preparation is recommended to reduce the possibility of postoperative impaction and to maintain optimal visualization. The procedure can be performed with the patient in either the lithotomy or the prone jackknife position. The prone position has the advantages of providing easier access for an assistant surgeon and of being suitable for rectal cancers in any quadrant; the lithotomy position is most suitable for distal posterior tumors. The use of headlights or lighted retractors is highly recommended. A Lone Star self-retaining retractor or Gelpi retractors may be used to efface the anus, and a handheld bivalve retractor, a Ferguson-Hill

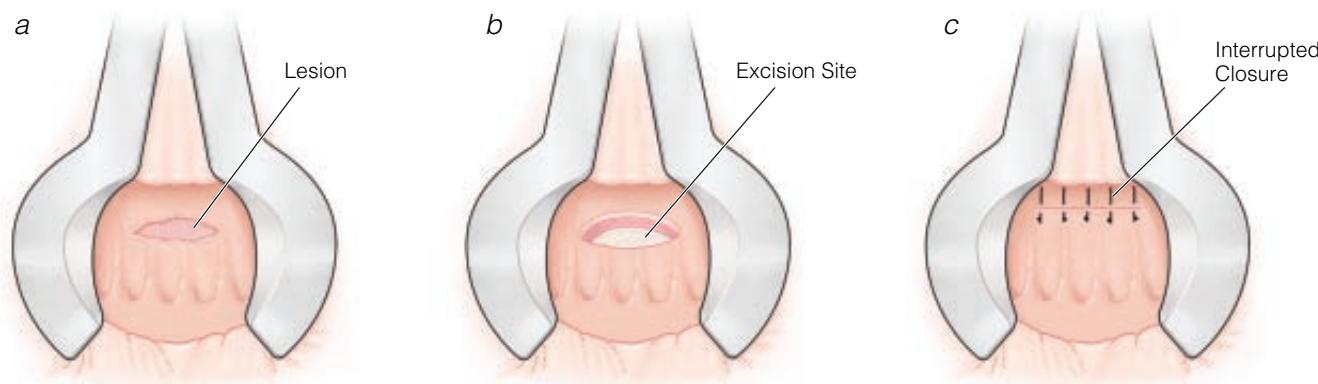

Figure 1 Local excision. (a) The rectal lesion is exposed with a bivalve retractor. (b) Full-thickness excision of the lesion is performed. (c) The defect is closed with interrupted sutures.

retractor, or a Parks anoscope may be used to provide endoanal exposure of the lesion. Deep retractors (e.g., narrow Deaver retractors) are often helpful for exposing more proximal cancers.

Dissection may be facilitated by injecting saline or a local anesthetic with epinephrine solution into the rectal wall near the lesion. It is sometimes helpful to place a traction suture 2 cm distal to the lesion to facilitate prolapse of the rectal wall before dissection is begun. An electrocautery with a needle tip is generally employed to perform a full-thickness excision of the cancer with a 1.0 cm margin, but surgeons are increasingly using laparoscopic instruments to facilitate local excision. Hemostasis and orientation must be maintained. If desired, the defect in the rectal wall may be closed as the dissection progresses. Each suture can be used for traction to keep the lesion in view. Innovative techniques making use of laparoscopic or conventional staplers have also been developed and have yielded good results.

Once the specimen has been resected, it is inspected to confirm that adequate margins have been obtained, then marked for orientation and pinned out for fixation before histologic examination. The operative site may be irrigated with sterile water or tumoricidal agents to minimize the risk that viable tumor cells will be left in the rectal wall. If the rectal wall defect is extraperitoneal, it may be left open to heal secondarily; however, many prefer to close all rectal wounds primarily.³⁸ If the defect is intraperitoneal, closure is essential and is usually performed with a durable absorbable suture. Care must be taken to prevent stricture formation. This is an especially critical concern if large or circumferential lesions are removed. In such cases, a sleeve closure with a handsewn anastomosis after advancement of the proximal rectal wall to the more distal rectum is often the best option. Once the defect is closed, the surgeon should perform proctoscopy to ensure that the rectal lumen has not been compromised.

Results. The data currently available suggest that local recurrence rates are unacceptably high and that survival may be compromised even when curative-intent local therapy is restricted to patients who have small, accessible intramural cancers with no signs of suspicious lymph nodes on preoperative imaging studies and no unfavorable histologic features on the pretreatment biopsy. The risk of local recurrence after local excision of selected, presumably favorable lesions is 18% for T1 cancers and 37% to 47% for T2 cancers.²⁷⁻³² Salvage surgery is often possible if follow-up shows progression of pelvic cancer. No prospective studies directly comparing the results of local excision with those of more radical extirpative procedures have yet been done, and it is unlikely

that such trials will ever be successfully completed. Studies involving short-term follow-up have not demonstrated any impact on cancer-free survival for T1 cancers but have indicated that survival is compromised if T2 cancers are treated with local excision alone. More information is needed before definitive therapeutic recommendations can be made.

Local recurrence rates after local excision can be lowered by adding adjuvant radiation therapy, with or without chemotherapy. Estimated local recurrence rates after adjuvant therapy range from 0% to 9% for T1 tumors and from 0% to 24% for T2 tumors.³⁹⁻⁴¹ Reliable long-term survival data are unavailable. To date, only three small retrospective series have evaluated a promising newer approach: neoadjuvant therapy followed by local excision of early-stage, favorable rectal cancers. Clinical trials aimed at studying this approach are being developed.

Transanal endoscopic microsurgery TEM is a novel technique that has found a niche in local treatment of sessile polyps and of favorable T1 cancers in the middle to upper rectum. It may be used in combination with chemoradiation to treat more advanced cancers of the middle and upper rectum, especially in high-risk patients who cannot tolerate an anterior resection. More proximal lesions of the rectum that are not amenable to transanal excision or to endoscopic removal may be best treated by TEM, with low morbidity and mortality.

TEM begins with insufflation of CO₂ into the rectum via a 4 cm operating rectoscope. Endoscopic instruments are then inserted and used under magnification to perform the local resection. The principles of resection are the same as for endoanal excision (see above).

Results. The largest review of TEM results to date included 137 patients and reported an 8% minor morbidity rate, a 2% major morbidity rate, and a combined 5% recurrence rate for T1 to T3 tumors over a period of 6 months.²¹ These results are promising, but the follow-up period is too short for definitive conclusions to be drawn.

Posterior approach to local excision Local excision of rectal cancers can be performed via either a transsacral or a transsphincteric approach with the patient in the prone jackknife position. The Kraske procedure takes a transsacral approach. An incision is made in the midline of the sacrum to expose the posterior rectum by excising the coccyx and the last two sacral vertebrae. Either a short segmental resection of the rectum with pri-

mary anastomosis or a proctectomy to expose and locally excise an intraluminal lesion is performed. In closing the rectal wall defect, care is taken not to compromise the lumen and create a stricture.

The York-Mason procedure takes a transsphincteric approach to expose the posterior rectum without resection of the sacrum. Instead, the pelvic floor muscles are divided in the posterior plane, and the resection then proceeds as in the Kraske procedure. The sphincter muscles must be carefully reconstructed. Unfortunately, morbidity is relatively high (e.g., a 20% incidence of fecal fistula) after both procedures.⁴²

Fulguration (Electrocoagulation)

Fulguration, or electrocoagulation, involves destroying a cancer with an electrode inserted into the wall of the lesion. As coagulum builds up, it is debrided to allow additional coagulation until the lesion and a circumferential rim of normal tissue have been ablated. The disadvantages of this procedure include postoperative fever, the lack of a surgical specimen for staging, the requirement for repeated procedures, and the need to convert to more radical procedures in a large number of patients.⁴³

Fulguration has often been used as curative-intent treatment, with reported 5-year survival rates reaching 58%, but it is now used primarily for palliative purposes. Fulguration may be optimal for patients with bulky bleeding rectal cancers who are too ill to undergo radical resection.

Endocavitary Radiation (Papillon Technique)

Endocavitary radiation involves high-dose contact (superficial) radiotherapy delivered via a specially designed proctoscope. A total radiation dose of 9 to 15 Gy is delivered in several sessions, usually over a period of 60 days. This modality is appropriate for small noncircumferential lesions located within 10 cm of the anal verge. The reported 5-year survival rate is 76%, with a local recurrence rate of 8.3% and a mortality of 7.7%.⁴⁴

Radical Procedures

OPERATIVE PLANNING

Preoperative Preparation

The possibility that a permanent or temporary stoma may be necessary should prompt a consultation with an enterostomal therapy nurse for the purpose of counseling the patient and marking the abdominal wall at the appropriate location for a colostomy or temporary ileostomy [see 5:30 Intestinal Stomas].

Generally, full mechanical and antibiotic bowel preparation is performed on an outpatient basis the day before operation. An antibiotic is administered intravenously just before induction of anesthesia. General anesthesia is employed, and an epidural catheter is often inserted to provide postoperative analgesia. If there is a large, bulky rectal tumor or an associated inflammatory mass, ureteral stents may be placed to facilitate intraoperative identification and protection of the ureters. A bladder catheter is inserted, and the patient is placed in a modified lithotomy position with the legs in stirrups. Pneumatic compression stockings and compression devices are used routinely, with or without heparin. Digital rectal examination and rigid proctoscopy are performed to empty the rectum and reassess the rectal cancer. The degree of involvement of the anal sphincter or other organs, the level of the distal edge of the tumor, and the response of the tumor to chemoradiation are noted.

A number of instruments are required to facilitate the conduct

of radical extirpative procedures. Headlights and lighted retractors allow visualization deep in the pelvis. Self-retaining retractors (e.g., Balfour or Bookwalter retractors) are necessary. The St. Mark pelvic retractor and the Wylie renal vein retractor facilitate deep pelvic dissection. Long instruments are essential, and a variety of staplers should be available. The presence of an experienced second surgeon or a highly trained assistant is invaluable.

Intraoperative Decision Making

The surgeon always has a plan in place for the operation before laparotomy, but it often happens that intraoperative findings necessitate a change in the plan. Thus, the surgeon must be flexible and willing to alter the planned operation in accordance with the situation.

After a midline incision is made, a thorough abdominal exploration is performed. At this point, the surgeon can confirm or revise the operative plan. Most often, the choice between a sphincter-sparing approach and a sphincter-sacrificing approach has been made before operation, but for distal rectal cancer, it is not always possible to determine whether a restorative anastomosis is feasible until the rectum has been fully mobilized. In such cases, the choice between sphincter-sparing and sphincter-sacrificing proctectomy must be based on assessment of the adequacy of the distal margin [see Anterior Resection, Operative Technique, Step 4, below].

Neoadjuvant therapy can reduce the size of a tumor so that it is amenable to low anterior resection instead of requiring APR.⁴⁵ After full rectal mobilization, the surgeon assesses the possibility of obtaining clean radial and distal margins, then decides to proceed with either resection and anastomosis or APR. The desire to perform an anastomosis must not be allowed to compromise oncologic outcome. Occasionally, circumstances arise in which the cancer is larger than anticipated or is extending into the sacrum or other pelvic structures. In such circumstances, a more extensive operation than was originally planned is appropriate if curative resection can be achieved. Alternatively, the surgeon may be forced to perform a palliative operation.

ANTERIOR RESECTION

Operative Technique

All curative-intent radical resections for rectal cancer use the same technique for mobilizing the rectum and achieving proximal, lateral, and radial margin clearance. Anterior resections are classified as high, low, or extended low, depending on the extent of rectal mobilization and resection and on the level of the restorative anastomosis.

Step 1: mobilization of colon After abdominal exploration, the small bowel is packed into the upper abdomen, and the patient is placed in a slight Trendelenburg position. The rectosigmoid is retracted to the right, and the peritoneal attachments to the left of the sigmoid colon are incised along the avascular plane. The left ureter and gonadal vessels are identified and preserved by using sharp and gentle blunt dissection to separate the retroperitoneal tissues from the sigmoid mesentery. The peritoneum is incised along the left side of the descending colon as far as the splenic flexure. Adhesions to the spleen are divided, and the splenic flexure is taken down. The colon mobilization extends proximally to the left transverse colon.

Step 2: ligation of inferior mesenteric artery The mobilized rectosigmoid is retracted anteriorly and to the left to expose

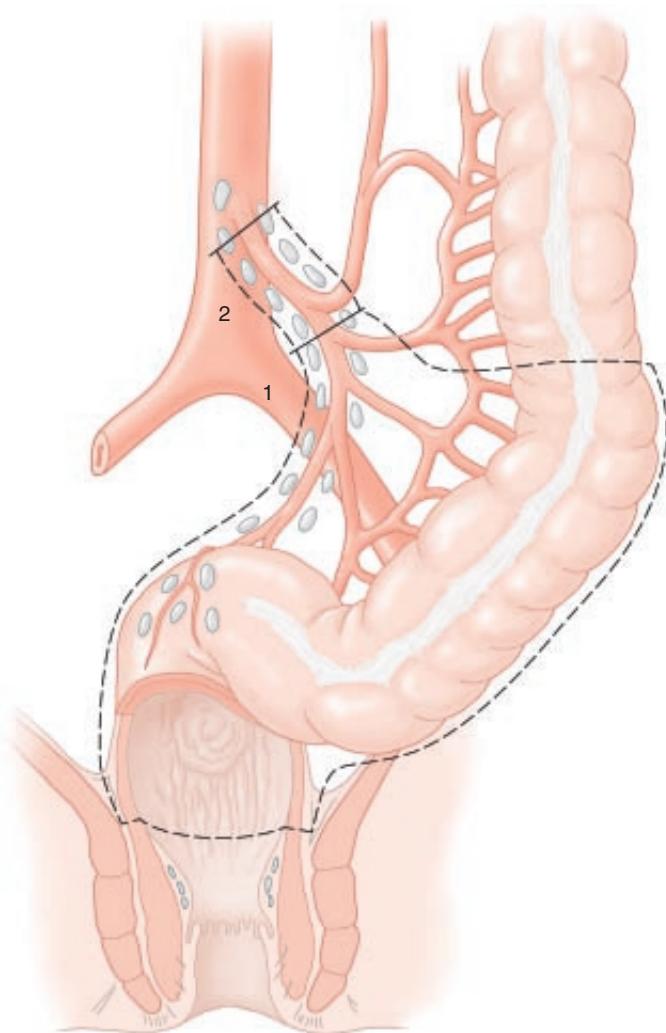

Figure 2 Anterior resection. Illustrated is the tissue excised during anterior resection. The surgeon may perform either a low ligation of the IMA (1), with preservation of the ascending branch, or a high ligation (2), where the IMA branches from the aorta.

the inferior mesenteric artery (IMA). Transillumination of the mesentery facilitates identification of an avascular space adjacent to the IMA at the base of the mesentery. The peritoneum overlying this space is incised on either side of the IMA. Some surgeons prefer a high ligation of the IMA where it branches from the aorta, suggesting that this measure provides a more complete lymph node harvest. Others prefer a low ligation of the IMA just distal to the left colic artery, suggesting that this approach ensures better blood supply to the proximal colon and prevents nerve injury at the base of the IMA [see Figure 2]. At present, there is not enough evidence to recommend one approach over the other. After ligation of the IMA, it is convenient to divide the colon at the descending-sigmoid junction with a linear stapler.

Step 3: total mesorectal excision and preservation of autonomic nerves The rectosigmoid is retracted anteriorly and inferiorly toward the pubis to expose the avascular plane posterior to the rectum. Sharp incision of this avascular plane while traction is placed on the rectosigmoid typically allows air to enter the areolar tissue posterior and lateral to the rectum. The surgeon follows the air, sharply dividing the loose areolar tissue posteriorly and laterally [see Figure 3].

During the retrorectal dissection, the hypogastric nerves are identified at the sacral promontory. These nerves descend in the presacral space in a wishbone shape and must be preserved to maintain postoperative sexual and urinary function. In the 1940s, sexual dysfunction after proctectomy was reported in 95% of male patients.⁴⁶ If attention is given to nerve preservation during proctectomy, however, 86% of male patients younger than 60 years retain sexual function.⁴⁷ Posteriorly, the rectosacral fascia is divided under direct vision, and the dissection proceeds distally to the level of the coccyx. In mobilizing the rectum, it is helpful to dissect in a posterior-to-lateral direction, with care taken to maintain the integrity of the endopelvic fascial envelope encasing the bilobed mesorectum. The nervi erigentes are identified and preserved on the lateral pelvic sidewalls. When the middle rectal artery is present as a distinct vessel, it can generally be fulgurated during the lateral dissection; occasionally, however, the vessel is large enough that ligation is necessary.

The final attachments are divided anterolaterally, and the anterior pelvis is exposed. Exposure may be facilitated by reducing the angle of the Trendelenburg position or even shifting the patient to a reverse Trendelenburg position. The cul-de-sac is opened, and Denonvillier's fascia is incised. Deep pelvic retractors are placed to protect the seminal vesicles and prostate (in males) or the vagina (in females) as the dissection continues distally.

Step 4: assessment of distal margin At this point in the operation, the rectum has been fully mobilized via the abdominal approach, and the surgeon must decide whether a sphincter-preserving anastomosis is possible or whether a sphincter-sacrificing resection with construction of a permanent colostomy is necessary. Because all radical resections for rectal cancer use the same proximal, lateral, and radial dissection technique, the decision to perform an anastomosis is based primarily on the ability to obtain a clear distal margin.

There are two components to the distal margin: intramural and mesorectal. At one time, a 5.0 cm intramural margin was recommended; however, subsequent studies demonstrated that a 2.0 cm intramural margin was adequate for curative resection. Margins smaller than 1.0 cm were associated with increased local recurrence rates and decreased survival.⁴⁸⁻⁵⁰ Considerable emphasis is now being placed on ensuring adequate mesorectal clearance. It was observed that local recurrence after radical resection correlated not just with the stage of the disease but also with the surgeon performing the operation. Careful analysis suggested that some surgeons did not remove the mesorectum completely and that tumor deposits in the mesorectum distal to the rectal cancer were responsible for high recurrence rates.⁵¹ Total mesorectal excision (TME) was recommended as a means of minimizing local recurrences. The current view is that a 5.0 cm mesorectal clearance is essential to prevent local recurrence in the pelvis.

If distal clearance (both intramural and mesorectal) is adequate and if anal sphincter function justifies proceeding with an anastomosis, a right-angle clamp is placed distal to the tumor, and the distal rectum is irrigated with sterile water or a tumoricidal agent. A second right-angle clamp is then placed distally, and the rectum is divided between the two clamps. This technique is used if an open purse-string suture is to be placed in the distal rectal cuff. If a double-stapled reconstruction is planned instead, a transverse anastomosis (TA) stapler is placed distal to the right-angle clamp. The stapler is fired and the rectum divided, leaving a closed rectal cuff for subsequent anastomosis.

The surgeon should then examine the resected specimen to assess the radial and distal margins and evaluate the integrity of

the mesorectal dissection. If the margins are inadequate or the mesorectum has been violated, local recurrence is a major concern. The treatment plan may have to be altered to reduce the risk of recurrence.

Step 5: creation of anastomosis Several reconstructive options are available for restoring bowel continuity after radical proctectomy. An end-to-end anastomosis is the traditional choice, but alternative anastomoses are acceptable options in some situations [see Alternative Anastomoses, below].

A straight or an end-to-side colorectal anastomosis (the Baker technique) is appropriate after resection of most cancers in the proximal half of the rectum. The anastomosis can be handsewn, but most surgeons prefer to use a circular stapler. Functional results after such proximal anastomoses are generally good. As surgeons developed reliable means of performing lower colorectal and coloanal anastomoses, functional results were often suboptimal: patients reported urgency, frequency, seepage, and incontinence. To overcome these problems, surgeons devised newer techniques aimed at increasing rectal reservoir capacity (e.g., the colonic J pouch and coloplasty).

Double-stapled end-to-end anastomosis. The double-stapled technique was devised to eliminate the need for a purse-string suture on the rectal cuff and to prevent fecal contamination. A purse-string suture is placed in the cut edge of the distal descending colon [see Figure 4a]. The anvil of a circular stapler is inserted into the descending colon, and the purse-string is tied.

The integrity of the stapled distal rectal stump is checked by insufflating air into the rectum via a proctoscope while the rectal stump is covered with saline. If no air leaks are noted, the circular

stapler, without the anvil but with a trocar attachment, is inserted through the anus and advanced proximally to the apex of the closed stump [see Figure 4b]. The stapler is opened to drive the trocar through the apex of the rectal stump adjacent to the staple line. The trocar attachment is removed, and the mobilized descending colon, with the anvil in place, is mated to the stapler [see Figure 4c]. The stapler is closed and fired, resulting in an end-to-end anastomosis [see Figure 4d]. The integrity of the anastomosis is assessed by insufflating air into the rectum with a proctoscope while the anastomosis is under water [see Figure 5].

Purse-string end-to-end anastomosis. The alternative to the double-stapled technique is to place purse-string sutures on both the proximal and the distal end of the bowel to be anastomosed. A continuous 2-0 purse-string suture is placed in the proximal end of the open rectal cuff, and a second purse-string suture is placed in the descending colon [see Figure 6]. The circular stapler is placed through the anus, and the anastomosis is fashioned and checked for leaks as in the double-stapled technique.

Handsewn end-to-end anastomosis. The alternative to a stapled anastomosis is a handsewn colorectal end-to-end anastomosis, which may be done in one or two layers with interrupted or continuous sutures. Handsewn colorectal anastomoses are typically performed from the abdominal field. It is often easiest to place all of the sutures first, then “parachute” the proximal bowel down to the rectal cuff as the sutures are tied. The knots are generally tied on the inside to produce mucosal inversion.

Alternatively, if the distal cuff cannot be visualized from the abdominal field, a handsewn anastomosis may be performed transanally. This is generally more easily accomplished with the patient in the prone jackknife position.

Alternative anastomoses. Three alternative reconstruction procedures have been devised to facilitate restoration of bowel continuity deep in the pelvis. The colonic J pouch and the Baker technique involve an end-to-side anastomosis, an approach that some surgeons believe offers a more reliable blood supply than the traditional end-to-end anastomosis. The colonic J pouch and coloplasty were designed to overcome the poor functional outcomes frequently observed after straight coloanal or low colorectal anastomoses by increasing the capacity of the neorectum.

A colonic J pouch is considered only for low anastomoses less than 5 cm from the anal verge; if the procedure is performed more proximally than 8 cm from the anal verge, it offers no functional advantages over a straight colorectal anastomosis.⁵² Patients with a colonic J pouch anastomosis 4 cm or less from the anal verge demonstrate the greatest functional improvements.⁵²

To create a colonic J pouch, the splenic flexure is mobilized to provide adequate bowel length, and a well-vascularized segment of the colon is selected for the pouch. The distal descending colon is then folded into a J configuration [see Figure 7a]. It is essential that the hook (i.e., the efferent limb) of the J be no longer than 5 to 6 cm, because longer limb lengths are associated with difficulty in evacuation.⁵³ A linear cutting stapler is inserted through a colotomy on the antimesenteric surface of the inferior aspect of the J pouch, then closed and fired. Once the linear staple line has been checked for bleeding, the anvil of a circular stapler is placed in the colotomy of the J pouch and secured in place with a 2-0 nonabsorbable suture. The J pouch-anal anastomosis is then performed with the circular stapler [see Figure 7b].

Approximately 25% of patients are not suitable candidates for a colonic J pouch because of a narrow pelvis or obesity.⁵⁴ For

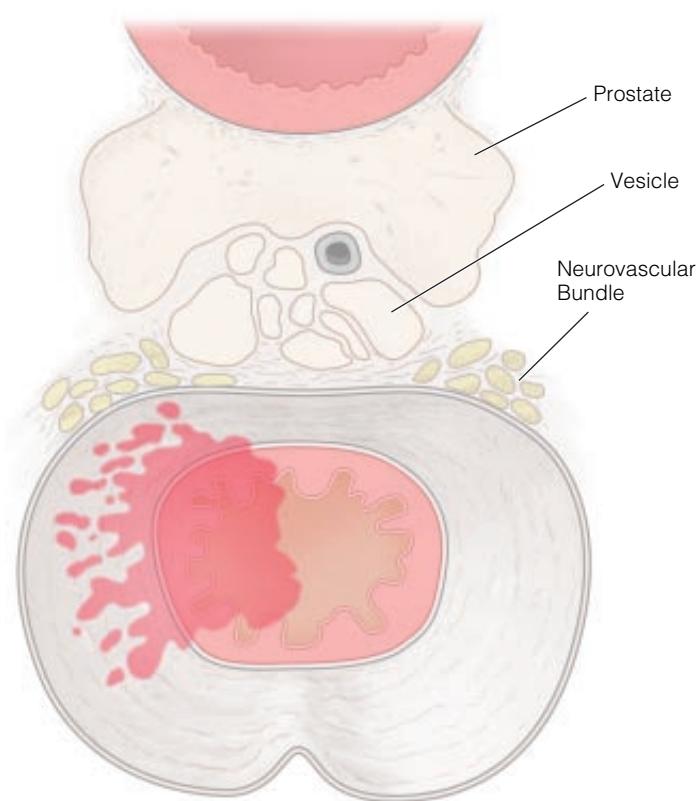

Figure 3 Anterior resection. Shown is a schematic depiction of total mesorectal excision, highlighting the endopelvic fascial dissection plane.

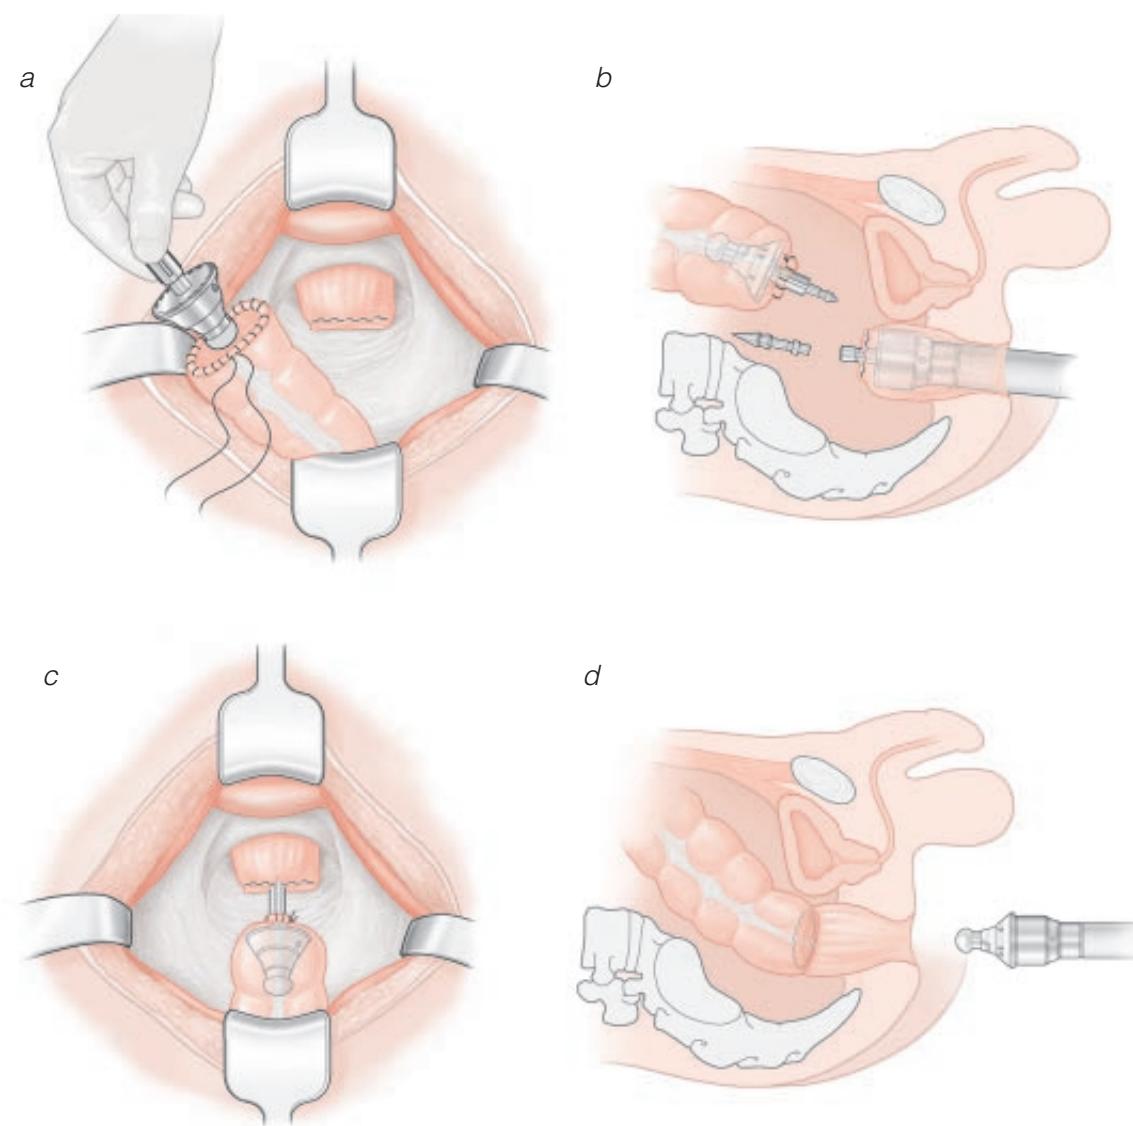

Figure 4 Anterior resection. Shown is a double-stapled end-to-end anastomosis. (a) The rectal stump is closed with a linear noncutting stapler. A purse-string suture is placed around the colotomy, and the anvil of the circular stapler is placed in the open end and secured. (b) The stapler, with the sharp trocar attachment in place, is inserted into the anus, and the trocar is made to pierce the rectal stump at or near the staple line, after which the trocar is removed. (c) The anvil in the proximal colon is joined with the stapler in the rectal stump, and the two edges are slowly brought together. (d) The stapler is fired and then gently withdrawn.

these patients, coloplasty is an alternative. Coloplasty is similar to Heineke-Mikulicz pyloroplasty. An 8 to 10 cm long antimesenteric colotomy is initiated at a point 5 to 6 cm from the cut end of the descending colon and extended proximally [see Figure 8a]. The anvil of a circular stapler is placed in the colon and brought out the end of the colon before closure of the coloplasty. The colotomy is closed in a transverse direction, perpendicular to the antimesenteric border, with either absorbable sutures or a linear stapler [see Figures 8b and 8c]. An end-to-end anastomosis is then performed with the circular stapler [see Figure 8d]. This procedure has not been accepted by most surgeons because of the long longitudinal colotomy along the antimesenteric border.

Although the end-to-side (Baker) anastomosis is not a new technique, it is gaining popularity as an alternative to the more difficult and time-consuming pouch procedures. After the rectal

resection, the stapler anvil is inserted through the cut end of the descending colon. The trocar end of the anvil is brought out through the antimesenteric side of the colon approximately 3 to 4 cm from the distal cut end. The open end of the descending colon is closed. A circular stapler is then used to anastomose the side of the colon to the end of the rectum or the anal canal [see Figure 9].

Troubleshooting

Criteria for temporary fecal diversion The incidence of anastomotic complications, including leakage, correlates with the level of the anastomosis: in general, the lower the anastomosis, the higher the complication rate. Other factors, including previous radiation therapy, immunosuppression, and underlying vascular insufficiency or diabetes, may also increase the risk of anastomotic complications.

The consequences of a leaking anastomosis remain a major

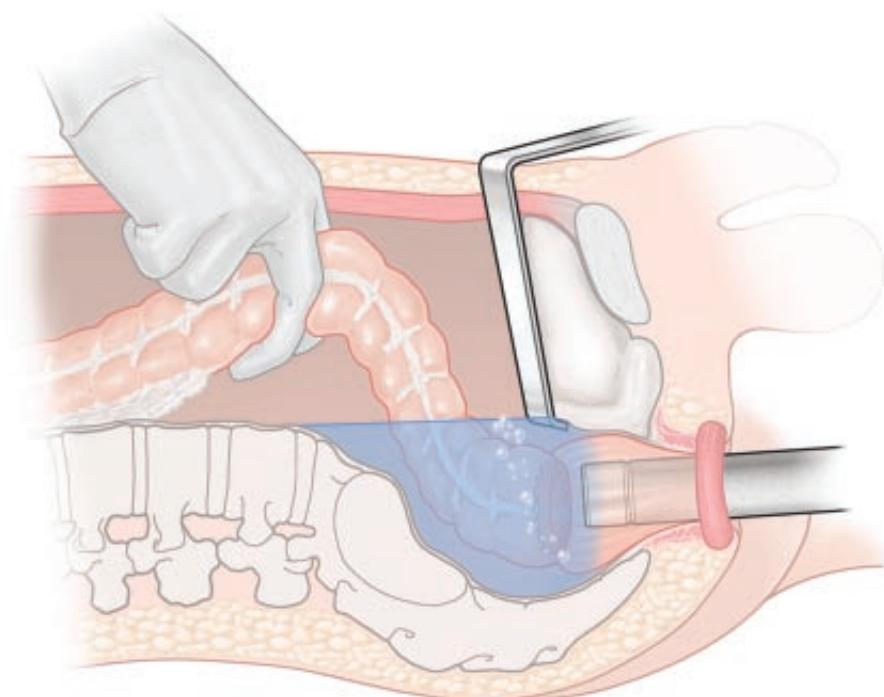

Figure 5 Anterior resection. The integrity of the anastomosis is assessed by holding it under water and insufflating air via a proctoscope while the bowel is clamped.

source of morbidity and death after surgical resection of rectal cancer. Consequently, many surgeons perform routine temporary fecal diversion for patients undergoing low anastomoses, especially for those subjected to preoperative irradiation or receiving steroid treatment. Loop ileostomy is the most commonly performed temporary diversion, though some surgeons prefer proximal loop colostomy [see 5:30 *Intestinal Stomas*]. Proximal fecal diversion does not protect against anastomotic leakage or prevent anastomotic complications, but it does diminish the morbidity resulting from leakage and reduce the likelihood of an emergency operation.⁵⁵ Our practice is to perform diversion for all patients with a colorectal or coloanal anastomosis within 5 cm of the anus, especially if they have undergone preoperative radiation therapy or are immunosuppressed.

Outcome Evaluation

Information is now available on functional outcome and qual-

ity of life after coloanal or colorectal reconstruction. The data indicate that the functional advantages of coloplasty and colonic J pouches are most discernible in the first 2 years after operation. Measures of function—including urgency, frequency, nocturnal stooling, and continence—all show significant improvements in patients who undergo colonic J pouch or coloplasty reconstruction⁵⁶; quality-of-life indicators and physiologic measures show significant improvements as well.⁵⁷ A 2002 trial from Singapore found the incidence of anastomotic leaks to be higher after coloplasty reconstruction than after colonic J pouch reconstruction.⁵⁸ Although this finding has tempered the enthusiasm for coloplasty reconstruction, the procedure remains a viable option in the patient with a narrow pelvis.

The functional and surgical results seen with end-to-side anastomoses are similar to those seen with colonic pouch anastomoses.⁵⁹ More data are needed to determine which reconstructive technique is best in which setting.

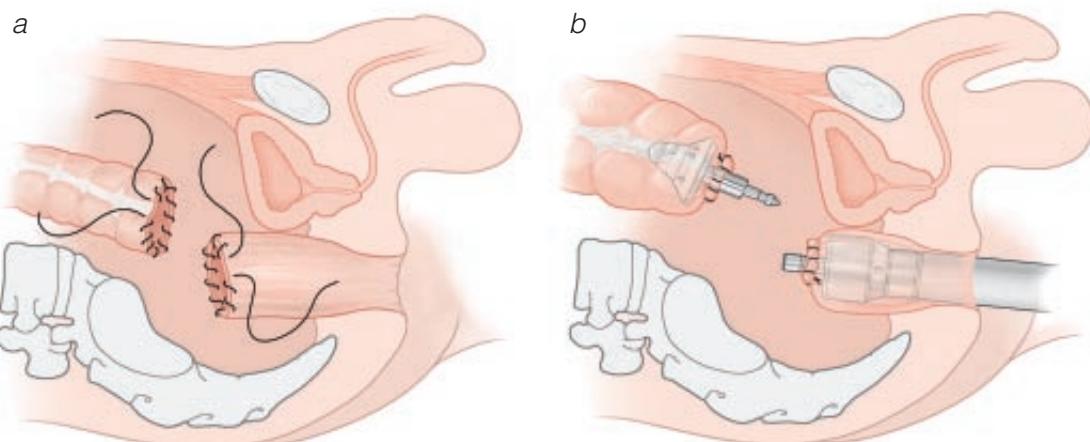

Figure 6 Anterior resection. Shown is a purse-string end-to-end anastomosis. (a) Purse-string sutures are placed on the rectum and on the proximal bowel. (b) The anvil of a circular stapler is placed in the proximal bowel, and the stapler is placed through the anus. The anvil is joined with the body of the stapler, and the stapler is fired to complete the anastomosis.

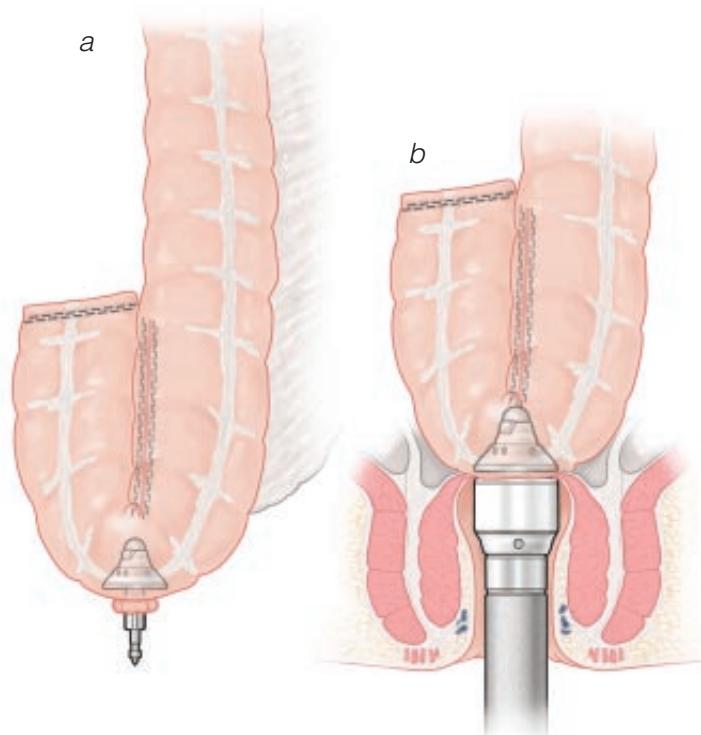

Figure 7 Anterior resection. Shown is the creation of a coloanal anastomosis with a colonic J pouch. (a) The proximal bowel is stapled closed and folded into a J shape, with the hook of the J being about 5 to 6 cm long. A colotomy is made in the base of the J, and a J pouch is formed by inserting and firing a linear stapler. The anvil of a circular stapler is placed in the base of the pouch. (b) The J pouch is brought down to the anus, and the circular stapler is used to create the coloanal anastomosis.

ABDOMINOPERINEAL RESECTION

APR involves en bloc resection of the rectosigmoid, the rectum, and the anus along with the surrounding mesentery, mesorectum, and perianal soft tissues [see Figure 10]. Current efforts to perform

more restorative anastomoses after radical resection of rectal cancer are based on data suggesting that APR offers no survival advantage over sphincter-sparing procedures.¹⁷ Nevertheless, APR is still performed in an estimated 30% to 60% of rectal cancer patients. A large review of 7,400 patients in the United States documented a 58% rate of APR performance.⁶⁰ The reasons for this persistently high APR rate are unclear.

Operative Planning

Synchronous APR APR, as the name suggests, may be thought of as comprising two phases: an abdominal phase and a perineal phase. The perineal phase of the operation may be done synchronously with the abdominal phase, with the patient maintained in a modified lithotomy position. Proper positioning and exposure are critical. The buttocks should be elevated with a pad extending over the edge of the operating table and should be taped laterally to provide good exposure of the perineum. The synchronous approach may reduce operating time and is useful if the surgeon anticipates any difficulty in removing the rectum because of lateral fixation. Working from above and below the area of fixation simultaneously usually allows the proctectomy to be safely completed en bloc. This approach demands the presence of two experienced surgeons: performing the perineal phase with the patient in the lithotomy position can be very demanding technically, especially if the patient is obese.

Sequential APR Alternatively, the perineal phase may be performed with the patient in the prone jackknife position after completion of the abdominal phase. This approach is generally preferred because it provides excellent visualization for the perineal dissection and is especially useful if the tumor is fixed anteriorly. In addition, it has the advantage of providing more room for an assistant.

Operative Technique

Steps 1 through 4 The abdominal phase of APR, including TME and nerve preservation, is identical to steps 1 through 4 of an anterior resection [see Anterior Resection, Operative Technique, above].

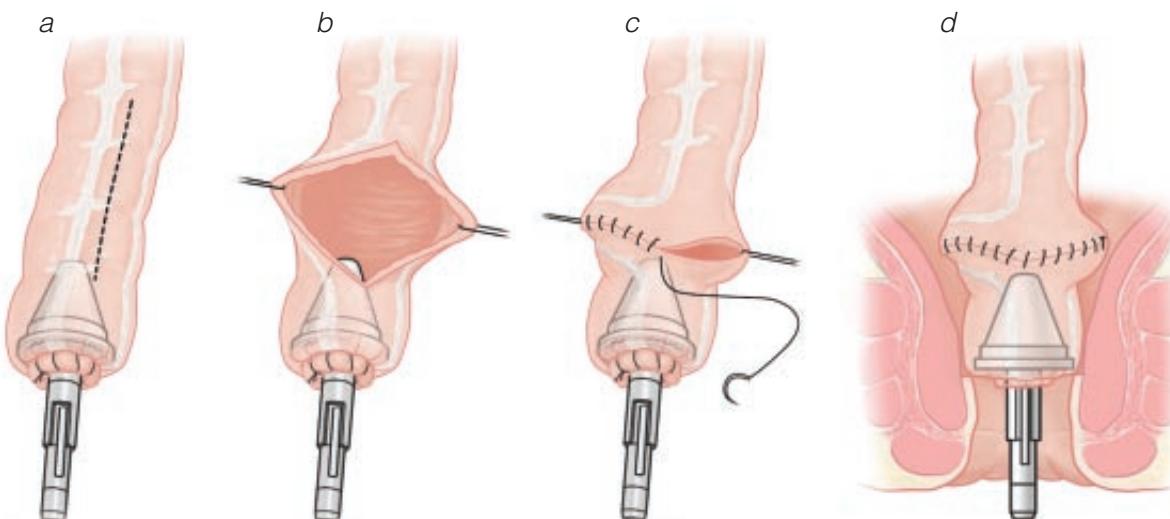

Figure 8 Anterior resection. Illustrated is the coloplasty technique. (a) A longitudinal colotomy is made in the antimesenteric side of the colon. (b) Sutures are placed on either side of the incision and used to apply traction transversely. (c) The colotomy is closed in a transverse direction. (d) An end-to-end anastomosis to the anus is performed.

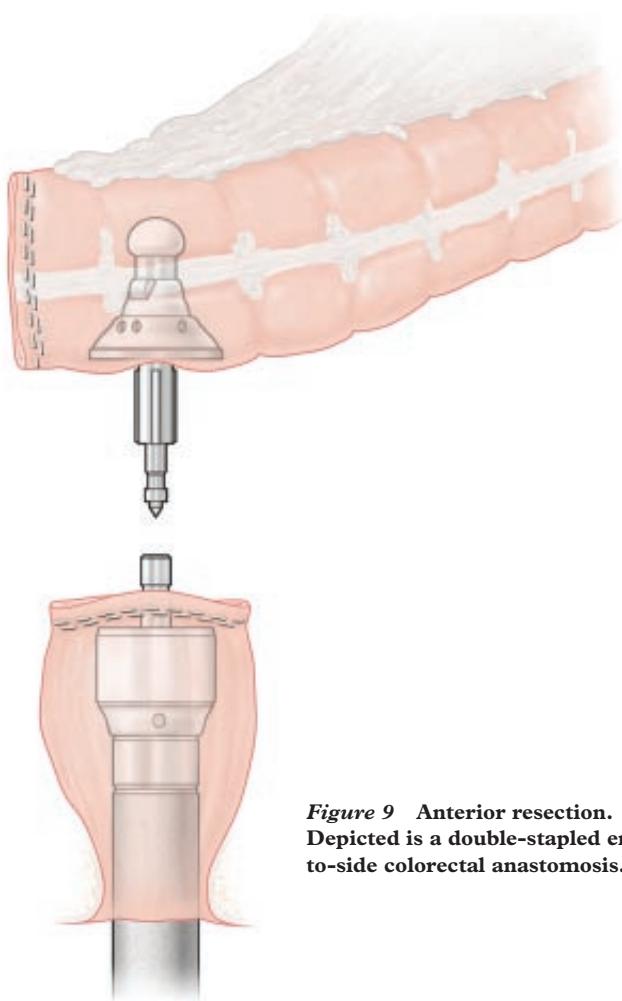

Figure 9 Anterior resection.
Depicted is a double-stapled end-to-side colorectal anastomosis.

Step 5: perineal resection The perineal phase of APR is performed with the patient in either the lithotomy or the prone jackknife position, depending on whether the synchronous or the sequential approach is followed. The perineum is exposed with the aid of self-retaining retractors [see Figure 11]. The anus is closed with a heavy purse-string suture to minimize the risk of spillage of feces or tumor. An alternative means of accomplishing this goal is to make the initial elliptical incision around the anus and then approximate the perianal skin edges with sutures or Kocher clamps. The elliptical incision should extend from the perineal body anteriorly to the coccyx posteriorly. Laterally, the incision should overlie the ischium. The incision is deepened into the ischioanal fossa bilaterally with the electrocautery. The anococcygeal ligament is divided posteriorly. The perineal surgeon can then insert an index finger into the pelvis to guide division of posterolateral soft tissue with the electrocautery. An appendectomy retractor or springs may be used to improve retraction during deeper dissection into the perineum. The dissection is continued laterally and anterolaterally. When an ample aperture is created, the proximal end of the specimen is passed between the coccyx and the anus.

Traction is applied to the everted specimen to help the surgeon develop the anterior dissection plane. In a female patient, an anterior lesion may necessitate a posterior-wall vaginectomy to ensure adequate margins. In a male patient, anterior dissection may lead to injury to the urethra or excessive bleeding from the prostate capsule; to minimize the risk of the former, it is helpful to palpate the Foley catheter during anterior dissection. Once the dissection

is completed anteriorly, the specimen is inspected and sent for pathologic examination. The pelvis is irrigated and hemostasis secured. Some surgeons prefer to place a mobilized pedicle of omentum into the pelvis to facilitate healing and reduce the risk of small-bowel adhesions in the depths of the pelvis. The perineal incision is closed in several layers with absorbable sutures. A transabdominal drain is placed in the pelvis.

Step 6: creation of colostomy An end colostomy [*see 5:30 Intestinal Stomas*] is created before the perineal dissection if sequential APR is performed but may be created simultaneously with the perineal resection if a two-team synchronous APR is performed. A 2 cm circular incision is made in the skin and subcutaneous tissues overlying the premarked stoma site, which is usually in the left lower quadrant of the abdomen. A cruciate incision is made in the anterior fascia, the rectus abdominis is split, and a second cruciate incision is made in the posterior fascia. The mobilized colon is passed through this site and fixed to the skin with 3-0 or 4-0 absorbable sutures. Because many enterostomal therapists and patients find it easier to pouch an elevated left-side colostomy, an eversion technique is used to mature the stoma.

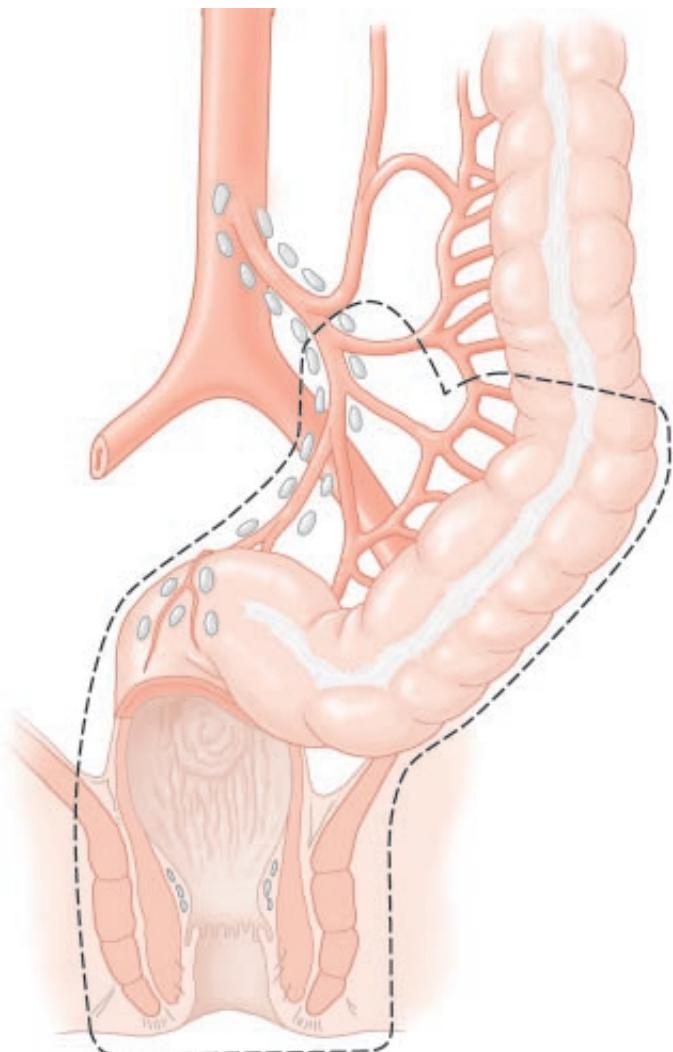

Figure 10 Abdominoperineal resection. Illustrated is the tissue excised during APR.

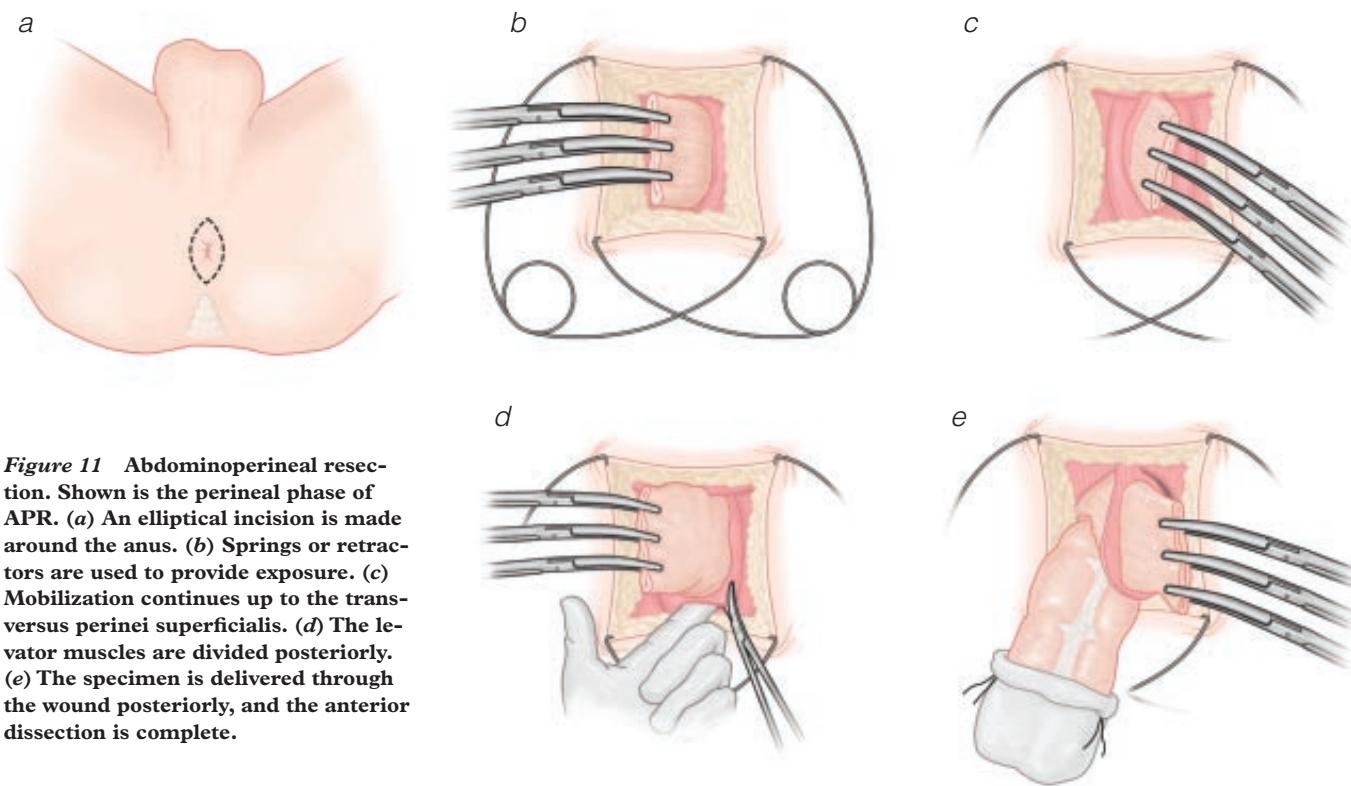

Figure 11 Abdominoperineal resection. Shown is the perineal phase of APR. (a) An elliptical incision is made around the anus. (b) Springs or retractors are used to provide exposure. (c) Mobilization continues up to the transversus perinei superficialis. (d) The levator muscles are divided posteriorly. (e) The specimen is delivered through the wound posteriorly, and the anterior dissection is complete.

OTHER RADICAL PROCEDURES

Hartmann Procedure

The Hartmann procedure [see 5:32 *Procedures for Diverticular Disease*] is a seldom-used option that plays only a limited role in the treatment of rectal cancer. It may be a good choice if the likelihood of local recurrence is high (as with a perforated cancer) or if the patient manifests preexisting sphincter dysfunction. In these situations, perineal dissection subjects the patient to unnecessary morbidity. The distal rectum or anal canal is stapled closed and left in situ in the pelvis. The end colostomy is performed as in APR.

Pelvic Exenteration and Sacrectomy

The indications for pelvic exenteration are limited by the relatively high morbidity and mortality associated with the procedure. Pelvic exenteration for locally advanced or recurrent rectal cancer has been shown to have oncologic and palliative benefits. Reported 5-year survival rates after pelvic exenteration for locally recurrent rectal cancer range from 20% to 30%.⁶¹ Primary advanced rectal cancer, however, is less often amenable to pelvic exenteration.

Pelvic exenteration may involve resection of the anus, the rectum, the bladder, the ureters, and the pelvic reproductive organs. Sacrectomy is sometimes necessary as well if the rectal cancer is invading posteriorly.⁶² Reconstruction after these procedures involves both fecal and urinary diversion; consequently, a multidisciplinary team is usually needed.

Detailed preoperative and intraoperative examination is essential to verify the presence of localized resectable disease before proceeding with exenteration. If there is evidence of carcinomatosis, liver metastases, pelvic sidewall invasion, bilateral ureteral obstruction, or aortic node metastases, curative exenteration cannot be performed. Invasion of the upper sacral vertebra is a con-

traindication to sacrectomy because in this setting, the procedure would result in unacceptably high morbidity and functional sequelae. In the setting of advanced disease, the surgeon should consider comfort care or additional adjuvant therapy before performing palliative exenteration. Other treatment modalities (e.g., intraoperative radiotherapy, brachytherapy, and further chemoradiation) may be useful in this population.

Outcome Evaluation

FOLLOW-UP REGIMENS

The primary purpose of surveillance after treatment of rectal cancer is to detect early recurrence so that salvage therapy can be instituted. A secondary purpose is to prevent development of a metachronous cancer by identifying and removing new polyps. Symptoms of pain, pressure, weight loss, or bowel dysfunction should be investigated. In addition to the physical examination, various laboratory studies, endoscopic procedures, and imaging modalities are used to detect or exclude recurrences. Although survival is improved after resection of recurrent lesions, especially in the setting of hepatic metastases, few data exist on the utility of close follow-up. Some studies have questioned the utility of follow-up protocols.^{63,64} A survey of the American Society of Colon and Rectal Surgeons and the Society of Surgical Oncology found that practice patterns were highly variable and that there was no clear consensus on what constitutes appropriate follow-up after treatment of rectal cancer.⁶⁵

Most follow-up regimens include a routine history and physical examination, carcinoembryonic antigen (CEA) testing, CT scanning, and routine colonoscopic evaluation. The roles of MRI, PET, and other imaging studies have not been defined. Our practice is to follow good-risk rectal cancer patients who have undergone curative-intent therapy every 4 months with ERUS and rigid

proctoscopy for the first 3 years, then every 6 months for 2 more years. Data on the efficacy of such regimens are limited. A meta-analysis of 3,000 patients revealed a 9% increase in 5-year survival in patients who underwent intensive investigation with routine CEA testing and aggressive resection. Unfortunately, this meta-analysis involved patients enrolled in nonrandomized trials.⁶⁶ Patients with limited lifespans or multiple medical problems were probably more likely to opt out of close surveillance.

RECURRENT DISEASE

Recurrence of rectal cancer after treatment may be classified as either local (if it arises at the anastomosis or in the pelvis) or systemic (if it develops in distant sites). One autopsy series found local recurrence in one quarter of patients, distant metastases in one quarter, and combined local and distant recurrence in one half.⁶⁷ Patients with systemic recurrences generally are not candidates for extensive surgical procedures. Instead, they should be evaluated by a multidisciplinary team that includes a surgeon, a radiation oncologist, and a medical oncologist. A multimodality approach comprising chemotherapy, irradiation, and, if the disease becomes more manageable, surgery is individualized on the basis of each patient's needs and condition.⁶⁸ The 5-year survival rate for patients treated with this aggressive approach ranges from 12% to 27%.⁶⁹⁻⁷¹

Recurrence after Local Resection

Recurrence rates after local resection vary, depending on the extent of the primary disease. Positive margins, transmural bowel wall invasion, and lymphovascular invasion are associated with an increased risk of local recurrence.⁷² One quarter of patients with recurrent disease after local excision have local recurrences that can be managed with surgical extirpation or other treatments.⁷³ Recurrences after local resection in patients who have metastatic disease or comorbidities that make them poor candidates for rad-

ical surgery are best managed with palliative procedures. Good surgical candidates with isolated local recurrences are best treated with a combination of radical surgery and adjuvant therapy. Repeat local procedures are rarely recommended for these patients.

Recurrence after Radical Resection

In the past, reported local recurrence rates after radical proctectomy reached 30% to 40%. Currently, however, with the general acceptance of TME techniques, reported local recurrence rates are as low as 3% to 5%.⁷⁴ Recurrence rates are primarily a reflection of the stage of the original disease at the time of initial treatment. Approximately 7% to 20% of patients with local nonhepatic colorectal recurrences can undergo repeat resection.⁷⁵ Recurrence is more likely to manifest as a surgically correctable lesion after low anterior resection than after APR.⁶¹ Recurrence at the anastomosis after high anterior resection may be amenable to treatment with either curative repeat resection and a lower anastomosis or APR. The surgical options available for treating recurrence after APR are usually limited to exenteration and sacrectomy; the likelihood that an isolated local perineal recurrence amenable to local excision will be identified after APR is small.

Patients scheduled for repeat resection should undergo an extensive workup with modalities such as CT, MRI, and PET to exclude any extrapelvic recurrence. Before committing to a potentially morbid repeat resection, the surgeon should carry out an extensive operative exploration to confirm that a curative-intent resection is feasible. If preoperative imaging and abdominal exploration reveal no contraindications to repeat resection, the surgeon may proceed cautiously with anterior resection, APR, or pelvic exenteration. Alternatively, in the palliative setting, local control may be obtained with chemoradiation, fulguration, or local excision techniques rather than procedures that call for a major laparotomy.

36 PROCEDURES FOR RECTAL PROLAPSE

Steven D. Wexner, M.D., F.A.C.S., F.A.S.C.R.S., and Susan M. Cera, M.D.

Rectal prolapse is an intussusception of the rectum, which may be categorized as occult (internal), mucosal, or complete. Occult rectal prolapse does not extend beyond the anal canal and often is not associated with any symptoms; it may be a precursor to complete prolapse. Mucosal prolapse involves protrusion of the mucosa only, with the muscular layers of the rectum remaining in place. Complete rectal prolapse, or rectal procidentia, involves full-thickness protrusion of the rectum through the anus [see Figure 1].

Whereas the exact pathophysiology of rectal prolapse remains unclear, several factors have been associated with its development, including constipation, female sex, postmenopausal status, and previous anorectal surgical procedures. The constipation frequently arises from conditions such as colonic inertia, neurologic disease, psychiatric illness, and obstructed defecation. Obstructed defecation is also referred to as anismus, spastic pelvic floor, and paradoxical or nonrelaxing puborectalis syndrome. Patients with this condition experience significant pain and have difficulty passing stool; digital compression or any of a variety of perineal maneuvers may be necessary to relieve the functional obstruction.

Chronic constipation and straining are thought to lead to herniation of the rectum through the muscular aperture of the pelvic floor, much as occurs with a hiatal or ventral hernia. As herniation progresses, the mesorectum lengthens and the lateral and rectosigmoid attachments stretch. Weakened pelvic floor muscles (from aging and the postmenopausal state) contribute to the herniation process, as do sphincter defects and pudendal neuropathy from previous anorectal operations or obstetric injuries.

Initially, prolapse occurs only with straining; later in the course of the disease, it occurs with any increase in intra-abdominal pressure

or may develop into a chronic condition. Chronic prolapse results in the development of a patulous anus and incontinence. The incontinence may derive from direct sphincteric stretching, from traction injury of the pudendal nerves caused by straining, or from continuous stimulation of the rectoinhibitory reflex by the intussusception, which results in chronic reflexive relaxation of the internal anal sphincter and inappropriate leakage of stool and mucus.

The anatomic abnormalities resulting from rectal prolapse include a deep cul-de-sac, a redundant rectosigmoid, an elongated mesorectum, diastasis of the levator ani, perineal descent, a patulous anus, and loss of support of the uterus and the bladder [see Table 1]. Rectal prolapse also is frequently associated with other anatomic defects of the pelvic floor, such as rectoceles, enteroceles, cystoceles, and uterine and vaginal prolapse. Recognition of how the functional pathology of the pelvic floor results in the anatomic abnormalities seen with rectal prolapse is essential to understanding the various operative approaches and determining appropriate long-term management. Patients with rectal prolapse, like most patients with pelvic floor dysfunction, frequently require postoperative bowel retraining with fiber therapy, laxatives, or biofeedback to address the functional component of this disease and thereby prevent recurrence once the prolapse has been surgically corrected.

More than 120 operations for treating rectal prolapse have been described. A detailed description of all available options is clearly beyond the scope of this chapter. Instead, we focus on a few key procedures that currently are frequently employed and enjoy widespread acceptance. For present purposes, we have excluded a number of procedures that, though popular in certain regions of the world, are not universally accepted.

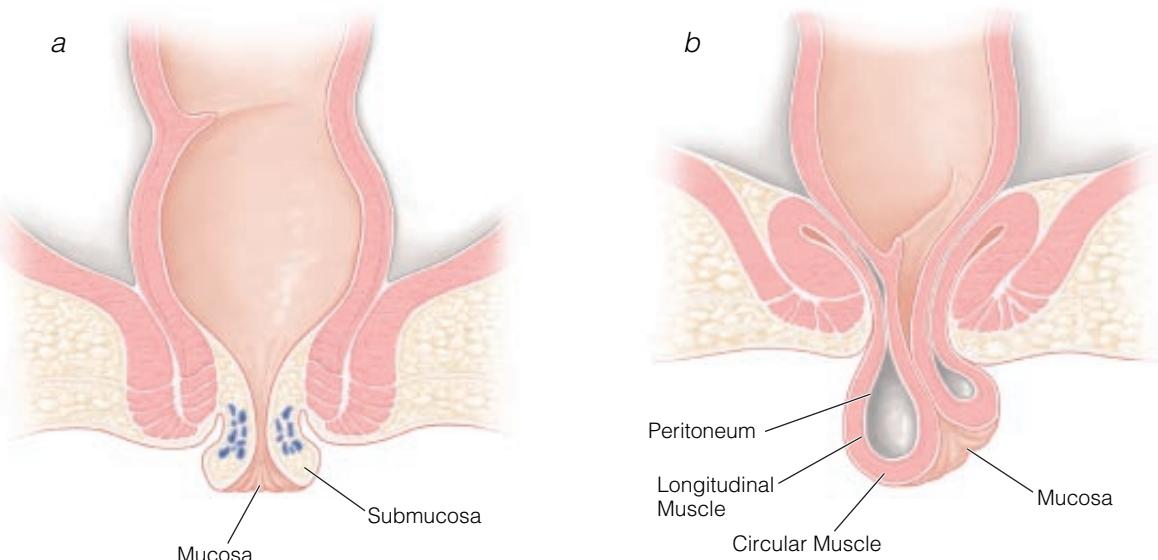

Figure 1 In mucosal prolapse (a), only the mucosa protrudes, whereas in complete rectal prolapse (b), the full thickness of the rectal wall protrudes.

Table 1 Anatomic Abnormalities Associated with Rectal Prolapse

Deep cul-de-sac	Herniation of pelvic organs through pelvic funnel
Redundant rectosigmoid colon	Patulous anus
Elongated mesorectum	Loss of support of uterus and bladder
Diastasis of levator ani	
Perineal descent	

Preoperative Evaluation

Because of the protrusion of tissue through the anus and the frequent bloody discharge, most patients initially mistake rectal prolapse for hemorrhoids [see Table 2]. Such patients often present with a complaint of “persistent hemorrhoids” after a recent hemorrhoid operation. Similarly, many patients mistake incarcerated rectal prolapse for thrombosed hemorrhoids. Consequently, a high level of suspicion and careful physical examination are required to differentiate hemorrhoids from rectal procidentia [see Table 3].

The diagnosis is most easily made with the patient straining while seated on the toilet. If the prolapse cannot be reproduced in the office setting, administration of a phosphate enema may reveal it. The appearance of circumferential, concentric folds of rectal mucosa serves to differentiate rectal prolapse from hemorrhoids, in which the folds (sulci) occur in a radial pattern, yielding three discrete anatomic bundles [see Figure 2]. In addition, close inspection of a full-thickness rectal prolapse reveals a circumferential sulcus between the anus and rectum, and palpation reveals a double rectal wall. The prolapse should be easily reducible unless incarcerated.

Chronic prolapse leads to inflammation, edema, and ulceration of the rectal mucosa. Biopsy of these areas should be undertaken to determine whether there is a neoplastic lesion acting as the source of the intussusception. In addition, complete colonoscopy is performed to search for lesions elsewhere in the colon, which may affect the surgical approach to the proplapse. Occasionally, a solitary rectal ulcer in the anterior rectum is seen in a patient with obstructed defecation caused by ischemia of the rectal wall from chronic straining. Barium enemas may induce strangulation and thus should be avoided; however, water-soluble contrast enemas may be of some use in identifying pathologic conditions in the remainder of the colon. Defecography is useful when occult intussusception or mucosal prolapse is suspected or when the patient has a history of prolapse but is unable to reproduce the prolapse in the office. If the prolapse is associated with conditions arising from pelvic floor defects (e.g., urinary incontinence, rectocele, enterocle, cystocele, and uterine and vaginal prolapse), consultation with a gynecology team for combined surgical intervention is warranted.^{1,2}

About 50% of patients with prolapse have a history of constipation.^{1,3} Possible causes of the underlying constipation—such as electrolyte (calcium) imbalance, hormonal (thyroid) dysfunction, obstructed defecation, and colonic inertia—should be investigated. Surface electromyography may be used to diagnose paradoxical contraction of the puborectalis muscle. In patients with severe constipation, a colonic transit study using ingested radiopaque markers aids in diagnosing colonic inertia, which may necessitate inclusion of subtotal colectomy as part of surgical management.

Fecal incontinence is a presenting symptom in 30% to 80% of patients with rectal prolapse.^{3,4} For these patients, anal ultra-

sonography, manometry, electromyography, and pudendal nerve terminal motor latency testing are indicated to help guide the choice of surgical procedure to treat the prolapse.

Operative Planning

CHOICE OF PROCEDURE

Because the etiology and pathophysiology of rectal prolapse are not well understood and appear to vary, it has not proved possible to identify any individual procedure as the optimal surgical approach to this condition. The current focus in the literature is on developing criteria by which specific patients can be matched to the specific operations that are most appropriate for them. The choice of operation is determined by the patient's age, sex, level of operative risk, associated pelvic floor defects, degree of incontinence, and history of constipation, as well as by the surgeon's experience. The goal is to correct the greatest number of anatomic problems (including the prolapse and any associated functional disorders) safely and efficiently while minimizing both perioperative morbidity and postoperative recurrence.

The procedures performed for repair of rectal prolapse may be divided into two broad categories: perineal and abdominal [see Table 4]. The perineal operations include anal encirclement (the Thiersch wire procedure), mucosal sleeve resection (the Delorme procedure), and perineal rectosigmoidectomy (the Altemeier procedure). In the original description of the Thiersch wire procedure, silver wire was placed in the subcutaneous tissues surrounding the anus through two small incisions, then tied around the assistant's finger to narrow the anal aperture.⁵ It was believed that this operation controlled the prolapse by reinforcing the anal sphincter and fixing the rectum to surrounding structures through induction of tissue reaction to the foreign material. The simplicity of the operation was offset by many problems, including breakage of the wire, sloughing of the overlying skin, perineal sepsis, and fecal impaction. Various other, more compliant materials (e.g., Marlex mesh and Silastic rods) have since been used in place of the silver

Table 2 Symptoms of Rectal Prolapse

Sensation of protrusion of tissue through anus	Incontinence
“Persistent hemorrhoids”	Incomplete evacuation
Mucoid or bloody discharge	Perineal pressure
Constipation	Excoriation of perianal skin
Straining	

Table 3 Differences between Rectal Prolapse and Hemorrhoids

	Rectal Prolapse	Hemorrhoids
Tissue folds	Circumferential	Radial
Sulcus between prolapse and rectum	Circumferential	None
Abnormality on palpation	Double rectal wall	Hemorrhoidal plexus
Resting and squeeze pressure	Decreased	Normal

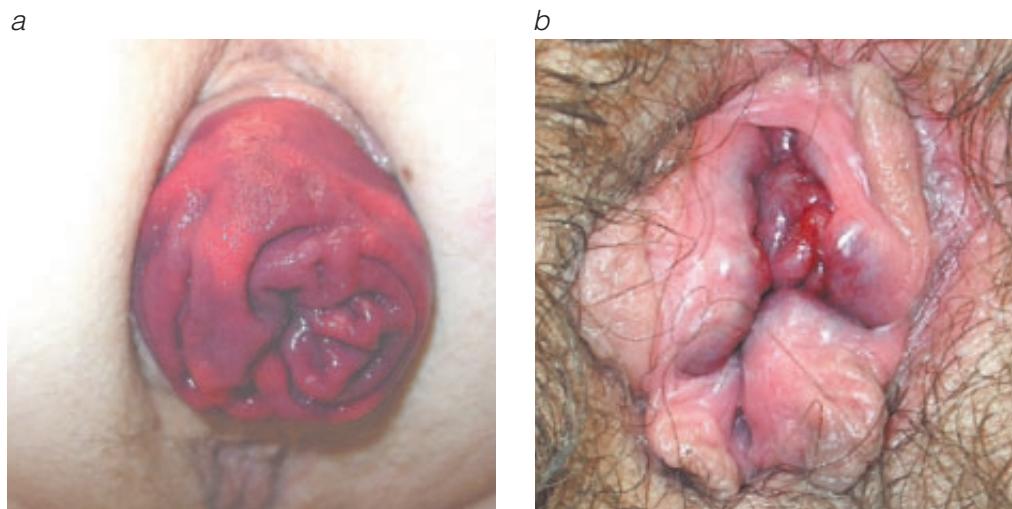

Figure 2 Rectal prolapse can be differentiated from hemorrhoids on the basis of physical appearance. (a) Rectal prolapse is distinguished by concentric mucosal folds. (b) Hemorrhoids are distinguished by radial sulci and discrete hemorrhoidal bundles.

wire, but none of these modifications have proved successful. In addition, better anesthetic techniques and improved perioperative medical management have made it possible to employ other perineal or abdominal procedures safely in most patients. Consequently, anal encirclement remains an option only for those patients who would be at unacceptably high risk with other types of procedures.

Mucosal sleeve resection, as described by Delorme in 1900, involves stripping the mucosa from the redundant rectum and plicating the denuded rectal wall with sutures to create bulk and thus prevent future prolapse.⁶ Perineal rectosigmoidectomy, originally described by Mikulicz⁷ and subsequently modified by Altemeier,⁸ involves transanal amputation of the prolapsed rectum coupled with a coloanal anastomosis.

The various abdominal operations may be performed as either open or laparoscopic procedures, and they differ with respect to how far rectal mobilization extends, whether the lateral ligaments are divided, whether the rectum is fixed anteriorly or posteriorly, what fixation material is used (sutures, mesh, or sponge), and whether sigmoid resection is included. At present, the operation most commonly performed to treat rectal prolapse in the United States is suture rectopexy, with sigmoid resection added (the Frykman-Goldberg procedure) if constipation is a significant presenting complaint. The various posterior rectopexies with sutures or mesh are more popular than the procedures involving anterior fixation with mesh or posterior placement of a polyvinyl alcohol (Ivalon) sponge. Anterior fixation of the rectum using a sling was proposed by Ripstein and Lantern as a way of restoring the natural contour of the rectum and preventing intussusception.⁹ Originally, fascia lata was used for the sling; subsequently, various artificial materials (e.g., Teflon, Marlex, and Gore-Tex mesh) came to be used instead. The Ivalon sponge operation (the Wells procedure) entails placement of the sponge posterior to the rectum to create an inflammatory reaction and a consequent rectopexy.¹⁰ Because of the risks imposed by the foreign materials (including infection, erosion, and stenosis), few surgeons now perform either anterior fixation or foreign body placement.

Laparoscopic resection rectopexy involves a laparoscopic-assisted approach with intracorporeal mobilization of the sigmoid colon and the rectum, division of the mesenteric vessels, and distal transection of the bowel. The bowel is then exteriorized through a small incision (often, a Pfannenstiel incision), and the proximal transection is per-

formed. The rectopexy sutures are placed by means of an open technique, and the anastomosis is created with a transanally placed circular stapler. Laparoscopic suture rectopexy without resection is performed entirely laparoscopically, with intracorporeal mobilization and suture placement.

Perineal Procedures

MUCOSAL SLEEVE RESECTION (DELORME PROCEDURE)

Both mucosal sleeve resection and perineal rectosigmoidectomy may be performed with the patient under either general or spinal anesthesia. Preoperatively, the patient undergoes mechanical and antibiotic bowel preparation. Such preparation consists of oral administration of 45 ml of sodium phosphate solution, followed by three 8 oz glasses of water, at 4 P.M. and 9 P.M., and administration of 1 g of neomycin with 500 mg of metronidazole at 7 P.M. and 11 P.M. Before the procedure, the patient receives prophylactic antibiotics, and subcutaneous heparin is used in conjunction with sequential compression devices to prevent venous thromboembolism.

Table 4 Operations Performed to Treat Rectal Prolapse

Perineal procedures	Anal encirclement (Thiersch wire procedure) Mucosal sleeve resection (Delorme procedure) Perineal rectosigmoidectomy (Altemeier procedure)
Transabdominal procedures	Rectopexy Suture Anterior sling (Ripstein procedure) Ivalon sponge (posterior rectopexy) Posterior sling (modified Ripstein procedure) Resection Suture rectopexy with resection (Frykman-Goldberg procedure) Laparoscopic repairs Resection rectopexy Suture rectopexy Rectopexy with mesh

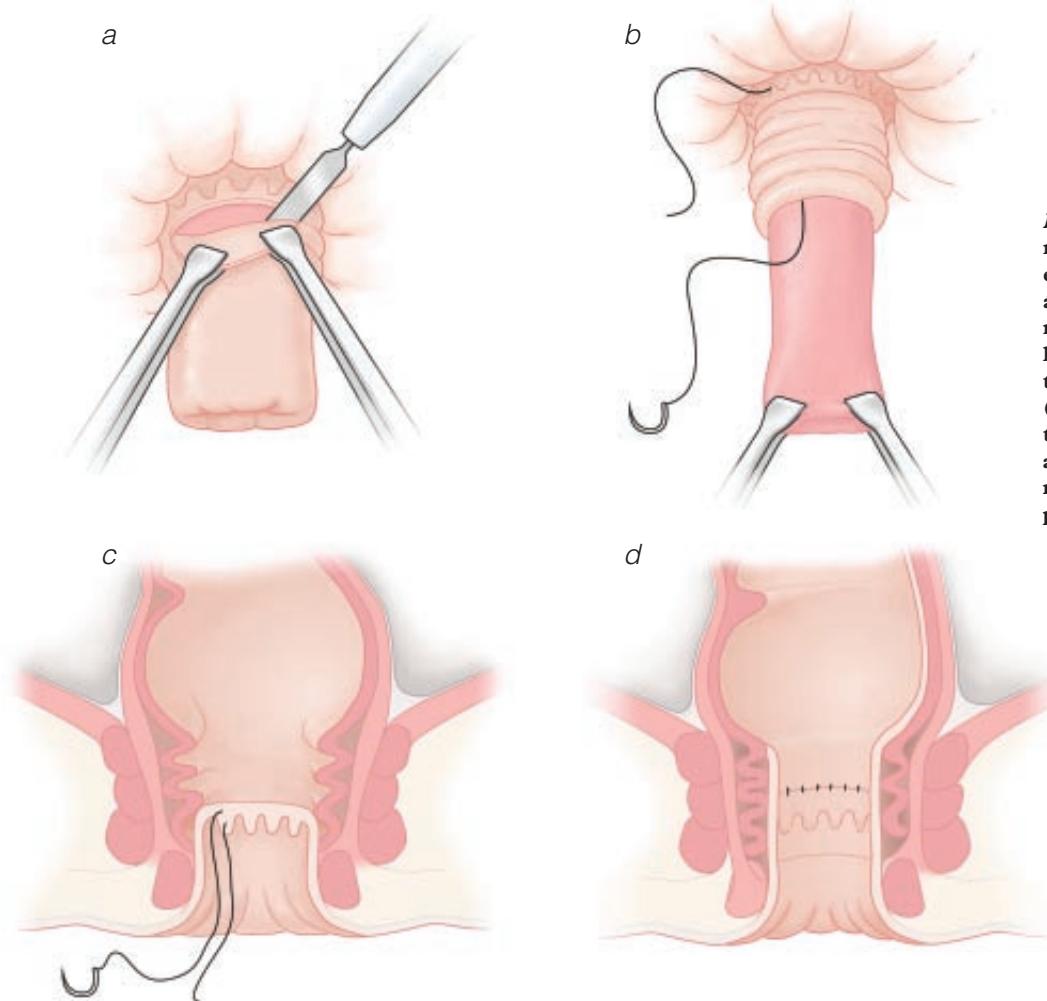

Figure 3 Mucosal sleeve resection. (a) With the rectum everted, the mucosa is incised and dissected away from the muscular tube. (b) The muscular tube is plicated with sutures to form a muscular pessary. (c) A mucosa-to-mucosa anastomosis is fashioned. (d) The anastomosis spontaneously reduces into its anatomic position.

After induction of anesthesia or administration of intravenous sedation, a bladder catheter is inserted, and the patient is placed in the prone jackknife position with a Kraske roll beneath the hips and the buttocks abducted with tape. A self-retaining retractor may be used to evert the anus. The muscular stripping can be undertaken with the prolapse either everted or reduced. Our preference is to evert the prolapse, and the following technical description embodies that preference.

Operative Technique

Step 1: eversion of rectum The rectal prolapse is everted by placing gentle traction on the rectal wall with Babcock tissue forceps passed through the anus. As the prolapsed tissue emerges, the Babcock forceps are repositioned more proximally on the rectal wall to provide a better grasp and facilitate delivery of the prolapse through the anus and into the operative field.

Step 2: submucosal injection of anesthetic Once the rectum has been everted, a local anesthetic solution containing 0.25% bupivacaine, 0.5% lidocaine, and epinephrine (in a 1:400,000 dilution) is circumferentially injected 1 to 1.5 cm above the dentate line to minimize bleeding.

Step 3: circumferential incision of mucosa The rectal mucosa is incised at this level with a conventional diathermy, and four clamps are placed on the proximal mucosal edge for traction [see Figure 3].

Step 4: dissection of mucosa from muscle Gentle traction is placed on the clamps, and the mucosa is dissected away from the muscle with the electrocautery. A finger is placed inside the muscular tube to facilitate traction and help prevent full-thickness injury. Resection of the mucosal sleeve is continued until resistance prevents further dissection. A tube of redundant muscular tissue then remains.

Step 5: plication of rectal muscle The muscular tube is plicated by placing eight reefing sutures circumferentially in the wall.

Step 6: resection of mucosa and anastomosis The excess mucosa is transected in a superior-to-inferior direction, and the two cut edges of mucosa are approximated with sutures. Transection is continued on one side for a quarter of the circumference, at which point a second suture is placed. With traction applied to these two sutures, two additional sutures are placed at 90° intervals to establish four quadrants. Transection and anastomosis are serially performed in each of the four quadrants until the mucosa is completely excised and the anastomosis has been completed. With the removal of the retractor, the anastomosis should spontaneously reduce into its anatomic position.

Postoperative care Because the patients are often elderly, 1 to 3 days of observation may be indicated. The bladder catheter is removed on the following morning, and the patient is advanced to a regular diet as soon as he or she can tolerate it. The patient

is sent home on a regimen of fiber supplementation and sitz baths as soon as medical stability is ensured and appropriate social circumstances arranged.

Troubleshooting

The Delorme procedure prevents rectal intussusception by resecting redundant mucosa and by removing laxity in the rectal wall through plication of the muscular redundancy. The key to success is to continue the sleeve resection until some resistance is met and the dissection cannot proceed further. Sometimes, the anterior wall is longer than the posterior wall or vice versa, but such discrepancies should not affect the repair. The anastomosis is performed one quadrant at a time to prevent retraction of the transected mucosa into the proximal bowel.

PERINEAL RECTOSIGMOIDECTOMY

Operative Technique

Anesthesia and positioning are the same for perineal rectosigmoidectomy as for mucosal sleeve resection.

Steps 1 and 2 Steps 1 and 2 of this procedure are the same as steps 1 and 2 of mucosal sleeve resection (see above).

Step 3: circumferential incision through rectal wall
With the rectum everted, the prolapse consists of two tubes of

rectal wall, with the inner tube consisting of rectum attached to the sigmoid and the outer tube consisting of rectum attached to the dentate line. The mucosa is circumferentially scored with a standard diathermy 1 to 1.5 cm cephalad to the dentate line [see Figure 4]. The incision should be made at the top of the anal columns to preserve the entire transition zone, which is important for nocturnal continence. The incision is deepened through all layers of the outer rectal tube until perirectal fat is encountered and the mesorectum is identified on the superior aspect of the prolapse with the patient prone.

Step 4: mobilization of rectum and division of mesentery Rectal mobilization is accomplished by clamping, ligating, and dividing the vessels of the mesorectum. As the mesorectum is divided, tension on the rectum delivers more of the prolapse into the operative field. Division of the mesorectum is continued close to the bowel wall until no more bowel can be delivered. During this phase, the sliding hernia of peritoneum (cul-de-sac) anterior to the rectum (on the inferior aspect of the prolapse with the patient prone) may be opened to allow palpation of the intraperitoneal contents and determination of whether the colon is straight in the pelvis.

A finger may be inserted into the pelvis alongside the rectum to facilitate assessment of the redundancy of or the tension on the remaining rectum and sigmoid. If redundancy is still encountered, more mesorectum is divided to allow further mobilization

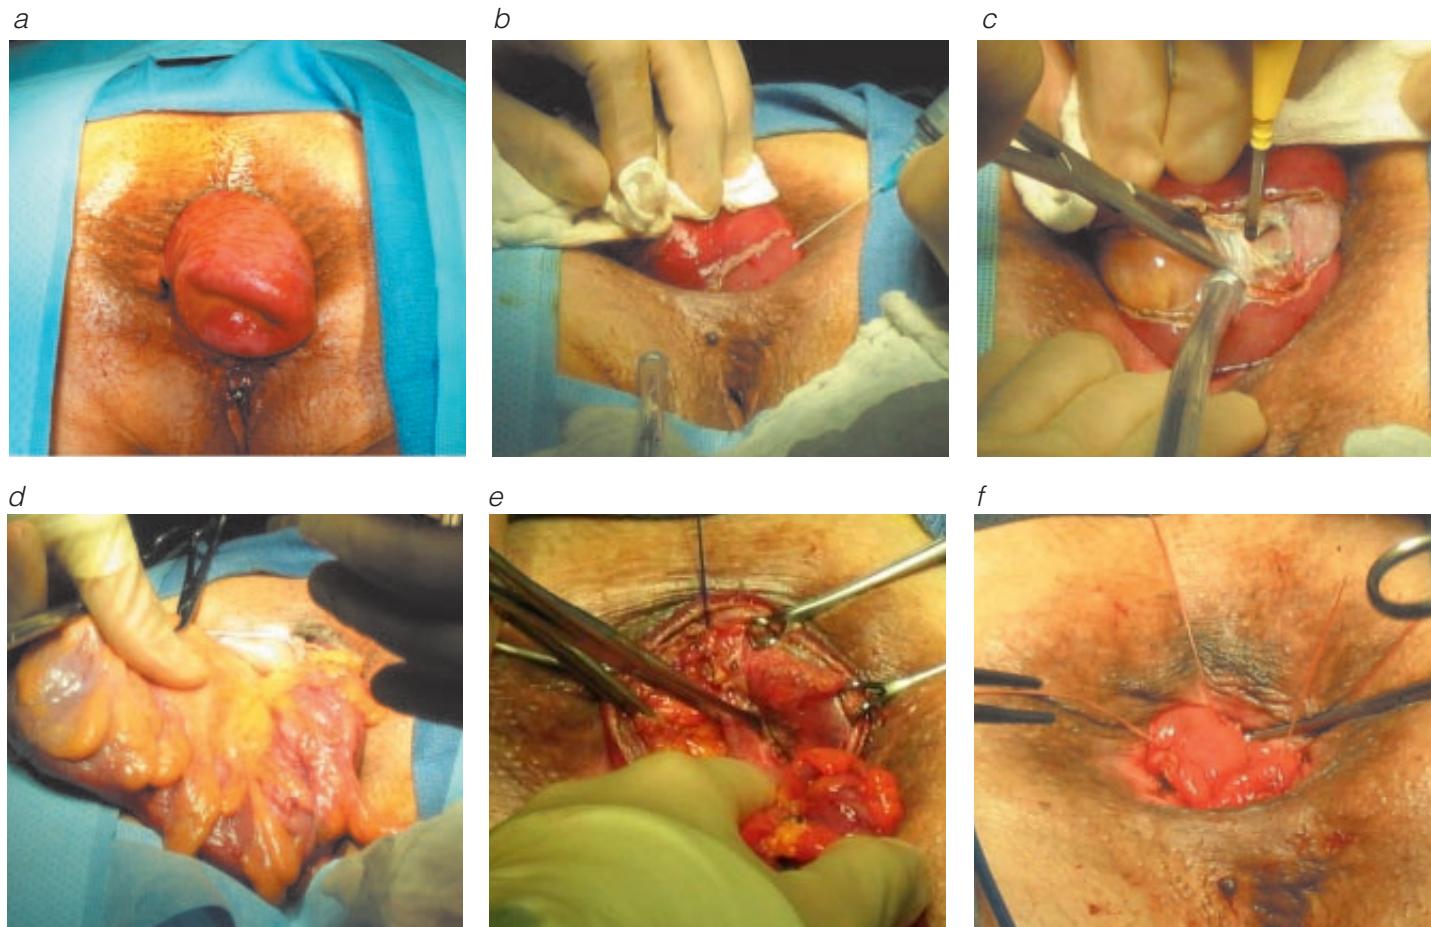

Figure 4 Perineal rectosigmoidectomy. (a) The rectum is everted. (b) The anesthetic is injected submucosally. (c) A circumferential incision is made and deepened through the outer rectal tube until perirectal fat is encountered. (d) The rectum and the sigmoid are mobilized with division of the mesentery; levatorplasty is then done. (e) The first suture of the anastomosis is placed. (f) The remaining sutures are placed.

of the bowel through the anus. Careful control of the mesentery with ligatures is advised to prevent retraction of bleeding vessels into the pelvis.

Step 5: ligation of hernia sac Once the redundant rectum and sigmoid have been adequately mobilized, the hernia sac of peritoneum is sutured closed. Care is taken to resect any redundant hernia sac to prevent future anterior intussusception; this step is similar to the high ligation performed for other types of hernias.

Step 6: levatorplasty Levatorplasty is then performed to restore the appropriate angles of the pelvic floor muscles, to aid in treatment of incontinence, and to narrow the aperture through which herniation occurs and thereby prevent recurrence. It can be performed anterior to the rectum, posterior to the rectum, or both. A narrow retractor is employed to expose the outer tube of rectum and uncover the levator muscles. Interrupted 2-0 nonabsorbable sutures are placed through the levator muscles on each side and secured loosely enough to allow a finger to be inserted alongside the rectum.

Step 7: proximal transection of rectum and anastomosis

The point at which the redundant rectum is to be transected is identified at the level at which the mesorectum is divided. The bowel wall is circumferentially cleared of appendages in preparation for transection and anastomosis. Transection is begun by dividing a small area of the bowel wall superiorly and placing a suture through the edge of the outer tube of rectum and the newly transected proximal edge of the bowel. Transection is continued inferiorly on one side for a quarter of the circumference, and a second suture is placed. With traction on these two sutures, two additional sutures are placed around the remaining circumference to mark four quadrants. Transection and anastomosis are serially performed in each of the four quadrants until the rectum is completely transected. When the anastomosis is complete, it retracts into the pelvis, where it may be inspected with a bivalve retractor.

Postoperative care Patients are often observed in the hospital for 1 to 3 days. Their diet is advanced as tolerated, and the bladder catheter is removed on postoperative day 1. Patients are sent home on a regimen of fiber supplementation and sitz baths.

Troubleshooting

Perineal rectosigmoidectomy involves a combination of repairs of anatomic abnormalities associated with rectal prolapse. Rectal mobilization yields a rectopexy from scarring; resection removes redundant bowel; ligation of the enterocele obliterates the hernia sac; and levatorplasty provides reconstruction of the pelvic floor. Each step requires that attention be paid to appropriate planes of dissection and that meticulous hemostasis be maintained. For example, transection of the outer rectal wall may lead to inadvertent division of the mesentery before vascular control is obtained; if this occurs, traction should be placed on the inner wall to expose the proximal mesentery and allow the surgeon to regain vascular control. In addition, transection of the outer rectal wall may lead to inadvertent simultaneous transection of both walls; if this occurs, clamps should be placed on the inner wall to prevent retraction into the pelvis and to facilitate rectal mobilization and division of the mesorectum [see Step 4, above].

To help prevent recurrence, all redundant bowel should be resected once mobilization of the rectum and division of the mesentery are complete. If, at the start of the procedure, only a

short segment of prolapse is produced or the patient is found to have only a mucosal prolapse, a Delorme operation may be performed instead.

COMPLICATIONS

Partial separation of the mucosal anastomosis after mucosal sleeve resection is not uncommon and usually does not warrant intervention. After perineal rectosigmoid resection, anastomotic separation may lead to leakage and pelvic sepsis, which must be treated with bowel rest and antibiotics or, in extreme cases, with debridement, repair, and stoma formation.

Early postoperative bleeding from the mucosal edges or, in the case of the perineal rectosigmoidectomy, from the presacral space may be observed. Late postoperative bleeding may result from tearing of the sutures through the mucosa or from separation of the anastomosis. All significant bleeding should be evaluated and controlled in the OR, with the source of the bleeding dictating the type of repair required.

Anastomotic strictures may occur after either mucosal sleeve resection or perineal rectosigmoidectomy. They are treated with serial dilations either at home or in the OR.

OUTCOME EVALUATION

The advantages of the perineal procedures include (1) the option to use spinal anesthesia, (2) avoidance of peritoneal adhesions, (3) short hospital stays (1 to 4 days), (4) a lower risk of injury to the pelvic nerves, (5) reduced pain, and (6) the opportunity for concomitant repair of other anorectal problems (e.g., sphincter defects, hemorrhoids, rectoceles, cystoceles, and vaginal prolapse). The disadvantages include (1) a higher recurrence rate and (2) reduced improvement of any fecal incontinence.

Reported recurrence rates for the perineal approaches range from 5% to 21%¹¹⁻¹³ and are higher than those for the abdominal approaches; however, the perineal repairs can be performed multiple times in the same patient as necessary.¹⁴ Because they are less invasive, perineal procedures generally carry a lower morbidity than abdominal procedures do, with the majority of the complications being medical in nature.^{11,12} Whereas constipation is neither exacerbated nor alleviated by the perineal procedures, continence is significantly improved, though not as much as it is improved by the abdominal procedures.^{15,16} The improvement in continence seen after both abdominal and perineal procedures for rectal prolapse is related to cessation of rectoanal inhibition and recovery of sphincter function with reduction of the prolapse. The lesser improvement reported after perineal procedures may be related to sphincter stretching or, in the case of perineal rectosigmoidectomy, to loss of the rectal reservoir. A comparison of various perineal procedures—including the Delorme procedure, perineal rectosigmoidectomy, and rectosigmoidectomy with levatorplasty—found that the addition of a levatorplasty yielded the greatest improvement in continence, the least morbidity, and the lowest recurrence rate.¹⁶

Because the incidence of rectal prolapse peaks in the sixth and seventh decades of life, patients undergoing these procedures frequently are elderly and have significant comorbid conditions.¹⁷ The perineal procedures are economically and physiologically advantageous in the short term and are therefore ideal for elderly patients or for any patients with multiple comorbid conditions, as well as for those who are at high operative risk or who need combined intervention from various pelvic surgical specialists. In these patients, who generally have limited life expectancies, the high risk of recurrence associated with the perineal procedures may be irrelevant. Perineal operations may also be indicated for

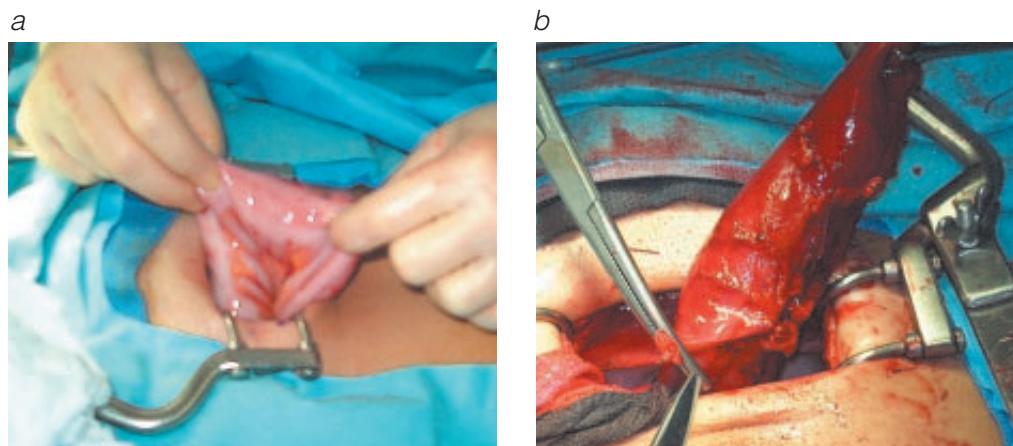

Figure 5 Open resection rectopexy. (a) The redundant sigmoid is mobilized through the abdominal wound. (b) The proximal sigmoid is transected, and the sigmoid mesentery is clamped, ligated, and divided.

patients who have undergone multiple previous abdominal operations and are likely to have dense adhesions, as well as for young men who do not wish to risk impairment of sexual function.

Abdominal Procedures

OPEN RECTOPEXY

Resection Rectopexy (Frykman-Goldberg Procedure)

Just as with perineal procedures, patients undergo mechanical and antibiotic bowel preparation on the day before surgery. Before operation, parenteral antibiotics and subcutaneous heparin are administered, and sequential compression devices are placed on the legs.

After induction of general anesthesia, the patient is placed in the modified lithotomy position with the legs in padded stirrups. If there is a history of one or more previous pelvic operations, bilateral ureteral stents are placed by a urologist, and a urinary catheter is inserted. The rectum is irrigated with saline through a transanally placed mushroom catheter until the effluent is clear, after which point additional irrigation is undertaken with a povidone-iodine solution. The catheter is left in place for the initial portion of the procedure, and the extra effluent is allowed to drain into a plastic bag secured to the catheter. The surgeon stands on the patient's left side.

Operative technique *Step 1: initial incision and exploration.* A low midline or Pfannenstiel incision is made, the pelvis is explored, a Balfour or Buchwalter retractor is placed, and the small bowel is packed into the upper abdomen.

Step 2: mobilization of sigmoid. The sigmoid colon is mobilized away from the left lateral wall by incising the lateral peritoneal reflection [see Figure 5a]. The gonadal vessels and the ureter are identified and swept posteriorly. The peritoneal incision is continued to the left of the rectum, curving anteriorly in the rectouterine or rectovesical sulcus. The peritoneum at the base of the sigmoid mesentery on the right is also incised, and this incision is continued to the right of the rectum to unite with the previous incision at the anterior rectum.

Step 3: proximal transection of sigmoid colon and placement of stapler anvil. Once the entire sigmoid is mobilized, the proximal

point of transection is chosen by finding an area of colon that easily falls into the pelvis but includes all of the redundant sigmoid colon. This level of the colon, the sigmoid-descending portion, is circumferentially cleaned of surrounding tissue. A straight clamp is placed proximally and an adjacent bowel clamp distally. The bowel is divided with a knife along the straight clamp. The straight clamp is released, and three Babcock forceps are placed to hold open the lumen. A purse-string suture of 2-0 Prolene is placed, and the head of a 33 mm circular stapler is secured in the lumen. Alternatively, a purse-string clamp may be used.

Step 4: division of sigmoid mesentery. The mesentery of the sigmoid is clamped, ligated, and divided close to the colon [see Figure 5b]. The superior rectal vessels are carefully preserved.

Step 5: mobilization of rectum and division of lateral ligaments. A Babcock clamp is placed on the rectal stump and lifted upward. The avascular plane of areolar tissue between the mesorectum and the presacral fascia is identified and divided with the electrocautery. A St. Mark's retractor is placed behind the rectum to provide traction, then advanced with dissection distally along the rectum to the level of the coccyx.

Dissection of the right side of the rectum is performed with the surgeon standing to the patient's left. The left hand places traction on the rectum, while the right hand uses the electrocautery to divide the lateral stalk in a posterior-to-anterior direction. The St. Mark's retractor is used to retract the tissues of the sidewall away from the rectum.

Dissection of the left side of the rectum is performed with the surgeon on the patient's right. Again, the left hand places traction on the rectum, while the right hand performs the dissection in a posterior-to-anterior direction.

Dissection anterior to the rectum is performed by using the retractor to place traction on either the uterus (in women) or the bladder (in men), then proceeding anterior to the rectum down to the level of the lower third of the vagina (in women) or below the seminal vesicles (in men). The lower one third to one half of the lateral stalks may be preserved, though the overlying peritoneum should be incised.

Step 6: placement of sutures for rectopexy. With upward traction applied to the rectal stump, horizontal mattress sutures of 2-0 Prolene are placed to perform the rectopexy. Starting on one

side, a suture is placed through the peritoneum and the endopelvic fascia adjacent to the rectum, with care taken not to penetrate the rectal wall. The suture is guided through the presacral fascia and the periosteum to the side of the midline and approximately 1 cm below the level of the sacral promontory. It is then completed by passing it back through the peritoneum and the endopelvic fascia. One or two sutures are placed on each side; they are left untied and are tagged with hemostats.

Step 7: transection of bowel at upper rectum. The rectosigmoid junction is identified on the basis of the splaying of the taeniae coli, the absence of appendices epiploicae, and the proximity to the sacral promontory. This junction marks the site of distal transection. Proctoscopic examination is helpful for determining the appropriate location. Transection may be performed with a stapler, a purse-string suture clamp, or a knife followed by a handsewn purse-string suture.

Step 8: completion of colorectal anastomosis. The circular stapler is advanced through the anus to the rectal stump. Under the manual and visual guidance of the abdominal and perineal operating surgeons, the trocar is advanced and the anvil engaged. The circular stapler is closed and fired. The stapler is then gently removed, and the "doughnuts" are checked for integrity. The anastomosis is tested for leaks by filling the pelvis with irrigant, clamping the colon proximal to the anastomosis, and insufflating air into the rectum. Air bubbles from the anastomosis indicate a leak that requires suture reinforcement. The rectopexy sutures are secured snugly to complete the procedure, and the abdomen is irrigated and closed in the usual fashion.

An alternative approach to this step is to perform endoscopic visualization of the anastomosis while simultaneously insufflating air through either the rigid proctoscope or the flexible sigmoidoscope. This method allows reliable confirmation of mucosal viability and anastomotic integrity. Moreover, if any supplemental anastomotic reinforcement sutures are needed, they can be placed much more easily at this time than after the rectopexy sutures have been secured. Sheets of sodium hyaluronate-based bioresorbable membrane are placed before closure of the fascia to help minimize postoperative adhesion formation; at our institution, these sheets are routinely used during most laparotomies.¹⁸ The abdominal incision is closed in the usual fashion.

Postoperative care. After operation, the patient is started on a clear liquid diet, then advanced to a regular diet when bowel function returns. The bladder catheter is removed on postoperative day 1, when ambulation also begins.

Troubleshooting Either suture rectopexy or sigmoid resection can be performed alone by following some of the steps just outlined (see above). Circumferential mobilization of the rectum to the level of the coccyx posteriorly and the upper third of the vagina anteriorly, with division of the lateral ligaments, is advocated to minimize recurrence. Division of the lateral ligaments increases the risk of postoperative constipation; however, inadequate distal mobilization or posterior mobilization performed without lateral ligament division results in laxity of the rectum and the attachments below the level of sacral fixation, which increases the risk of early recurrence. During the sigmoid resection, it is important to remove all redundant bowel; however, it is equally important to ensure that the anastomosis is tension free and well vascularized. During both rectal mobilization and sigmoid resection, careful attention should be paid to preserving the superior rectal artery and the sacral nerves.

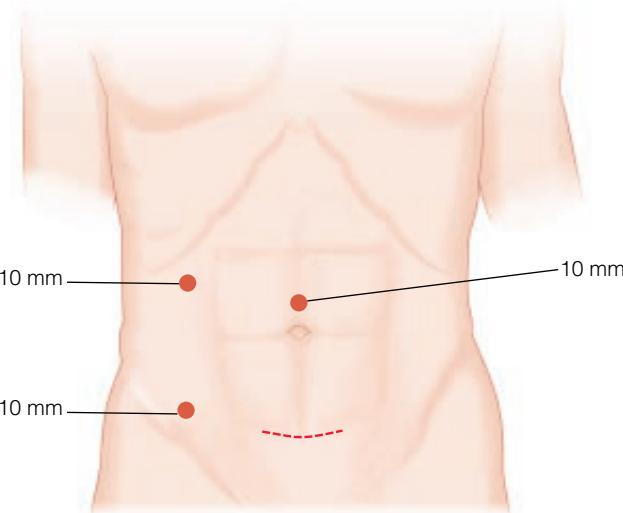

Figure 6 Laparoscopic resection rectopexy. Shown is the recommended port placement. A 10 mm trocar is placed in the periumbilical region by means of an open technique. Two 10 mm trocars are then placed in the right abdomen.

Complications Presacral bleeding may result from placement of sutures in the presacral fascia and consequent injury to the presacral veins. It may be controlled by tying down the sutures and applying direct manual pressure. For persistent bleeding, thumbtacks may be required.

Injury to the pelvic nerves and consequent impotence are possibilities with any procedure in which the rectum is mobilized. Performing the dissection close to the bowel wall minimizes the chances that these complications will occur.

Suturing the rectum too close to the sacrum may compress the lumen. This problem may be corrected by removing and replacing the sutures. Any uncertainty about rectal compression can be resolved by means of intraoperative proctoscopy.

The incidence of abdominal sepsis from an anastomotic leak can be minimized by ensuring a well-vascularized and tension-free anastomosis.

LAPAROSCOPIC RECTOPEXY

Laparoscopic Resection Rectopexy

Preoperative management includes full mechanical bowel preparation and both oral and parenteral antibiotic preparation. In addition, cefotetan, 2 g I.V., is administered along with heparin, 5,000 units subcutaneously, at the start of the operation.

After the induction of general anesthesia, the patient is placed in the modified lithotomy position with the legs in pneumatic compression stockings and padded stirrups. The arms are tucked at the sides, and extra care is taken to secure the patient to the bed because of the rotation and tilting required during operation. Two or more monitors are placed on opposite sides of the operating table. The rectum is irrigated with saline through a transanally placed mushroom catheter until the effluent is clear, at which point additional irrigation is initiated with a povidone-iodine solution. The catheter is left in place for the initial portion of the procedure, and the extra effluent is allowed to drain into a plastic bag secured to the catheter. If requested, lateral ureteral stents are placed by a urologist, and a urinary catheter and an orogastric tube are inserted. The abdomen is shaved, prepared with povidone-iodine solution, and appropriately draped.

Operative technique *Step 1: placement of ports.* A 10 mm trocar is placed infraumbilically or supraumbilically (depending on patient size) by means of the open Hasson technique; this port will be used for the camera. Pneumoperitoneum is established, and two additional 10 mm trocars are placed along the lateral edge of the rectus abdominis in the right midabdomen and the right iliac fossa [see Figure 6]. If necessary, one or two additional trocars may be placed laterally on the left of the abdomen to assist with sigmoid retraction.

Step 2: mobilization of sigmoid and rectum. The operating table is tilted to the patient's right to facilitate medial retraction of the left colon, which is gently grasped with a Babcock forceps. An ultrasonic scalpel is placed through the right lower port and used to mobilize the sigmoid colon and the descending colon away from the left lateral side wall. Early identification of retroperitoneal structures, including the left ureter and the gonadal and iliac vessels, is achieved. The extent of mobilization is limited because the goal is to resect only the redundant portion of the colon. Laparoscopic resection rectopexy is the only type of left-side resection in which the splenic flexure is deliberately not mobilized in order to prevent redundancy and therefore recurrence of the prolapse. Dissection is extended into the pelvis, and the upper lateral rectal attachments are divided. With cephalad traction applied to the rectum, the mesorectum is circumferentially divided to the level of the coccyx.

Step 3: division of mesenteric vessels. The peritoneum of the left mesocolon is scored to permit identification and preparation of the vessels for transection. A 30 mm linear vascular cutting stapler is inserted through the right iliac fossa port, and the vessels are individually transected. The use of endoscopic hemostatic clips or endoscopic vessel loops is the most expedient option for managing imperfections of hemostasis. The location of the ureter is reconfirmed before each application of the stapler.

Step 4: intracorporeal transection of rectum at rectosigmoid junction. At the point where the taeniae coli coalesce, the rectosigmoid junction is divided with a laparoscopic linear stapler passed through the right lower quadrant port.

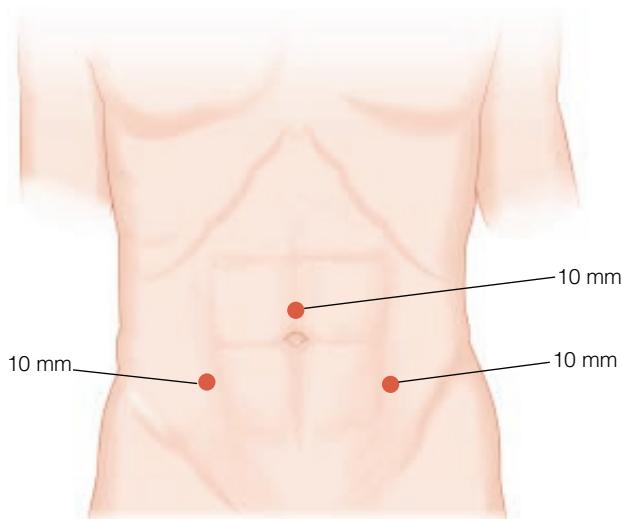

Figure 7 Laparoscopic suture or mesh rectopexy. A 10 mm trocar is placed in the periumbilical region. Two additional 10 mm trocars are then placed, one in each lower quadrant.

Step 5: extracorporeal transection of proximal bowel. A small (4 to 5 cm) Pfannenstiel incision is made, a wound protector drape is inserted, and the sigmoid is delivered through the wound. Transection of the proximal bowel is performed in an area of the colon that easily reaches the sacral promontory without redundancy. A purse-string suture is placed in the edge of the proximal bowel, and the anvil of a 33 mm circular stapler is inserted and secured. The bowel is then placed back into the abdomen.

Step 6: placement of rectopexy sutures. Via the Pfannenstiel incision, mattress sutures of nonabsorbable material are passed through the peritoneum and fascia on the lateral rectum, through the presacral fascia just off the midline and 1 cm below the sacral promontory, and back through the lateral tissue. One or two sutures are placed on each side but are not secured until the anastomosis has been created.

Step 7: creation of anastomosis. The circular stapler is inserted transanally to the level of the rectal stump, and its trocar is carefully advanced. The anvil is engaged on the trocar, the surgeon confirms that there is no inclusion of extraneous tissue and no rotation of the bowel or its mesentery, and the stapler is closed. The locations of the ureters and the vagina are reconfirmed to ensure that these structures are not incorporated into the staple line. The stapler is fired, and the tissue doughnuts are inspected to verify circumferential integrity. The anastomosis should be tension free and well vascularized. Its integrity is tested by insufflating air into the rectum with the anastomosis submerged in fluid, and any leaks identified are reinforced with sutures. As with open rectopexy, endoscopic visualization can be a useful alternative; this is in fact our preferred approach for all circular stapled anastomoses. Insufflation of air during visualization completes the assessment.

Finally, the rectopexy sutures are tied and the abdominal and port site incisions closed.

Postoperative care. Patients are immediately started on a clear liquid diet and advanced to a solid diet when bowel function returns. The bladder catheter is removed on postoperative day 1.

Laparoscopic Suture or Mesh Rectopexy

Patient preparation, positioning, and placement of ureteral stents are the same for laparoscopic suture or mesh rectopexy as for laparoscopic resection rectopexy.

Operative technique *Step 1: placement of ports.* An infraumbilical or supraumbilical port is placed, followed by two additional ports in the lower abdomen (one in each quadrant), positioned so that the camera and the needle holders can be exchanged to afford access to both sides of the rectum [see Figure 7]. The surgeon stands to the patient's left.

Step 2: mobilization of rectum. Two bowel graspers are used to retract the rectosigmoid junction and the midrectum upwards. An ultrasonic scalpel is employed to perform the presacral dissection and to divide the upper half to two thirds of the lateral ligaments.

Step 3: intracorporeal placement of sutures or mesh. With upward traction applied to the rectum, sutures are passed through the lateral rectal fascia and peritoneum, through the presacral fascia just off the midline and 1 cm below the sacral promontory, and back through the lateral tissue. Two sutures are placed on each side and tied with the laparoscopic needle holders. The port sites are closed in the usual fashion.

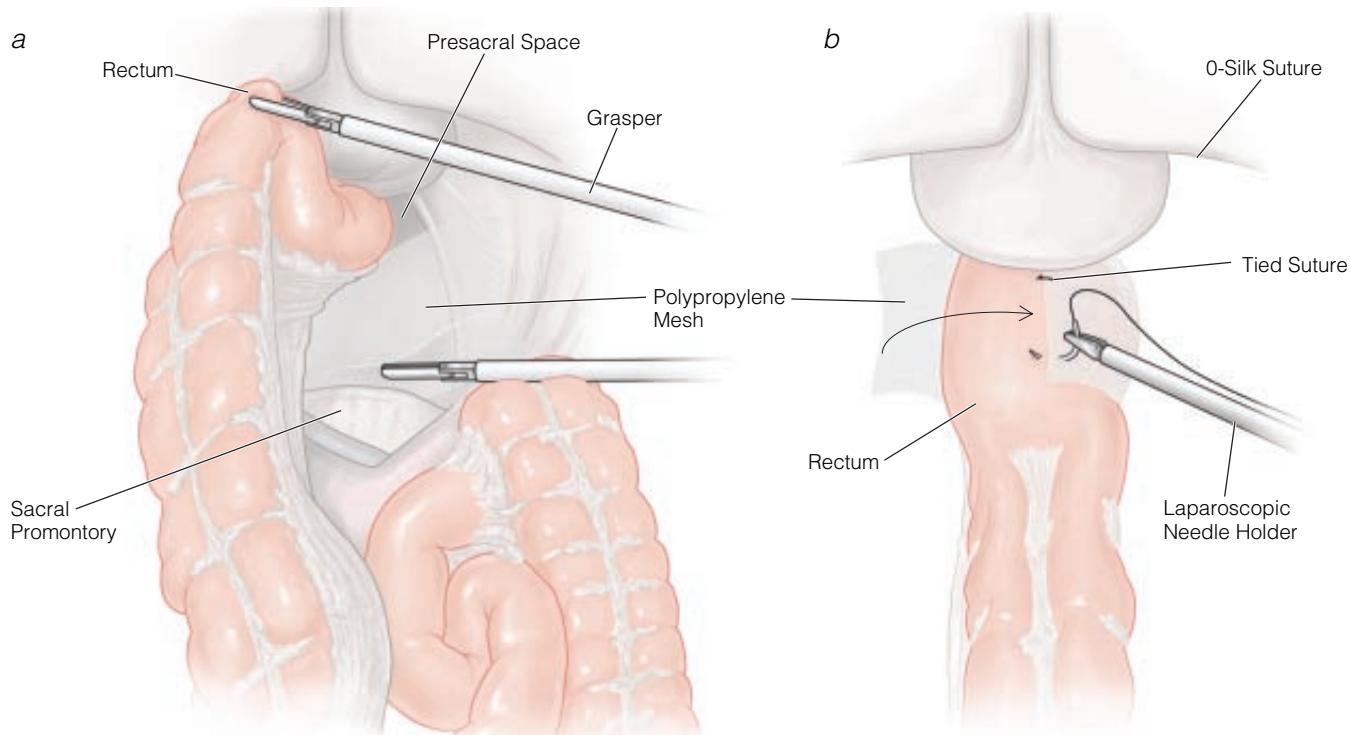

Figure 8 Laparoscopic mesh rectopexy. (a) A piece of mesh is inserted into the abdomen through a port, then stapled to the sacrum. (b) The lateral edges of the mesh are wrapped around three quarters of the rectal circumference and sutured to the rectal wall.

Alternatively, a piece of mesh is rolled up and inserted through a port. The mesh is tacked to the sacrum with a laparoscopic stapler, and the lateral edges of wrapped mesh are secured to the rectal wall with sutures [see Figure 8]. This type of posterior mesh sling procedure is also known as the modified Ripstein procedure.

Postoperative care. The patient is started on a clear liquid diet and advanced to a regular diet on the morning of postoperative day 1. The bladder catheter is also removed at this time.

Troubleshooting

Laparoscopic repair of rectal prolapse follows the same basic principles as open repair. There are multiple variant forms of laparoscopic rectopexy, differing not only with respect to technical details (e.g., resection versus no resection and suture versus mesh) but also with respect to whether the procedure contains an open component or is fully laparoscopic. The essential steps, however, are the same in all of the variants and include adequate mobilization of the rectum, careful placement of sutures, and appropriate resection with healthy anastomosis of the segments. For example, in the approach to laparoscopic resection rectopexy we describe (see above), most of the mobilization is performed laparoscopically, with resection, anastomosis, and suture placement performed in an open fashion, whereas in laparoscopic rectopexy performed without resection, sutures are placed and tied (or mesh secured) intracorporeally. The modified Ripstein procedure (see above) can be performed in a totally laparoscopic fashion if desired.

Complications

Intraoperative complications of laparoscopic rectopexy include inadvertent enterotomy or colotomy, ureteral injury, and organ injury from trocar placement. Most of these injuries are associated with the presence of adhesions and can usually be prevented by careful intra-abdominal dissection in appropriate planes. The

incidence of ureteral injury can be minimized by early identification of these structures, which may be facilitated by the use of ureteral catheters.

Vascular injury can occur at several different points of the operation. Injury to the epigastric vessels during port placement is usually avoided by transilluminating the abdominal wall with the camera to identify the vessels. The iliac and gonadal vessels are retroperitoneal structures, which, like the ureter, can be avoided with careful dissection and identification. The mesenteric vessels must be properly identified and controlled with graspers before the mesocolon is transected. The use of endoscopic clips as the sole means of vascular control before transection is discouraged; the calcified vessels commonly encountered in this mainly elderly population lead to clip slippage and incomplete hemostasis.

The incidence of anastomotic leakage can be minimized by ensuring a tension-free, nonrotated, airtight connection with a good blood supply and by making sure not to incorporate diverticula into the suture line.

Surgical site infections are a common complication of all colorectal resections. Their incidence can be minimized by performing appropriate bowel preparation, providing I.V. antibiotic prophylaxis before operation, and, possibly, employing a plastic wound protector at the site of colon extraction. Copious wound irrigation before closure at the end of the procedure is also helpful.

MESH AND SPONGE REPAIRS

Ripstein Procedure

Preoperative care and patient positioning are the same for the Ripstein procedure as for open resection rectopexy.

Operative technique Step 1: initial incision and exploration. Step 1 in the Ripstein procedure is identical to step 1 in resection rectopexy.

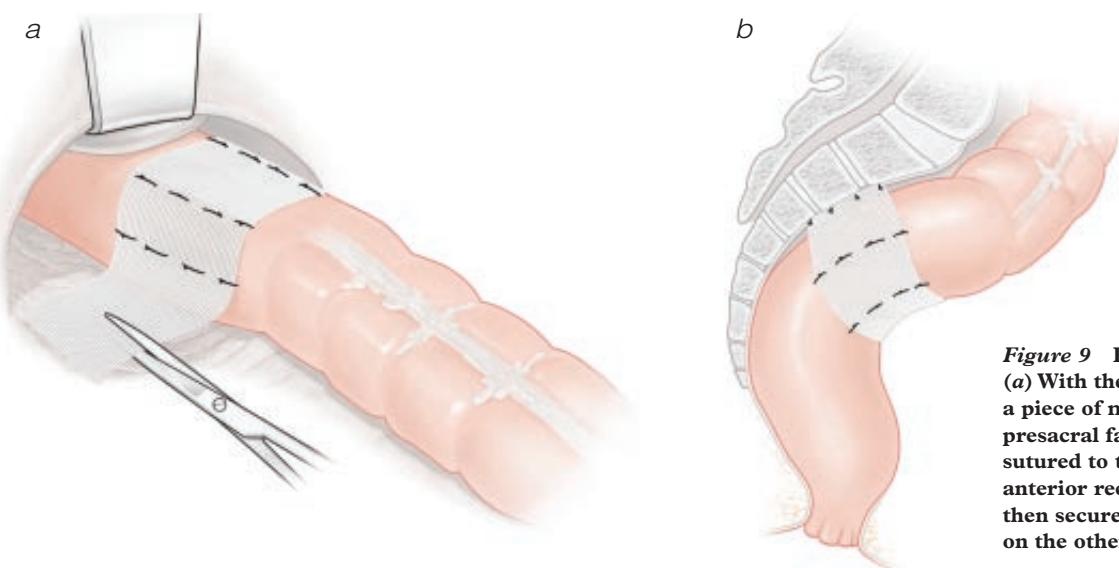

Figure 9 Ripstein procedure.
(a) With the rectum under tension, a piece of mesh is sutured to the presacral fascia on one side, then sutured to the muscularis of the anterior rectum. **(b)** The rectum is then secured to the presacral fascia on the other side to form a sling.

Step 2: mobilization of rectum. The lateral peritoneal folds of the rectum in the pelvis are incised from the rectosigmoid junction to the anterior midline on each side. With the St. Mark's retractor used to supply traction, the rectum is dissected away from the sacrum with the electrocautery down to the level of the coccyx. Anterior dissection separates the rectum from the vagina or the seminal vesicles. The upper one third to two thirds of the lateral stalks are divided to facilitate mesh placement.

Step 3: placement of mesh. A 5 cm rectangle of mesh is placed around the anterior rectum at the level of the peritoneal reflection and firmly sutured to the presacral fascia on one side, 5 cm

below the promontory [see Figure 9a]. The rectum is pulled taut with upward traction, partial-thickness nonabsorbable sutures are placed in rows along the anterior rectum to hold the mesh in place, and the mesh is sutured to the presacral fascia on the other side [see Figure 9b]. The sling is left loose enough to allow two fingers to pass between the bowel and the sac.

Because of the high risk of constipation and even obstipation after anterior mesh encirclement, a modified version of the Ripstein procedure was developed that involved posterior fixation of mesh to the sacrum, leaving the anterior rectal wall free of any potential constriction. In this modified approach, the mesh is tacked to the sacrum first. The lateral edges of the mesh are then wrapped around three quarters of the circumference of the rectum and sutured anterolaterally to the rectal wall. Intraoperative rigid proctoscopy may be helpful for ensuring that the positioning of the mesh does not result in obstruction.

Step 4: closure of peritoneum. The peritoneal reflection is closed so that the mesh is excluded from the peritoneal cavity and the small bowel is prevented from migrating into the pelvis on top of the mesh. The abdomen is irrigated and closed in the usual fashion.

Postoperative care. The patient is started on a clear liquid diet and advanced to a solid diet with resumption of bowel function. The bladder catheter is removed 2 days after operation.

Ivalon Sponge Repair (Wells Procedure)

Preoperative care and positioning are the same for the Wells procedure as for open resection rectopexy.

Operative technique Steps 1 and 2. Steps 1 and 2 are the same as in the Ripstein procedure.

Step 3: placement of sponge. A rectangular piece of sterilized and moistened Ivalon sponge is secured in place with mattress sutures passed through the sponge, through the presacral fascia, and back through the sponge. Careful hemostasis is ensured to prevent purulent collections in the area of the sponge. The rectum is retracted cephalad, and the lateral edges of the sponge are folded around it for approximately three fourths of its circumference. The edges are secured to the anterior portion of the rectum with seromuscular sutures [see Figure 10].

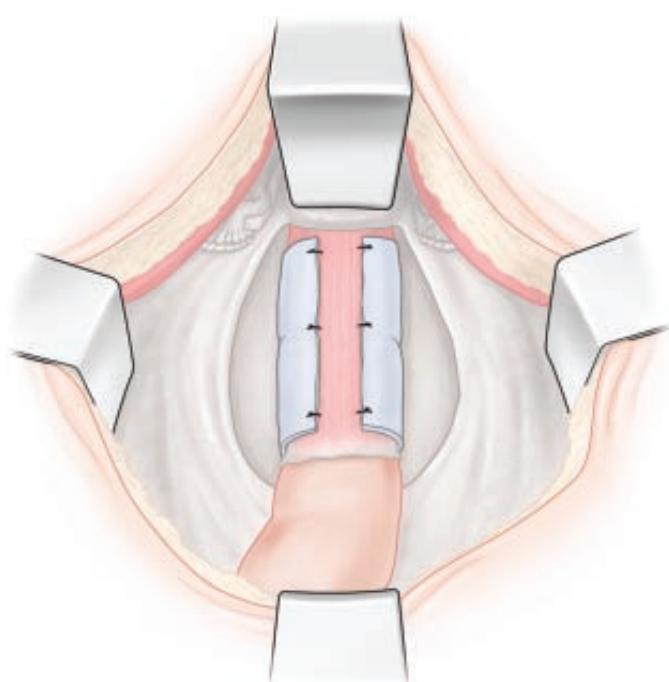

Figure 10 Ivalon sponge repair (Wells procedure). The sponge is anchored to the sacrum. With the rectum under tension, the edges of the sponge are brought around three quarters of the rectal circumference and sutured to the muscularis of the anterior rectum.

Step 4: closure of peritoneum. The pelvic peritoneum is closed to exclude the small bowel from the pelvis and thus prevent it from coming in contact with the sponge.

Postoperative care. Postoperative care is the same for the Wells procedure as for the Ripstein procedure.

Complications

Fecal impaction may result from making the sling too tight or from severe constipation caused by leaving a redundant rectosigmoid colon above the level of the repair.

Presacral bleeding may result from placement of sutures in the presacral fascia and consequent injury to the veins. If bleeding occurs, the sutures should be immediately secured and manual pressure applied. If these measures fail, thumbtacks may be required.

Strictures may result at the site of the sling and may be diagnosed by means of barium enema or sigmoidoscopy. If the mesh is wrapped anteriorly, revision may involve laterally transecting the mesh where it is not fused to the rectum, removing the mesh, or resecting the portion of the rectum where stricture occurs. To minimize the risk of this complication, either the mesh should be placed posteriorly (see above) without a circumferential wrap or, if an anteriorly based sling is employed, care should be taken not to encircle the rectum too tightly.

Sepsis may result when placement of full-thickness sutures or erosion into the bowel wall leads to mesh or sponge infection. Pelvic abscesses and fistulas are treated by removing the mesh or sponge and, in some circumstances, by performing a diverting colostomy. Preventive measures include giving perioperative antibiotics, placing seromuscular sutures, and ensuring that the synthetic material is not too tightly wrapped.

Adhesions to the mesh may be associated with small bowel obstruction. This complication can be prevented by reperitonealizing the pelvis to prevent migration of the small bowel onto the foreign substances. Placement of Seprafilm beneath the fascial closure helps reduce adhesions.

OUTCOME EVALUATION

Overall, abdominal operations yield better results than perineal operations with respect to recurrence rates (which range from 0% to 8%) and functional outcome.¹⁹ The abdominal approach allows the rectum to be maximally mobilized and fixed to the sacrum. In addition, transabdominal procedures can be tailored to the presence or absence of functional disorders (e.g., constipation or incontinence) through the addition or omission of sigmoid resection. Morbidity, however, is greater with abdominal procedures than with perineal procedures. In planning surgical treatment of rectal prolapse, therefore, it is essential to consider risk factors for complications in addition to likelihood of cure.

For many surgeons, posterior rectopexy is the procedure of choice because of its low morbidity and recurrence rates.^{13,20,21} Some 50% to 88% of patients show improved continence,^{22–24} but as many as 53% experience either new-onset constipation or exacerbation of preexisting constipation.²² The constipation is thought to be attributable to rectal denervation resulting from division of the lateral ligaments; however, preservation of these ligaments is associated with a significantly higher (> 50%) recurrence rate.^{25,26} The type of material used to perform the rectopexy has no effect on recurrence: recurrence rates are the same for suture repairs as for mesh repairs.²⁷ Suture repairs, however, carry a lower risk of associated pelvic sepsis and luminal constriction, especially when compared with repairs involving mesh wrapped around the anterior rectum. Our practice, therefore, is to resect the upper one third to one

half of each lateral stalk in an attempt to balance functional outcome against cure of the prolapse.

The constipation produced by rectopexy and lateral ligament division may be overcome by adding sigmoid resection to the procedure. Several prospective randomized trials revealed a reduction in postoperative constipation when resection was added to rectopexy in patients with preoperative constipation.^{28,29} Recurrence rates after resection rectopexy were comparable to those after rectopexy alone, and although the resection imposed additional risks (i.e., anastomotic leakage and wound infection), morbidity rates were comparable as well. Continence rates are improved with resection rectopexy because the rectal reservoir is maintained (by limiting resection to the portion of the large bowel above the peritoneal reflection). Because of the risk of pelvic sepsis, resection is only combined with suture rectopexy, not with Ivalon sponge or mesh repairs.

Isolated resection of the sigmoid colon is an effective method of preventing recurrence permanently; limiting the length of the bowel definitively inhibits the mobility of the rectum.³⁰ Recurrence rates are the same for this procedure as for other abdominal procedures, and morbidity is determined by the level of the anastomosis. Patients with constipation secondary to colonic inertia associated with rectal procidentia may require an extended resection that includes subtotal colectomy with ileorectal anastomosis.³¹

Disadvantages of the open abdominal procedures for rectal prolapse include a significant incidence of peritoneal adhesions, the need for general anesthesia, a longer hospital stay, greater morbidity, and possible compromise of sexual function. Certain disadvantages (e.g., more extensive intra-abdominal invasion, scarring, and longer recovery time) are reduced when the laparoscopic approach is employed. Controlled studies of laparoscopic rectopexy revealed recurrence rates and morbidity comparable to those of open approaches.^{32,33} A subsequent study comparing laparoscopic resection rectopexy with the corresponding open approach found that with the former, though longer operating times were noted, less time was required for return of bowel function, toleration of a regular diet, and hospital stay.³⁴ Another study found that continence improved to a significant extent after laparoscopic rectopexy without significant changes in postoperative constipation.³⁵

Special Situations

INCARCERATION, STRANGULATION, AND GANGRENE

On rare occasions, a rectal prolapse becomes incarcerated. If the bowel is viable, sedation and gentle manual reduction in the emergency department usually suffice. Sprinkling table sugar on the prolapse helps reduce edema.³⁶ If such measures are unsuccessful, paralyzing the perianal muscles with an anal block or general anesthesia in the OR may help resolve the problem. If the incarceration is irreducible or the viability of the bowel is questionable, emergency perineal rectosigmoidectomy should be performed, with or without fecal diversion.³⁷

RUPTURED PROLAPSE

Rupture of the prolapse usually involves opening of the hernia sac and exposure of the small bowel to the perineum. Emergency transabdominal repair is indicated, with closure of the peritoneal hernia sac and suture rectopexy constituting the safest and most efficient repair.

PROLAPSE IN MALE PATIENTS

Prolapse in male patients, though relatively rare, may occur at any age. Rectal mobilization should be modified so as to preserve the presacral nerves, keep from damaging Denonvillier's fascia, and avoid division of one of the lateral ligaments.³⁸ Lateral pararectal tissues carry parasympathetic fibers and are important in normal ejaculatory function. Consideration should be given to taking a perineal approach or performing resection alone.

RECURRENT PROLAPSE

Rectal prolapse is the anatomic consequence of an underlying functional disorder of the colon and the rectum. Although surgical intervention corrects the anatomic abnormalities present, the functional disorder often persists, resulting in a tendency for the prolapse to recur.³⁹ Recurrence rates differ among the various types of procedures but are generally higher with the perineal operations than with the abdominal operations. In most cases, the cause of the recurrence cannot be identified, though early recurrences (those occurring less than 2 years after operation) are thought to be related to technical factors associated with the original procedure.³⁹

The initial operation for rectal prolapse is chosen on the basis of several different factors, but the choice of operation for recurrent prolapse is based primarily on the procedure chosen for initial man-

agement. Some authorities advocate an abdominal procedure for the second operation, regardless of what the initial operation was, because of the superior rates of success with such procedures³⁹; however, care must be taken in performing repeat resectional procedures (e.g., anterior resection after perineal rectosigmoidectomy, or vice versa) because of the risk of bowel ischemia between the two anastomoses. In our view, unless the previous anastomosis can be resected in the second procedure, repeat resectional procedures should be avoided.^{39,40} Perineal rectosigmoidectomies are an exception to this broad rule: they can be safely repeated because the recurrent prolapse contains the previous anastomosis.⁴¹ Recurrence rates and morbidity after operative treatment of recurrent rectal prolapse are essentially the same as those after operative treatment of primary rectal prolapse.⁴²

RECTAL PROLAPSE WITH SOLITARY RECTAL ULCER SYNDROME

As many as 80% of patients with solitary rectal ulcer syndrome (SRUS) have an associated rectal prolapse,^{43,44} a finding that indicates a close relationship between these two entities. In cases of symptomatic SRUS associated with asymptomatic prolapse, a trial of medical therapy is warranted⁴⁵; if such therapy fails, surgical intervention with procedures used for rectal prolapse should be considered.⁴⁶ In cases of symptomatic prolapse associated with asymptomatic SRUS, healing of the ulcer can be demonstrated in one third of patients undergoing operation for the prolapse.⁴⁶

37 ANAL PROCEDURES FOR BENIGN DISEASE

Ira J. Kodner, M.D., F.A.C.S., F.A.S.C.R.S.

Operative Management of Hemorrhoids

The frequency of hemorrhoid surgery continues to diminish. More patients seem to be achieving adequate symptomatic relief by means of bowel control medications and improved diet (e.g., increased intake of fiber, fruit, vegetables, and grain) [see 5:17 *Benign Rectal, Anal, and Perineal Problems*]. It is probable that both for these reasons and because more and better patient information is available, fewer patients today have hemorrhoids that progress to a stage advanced enough to necessitate operative treatment for relief of symptoms.

OPERATIVE PLANNING

It is important to distinguish between internal and external hemorrhoids [see Figure 1]. Internal hemorrhoids are treated to relieve specific symptoms, including prolapse and bleeding, not simply because hemorrhoidal tissue was seen on routine examinations. Prolapsing tissue occasionally results in maceration of the perianal skin that may not be clearly evident at the time of examination, especially if the patient is in the prone position. External hemorrhoids are treated because they thrombose and cause pain. There are no other symptoms of the anorectum that should be attributed to the presence of hemorrhoids [see Table 1]; in particular, difficulties with bowel movements (e.g., straining, the need for digital evacuation of the rectum, and cramping abdominal pain) must not be ascribed to hemorrhoids.

Accordingly, the ability to recognize and diagnose the spectrum of pelvic floor abnormalities (of which rectal prolapse is the most florid manifestation), especially obstructed defecation, is critical to the decision whether to correct hemorrhoids surgically. Attempting to alleviate nonhemorrhoidal symptoms by means of hemorrhoid

surgery is likely to yield unsatisfactory results for both patient and surgeon. It is not uncommon for anal fissure/ulcer disease to coexist with hemorrhoids, in which case the chances of a good operative result can be increased by performing a posterior lateral internal sphincterotomy at the time of hemorrhoid surgery.

Before embarking on the surgical treatment of hemorrhoids, one must always rule out neoplastic disease, compromise of the immune system, and defective clotting mechanisms. Patients with a personal or family history of colorectal cancer and those 50 years of age or older should undergo colonoscopy to eliminate the possibility of polyps or cancer before surgical treatment of hemorrhoids is initiated. The patient's general health status and ability to tolerate pain and an operative procedure should also be taken into account. The postoperative response to anorectal surgery varies enormously among patients. For example, young men tend to strain to have bowel movements after anorectal procedures, and this tendency can lead to bleeding and disruption of postoperative healing. These patients often benefit from the administration of parenteral pain medication for the first 12 to 24 hours after operation, which usually requires hospitalization. Elderly patients, on the other hand, prefer not to be in the hospital. For these patients, single elastic ligation of individual clusters of internal hemorrhoids is performed in the outpatient office.

The next step is to determine the appropriate procedure for the patient. The options include (1) elastic ligation of internal hemorrhoids, (2) excision of thrombosed external hemorrhoids, (3) complete excisional hemorrhoidectomy, and (4) elastic ligation of internal hemorrhoids combined with excision of external hemorrhoids. One should always consider whether complete sigmoidoscopy, rigid or flexible, will be necessary at the time of the procedure and

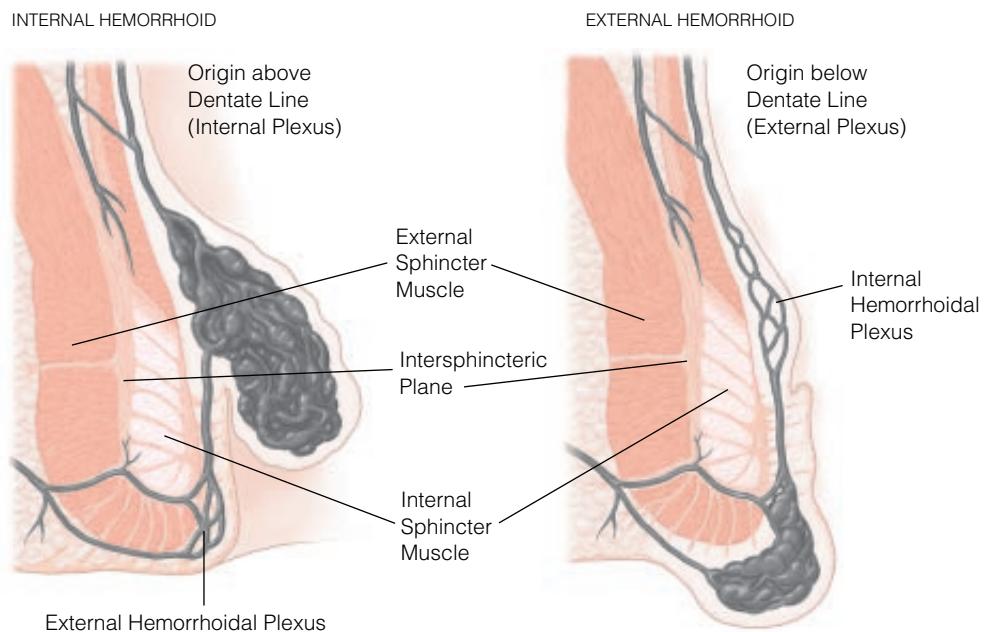

Figure 1 Operative management of hemorrhoids. A key issue is the differentiation of internal hemorrhoids from external hemorrhoids. Internal hemorrhoids (left) originate from the internal hemorrhoidal plexus, above the dentate line. External hemorrhoids (right) originate from the external hemorrhoidal plexus, below the dentate line.

Table 1 Anal Symptoms Mistakenly Attributed to Hemorrhoids

Symptoms	Cause
Pain and bleeding after bowel movement	Ulcer/fissure disease
Forceful straining to have bowel movement	Pelvic floor abnormality (paradoxical contraction of anal sphincter)
Blood mixed with stool	Neoplasm
Drainage of pus during or after bowel movement	Abscess/fistula, inflammatory bowel disease
Constant moisture	Condyloma acuminatum
Mucous drainage and incontinence	Rectal prolapse
Anal pain with no physical findings	<i>Caution:</i> possible psychiatric disorder

whether anal sphincterotomy will be indicated, especially in young men with a history of straining. This second consideration is important because many patients are treated for hemorrhoids when in fact their primary disease is anal ulcer/fissure disease, the symptoms of which are pain and some bleeding at defecation. These are not symptoms that can be attributed to hemorrhoids. If a patient undergoes hemorrhoid surgery when the primary disease is anal fissure, proper healing will be impeded.

Finally, one should explain the procedure and its attendant risks to the patient in the outpatient office because in most cases, given the restrictions imposed by health care insurers and managed care administrators, one will not see the patient again until arriving at the day of operation. Specific complications to be discussed preoperatively include urinary retention, bleeding, and infection. In the event that several symptomatic hemorrhoids are present, surgeon and patient should jointly decide between multiple small procedures done in the office and a single larger procedure done in the OR. Individual economic concerns, as well as employment and lifestyle, should be considered.

Special Situations

Acute thrombosed external hemorrhoids This condition is signaled by acute pain and a swelling blood clot within the skin-covered external hemorrhoid. Often, the clot is eroding through the skin, causing bleeding that may be frightening to the patient but is typically insignificant. If I encounter this problem days after its onset, I generally treat it with bowel control and topical medications as the process resolves. If the hemorrhoid is acutely painful or the clot is eroding, the best therapy is surgical excision of the external hemorrhoid, with the anoderm left intact; this is best done with the patient under adequate local anesthesia. Mere evacuation of the clot is rarely appropriate.

Postpartum hemorrhoids The postpartum rosette of acute thrombosed external (and, often, prolapsed internal) hemorrhoidal tissue is appropriately treated with hemorrhoidectomy (see below), carried out as soon after delivery as is convenient. The risk of infection is minimal, and I know of no good reason to send a new mother home with hemorrhoids in addition to a new baby and a healing episiotomy.

OPERATIVE TECHNIQUE

Step 1: Positioning

Operative treatment of hemorrhoids, like the vast majority of anorectal procedures, should be done with the patient in the prone-flexed position [see Figure 2]. The transporting stretcher should be kept in the room. The patient will be given I.V. narcotics to allow painless injection of local anesthetics, and if any respiratory compromise results because of the prone-flexed position, the patient can quickly be returned to the supine position on the stretcher until respiration resumes without difficulty.

Step 2: Intravenous Sedation and Local Anesthesia

Before administering a local anesthetic, I usually give the following drugs for sedation: midazolam, 2 to 5 mg, given in the holding area for sedation and amnesia; alfentanil, 0.5 to 1 mg, or fentanyl, 50 to 100 µg, for analgesia to help alleviate the discomfort of the local anesthetic injection; and propofol, 20 to 50 mg, or methohexitol, 20 to 50 mg, to achieve patient cooperation with the injection. Sedation is followed by the injection into perianal tissue of 40 ml of bupivacaine (0.5%) along with a buffer that is added immediately before injection (0.5 ml of 8.4% sodium bicarbonate [1 mEq/ml] added to 50 ml of local anesthetic). If resection is anticipated, epinephrine (1:200,000) is usually included with the local anesthetic. To achieve adequate local anesthesia, 5 ml of bupivacaine is injected into the subcutaneous tissue in each quadrant of the tissue immediately surrounding the anus [see Figure 3a]. Next, 10 ml of local anesthetic is injected deep into the sphincter mechanism on each side of the anal canal [see Figure 3b].

Step 3: Anoscopy or Sigmoidoscopy

Anoscopy, sigmoidoscopy, or both should be performed at this point if neither procedure was done before the operation.

Step 4: Sphincterotomy

As noted, sphincterotomy should always be considered, especially if a hypertrophic band of the lower third of the internal sphincter muscle persists after the local anesthetic has been injected and an anoscope has been inserted. It is always best to obtain permission to do this beforehand on the operative consent form.

Figure 2 Operative management of hemorrhoids. The patient is positioned on the operating table in the prone-flexed position, with a soft roll under the hips.

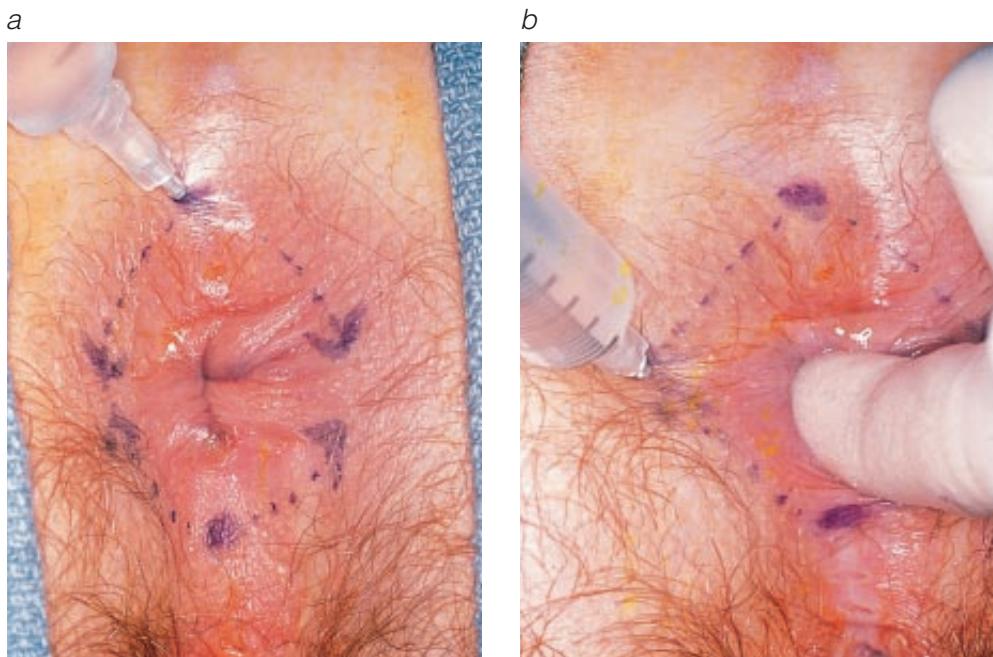

Figure 3 Operative management of hemorrhoids. (a) Five milliliters of bupivacaine is injected into subcutaneous tissue. (b) Ten milliliters of local anesthetic is injected deep into the sphincter muscle on each side of the anal canal.

Step 5: Treatment of Hemorrhoids

Elastic ligation of internal hemorrhoids This is a very safe operation because by the nature of the banding procedure [see Figure 4], bridges of normal mucosa are maintained between treated clusters of hemorrhoids. Any clusters of tissue with squamous metaplasia and obviously friable internal hemorrhoids can be treated in this manner. I find that these tissue clusters are not always confined to the three classic positions identified for hemorrhoids and that in many cases it is necessary to band three or four clusters. If the bands do not stay on, then the tissue probably need not be treated and no further action need be taken.

I use two rubber bands on each cluster. If one of them breaks, bleeding is unlikely to occur, because the tissue rapidly becomes edematous and necrotic. It is important that the placement of the rubber band be proximal to the mucocutaneous junction; if it is not, the procedure will be too painful, given the extensive innervation of the skin. On the other hand, the band should not be placed so proximally as to incorporate the full thickness of the rectal wall; to do so can be risky for patients in whom difficulties with bowel movements indicate the presence of intussusception or some other pelvic floor abnormality. Occasionally, the friable tissue gives rise to a suspicion of cancer. If this is the case, rub-

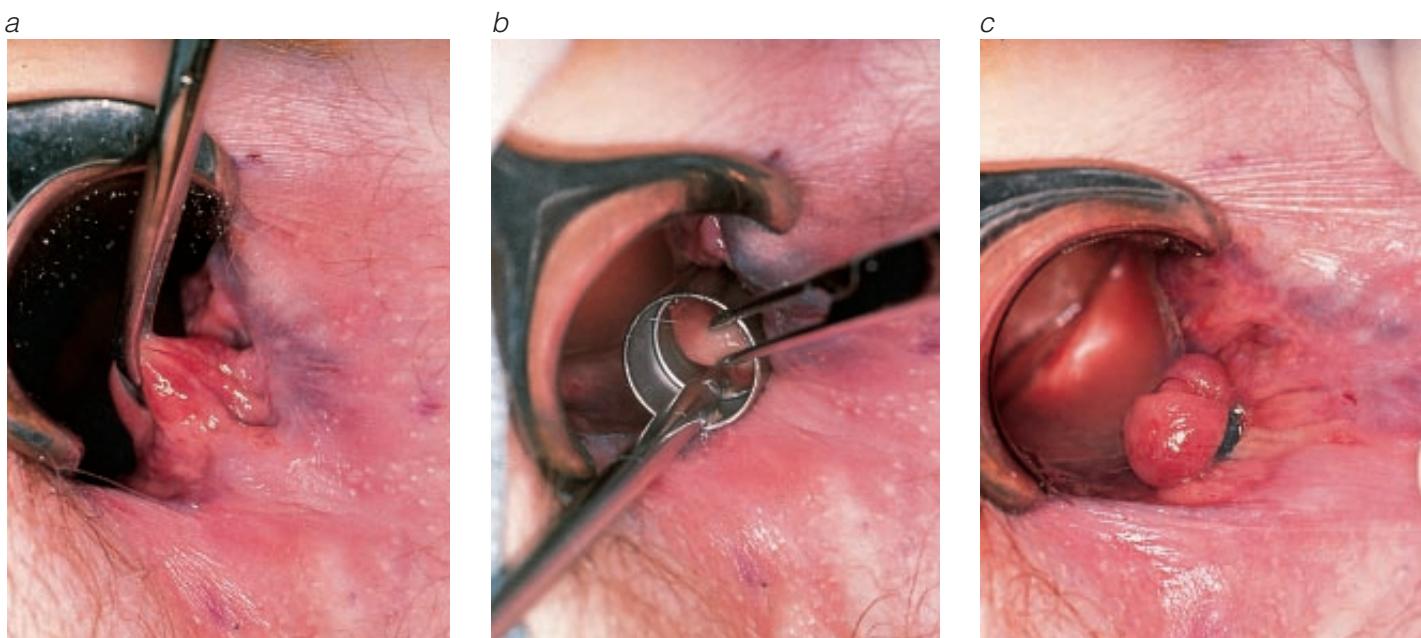

Figure 4 Operative management of hemorrhoids. Shown is the elastic ligation technique for internal hemorrhoids. (a) The hemorrhoidal tissue is identified. (b) The hemorrhoid is grasped and pulled through the drum. (c) The elastic band is applied to the base of the hemorrhoid.

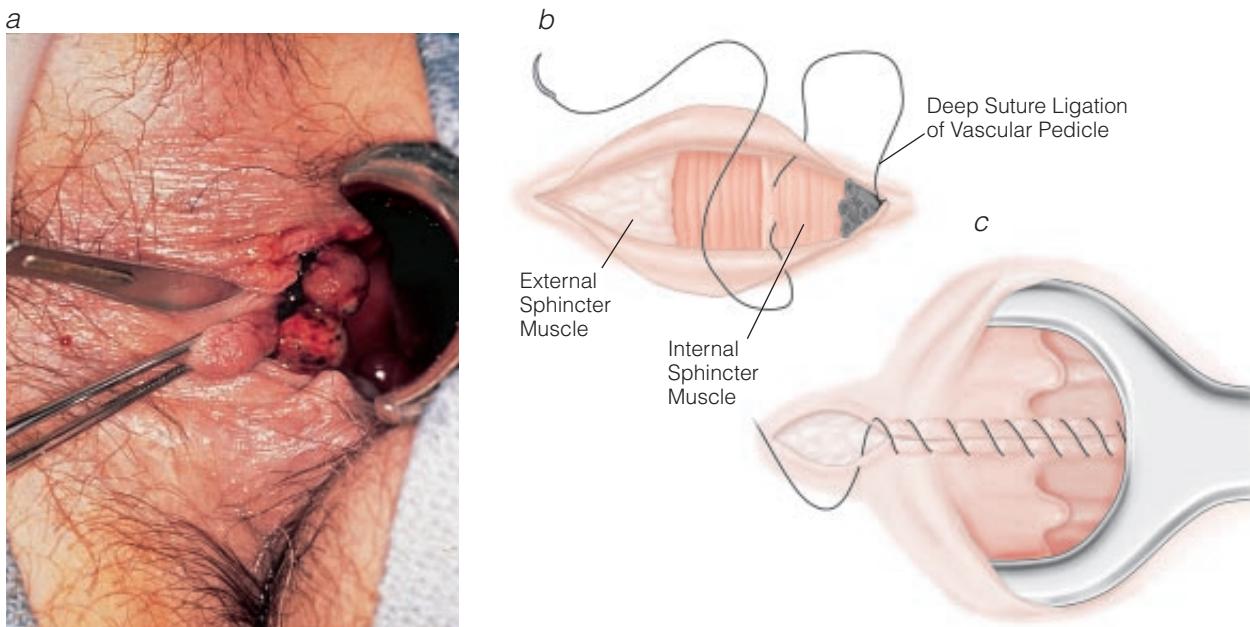

Figure 5 Operative management of hemorrhoids. Shown is an excisional hemorrhoidectomy. (a) An elliptical incision is made in the perianal skin. (b) A continuous suture is used in a three-point placement in such a way as to incorporate skin edges and muscle. (c) The elliptical defect is closed and the dead space obliterated.

ber bands may be placed at the base, and the tip may be excised for biopsy.

Excision of residual external hemorrhoids Residual external hemorrhoids are rarely treated as a primary problem: true symptoms are few, and the main indication for treatment is maintenance of hygiene. In addition, I find that much of the external tissue is pulled in when the internal hemorrhoids are ligated. Accordingly, I do the internal ligation first and then excise any residual symptomatic external tissue. An elliptical incision is made in the perianal skin, with care taken to protect the underlying sphincter muscle and avoid the previously placed elastic band [see Figure 5a]. Although the perianal skin is very forgiving, it is essential to protect the anoderm; this is achieved through careful placement of the rubber band. The elliptical defect is then closed with a continuous absorbable suture in a three-point placement to obliterate the underlying dead space [see Figures 5b and 5c]. The suture is tied loosely to allow for swelling. There is no need for separate ligation or coagulation of the small bleeding vessels; this problem is obviated by the continuous suture. It is important not to use slowly absorbable suture material, because it may give rise to infection in this highly susceptible tissue. I prefer to use 3-0 chromic catgut on an exaggeratedly curved needle.

Complete excisional hemorrhoidectomy This procedure is indicated in patients who have large combined internal and external hemorrhoids, patients who are receiving anticoagulants, and patients who have massive edema and thrombosis, as seen in the postpartum rosette of tissue [see Figure 6]. I find that even massive edema generally resolves after the local anesthetic is injected and the muscle is allowed to relax. Resolution of edema then permits identification of the specific clusters of hemorrhoids, which can be isolated with a forceps and excised via an elliptical incision. Care must be taken to preserve the underlying muscle, especially in the anterior region in women. I use 3-0 chromic catgut with a deep stitch at the apex and a continuous three-point suture that is extended on the perianal skin [see Figure

5b]. It is important to preserve a bridge of anoderm between the areas of excision. I know of no indications for a radical circumferential procedure (the so-called Whitehead procedure); in fact, I see numerous patients who are seeking a remedy for the stenosis and ectropion that frequently occur after this radical operation [see Figure 7].

A newer technique, in which a circumferential band of anorectal mucosa is excised with a special circular stapler, is currently under investigation. This technique is intended for patients who have profound prolapsing internal hemorrhoids without much of

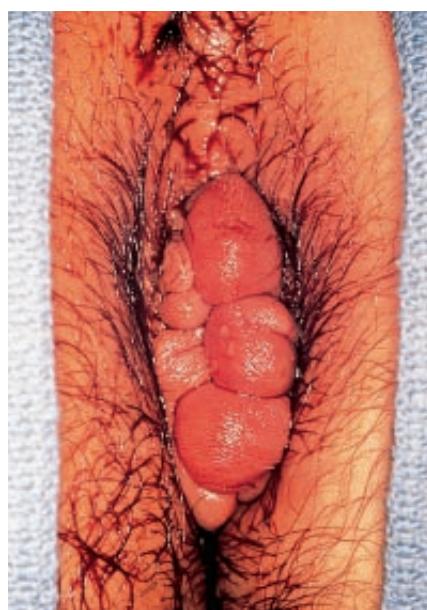

Figure 6 Operative management of hemorrhoids. Massive edema and thrombosis, as seen in the postpartum rosette of tissue, can be reduced after a local anesthetic is injected and the muscle is allowed to relax.

Figure 7 Operative management of hemorrhoids. Stenosis and ectropion often result from radical circumferential (Whitehead) procedures.

an external component. Its proponents claim that it results in minimum postoperative discomfort; however, special training with the instrument is required. European centers have reported excellent success rates, and trials have now been completed in the United States. There appears to be some advantage to this procedure, in that patients tend to experience less immediate postoperative pain; however, the long-term results seem no better than those achieved with more conventional approaches, and the rate of recurrent tissue prolapse may in fact be higher than that noted after standard excisional hemorrhoidectomy.¹ In addition, the circumferential stapling procedure has not yet been compared with rubber band ligation, which is now used almost routinely. Perhaps the greatest disadvantage of the new procedure is the finding that there is a significant incidence of serious postoperative complications. At present, given the results available to date, it is difficult to advocate routine use of this modality.

There also exist various forms of nonsurgical treatment for grade 1 and early grade 2 internal hemorrhoids. These entail some form of local tissue destruction (e.g., with infrared coagulation or injection of a sclerosing agent). I do not use these modalities myself, because I find that the symptoms they are used to treat can be managed just as easily, and more safely, by means of dietary changes, bulk-forming agents, and stool softeners.

Step 6: Postoperative Care

Immediately after the procedure—in fact, after any anorectal procedure—antibiotic ointment and a gauze pad are applied. Pressure dressings are unnecessary. Only a very small amount of adhesive tape should be used, so as to prevent traction avulsion of the perianal skin, an event for which we surgeons too often avoid responsibility by ascribing it to a “tape allergy” on the part of the patient.

TROUBLESHOOTING

The most fundamental way of preventing problems is to make an accurate diagnosis. Surgical treatment of hemorrhoids in a patient whose main disease process is Crohn’s disease, a pelvic floor abnormality, or ulcer/fissure disease inevitably yields inferior results. It is especially important to recognize the anal pain and spasm of ulcer/fissure disease because in patients with this condi-

tion, excision of hemorrhoidal tissue without sphincterotomy leads to increased postoperative pain and poor wound healing.

I prefer to operate with the patient in the prone-flexed position, using local anesthesia supplemented by I.V. medication. I have found over the years that with this approach, patients retain no unpleasant memories of the OR experience, and good pain control is achieved in the immediate postoperative period.

In the postoperative period, efforts must be made to minimize straining on the part of the patient. To accomplish this, pain must be kept at a low level. I prefer to give only parenteral pain medication, in relatively high doses, on the first night. The patient and the nursing staff must be cautioned that the first sensation of pain, especially after elastic ligation of hemorrhoids, is the urge to defecate. This urge is an indication that pain medication should be given. The patient must not sit on the toilet and strain; to do so is likely to result in extrusion of the recently ligated tissue.

At least 20% of patients experience some degree of urinary retention. If this occurs, an indwelling catheter should be placed. In-and-out straight catheterization is contraindicated. No bladder stimulants should be given: such agents encourage straining and increase the risk of complications.

Bulk-forming agents and stool softeners are started in the immediate postoperative period. I encourage patients to take warm soaks, either in a bathtub or in a shower, rather than try to squeeze into the disposable sitz-bath mechanisms provided by the hospitals, which are often too small. I also encourage patients to sit on soft cushions rather than the rubber rings marketed for postoperative care; the rings seem to cause more dependent edema and pain.

COMPLICATIONS

Bleeding

Either immediate or delayed bleeding may occur after hemorrhoid surgery. Bleeding within the first 12 to 24 hours after the operation represents a technical error. The only management is to return the patient to the OR, with good anesthesia and adequate visualization, so that the bleeding site can be suture ligated. Frequently, spinal or epidural anesthesia is necessary because the patient is too uncomfortable, and the tissue perhaps too edematous, to allow local anesthesia. Bleeding within 5 to 10 days after the operation usually results from sloughing of the eschar created by suturing or elastic ligation. This delayed bleeding is usually minimal, and the patient is encouraged to rest and to take stool softeners. If the bleeding is significant, examination with adequate anesthesia is indicated to allow cauterization or suture ligation of the bleeding site.

It is important to discourage patients from taking aspirin-containing compounds in the postoperative period, and it is especially important to follow patients taking systemic anticoagulants closely. I prefer to treat these patients with excisional hemorrhoidectomy so that sutures can be placed; in this way, I avoid the risk that the elastic-ligated tissue will slough after 5 to 10 days.

Infection

Infection is unusual after hemorrhoidectomy because perianal tissue is normally well vascularized and extremely resistant to infection despite constant bombardment by bacteria. When it does occur, it is most likely to be in an immunocompromised patient—that is, one who has a blood dyscrasia, diabetes, or AIDS or has recently undergone chemotherapy. In my view, it is imperative to obtain at least a complete blood count and a chemistry profile before embarking on anorectal procedures; if the results are abnormal, elective hemorrhoid surgery is contraindicated.

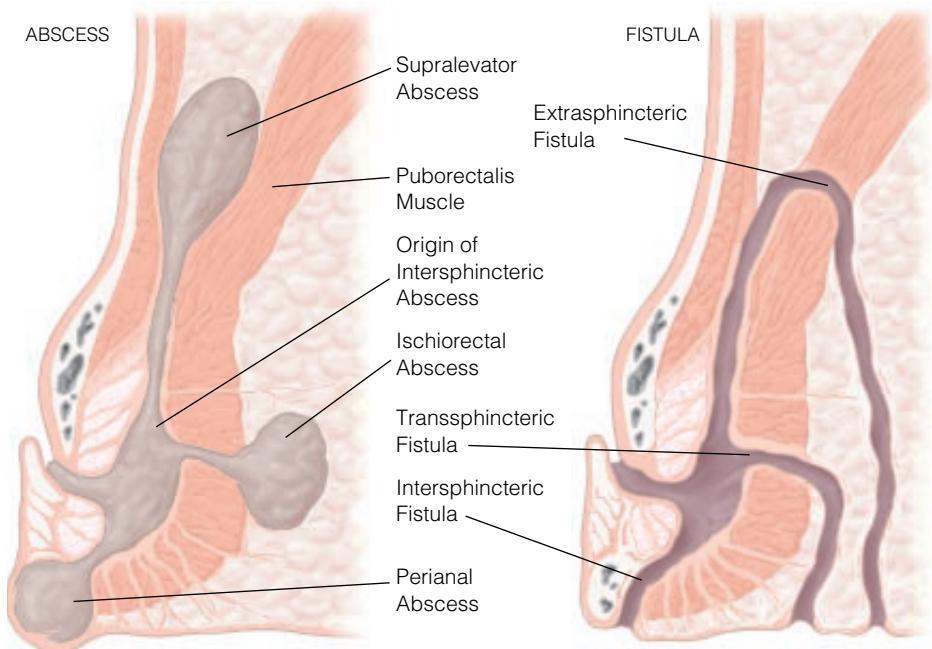

Figure 8 Abscess and fistula are, respectively, the acute aspect and the chronic aspect of a single disease process. Acute inflammation can lead to different types of abscesses (left), depending on the direction in which the inflammation extends. Chronic inflammation leads to communication of the abscess sites with the surface—that is, fistula tracts (right).

Any local focus of infection noted in the postoperative period must be drained. I have seen this complication only when slowly absorbable suture material was used, which is the reason why I have returned to using 3-0 chromic catgut. Postoperative perianal infection can be severe and life-threatening, and it is therefore critically important to be familiar with its symptoms and to treat it intensively. Frequently, such infection is initially manifested by pain that is greater than anticipated, urinary retention, and fever. These symptoms have occasionally been reported after elastic ligation of hemorrhoids. In this event, it is critical that the patient be seen on an emergency basis, the elastic bands removed, the patient hospitalized, and parenteral administration of antibiotics begun. In retrospect, I find that all such patients whom I have seen had preoperative symptoms of a pelvic floor abnormality with difficulty in defecation—not clear symptoms of hemorrhoids.

Urinary Retention

Urinary retention is apparently caused by reflex spasm of the pelvic musculature, which may not become evident until the local anesthesia wears off. Often, a patient still under the influence of local anesthesia seems to be doing exceedingly well for the first few hours after operation, only to go into urinary retention later that night. It may be helpful to reduce the fluid load in the perioperative period. When a patient has trouble urinating, an indwelling urinary catheter should be placed and left in place for at least 12 hours. This, in my view, is one of the major reasons for in-hospital observation after treatment of more than one cluster of hemorrhoids. Placement of the indwelling catheter is of particular importance for the patient's well-being, even if it is not looked on with favor by managed care administrators. Urinary retention is a frightening experience for the patient to undergo at home. What is more, if placement of an indwelling catheter is postponed for 12 to 24 hours, recovery may be delayed. Again, it is important to remember that urinary retention may be an early sign of pelvic infection.

Stricture

Stricture, with or without ectropion, results from circumferential excision of hemorrhoids. I mention this point only to discourage the performance of this procedure.

OUTCOME EVALUATION

Because hemorrhoids are treated only when symptoms—bleeding, prolapse, pain, and difficulty with hygiene—are present, success is determined simply by the extent to which the symptoms are alleviated. If other symptoms were present before operation and persist after the procedure, the primary diagnosis should be called into question. Many elderly patients with a single prolapsing hemorrhoid that causes bleeding or maceration of the perianal skin are well served by outpatient ligation; occasionally, there is a second cluster that requires treatment some months later.

The basic point is that any patient treated surgically for hemorrhoids should experience symptomatic relief. With newer surgical techniques and improved methods of postoperative management, there is no reason for the patient to experience the severe pain described by those who have undergone extensive excisional procedures.

Operative Management of Abscess and Fistula

The conditions that cause suppurative processes in the anopereineum are cryptoglandular abscess and fistula, Crohn's disease, and hidradenitis suppurativa [see 5.17 Benign Rectal, Anal, and Perineal Problems]. Accurate diagnosis is essential for proper surgical management. Although these conditions may appear similar at times, each one is managed somewhat differently.

OPERATIVE PLANNING

The most important initial step is to determine the activity and severity of the disease process and the immune status of the patient. For example, a large, fluctuant abscess surrounded by erythema, induration, and superficial necrosis of the skin in an insulin-dependent diabetic is a surgical emergency. On the other hand, a chronic abscess or fistula that drains periodically over a matter of months is not nearly as urgent a problem. Multiple fistula tracts to the perineum in a patient with Crohn's disease require that one perform an adequate study of the intestinal tract and the sphincter mechanism before attempting definitive surgical treatment. It is important to determine the etiology of the process whenever possible. Unfortunately, the determination cannot always be made without examination under anesthesia, during which treatment as well as

diagnosis could be accomplished, and this complicates the obtaining of informed consent and the choice of anesthesia.

It is also important to gain as accurate a picture as possible of the complexity of the disease process; this facilitates the planning of the procedure, the choice of anesthesia, and the selection of the information given to patient and family before treatment. For example, in the absence of other significant health problems, a small, well-localized, low intersphincteric abscess often can be easily drained with the patient under local anesthesia if an internal opening can be seen preoperatively on anoscopy, although on occasion even this procedure calls for spinal or epidural anesthesia. (It should be remembered that use of the prone-flexed position [see Figure 2], which is my preference, makes general anesthesia more difficult.) Multiple infected tracts associated with undrained infectious foci in a case of rectal Crohn's disease necessitate examination with the patient under spinal or epidural anesthesia. The treating surgeon should perform careful anoscopy and sigmoidoscopy and conservative temporary drainage procedures until consultation with a specialist can be arranged. Severe destruction and suspected deep tissue necrosis, especially in immunocompromised patients, may necessitate extensive resection of tissue and perhaps a completely diverting colostomy.

Bowel preparation should include mechanical cleansing and antibiotics but may not be possible when the situation is urgent (as is most often the case). Appropriate antibiotic coverage (i.e., agents effective against gram-negative organisms and anaerobes) is indicated for all but the simplest cases, with special consideration given to patients who require prophylaxis because of cardiac disease or the presence of prosthetic material.² Usually, a urinary catheter should be inserted before operation, especially if the infectious process is located in the anterior region in a man, where the urethra is at risk for injury.

OPERATIVE TECHNIQUE

Many technical elements are common to all operations for conditions that cause suppurative processes in the perineum. The patient should be in the prone-flexed position, with the buttocks taped apart. Conduction anesthesia (spinal, caudal, or epidural) is usually required. The perineum should be examined carefully with an eye to areas of abscess or external drainage sites. Endoscopic examination of the anus, the rectum, and the vagina should be undertaken to search for primary inflammatory bowel disease, internal openings of the fistula, or vaginal openings of the fistula.

Cryptoglandular Abscess and Fistula

The abscess must be located and characterized because drainage will depend on the location of the abscess, the course of the fistula tract, and any related infectious processes [see Figure 8].³ It is important not to create a fistula through the levator plate of the pelvic floor. This means that an abscess with a low origin must be drained low, with care taken to avoid iatrogenic perforation of the rectum, and an abscess with a high origin (e.g., a high intersphincteric abscess) must be drained high by incising the mucosa and the longitudinal (internal sphincter) muscle of the rectal wall (not a procedure for the occasional rectal surgeon). The internal opening—that is, the crypt where the abscess originated—must be sought; this is best done by means of anoscopy, very careful probing, and sigmoidoscopy to rule out a high source (e.g., Crohn's disease). If the internal opening is found, the abscess can be drained or a fistulotomy can be performed [see Figure 9]. With a fistulotomy, determination of safety is a paramount concern. Careful consideration must be given to which

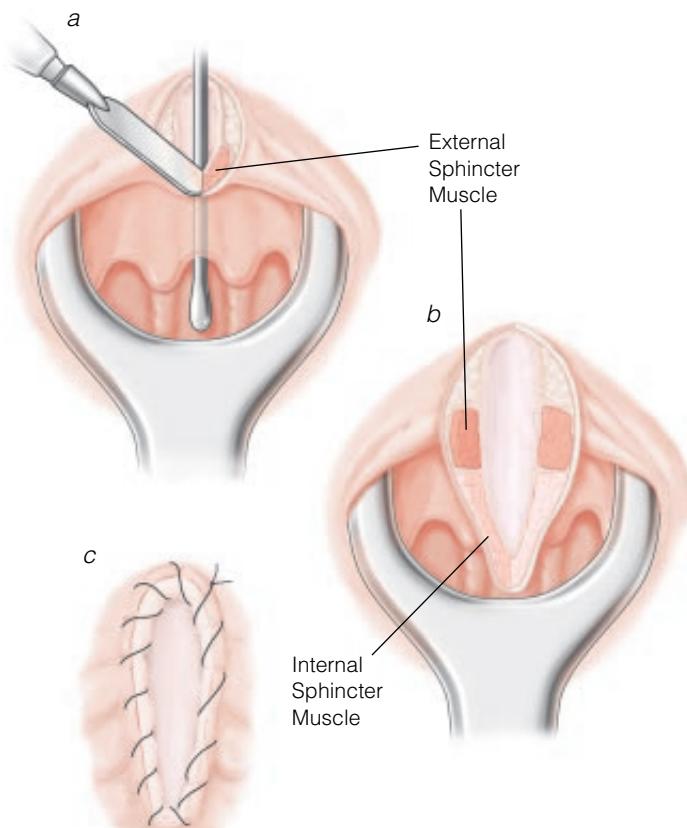

Figure 9 Operative management of abscess and fistula. Shown is a fistulotomy in a patient with cryptoglandular abscess/fistula. (a) The fistula tract is carefully probed, a decision is made about which muscle and how much muscle to cut, and the tract is incised. (b) Once the tract is open, the involved crypt is excised. (c) The defect is marsupialized by sewing skin to the tract.

muscle—and how much of the muscle—is to be cut. The anterior location in a woman is especially precarious. If the fistula involves a significant amount of muscle, or any muscle in the anterior region in a woman, either a seton should be placed or a drain should be placed without disruption of the muscle, in preparation for advancement flap closure of the internal opening.

If the internal opening is not found, one should not make one by probing. The abscess should be drained with a mushroom-tipped catheter [see Figure 10]; in my experience, this is preferable to unroofing and eliminates painful packing. The catheter can be left in place for an extended period, and it permits subsequent injection of dye or contrast material. Once the mushroom catheter is in place in the OR, the surgeon can inject diluted methylene blue to search again for internal openings, which, if found, allow one to consider fistulotomy. The drain is usually sutured in place. The patient should be seen a few days after the operation to confirm that the abscess is adequately drained.

After 2 weeks, the patient is seen in the office, and povidone-iodine is injected through the drain while the inside of the anal canal is inspected via an anoscope. If an internal opening is seen, then fistulotomy is planned. If no internal opening is seen (as is the case in about 50% of patients), the drain should be removed 1 week later. This allows any irritant effect of the povidone-iodine to resolve and prevents the abscess from recurring.

If the fistula tract is known to have an external opening and fistulotomy is planned, the following approach should be considered. First of all, fistulectomy is never indicated. Fistulotomy is

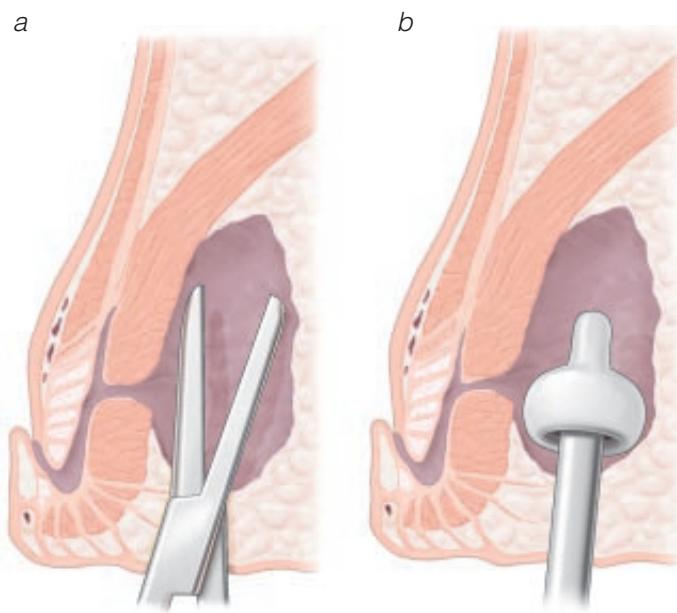

Figure 10 Operative management of abscess and fistula. Shown is drainage of an ischiorectal abscess. Such abscesses may be palpated above the anorectal ring, even though their location is more inferior. (a) The abscess is incised. (b) A mushroom-tipped catheter is placed.

performed rarely and with great caution in the face of Crohn's disease. To perform the fistulotomy, one must first find the internal opening. In this regard, Goodsall's rule is often helpful: external fistula openings anterior to the midanal line are usually connected to internal openings via short, straight tracts, whereas external openings posterior to this line usually follow a curved course to internal openings in the posterior midline. Dilute meth-

ylene blue is injected through the external opening, often via a plastic I.V. catheter.

Careful probing, perhaps with a lacrimal duct probe, is then carried out. If the internal opening still cannot be found, a drain is placed so that the surgeon can return at another time to search for the internal opening. If the internal opening is found, a probe is passed and an effort is made to determine how much muscle and which muscle must be transected to accomplish the fistulotomy and how much muscle will remain to maintain continence [see Figure 11].

If the surgeon is not sure of the extent of muscle involvement or of how safe a fistulotomy would be, the infectious process should be drained, and either the patient should be referred to a specialist, or plans should be made for an advancement flap procedure to close the internal opening. If a fistulotomy is done, a biopsy specimen should be obtained from the infected tract, and the tract should be marsupialized to prevent premature healing of the superficial aspect.

It is important to keep in mind that the sphincter mechanism is innervated by a branch of the pudendal nerve that enters the sphincter from the posterolateral aspect. Accordingly, extreme caution must be exercised when a deep fistulotomy is required in the posterolateral perianal quadrants.

There is a growing body of evidence suggesting that injection of commercially available fibrin glue is effective for treatment of fistulas in perianal tissue. Longer tracts appear to respond better to this modality than shorter tracts do. The long-term efficacy of this approach remains to be proved.

Special problems A cryptoglandular abscess that extends into the posterior anal and posterior rectal spaces is often missed as a source of infection. Diagnosis of such abscesses typically involves bidigital examination, often with the patient under anesthesia; needle aspiration may be required as well. Fistulotomy in this area often

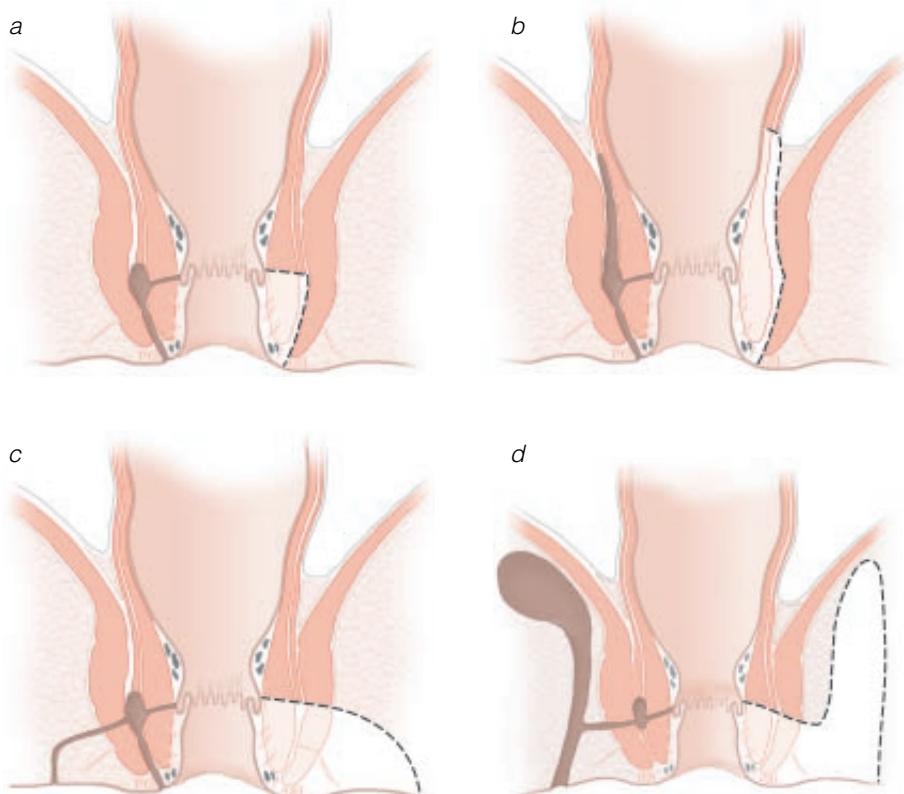

Figure 11 Operative management of abscess and fistula. Shown are examples of the different types of fistulotomies indicated for some of the many types of fistulas: intersphincteric fistula with a simple low tract (a), intersphincteric fistula with a high blind tract (b), uncomplicated transsphincteric fistula (c), and transsphincteric fistula with a high blind tract (d). In each image, the left half of the drawing shows the disease process, and the right half illustrates the recommended operation.

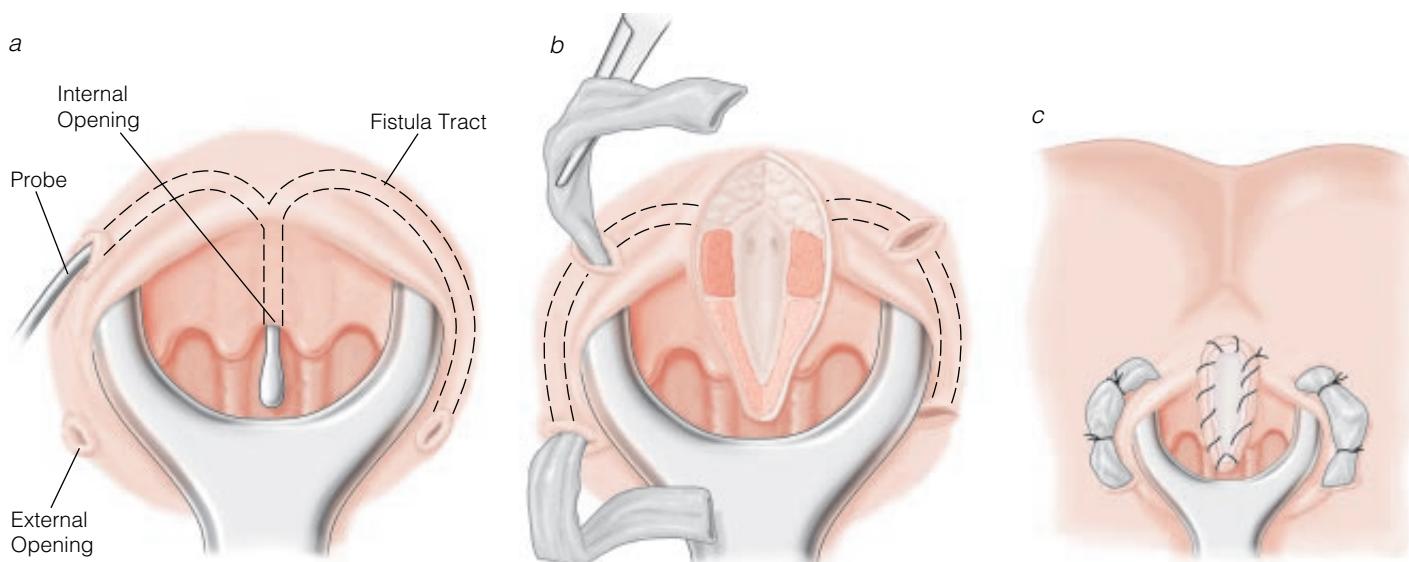

Figure 12 Operative management of abscess and fistula. Shown is the surgical treatment of a horseshoe fistula. (a) The main posterior tract of the fistula is identified by probing. (b) The posterior tract is opened, and drains are placed laterally. (c) The posterior tract is marsupialized.

necessitates opening large amounts of tissue, including partial transection of the sphincter muscle; the tract may also have to be marsupialized. If one is unsure of the anatomy or has never done the procedure before, the abscess should be drained as simply as possible and the patient referred to a specialist.

The so-called horseshoe abscess [see Figure 12] results from an undiagnosed posterior-space abscess that has dissected laterally and may have been drained several times through the lateral extension into one or both ischiorectal fossae. This condition is cured by opening the posterior space and placing a long-term lateral drain, after which healing proceeds by secondary intention (the so-called Hanley procedure). The drain should not be removed until there is solid healing in the posterior midline; this may take weeks or even months.

Abscess and Fistula Associated with Crohn's Disease

The goals of treatment are to drain and control the focus of infection, to preserve sphincter function, to plan and implement a staged approach to preservation of anorectal function, and to make the correct diagnosis. To these ends, careful identification of the location and course of the abscess and any associated fistulas is essential; this is accomplished via endoscopic dye injection, probing, and vaginoscopy.

The safest approach, in my view, is to place mushroom catheters in abscesses and complicated fistula tracts or, in some cases, to use setons to allow drainage of the fistulas (not to cut through the tissue, which is often the intended result of seton placement) [see Figure 13]. For optimal resolution of inflammation at the site of the internal opening in anticipation of a possi-

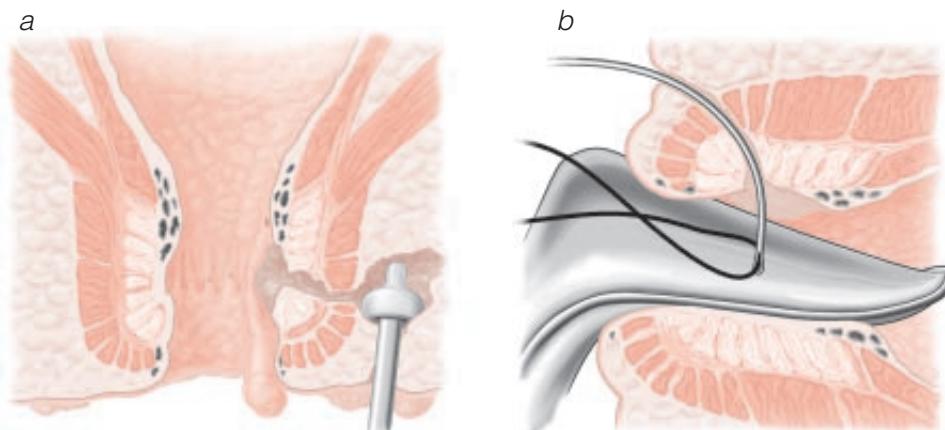

Figure 13 Operative management of abscess and fistula. Shown are alternatives for treating abscess or fistula associated with Crohn's disease. In Crohn's disease, multiple perianal and perineal fistulas and abscesses may be seen, often in atypical locations. (a) Abscesses may be drained by placing a small mushroom-tipped catheter as close to the anus as possible. A Malecot catheter should not be used. (b) In some settings, it is appropriate to place a seton between internal and external openings. This seton may then be left in situ for a time for drainage and for prevention of further disease progression.

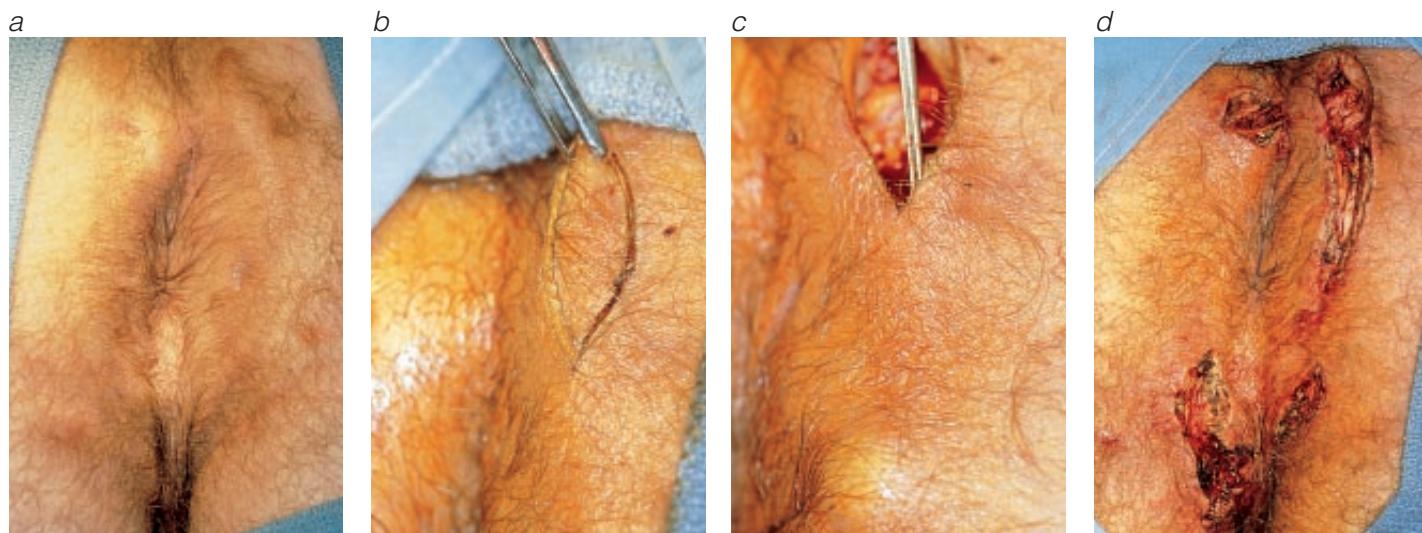

Figure 14 Operative management of abscess and fistula. In this patient, the causative condition is hidradenitis suppurativa. (a) Multiple openings of sinus tracts can be seen and extensive indurated tracts palpated. (b) Abscesses are unroofed. (c) Indurated tracts are probed. (d) All tracts are identified and incised.

ble advancement flap procedure, perirectal mushroom catheters are preferable to setons placed through the internal opening. Superficial fistula tracts may occasionally be managed with fistulotomy if the Crohn's disease is otherwise inactive. Sphincterotomy is never indicated in a patient with Crohn's disease if severe infection is present or the disease is active. When a patient is known or believed to have Crohn's disease, biopsy of the edematous external skin tags that are often present can be a good way of finding granulomatous tissue to confirm the diagnosis.

The newer forms of medical treatment of Crohn's disease, in which a monoclonal antibody to tumor necrosis factor (infliximab) is given either by itself or in combination with immunosuppressive agents, seem to display some of their most beneficial results in patients with complicated anoperineal fistulas. In my view, a good way of managing abscess and fistula associated with Crohn's disease is for the surgeon to drain and control the suppurative process and for the gastroenterologist then to employ the latest medical regimen to force the disease into remission.

Hidradenitis Suppurativa

Patients with infected fistula tracts or abscesses secondary to hidradenitis suppurativa must be positioned in such a way as to allow visualization of and access to all tracts. This is crucial because some of the tracts may extend into the scrotum, the labia, the inguinal areas, or the suprapubic area. Conduction anesthesia is important in that it covers broad areas of the perineum; adequate local anesthesia is impossible unless one is dealing with very small, isolated tracts.

The definitive therapeutic surgical procedure is incision (rather than excision) of these often extensive inflammatory tracts [see Figure 14]. The surgeon should do as much as possible at one time, with the understanding that it is not unusual to leave a few tracts undrained or to return later to address new areas of dissection. Because the primary disease process does not involve the sphincter, intestinal diversion is rarely indicated. Biopsy is indicated because on rare occasions, these long infected tracts exhibit malignant changes or result from an anal malignancy. The perineal skin can tolerate the extensive incisions necessary to cure the process. Special precautions must be taken not only to pre-

serve the sphincter itself but also to avoid damaging the neurovascular bundle that enters the anus from the posterolateral aspect. In male patients, efforts must be made to avoid the urethra during incision in the anterior midline; to this end, a Foley catheter should always be placed before the surgical procedure is begun. Because so many incised skin edges remain after treatment of extensive hidradenitis, it is imperative to achieve adequate hemostasis. The disposable suction cautery units currently available can be especially helpful for this purpose. The wounds may be either left open or loosely packed until good granulation tissue forms.

Bathing the perineum, especially after a bowel movement, is helpful. Often, showers are better for this purpose than the portable minuscule sitz baths commonly used. For patients who have undergone extensive procedures, twice-daily trips to a whirlpool bath (often located in the physical therapy department) are helpful. Despite the multiple lengthy incisions, there is usually little pain, and most of the postoperative care can be done at home. Adequate follow-up is necessary to treat residual or new areas of disease before the dissection becomes extensive again. Care must be taken, especially in the OR, to search for the infected tracts, which may contain little pus and may be apparent only as indurated cords within the perineal skin.

TROUBLESHOOTING

Most of the important steps for avoiding problems have already been described in the course of addressing preoperative planning and operative technique (see above). The goals in the treatment of all of the processes associated with anorectal abscess and fistula in ano are to preserve sphincter function, to control acute infection, and to eliminate the source of the infection. If it is likely that sphincter function will be compromised at all, a baseline level of sphincter function (including the status of muscles and nerves) must be determined before any surgical procedure is initiated. One should never hesitate to perform an examination with the patient under anesthesia and to inject dilute methylene blue to delineate the extent and location of the infectious process.

Anyone embarking on surgical management of such processes must keep in mind the option of performing an advancement flap

procedure to close the internal opening, especially in the anterior region and most particularly in women. If such a procedure is planned, initial drainage should be done external to the rectum with a mushroom catheter rather than through the internal opening with a seton. Simple 3-0 chromic catgut should be used to marsupialize fistula tracts because employing the newer, less quickly absorbable materials may lead to a chronic nidus that gives rise to ongoing infection. Patients should be watched closely in the immediate postoperative period to ensure that all infection is controlled. Not uncommonly, a superficial collection is drained, but a deeper abscess remains that must be sought more aggressively.

One should always take into account the risk of anoperineal infection in immunocompromised patients. Given that the anatomy of the anal tissue planes is complex and can be rendered even more so by multiple surgical procedures, one should not venture beyond one's level of expertise. One should never hesitate to drain an infectious focus with a simple mushroom-tipped catheter and, if appropriate, refer the patient to a colon and rectal surgical specialist who is trained to manage complex anoperineal suppurative processes safely and definitively.

COMPLICATIONS

Complications occur if one or more of the goals just mentioned (see above) have not been achieved. Persistent or recurrent infection is seen with some frequency. In patients with cryptoglandular abscess or fistula, infection usually results from failure to locate the internal opening or to discover a deep posterior midline abscess; such failure is often seen in patients with a horseshoe abscess, in whom repeated lateral drainage procedures may have been undertaken without the primary cavity in the posterior anal or posterior rectal space being discovered and dealt with.

In patients with Crohn's disease, infection can persist if a deeper pocket or extension has gone undiscovered or if the disease has recurred, leading to further penetration and infection in the anoperineum or the perirectal tissue. Extensive examination with the patient under anesthesia, including transrectal ultrasonography or CT scanning, may be required to determine the source and extent of the infection. It is always possible that the infection derives from a superlevator abscess secondary to intestinal disease; consequently, a detailed evaluation of the intestinal tract is indicated in patients with Crohn's disease.

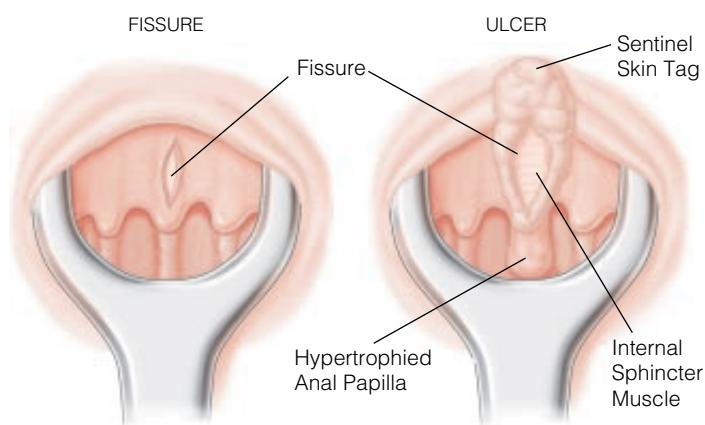

Figure 15 Operative management of ulcer/fissure disease. Anal fissure (left) and anal ulcer (right) are, respectively, the acute aspect and the chronic aspect of a single disease process.

In patients with hidradenitis suppurativa, the most common problems are residual undrained tracts and recurrent disease. Again, examination with the patient under anesthesia and repeated drainage are called for. Because this disease process does not originate in the rectum, care must be taken not to enter the rectum or to cut any of the nerves entering the anus from the posterolateral aspect. It has been reported anecdotally that very chronic or persistent fistula tracts may eventually exhibit malignant changes (squamous cell carcinoma); for this reason, such tracts should be biopsied.

OUTCOME EVALUATION

No sophisticated surveillance is necessary: if drainage persists or some degree of incontinence develops, the patient usually will volunteer the information freely. Either of these complaints could be an indication for a detailed examination, including a sophisticated evaluation of sphincter function.

Operative Management of Ulcer/Fissure Disease

Ulcer and fissure are two aspects of a single anorectal disease process with an unclearly defined pathophysiology [see Figure 15]. Accurate diagnosis is crucial [see 5:17 Benign Rectal, Anal, and Perineal Problems]. Not uncommonly, patients are treated for hemorrhoids when the true primary condition is ulcer/fissure disease.

OPERATIVE PLANNING

Fundamental concerns in planning the operation—besides confirming the diagnosis—are to verify that there are no other conditions that could threaten complete healing of an incision in the anal tissue and to make sure that there is no significant incontinence before the sphincterotomy.

For example, a history of diarrhea compatible with the presence of inflammatory bowel disease indicates the need for further evaluation to eliminate the possibility of Crohn's disease; if Crohn's disease is present, the risk of poor healing is greater, and it will be necessary to preserve all of the available sphincter function of the anus for a long period. As another example, a woman who has borne children by vaginal delivery and has any degree of incontinence should undergo manometry, ultrasonography, and perhaps electromyography to confirm that the sphincter is not compromised by a mechanical or neurologic deficiency. Yet another example is a patient with irritable bowel syndrome or a pelvic floor abnormality who experiences a multitude of difficulties with bowel movements. It is important to recognize such conditions and to advise the patient of the need for special attention to maintain adequate bowel function in the postoperative period.

It is essential to clearly explain the nature of the operative procedure (i.e., the incision of a portion of the internal sphincter mechanism) to the patient and to warn him or her that minor incontinence or flatus may persist for as long as a few months postoperatively. To be fair, significant incontinence is highly unusual: in fact, most patients experience very rapid relief of their often distressing symptoms. One should also advise the patient that any other anal procedures that may be indicated (e.g., elastic ligation of internal hemorrhoids or excision of symptomatic external hemorrhoids) can and should be accomplished at the time of sphincterotomy, with or without excision of the anal ulcer, and that he or she should take 3 to 5 days off from work. The risk of urinary retention, pain, and bleeding must also be discussed. In planning the operative procedure and immediate postoperative care, one must take into account the

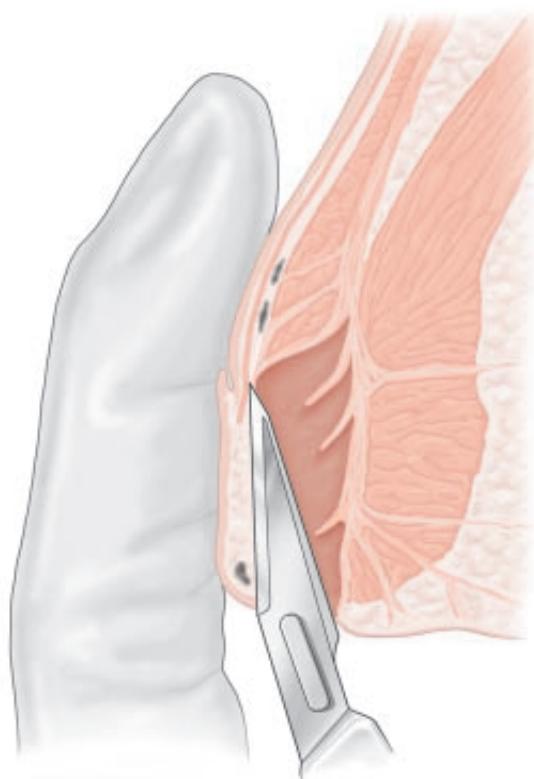

Figure 16 Operative management of ulcer/fissure disease. Shown is the closed approach to posterior lateral internal sphincterotomy. A No. 11 blade is inserted in the intersphincteric groove and moved upward to the level of the dentate line. Medial movement of the blade divides a portion of the internal sphincter muscle. The anoderm and the other anal muscles are not divided.

patient's specific needs, idiosyncrasies, and home environment. Some patients are comfortable undergoing the procedure completely on an outpatient basis, whereas others clearly need to be admitted for short-term observation and parenteral administration of pain medication.

When possible, I keep patients on a liquid diet for 24 hours before operation and use small, self-administered enemas to empty the rectum immediately before the procedure. I advise patients to discontinue any aspirin-containing products and any other anticoagulants, if possible, at least 10 days beforehand.

OPERATIVE TECHNIQUE

Operative treatment of ulcer/fissure disease consists of a posterior lateral anal sphincterotomy, in which the internal sphincter is divided but the external sphincter, the anoderm, and the longitudinal muscle remain intact. I generally prefer to place the patient in the prone-flexed position with the buttocks taped apart and adequate local anesthesia in place. The operation can then be performed in one of three ways: (1) as a closed procedure involving the use of a No. 11 blade and digital palpation of the muscle [see Figure 16], (2) as an open procedure without direct visualization of the muscle, or (3) as an open procedure with clear identification of the muscle before its transection. The third option is the one I prefer.

An open procedure with visualization of the muscle is done as follows [see Figure 17]. The first step is anoscopy, preferably with a medium Hill-Ferguson instrument. The hypertrophied band of the lower third of the internal sphincter muscle is clearly identified. If this band is not a distinctly identifiable entity, sphincterot-

omy should not be performed. The ulcer or fissure itself need not be present, because the disease may be in a relatively inactive state at the time of surgery.

Rigid or flexible sigmoidoscopy should then be performed if it was not done in the immediate preoperative period. The primary purpose of this step is to make sure that no features of Crohn's disease are visible in the rectum. When the endoscopic examination is complete, I usually repeat the preparation of the anal opening.

A 1 cm incision is made in the posterior lateral aspect of the perianal skin, hemostasis is obtained, and a delicate dissection is done with a curved hemostat in the intersphincteric plane. The posterior midline is avoided because healing in this position may result in scar tissue that interferes with perfect continence (the so-called keyhole deformity). The white hypertrophied band of muscle is then elevated into the wound with a curved hemostat. If a rent is made in the anal mucosa, it must be repaired with 3-0 chromic catgut. The band of muscle is then incised with the electrocautery, and pressure is maintained for a few minutes to ensure hemostasis. Digital examination confirms adequate transection of the band. The skin is left open.

Attention is then directed to the ulcer, which may be excised sharply in an elliptical fashion so as to incorporate the entire triad of the ulcer (i.e., the ulcer itself, the sentinel hemorrhoidal tag, and the hypertrophied anal papilla) while avoiding additional transection of the underlying muscle. If I excise the ulcer complex, I usually close the wound with a continuous three-point suture of 3-0 chromic catgut to obliterate any dead space and thus to lower the risk of postoperative infection.

Any additional anal surgery required is then completed, the surgical site is covered with antibiotic ointment, and a very light gauze bandage is applied with a minimum of tape and traction on the perianal skin.

TROUBLESHOOTING

To perform this simple procedure well, one must have a clear understanding of the surgical anatomy of the anal canal and must be able to clearly identify the internal sphincter, the intersphincteric groove, and the external sphincter muscle. The hypertrophied band of muscle must be accurately identified and cleanly transected. No attempt should be made to extend or amplify the procedure by stretching the anal canal and thus bursting the muscle. Although the procedure and anatomy are simple, the best way of learning the operation is to watch an experienced surgeon perform it. I do not believe this procedure can be learned through reading alone.

COMPLICATIONS

Because the internal sphincter muscle is responsible for resting, involuntary continence, injury to this structure can lead to nocturnal incontinence. Again, special caution is advised with respect to the anterior aspect of the anoperineum in women. On the other hand, incising the posterior midline can also lead to the keyhole deformity, which may cause prolonged anal seepage because of the configuration of the scar tissue; a good analogy is a bent rim on a tubeless tire. It is tempting to close the tiny skin incision at the site of sphincterotomy, but I think it should be left open to reduce the already low risk of infection.

There should be very little postoperative pain. If the patient does complain of significant pain, especially in the presence of fever or urinary hesitancy, one must assume that infection is present in the anoperineum, a structure that is normally highly resistant to microbial invasion. Urgent evaluation, removal of sutures, antibiotic therapy, bowel rest, placement of a urinary catheter, and very close observation in the hospital are indicated.

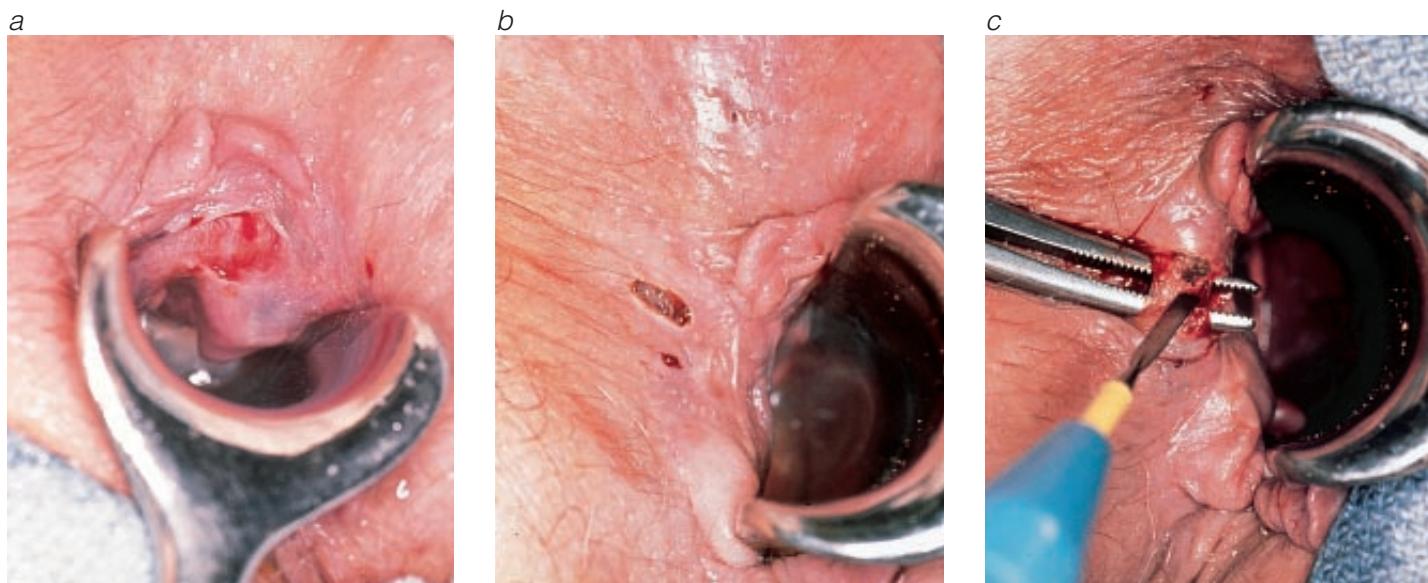

Figure 17 Operative management of ulcer/fissure disease. Shown is the open approach to posterior lateral internal sphincterotomy. (a) The triad of the ulcer complex is visualized. (b) Once the hypertrophied band of internal sphincter muscle is identified, a 1 cm incision is made in the posterolateral aspect of the perianal skin. (c) The hypertrophied band is elevated into the wound and divided with the electrocautery.

The major causes of complications are incorrect diagnosis of the disease process (especially overlooking the presence of Crohn's disease) and failure to fully understand the anatomy of the continence mechanism of the anal canal. If too much of the internal sphincter muscle is cut, if this muscle is already compromised, or if the external sphincter muscle is transected by mistake, the patient will be rendered incontinent. On the other hand, if not enough of the internal muscle is transected, the ulcer will not heal and the symptoms will persist.

Overall, the single most common cause of complications that I have observed is the failure even to suspect, much less diagnose, ulcer/fissure disease as the source of a patient's symptoms. I frequently see patients who seem to have failed to heal months after a hemorrhoidectomy. When their symptoms are reviewed and a thorough examination performed, it becomes apparent that the underlying disease process was always ulcer/fissure disease rather than hemorrhoids and that the hemorrhoidectomy only intensi-

fied the anal pain and bleeding. These patients are finally cured when an adequate sphincterotomy is performed.

In very rare instances, drainage continues at the site of the sphincterotomy. If drainage persists for weeks, the patient should be examined under appropriate anesthesia, and the focus of infection should be opened. This is essentially equivalent to a very superficial fistulotomy.

OUTCOME EVALUATION

Again, no sophisticated surveillance is necessary: when the patient returns 2 weeks after the procedure, free of pain and bleeding and able to have bowel movements without difficulty, one may be sure that an acceptable outcome has been achieved. Digital rectal examination should confirm good healing and normal sphincter tone (both while resting and while contracting). For additional confirmation, I have patients continue to take bulk-forming agents and stool softeners and then examine them 1 month later to verify that healing is complete.

1 STROKE AND TRANSIENT ISCHEMIC ATTACK

Thomas S. Maldonado, M.D., and Thomas S. Riles, M.D., F.A.C.S.

Assessment and Management of Stroke and TIA

Stroke is defined as any damage to the central nervous system caused by interruption of the blood supply. Ischemic strokes result from the failure of oxygen and nutrients to reach the affected brain. Transient ischemic attacks (TIAs) are defined as transient neurologic deficits lasting no longer than 24 hours; longer-lasting deficits are considered to be indicative of a cerebral infarction (“brain attack”).

Infarction from ischemia is typically confined to a vascular territory, at whose center can be found the injured or obstructed artery supplying that parenchyma. The full extent of a stroke may not become apparent until days or weeks later, when the tenuous peripheral watershed zone, or penumbra, either survives or succumbs to cell death. Smaller infarcts, adequate collateral circulation, and prompt intervention and resuscitation are associated with improved outcome.

Hemorrhagic stroke damages the brain by cutting off connecting pathways and causing localized or generalized pressure injury. Brain edema and hydrocephalus after hemorrhagic stroke may also be deleterious. In some cases, hemorrhagic stroke can lead to ischemia as a consequence of vasospasm, as is seen in the setting of subarachnoid hemorrhage (SAH). Likewise, some ischemic strokes can undergo hemorrhagic transformation.

Incidence and Risk Factors

Stroke is the third leading cause of death in the United States: about 168,000 stroke-related deaths are reported each year.¹ Approximately 500,000 first-time strokes are reported annually. In addition, stroke is the leading cause of serious long-term disability in the United States and poses a substantial economic burden. For 2003, U.S. expenditure on stroke-related medical costs and disability payments amounted to roughly \$51 billion. Although a sharp decline in stroke incidence and mortality was noted throughout most of the 20th century, the decline leveled off in the early 1990s, and stroke incidence and mortality are now rising for the first time since 1915.^{2,3}

Numerous population studies and stroke registries have been designed to examine the incidence, risk factors, and natural history of stroke.⁴⁻¹⁰ Some of the independent risk factors that have been identified—such as age (> 55 years), sex (male), race (African American and Asian), and genetic predisposition—cannot be modified and therefore carry a fixed level of stroke risk. The Rochester (Minnesota) population study demonstrated a marked progressive incidence of cerebral infarction with advancing age, as well as a nearly 1.5 times greater risk of stroke in males.⁴ The Lausanne Stroke Registry data confirmed the overall higher incidence of stroke in males, though it also demonstrated a female preponderance in very young (< 30 years) and very old (> 80 years) patients. These latter findings may be attributable to the high frequency of oral contraceptive use in young women in that

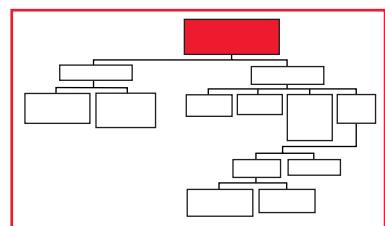

study, as well as to the lower life expectancy of men, especially those with vascular risk factors.⁹ Race and genetic predisposition are also considered independent risk factors, with African Americans more than twice as likely to die of stroke as whites.¹⁰ The underlying mechanism of stroke appears to vary with race as well: intracranial occlusive disease tends to occur more frequently in African and Asian Americans than in whites or in males as a whole.^{11,12} The importance of hereditary risk for stroke has long been recognized. In the Framingham Study, both paternal and maternal histories of stroke were associated with an increased risk of stroke.^{10,13}

There are, however, certain risk factors for stroke that are clearly modifiable, including hypertension, smoking, hyperlipidemia, asymptomatic high-grade carotid stenosis, and atrial fibrillation (AF).¹⁴⁻¹⁶ Other purported modifiable risk factors for stroke (e.g., obesity, diabetes, oral contraceptive use, and alcohol intake) are more controversial.¹⁷⁻²⁰ Hypertension (systolic as well as diastolic) is perhaps the most prominent modifiable risk factor for stroke and is associated with a substantial risk of atherothrombotic, lacunar, or subarachnoid hemorrhage. The Systolic Hypertension in the Elderly Program (SHEP) study demonstrated that treating systolic hypertension in patients 60 years of age or older can reduce the incidence of stroke by as much as 36%.²¹ Prompt diagnosis and intervention for stroke may be critical, but many authorities feel that primary prevention is the true cornerstone of therapy for this lethal disease.

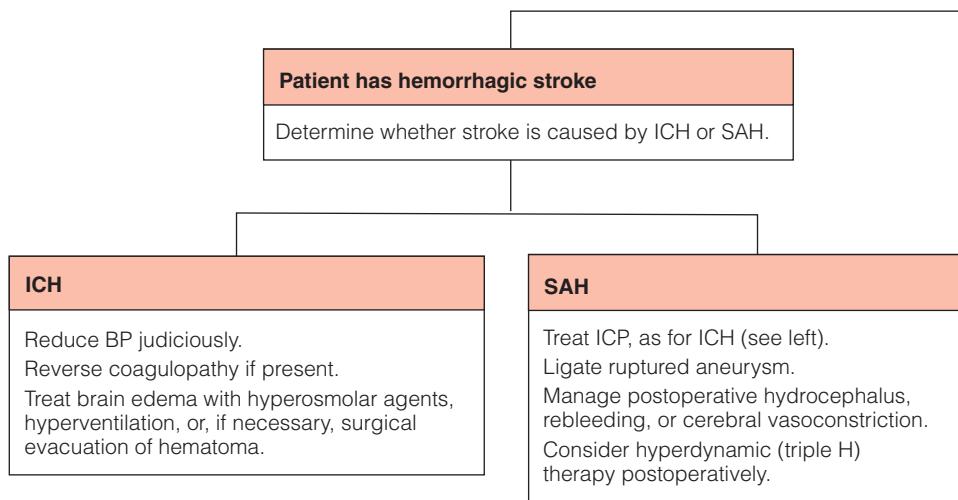

Clinical Evaluation

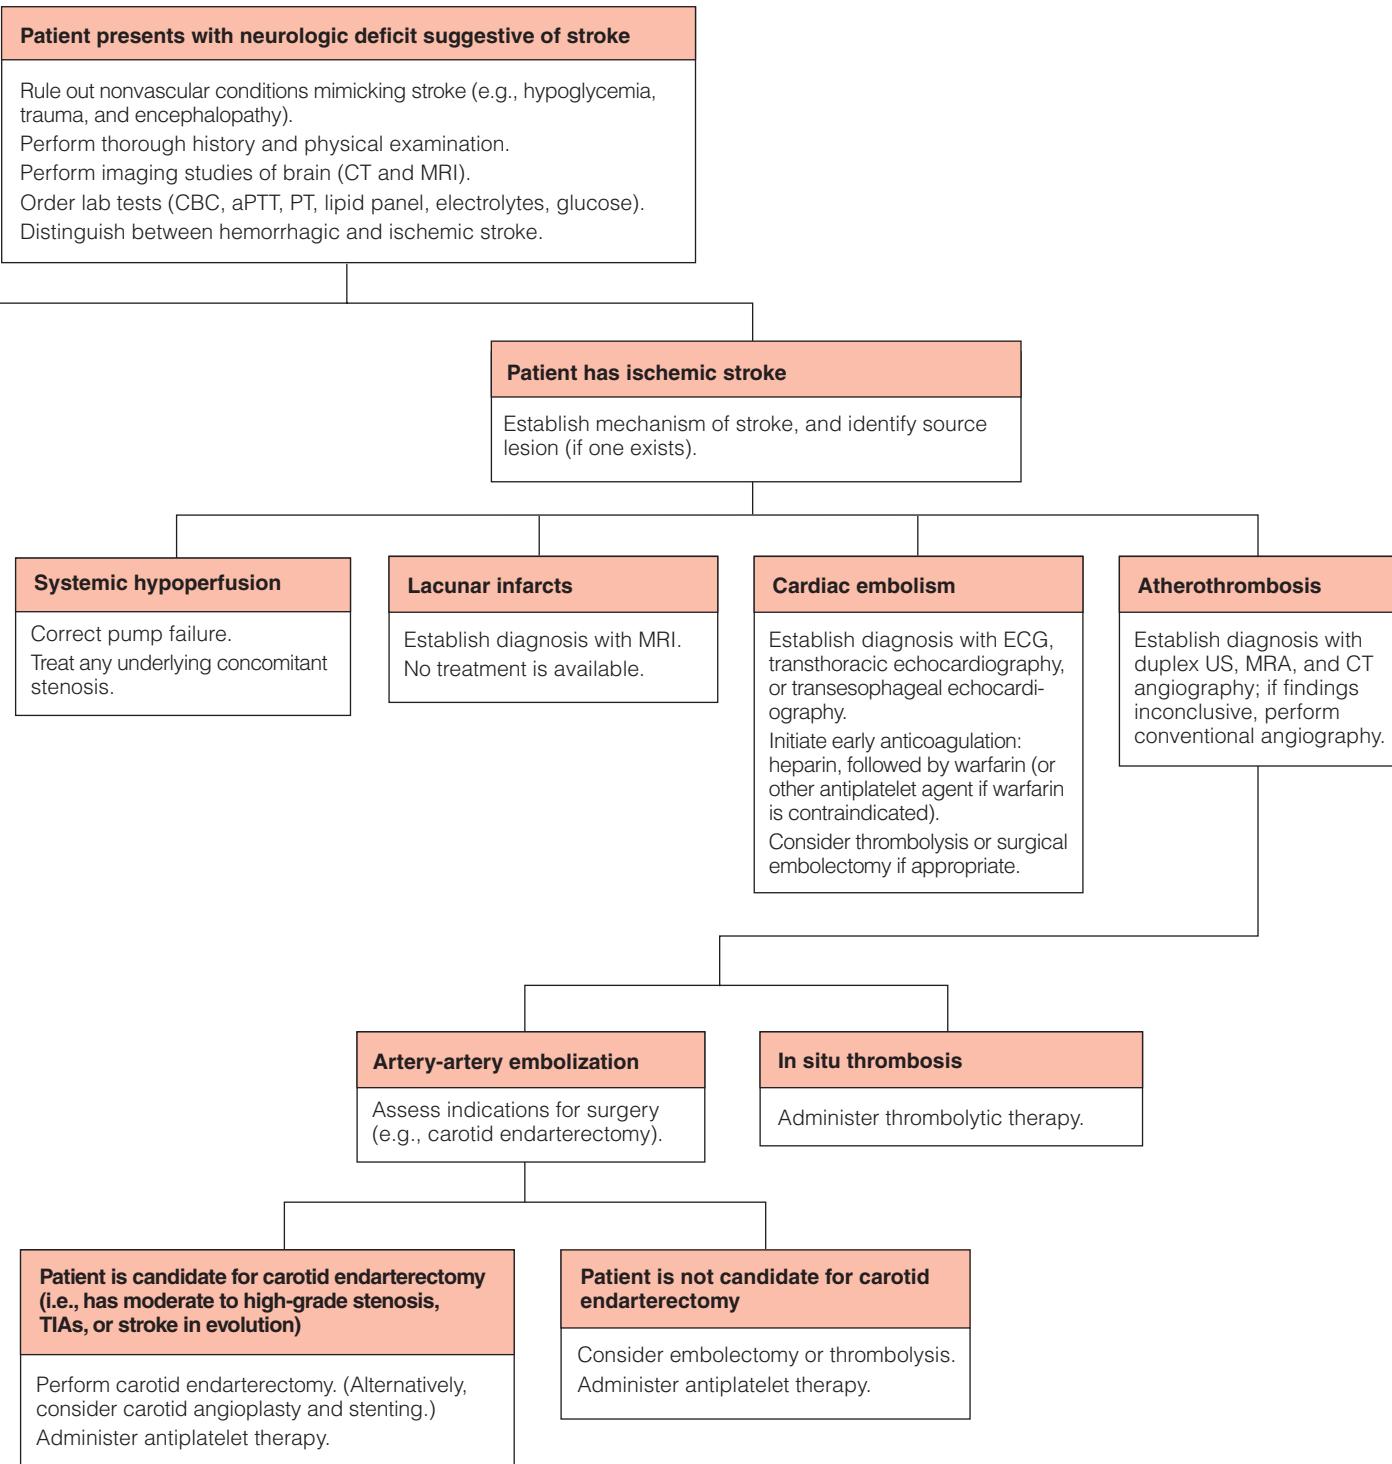

When assessing patients who present with a neurologic deficit, clinicians must immediately ask themselves the following two questions: (1) what is the mechanism of the deficit (i.e., ischemic or hemorrhagic), and (2) where is the lesion (e.g., cerebral lacunae, the territory around a large vessel, or a watershed region)? A thorough history and physical examination, in conjunction with brain imaging studies, usually suffice to guide initial management. Nonvascular conditions that can mimic stroke (e.g., hypoglycemia, migraine, a postictal state, encephalopathy, trauma, and brain tumors or abscesses) must be excluded. Although these syndromes can all cause focal findings, they usually lack the abrupt onset of symptoms consistently seen with stroke.

Ischemic and hemorrhagic stroke must be differentiated early in the course of an acute stroke because a number of therapeutic interventions that are beneficial for some subtypes of stroke are potentially catastrophic for others. Approximately 71% of all strokes are ischemic and 26% hemorrhagic; the remaining 3% are

Assessment and Management of Stroke and TIA

of unknown origin [see *Table 1*.²² Hemorrhagic strokes result from subarachnoid or intracerebral bleeding, whereas ischemic strokes result from systemic hypoperfusion, cardioembolism, or atherosclerosis. Although various different laboratory and radiographic tests are available and should be performed, the diagnosis of stroke is primarily a clinical one.

HISTORY

A patient who has suffered a stroke typically presents with a history of sudden onset of a focal brain deficit and a clinical syndrome on neurologic examination. A medical history should elicit any of a number of risk factors associated with either ischemic or hemorrhagic stroke. For example, hypertension is often associated with deep infarcts and hemorrhages, whereas cigarette smoking and hyperlipidemia are more commonly associated with ischemic infarcts resulting from atherosclerosis.⁹ (Hypertension can, however, be associated with infarcts caused by hypertensive arteriolopathy.) The presence of atrial fibrillation, a recent myocardial infarction (MI) (< 6 weeks old), or a prosthetic heart valve suggests a possible cardioembolic mechanism.

The onset and course of the neurologic deficit may also be telling. A steady onset is suggestive of hemorrhage, whereas symptoms that progress in a stepwise fashion are more likely to derive from ischemia. Likewise, accompanying signs are frequently useful in differentiating stroke mechanism subtypes. Headache, vomiting, and loss of consciousness constitute the classic picture of hemorrhagic stroke, whereas a focal deficit preceded by TIAs is more suggestive of ischemic stroke.²³ Although the clinical manifestations are generally helpful in differentiating stroke subtypes, it sometimes happens that large infarcts mimic the classic picture of hemorrhage or that lobar or small deep hemorrhages resemble infarction resulting from atherosclerosis. Analysis of 1,000 consecutive patients from the Lausanne Stroke Registry who experienced their first stroke confirmed that the classic hemorrhagic picture (headaches, progressive neuralgic deficits, and decreased level of consciousness) was indeed more common in patients with hemorrhage but found that only one third of patients with hemorrhagic strokes had this clinical triad.⁹

PHYSICAL AND NEUROLOGIC EXAMINATION

A general physical and neurologic examination should detect vascular and cardiac abnormalities, as well as localize the process within the CNS. Heart size and sounds, irregular rhythms or dis-

Table 1 Causes of Stroke as Recorded in NINCDS Data Bank²²

Cerebral ischemia	71%
Atherosclerosis	10%
Larger-artery stenosis	6%
Tandem arterial lesions	4%
Lacunae	19%

crepant pulse exams, and carotid bruits should all be noted. Careful examination of the extremities is essential, in that peripheral vascular disease is highly correlated with the presence of atherosclerosis of the carotid and vertebral arteries.^{6,24} An ophthalmologic examination should detect subhyaloid hemorrhages, as well as cholesterol emboli (Hollenhorst plaques).

Besides localizing the lesion anatomically, the neurologic examination should be able to identify a probable cause. The absence of major focal neurologic signs is often consistent with SAH; focal deficits localized to the superficial cortex are often attributable to thromboembolism or ischemia. A number of well-described lacunar syndromes also exist; these typically suggest small-vessel disease.

Investigative Studies

IMAGING

Imaging is a mandatory and integral part of evaluation for acute stroke and should be performed expeditiously. Computed tomography is the initial test of choice; it is readily available in most hospitals and is well tolerated by critically ill patients.²⁵ CT can promptly identify nonvascular causative conditions (e.g., masses) and can readily diagnose intracerebral hemorrhage (ICH) [see *Figure 1*]. Diagnosis of SAH without I.V. contrast can be more difficult, especially if bleeding is minor or occurred more than 1 day before; the accuracy of CT in detecting SAH decreases after 24 hours.²⁶ SAH should appear as an increased density in the CSF. If SAH is clinically suspected, lumbar puncture may be necessary for definitive diagnosis.

In cases of acute ischemic stroke, diagnosis of infarction by means of CT can be more difficult. I.V. contrast CT is of limited value in this setting. Signs of infarction can be absent or subtle in the first few hours after the stroke. A lesion may appear as a slight hypodensity within the infarcted zone or as a loss of definition between gray and white matter.²⁷ Newer CT scanners may be better at delineating these nuances.^{28,29} In the days following an ischemic stroke, an infarct may first appear round or oval and then as a hypodense, dark, or wedge-shaped lesion on CT.

Magnetic resonance imaging is more expensive and time-consuming than CT and is less well tolerated by critically ill patients. Nonetheless, MRI is more sensitive than CT in detecting early ischemic changes after a stroke. It can be used to distinguish an old stroke from a new one and to assess the size and location of a lesion, especially when the lesion is adjacent to bony structures [see Figure 2].³⁰ The size of the infarct as determined by MRI may be of great importance for prognosis. Although lesion size may not correlate with severity of clinical presentation, larger infarcts in the same vascular territory are associated with more severe deficits than smaller infarcts in similar anatomic locations are.

MRI is especially useful for diagnosing lacunar infarcts. In a review of 227 patients with lacunar infarcts, 44% were diagnosed by CT and 78% by MRI.³¹ Infarction appears as dark, hypodense areas on T₁-weighted sequences and as bright areas on T₂-weighted sequences. Edema usually develops around the infarct within the first few days and is readily apparent on MRI as a low-density area surrounding the lesion with mass effect. Sometimes, the infarct is small but is still associated with substantial edema. Such edema may be insignificant in an older patient with an atrophied brain whose cranium is able to accommodate a mass effect but may be life-threatening in a younger patient with little intracranial room to spare.

The high sensitivity of MRI in detecting infarction has been demonstrated in studies evaluating patients experiencing TIAs. When patients without signs or symptoms of infarction underwent brain imaging after a TIA, 27% were found to have evidence of so-called silent infarcts on CT and 73% on MRI.³²

Diagnosis of ICH can be a more delicate task with MRI than with CT. Careful scrutiny by an experienced observer using different acquisition techniques is required. The appearance of a cerebral hematoma on T₁- and T₂-weighted sequences varies as the lesion matures and edema resolves. Acute hematomas are black on T₁-weighted images, and chronic hematomas are white on T₁- and T₂-weighted images.

Normal neuroimaging findings are not uncommon in patients presenting with neurologic deficits suggestive of acute stroke. A patient with a neurologic deficit and a negative CT scan should undergo further cerebral imaging with MRI. The absence of ischemic infarction and hemorrhage on both CT and MRI may suggest transient ischemia or persistent ischemia without infarction. In such cases, one may have to rely on signs and symptoms to localize the ischemic lesion responsible for the stroke. Alternatively, electroencephalography (EEG), positron emission tomography (PET), single-photon emission CT (SPECT), or xenon-enhanced CT (XeCT) may be employed to help localize ischemic foci.^{33,34}

LABORATORY TESTS

Blood should be sent to the laboratory as part of the initial assessment of a patient with an acute stroke. Measurement of serum electrolyte and glucose levels is essential to rule out nonvascular conditions mimicking stroke (e.g., hypoglycemia and dehydration). A complete blood count (CBC), an activated partial thromboplastin time (aPTT), a prothrombin time (PT), and a

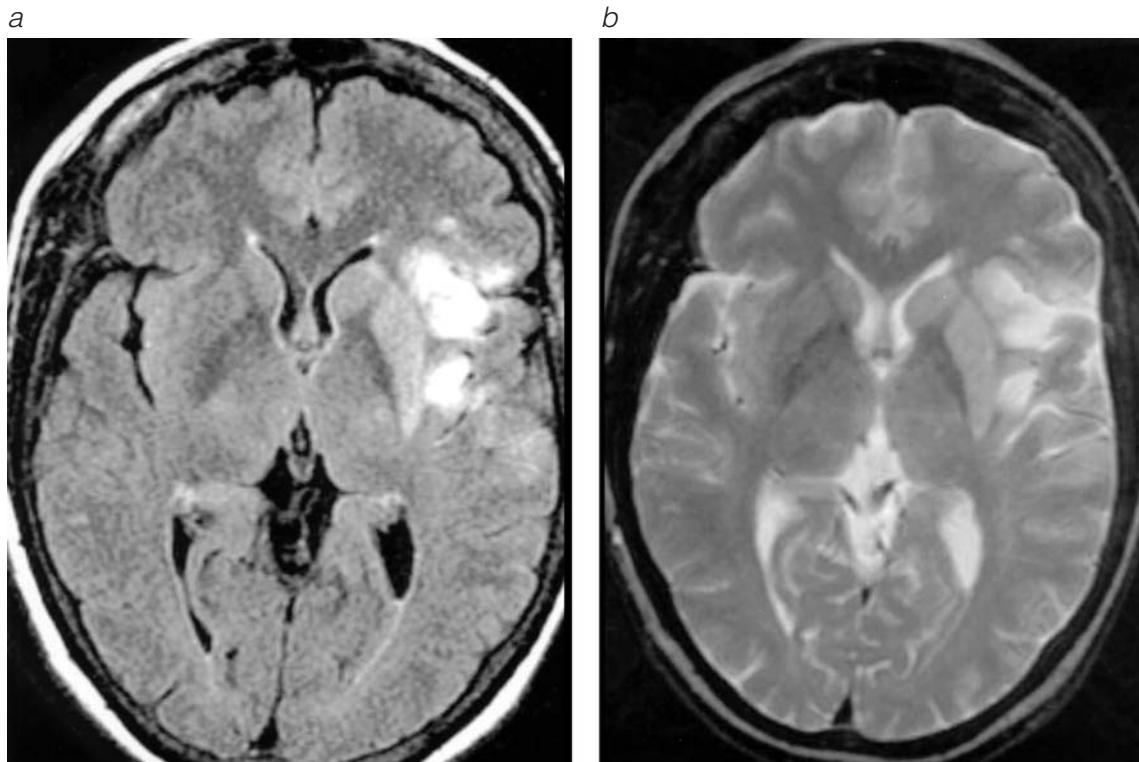

Figure 2 Shown are (a) a fluid-attenuated inversion-recovery (FLAIR) MRI image and (b) a T₂-weighted MRI image of an acute ischemic infarct in the left middle cerebral artery distribution.

lipid panel are likewise essential components of the initial assessment. Severe anemia has the potential to exacerbate or precipitate cerebral ischemia in stroke; though this is an uncommon occurrence, it should be considered and, if present, corrected.³⁵ Additional laboratory blood tests (e.g., a cardiac injury panel to rule out myocardial infarction or an erythrocyte sedimentation rate to assess the possibility of vasculitis) may be helpful.

Screening should be performed for hematologic disorders that result in hypercoagulable states, including homocystinuria,³⁶ antiphospholipid antibody syndrome, protein C and S deficiency, antithrombin deficiency, and activated protein C resistance from factor V Leiden mutation [see 6:6 *Venous Thromboembolism*.]^{37,38} Hemoglobinopathies (e.g., sickle cell disease and thalassemia) can also lead to altered blood flow, hypercoagulability, and stroke.³⁹ Finally, hyperviscosity syndromes (e.g., polycythemia vera, thrombocytosis, and myeloproliferative disorders) should be included in the differential diagnosis. If a hyperviscosity syndrome is recognized in the setting of acute stroke, hemodilution therapy may be warranted. Experimental and clinical trials have shown hemodilution to increase blood flow in the ischemic brain; however, other studies have failed to show improvement of neurologic status.^{40,41} Hemodilution remains indicated in stroke patients who have a high hematocrit or are in a hyperviscosity state; however, close monitoring is required in patients with heart disease or cerebral edema.

Recognition and Management of Specific Stroke Subtypes

HEMORRHAGIC STROKE

Hemorrhagic stroke can result from ICH or SAH.

The consequences of cerebral bleeding can progress rapidly from neurologic deficit to coma to death in a significant number of patients.

Intracerebral Hemorrhage

ICH accounts for approximately 10% to 15% of all strokes in the United States and Europe.^{22,42} Potential causative mechanisms include hypertension, trauma, arteriovenous malformations, cerebral amyloid angiopathy, brain tumors, blood dyscrasias, and medications (e.g., anticoagulants and thrombolytics). Of these, hypertensive arteriopathy is most commonly responsible for nontraumatic ICH.^{22,43} Hypertensive brain hemorrhages are usually deep and are typically located in the lateral ganglionic region, the subcortex, the thalamus, the caudate nucleus, the pons, or the cerebellum. As early as the 1870s, Charcot and Bouchard correctly postulated that such events were the result of microaneurysmal disease of arteries and arterioles penetrating deep into the brains of hypertensive patients.^{44,45} These discrete hemorrhages go on to compress neighboring capillary networks, causing them to burst and bringing about a rapid enlargement of the intracerebral hematoma. Indeed, such enlargement is not uncommon: one prospective study found that 38% of patients with ICH had a hematoma that was enlarged at 3 hours in comparison with its size on baseline CT after the initial bleeding event.⁴⁶

Patients presenting with sizable ICH often rely on a marked compensatory elevation of blood pressure to maintain a pressure gradient in the setting of acute increases in intracranial pressure (ICP). It is vital to resist the impulse to lower blood pressure aggressively in these patients: a rapid drop in blood pressure may induce

brain ischemia. Short-acting antihypertensives should be administered only when the systolic blood pressure is persistently higher than 180 to 200 mm Hg or when there is evidence of active bleeding or an enlarging hematoma. Other medical treatment of hemorrhagic stroke from ICH includes reversal of coagulopathies with transfusions of fresh frozen plasma and platelets when appropriate.

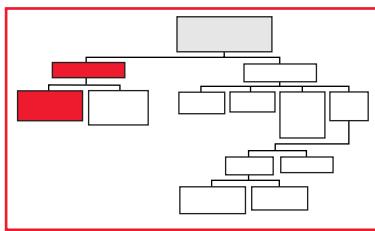

Mortality from ICH has plummeted from 90% before the 1970s to less than 50% in the first decade of the 21st century.^{2,22,47} This precipitous decline probably reflects improved antihypertensive therapy, as well as a decreased prevalence of hypertension.⁴⁸ Death from ICH most commonly occurs secondary to herniation from the hematoma itself coupled with brain edema, which can develop within the first hours after ICH.^{47,49} Thus, treatment of brain edema is the main focus of treatment. Corticosteroids, though indicated for reducing cerebral edema in patients with tumors or abscesses, are contraindicated in patients with ICH because they are not beneficial and may in fact be injurious, predisposing patients to infection and worsening diabetes.⁵⁰ Hyperosmolar agents (e.g., mannitol or glycerol solutions) may be more useful for reducing cerebral edema rapidly.⁵¹ Alternatively, in cases of severe brain edema, hyperventilation may reduce ICP by inducing diffuse vasoconstriction in the brain. Any physiologic perturbation that might increase cerebral blood volume (e.g., hypercarbia, hypoxia, or vasodilation) or reduce cerebral perfusion (e.g., hypotension) should be avoided. Finally, surgical evacuation of a hematoma, though controversial, may be employed as a last resort for decompression after ICH.⁵²

Subarachnoid Hemorrhage

Rupture of saccular or berry aneurysms with subsequent SAH carries significant morbidity and mortality, depending largely on the patient's age, the extent of the hemorrhage, and the presence and severity of rebleeding, cerebral vasospasm, and surgical complications.⁵³ SAH accounts for 6% to 10% of all strokes and 22% to 25% of all deaths from cerebrovascular accidents.⁵⁴ The reported incidence of incidental aneurysms discovered in autopsy studies ranges from 0.8% to 18%.⁵⁵⁻⁵⁷ SAH tends to occur more often in patients 50 to 60 years of age than in younger or older patients and in women more often than in men (12.3% versus 7.9%).⁵⁸ The pathogenesis of saccular aneurysms has not been fully explicated, but the risk factors are well described and include a family history of SAH,⁵⁹ hypertension, pregnancy,⁶⁰ and black race.⁶¹

SAH presents with warning signs in as many as 20% of patients within the 3 months preceding a major rupture, presumably because a minor leak develops before the rupture. Such warning signs include a so-called sentinel headache, oculomotor symptoms, nausea and vomiting, and loss of consciousness.⁶² The rupture itself is accompanied by sudden severe headache, nuchal rigidity, back pain, nausea, vomiting, photophobia, lethargy, loss of consciousness, and seizure.^{60,63}

Medical management of SAH includes tranquil bed rest with the head elevated 30°, stool softeners, antiemetics, and analgesics, as well as deep vein thrombosis (DVT) prophylaxis using pneumatic compression boots [see 6:6 *Venous Thromboembolism*.] Management of ICP in SAH patients is similar to that in ICH patients (see above). Furthermore, one must be vigilant for signs of hypothalamic dysfunction manifesting as cardiac dysrhythmias or the syndrome of inappropriate antidiuretic hormone secretion (SIADH).

The timing of microsurgical clip ligation of aneurysms after SAH is somewhat controversial. The International Cooperative Study on the Timing of Aneurysm Surgery showed no overall differences in outcome between early surgery (0 to 3 days after SAH) and delayed surgery (11 to 14 days after SAH).⁶⁴ Nonetheless, patients who were alert preoperatively did better with early surgery and demonstrated significantly better rates of good recovery.

Three major neurologic complications affect outcome after surgery for SAH: hydrocephalus, rebleeding, and cerebral vasoconstriction. Hydrocephalus may develop acutely as a result of obstruction of CSF outflow. Ventricular drainage can lead to immediate reduction of ICP and improvement in neurologic symptoms. The risk of rebleeding peaks on postoperative day 1; it is as high as 20% in the first 2 weeks and rises to 50% within 6 months if the aneurysm is not treated.⁵³ Unlike rebleeding, vasospasm manifests itself gradually over hours to days; it may be associated with up to a threefold increase in mortality during the 2 weeks after SAH.⁶⁵⁻⁶⁷ The diagnosis is initially made via angiography and followed via transcranial Doppler sonography.^{68,69}

Hyperdynamic, or triple H, therapy consists of keeping patients hyperdynamic (to increase cardiac output), hypervolemic-hypertensive (to augment cerebral perfusion pressure), and hemodiluted (to improve cerebral microcirculation by decreasing viscosity). Because of the risk that the aneurysm will rerupture before operation, triple H therapy is reserved for postoperative patients.^{70,71} Calcium blockers may also reduce the incidence of symptoms secondary to vasospasm, though they most likely have little effect on spasm per se.⁷²

ISCHEMIC STROKE

If hemorrhagic stroke is ruled out and ischemic stroke is diagnosed, the next step is to establish the mechanism of the stroke and identify the source lesion responsible (if one exists).

Systemic hypoperfusion, cardiac embolism, large-artery atherosclerosis, and small-vessel disease should be systematically considered as potential causes.

Systemic Hypoperfusion

Only a small fraction of all ischemic strokes are attributable to systemic hypoperfusion. A quick assessment of vital signs and symptoms may provide the first clues that a patient is suffering from cerebral ischemia secondary to systemic hypoperfusion. Patients are characteristically either unconscious on arrival in the emergency department or awake but exhibiting neurologic symptoms resembling near-syncope.⁷³ Generally, they are pale, diaphoretic, and hypotensive. Neurologic signs and symptoms are varied and are explained by ischemia in the border zone (or watershed) between two or three adjacent arterial territories. Difficulty in reading or identifying visual stimuli (or even frank blindness) may be observed; this may be attributed to ischemia between the middle and posterior cerebral arteries. Bilateral arm weakness or cognitive difficulty may suggest ischemia between the middle and anterior cerebral arteries. Global symptoms usually arise from bilateral border-zone infarcts, which can develop in association with prolonged cardiogenic shock, dysrhythmias, or cardiac arrest.^{74,75} Alternatively, symptoms may be asymmetrical if they derive from inadequate perfusion distal to a site of severe stenosis or occlusion of major feeding cerebral vessels.

Treatment should focus primarily on correcting the pump fail-

ure. Certain patients with concomitant underlying stenosis proximal to border-zone ischemic territories may benefit from treatment of the flow-limiting lesions to eliminate the hemodynamic impairment and thus may do better than patients with systemic hypoperfusion.⁷⁶

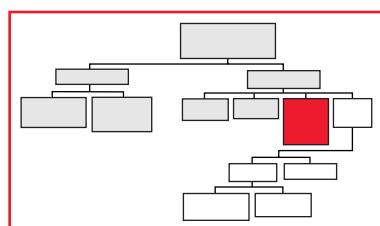

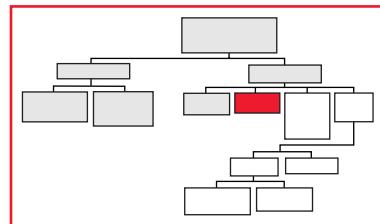

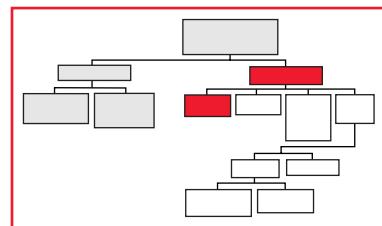

Lacunar Infarcts

Neurologic examination of a patient believed to have experienced an acute ischemic stroke should be attentive to the possibility of lacunar infarcts, manifested by pure motor hemiparesis, pure sensory syndrome, sensorimotor syndrome, ataxic hemiparesis, and dysarthria-clumsy hand syndrome.^{77,78} Lacunae are small (1 to 2 cm) subcortical lesions that result from small-vessel disease deep in the brain. They can occur either alone or in groups and may be present in as many as 23% of persons over the age of 65 years. Lacunar infarcts, unlike other forms of stroke, do not present with headache and are associated with hypertension and diabetes.⁷⁹ Although they are asymptomatic (silent) in as many as 89% of patients, their benignity is currently in some doubt: there is evidence to suggest that they may increase the risk of dementia and cognitive decline.^{80,81} Lacunar syndromes are characteristic and highly predictive of the presence of lacunae, but they may be less reliable for excluding other mechanisms of stroke. A review of the Northern Manhattan Stroke Study experience demonstrated that as many as 25% of patients presenting with radiographically confirmed lacunar infarcts were ultimately found to have other mechanisms of ischemic stroke.⁸² Thus, MRI should be used to confirm or exclude the presence of lacunar infarcts, as well as to screen for nonlacunar mechanisms of stroke.

At present, there is no treatment for lacunar infarcts, but the prognosis is quite good. The survival rate is high, the recurrence rate is low (mean annual stroke rate, 4% to 7%), and patients generally achieve relatively good functional recovery, with as many as 74% experiencing mild or no disability at 1 year.⁸³⁻⁸⁶

Cardiac Embolism

Embolism of cardiac origin accounts for approximately 14% of ischemic strokes [see Table 1]. Given that many infarcts of undetermined cause are probably of cardioembolic origin, this figure may in fact be an underestimate.²² Whereas clinical suspicion for cardioembolism may be high in the setting of acute stroke, confirming the diagnosis can be more difficult. In most instances, cardioembolic stroke can be diagnosed on the basis of the history, the physical examination, and electrocardiography. A number of conditions are known to predispose to cardioembolism, including AF or atrial flutter, recent MI (< 6 weeks old), placement of a prosthetic valve, disease of the aortic or mitral valves, and paradoxical emboli (usually from DVT).⁸⁷ Key clinical manifestations include sudden onset with rapid progression to maximal deficit, infarcts in different arterial territories, rapid regression of symptoms, and decreased consciousness at onset.⁸⁸⁻⁹⁰ Headache and seizure activity are not specific for cardioembolic stroke. The rapid regression of symptoms—also known as the spectacular shrinking deficit (SSD)—is thought to result from rapid recanalization or fragmentation and migration of cardioembolus downstream.⁹¹ Ironically,

the very mechanism purported to result in rapid regression of symptoms may trigger the hemorrhagic transformation seen in as many as 70% of cardioembolic strokes.^{92,93} The vast majority of hemorrhagic transformations are caused by cardioembolism. A 2001 study found that delayed recanalization occurring less than 6 hours after an acute cardioembolic stroke developed in 52.8% of patients and was an independent risk factor for hemorrhagic transformation.⁹³ Other risk factors for such transformation are severe strokes, decreased alertness, and absence of collateral flow.⁹⁴

Atrial fibrillation may or may not be detected on ECG, especially if it is paroxysmal; it remains an elusive but increasingly important risk factor for cardioembolic strokes in older patients.⁹⁵ Holter monitoring and electrophysiologic testing may be especially useful for diagnosing paroxysmal AF.⁹⁶ Likewise, transthoracic echocardiography and transesophageal echocardiography are useful for detecting mural thrombus caused by AF or another cardiomyopathy, as well as for detecting valvular diseases, vegetations, tumors, and patent foramina ovalia.

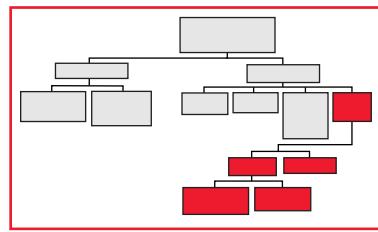

In the presence of nonrheumatic AF, the overall incidence of stroke is nearly five times higher, rising from 1.5% in persons 50 to 59 years of age to 23.5% in those 80 to 89 years of age.⁹⁷ Moreover, data from the International Stroke Trial indicate that mortality is twice as high in patients with AF as in those without AF (17% versus 7.5% at 2 weeks).⁹⁸ It is noteworthy that noncardioembolic strokes are estimated to account for about one third of the strokes that occur in AF patients. A 1997 autopsy study of 82 consecutive patients with symptomatic stroke and nonrheumatic AF demonstrated that 29 (35%) of the infarctions in patients with nonrheumatic AF were in fact of noncardioembolic origin.⁹⁵

As a rule, acute ischemic stroke of cardioembolic origin is best treated with early anticoagulation to prevent recurrent brain embolism. Numerous studies have shown that recurrent embolism to the brain occurs within 2 weeks in 6% to 12% of patients after an initial ischemic infarct from a cardioembolic source.⁹⁹⁻¹⁰¹ A 1999 meta-analysis of 16 AF trials indicated that the overall risk of stroke could be reduced by an average of 62% with anticoagulation.¹⁰² Thus, once a hemorrhagic stroke has been ruled out, heparinization and treatment with warfarin are indicated. Patients with ischemic stroke of cardioembolic origin who are at increased risk for hemorrhage or who have a contraindication to warfarin may be treated with aspirin or another antiplatelet agent; however, such agents are less effective than warfarin in secondary prevention of cardioembolic ischemic stroke.^{103,104} Finally, despite the clear benefits of early anticoagulation in stroke patients with cardioembolism, such therapy has not been shown to be advantageous in the general stroke population.

For patients who suffer ischemic strokes of noncardioembolic origin, warfarin appears to offer no additional benefit over aspirin in preventing stroke recurrence.¹⁰⁵ Furthermore, most authorities would agree that patients with acute ischemic stroke who present within 48 hours of the onset of symptoms should be given aspirin, 160 to 325 mg/day, to reduce mortality and morbidity from stroke.^{106,107}

Atherothrombosis

Roughly 10% of acute ischemic strokes are believed to occur secondary to large-vessel atherosclerosis, thrombosis, or artery-to-artery distal embolization.²² Smoking and age are the most important contributors to the development of carotid atheroma.¹⁰⁸

Unlike cardioembolism, carotid atheroemboli and thrombosis are more likely to be associated with TIAs. Moreover, TIAs of carotid arterial origin tend to occur in the same vascular territory, whereas TIAs of cardioembolic origin are more haphazard in location.^{88,90} Once the history, the physical examination, and brain imaging studies are complete, duplex ultrasonography should be performed to search for extracranial atherosclerosis of the carotid arteries. Duplex examination of the carotid arteries may also identify ulceration and assess plaque echolucency, both of which may increase the level of risk.^{109,110} Other important diagnostic modalities commonly used to assess extracranial sources for atherothrombotic-embolic mechanisms of stroke are magnetic resonance angiography (MRA) and CT angiography. We routinely use these modalities to corroborate the findings of duplex ultrasonography. In patients with carotid arterial stenosis, conventional angiography is usually limited to cases in which duplex ultrasonography disagrees with MRA or CT angiography; in patients with vertebral arterial stenosis, angiography is mandatory before any attempt is made at reconstruction.

Diagnosis of symptomatic carotid artery lesions in the setting of acute ischemic stroke is critical because this subtype of stroke patient stands to benefit significantly from surgical intervention. The results of three prospective randomized trials from the early 1990s comparing medical with surgical treatment of symptomatic carotid arterial stenosis demonstrated that carotid endarterectomy (CEA) had a significant advantage over medical treatment (aspirin).¹¹¹⁻¹¹³ Perhaps the most convincing of the three studies was the North American Symptomatic Carotid Endarterectomy Trial (NASCET), which was terminated prematurely because of the clear superiority of the results in the surgical arm.¹¹¹ In NASCET, the cumulative risk of ipsilateral stroke was 9% with surgical treatment and 26% with medical treatment at 2-year follow-up, for an absolute risk reduction of 17% and a relative risk reduction of 65.4%. Patients with carotid arterial stenosis of less than 50% did not benefit from CEA. Conversely, studies have shown that patients who have a completely occluded carotid artery in the setting of an acute stroke should not undergo CEA either. Emergency CEA in an acutely occluded artery can result in conversion of an ischemic infarct to a hemorrhagic cerebral infarct, with potentially catastrophic results.¹¹⁴

Indications for and Timing of Therapy

SURGICAL THERAPY

Carotid Endarterectomy

CEA [see 6:9 *Carotid Arterial Procedures*] should be performed only when a low (< 5%) morbidity and mortality from stroke can be expected.^{111,115} When a symptomatic patient with moderate or high-grade stenosis presents with TIAs or a mild stroke, the decision to perform a CEA is relatively straightforward. Patients who have suffered devastating infarcts, however, usually are not appropriate surgical candidates. Generally speaking, the extent to which neurologic function is spared, the presence and severity of medical comorbidities, and the patient's life expectancy should all be assessed before the decision is made to embark on CEA.

The timing of CEA after an acute stroke continues to be a subject of controversy. According to some authorities, the risk that an ischemic infarct will undergo hemorrhagic transformation after urgent CEA is a contraindication to early surgery.^{116,117} ICH after endarterectomy is most likely the result of postoperative hyperperfusion. The combination of hypertension (which is common after

stroke) and diminished vasomotor regulation in the penumbra may predispose small vessels in this region to hemorrhage. Other authorities, however, argue that delaying surgery exposes the patient to a substantial risk of recurrent stroke or carotid occlusion and that early intervention is therefore warranted.¹¹⁸ Although it would probably be generally agreed that waiting an obligatory 30 days before surgery is prudent, there are numerous small series in the literature supporting the idea that early CEA after an acute ischemic stroke is indeed safe and may be indicated.^{119,120} Furthermore, documentation of the location and size of the lesions may help identify infarcts that are at increased risk for hemorrhagic transformation after CEA.¹²⁰ Ultimately, the optimal timing of surgery after an acute ischemic stroke must be determined on the basis of prospective, randomized clinical trials.

Stroke in evolution A patient with neurologic deficits that worsen progressively in a stuttering fashion is considered to have a stroke in evolution. This state is associated with the highest level of risk, whether it is treated medically or surgically.¹²¹ A patient with a stroke in evolution should promptly undergo CT to rule out hemorrhagic stroke, followed immediately by systemic anticoagulation with heparin and urgent operation. In a 1981 study of patients with stroke in evolution or crescendo TIAs that compared medical treatment (N=31) with urgent CEA (N=24), nonoperative management of stroke in evolution yielded a significantly higher mortality than surgical management (15% versus 6%).¹²² Furthermore, 70% of the patients who underwent CEA achieved complete or near-complete recovery, compared with 19% of those managed medically.

Carotid Angioplasty and Stenting

In keeping with the continuing growth of minimally invasive surgery, carotid angioplasty and stenting (CAS) has come to play an emerging role in the management of both symptomatic and asymptomatic carotid stenosis [see 6:10 *Carotid Angioplasty and Stenting*]. The advent of neuroprotection techniques using balloon occlusion and aspiration of debris, filter wires placed distal to the culprit lesion, or reversal-of-flow technology has allowed interventionalists to perform CAS more safely, with complication rates approximating those of CEA.^{123,124} Nevertheless, the precise role of carotid artery stenting in treatment or prevention of stroke has not yet been defined. The two primary questions that remain unresolved are (1) which patients benefit most from carotid stenting as opposed to open surgery, and (2) are the immediate and long-term results of CAS as good as those of CEA? Determination of the part CAS will eventually play in the management of cerebrovascular disease awaits the results of ongoing clinical trials comparing CAS with CEA.

Selection of patients Initially, CAS was considered a procedure that would be most beneficial for high-risk patients—for example, patients who were poor surgical candidates because of substantial medical comorbidities and patients with so-called hostile anatomy (such as an extremely high or low bifurcation or a neck that had previously been irradiated or operated on). Indeed, one clear benefit of CAS over CEA is that the risk of nerve injury for patients undergoing the former procedure is 0%. A precise definition of a high-risk patient, however, has proved elusive. One study reviewed CEAs that were performed in 228 patients who, because of their increased level of risk, would not have met the NASCET inclusion criteria.¹²⁵ This study was unable to demonstrate that these supposedly high-risk patients actually had inferior outcomes with CEA. A subsequent study that included more than

13,000 CEAs found that cardiopulmonary comorbid conditions did not increase the risk of perioperative stroke, death, or cardiac events.¹²⁶ Finally, though many investigators have considered patients over the age of 80 (who were ineligible for NASCET and the Asymptomatic Carotid Atherosclerosis Study [ACAS]) to be at increased risk with open surgery, the interim results from the lead-in phase of the Carotid Revascularization Endarterectomy versus Stent Trial (CREST), which is currently in progress, indicated that the risk of periprocedural stroke and death for patients undergoing CAS, surprisingly, was substantially higher (12.1%) in the 99 patients who were over the age of 80.¹²⁷ The reason for this increasing risk in older patients is not clear; the CREST results were not affected by adjustment for potential confounding factors such as symptomatic status, the use of antiembolic devices, gender, the degree of carotid stenosis, or the presence of distal arterial tortuosity.

The goal of reliably predicting which patients may be at high risk with either stenting or open surgery has impelled some investigators to develop risk stratification scales for CAS. A 2006 prospective study of 606 consecutive patients who underwent CAS identified the following independent risk factors: diabetes mellitus with inadequate glycemic control (hemoglobin A_{1c} level > 7%), advanced age (80 years), ulceration of the carotid artery stenosis, and a significant contralateral stenosis (50%). Patients with two or more of these risk factors had an 11% risk of a periprocedural complication, whereas patients with none or only one had a 2% risk.¹²⁸

Assessment of results The results of various clinical trials comparing CAS with CEA, some already completed and some still under way, will help determine whether there is clinical equipoise between the two procedures.^{127,129-133} The SAPPHIRE (Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy) trial randomly compared CAS with CEA in 334 patients with coexisting conditions that potentially increased the risk associated with endarterectomy.¹³⁰ Analysis of 30-day and 1-year outcomes (including death, stroke, and MI) found that CAS was not inferior to CEA. However, the overall risk levels were disturbingly high in both arms of this trial: 12.2% for CAS patients and 20.1% for CEA patients. The CaRESS (Carotid Revascularization using Endarterectomy or Stenting Systems) trial was a multicenter prospective study that compared the two techniques in 397 patients on a nonrandom basis.¹³² The results indicated that both the 30-day risk and the 1-year risk of death, stroke, or MI were essentially the same in CAS patients as in CEA patients. The Carotid And Vertebral Artery Transluminal Angioplasty Study (CAVATAS) randomly assigned 504 patients to the two treatments.¹³¹ The incidence of major stroke or death in the 30 days following the procedure did not differ significantly between the two groups: 6.4% for CAS patients and 5.9% for CEA patients. At 1 year, severe carotid restenosis was noted more frequently in the CAS group (14% versus 4%). Finally, the Stent-supported Percutaneous Angioplasty of the Carotid artery versus Endarterectomy (SPACE) trial randomly assigned 1,200 patients with symptomatic carotid artery stenosis to undergo either CAS or CEA. At 30 days, the incidence of stroke or death was 6.9% in the CAS group and 6.3% in the CEA group.¹³³ The investigators concluded (1) that the results failed to prove the noninferiority of CAS in comparison with CEA and (2) that the results did not justify the widespread use of CAS in the short term for the treatment of carotid artery stenosis.

MEDICAL THERAPY

Thrombolysis

Any patient who presents with an acute ischemic stroke, regardless of subtype, is potentially a candidate for thrombolytic therapy. However, ICH documented on the initial head CT is a clear absolute contraindication to I.V. thrombolysis. Other considerations affecting the decision whether to administer thrombolytic agents include a history of GI or urologic hemorrhage, recent major surgery, and rapidly improving neurologic signs, any of which may constitute a clinical contraindication to medical treatment. Vigilant monitoring of the aPTT, the PT (or the international normalized ratio [INR]), the platelet count, and the fibrinogen level is essential throughout the course of thrombolytic treatment.

It has been suggested that maximal benefit is derived from I.V. thrombolytic therapy for acute ischemic stroke when it is delivered within a "golden 3-hour window" starting from the onset of symptoms. The National Institute for Neurological Disorders and Stroke (NINDS) trial (parts 1 and 2) randomly assigned 624 patients to receive either recombinant tissue plasminogen activator (rt-PA), 0.9 mg/kg I.V. to a maximum of 90 mg/kg, or placebo.¹³⁴ Patients with all types of ischemic stroke were eligible, provided that they could be treated within 3 hours of the onset of symptoms. Outcome at 3 months was better with rt-PA than with placebo on each of the four outcome measures studied. The odds ratio for a favorable outcome in the rt-PA group was 1.7. The overall rate of symptomatic hemorrhage was 6.4% in the rt-PA group and 0.6% in the placebo group. The beneficial effects of rt-PA were similar for all stroke subtypes and persisted for up to 12 months after the stroke.¹³⁵ Patients treated with rt-PA were at least 30% more likely to have minimal or no disability at 12 months than patients treated with placebo were. Mortality at 1 year was comparable in the two groups.

Other randomized, double-blind, placebo-controlled trials of rt-PA for treatment of acute ischemic stroke have examined the effect of thrombolytic therapy given within the first 6 hours after the onset of symptoms. The European Cooperative Acute Stroke Study (ECASS) found no significant differences in functional out-

come measures at 90 days between placebo and rt-PA in an intention-to-treat analysis.¹³⁶ Similarly, the Alteplase ThromboLysis for Acute Noninterventional Therapy in Ischemic Stroke (ATLANTIS) trial reported no benefit in patients treated with rt-PA within 3 to 5 hours of the onset of symptoms.^{137,138} However, patients treated within the golden 3-hour window were more likely to have a favorable outcome at 90 days than patients treated with placebo (60.9% versus 26.3%).

Unfortunately, most patients are ineligible for I.V. rt-PA because of delays in obtaining treatment. Indeed, studies show that only 1% to 2% of ischemic stroke patients receive I.V. rt-PA.^{139,140}

Compared with I.V. thrombolysis, intra-arterial thrombolytic therapy ought, in theory, to be able to deliver a higher local concentration of the agent where it is needed while minimizing the systemic concentration. Proponents of intra-arterial thrombolysis hope that it may lengthen the 3-hour treatment window. The PROACT II trial provided the best evidence to date that intra-arterial thrombolysis can improve patient outcomes.¹⁴¹ This randomized, open-label, multicenter study with blinded follow-up randomly assigned 180 patients with stroke of less than 6 hours' duration to receive either heparin with recombinant prourokinase (r-proUK), 9 mg intra-arterially, or heparin alone. Intra-arterial thrombolysis resulted in significantly better recanalization rates than heparin alone did (66% versus 18%). In addition, more of the r-proUK group had no neurologic deficit or only a slight deficit at 90 days (40% versus 25%). However, intra-arterial thrombolysis did result in significantly increased rates of ICH (35% versus 13%). Symptomatic ICH with neurologic deterioration within 24 hours occurred in 10% of r-proUK patients and 2% of control patients. Patients who experienced ICH after r-proUK therapy had a high mortality (83%).¹⁴² It is noteworthy that only 2% (180/12,333) of the screened patients in the PROACT II trial were randomized according to inclusion criteria, which suggests that intra-arterial thrombolysis may be of limited applicability. Finally, intra-arterial thrombolysis requires an experienced staff capable of performing cerebral angiography and navigating a microcatheter to the clot. At present, I.V. thrombolysis is certainly more practical than intra-arterial thrombolysis; more important, it can be done earlier in the course of the stroke.

2 ASYMPTOMATIC CAROTID BRUIT

Claudio S. Cinà, M.D., Sp.Chr. (It.), M.Sc., F.R.C.S.(C), Catherine M. Clase, M.B., B.Chr., M.Sc., and Aleksandar Radan, M.D., B.Sc., B.F.A.

Assessment of Asymptomatic Carotid Bruit

The term bruit refers to any noise detected on auscultation in the neck. The conventional method of auscultation is to use the bell of the stethoscope and listen over an area extending from the upper end of the thyroid cartilage to just below the angle of the jaw.¹⁻³ The principal reason why bruits in the neck are matters of some concern is that they may reflect underlying occlusive carotid artery disease, which carries an increased risk of stroke.

In what follows, we outline a problem-oriented approach to the workup of patients found to have cervical bruits at the time of routine or focused vascular examination.

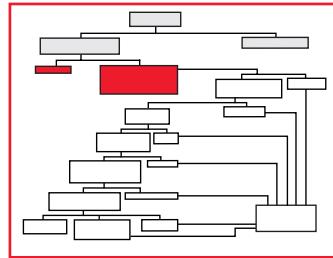

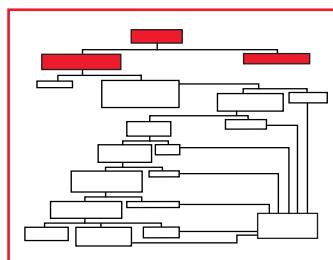

Clinical Evaluation

CAROTID BRUITS VERSUS OTHER CERVICAL SOUNDS

Clinical assessment begins with evaluation of the character of the bruit and examination of the precordium and the cervical structures. Carotid bruits must be distinguished from other sounds heard in the neck. Venous hums are relatively common, being reported in 27% of young adults.⁴ They tend to have a diastolic component, are louder when the patient sits or turns the head away from the side of auscultation, and disappear when the patient lies down or when the Valsalva maneuver is performed.⁴ Ejection systolic murmurs of cardiac origin may radiate into the neck, but generally, they are bilateral, are louder within the chest, and are less audible distally in the neck⁵; the same is true of bruits arising in other intrathoracic vessels.^{6,7} No definitive clinical sign has yet been identified that clearly differentiates bruits from transmitted cardiac murmurs. On occasion, a bruit may be heard over the thyroid gland; however, this finding is extremely rare and is usually accompanied by thyromegaly and other features of autoimmune thyroid disease.⁵ In dialysis patients, a bruit may be generated by the increased flow resulting from the creation of an arteriovenous fistula in the forearm.⁸

SYMPTOMATIC VERSUS ASYMP-TOMATIC CAROTID BRUITS

Transient ischemic attacks (TIAs) are defined as brief episodes of focal loss of brain function that can usually be localized to a specific portion of the brain supplied by a single vascular system.⁹ By arbitrary convention, such an ischemic episode is considered a TIA if it lasts less than 24 hours; a similar episode, in the absence of evidence of trauma or hemorrhage, is considered an ischemic stroke if it lasts more than 24

hours or causes death.⁹ Amaurosis fugax is a transient (< 24 hours) loss of vision in one eye or a portion of the visual field.⁹ If a patient with a carotid bruit has a history of any of these conditions in the ipsilateral eye or brain, then the bruit is regarded as neurologically symptomatic, and the relevant question at that point is whether the patient has significant carotid stenosis and may be a candidate for carotid endarterectomy on that basis. Given the substantial differences between the management of patients with symptomatic bruits and those with asymptomatic bruits, the distinction between these two patient groups is crucial.

The history is of critical importance in the diagnosis of TIA because most TIAs last less than 4 hours,¹⁰ which means that patients typically are not seen by physicians during the period of neurologic deficit.¹¹ Patients should be specifically asked about transient focal problems with vision, language, facial paresis, dysarthria, and arm or leg numbness or weakness. A 1984 study reported good interobserver agreement ($\kappa = 0.65$) [see Table 1] between clinicians diagnosing previous ischemic episodes.¹² Assigning a probable neurologic territory to a TIA or stroke, however, proved more difficult: for TIAs, the interobserver agreement between two independent neurologists asked to distinguish between carotid and vertebrobasilar events was relatively poor ($\kappa = 0.31$).¹² There is some evidence that using a standardized protocol for the diagnosis of previous ischemic episodes might improve this low interobserver agreement (e.g., to $\kappa = 0.65^{12}$ or $\kappa = 0.77^{13}$). Similar difficulties attend diagnosis of stroke by means of history and physical examination.¹⁴

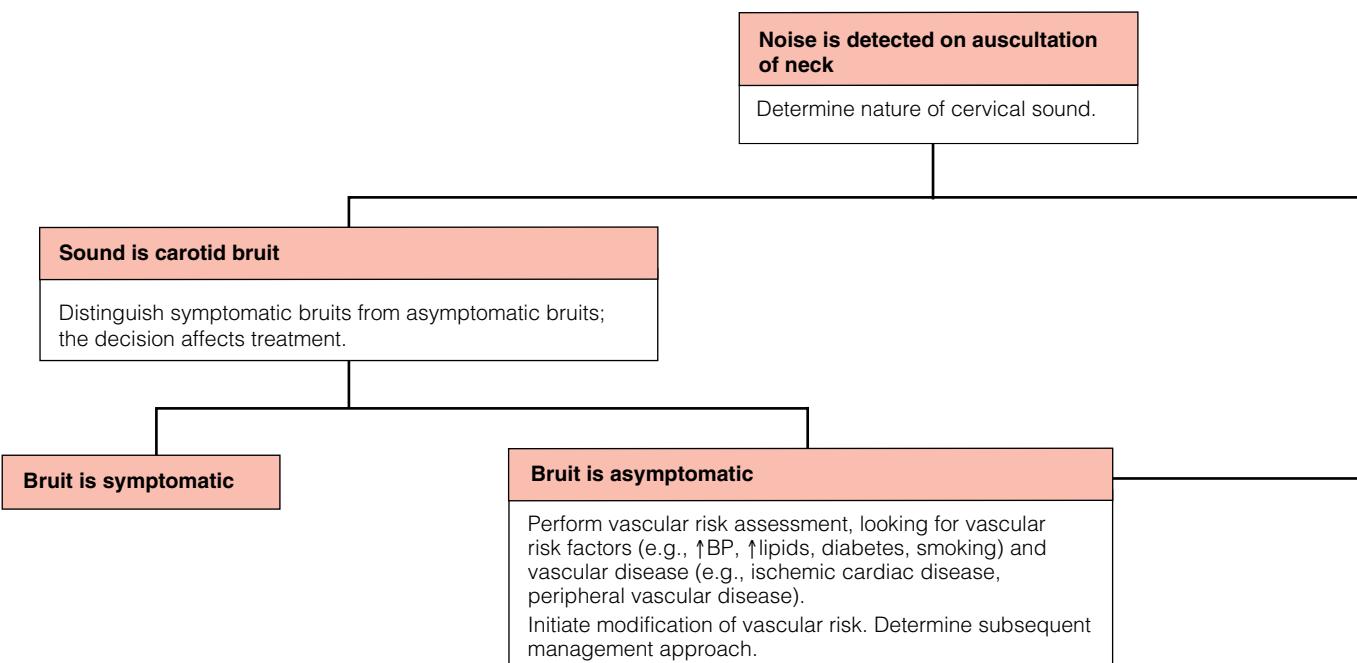

Many patients with a possible TIA or stroke will have undergone neurologic imaging. Such imaging is unhelpful if it yields negative results; however, in some cases, it reveals the presence of an infarct, thereby confirming the ischemic nature of the event and establish-

Table 1 Quantification of Interobserver Agreement*

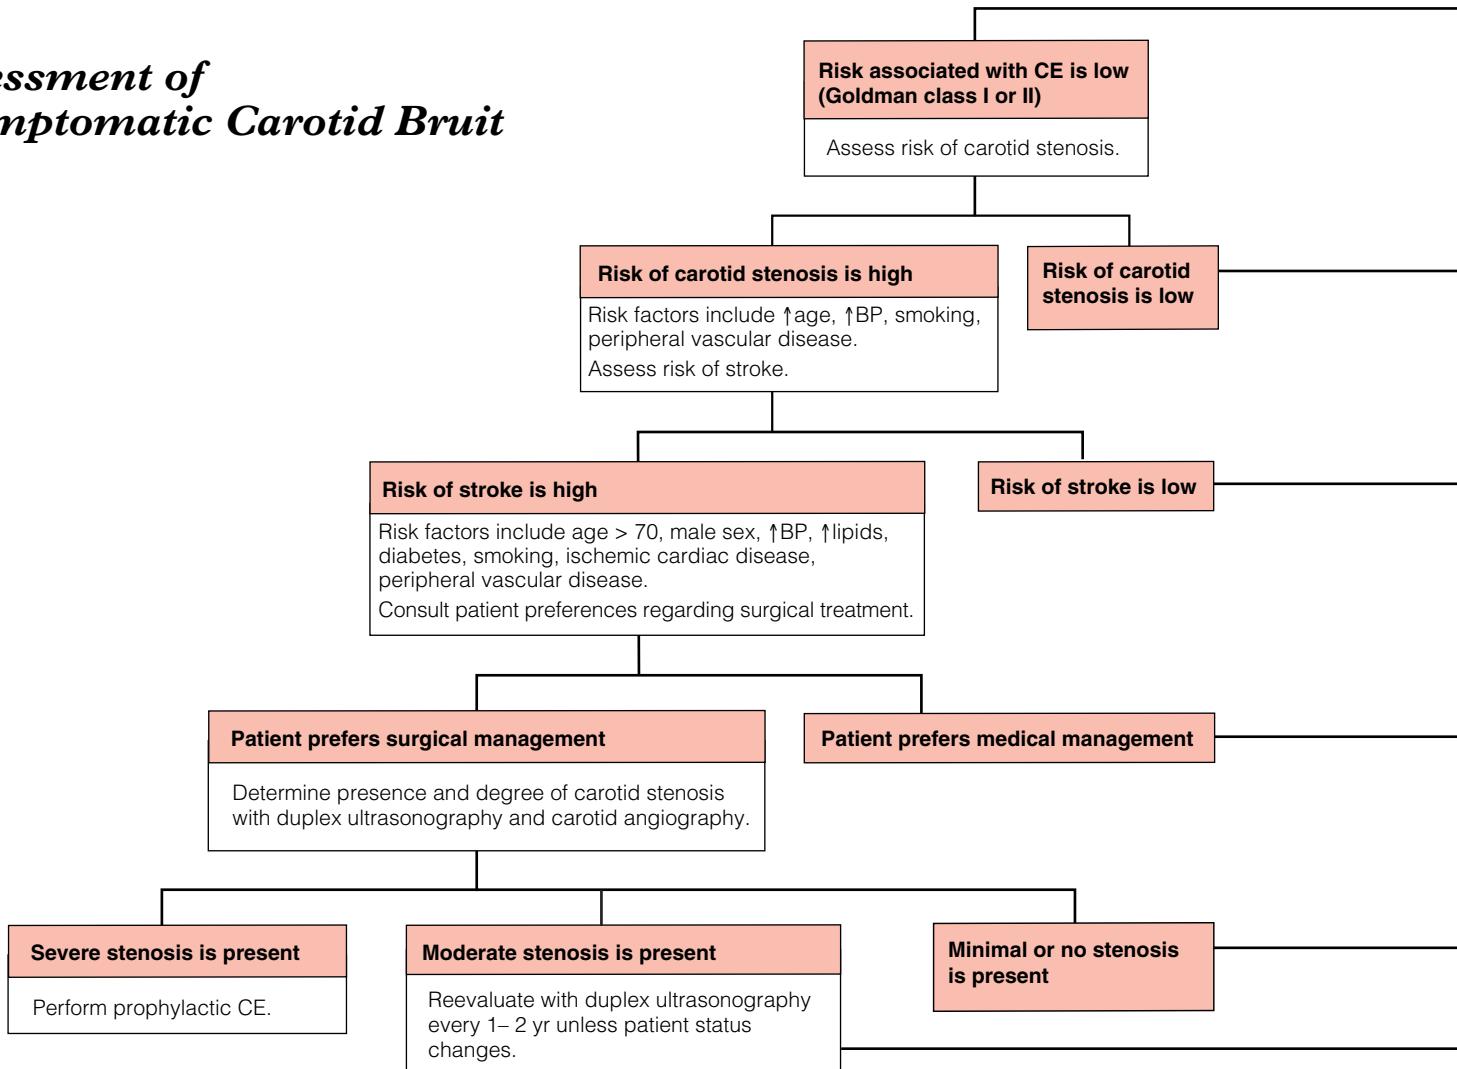

κ^{\dagger}	Strength of Agreement
≤ 0.2	Poor
$> 0.2, \leq 0.4$	Fair
$> 0.4, \leq 0.6$	Moderate
$> 0.6, \leq 0.8$	Good
$> 0.8, \leq 1$	Very good

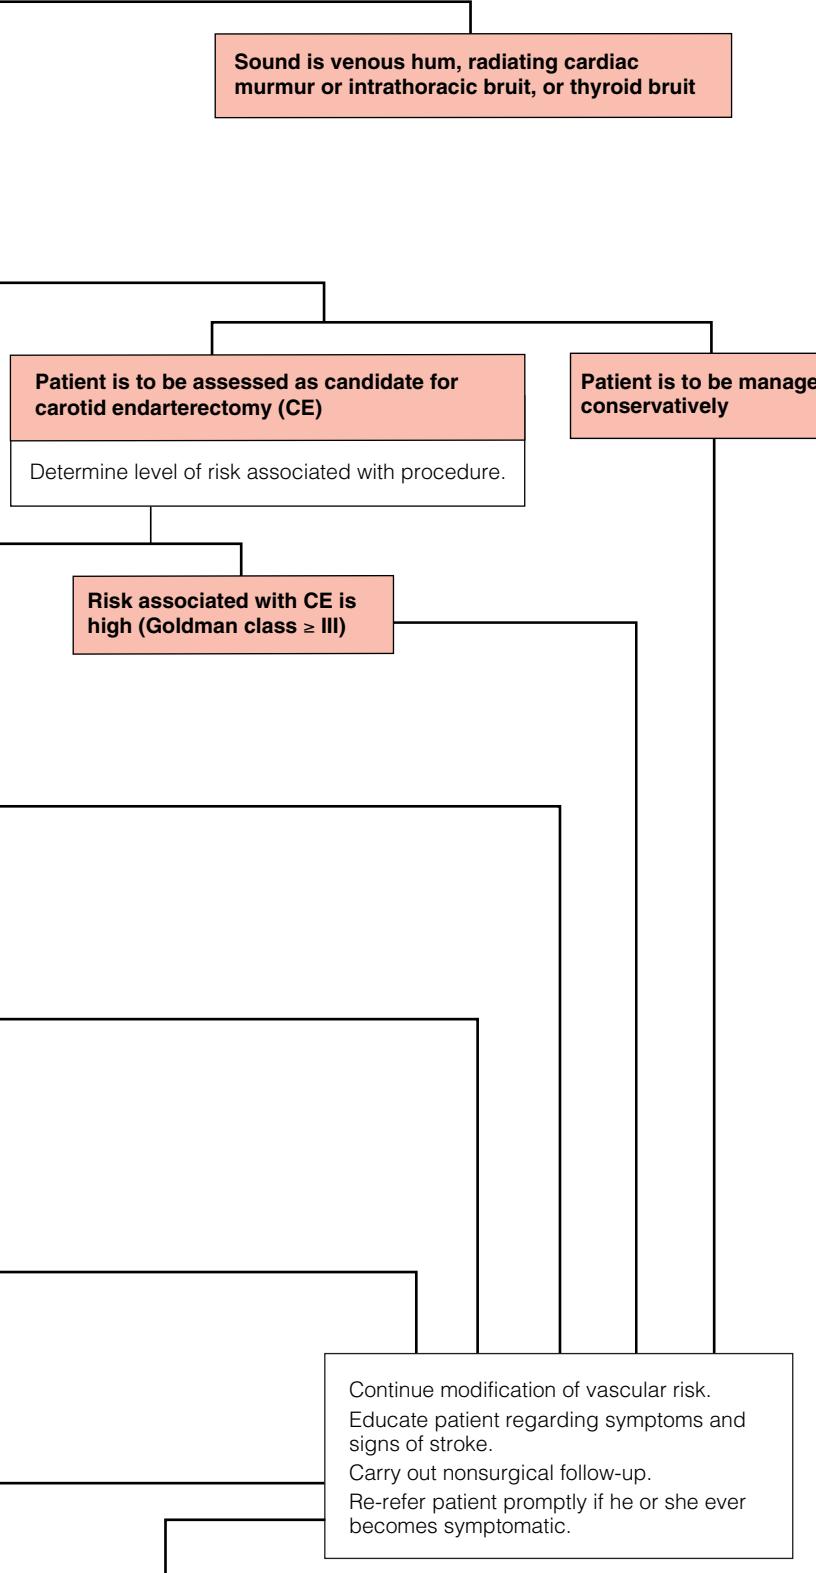

*Reliability (how closely an assessment agrees with another similar assessment on a second occasion or by a second observer) and validity (how closely the assessment agrees with another criterion or a gold standard) are the key properties of any assessment. When agreement between two observers is poor, the assessment in question, whether it is a physical finding, a clinical diagnosis, or an interpretation of a diagnostic test, is lacking in reliability; if more reliable methods are available, they should be considered instead. In clinical medicine, however, more reliable methods are not always available. When this is the case, the physician must use a relatively unreliable assessment as the best available alternative, while remaining aware of its limitations.^{11B}

[†] κ is a statistical measure used to quantify agreement between two or more observers. It takes a value between 0 and 1, where 0 represents agreement no better than that expected by chance alone and 1 represents perfect agreement.^{11B}

Assessment of Asymptomatic Carotid Bruit

ing its location. For a bruit to be regarded as symptomatic on the basis of imaging studies, at least one infarct must be seen in the appropriate ipsilateral anterior vasculature.

It is evident that distinguishing between symptomatic and asymptomatic bruits on clinical grounds may be difficult; nonetheless, it is worthwhile to make the effort because the risk of stroke in the asymptomatic population is quite different from that in the symptomatic population. For example, whereas the Asymptomatic Carotid Atherosclerosis Study (ACAS), which included patients believed on clinical grounds to be neurologically asymptomatic, reported an overall stroke rate of 6.2% at 2.7 years in its medically managed group,¹⁵ the North American Symptomatic Carotid Endarterectomy Trial (NASCET), which included patients assessed as neurologically symptomatic (i.e., with a history of amaurosis fugax, TIA, or minor stroke), reported a stroke rate of 26% at 3 years in its medically managed group.¹⁶

In determining whether a unilateral bruit is symptomatic or asymptomatic, the physician should concentrate primarily on ischemic deficits in the ipsilateral hemisphere (i.e., those causing focal contralateral motor or sensory deficits) and ipsilateral amaurosis fugax. However, symptoms referable to the contralateral carotid artery, even if no bruit is heard on that side, might prompt evaluation of the patient for symptomatic carotid stenosis on the contralateral side. The absence of a bruit by no means excludes the diagnosis: carotid bruits are absent in 20% to 35% of patients with high-grade stenosis of the internal carotid artery.¹⁷ In the NASCET subgroup in which the physical finding of a carotid bruit was compared with angiographic imaging of the carotid system, the presence of a focal ipsilateral carotid bruit had a sensitivity of 63% and a specificity of 61% for high-grade (70% to 99%) stenosis; the absence of a bruit did not significantly change the probability of significant stenosis in this population (pretest 52%, posttest 40%).¹⁸

Workup of patients with symptomatic bruits is beyond the scope of this chapter. Accordingly, the ensuing discussion focuses on assessment of patients with asymptomatic bruits.

VASCULAR RISK ASSESSMENT

Vascular diseases and other vascular risk factors are common in patients with asymptomatic carotid bruits. Hypertension is twice as common in patients who have bruits as in those who do not;¹⁹ smoking, ischemic heart disease, and peripheral vascular disease are also more prevalent.^{20,21} Consequently, detection of a bruit should prompt a thorough vascular risk assessment. Standard vascular risk factors—hypertension, hyperlipidemia, diabetes, and smoking—can be integrated into risk profiles for particular patients by using either the New Zealand risk tables (http://www.nzgg.org.nz/library/gl_complete/bloodpressure/appendix.cfm) or the formula and spreadsheets provided by Anderson et al.^{22,23} The probability of stroke for various follow-up periods may be quantified by using the Framingham stroke-risk profile.²⁴ From age, systolic blood pressure, diabetes, smoking, cardiovascular disease, atrial fibrillation, and left ventricular hypertrophy, probability of stroke may be calculated for men and women according to a point system.²⁴

Smoking cessation should be recommended to all patients,^{25–27} and hypertension should be controlled (BP < 140/90).^{28–31} Depending on a patient's individual risk profile, dietary and pharmacologic management of hyperlipidemia may also be warranted.^{32–34} Diabetic control should be optimized.^{35,36}

Patients should be asked specifically about any concurrent vascular disease—in particular, symptoms suggestive of ischemic heart disease or of claudication or rest pain. In patients with established vascular disease, the risk that future vascular events (e.g., coronary-related death, myocardial infarction [MI], new angina, stroke, TIA, new con-

Table 2 Annual Risk of Stroke

Patient Population	Annual Risk of Stroke
Population without bruits, age > 60 yr ^{19,43,44}	0.86% (95% CI, 0.8–0.9)
Population with bruits, age > 60 yr ^{19,20,43}	2.1% (95% CI, 0.6–8.5)
Male population without bruits, age > 60 yr ^{19,24}	0.9% (95% CI, 0.1–3.0)
Male population with bruits, age > 60 yr ¹⁹	8.0% (95% CI, 0.2–38.0)
Female population without bruits, age > 60 yr ²⁴	2.0% (95% CI, 0.8–4.2)
Female population with bruits, age > 60 yr ¹⁹	2.4% (95% CI, 0.7–5.5)

gestive heart failure, or peripheral vascular syndrome) will occur in the next 5 years is greater than 20%.^{22,37} In such patients, consultation of formulas or tables is unnecessary, and all modifiable risk factors should be aggressively managed (target BP < 140/90; target ratio of total cholesterol to high-density lipoprotein [HDL] cholesterol < 4).²²

A meta-analysis of randomized, controlled trials showed that aspirin reduced the risk of subsequent stroke, MI, and death from vascular events for patients who had previously experienced a cerebrovascular event, MI, or unstable angina.³⁸ Other meta-analyses of randomized, controlled trials^{39,40} were unable to confirm the effectiveness of aspirin in preventing cerebrovascular events in asymptomatic patients or in patients with TIAs or strokes of noncardiac (and presumably vascular) origin⁴¹; however, one randomized, controlled trial involving hypertensive patients at modest vascular risk found that aspirin reduced the risk of vascular events, if not the risk of stroke.⁴² In the absence of contraindications, we recommend that aspirin be considered for all patients who have established vascular disease elsewhere and for all patients who have a bruit in association with any vascular risk factors.

INDICATIONS FOR SURGICAL INTERVENTION

The absolute risk of stroke is increased in the presence of a carotid bruit. In population-based studies, the annual risk of stroke was 2.1% (95% confidence interval [CI], 0.6 to 8.5)^{19,20,43,44} for persons who had a carotid bruit and 0.86% (95% CI, 0.8 to 0.9) for those who did not.^{19,43,44} These figures represent an absolute risk increase for stroke of 1.24% a year and a relative risk for stroke of 2.4. The mean patient age in these studies was approximately 65 years, and sex distribution and prevalence of risk factors for atherosclerotic disease were similar in patients with bruits and those without bruits. Even after adjustment for age, sex, and the presence of hypertension, the presence of a carotid bruit remained an independently significant variable, with a relative risk of 2.0.¹⁹

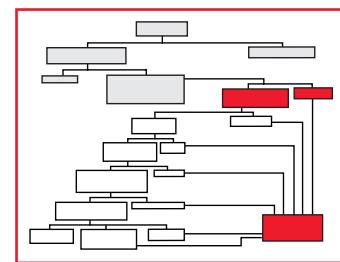

Table 3 Prevalence of Carotid Stenosis in Patients with Bruits and in Healthy Volunteers

Patient Population	Prevalence of Carotid Stenosis
Overall population with cervical bruits	
> 35% stenosis ^{20,56–58,119}	58% (95% CI, 55–60)
> 60%–75% stenosis ^{56–58}	21% (95% CI, 18–24)
Healthy volunteers*	
Age > 70 yr ⁸⁹	5.1% (95% CI, 2.6–9.0)
Age ≤ 70 yr ⁸⁹	1.5% (95% CI, 0.2–5.3)

*In healthy volunteers, the incidence of asymptomatic carotid stenosis is significantly correlated with age ($P < 0.01$) and with the presence of hypertension ($P < 0.005$).

Table 4 Necessary Criteria for Offering an Interventional Approach to Selected Patients with Carotid Bruits

Center-specific criteria

Either

DUS is documented to have a > 90% PPV for stenosis > 50% on angiography and is used alone

or

DUS has a lower PPV and is used as a screening test only, and angiography in patients with cerebrovascular disease has a documented complication (stroke or death) rate of around 1%

Surgeon-specific criterion

Perioperative rate of stroke or death is < 3% for carotid endarterectomy

DUS—duplex ultrasonography PPV—positive predictive value

Given the low absolute risk of stroke in asymptomatic patients with bruits [see Table 2], the low prevalence of surgically relevant stenosis in patients with bruits [see Table 3], and the small (and only marginally statistically significant) absolute benefit of carotid endarterectomy in patients with asymptomatic stenosis,^{45,46} we and others^{47–51} do not believe that further investigation with a view to carotid endarterectomy is mandatory in the asymptomatic population. Many surgeons may prefer to manage these patients conservatively, reevaluating them promptly if they become symptomatic [see Discussion, below]. Other surgeons may wish to pursue a more interventional strategy with selected patients, in which case further evaluation with an eye to surgical treatment depends on the presence of the following key findings in a given patient: (1) low risk associated with carotid endarterectomy, (2) relatively high risk of carotid stenosis, and (3) high risk of stroke if carotid stenosis is documented. In addition, the patient's preferences should be consulted: no patient should be subjected to further evaluation who is not prepared to undergo surgical treatment if such management is recommended. Patients who, on the basis of any of these criteria, are not suitable candidates for intervention will not benefit from imaging studies and should be managed medically.

Finally, surgeons and centers who are contemplating offering prophylactic carotid endarterectomy for asymptomatic stenosis should be able to document that their rates of stroke or perioperative death for this procedure are lower than 3% [see Table 4]. When complication rates exceed this threshold, the value of carotid endarterectomy becomes negligible, and surgeons may find themselves doing more harm than good.^{45,46}

Low Risk Associated with Carotid Endarterectomy

In NASCET and ACAS, patients were excluded if they had coexisting medical disease likely to produce significant mortality and morbidity (e.g., cardiac valvular or rhythm disorders, uncontrolled hypertension or diabetes, unstable angina pectoris, or MI in the previous 4 months)¹⁶; accordingly, the results of these trials are not generalizable to patients who have such conditions. Further evidence for the impact of operative risk on outcomes is provided by a retrospective review of 562 patients who underwent carotid endarterectomy for symptomatic and asymptomatic disease in a large community hospital.⁵² For patients in Goldman class I or II,⁵³ the overall rate of death or

nonfatal MI was 2% (95% CI, 1.1 to 3.9), whereas for patients in class III or IV, the corresponding figure was 21% (95% CI, 9.2 to 39.9) [see Table 5]. Given that 50 prophylactic carotid endarterectomies would have to be performed to prevent one stroke over the subsequent 3-year period (i.e., the number needed to treat [NNT] is 50), it is clearly unacceptable to perform this procedure in a population facing a 21% incidence of MI or death, in which for every 5 patients undergoing the operation, one would experience an MI or die (i.e., the number needed to harm [NNH] is only 5). Further consideration of prophylactic carotid endarterectomy in patients for whom the procedure carries a high risk is not warranted.

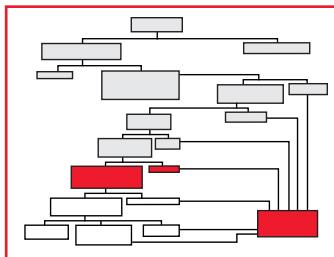

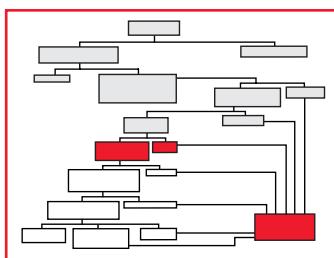

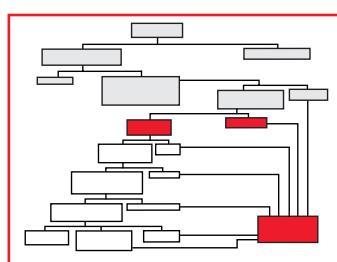

High Risk of Carotid Stenosis

Cohort^{45,54–60} and population-based^{19,61,62} studies suggest that patients with asymptomatic carotid bruits are more likely to have significant carotid stenosis if they are older, are hypertensive, smoke, or have advanced peripheral vascular disease. In one study, hemodynamically significant stenosis (i.e., > 50%) was found by means of ultrasonography in 32% of patients scheduled to undergo peripheral vascular procedures but in only 6.8% of those scheduled to undergo coronary artery bypass grafting (CABG).⁶³ (All figures for degree of stenosis in this chapter are determined according to the formula used in NASCET [see Table 6 and Figure 1].)

Further consideration of carotid endarterectomy may be warranted in patients with vascular risk factors or known peripheral vascular disease; in the absence of these findings, the risk of significant carotid stenosis is low. Further evaluation is unnecessary for patients who are younger, do not smoke, are not hypertensive or diabetic, and are not known to have peripheral vascular disease.

High Risk of Stroke

Within the group of patients with asymptomatic carotid stenosis, there is only limited direct evidence for the existence of subgroups of patients at higher risk for stroke. Men seem to be at higher risk for stroke than women are: in the medical arm of ACAS, the incidence of stroke or death at 2.7 years was 7.0% (95% CI, 4.9 to 9.4) for men and 4.9% (95% CI, 2.7 to 8.0) for women. Gender-related differences aside, however, identification of other subgroups at higher risk relies on extrapolation of data from other populations at risk for artery-to-artery embolism. Data from NASCET indicate that for symptomatic patients with greater than 70% carotid stenosis, the presence of a higher number of identifiable clinical risk factors (age > 70 years; male sex; systolic or diastolic hypertension; the occurrence of a cerebrovascular event within the preceding 31 days; the occurrence of a more serious cerebrovascular event, namely, stroke rather than a TIA or amaurosis fugax; smoking; MI; congestive heart failure; diabetes; intermittent claudication; or hyperlipidemia) was associated with a higher annual stroke risk. For patients with zero to three risk factors, the annual stroke risk was 6.6%; for those with four or five, 9.2%; and for those with six or more, 15.8%. Data from the same study indicate that among patients with a contralateral asymptomatic stenosed carotid artery, patients with zero to three risk factors have an annual stroke risk of 1.4% in the territory of the asymptomatic stenosis; those with four or five, 2.8%; and those with six or more, 3.8%.⁶⁴

Obesity is another risk factor for stroke.^{49,50} Some 60% of patients who experience a stroke before 65 years of age have a body mass index greater than 24 kg/m².⁴⁹ This finding, in conjunction with a history of smoking, was found to predict 60% of strokes in men in this age group.⁵⁰

Patients with carotid bruits who do not have significant systemic risk factors or other vascular disease are at low absolute risk for stroke and are unlikely to benefit from carotid endarterectomy; hence, further investigation is not warranted.^{5,18,49} Patients with numerous (i.e., six or more) clinical risk factors [see Table 7] are at relatively high risk for stroke, and it is in this population that most of the benefit from carotid endarterectomy is likely to be concentrated.

Patient Preference for Surgical Intervention

Before pursuing the diagnosis of carotid stenosis with imaging techniques, the surgeon must discuss prophylactic surgical intervention with the patient. The essential question is, if significant stenosis is documented, will the patient wish to undergo carotid endarterectomy? It should be remembered that at this point in the workup, we are considering only those patients (1) for whom the cardiac risk associated with the procedure is acceptably low and (2) who are considered to be at relatively high risk for stroke if carotid stenosis is demonstrated.

Patients should be informed that if they are found to have significant carotid stenosis, their risk of stroke is 6.3% over the ensuing 2.7 years if they do not undergo operation and 4.0% over the same period if they do.¹⁵ They should also be informed that these figures take into account a 3% risk of perioperative stroke or death (2.7% risk of stroke and 0.3% risk of death).¹⁵ The 2.3% absolute risk reduction associated with surgical treatment translates into an NNT of 43, meaning that 43 patients would have to undergo endarterectomy to prevent one stroke over the next 2.7 years.

Given the front-loaded risks of surgery, some patients will prefer a simple risk-modification strategy to a strategy including both risk modification and surgical intervention. In such cases, carotid imaging is not necessary, because knowledge of the degree of stenosis will not affect subsequent management.

Investigative Studies

The purpose of investigation of asymptomatic neck bruits is to identify persons with significant carotid stenosis who are at increased risk for cerebrovascular disease^{65,66} and who are likely to benefit from carotid endarterectomy. In the absence of other significant findings, cervical bruits are not sufficiently predictive of significant carotid stenosis or ischemic stroke to be useful in selecting candidates for noninvasive imaging.⁵¹ Noninvasive testing is a reasonable step in patients with the characteristics listed above, but routine screening of all patients with asymptomatic carotid bruits is not warranted.⁵¹

DUPLEX ULTRASONOGRAPHY

Duplex ultrasonography (DUS) should be performed bilaterally. A meta-analysis conducted in 1995 found that for detecting greater

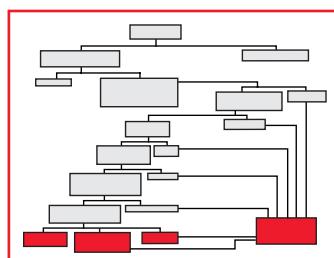

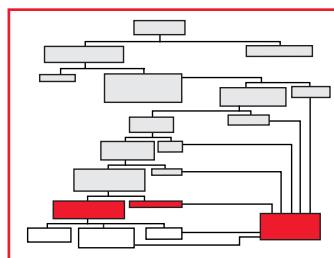

Table 5 Cardiac Risk Assessment*

Risk of Perioperative Cardiac Events

Low	0–12 (class I, II)	0–15	0
Intermediate	13–25 (class III)	16–30	1–2
High	> 25 (class IV)	> 30	≥ 3

*The Goldman cardiac risk index⁵³ is a multifactorial index of cardiac risk in patients undergoing noncardiac surgery. Modifications have been proposed by Detsky,^{121–123} who included angina and institution-specific perioperative cardiac event rates in the model. The Eagle index^{124–126} is another risk index based on five clinical variables. Despite the lack of consensus regarding the relative merits of these tools for preoperative cardiac risk assessment, stratification of patients into risk categories is helpful in assessing the risk and benefits of a procedure such as carotid endarterectomy.

†P_aO₂ < 60 mm Hg; P_aCO₂ > 50 mm Hg; K⁺ < 3 mmol/L; serum HCO₃ < 20 mmol/L; serum urea > 18 mmol/L; creatinine > 260 µmol/L; abnormal ALT; signs of chronic liver disease; bedridden from cardiac causes.

CHF—congestive heart failure MI—myocardial infarction PVC—premature ventricular contraction

than 50% stenosis (determined by means of angiography, the gold standard), DUS had a sensitivity of 91% (95% CI, 89 to 94) and a specificity of 93% (95% CI, 88 to 95).⁶⁷ Given a disease prevalence of approximately 41% in patients referred for DUS, these findings translate into a positive predictive value of 90% and an accuracy of 92%.⁶⁷ A subsequent prospective study of patients (both symptomatic and asymptomatic) in whom carotid endarterectomy was being considered reported a sensitivity of 100% and a specificity of 98% for greater than 60% stenosis, with a positive predictive value of 99%.⁶⁸

At centers where DUS has been internally validated in comparison with angiography and where this level of performance has been documented, the surgeons may choose to proceed to surgery without angiography.^{68–70} At centers where DUS is less reliable, however, it should be regarded as a screening test, and angiography should be performed when DUS suggests greater than 50% stenosis.

CAROTID ANGIOGRAPHY

As an invasive procedure, carotid angiography carries a significant risk of morbidity and mortality. All centers performing carotid angiography for cerebrovascular disease should audit their stroke rates

Table 6 Conversion between Different Methods of Measuring Degree of Carotid Stenosis

Method	Severity of Disease			
	Minimal	Moderate	Severe	Occlusion
ECST*	24%–57%	58%–69%	70%–81%	82%–99%
NASCET	0%–29%	30%–49%	50%–69%	70%–99%
CC method†	35%–56%	57%–61%	62%–80%	81%–99%

*Conversion from ECST to NASCET was done according to the following formula: ECST % stenosis = 0.6(NASCET % stenosis) + 40.¹²⁷

†The relation of the NASCET method to the CC method is linear, with a ratio of 0.62 between the distal internal carotid diameter and the common carotid diameter.¹¹⁷

periodically. Since 1990, four prospective studies^{71–74} have addressed the question of the risks associated with angiography in patients with atherosclerotic cerebrovascular disease. When the data from these studies were pooled, the risk of permanent neurologic deficit or death was 1.1% (95% CI, 0.6 to 2.0).⁷⁵ In ACAS, the 1.2% of patients in the intervention arm who experienced stroke or died after angiography accounted for 40% of the strokes and deaths attributable to surgical intervention.¹⁵ Angiographic complication rates significantly worse than these will adversely impact the risk-benefit ratio associated with surgical intervention. Centers that consistently record relatively high angiographic complication rates should not offer evaluation for and surgical treatment of asymptomatic carotid disease.

Management

CAROTID ENDARTERECTOMY

At this point in management, it is reasonable to offer surgical treatment of asymptomatic disease to patients with greater than 50% stenosis. ACAS¹⁵ and two meta-analyses^{45,46} that included other trials of surgical therapy for asymptomatic carotid stenosis documented a small and marginally statistically significant benefit from prophylactic carotid endarterectomy in asymptomatic patients with greater than 50% to 60% carotid stenosis. Because the absolute benefit is small, we do not consider it obligatory to pursue the diagnosis or to follow an invasive strategy in patients identified solely on the basis of an asymptomatic bruit; however, patients possessing all the characteristics listed earlier [see Indications for Surgical Intervention, *above*] probably constitute a group that is particularly able to benefit from surgical intervention. Patients with higher degrees of stenosis are at higher risk for stroke and are therefore most likely to benefit.^{76–79}

The degree of stenosis and the presence or absence of plaque ulceration may modify the final decision for or against operative management [see Discussion, Subgroup Analyses for Potential High-Risk Factors, *below*].

In May 2004, the United Kingdom Medical Research Council Asymptomatic Carotid Surgery Trial (ACST) collaborative group reported the results of a prospective, randomized trial of carotid endarterectomy in asymptomatic patients.⁸⁰ More than 3,000 patients were randomly assigned either to undergo immediate carotid endarterectomy or to be placed on indefinite deferral. In the patients referred for immediate carotid endarterectomy, one half underwent endarterectomy within 1 month of referral; 88% underwent endarterectomy within 1 year. Combining the rate of perioperative events and nonperioperative strokes, the 5-year results indicate a stroke rate of 6.4% in the group undergoing immediate carotid endarterectomy, as compared with 11.8% in the deferral group. These findings are strikingly similar to the ACAS findings. However, the ACST found a similar benefit for women. In addition, in the ACST, no difference was found in the degree of stenosis and the benefit of surgery—an interesting observation, because one would expect that

greater degrees of stenosis would be associated with greater risk of stroke. This finding may be explained either by the fact that duplex ultrasound was the sole imaging criterion or that plaque morphology plays a greater role in determining stroke risk than degree of stenosis. Furthermore, unlike previous studies, many of the patients in the ACST were receiving lipid-lowering drugs and other antiplatelet agents. As Barnett pointed out in his discussion of the ACST article, the perioperative stroke rate must be low for the results of this study to be generalized.⁸¹ In the ACST, the risk of stroke or death within 30 days of undergoing carotid endarterectomy was 3.1%.

Technical details of carotid endarterectomy are discussed elsewhere [see 6:9 *Carotid Arterial Procedures*].

PATIENT EDUCATION

All patients with asymptomatic carotid bruits, whether they are undergoing prophylactic endarterectomy or not, should be carefully advised regarding the symptoms and signs of stroke, TIAs, and amaurosis fugax and should be strongly encouraged to seek urgent medical attention if such problems arise. Patients who experience one of these untoward events should undergo full reevaluation for stroke risk factors (e.g., hypertension, hyperlipidemia, diabetes, smoking, and atrial fibrillation); in the absence of atrial fibrillation (which

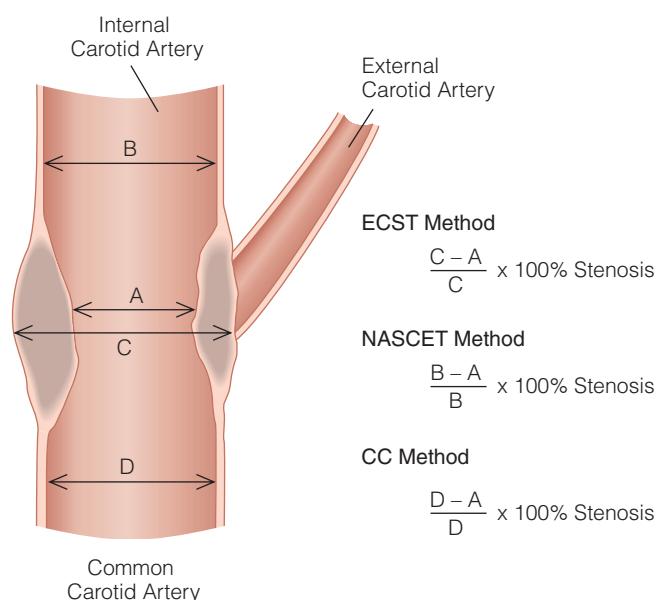

Figure 1 Carotid angiography remains the gold standard for determining the extent of carotid arterial disease. Several methods of reporting angiographically defined stenosis have been described in the literature.¹¹⁵ The most commonly used methods are those adopted by the NASCET and ECST investigators, though the so-called common carotid (CC) method has its advocates as well.^{116,117}

Table 7 Risk Factors for Stroke^{128,129}

Age > 70 yr	Smoking (or history of smoking)
Male sex	> 80% carotid stenosis
Hypertension*	Presence of ulceration
Hyperlipidemia	Ischemic heart disease†
Diabetes	Peripheral vascular disease

†MI or CHF.

should prompt consideration of prophylactic anticoagulation⁸²⁻⁸⁴), a change in antiplatelet therapy should be considered. Both ticlopidine⁸⁵ and clopidogrel⁸⁶ are more effective than aspirin in preventing stroke. (Ticlopidine is associated with reversible but severe neutropenia in fewer than 1% of cases; accordingly, monitoring for this complication is indicated.)

If a patient who is a surgical candidate experiences a TIA or stroke as a result of an ischemic event in the carotid region in the absence of atrial fibrillation, he or she must be promptly referred back to the vascular surgeon. This possibility should be clearly explained to patients once the initial evaluation is complete and they have been referred back to their primary care physicians. Patients referred back to a vascular surgeon under these circumstances should then be regarded as having symptomatic carotid disease. A subgroup analysis of patients with symptomatic stenosis reported that carotid endarterectomy performed soon after a nondisabling stroke was not associated with a significantly higher operative complication rate than endarterectomy performed 30 days or longer af-

ter a stroke.⁷⁵ Performing endarterectomy early reduces the risk period for recurrent stroke and may therefore increase the potential benefit of the intervention; the usual approach is to perform the procedure within a week or two of a patient's first neurologic event.

Management of cardiovascular risk factors and concurrent vascular disease should continue. In the absence of concurrent vascular disease, patients may be referred back to the family practitioner, internist, or cardiologist in place of specific surgical follow-up.

FOLLOW-UP OF PATIENTS WITH LOWER-GRADE STENOSIS

Carotid stenosis progresses in about one quarter of patients with asymptomatic carotid stenosis monitored with DUS over a 2-year period.⁸⁷ In a population of asymptomatic patients with bruits who were referred to a vascular laboratory, 282 stenotic carotid arteries (average stenosis, 50%) were followed for 38 ± 18 months. Progression of stenosis, defined as an increase in degree of stenosis to 80% or beyond, occurred in 17% of arteries, and 2% became completely occluded. Progression was associated with an increase in stroke risk of 4.9% at 1 year, 16.7% at 3 years, and 26.5% at 5 years. In comparison, the estimated stroke risk in an asymptomatic population of patients with 50% to 79% stenosis was 0.85%, 3.6%, and 5.4% for the same three periods ($P = 0.001$).⁷⁶

Although carotid stenosis, once identified, tends to progress over time,^{20,54,76,88} the data are currently insufficient to permit recommendation of routine ultrasonographic or other surveillance for all patients with neck bruits outside a research setting. In our view, reevaluation every 1 to 2 years with noninvasive diagnostic tests is a reasonable approach to patients (1) who are already known to have greater than 50% stenosis, (2) who do not undergo surgery, and (3) who are at high risk for stroke, are surgical candidates, and are not averse to surgery.

Discussion

Epidemiology

In cross-sectional and population-based studies, the overall prevalence of greater than 75% carotid stenosis has been low. A 1992 study reported a 2.3% prevalence in men and a 1.1% prevalence in women; there was a significant ($P < 0.0001$) increase with age with each decade from 65 years to beyond 85 years, but there were no significant differences between men and women.⁶² In the Framingham study population, the incidence of greater than 50% stenosis was 8% (95% CI, 6.5 to 9.8).⁶¹ In a study of healthy volunteers, the incidence of greater than 50% stenosis was 5.1% (95% CI, 2.6 to 9.0) in patients 70 years of age or older and 1.5% (95% CI, 0.2 to 5.3) in younger patients.⁸⁹

The pooled risk of greater than 60% to 75% stenosis in patients with carotid bruits referred for noninvasive vascular evaluation at an average age of 65 years is reported to be 21% (95% CI, 18 to 24),⁵⁶⁻⁵⁸ which is three to four times the prevalence expected on the basis of population-based studies. Thus, five persons with neck bruits must be screened to detect one patient with moderate to severe carotid stenosis. The absolute benefit of surgery is small and of borderline statistical significance. In ACAS, as noted (see above), the relative risk reduction for an ipsilateral major stroke or perioperative death over a 2.7-year period was 36.5% (95% CI, 27.5 to 47.1), the absolute risk reduction was 2.3% (95% CI, 0.2 to 7.0), and the NNT was 43 (95% CI, 14 to 500); the number of patients that would have to be screened with DUS to prevent one stroke over a 3-year follow-up period was 250 (95% CI, 70 to 2,500).

Economic Considerations

A cogent argument in favor of pursuing a surgical strategy in at least some patients was made by a 1997 economic analysis,⁹⁰ which demonstrated that although prophylactic endarterectomy in patients with asymptomatic carotid stenosis did not reduce societal costs appreciably, it was nonetheless, at a cost of \$8,000/quality-adjusted life year (QALY), within the range of many interventions considered by society to be cost-effective. It should be pointed out, however, that this economic analysis addressed only carotid endarterectomy in patients with identified carotid stenosis, not screening strategies for patients with bruits, and consequently did not consider costs associated with investigation and follow-up to the point of recommendation for or against carotid endarterectomy in the broader group of patients with bruits. These costs would alter the economic analysis substantially, and if they are included, it is far from clear whether the resulting overall cost/QALY would still be acceptable. To date, no trial or economic analysis of a screening strategy has been published.

Screening Issues

For the reasons previously discussed, we do not feel justified in recommending routine screening for patients with asymptomatic carotid bruits. Given the available evidence, we believe that such patients may reasonably be managed in either of two ways. One choice is simply to conclude that screening patients with carotid bruits as possible candidates for carotid endarterectomy has not

been proved to be a useful intervention and to concentrate instead on general vascular risk reduction. The other, which is appropriate in centers where noninvasive or invasive diagnostic tests reach acceptable standards with an acceptable degree of risk and where the procedure is done by surgeons whose documented perioperative stroke and death rates are less than 3%, is to take a selective approach that addresses various issues related to stroke risk, cardiac risk, and patient preferences before noninvasive tests are ordered.

Subgroup Analyses for Potential High-Risk Factors

Given the small absolute risk reduction reported by ACAS¹⁵ and by the two meta-analyses of all asymptomatic carotid stenosis trials,^{45,46} it would be useful to be able to identify one or more high-risk groups within the broader group of patients identified as having stenosis.

SEX

ACAS included a subgroup analysis addressing the effect of sex on ability to benefit from surgery: the absolute reduction in the risk of perioperative stroke or death or ipsilateral stroke at 2.7 years was 3.6% (95% CI, 1.1 to 9.9) for men and 0.5% (95% CI, 0.01 to 2.7) for women.

DEGREE OF STENOSIS

In asymptomatic patients stratified according to their ultrasonographically determined degree of stenosis, the risk of stroke is low both for patients with less than 30% stenosis (4% cumulative event rate at 3 years) and for those with 30% to 74% stenosis (9% cumulative event rate at 3 years); it is highest for those with greater than 75% stenosis (21% cumulative event rate at 3 years).²⁰ The European Carotid Surgery Trialists (ECST) study,⁴⁷ using angiographic data from the asymptomatic carotid arteries of 2,295 patients, reported that the Kaplan-Meyer estimate of stroke risk at 3 years was only 2% and remained low (< 2%) when patients with less than 79% stenosis were considered; stroke risk increased to 9.8% for patients with 70% to 79% stenosis and to 14.4% for those with 80% to 99% stenosis. In a population of patients referred to a vascular laboratory with asymptomatic carotid stenosis on DUS who were followed for a mean of 38 months, the incidence of stroke was 2.1% in patients with 50% to 79% stenosis and 10.4% in those with greater than 80% stenosis.⁷⁶

In ACAS, there were too few strokes to permit subgroup analysis of the effect of degree of stenosis on ability to benefit from carotid endarterectomy. In both ECST⁷⁹ and NASCET,^{75,77,78,91} however, higher degrees of stenosis in symptomatic patients were consistently observed to be associated with higher stroke risk as well as with greater ability to benefit from surgical treatment [see Table 8].

PLAQUE ULCERATION AND PLAQUE STRUCTURE

At present, there are no subgroup analyses examining the effect of plaque ulceration on the ability of asymptomatic patients to benefit from surgical treatment. In NASCET, however, when symptomatic patients with 70% to 99% stenosis were considered, those with angiographic evidence of plaque ulceration were at higher risk for stroke than those without ulceration⁹² and derived greater benefit from surgery.⁷⁵ Angiography had a sensitivity of 46% and a specificity of 74% in the detection of ulcerated plaques, with a positive predictive value of 72%.⁹³ A 1994 study reported that when ulceration was detected with B-mode imaging in patients with asymptomatic carotid stenosis, the incidence of silent cerebral infarction detected by magnetic resonance imaging was 75%, compared with an incidence of 25% when ulceration was absent.⁹⁴

It has also been suggested that carotid plaques of differing structures may have differing embolic potentials.⁹⁵ DUS can distinguish between fibrous plaques (which are highly echogenic) and plaques with high concentrations of lipid and necrotic material (which are echolucent). Echolucent plaques are more frequently associated with neurologic symptoms and computed tomography-proven cerebral infarction.⁹⁵⁻⁹⁷ Interobserver reliability for plaque echostructure, however, seems to be highly variable, ranging from good ($\kappa = 0.79$) for greater than 70% stenosis⁹⁵ to average ($\kappa = 0.51$) for greater than 40% stenosis⁹⁸ to poor ($\kappa = 0.29$) for greater than 80% stenosis.⁹⁹ A 1994 report found no correlation between the presence or type of symptoms and plaque structure as determined by DUS.¹⁰⁰ The true importance of carotid plaque echomorphology and surface characteristics as predictors of cerebrovascular events remains to be defined.

CONTRALATERAL DISEASE

It has been suggested that the presence of contralateral carotid disease is a risk factor for future cerebrovascular events. In NASCET patients with greater than 70% stenosis,¹⁰¹ contralateral occlusion significantly increased the benefit of surgery with respect to the incidence of stroke or death, but contralateral high-grade stenosis did not.⁷⁵

ASYMPTOMATIC CEREBRAL INFARCTION

The presence of areas of asymptomatic cerebral infarction ipsilateral to the area of carotid stenosis on head CT may identify patients who would benefit from surgery.¹⁰² In asymptomatic patients with carotid stenosis, the incidence of silent strokes demonstrated by CT has been reported to be 10% in patients with 35% to 50% stenosis on DUS, 17% in those with 50% to 75% stenosis, and 30% in those with greater than 75% stenosis.¹⁰³ The incidence of silent cerebral infarctions demonstrated by MRI in the same type of population has been reported to be 42%, increasing to 75% for greater than 50% stenosis.⁹⁴ Use of CT and MRI of the brain in risk strati-

Table 8 Effectiveness of Surgery by Degree of Stenosis in Patients with Symptomatic Carotid Stenosis⁷⁵

Degree of Stenosis	Relative Risk Reduction or Increase	Absolute Risk Reduction or Increase	Number Needed to Treat or Harm
70%-99%	RRR, 48% (95% CI, 27-63)	ARR, 6.7% (95% CI, 3.2-10)	NNT, 15 (95% CI, 10-31)
50%-69%	RRR, 27% (95% CI, 5-44)	ARR, 4.7% (95% CI, 0.8-8.7)	NNT, 21 (95% CI, 11-125)
≤ 49%	RRI, 20% (95% CI, 0-44)	ARI, 2.2% (95% CI, 0-4.4)	NNH, 45 (95% CI, 22-∞)

ARI—absolute risk increase
RRI—relative risk increase

ARR—absolute risk reduction
RRR—relative risk reduction

NNH—number needed to harm
NNT—number needed to treat

fication of patients with asymptomatic carotid stenosis is controversial and currently is not advised.

CONCLUSIONS

Although only limited data on patients with asymptomatic stenosis are available, we believe that consideration of sex, degree of stenosis, and possibly the presence of plaque ulceration may be helpful in making the final decision on whether to offer carotid endarterectomy to these patients; at present, plaque morphology is insufficiently reliable to be a useful guide to clinical management.

Special Situations

RESTENOSIS OR PREVIOUS CAROTID SURGERY

Patients who have previously undergone carotid surgery have been excluded from most studies of asymptomatic patients; when they have been included in trials addressing symptomatic stenosis, they have experienced increased rates of perioperative complications.^{16,50} Patients in whom restenosis occurs after an earlier carotid endarterectomy should be advised against surgery while they remain asymptomatic.¹⁵ It is therefore unnecessary to follow patients with ultrasonography after carotid endarterectomy if no symptoms develop.

PREOPERATIVE ASSESSMENT FOR CORONARY ARTERY BYPASS GRAFTING

Some 20% to 30% of patients undergoing assessment for CABG are found to have carotid bruits,^{49,104} and 5% to 20% have greater than 50% stenosis on DUS¹⁰⁵⁻¹⁰⁷ or ocular plethysmography.¹⁰⁸ In asymptomatic patients with carotid stenosis who are undergoing CABG, there is no direct evidence favoring prophylactic carotid endarterectomy either before or in conjunction with CABG. Cohort studies including symptomatic and asymptomatic carotid stenosis indicate that patients undergoing CABG and carotid endarterectomy in the same operation have a stroke rate of 6% (95% CI, 4.6 to 7.8), an MI rate of 4.6% (95% CI, 3.1 to 6.5), and a mortality of 4.7% (95% CI, 3.4 to 6.4).¹⁰⁹ For cohorts in which carotid endarterectomy was performed before CABG, the stroke rate is 3.2% (95%

CI, 2.1 to 4.5), the MI rate is 5.2% (95% CI, 3.6 to 6.9)—a non-significant increase—and the mortality is 4.7% (95% CI, 3.4 to 6.4).¹⁰⁹ For cohorts in which CABG was done first and carotid stenosis was treated on its own after the cardiac procedure, the stroke rate is 3.5% (95% CI, 1.0 to 9.0), the MI rate is 2% (95% CI, 0.2 to 6.0), and the mortality is 0.8% (95% CI, 0.02 to 4.8).¹¹⁰⁻¹¹²

We recommend against a combined surgical approach in patients with asymptomatic carotid stenosis. Given the equivalent stroke rate and the lower MI rate and mortality, we believe that the preferred strategy in patients with bruits is first to proceed with CABG if indicated and then to determine whether the patient should be further evaluated as a candidate for carotid endarterectomy in the same manner as other elective patients would be.

Effect of Center-Specific Variations on Risk-to-Benefit Ratio

In ACAS, 1.2% of the overall 2.7% perioperative stroke rate was accounted for by strokes occurring after angiography. Centers where ultrasonography has been documented to have high predictive values may avoid this risk by proceeding directly from ultrasonography to surgery. If these complications had been avoided in ACAS, the absolute risk reduction would have been more substantial: 3.43% (95% CI, 1.1 to 9.9), corresponding to an NNT of 29 (95% CI, 1 to 80). The true perioperative combined stroke and death rate achieved in this study was 1.5%, a result that is definitive of excellence in the surgical management of carotid endarterectomy and that constitutes a useful quality assurance measure for centers and individual surgeons.

Issues for the Future

It is possible, perhaps likely, that in the future, magnetic resonance angiography⁶⁷ and three-dimensional CT angiography,^{113,114} together with DUS, will replace angiography as preferred imaging methods for diagnosing internal carotid artery stenosis. As for surgical treatment and screening, further data on patients with asymptomatic carotid stenosis are necessary before definitive recommendations can be made.

3 PULSATILE ABDOMINAL MASS

Timothy A. Schaub, M.D., and Gilbert R. Upchurch, Jr., M.D., F.A.C.S.

Assessment of a Pulsatile Abdominal Mass

When a pulsatile abdominal mass is found on physical examination, the location of the mass and the symptoms associated with it become essential clinical clues. The underlying condition may range in severity from benign to life threatening. Further evaluation is imperative; in certain clinical settings, immediate transport to the operating room is indicated. Because inappropriate treatment can be catastrophic, it is important to base one's approach to assessment and management of a pulsatile abdominal mass as firmly as possible on the available evidence. In what follows, a clinical approach based on relevant evidence is outlined.

Clinical Evaluation

The most feared cause of a pulsatile abdominal mass is an abdominal aortic aneurysm (AAA). In the United States, AAAs are present in 3% to 9% of the population, resulting in approximately 15,000 fatalities each year.¹

In 1999, AAAs were the 15th leading cause of death in the United States.² Deaths from AAA declined in subsequent years,³ but with the overall aging of the U.S. population, this disease remains a major threat to public health.

PRESENTATION

Asymptomatic AAAs are considerably more common than symptomatic AAAs and are often discovered on abdominal or pelvic scans done for other indications (e.g., back pain or renal cysts) rather than on physical examination.^{4,5} Plain films of the lumbar region, routinely obtained in patients with back pain, may show a calcified shell of the aorta [see Figure 1]. In one review of 31 patients with surgically proven ruptured AAAs, 65% had calcification of the aneurysm that was visible on a plain abdominal radiograph.⁶ In addition, ultrasonography and computed tomography are nearly 100% sensitive in detecting AAAs.⁷ In elderly patients, evaluation of the aorta should be routinely included in abdominal ultrasonography; scanning of the aorta adds, on average, only 43 seconds to the study.⁸ If an AAA is unexpectedly found, either the patient is followed or the aneurysm is repaired, depending on the clinical situation and the size of the aneurysm (see below).

Ruptured AAAs, on the other hand, give rise to pronounced symptoms, and the patient's condition may range from hemodynamic stability to class IV shock. When the patient is unstable, further workup is unnecessary and emergency repair is indicated. The situation is less clear when the patient is stable. The traditional pre-

sentation of a ruptured AAA is a triad comprising hypotension, back or abdominal pain, and a pulsatile abdominal mass. Unfortunately, this traditional presentation occurs less than half of the time. In a study of 116 patients with ruptured AAAs, 45% were hypotensive, 72% had pain, and 83% had a pulsatile abdominal mass.⁹ Accordingly, it is essential not to be lulled into a false sense of security when evaluating a hemodynamically stable patient with a pulsatile abdominal mass. Although a ruptured AAA is an uncommon event in a patient with a stable blood pressure and no abdominal pain, the absence of these symptoms does not rule out the possibility.

Symptomatic or ruptured aneurysms can mimic many other acute medical conditions and therefore are part of multiple differential diagnoses. The following conditions all may be confused with ruptured AAAs: (1) perforated viscus, (2) mesenteric ischemia, (3) strangulated hernia, (4) ruptured visceral artery aneurysm, (5) acute cholecystitis, (6) acute pancreatitis, (7) ruptured appendix, (8) ruptured necrotic hepatobiliary cancer, (9) lymphoma, and (10) diverticular abscess. Fortunately, misdiagnosis of a ruptured AAA is rare. Moreover, most patients who do undergo an operation for a misdiagnosis either benefit from or at

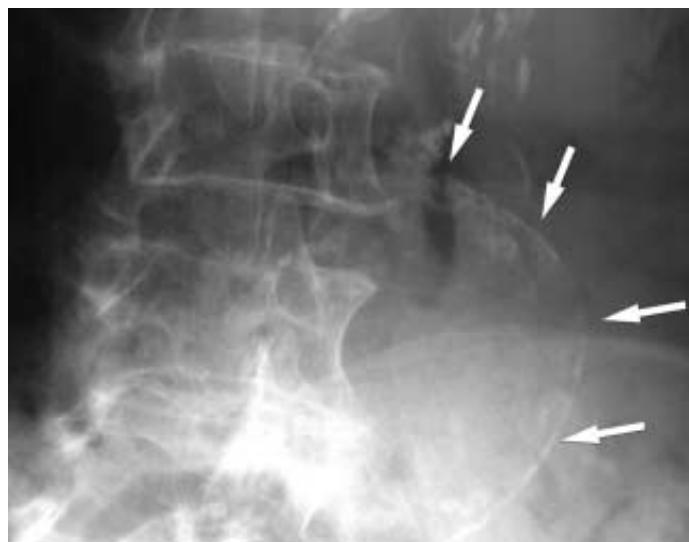

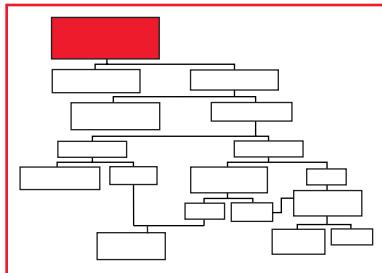

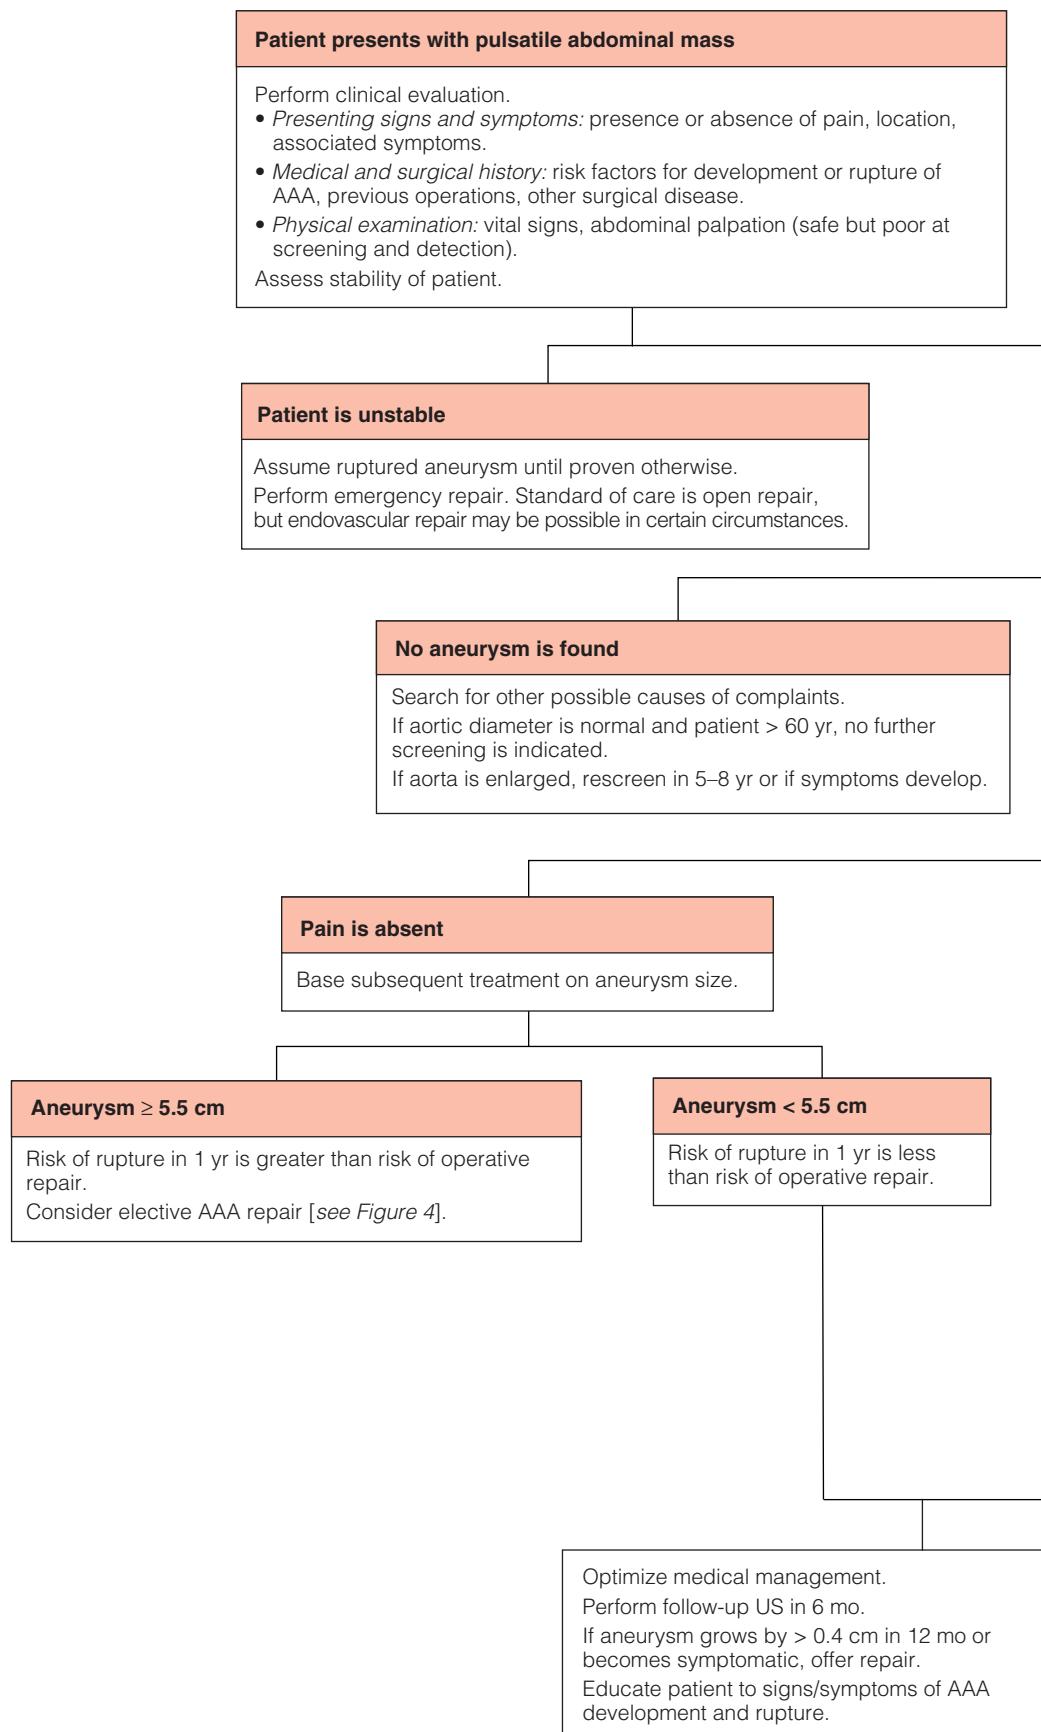

Figure 1 Shown is a plain film of the abdomen (anterior-posterior view) in an elderly woman who presented complaining of vague abdominal pain. The patient was found to have an AAA, diagnosed by plain film and believed to be approximately 5 cm in size. Arrows follow the course of calcium outlining her aorta.

Assessment of a Pulsatile Abdominal Mass

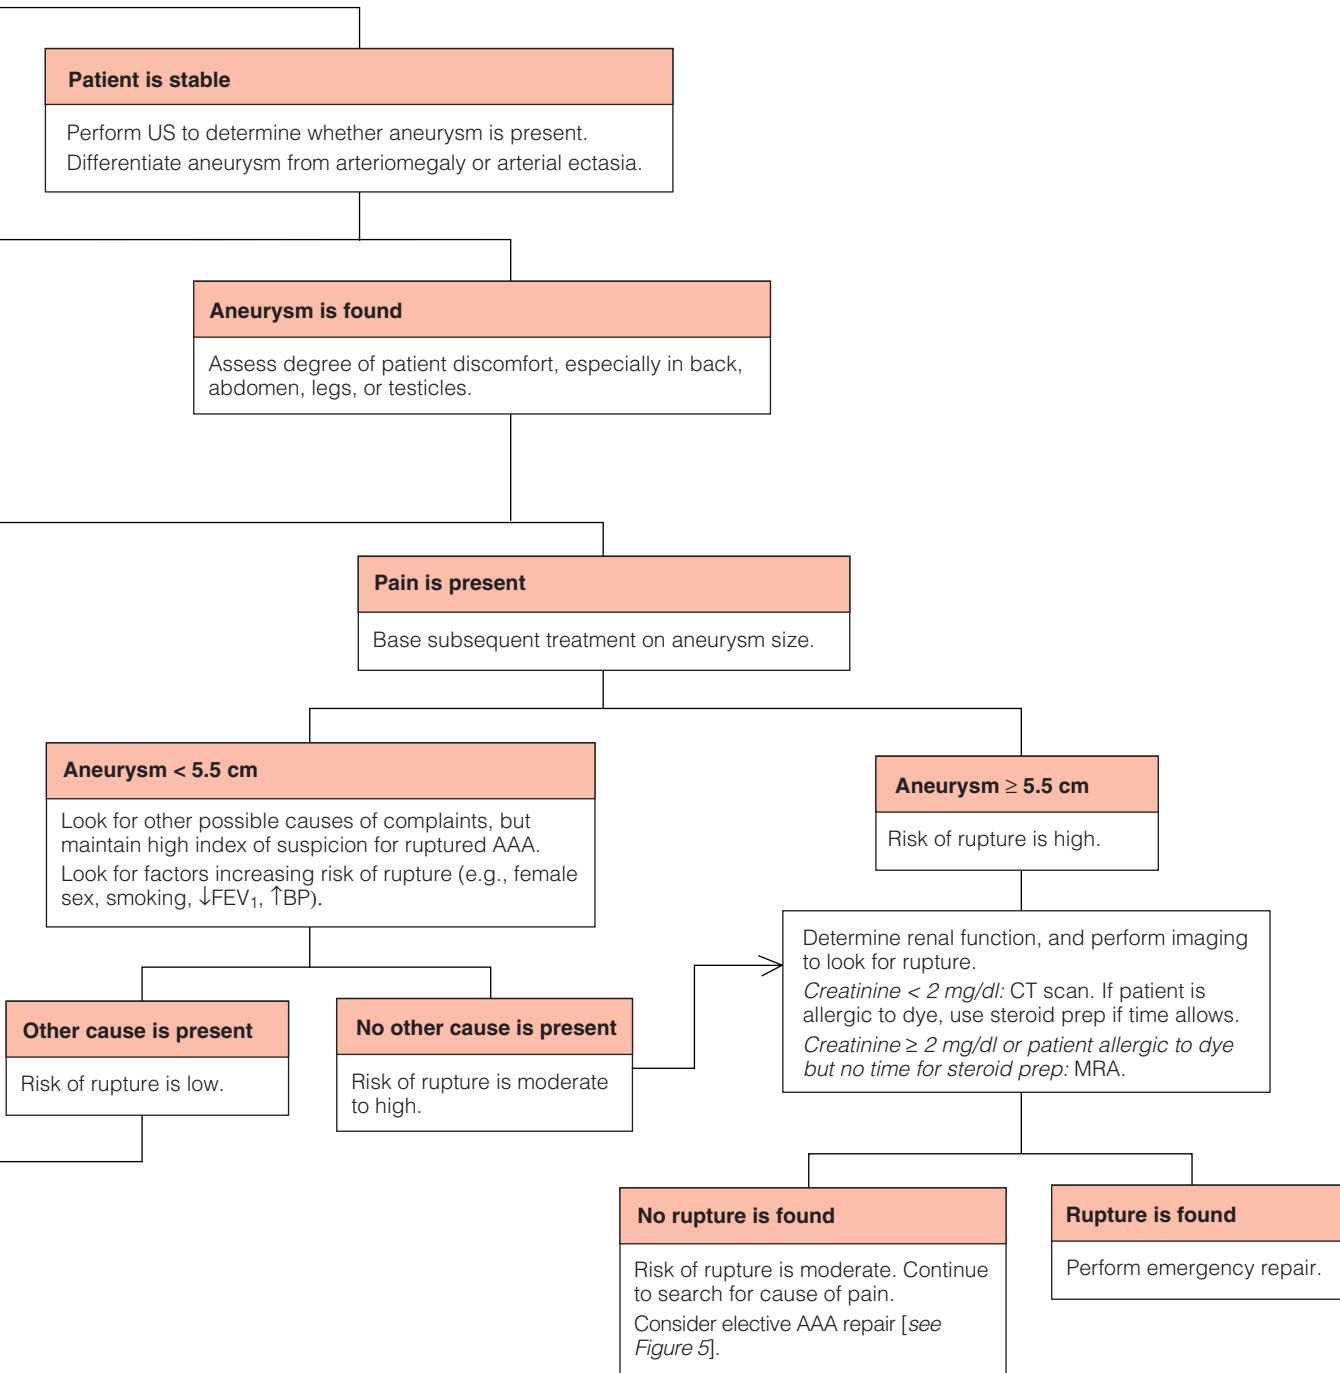

Table 1 Risk Factors Associated with AAA Development

Factors Positively Associated with Development of AAA	Factors Negatively Associated with Development of AAA
Increased age	Female sex
Increased height	Black race
Coronary artery disease	Presence of diabetes
Any atherosclerosis	
High cholesterol levels	
Hypertension	
Smoking	
Male sex	
Family history (first-degree relative)	

least are not harmed by the operation, which should alleviate some potential concerns about taking an aggressive approach to a suspected ruptured AAA.¹⁰ Conversely, AAAs can mimic other disease processes: in one study, nearly one in five patients with symptomatic AAAs in an emergency department were originally diagnosed as having nephroureterolithiasis.¹¹ Patients who have urologic symptoms but whose urinalysis is normal may benefit from an AAA workup; radiologic evidence of ureteric involvement is present in as many as 71% of AAAs.¹²

HISTORY

The medical history may be helpful in determining the patient's level of risk for an AAA. Even in the absence of clinical symptoms, knowledge of the risk factors may facilitate earlier diagnosis. The Aneurysm Detection and Management Veterans Affairs Cooperative Study Group trial (commonly referred to as the ADAM trial) found a number of factors to be associated with increased risk for AAA: advanced age, greater height, coronary artery disease (CAD), atherosclerosis, high cholesterol levels, hypertension, and, in particular, smoking.¹³ The risk was lower in women, African Americans, and diabetic patients.

AAAs occur almost exclusively in the elderly and are rarely seen in patients younger than 50 years. In a 2001 study, the mean age of patients undergoing repair for AAAs in the United States was 72 years.¹⁴ Male patients outnumber female by a factor of 4 to 6, depending on the study cited.¹⁴⁻¹⁸ Family members of AAA patients are also at significant risk: 12% to 19% of persons undergoing AAA repair have a first-degree relative with an AAA.¹⁹⁻²¹ Accordingly, screening is recommended in all men and women older than 50 years who have a family history of AAA.²² AAAs are over seven times more likely to develop in smokers than in nonsmokers, with the duration of smoking, rather than total number of cigarettes smoked, being the key variable [see Table 1].²³

Of particular importance is identification of risk factors for rupture. The United Kingdom Small Aneurysm (UKSA) trial reported 103 AAA ruptures in 2,257 patients over a period of 7 years, with an annual rupture rate of 2.2%.²³ The factors found to be significantly and independently associated with an increased risk of rupture were female sex, a larger initial AAA diameter, a lower forced expiratory volume in 1 second (FEV₁), a current smoking habit, and a higher mean blood pressure.^{23,24} Women are two to four times more likely to experience rupture of an AAA than men are.^{24,25} AAAs in cardiac and abdominal transplant patients also appear to have high expansion and rupture rates.²⁶

The patient's surgical history is also crucial, particularly in that it can shorten the differential diagnosis at presentation by ruling out disease processes (e.g., appendicitis and cholecystitis). In addition, the nature and extent of any previous abdominal procedures may influence the surgeon's operative approach to the AAA repair. When a pulsatile abdominal mass is discovered in a patient who previously underwent open repair of an AAA, it is important to remember that anastomotic pseudoaneurysms²⁷ or synchronous lesions (e.g., iliac artery aneurysms²⁸) can occur at sites remote from the previous repair.

Patients who have undergone endovascular AAA repair may also present with symptoms in the presence [see Figure 2] or absence of an endoleak. In a 2002 review, most ruptures after endovascular AAA repair occurred with type I endoleaks in the tube endograft configuration.²⁹ This clinical scenario is well described and can present as a pulsatile abdominal mass.²⁹⁻³¹ The risk of rupture after endovascular repair is small,²⁹ but the long-term outcome of this relatively new approach remains to be determined. Overall mortality after rupture in patients with previous endografts approaches 50%, and the operative mortality is 41%.²⁹

PHYSICAL EXAMINATION

Before the advent of modern radiologic tests, the abdominal examination was the key to detecting an AAA. *Gray's Anatomy*, first published in 1858, noted that AAAs formed "a pulsating tumour, that presents itself in the left hypochondriac or epigastric regions."³² The abdominal aorta begins at the level of the diaphragm and the 12th thoracic vertebra and runs in the retroperitoneal space just anterior to and slightly to the left of the spine. At approximately the level of the umbilicus and the 4th lumbar vertebra, it bifurcates into the right and left common iliac arteries. In young, thin individuals, the abdominal aorta runs close to the surface of the abdomen and thus can often be palpated during a normal physical examination. Palpation of an AAA is safe and has not been reported to precipitate rupture. A 1997 report found, however, that only 31% of the AAAs studied

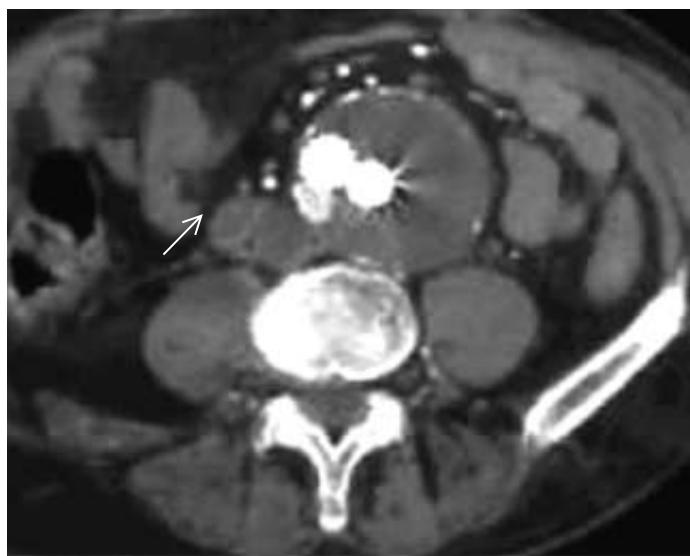

Figure 2 Shown is a CT scan of a patient who presented to the emergency room with increasing back pain 2 years after an endovascular AAA. The patient was found to have a type II endoleak (arrow), which was treated with coil embolization of a lumbar artery.

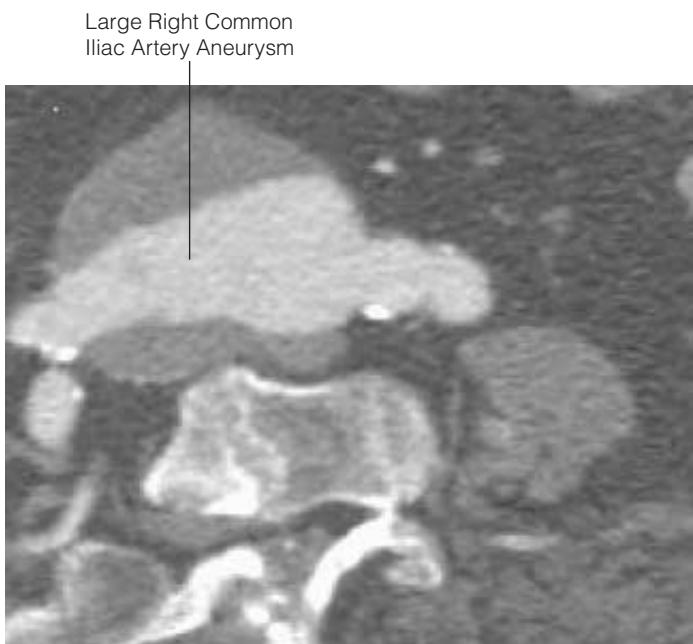

Figure 3 Shown is a CT scan of a patient presenting with an abdominal mass who, in addition to having a small AAA, was found to have a large right common iliac artery aneurysm, palpable in the right lower quadrant of the abdomen.

at a major teaching institution were initially detected by physical examination.³³ Nonaneurysmal common iliac arteries also are often difficult to palpate, even in thin individuals.

There are several methods of conducting a proper physical examination of the abdominal aorta. Our preferred approach resembles that of Lederle and Simel³⁴:

1. Have the patient lie supine with the knees raised. Encourage the patient to relax the abdomen. A relaxed abdomen is often obtainable with passive exhalation after a deep inhalation.
2. Beginning a few centimeters cephalad to the umbilicus and just to the left of the midline, palpate deeply for the pulsation of the aorta.
3. To confirm that the aorta is being palpated, place both hands on the abdomen with the palms down in such a way that the pulsation is between the tips of the index fingers. The index fingers should move apart with each heartbeat.
4. Once it is certain that the index fingers are bracketing the aorta, estimate the diameter of the aorta by measuring the distance between the fingertips, taking into account the thickness of the overlying tissue.

Unfortunately, physical examination is not very accurate in detecting AAAs: in one study, approximately 62% of known AAAs were missed.³⁵ Whether an AAA is detectable on physical examination alone depends primarily on the size of the aneurysm. AAAs more than 5 cm in diameter are detectable on physical examination in 76% of the population, whereas those 3 to 3.9 cm in diameter are detectable in only 29%. Palpation of an AAA 3.0 cm in diameter or larger has a positive predictive value of only 43%.³⁴ In addition, detection of AAAs is significantly limited by truncal obesity.^{36,37} Thus, physical examination is clearly insufficient for ruling out or screening for AAAs.^{34,36}

In the past, it was considered important to measure the abdominal aorta accurately by means of physical examination. Several

studies have been published comparing ultrasonography, the currently preferred screening method, with physical examination.^{37,38} One such study found that abdominal palpation had a poor (14.7%) positive predictive value for detecting AAAs greater than 3.5 cm in diameter.³⁸ At present, with the wide availability of ultrasound screening, physical examination is playing a smaller role in AAA detection.

Although most AAAs appear supraumbilically, not all pulsatile abdominal masses appear there. In some patients, the abdominal aorta becomes more tortuous and elongated with age. As a result, an AAA may appear infraumbilically or to one side of the abdomen or the other. The common iliac arteries may become aneurysmal and palpable in one of the lower abdominal quadrants as well [see *Figure 3*.]³⁹

Another indication that an AAA may exist is the presence of a femoral or popliteal artery aneurysm on physical examination. A patient with a femoral artery aneurysm has an 85% chance of having a concomitant AAA, and a patient with a popliteal artery aneurysm has a 62% chance.^{40,41} Conversely, in a study evaluating 251 patients with documented AAAs, 14% had either a femoral or a popliteal artery aneurysm.⁴² There is a significant male predominance, for unknown reasons.^{15,42,43}

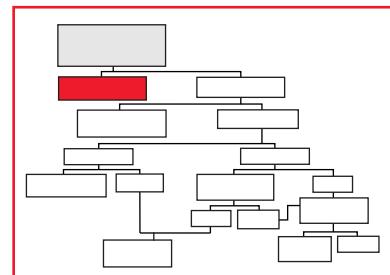

Indications for Emergency Repair versus Further Workup

PATIENT IS UNSTABLE

If a patient presents with a pulsatile abdominal mass and is medically unstable, no further study or workup is necessary: the diagnosis, until proved otherwise, is a ruptured AAA. The only cure for a ruptured AAA is an emergency operation. Indeed, when all patients experiencing a ruptured AAA are taken into account, including both those who arrive at the hospital alive and those who do not, overall mortality is still between 77% and 94%, with over 50% of patients expiring before reaching the hospital.^{44,45} Most ruptured AAAs leak into the left retroperitoneum, which may serve to confine the bleeding.⁴⁶ However, AAAs that rupture freely into the abdominal cavity usually result in death, either at home or en route to the hospital. Even if the patient makes it to the OR, the expected mortality exceeds 50%⁴⁷ (though values as low as 15% and as high as 90% have been noted⁴⁸). Mortality after a ruptured AAA has declined since the middle of the 20th century by approximately 3.5% per decade; however, the most recent estimate, for the year 2000, is still 41%.⁴⁸

Although some physicians suggest that patients with predictably high morbidity and mortality from a ruptured AAA may not benefit from attempted repair,⁴⁹ most would still maintain that even in this population, this presentation necessitates operative intervention.⁵⁰ The high cost of repair and the substantial operative mortality notwithstanding, surgical repair of ruptured AAAs appears to be cost-effective in comparison with no intervention.⁵¹ Thus, cost should not be considered in the management of patients with AAAs.

Open repair of ruptured AAAs is the current standard of care [see **6:11 Repair of Infrarenal Abdominal Aortic Aneurysms**]. There is evidence, however, that endovascular approaches may come to play a more significant role. A 2003 study described endovascular repair of 29 ruptured AAAs and reported a mortality of only 11%.⁵²

PATIENT IS STABLE

If a patient with a pulsatile abdominal mass is medically stable, further workup is called for. As noted, ultrasound imaging is significantly more accurate in detecting an AAA than physical examination alone is.³⁸ Duplex ultrasonography is used extensively as a primary screening tool for evaluating the size of an abdominal aorta because of certain advantages it possesses over other, more extensive modalities, such as CT, magnetic resonance angiography (MRA), and conventional angiography. Its main advantages are that (1) it is noninvasive, (2) it is relatively inexpensive, (3) it does not require exposure to radiation, (4) it is portable, and (5) it is as reliable as the other modalities in determining aortic anterior-posterior (AP) diameter. Ultrasound-derived measurements are reproducible to within 3 to 5 mm,⁵³ and the interobserver variability is less than 5 mm in 84% of AP measurements.⁵⁴ In about 75% of cases, ultrasonography underestimates the size of the aorta. A comparison study found that AAA diameter measurements were consistently and significantly larger with CT than with ultrasound (5.69 ± 0.89 cm versus 4.74 ± 0.91 cm).⁵⁵ It appears that when radiologists take more care with their measurements (e.g., by using magnifying glasses and calipers), the results correlate better.⁵⁶

Ultrasonographic measurement of the infrarenal aorta and the common iliac arteries has been evaluated in patients with no known vascular disease. In one study of patients older than 50 years (the age group in which abdominal aortic and iliac artery aneurysms are most common), the aorta measured 1.68 ± 0.29 cm in men and 1.46 ± 0.19 cm in women ($P < 0.001$).⁵⁷ The common iliac arteries measured 1.01 ± 0.20 cm in men and 0.92 ± 0.13 cm in women. An aneurysm is commonly defined as a permanent localized or focal expansion of an artery to 1.5 times its expected diameter.⁴⁶ Thus, an infrarenal AAA would be considered to be approximately 3 cm in diameter. It must be remembered, however, that infrarenal aortic diameter is affected by height, age, race, body surface area, and sex.⁵⁸⁻⁶⁰ An aneurysm should be differentiated from arteriomegaly and from arterial or aortic ectasia. Arteriomegaly is a diffuse enlargement of an artery by an amount that is at least 50% of the normal diameter; ectasia

is an enlargement of an artery by an amount that is less than 50% of the normal diameter.⁶¹

The main limitations of ultrasonography are that (1) the results are highly technician dependent and (2) resolution is dependent on body habitus and intestinal gas.⁴⁶ Another limitation is that it is unreliable in detecting rupture [see Figure 4]. Because ultrasonography does not provide an accurate picture of the aorta proximal to the renal arteries and because it is subject to the limitations already mentioned, it cannot be routinely used to differentiate a ruptured AAA from a symptomatic intact AAA. If ultrasonography is inconclusive in the evaluation of a palpable abdominal mass, then either CT or MRA (see below) is the next step [see Table 2].

Management

STABLE PATIENT WITHOUT ANEURYSM

If ultrasonography indicates that a patient with a pulsatile abdominal mass does not have an aneurysm, the risk of aortic or common iliac artery rupture is very low. Consequently, if symptoms (e.g., abdominal pain) persist, another causative condition must be considered.

If arteriomegaly is found to be the cause of the pulsatile abdominal mass and there are no symptoms of occlusion, then no specific treatment is required. Routine ultrasonographic follow-up is indicated because the risk of rupture still applies as the aorta continues to expand. In one study, an aneurysm was present in 1.6% of aortas with arteriomegaly.⁶² If aortic ectasia (by most standards, an aorta measuring 2.5 to 3 cm) is found to be the cause, follow-up ultrasonography in 5 to 8 years is recommended.^{61,63} It has been suggested that for a 65-year-old man with a normal aortic diameter (defined as less than 2.6 cm), the risk that a significantly dilated aneurysm will develop during the remainder of his life is essentially zero.⁶⁴ The distinction between a normal and an ectatic aorta remains something of a gray area, and the preferred follow-up period remains controversial. In general, ectatic infrarenal aortas expand slowly and are not associated with rupture.⁶¹

In the ADAM trial, independent and significant predictors of a new aneurysm on follow-up ultrasonography included (1) current smoking (odds ratio, 3.09), (2) coexisting CAD (1.81), and, in a separate model with composite variables, (3) any atherosclerosis (1.97).⁶³ Accordingly, when a patient has any of these risk factors, a lower threshold for follow-up ultrasonography and a shorter period between examinations may be practical.

STABLE PATIENT WITH ANEURYSM

Once the diagnosis of an aneurysm is made in a stable patient, the subsequent course of action is determined by the clinical presentation and the size of the pulsatile abdominal mass. It must be emphasized that if the patient becomes hemodynamically unstable at any point during evaluation, operative intervention is necessary—unless the patient has a terminal condition or has indicated that nothing further should be done to prolong life.

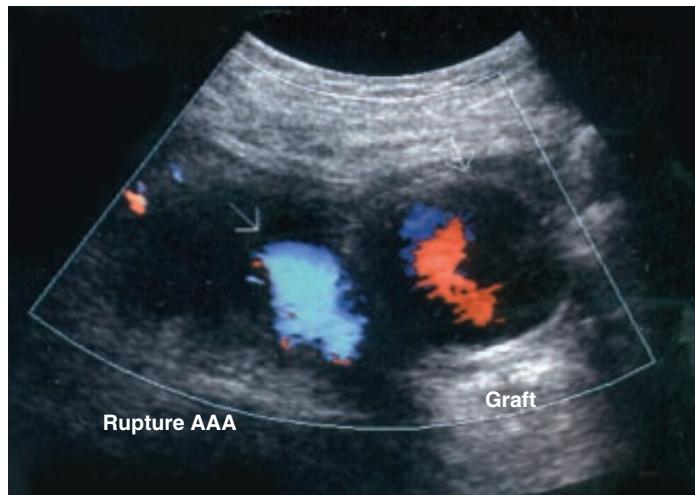

Figure 4 Depicted is rare ultrasonographic documentation of a ruptured AAA proximal to an old aortic tube graft.

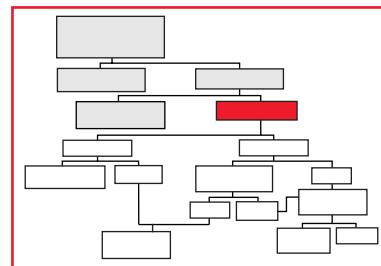

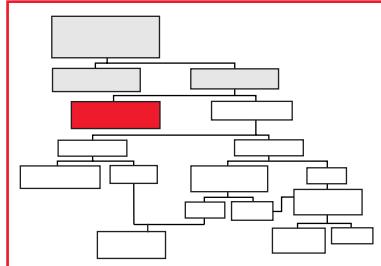

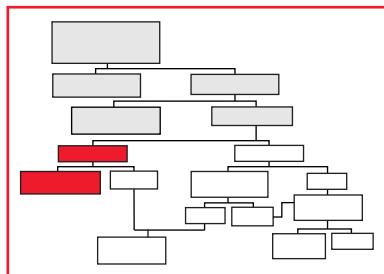

Table 2 Advantages and Disadvantages of Aortic Imaging Techniques

Imaging Modality	Advantages	Disadvantages
Ultrasonography	Noninvasive Relatively inexpensive Does not require radiation exposure Portable Comparable in reliability to other modalities in determining aortic AP diameter	Highly technician dependent Resolution dependent on body habitus and intestinal gas Unreliable in detecting AAA rupture Achieves poor visualization of aorta proximal to renal arteries and of iliac arteries
CT	Yields highly precise measurements Defines proximal and distal extent of AAAs precisely Delineates anatomy of iliac arteries Evaluates AAA wall integrity (notes location and amount of calcification and thrombus) Effective at discovering venous anomalies, retroperitoneal blood, aortic dissection, inflammatory aneurysms, and other intra-abdominal pathology and anomalies	Requires radiation exposure Requires iodinated contrast Expensive
MRA	Comparable to CT in preoperative evaluation Uses nonnephrotoxic contrast agent (gadolinium) Highly sensitive and specific in detecting stenoses of splanchnic, renal, and iliac arteries	Not widely available Very expensive May cause claustrophobia in select patients Requires longer scan time Contraindicated in patients with certain metal foreign bodies
Angiography	Superior in evaluating intraluminal characteristics of aorta Superior in determining visceral branch involvement Superior in delineating variations in vascular anatomy	More expensive than spiral CT Associated with multiple risks (e.g., infection, arterial thrombosis, distal embolization, groin hematoma, local arterial dissection, and risk of renal failure secondary to contrast)

If the patient is experiencing no discomfort and is otherwise stable, the risk of active rupture can be considered extremely low. If, however, the patient is experiencing significant pain or discomfort, especially in the back, the abdomen, the legs, or the testicles, AAA rupture should remain a strong diagnostic possibility.

Pain Is Absent

A patient with a pulsatile abdominal mass who has a known AAA and who is hemodynamically stable without complaints of pain should be further categorized on the basis of the size of the aneurysm. This categorization is traditionally based on the physics of an expanding aneurysm and on the association between increased risk of rupture and increased aneurysm size. The key considerations in these patients are (1) whether the risk associated with AAA repair exceeds the risk of rupture in a given period and (2) what other factors are present that may affect this decision.

Indications for operative intervention The physics of aneurysm expansion and rupture are probably best understood via the law of Laplace,⁸ according to which the tangential stress (τ) placed on a cylinder filled with fluid (e.g., a blood vessel) is determined by the equation

$$\tau = Pr/\delta$$

where P is the pressure (dynes/cm^2) exerted by the fluid, r is the internal radius (cm) of the cylinder, and δ is the thickness (cm) of the cylinder wall. When the aorta expands, its radius increases while its wall thickness decreases; thus, there is a geometric increase in tangential stress. As an aneurysm grows from 2 cm in diameter to 4 cm, tangential pressure increases not twofold but

fourfold. When the increased tangential stress exceeds the elastic capacity of the wall, rupture occurs. Elastic tissue in the abdominal aorta becomes attenuated as a result of age and of certain acquired and genetic factors; thus, a modest degree of expansion over time is not uncommon. An abnormal rate of expansion is usually considered to be 5 mm/yr or greater. Documentation of an accelerated aneurysm growth rate should cause the surgeon to give serious consideration to operative intervention [see **6:11 Repair of Infrarenal Abdominal Aortic Aneurysms**.⁴⁶]

Multiple studies have examined aneurysm diameter, usually indicated by the greatest AP diameter of the aorta, as a risk factor for rupture; several studies have documented that increased AP diameter is in fact the greatest predictor of rupture. This conclusion has been challenged, however, by studies using three-dimensional CT scanning to evaluate wall stress via a mathematical technique called finite element analysis.⁶⁵⁻⁶⁷ In these studies, maximal wall stress was a better predictor of rupture than maximal AP diameter was. For example, one patient with a ruptured 4.8 cm aneurysm had a wall stress equivalent to that of a patient with an electively repaired 6.3 cm AAA.⁶⁶ Future management of AAAs may be based on actual wall stress in addition to maximum AP diameter.

In a 2001 study addressing open operative repair of intact AAAs, increased mortality was associated with increased patient age, female sex, cerebral vascular occlusive disease, preoperative renal insufficiency, and the presence of more than three comorbid conditions before operation.¹⁴ In the UKSA trial, the 30-day mortality in patients undergoing elective open AAA repair was 5.8%.⁶⁸ The point at which the risk of elective repair became acceptable in relation to the risk of rupture with medical management and serial ultrasonographic follow-up was an aneurysm diameter of 5.5 cm. The investigators suggested that in patients with AAAs less than 5.5 cm in diameter, medical management is the best course of action. The operative mortality reported in this study is considered high, in that many single-center series have documented mortalities of 1% to 3% after open repair of intact AAAs.⁶⁹⁻⁷¹ The ADAM investigators also found that survival was not improved

when AAAs smaller than 5.5 cm were repaired electively, even if a low operative mortality was associated with the procedure.⁷⁰

Hospital volume may have a significant effect on patient outcome after elective AAA repair. A 2002 study found that mortality after this procedure was 56% higher at low-volume hospitals than at high-volume hospitals.⁷² Moreover, mortality after repair of an intact AAA exhibited a ninefold variation that could be attributed to hospital volume, sex, and age alone. Thus, when a patient is being evaluated for AAA repair, it is important to take into account not only the size of the aneurysm but also age, sex, comorbidities, and hospital volume. In turn, more than half of the effect of hospital volume on operative mortality in elective AAA repair appears to be mediated by surgeon volume.⁷³ Surgeon specialty also appears to affect operative mortality after elective AAA repair.⁷⁴

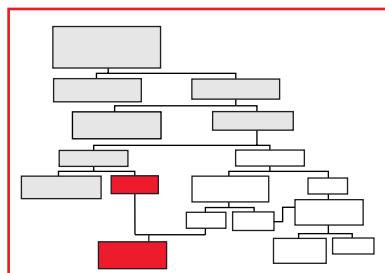

Given the various possible complicating factors, it is clear that no single aortic diameter can serve as a definitive indication for operative intervention in every patient. It is well known that ruptures can occur unpredictably at aneurysm diameters smaller than 5.5 cm.⁷⁵ Therefore, the timing of AAA repair must be individualized, with the 5.5 cm figure serving as a general guideline in the counseling of patients.

Advanced age, terminal conditions, and various end-of-life issues may deter patients from wishing to proceed with operative intervention. In addition, severe coexisting diseases significantly affect the morbidity and mortality associated with AAA

repair.^{47,76} Accordingly, older patients with multiple comorbidities may be preferentially offered endovascular AAA approach in place of open repair.³⁰ The surgeon must, however, consider the possibility that any operative intervention will be too risky in this population or that other interventions must be carried out before AAA repair can be attempted. These issues should be addressed via appropriate preoperative evaluation [see Figure 5].

Small AAAs (< 5.5 cm): medical management and follow-up

When a patient with stable vital signs and no abdominal pain is diagnosed as having a small AAA (i.e., < 5.5 cm), serial ultrasonography and optimization of medical management are indicated.^{77,78} Small AAAs usually do not rupture.^{24,79} Most small AAAs continue to grow, however, typically by 0.2 to 0.4 cm in diameter per year.^{70,77,80} Small AAAs can also expand rapidly with unpredictable frequency. A rapidly expanding AAA is at high risk for rupture, regardless of how small it may be.^{68,70,80,81}

Many risk factors have been identified that may affect the risk of small aneurysm expansion and rupture. For example, one study suggested that diastolic hypertension and chronic obstructive pulmonary disease (COPD) increased the risk that a small AAA would rupture,⁷⁵ whereas another found advanced age, severe cardiac disease, previous stroke, and a history of cigarette smoking to be risk factors for rapid expansion.⁸⁰ AAAs smaller than 5.5 cm may rupture more frequently in women than in men. A 2002 study found that in almost one quarter of women with ruptured AAAs, the diameter of the aneurysm was less than 5.5 cm at the time of rupture.⁴⁴ Currently, the safest and easiest method of following small AAAs is serial ultrasonography.^{11,82} When the diameter of an AAA approaches 5.5 cm, a more detailed study (e.g., CT or MRA) is indicated if repair is being considered.⁴⁶

Over the past several decades, the number of AAAs (especially smaller AAAs) detected has increased.⁸³ This increase has been attributed to two causes: (1) increased serendipitous detection in the course of scans done for other indications and (2) the “graying” of the population.^{46,83} With the potential advent of a screening program for AAA in the near future, thanks to growing evidence that such screening is cost-effective,^{22,84} it is likely that even more AAAs will be detected yearly. This prospect raises an interesting issue, in that at present, the only proven treatment for AAAs is operative; current medical therapy is notably limited. Clearly, there is a need to find medical therapies that can prevent, reduce, or stabilize the growth of AAAs. To that end, a better understanding of how AAAs develop is essential.

Basic science studies have helped elucidate the etiology of AAAs in greater detail. In particular, current research is focusing on (1) evaluating the role various proteolytic enzymes, such as matrix metalloproteinases (MMPs), play in processes involving the structural elements in the aortic wall; (2) investigating the importance of the immune system, specifically the macrophage, in the development of AAAs; (3) determining how hemodynamic and biomechanical stress affects aortic wall remodeling; and (4) identifying molecular genetic variables that contribute to AAA development.⁸⁵

Proteolytic enzymes are currently being evaluated as potential predictors of the course of AAA growth.⁸⁶ Doxycycline, which decreases MMPs in animal aneurysm models independently of its antibiotic properties, was evaluated in a prospective, randomized

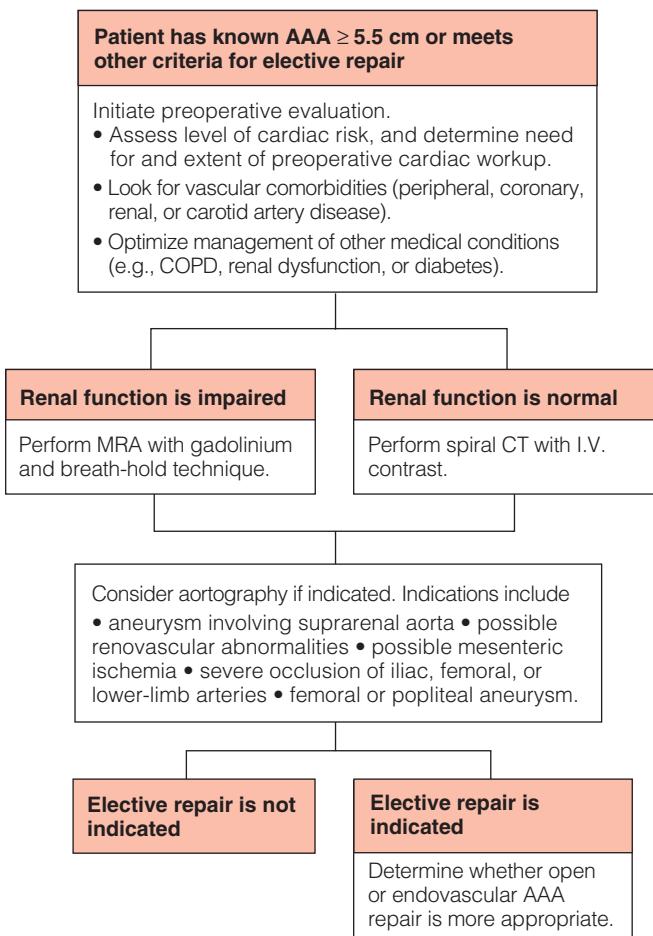

Figure 5 Shown is an algorithm that may be used to guide the preoperative workup of a patient who is to undergo elective AAA repair.

phase II trial published in 2002.⁸⁷ Although it did not exert a significant effect on aneurysm growth over the short study period (6 months), doxycycline significantly reduced serum levels of MMP-9, a gelatinase that plays a central role in degrading elastin and collagen in the abdominal aortic wall. Few side effects were noted, and most of them were easily reversible. These findings, though not conclusive, suggest that the use of doxycycline may one day prove to be a viable medical means of slowing AAA growth.

Control of hypertension would seem to be an obvious approach to medical control of aneurysms, in that hypertension is a significant risk factor for both development and rupture of AAAs.^{24,75,79,88} To this end, various antihypertensive agents, including beta blockers, calcium channel blockers, and angiotensin-converting enzyme (ACE) inhibitors, have been evaluated in patients with AAAs.²³ The results have been somewhat equivocal.

Beta blockers have been shown to reduce the expansion rate of large AAAs (≥ 5 cm) but not that of smaller AAAs.^{89,90} Some of them (e.g., propranolol) may be poorly tolerated at high doses.⁹⁰ In addition, beta blockers are often contraindicated in patients with severe COPD, though as many as 11% of COPD patients have AAAs.²⁴ A 1999 study suggested that receiving a calcium channel blocker was an independent risk factor for the presence of an AAA (odds ratio, 2.6).²³ The same study also noted, however, that patients receiving calcium channel blockers had stiffer aortic walls. ACE inhibitors, in contrast, were associated with decreased aortic wall stiffness and increased collagen turnover, whereas diuretics and beta blockers had no effect on aortic wall stiffness. None of the medications examined were found to affect the growth rate of AAAs. Aortic stiffness appears to be an important variable: increased aortic wall distensibility is associated with an increased risk of AAA rupture, and it is almost as powerful a predictor of rupture as actual AAA diameter.⁹¹

A link between COPD and AAAs is suggested by the presence of a common development pathway: both conditions are associated with elastin breakdown and smoking. A 1999 study argued, however, that the strong association between AAAs and COPD was most likely attributable to coexisting cardiovascular disease and medications.²⁴ In this study, the average annual aortic diameter expansion rate was 4.7 mm in patients who used oral steroids but only 2.6 mm in those who did not. The use of beta-adrenergic agonists was also a positive predictor of aneurysm expansion. Thus, oral steroids and beta agonists must be used cautiously in COPD patients who have AAAs. If an AAA patient must use one of these medications, close follow-up is indicated to monitor the expansion rate of the aneurysm.

Atherosclerosis is associated with AAAs but is currently believed to be a secondary phenomenon, with inflammation and matrix-degrading enzymes being the primary factors in AAA development.⁹² Lipoprotein (a) has been found to be an independent risk factor for atherosclerosis and is elevated in patients with AAAs independently of the patients' cardiovascular risk factors or the extent of atherosclerosis.⁹³ It seems reasonable that lowering lipid levels would decrease the development of atherosclerosis of the abdominal aorta. This is a potentially important effect because patients with small atherosclerotic AAAs often experience thrombotic complications involving the lower extremities.⁹⁴ Levels of apolipoprotein-AI and high-density lipoproteins have also been found to be significantly lower in patients with AAAs.⁹⁵ Overall, however, lipids appear to play only a minor role in AAA progression.⁹⁶ An animal study suggested that regression of plaque by lowering serum lipid levels after atherosclerotic aneurysm formation may result in increased aneurysm dilation in the abdominal aorta.⁹⁷ A subsequent study, however, demonstrated

that statins reduce the production of MMPs in the wall of AAAs.⁹⁸ The role of lipid-lowering medications in the treatment of AAAs remains to be clarified. Elevated levels of homocysteine in the blood are a recognized independent risk factor for atherosclerosis, and a study of AAA patients has found significantly higher levels of plasma homocysteine, along with lower levels of vitamin B₁₂.⁹⁹ Given this finding, and the possible role of vitamin B₁₂ in homocysteine regulation, use of supplemental vitamins may theoretically modify AAA progression.⁹⁹

Smoking is an independent risk factor for AAA development,^{63,88} expansion,^{80,96} and rupture.²⁴ Current smokers are 7.6 times more likely to have an AAA than nonsmokers are, and ex-smokers are three times more likely to have an AAA.²³ The duration of smoking is the key variable^{13,23,88}: the relative risk of AAA development is increased by 4% for each year of smoking.²³ The ADAM trial noted that a longer interval since the cessation of smoking was significantly associated with a decreased risk of AAA formation¹³; however, the decline in risk appears to be slow.²³ The UKSA trial showed that former smokers were at lower risk for death from AAA repair than current smokers were.⁶⁸ A 2002 study found that there was an independent association between smoking and high-grade tissue inflammation in AAAs,¹⁰⁰ lending support to the idea that smoking is an initiating event in AAA formation.

At present, intriguing possibilities notwithstanding, few definitive recommendations can be made regarding the use of medical therapy to reduce AAA growth. The indications for perioperative beta blockade are primarily cardioprotective. Administration of antihypertensives may be beneficial from a practical perspective, but current level I data supporting this practice are lacking. If an antihypertensive is given, the choice of agent should be based on associated clinical data (e.g., the presence of coexisting medical conditions, such as angina or renal insufficiency, whose management must be optimized). The administration of lipid-lowering drugs to patients with AAAs also requires further study, though the utility of such agents in the presence of CAD, which is found in almost 50% of AAA patients,¹⁰¹ is well documented, and long-term statin use after successful AAA surgery has been associated with reduced mortality (both all-cause and cardiovascular).¹⁰² Finally, smoking cessation is clearly mandatory.

Pain Is Present

When a patient presenting with a pulsatile abdominal mass is hemodynamically stable but complains of pain in the abdomen, the back, the testicles, or the femoral region, the index of suspicion must be high for a symptomatic or ruptured AAA. Other possible causes should be considered as well. As noted (see above), many abdominal processes may mimic an AAA; however, it is important that recognition of an AAA not be delayed unduly, because the length of the interval between the onset of symptoms and subsequent diagnosis and operation can have a direct bearing on overall survival. The size of the aneurysm, as determined by ultrasonography, is helpful for identifying patients at highest risk for rupture. Ultrasonography is sometimes able to detect a ruptured aneurysm, but it should not be relied on to rule out rupture. In one study, ultrasonography demonstrated extraluminal blood in only 4% of ruptured AAAs in the emergency department.¹⁰³

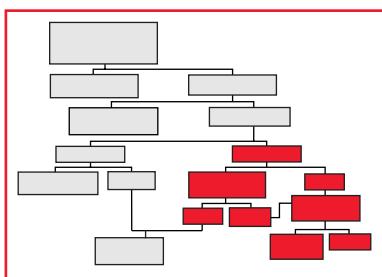

Figure 6 Shown is a CT scan of a patient presenting with a pulsatile abdominal mass and dull, aching back pain. The scan was obtained before contrast administration and demonstrates free extravasation of blood into the retroperitoneum.

In stable patients with AAAs larger than 5.5 cm who are experiencing pain, either CT or MRA may be used to detect AAA rupture; the choice typically depends on the patient's medical history [see Table 2]. After ultrasound evaluation, if an aneurysm smaller than 5.5 cm was found and no associated risk factors for rupture were identified, a search for other possible causes of the pain is reasonable, provided that it is performed expeditiously.

If no other cause for the pain can be found, possible rupture should remain a prime consideration, and the next step in evaluation—namely, spiral CT or MRA—should be implemented. Missing or delaying the diagnosis of a ruptured AAA can be disastrous. If retroperitoneal blood is noted, then the study need not be completed, and the patient should be taken to the OR [see Figure 6]. If the aneurysm is not ruptured, repair should be undertaken urgently (i.e., within the next 24 hours), with the patient's medical condition optimized to the extent possible [see 6:11 Repair of Infrarenal Abdominal Aortic Aneurysms]. Precipitous repairs of nonruptured symptomatic AAAs have an operative mortality five times that of elective repairs,¹⁰⁴ for reasons yet unknown.

Preoperative Evaluation of Nonemergency AAA Repair Candidates

Evaluation of a patient before elective AAA repair begins with assessment of the expected benefit of repair in relation to the estimated risk. If the decision is made to operate, the history and the physical examination should be completed as described earlier [see Clinical Evaluation, *above*]. The clinical findings, in conjunction with ECG and routine laboratory test results, provide most of the information that is needed for evaluating a patient's candidacy for AAA repair.

COMORBID CONDITIONS

CAD is common in patients with AAAs and is the leading cause of early and late mortality after AAA repair.¹⁰⁵ Renal insufficiency, COPD, and diabetes mellitus also may influence morbidity and mortality after AAA repair. Accordingly, when any of these disease entities is present, further evaluation before repair may be benefi-

cial. Optimization of perioperative medications is also important for maximizing risk reduction. Finally, adequate preoperative imaging is essential. The decision regarding which type of repair is most appropriate in an AAA patient should be based on the preoperative evaluation.

Coronary Artery Disease

Before AAA repair, it is important to identify patients who are at high risk for a perioperative cardiac event and who need a preoperative cardiac intervention. It is also important to identify patients who are at low risk, so that they are not subjected to unneeded testing. A report from the American College of Cardiology/American Heart Association (ACC/AHA) Task Force on Practice Guidelines provided useful guidelines for pre-

Table 3 ACC/AHA Guidelines for Preoperative Cardiac Evaluation in Patients Undergoing Elective High-Risk Vascular Procedures¹¹⁰

1. Revascularization in the past 5 years?	If yes, without recurrence of signs or symptoms of ischemia, then further cardiac testing is not indicated. Proceed with surgery. If no, go to 2.
2. Coronary evaluation in the past 2 years?	If yes, findings are favorable on adequate test without onset of new symptoms, or symptoms change, proceed with surgery. If no or findings are unfavorable, go to 3.
3. Major clinical predictor of risk present?	Major clinical predictors include Unstable coronary syndromes Decompensated CHF Significant arrhythmias Severe valvular disease Presence of these predictors cancels or delays intervention until they are ameliorated. Implement medical management. Consider coronary angiography. Go to 4.
4. Intermediate clinical predictor of risk present?	Intermediate clinical predictors include Mild angina pectoris Prior MI Compensated or prior CHF Diabetes mellitus Renal insufficiency When these indicators are present, performance of noninvasive testing in AAA repair candidates is indicated, especially if 2 or more are present. If, after noninvasive testing, patient is determined to be low risk, continue with operation. If risk is high, consider coronary angiography. If no predictors are present, go to 5.
5. Minor or no clinical predictors present?	Minor clinical predictors include Advanced age Abnormal ECG Nonsinus rhythm Low functional capacity Previous stroke Uncontrolled systemic hypertension If minor or no clinical predictors are present and patient can attain 4 METs or more, proceed with surgery. Consider noninvasive testing when < 4 METs are attained, especially in presence of multiple minor clinical predictors; then go to 6.
6. Risk after noninvasive testing?	Low risk: proceed with operation. High risk: consider coronary angiography.

ACC—American College of Cardiology AHA—American Heart Association
CHF—congestive heart failure MET—metabolic equivalent MI—myocardial infarction

Table 4 Estimated Energy Required for Various Activities^{110,137}

Activity Level	METs*	Sample Activities
Mild	1–3	Eating; playing a musical instrument; walking at 2 mph; getting dressed; golfing (with cart)
Moderate	3–5	Calisthenics without weights; climbing a flight of stairs; housework; golfing (without cart); running a short distance
Vigorous	4–12+	Chopping wood; strenuous sports such as football, basketball, singles tennis, karate, or jogging (10 min mile or faster)

*1 MET = 3.5 ml · kg⁻¹ · min⁻¹ oxygen uptake.

operative cardiac evaluation in patients undergoing noncardiac vascular surgery [see Table 3], with the express goal of limiting the use of perioperative cardiac procedures in patients at moderate and high risk for complications.¹⁰⁶ Use of these guidelines and permutations thereof has proved both safe and effective at reducing resource use and overall costs.^{107–109} According to the ACC/AHA guidelines, patients needing urgent or elective AAA repair are stratified first by whether coronary revascularization was done within the past 5 years. If so, and symptoms have not recurred, the patient is cleared for operation. If the patient never underwent coronary revascularization, underwent revascularization more than 5 years before, or is experiencing recurrent symptoms or signs of cardiac ischemia, further evaluation of clinical predictors is necessary.

Clinical predictors of major perioperative cardiovascular risk—defined as myocardial infarction (MI), congestive heart failure, or death—may be divided into three categories¹⁰⁶: major, intermediate, and minor. The presence of a major predictor requires that the symptom or disease be managed appropriately before nonemergency surgery. The presence of an intermediate predictor is associated with an increased risk of perioperative cardiac complications and requires that current status be fully investigated. The presence of a minor predictor is indicative of cardiovascular disease but has not been shown to independently increase the risk of perioperative cardiovascular complications.

Once the clinical predictors have been evaluated, additional predictive factors, involving the patient's ability to perform various activities (ranging from minor activities of daily living to strenuous

sports), are assessed. The energy required to perform an activity is quantified in terms of metabolic equivalents (METs). The number of METs of which a patient is capable directly correlates with the ability to perform specific tasks [see Table 4]. Patients who are unable to attain 4 METs are considered to be at high risk for perioperative cardiac events and long-term complications. Finally, the inherent risk of the procedure to be performed is evaluated. AAA repair is considered high-risk.

The original ACC/AHA recommendations for supplemental preoperative testing were updated in a 2002 statement.¹¹⁰ Currently, it is generally agreed that preoperative testing should be limited to patients in whom the results have the potential to alter the current course of management. The following noninvasive tests may be considered.

1. 12-lead ECG. This test is recommended. Certain ECG abnormalities are clinical predictors of perioperative and long-term cardiac risks in patients undergoing high-risk operative procedures [see Table 5].
2. Transthoracic echocardiography to evaluate resting left ventricular function. This test is indicated in the presence of heart failure. If it was previously done and demonstrated severe left ventricular dysfunction, repeat evaluation is unnecessary. It may be of benefit in patients with prior heart failure and those with dyspnea of unknown etiology. Routine use is not beneficial in the absence of heart failure.
3. Exercise or pharmacologic stress testing. Such testing is useful for diagnosing CAD in patients with an intermediate pretest probability of CAD, but its value is less well established in those with a high or low pretest probability. It is a good prognosticator for patients with suspected or proven CAD who are undergoing initial evaluation, for patients whose clinical disposition has changed significantly, and for those who have experienced an acute coronary syndrome. Stress testing is also recommended for demonstrating the presence of myocardial ischemia before coronary revascularization and for evaluating the efficacy of medical therapy. It may be useful in patients whose subjective assessment of exercise tolerance is unreliable and in whom evaluation in terms of METs is therefore impossible. Less clear are the following indications for stress testing: (1) diagnosis of CAD in patients who have resting ST depression of less than 1 mm, are on digitalis, or show evidence of left ventricular hypertrophy on ECG, and (2) detection of restenosis in high-risk patients who have recently (i.e., within the past few months) undergone percutaneous transluminal coronary angioplasty (PTCA). Exercise stress testing should not be done (1) to diagnose patients with ECG findings that would prevent adequate assessment, (2) in patients with severe comorbidities that would preclude coronary revascularization, (3) for routine screening of asymptomatic patients, or (4) to evaluate young patients with isolated ectopic beats on ECG.

Table 5 ECG Findings as Clinical Predictors of Increased Perioperative Cardiovascular Risk¹³⁶

Major predictors
High-grade atrioventricular block
Symptomatic ventricular arrhythmias in the presence of underlying heart disease
Supraventricular arrhythmias with uncontrolled ventricular rate
Intermediate predictor
Pathologic Q wave indicating previous myocardial infarction
Minor predictors
Left ventricular hypertrophy
Left bundle-branch block
ST-T abnormalities
Rhythm other than sinus (e.g., atrial fibrillation)

Coronary angiography, if indicated, may be performed next. Current indications in patients scheduled to undergo AAA repair include (1) high-risk status after noninvasive testing, (2) continued angina despite adequate medical therapy, (3) unstable angina, and (4) an equivocal result on noninvasive testing in high-risk patients. Coronary angiography may be beneficial in patients with multiple intermediate clinical risk factors. If noninvasive testing reveals moderate-sized to large areas of ischemia in a patient without high-risk criteria and a lower left ventricular ejection fraction, or if testing is nondiagnostic in a patient at intermediate clinical risk, coro-

nary angiography may also be indicated. The indication for coronary angiography is more controversial in patients who have experienced a perioperative MI. Coronary angiography is not indicated in patients who are asymptomatic after coronary revascularization and who are capable of at least 7 METs.

Both coronary artery bypass grafting (CABG) and PTCA have been employed to treat CAD before AAA repair. CABG is usually done in this setting only if it has been decided that the patient needs the intervention regardless of the current status of the abdominal aorta. Such patients have a high-risk coronary anatomy and have a long-term prognosis that may improve if coronary revascularization is performed. The combination of AAA repair and CABG has been evaluated, and there are some data to support its use in highly select patients.^{111,112}

To date, no controlled trials have evaluated the efficacy of PTCA against that of medical therapy before noncardiac aortic surgery. Although some small observational studies have indicated a low cardiac mortality when preoperative PTCA is performed in this setting, complications after PTCA are not infrequent and include the need for emergency CABG. One retrospective review found that patients who underwent prophylactic PTCA before noncardiac surgery were twice as likely to have an adverse cardiac outcome as healthy patients were.¹¹³ This study did not control for CAD severity, medical management, or comorbidities. A later study concluded that both CABG and PTCA offered only modest protection against adverse cardiac events after major arterial surgery (CABG, < 5 years; PTCA, < 2 years).¹¹⁴ General indications for PTCA use are outlined in the 2001 revision of the 1993 ACC/AHA Guidelines for Percutaneous Coronary Intervention.¹¹⁵ It is recommended that patients wait at least 2 weeks—preferably, 4 to 6 weeks—after PTCA before undergoing AAA repair; this delay allows the plaque to stabilize after stenting and permits full treatment with antiplatelet agents.

Pulmonary Disease

Between 7% and 11% of patients with COPD have an AAA.²⁴ Traditionally, when such patients are to undergo AAA repair, room air arterial blood gas values are determined and pulmonary function tests performed to assess the extent of COPD. If COPD is severe, formal pulmonary consultation may be necessary for prediction of short- and long-term prognoses and optimization of treatment. Several studies have reported that COPD is an independent predictor of operative mortality.^{14,71,116} A 2001 study of Veterans Affairs (VA) patients, however, found no significant correlation between the presence of COPD and increased operative mortality (though morbidity was notably higher).¹¹⁷ A 2003 study evaluating morbidity and mortality after AAA repair in patients with COPD showed that the preoperative factors significantly associated with a poor outcome included (1) suboptimal COPD management, as evidenced by fewer inhalers used, (2) a lower preoperative hematocrit, (3) preoperative renal insufficiency, and (4) the presence of CAD.¹¹⁸ It is noteworthy that abnormal preoperative pulmonary function tests and arterial blood gas values were not predictive of a poor outcome. Thus, COPD by itself is not a contraindication to AAA repair.

Renal Failure

Preoperative renal insufficiency [see 8.6 *Renal Failure*] is known to be a risk factor for a poor outcome after AAA repair^{14,71,117,118} and thus should be evaluated and corrected if possible. In certain patients with AAAs, renal artery stenosis may be contributing to impaired renal function; if so, it may be corrected either noninva-

sively, before AAA repair, or in the course of the repair.⁴⁶

Diabetes Mellitus

Whether diabetes mellitus is truly an independent risk factor for morbidity or mortality after aortic surgery is controversial. Several studies have shown that the risk of death is not increased in diabetic patients, but the risk of perioperative complications may be.¹¹⁹⁻¹²¹ Most of these studies had small study groups and thus lacked the statistical power needed to demonstrate that diabetes had a significant influence. A 2002 study of patients at VA medical centers who underwent major vascular procedures found that diabetic patients were indeed at higher risk for death and cardiovascular complications.¹²² When examined separately, however, patients undergoing AAA repair did not have higher rates of cardiovascular complications or death than patients undergoing other procedures.

PERIOPERATIVE MEDICATIONS

Multiple studies have addressed optimization of medical management in patients with AAAs. Beta blockers, alpha₂-adrenergic agonists, nitrates, and calcium channel blockers have all been evaluated in this setting. Other agents used in the treatment of cardiovascular disease (e.g., aspirin) have not been specifically evaluated in regard to reduction of perioperative cardiac complications in patients undergoing aortic surgery.¹²³

A review of the literature supporting perioperative beta blockade was published in 2002.¹²⁴ Five randomized, controlled trials were evaluated, and the results suggested that this measure had a beneficial effect on perioperative cardiac morbidity. The number needed to treat to prevent one MI was 2.5 to 6.7 patients; the number needed to treat to produce a significant effect on cardiac or all-cause mortality was 3.2 to 8.3 patients. All but one of the studies reported a significant reduction in postoperative MIs after beta blocker use, with the effect being most obvious in high-risk patients. Thus, it appears that perioperative beta blockade is most likely beneficial for patients at high risk for cardiac events who are to undergo AAA repair, unless it is otherwise contraindicated (e.g., by COPD). The therapeutic goal should be to attain a resting heart rate of 60 beats/min or lower before operation.¹²³

Alpha₂-adrenergic agonists (e.g., clonidine) have not been shown to reduce MI rates or mortality from cardiac causes. In one study, mivazerol did not exert a significant overall effect in patients undergoing major vascular or orthopedic procedures but was associated with a significant reduction in MI rates and mortality from cardiac causes in patients with known CAD.¹²⁵ Therefore, when perioperative beta blockade is contraindicated, administration of alpha₂-adrenergic agonists may be of benefit in high-risk patients.

To date, studies evaluating the perioperative use of nitroglycerin and diltiazem to lower the risk of cardiac events have not found this practice to be beneficial in this regard. It may be best to reserve these agents for patients who need them for angina or ischemic symptoms and for those who have myocardial ischemia after operation.¹²³

It is widely accepted that aspirin is beneficial in reducing the risks associated with CAD.¹²⁶ Its continued use throughout the perioperative period is controversial, however, as is the use of clopidogrel, because of the potential complications associated with decreased platelet function. Indications for the use of these antiplatelet agents may be patient dependent.¹²⁷ Traditionally, aspirin is discontinued at least 1 week before aortic surgery.

FURTHER IMAGING

The main methods used to evaluate the aortic anatomy before AAA repair are ultrasonography, CT, MRA, and aortography.

Which method is employed in a given situation depends largely on the clinical presentation, the history, the comorbid conditions present, and the availability of equipment and expertise. Each has its advantages and disadvantages [see *Table 2*].

Ultrasonography

Further ultrasonographic evaluation of the aortic anatomy, if indicated, is performed in accordance with the approach described earlier [see *Patient Is Stable, above*].

CT Scanning

The current standard for preoperative imaging of AAAs is contrast-enhanced CT scanning. This modality is more accurate than aortography at measuring AAA diameter and determining the presence of rupture.⁵³ With spiral CT, it is possible to obtain a three-dimensional view of the abdominal aorta. CT scanning is highly accurate, with measurements reproducible to within 2 mm. Measurement variations as great as 5 mm are sometimes seen, however, occurring 9% to 17% of the time.^{54,56} Such variations may be reduced by standardizing measurements, reducing the number of radiologists reading the images, and using calipers and magnification for greater accuracy.⁵⁶

The advantages of CT over ultrasonography include (1) more precise definition of the proximal and distal extent of AAAs, (2) better delineation of the iliac arterial anatomy, (3) the ability to evaluate AAA wall integrity, noting the location and amount of calcification within vessel walls, and (4) the ability to identify venous anomalies, retroperitoneal blood, aortic

dissection, inflammatory aneurysms, and other intra-abdominal pathologic conditions and anomalies (e.g., horseshoe kidney). Therefore, CT is the study of choice for excluding AAA rupture in stable but symptomatic patients.^{1,53,128} Thin-cut helical/spiral CT arteriography with multiplanar reconstruction is a recommended study for evaluating patients before endovascular AAA repair; CT arteriography is also preferred for determining whether an endoleak has occurred after endovascular AAA repair.¹²⁹ In the near future, ultrasonography may supplement CT for these applications.

The main drawbacks associated with CT scanning are (1) radiation exposure and (2) the requirement for iodinated contrast material, which cannot be used in patients with dye allergies or renal insufficiency. In addition, spiral CT with three-dimensional reconstruction is relatively expensive at present. Allergic reactions to the contrast agent can usually be prevented by giving a standard steroid-diphenhydramine preparation. Alternatively, CT scanning may be done without contrast to determine whether there is a large retroperitoneal hematoma, which would be indirectly suggestive of a ruptured AAA. If the patient has renal insufficiency, MRA may be more appropriate.

MRA

In patients with renal insufficiency who are scheduled for AAA repair, MRA with gadolinium and the breath-hold technique may be the preoperative study of choice; it is comparable to CT scanning in evaluating elective AAA repair candidates [see *Figure 7*.^{86,130} The main advantages of MRA are that (1) it does not require the use of nephrotoxic agents or radiation and (2) it is highly sensitive and specific in detecting stenoses of the splanchnic, renal, and iliac arteries.⁸⁵ Its main drawbacks are that (1) it is not widely available, (2) it is expensive, (3) it may cause claustrophobia in select patients, and (4) it takes longer to perform than CT scanning. MRA is contraindicated in patients with pacemakers, metallic foreign bodies in the eye, cochlear implants, and certain berry aneurysm clips. Over time, however, as MRA becomes faster, more widely available, and less expensive, its advantages may make it a more attractive alternative in the preoperative workup of patients with AAAs.

Aortography

Preoperative digital subtraction aortography is not routinely used for diagnosis but rather as an adjunct to other studies in preparation for AAA repair. Being an invasive test, it carries an added risk over other imaging modalities. Aortography is currently indicated in the preoperative evaluation of an AAA when (1) the extent of the aneurysm may include the juxtarenal or suprarenal aorta, (2) the clinical history is indicative of lower-extremity arterial occlusive disease (i.e., claudication or rest pain), (3) renovascular disease may be present, as evidenced by uncontrolled hypertension or azotemia, or (4) the patient has previously undergone arterial reconstruction.⁸² Aortography is superior at evaluating the intraluminal characteristics of the aorta, determining visceral-branch involvement, and delineating variations in the vascular anatomy.¹¹

Aortography has a number of important limitations in comparison with CT or MRA. In particular, it is associated with multiple risks that are not incurred with CT or MRA, such as infection, arterial thrombosis necessitating emergency thrombectomy and repair, distal embolization, groin hematoma, and local arterial dissection.¹³¹ There is also a 10% risk of renal failure in patients with elevated creatinine levels (≥ 2.5 mg/dL)¹³¹; this can often be pre-

Figure 7 Shown is an MRA of a patient who had undergone both open infrarenal AAA repair and aortobifemoral bypass off the terminal aorta. The AAA grew between the two previous repairs and was subsequently managed endovascularly.

Figure 8 CT scan of a patient with Marfan syndrome who presented with increasing abdominal pain reveals a large hematoma along the lesser curvature of the stomach. The hematoma was localized via angiography and was found to be consistent with a ruptured left gastric artery aneurysm.

vented with adequate hydration before the study. Finally, the cost of aortography is three to four times that of spiral CT, which gives health care providers an incentive to replace aortography with spiral CT whenever possible.¹³²

Complications of AAAs

Rupture of an AAA obviously is often life threatening, but erosion of an aneurysm into adjacent structures may be catastroph-

ic as well. In certain instances, ruptured AAAs may form a continuous luminal connection with a surrounding structure. High-output cardiac failure may result from an arteriovenous shunt between the aorta and the inferior vena cava, which occurs in as many as 2% to 4% of patients with ruptured AAAs.^{133,134} AAA patients with intermittent GI bleeding may present with a so-called herald bleed from a primary aortoenteric fistula. Most such fistulas occur in the third or fourth part of the duodenum.¹³⁵ Aorta-inferior vena cava shunts and aortoenteric fistulas are medical emergencies that demand immediate operative attention.

AAAs may also give rise to distal lower-extremity atheroemboli [see **6:5 Pulseless Extremity and Atheroembolism**]. Small AAAs appear to be the most common sources: infrarenal AAAs with mean diameters of 3.5 cm have been linked to lower-extremity atheroemboli.¹³⁶ Thrombosis of an AAA also occurs; if it develops acutely, severe ischemia of the entire lower torso may result, manifested by a bilateral lack of femoral pulses, a drop in skin temperature beginning at the level of the upper thigh, and a change in skin color beginning at the level of the knees.¹³⁵ Recognizing these symptoms as potential complications of AAAs can facilitate diagnosis.

Rare Causes of Pulsatile Abdominal Mass

Finally, when a patient presents with a pulsatile abdominal mass that is suggestive of aneurysmal disease, the most likely diagnosis is an infrarenal AAA, in that 80% of aortic aneurysms are found in this location. It is important to keep in mind, however, that various less common types of aneurysms may also present as a pulsatile abdominal mass, including (but not limited to) iliac artery aneurysms [see *Figure 3*], traumatic pseudoaneurysms, and visceral artery aneurysms [see *Figure 8*].

4 ACUTE MESENTERIC ISCHEMIA

Melina R. Kibbe, M.D., and Heitham T. Hassoun, M.D.

Diagnosis and Management of Acute Bowel Ischemia

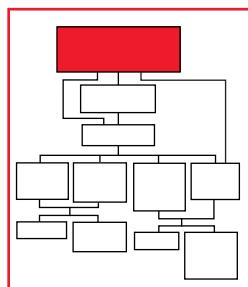

Acute mesenteric ischemia is an uncommon life-threatening clinical entity that ultimately leads to death unless it is diagnosed and treated appropriately. Despite diagnostic and therapeutic advances and an improved understanding of the pathophysiology, the morbidity and mortality associated with acute mesenteric ischemia remain high, having changed relatively little over the past several decades. Accordingly, the index of suspicion for this disease should be high whenever a patient presents with acute-onset severe abdominal pain that is out of proportion to the physical findings. Once the diagnosis is made, prompt intervention is required to minimize morbidity and mortality.

Acute mesenteric ischemia can result from any of four distinct processes: (1) embolic occlusion of the mesenteric circulation (usually the superior mesenteric artery [SMA]); (2) acute thrombosis of the mesenteric circulation; (3) intense splanchnic vasoconstriction—so-called nonocclusive mesenteric ischemia (NOMI)—which is usually associated with a low-flow state or profound hypovolemia; or (4) mesenteric venous thrombosis (MVT).

Clinical Evaluation

HISTORY AND PHYSICAL EXAMINATION

The classic presentation for patients with embolic disease of the mesenteric vessels is sudden-onset midabdominal pain that is described as being out of proportion to the physical findings and is associated with immediate bowel evacuation. In fact, only about one third of patients present with the triad of abdominal pain, fever, and heme-positive stools. A study that considered all causes of acute mesenteric ischemia found that 95% of patients presented with abdominal pain, 44% with nausea, 35% with vomiting, and 35% with diarrheal¹; only 16% presented with blood per rectum.

Patients with thrombotic mesenteric occlusion also present with sudden-onset severe midabdominal pain that is out of proportion to the physical findings, but unlike patients with acute embolic occlusion, they typically have a history of chronic postprandial abdominal pain and significant weight loss.

Patients with NOMI present somewhat differently. The pain reported is usually not as sudden as that noted with embolic or thrombotic occlusion: it is generally more diffuse and tends to wax and wane (unlike the pain associated with embolic or thrombotic disease, which tends to get progressively worse).

Patients with MVT often present with various nonspecific abdominal complaints; accordingly, this diagnosis may be especially challenging. Common complaints include nausea, vomiting, diarrhea, abdominal cramping, and nonlocalized abdominal pain. As a rule, these symptoms are not acute. A study of MVT patients found that 84% presented with abdominal pain.² Of those 84%, only 16% presented with peritoneal signs, whereas

68% presented with vague abdominal pain. Other presenting symptoms included diarrhea (42%), nausea and vomiting (32%), malaise (16%), and upper GI bleeding (10%).²

In addition to the clinical presentation, risk factors provide essential clues for correct identification of these disease processes. Certain general risk factors for acute mesenteric ischemia have been identified. In one study, 78% of the patients presented with a history of hypertension, 71% with a history of tobacco use, 62% with a history of peripheral vascular disease, and 50% with a history of coronary artery disease (CAD).¹

There are also more specific risk factors for individual causes of acute mesenteric ischemia. Patients with embolic occlusion of the mesenteric circulation typically have a history of recent cardiac events (e.g., myocardial infarction, atrial fibrillation, mural thrombus, mitral valve disease, or left ventricular aneurysm) or previous embolic disease. In the study just cited, 50% of the patients who presented with embolic occlusive disease had atrial fibrillation.¹ Patients with acute mesenteric ischemia secondary to thrombotic occlusive disease typically have other manifestations of diffuse atherosclerotic disease (e.g., CAD, peripheral artery disease, and carotid stenosis). The risk factors for NOMI are slightly different. This condition usually occurs during severe low-flow states and represents extreme mesenteric vasoconstriction. It is much more common among severely ill patients in an intensive care unit who require vasopressors and among patients undergoing dialysis with excessive fluid removal. The risk factors for MVT include a history of previous venous thrombosis or pulmonary embolism, a known or suspected hypercoagulable state, oral contraception, and estrogen supplementation. In a study of 31 patients who presented with MVT at Northwestern University, 13 (42%) were diagnosed with a hypercoagulable state, six (19%) had a history of previous thrombotic episodes, and four (13%) had a history of cancer.²

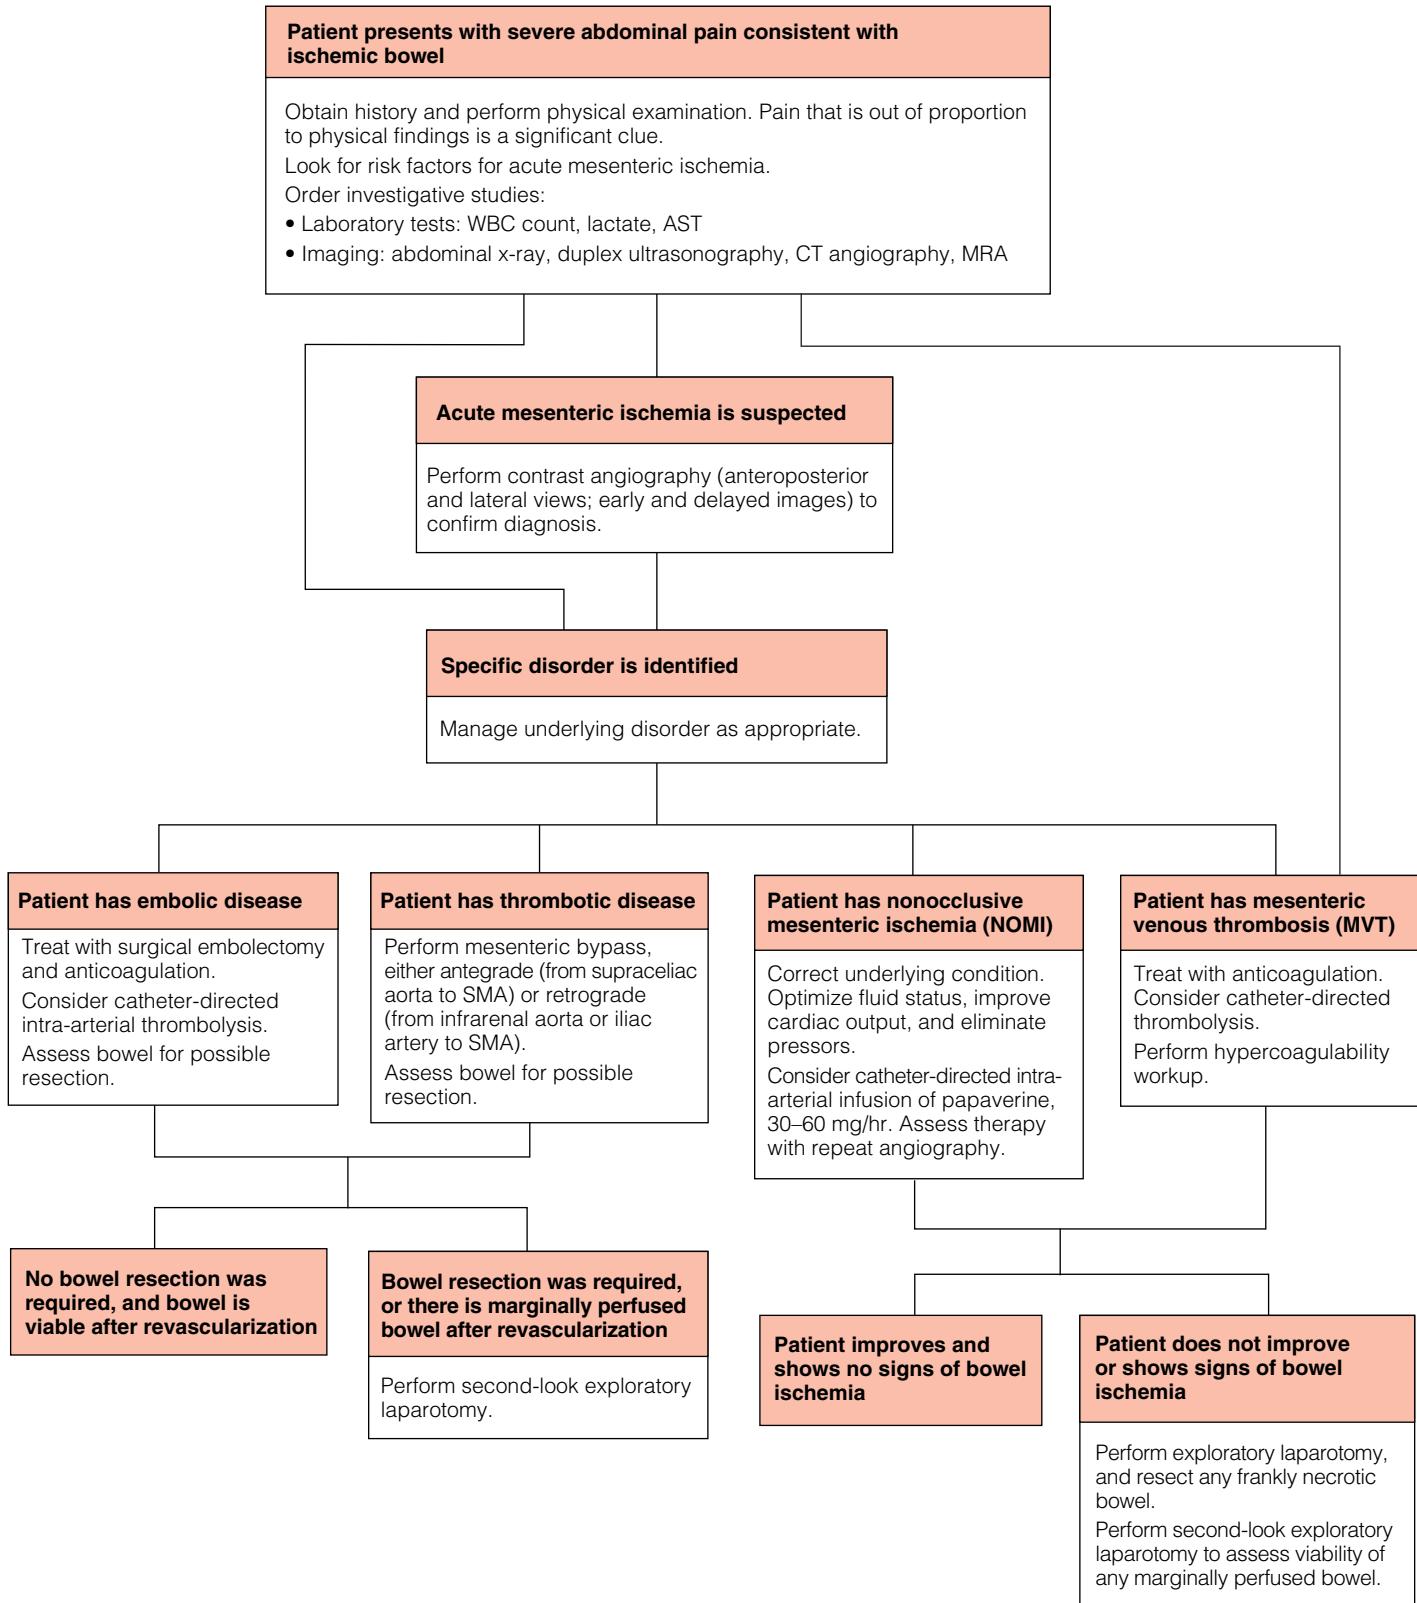

Investigative Studies

Although there are no basic laboratory or radiographic studies that are diagnostic for acute mesenteric ischemia, such studies can help confirm the diagnosis when it is suspected on the basis of the history and the physical examination.

LABORATORY TESTS

In most cases, the white blood cell count is elevated. In a study from the Mayo Clinic, 98% of patients who presented with acute mesenteric ischemia were found to have an elevation of the leukocyte count, and 50% were found to have counts higher than 20,000/mm³.¹ Lactate is another nonspecific indicator of mesenteric bowel ischemia. In the same Mayo Clinic study, approximately 91% of patients had elevated lactate levels, with 61% having levels higher than 3 mmol/L.¹ In addition, 71% of patients presented with an elevated AST, whereas 52% presented with an abnormal base deficit.¹

Diagnosis and Management of Acute Bowel Ischemia

IMAGING

Abdominal X-rays

Although abdominal radiographic films can neither establish nor exclude the diagnosis of acute mesenteric ischemia, they may reveal signs that are consistent with bowel ischemia. If obtained early, abdominal plain films should show no abnormalities. If obtained late in the presentation, however, they may reveal edematous bowel with thumbprinting. In severe cases, abdominal plain films may reveal gas in the bowel wall and the portal vein. More commonly, however, they reveal a pattern consistent with ileus or are completely unremarkable. In a study of patients operated on for acute mesenteric ischemia, mortality was 29% in patients with normal plain radiographic films, compared with 78% in those with abnormal films.³ Nevertheless, it must be emphasized that the primary role of abdominal plain radiographic films in this setting is to exclude other identifiable causes of abdominal pain (e.g., obstruction and perforation with free air).

Duplex Ultrasonography

Duplex ultrasonography plays only a limited role in the management of acute mesenteric ischemia—not surprisingly, given the acute nature of the presentation, the accompanying ileus with excessive bowel gas and bowel edema (which hinders visualization of the mesenteric vessels), and the reduced access to the vascular laboratory during off hours. Furthermore, duplex ultrasonography, though capable of imaging stenotic and occlusive lesions at the origin of a mesenteric vessel, is of no value in detecting emboli beyond the proximal portion of the vessel. Similarly, it has no role in the diagnosis of NOMI.

Duplex ultrasonography does have a definite and well-defined role in the diagnosis of chronic mesenteric ischemia. Well-accepted published criteria exist for the diagnosis of celiac artery and SMA stenosis on the basis of velocity measurements.⁴ In the diagnosis of acute mesenteric ischemia, however, where the primary goal is to determine whether there is an acute occlusion of the celiac artery or the SMA, the aforementioned technical limitations of this diagnostic modality limit its application.

CT Angiography

Computed tomographic angiography and magnetic resonance angiography (MRA) are more commonly used to confirm the

diagnosis of acute mesenteric ischemia than duplex ultrasonography is. Both CT and MRA have undergone significant advances over the past decade. Traditional CT scanning can evaluate arterial patency and anatomy and detect calcifications and aneurysms. In addition, it can evaluate the status of the bowel and help identify other causes of abdominal pain (e.g., pancreatitis, bowel perforation, and bowel obstruction). However, it was not until the advent of helical (spiral) CT scanning—and, subsequently, of multislice, multiarray helical CT scan technology with maximum-intensity projection—that the visceral arterial anatomy could be visualized with three-dimensional spatial resolution [see Figure 1]. This technology allows much more rapid acquisition of data and thereby improves the quality of vascular imaging tremendously. A study comparing spiral CT angiography with conventional contrast angiography found that the former had a sensitivity of 75% and a specificity of 100% for the detection of greater than 75% stenosis of the celiac artery.⁵ Furthermore, spiral CT angiography had a sensitivity of 100% and a specificity of 91% for the detection of SMA stenosis.

Although CT technology has become much more sophisticated and the image clarity and definition have improved greatly, there are still limits to what can be determined by means of CT in the setting of acute embolic or thrombotic disease. The origins of the celiac artery and the SMA are well visualized with CT, but secondary, tertiary, and smaller branches are less well defined; for visualizing these branches, contrast angiography remains the gold standard [see Contrast Angiography, below]. Another limitation of current CT scanning technology is the need to administer intravenous contrast agents, which can be nephrotoxic or, in some patients, trigger contrast allergies. CT angiography also tends to overestimate the degree of critical stenosis when compared with conventional angiography; however, this limitation appears to be less of an issue with the advent of multiarray or multidetector technology, which is more sensitive in detecting arterial stenosis. Finally, significant calcification at the origin of the vessel can make it difficult to determine the true degree of stenosis with CT scanning.

In contrast to its relatively limited role in the diagnosis of acute mesenteric ischemia of embolic or thrombotic origin, CT plays a valuable role in diagnosing MVT and is the preferred diagnostic imaging modality in patients presenting with abdominal pain who have a history of deep vein thrombosis (DVT) or a known hypercoagulable disorder.⁶ CT scanning can readily reveal thrombosis

Figure 1 Shown are CT scans of mesenteric vessels: (a) transaxial image of celiac artery (arrow); (b) transaxial image of SMA (arrowhead); and (c) three-dimensional reconstruction of aorta and origins of celiac artery (arrow) and SMA (arrowhead).

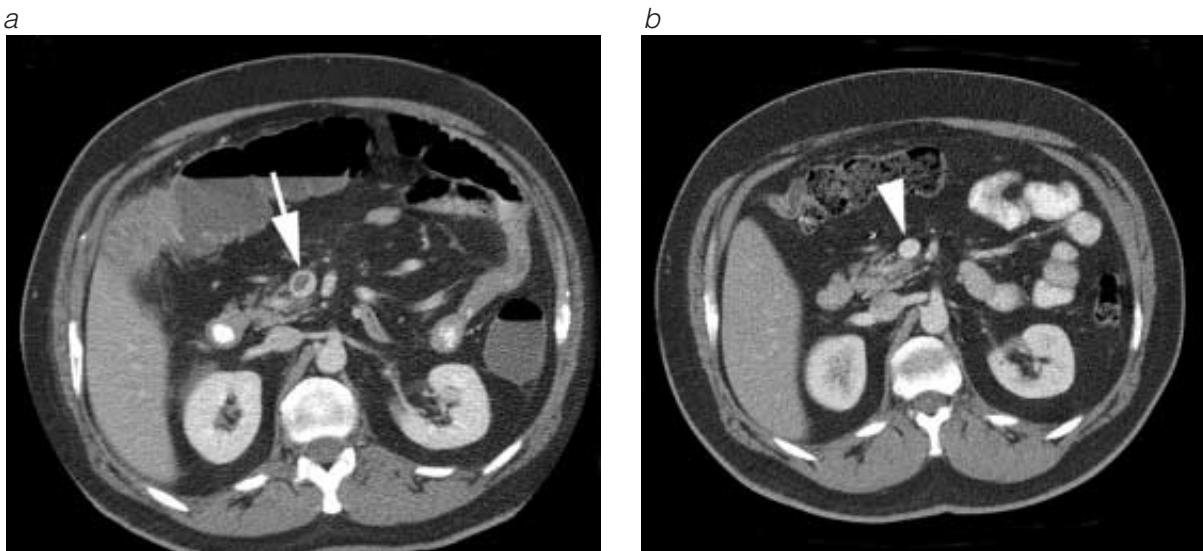

Figure 2 (a) CT scan shows partially occluding thrombus in SMV (arrow). (b) CT scan obtained 4 months later reveals complete resolution of thrombus (arrowhead).

of the superior mesenteric vein (SMV), with or without associated bowel abnormalities [see *Figure 2*]. In fact, CT scans of SMV thrombosis in asymptomatic patients have provided useful information on the pathophysiology of MVT and broadened our understanding of the wide spectrum of this disease entity. In a study from the Mayo Clinic, CT scanning correctly identified 100% of patients who presented with acute MVT and 93% of those who presented with chronic venous thrombosis.⁷ In a subsequent study from our institution (Northwestern University), CT scanning identified 100% of MVT patients who presented with vague abdominal pain or diarrhea and 90% of MVT patients who underwent a CT scan.² In contrast, conventional angiography correctly diagnosed MVT in only five of nine patients.²

Figure 3 Shown are contrast-enhanced three-dimensional MRAs of aorta and mesenteric vessels. (a) Anterior projection shows celiac artery (arrow) and SMA (arrowhead). (b) Lateral projection shows celiac artery (arrow) and SMA (arrowhead).

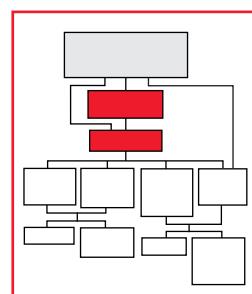

Magnetic Resonance Angiography

Advances in magnetic resonance technology—in particular, the development of contrast-enhanced three-dimensional MRA—have made MRA imaging of visceral vessels much more practical than was once the case. Fast imaging techniques using I.V. administration of gadolinium over a single breath-hold can provide high-quality three-dimensional images [see *Figure 3*] in axial, sagittal, or oblique planes. An advantage MRA has over CT angiography is that gadolinium is significantly less nephrotoxic than the contrast agents used for CT scans. Like CT angiography, however, MRA does not adequately assess the distal branches of the mesenteric vessels. One study compared contrast-enhanced breath-hold MRA with conventional digital subtraction angiography in 33 patients.⁸ There was excellent agreement between the two studies for the celiac artery and the SMA; however, there was poor agreement for the distal branches of the SMA, as well as for the intrahepatic branches of the hepatic artery.

Given the current state of imaging technology, it is possible to confirm the diagnosis of acute mesenteric ischemia with either CT angiography or MRA. If the cause of the ischemia is confirmed—and, in the case of SMA thrombosis, if distal targets are identified for revascularization—it is conceivable that the patient could be explored in the OR without undergoing conventional angiography. Many institutions, however, do not have ready access to all the latest imaging technology. In such situations, the best imaging modality for evaluation of the mesenteric vasculature remains contrast angiography.

Contrast Angiography

Contrast angiography has long been considered the gold standard for imaging the visceral vessels. This modality can visualize the aorta and the main trunks of the mesenteric vessels and can adequately assess several orders of distal branches. The images obtained with contrast angiography are superior to those obtained with CT angiography or MRA. The procedure is performed in a transfemoral manner by means of the Seldinger technique, with infusion of approximately 60 to 100 ml of contrast material. Arteriography should include

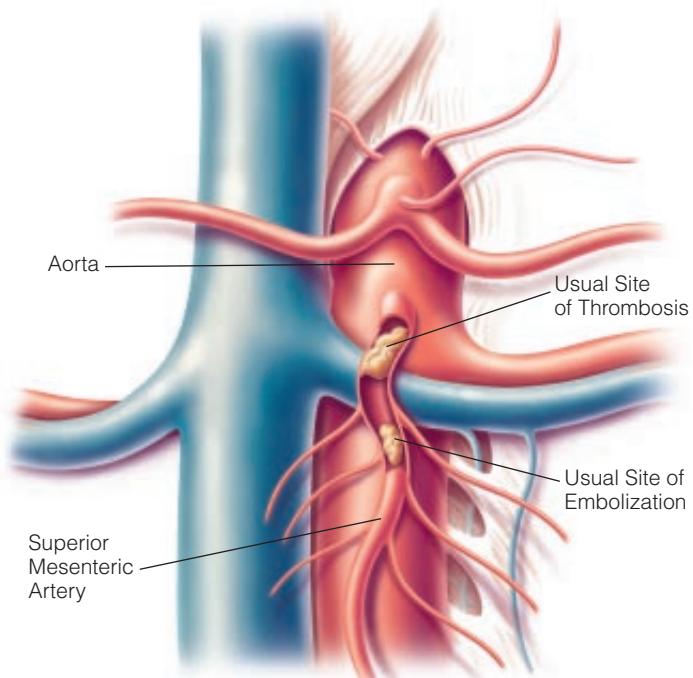

Figure 4 Schematic drawing demonstrates usual site for SMA thrombosis versus that for SMA embolus.

Figure 5 Selective angiogram of SMA in anterior projection demonstrates embolus within vessel (arrow) at typical location.

both anteroposterior and lateral views of the celiac artery, the SMA, and the inferior mesenteric artery (IMA). The origins of the celiac artery and the SMA are best seen on the lateral view, whereas the middle and distal SMA and the IMA are best seen on the anteroposterior view. Delayed views are useful in evaluating a patient for NOMI.

There are classic angiographic patterns that serve to distinguish mesenteric ischemia of embolic origin from that of thrombotic origin [see Figure 4]. Of the three mesenteric vessels, the SMA is most likely to be the site of embolic lodgment because it takes off from the main axis of the aorta at a less sharp angle than the celiac artery and the IMA, which arise from the aorta more perpendicularly. When emboli lodge in the SMA, they usually lodge distal to the middle colic branch and the jejunal branch [see Figure 5]. In thrombotic disease, the thrombus usually forms at the atherosclerotic plaque, which, for most patients, is usually at the origin of the mesenteric vessel. Consequently, the angiogram typically demonstrates complete absence of flow in the mesenteric vessel, which often makes it difficult to ascertain the location of the vessel's origin [see Figure 6].

Patients with NOMI typically exhibit angiographic evidence of SMA vasospasm. A small SMA trunk is visualized, with very few branching vessels visible, and the branches that are visualized show a characteristic tapering of the vessel to the point of occlusion [see Figure 7a]. These patterns are best seen on the anteroposterior projection.

Angiography is less useful for the diagnosis of MVT. Typically, MVT is diagnosed on the venous phase of the selective arterial contrast injection; however, as noted [see CT Angiography, above], conventional angiography is less sensitive and specific for MVT than the diagnostic imaging modality of choice—namely, CT.

Besides providing superior image quality, contrast angiography enables the surgeon to perform selective injection of any of the mesenteric vessels and to perform therapeutic intervention. In patients with NOMI, for example, the SMA may be selectively catheterized and papaverine infused directly into the vessel [see Figure 7b]. In a stable patient with acute mesenteric ischemia from a partially occluding embolus but no peritoneal signs, selective catheterization of the SMA allows the institution of catheter-directed intra-arterial thrombolytic therapy [see Figure 8]. Thus, contrast angiography not only represents the gold standard for diagnostic imaging but also provides important therapeutic options.

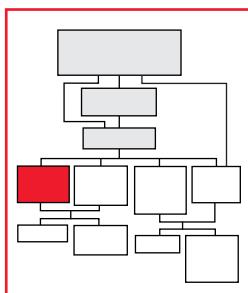

Management

TREATMENT OF SPECIFIC DISORDERS

Embolic Occlusion of Mesenteric Vessels

The goals in the surgical treatment of acute mesenteric ischemia are (1) to restore normal pulsatile flow to the SMA and (2) to resect any nonviable intestine. In general, revascularization precedes resection. The therapeutic approach varies, depending on the specific underlying cause. For embolic disease of the SMA, the standard treatment is surgical embolectomy; this procedure is described in more detail elsewhere [see 6:16 Mesenteric Revascularization Procedures].

Percutaneous interventional treatment of acute SMA occlusion has also been described in the literature. At present, however, the applicability of this approach is limited, in that most patients pre-

sent with symptoms that warrant an exploratory laparotomy for evaluation of intestinal viability. In patients who present with abdominal pain, have no peritoneal signs that would necessitate an exploratory laparotomy, and are found to have a partially occluding embolus in the SMA, catheter-directed intra-arterial thrombolytic therapy is worth considering. We have treated such patients in this manner at our institution. This route should be used cautiously, however, and if intra-arterial thrombolytic therapy is instituted, the patient should be closely monitored in the ICU with serial abdominal examinations. Even if thrombolytic therapy does restore blood flow to the ischemic intestine, the patient may still experience pain sufficient to necessitate exploration. For these reasons, our use of thrombolytic therapy is highly selective.

Thrombotic Occlusion of Mesenteric Vessels

Acute mesenteric ischemia secondary to thrombotic disease occurs in patients with long-standing atherosclerotic disease of the mesenteric vessels. In this situation, the entire midgut is usually involved. Surgical treatment consists of a bypass procedure [see 6:16 *Mesenteric Revascularization Procedures*], which may be done in either an antegrade or a retrograde manner. The conduit of choice is a reversed autologous greater saphenous vein graft. Synthetic graft material should be avoided in the setting of acute bowel ischemia, given the high risk of transmural bowel infarction and perforation.

There are several different inflow options for revascularizing the SMA that must be considered carefully. The main choices for inflow are the supraceliac aorta, the infrarenal aorta, and the iliac artery. In cases of acute mesenteric ischemia where time is of the essence and prompt revascularization of the bowel is required, it is often easier to perform a retrograde bypass from the infrarenal aorta or iliac artery, in that the exposure is relatively simple and readily familiar to all vascular surgeons. Furthermore, a retrograde bypass yields less hemodynamic compromise because it avoids supraceliac clamping and the associated mesenteric and renal ischemia. Accordingly, retrograde bypass is the preferred approach in our institution. In cases of acute mesenteric ischemia where the suprarenal aorta is easily approachable and not calcified, however, an antegrade vein graft from the suprarenal aorta to the SMA will lie better because it is less susceptible to kinking than a retrograde graft once the bowel is restored to its correct anatomic position.

Nonocclusive Mesenteric Ischemia

Management of NOMI is largely non-operative. Once the diagnosis has been established with angiography [see Figure 7], treatment of the underlying precipitating cause is the key therapeutic intervention. Optimization of fluid resuscitation, improvement of cardiac output, and elimination of vasopressors are the measures that have the greatest impact on outcome. Selective catheterization of the SMA with direct intra-arterial infusion of papaverine (30 to 60 mg/hr) may be employed as adjunctive therapy. The infusion is continued for at least 24 hours, with repeat angiography performed at regular intervals to determine the effectiveness of this therapy.

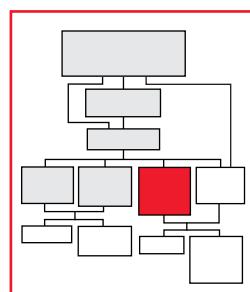

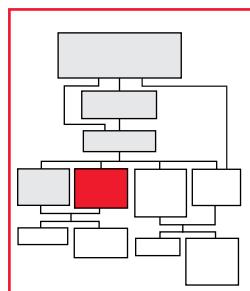

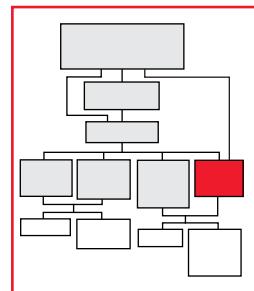

Figure 6 Lateral contrast angiogram of aorta demonstrates complete occlusion of both celiac artery (arrow) and SMA (arrowhead) at their origins, consistent with *in situ* thrombosis. Lack of collaterals suggests an acute process.

If the patient presents with peritoneal signs on physical examination, an exploratory laparotomy will be required for resection of frankly necrotic or gangrenous bowel. If an intra-arterial infusion of papaverine has been initiated, it should be continued throughout the exploratory laparotomy. Given the known propensity of this disease process for waxing and waning, a second-look laparotomy is also imperative [see Second-Look Laparotomy, below].

Mesenteric Venous Thrombosis

Once mesenteric venous thrombosis is diagnosed, the mainstay of therapy is anticoagulation. If the patient's condition does not improve or worsens after anticoagulation or if signs or symptoms of bowel ischemia (e.g., peritonitis) develop, abdominal exploration is warranted. Typically, the bowel is dusky and edematous. All frankly necrotic bowel should be resected. Within 24 to 48 hours, a second-look laparotomy should be done to evaluate the viability of any marginally perfused bowel [see Second-Look

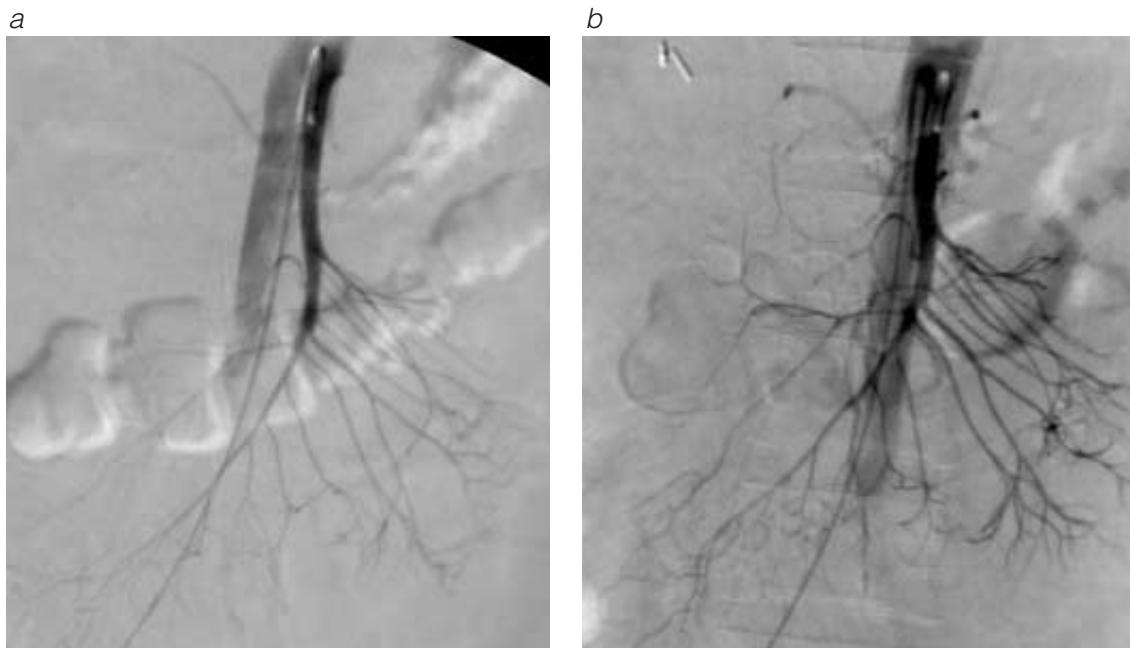

Figure 7 Shown are contrast angiograms of aorta and mesenteric vessels in a patient with NOMI. (a) Selective angiogram (anterior projection) of SMA demonstrates distal spasm of SMA. (b) Selective angiogram (anterior projection) of SMA after intra-arterial papaverine infusion demonstrates improved filling of distal branches of SMA.

Laparotomy, below]. In a study of 31 MVT patients from our institution,² the majority were successfully treated with anticoagulation alone and experienced complete resolution of their symptoms; however, 32% did require small bowel resection. Perioperative mortality was 23%. Among those who survived operation, the long-term survival rate was 88%; all of these survivors were symptom free at last follow-up.

Thrombolytic therapy has also been employed to treat MVT. The catheter may be directed into the SMA for lysis of portal vein thrombus.² Alternatively, it may be directed into the SMV or the portal vein intraoperatively.⁹

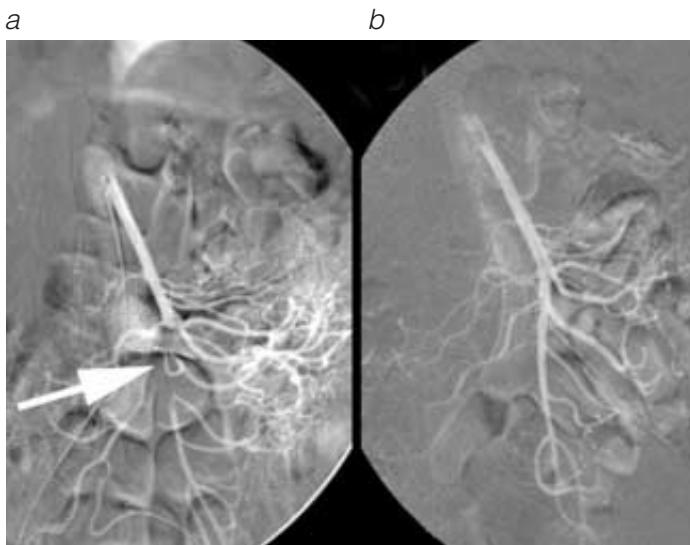

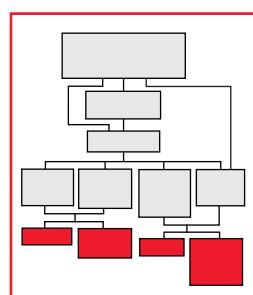

Figure 8 (a) Selective angiogram of SMA demonstrates partially occluding embolus in distal vessel (arrow). (b) Selective angiogram after catheter-directed intra-arterial thrombolytic therapy shows resolution of embolus.

Once the diagnosis of MVT has been established, a hypercoagulability workup should be performed in an effort to identify the underlying cause. If the cause is found to be a hematologic hypercoagulable state, lifelong anticoagulation is recommended. If the cause is reversible, anticoagulation may be discontinued after 3 to 6 months.

SECOND-LOOK LAPAROTOMY

Second-look laparotomy is an essential part of the management of acute mesenteric ischemia. No matter which adjunctive method is used intraoperatively to assess bowel perfusion and viability, second-look laparotomy is the most reliable means of determining the viability of marginally perfused bowel after revascularization. A second-look laparotomy should be preceded by adequate fluid resuscitation and correction of the acid-base imbalance. Furthermore, the decision to perform a second-look laparotomy should be made during the first operation and adhered to no matter what the patient's condition is 24 to 48 hours later. Occasionally, even though the patient is in better physical condition 24 to 48 hours later—largely because of aggressive fluid resuscitation and correction of the acid-base imbalance—there is still some necrotic bowel that must be resected. Accordingly, we adhere to a strict policy of planned reexploration for acute mesenteric ischemia patients who require bowel resection during the initial operation or who have areas of marginally viable bowel after revascularization.

Intraoperative Consultation

Vascular surgeons are frequently consulted intraoperatively to evaluate a patient for acute mesenteric ischemia. Often, the patient has been taken to the OR on an emergency basis for acute abdominal pain with peritoneal signs or hemodynamic

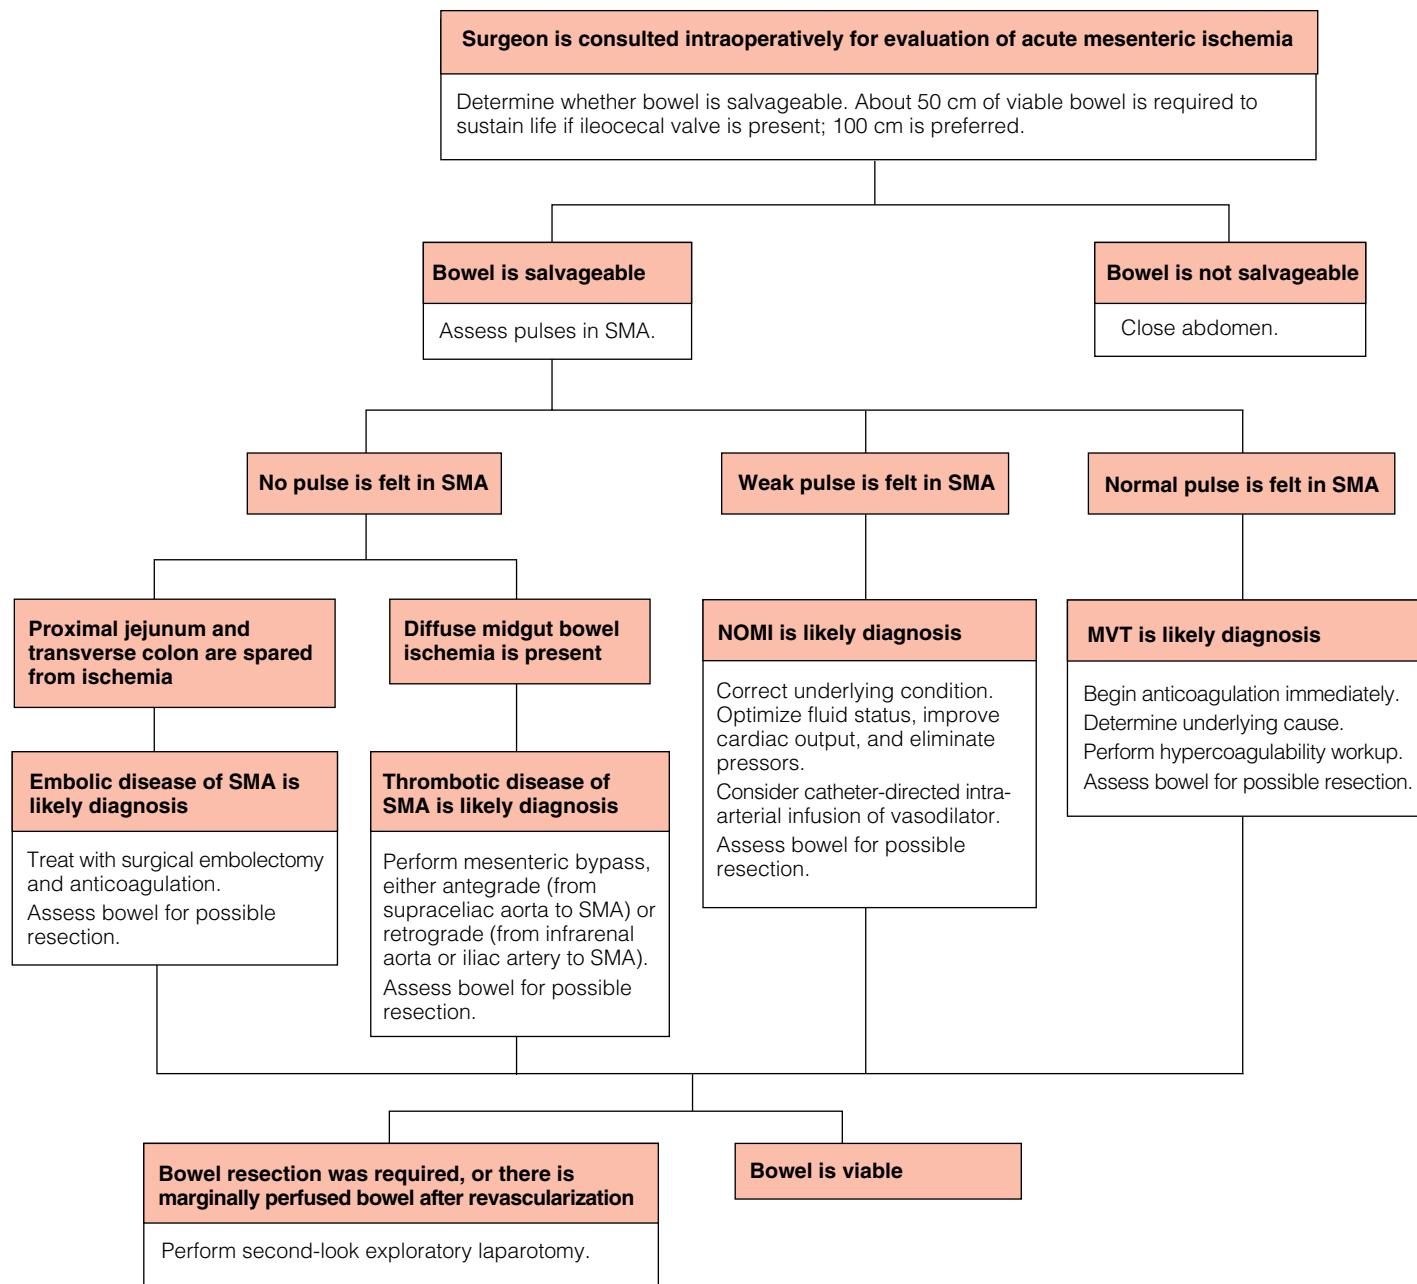

Figure 9 Algorithm illustrates intraoperative determination of bowel salvageability, evaluation of SMA pulses, and assessment of bowel viability after revascularization.

instability [see Figure 9]. In the OR, acute mesenteric ischemia typically presents as diffuse bowel ischemia. The first decision point in the evaluation is the determination of whether the bowel is salvageable.

DETERMINATION OF BOWEL SALVAGEABILITY

If diffuse bowel necrosis exists and the bowel is not salvageable, it is best to close the abdomen without attempting further therapy. Approximately 50 cm of viable bowel is required to sustain life if the ileocecal valve is present, and 100 cm is preferable.¹⁰ Therefore, if it is obvious that no bowel can be preserved, further intervention is pointless. If the bowel is salvageable, blood flow to the bowel must be evaluated by assessing the pulses in the SMA. If no pulse can be detected in the SMA, it is imperative that revascularization be undertaken before bowel resection.

INTRAOPERATIVE EVALUATION OF SUPERIOR MESENTERIC ARTERY

SMA pulses are assessed by palpating the root of the mesentery. The transverse colon is reflected superiorly, and the small bowel is reflected to the patient's right. The SMA is then palpated by placing four fingers of the hand behind the root of the mesentery, with the thumb opposite and anterior to the root. The SMA can also be identified by following the middle colic artery proximally until it enters the SMA. Alternatively, a handheld Doppler device may be employed to listen to the quality and character of the arterial signal at the root of the mesentery. Intraoperative angiography may also be used for evaluation, but it is often difficult to perform in the OR if there has not been adequate preparation and setup ahead of time, and it may not be feasible in some institutions.

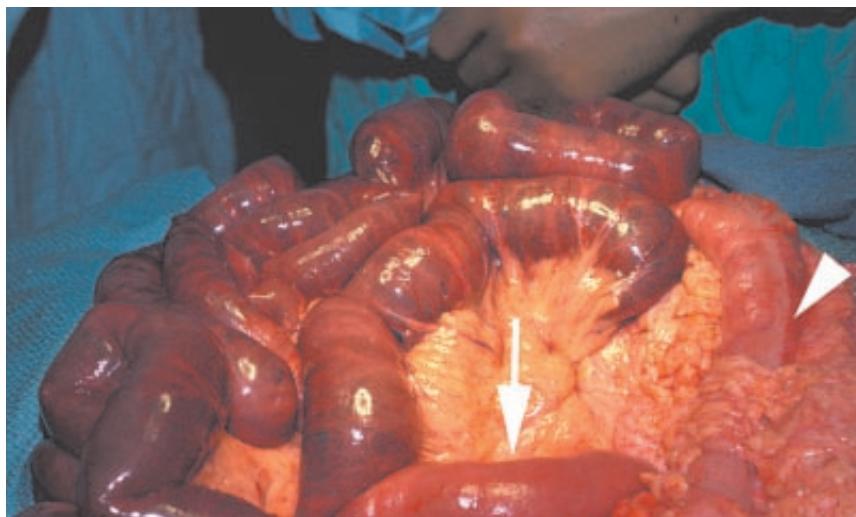

Figure 10 Intraoperative photograph of patient who presented with acute mesenteric ischemia secondary to embolus of SMA shows diffuse bowel ischemia with classic sparing of proximal jejunum (arrow) and transverse colon (arrowhead).

If a strong pulse is appreciated throughout the length of the SMA, MVT is the probable cause of the diffuse bowel ischemia. Once MVT is suspected, I.V. administration of heparin should immediately follow. If the bowel is viable, the patient should be observed closely for signs or symptoms of deterioration. If the patient's condition appears to be deteriorating, reexploration is indicated, with resection of any frankly necrotic bowel; thrombolytic therapy should be considered, and a second-look laparotomy should be performed. It is important to palpate the SMA pulse distally as well as proximally to ensure that the patient does not have an embolus to the distal SMA.

If the SMA pulse is weak, the diagnosis of NOMI should be entertained. The mainstay of therapy for NOMI is treatment of the underlying cause, which typically involves fluid resuscitation, administration of inotropes and calcium channel blockers, and cessation of vasoconstrictors. Catheter-directed intra-arterial infusion of papaverine for 24 to 48 hours may be beneficial as well. If bowel resection proves necessary at the time of exploration, it is best to plan on performing a second-look laparotomy, regardless of the patient's clinical status 24 to 48 hours after the initial exploration.

If there is no SMA pulse at the root of the mesentery, the most likely diagnosis is *in situ* thrombosis from chronic mesenteric arterial disease [see Figure 4]. If the SMA pulse is palpable proximally but not several centimeters distally, the likely diagnosis is an embolus to the SMA [see Figure 4]. Distinguishing between these two conditions is important because their surgical treatments differ significantly. To make this distinction correctly, the surgeon should be aware of how the patient presented, whether the patient experienced postprandial abdominal pain for an extended period before the acute presentation, and whether the patient has other risk factors of arterial occlusive disease [see Clinical Evaluation, above]. In addition, the surgeon should be aware of the specific pattern of bowel ischemia present.

DIFFERENTIATION OF PATTERNS OF BOWEL ISCHEMIA

The different causes of acute mesenteric ischemia are associated with different classic patterns of bowel ischemia, which must be distinguished from one another. The basic distinction between arterial and venous pathologic conditions is relatively simple. In mesenteric ischemia resulting from venous disease, the bowel typically is diffusely edematous, congested, and dilated. In mesenteric ischemia resulting from arterial disease, the small bowel is typically contracted during the early phase of presentation,

though it may be dilated and edematous when the patient presents late with frank bowel necrosis.

Within the category of arterial causes of acute mesenteric ischemia, the various underlying conditions are also associated with distinct patterns of bowel ischemia. Typically, in embolic disease, the small bowel and the proximal colon are affected, and the proximal jejunal segment and the transverse colon are spared [see Figure 10]; the reason is that the embolus usually lodges just past the middle colic artery and the jejunal branches of the SMA. If the entire small bowel is diffusely affected, as well as the ascending and transverse colon, the origin of the SMA is probably occluded; this disease pattern is consistent with thrombotic occlusion of the vessel by underlying atherosclerotic lesions. In NOMI, the entire small bowel may be affected, but the pattern of ischemia tends to be patchy, with segmental areas of involvement.

INTRAOPERATIVE ASSESSMENT OF BOWEL VIABILITY AFTER REVASCULARIZATION

Approximately 10 to 20 minutes after revascularization, the viability of the intestine should be assessed. Waiting until after revascularization to assess the extent of irreversible bowel ischemia or necrosis requiring resection makes it possible to preserve more bowel length. After restoration of flow, the bowel may contain frankly necrotic areas, normal areas, and marginally perfused areas. Obviously, clearly necrotic or nonviable bowel must be resected at the time of the operation. Determination of the viability of marginally perfused bowel is more difficult.

Intraoperatively, the color, motility, and integrity of the bowel should be evaluated. The characteristic appearance of ischemic bowel includes loss of the normal sheen, dull-gray discoloration, and lack of peristalsis. Determination of the character and quality of the pulses in the antimesenteric border and the mesenteric arcades may help determine which areas of the bowel will remain viable once revascularization has been performed. Intraoperative Doppler assessment of bowel perfusion may be performed with a sterilized continuous-wave Doppler ultrasound flow detector. The probe is placed on the antimesenteric border of the intestine to detect pulsatile Doppler signals. Even in the best of hands, however, this technique remains unreliable in predicting subsequent bowel viability.

Other diagnostic options include I.V. administration of fluorescein, transcutaneous oxygen measurement, and second-look exploratory laparotomy. All of these measures are relatively simple to perform, but each has its limitations.

Discussion

Mesenteric Ischemia and Reperfusion

Although acute mesenteric ischemia is initially managed surgically, significant morbidity and mortality remain after treatment, largely resulting from local and systemic inflammation and the subsequent development of multiple organ dysfunction syndrome (MODS). Mesenteric ischemia-reperfusion promotes local synthesis and release of various inflammatory mediators that exacerbate gut injury and prime circulating neutrophils for enhanced superoxide anion production and subsequent remote (i.e., pulmonary and hepatic) injury.¹¹ At the cellular level, mesenteric ischemia-reperfusion activates a cascade of oxidative stress-sensitive protein kinases that converge on specific transcriptional factors to regulate expression of proinflammatory genes. These gene products include enzymes (e.g., inducible nitric oxide synthase [iNOS], cyclooxygenase, and phospholipase A₂), cytokines (e.g., tumor necrosis factor- α [TNF- α] and interleukin-1 [IL-1]), chemokines (e.g., IL-8), and adhesion molecules (e.g., intercellular adhesion molecule-1 [ICAM-1]).¹²⁻¹⁸ Excessive gene activation leads to a maladaptive systemic inflammatory response syndrome that can trigger early MODS. Alternatively, this hyperinflammatory state can cause local gut dysfunction, characterized by histologic evidence of mucosal injury, increased intestinal epithelial and microvascular permeability, and impaired motility; patients become more susceptible to bacteremia and endotoxemia and, eventually, to late MODS.¹⁹

Experimental work suggests that mesenteric ischemia-reperfusion triggers protein phosphorylation cascades that converge on specific transcription factors to regulate the pattern, timing, and magnitude of expression of not only proinflammatory but also anti-inflammatory gene products.¹⁹ Presumably, this process is mediated by alterations in the cellular redox state induced by the conversion of xanthine dehydrogenase to xanthine oxidase during ischemia, with subsequent production of reactive oxygen metabolites and H₂O₂ during reperfusion.²⁰ Alterations in the cellular redox state activate families of stress-sensitive protein kinases, such as the nonreceptor tyrosine kinases c-Src and Syk, PI3-kinase/Akt, and the mitogen-activated protein kinases. These parallel kinase cascades phosphorylate nascent transcription factors (e.g., nuclear factor- κ B [NF- κ B] and AP-1), which target genes that encode proteins involved in mediator synthesis.^{19,21}

Therapies directed at attenuating these pathways have been successful in laboratory models of mesenteric ischemia-reperfusion and may eventually be able to affect outcome in patients presenting with acute intestinal ischemia.²²⁻²⁶ However, clinical trials investigating the efficacy of pharmacologic blockade of individual mediators (e.g., TNF- α , IL-1, and iNOS) have found this approach to be largely unsuccessful and sometimes even deleterious in treating patients with sepsis and MODS.²² The reasons for the failure of these trials are probably multifactorial, but it appears that both the redundancy and breadth of the inflammatory cascade and the poor timing of therapy (i.e., the inability to target early inflammatory events) are major contributing factors. Nonetheless, it is likely that to achieve any meaningful improvements in our ability to treat patients with acute mesenteric ischemia, we will have to expand our knowledge of the early molecular pathways involved in the activation and proliferation of both local and systemic inflammation.

Outcome after Surgical Treatment

Most studies that include a large number of patients with acute mesenteric ischemia report perioperative mortalities ranging from 32% to 69% and 5-year survival rates ranging from 18% to 50%.^{1,27,28} One group performed a systematic review of survival after acute mesenteric ischemia according to underlying cause by evaluating available data from the period between 1966 and 2002.²⁹ The investigators examined a total of 45 observational studies, which included 3,692 patients with acute mesenteric ischemia. They reported that mortality varied substantially according to the cause of the acute mesenteric episode. Overall mortality was lower with ischemia of venous origin (i.e., MVT) than with ischemia of arterial origin. Within the category of arterial causes, mortality was 54.1% after treatment of arterial embolic disease, 77.4% after treatment of arterial thrombotic disease, and 72.7% after treatment of NOMI. The difference in mortality between embolic and thrombotic disease may be accounted for by the tendency of thrombosis to occur more proximally and thus to be associated with a greater degree of bowel infarction than embolic disease is.

A 2003 study reviewed the institutional experience at Wake Forest University between 1990 and 2000.²⁷ A total of 76 patients were treated for acute mesenteric ischemia, of whom 42% had embolic disease and 58% had thrombotic disease. Various surgical treatment options were employed, including exploration alone, bowel resection alone, and revascularization with or without bowel resection. Overall perioperative mortality was 62%. When mortality was examined in relation to the cause of ischemia, however, patients with embolic disease tended to fare better: overall perioperative mortality was 62% to 70% for patients with thrombotic disease and 50% for those with embolic disease. None of the patients who underwent exploration alone survived; 33% of those who underwent intestinal resection alone survived. In contrast to perioperative mortality, morbidity was higher in the embolic disease group than in the thrombotic disease group (69% versus 46%). The 5-year survival rates were dismal in both groups (18%). Peritonitis and bowel necrosis at presentation were found to be independent predictors of death or survival dependent on total parenteral nutrition.

In a 10-year institutional review from the Mayo Clinic,¹ a total of 58 patients were treated for acute mesenteric ischemia. Overall 30-day mortality was 32%; however, when the data were further analyzed according to the cause of ischemia, it was found that mortality from embolic disease was 31%, mortality from thrombotic disease was 32%, and mortality from NOMI was 80%. Multiple organ failure was the most frequent cause of death. The 1-year and 3-year cumulative survival rates were 43% and 32%, respectively. Independent predictors of survival included age less than 60 years, bowel resection, and the absence of a recent major cardiovascular procedure.

From these studies, it is apparent that acute mesenteric ischemia is a lethal disease that carries a high morbidity and mortality. The only way to reduce the morbidity and mortality associated with this disease process is to diagnose and treat it early, before irreversible signs of bowel ischemia develop.

5 PULSELESS EXTREMITY AND ATHEROEMBOLISM

Vicken N. Pamoukian, M.D., and Cynthia K. Shortell, M.D., F.A.C.S.

Approach to the Acutely Ischemic Limb

Pulseless Extremity

Acute limb ischemia (ALI) is a sudden reduction in limb perfusion that poses a potential threat to the viability of an extremity. The incidence of ALI in the general population is approximately 1.7/10,000 per year.¹ The clinical presentation ranges from subtle to dramatic. Management of ALI is challenging and is complicated by the myriad comorbid conditions typically seen in conjunction with ALI.

In the early 1970s, a study comprising more than 3,000 patients with ALI from 35 centers documented a mortality of 26% and an amputation rate of 37%.² Substantial improvements in surgical management approaches, techniques, and instruments have been achieved since then, but morbidity and mortality remain high, with death rates around 15% and amputation rates between 10% and 30%.³

Cardiac risk assessment with the Goldman index allows rapid evaluation of the level of physiologic risk patients face. Again, the major cause of morbidity in ALI patients is the associated medical conditions typically present [see Table 1].

Given the general frailty of ALI patients and the multiplicity of available therapeutic options, it is important to take a logical, methodical approach to the treatment of this condition. In particular, the use of algorithms, decision trees, or clinical pathways for patient care helps the clinician visualize and evaluate multiple potential avenues for management and select the path likely to yield the best outcome.

CLINICAL EVALUATION

History

A thorough history should be taken. Generally, the dominant symptoms are related to pain or loss of function. The onset and duration of symptoms should be determined, and the location and the intensity of any changes should be established. The pain of ALI is not well localized and is not affected by gravity. Pain of sudden onset suggests that an embolic cause is likely, whereas long-standing pain before the acute event suggests a thrombotic cause [see Discussion, Etiology of ALI, below].

It is imperative to ask whether the patient experienced pain before the current ischemic episode and whether the current episode is the first. It is also important to ask about previous surgical revascularization as well as previous or current cardiac disease (e.g., myocardial infarction [MI], atrial fibrillation, or valvular disease), aneurysmal disease, or vasculitis. Finally, inquiries should be made about previ-

ous atherosclerotic disease, current risk factors for atherosclerosis (e.g., hypertension, smoking, diabetes, tobacco abuse, hyperlipidemia, and stroke), and previous clotting episodes.

Physical Examination

The characteristic signs and symptoms of ALI may be summarized as the six Ps: Pulselessness, Pain, Pallor, Poikilothermia, Paresthesia, and Paralysis.

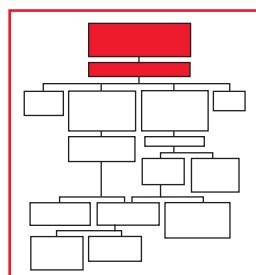

- Pulses should be palpated and documented. Any previous documentation should be noted.
- Pain should be documented with regard to severity, area, and progression.
- Pallor may be seen in the early stages, followed by cyanosis.
- Poikilothermia may propagate the ischemic cascade through its vasoconstrictive effects. The level of coolness and pallor is typically one level below the point of occlusion on the arterial tree, and it should correlate with the pulses or signals found. As always, baseline documentation should be done so that the progression or resolution of the process can be tracked.
- Paresthesia is an essential finding. The earliest sign of tissue loss is the loss of light touch, two-point discrimination, vibratory perception, and proprioception, especially in the first dorsal web space of the foot.
- Paralysis, if present, is an indication of advanced limb-threatening ischemia. The extent of paralysis must be determined. The intrinsic muscles of the foot are affected by ischemia of the vessels around the ankle. Dorsiflexion and plantar flexion of the foot are functions of muscles that rely on blood supplied by the popliteal and superficial femoral arteries. Loss of dorsiflexion and plantar flexion indicates that blood flow is cut off at a higher level and signals that more tissue may be at risk.

Peripheral Pulses

Careful assessment of peripheral pulses will help localize the area of arterial obstruction. When clot is fresh, its soft, semiliquid consistency allows the pulse to be translated at the level of obstruction. Only when the thrombus becomes organized and densely compacted is the pulse lost at the site of occlusion. As an example, in a patient with obstruction at the popliteal artery, popliteal pulses remain palpable in the earlier stages of the process, but distal pulses are lost [see Table 2].

Staging of Limb Ischemia

A prime goal of clinical evaluation is to determine the severity of the disease process so that appropriate management can be rapidly instituted. To this end, the key question that must be

Approach to the Acutely Ischemic Limb

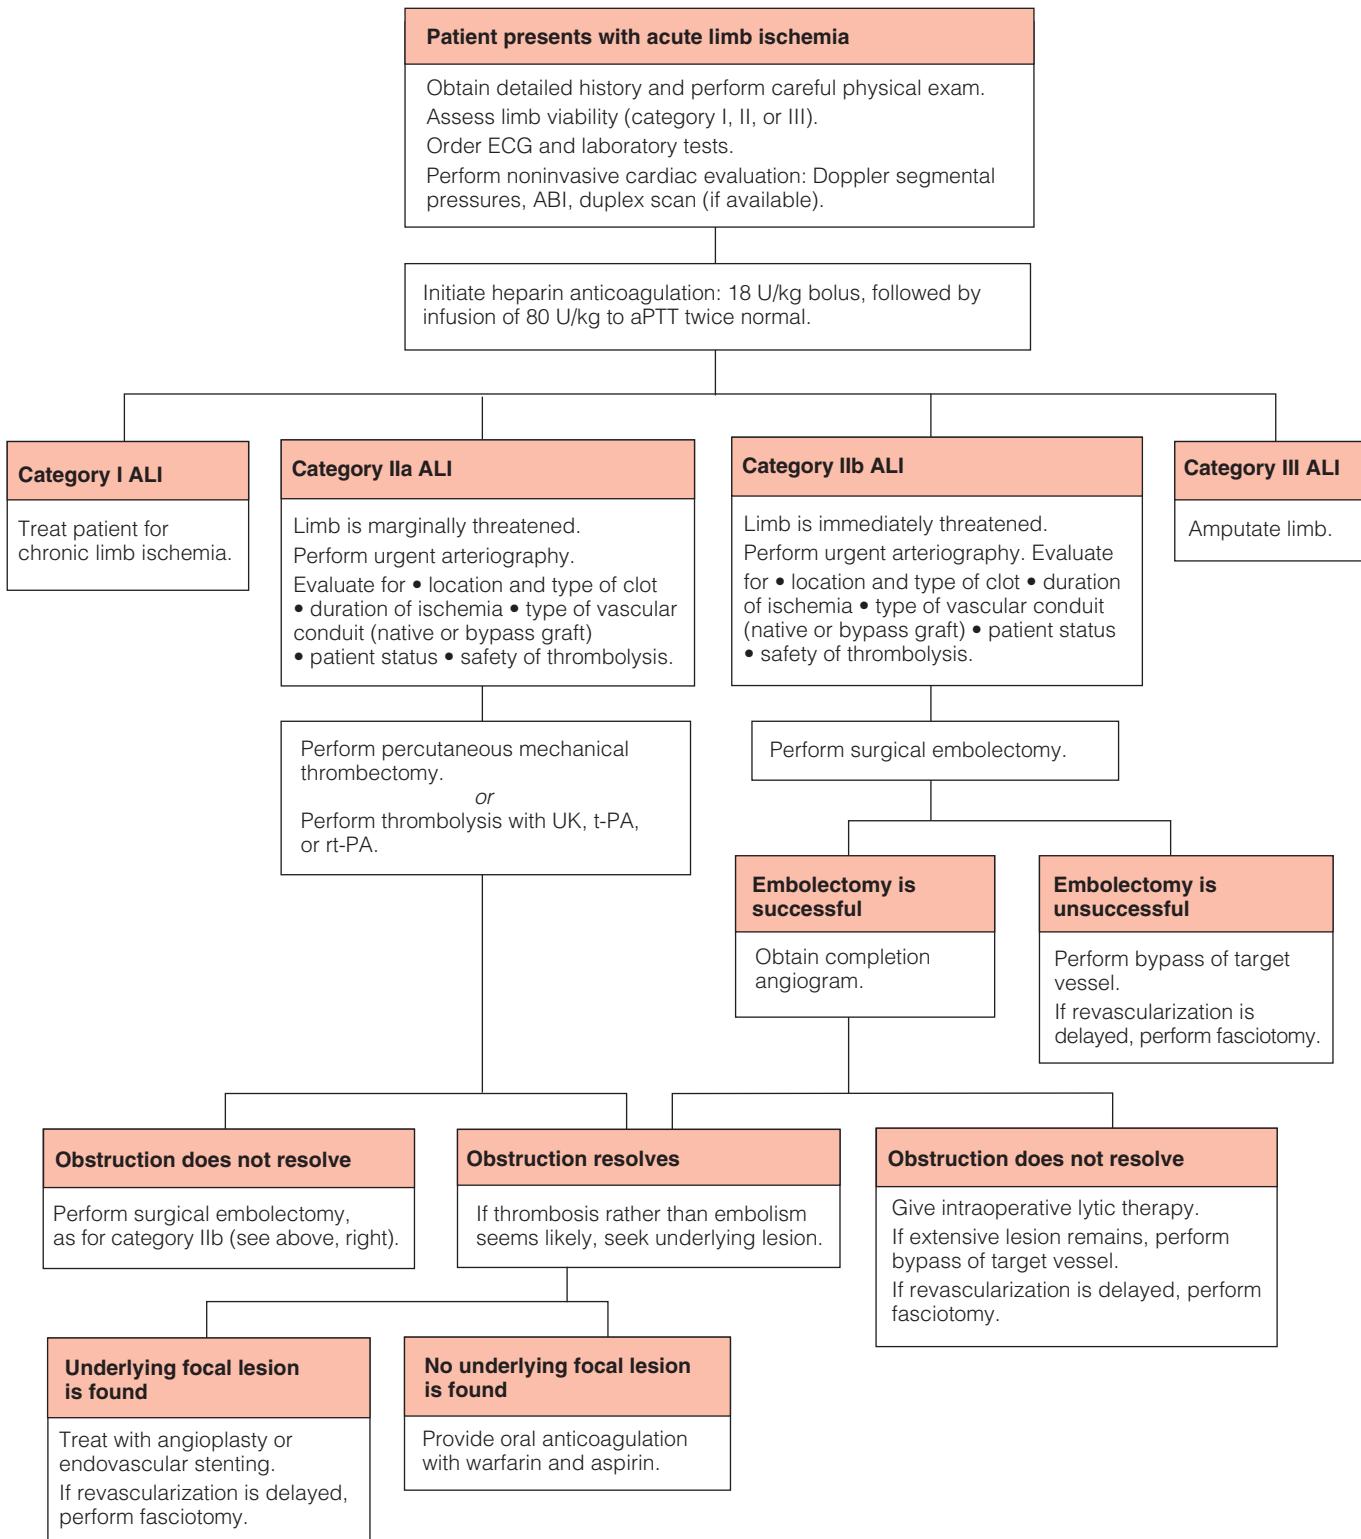

Table 1 Incidence of Medical Comorbidities in Patients Presenting with ALI⁹⁷

Comorbidity	Incidence (%)			
	Rochester Trial (N = 114)	TOPAS-1 Trial (N = 213)	TOPAS-2 Trial (N = 544)	Total (N = 871)
Cerebrovascular disease	NR	15.4	11.5	11.6

answered is whether the limb is viable or not. In 1997, the Joint Council of the Society for Vascular Surgery and the North American Chapter of the International Society for Cardiovascular Surgery developed reporting standards for ALI and stratified it into three distinct categories on the basis of the severity of the disease process [see Table 3].⁴

In category I ALI, patients present with acute occlusion of an artery that is chronically narrowed. Therefore, abundant collaterals can be found, and the limb is viable. In category II ALI, the ischemic limb is threatened but may be salvaged without the need for an amputation if adequate revascularization can be achieved. This category is further subdivided into categories IIa and IIb. Category IIa includes patients with mild forefoot numbness or any lesion for which prompt revascularization of the limb achieves a good result. Category IIb includes patients with diminished sensation of the entire foot and weakness of calf muscles whose limb is still salvageable but who require immediate revascularization. In category III, ischemia is irreversible and amputation is required. Clinical features include permanent tissue loss, anesthesia, and paralysis of the limb.

INVESTIGATIVE STUDIES

In addition to the clinical evaluation, a full battery of diagnostic tests should be performed. An electrocardiogram should be obtained, and if a cardiac source is suspected, a transesophageal echocardiogram should be obtained as well. A full set of laboratory tests, including a complete blood count and a platelet count,

blood chemistries, and coagulation profiles, should be ordered. In addition, chest and abdominal x-rays should be done to look for obvious calcifications. If it appears that a hypercoagulable state may be causing thrombosis, a hypercoagulability profile should be ordered [see 6:6 *Venous Thromboembolism*].

Evaluation of Arterial Tree

An objective evaluation of the arterial tree should be performed when feasible. If ischemia is particularly severe and long-lasting, a full angiographic evaluation may not be possible; however, noninvasive Doppler studies and, if time permits, angiography should be considered strongly in this setting.

Doppler segmental pressures and ankle-brachial index

Examination should begin at the level of the ankle and should include assessment of arterial signals and venous hums. When arterial signals are found, the ankle-brachial index (ABI) should be measured.

The ABI is derived from the ankle systolic pressure and the brachial systolic pressure and is determined as follows. The systolic pressure is measured in each arm, and the higher of the two measurements is taken to be the brachial systolic pressure. A cuff is then placed on each calf, and the examiner listens to signals in the dorsalis pedis and posterior tibial arteries. The cuff is inflated until the signal is no longer heard. At this point, the cuff is slowly released, and the systolic pressure is recorded at the point where the signal is once again audible. Again, the higher of the two systolic measurements is taken to be the ankle systolic pressure. The systolic ankle

Table 2 Localization of Arterial Obstruction through Palpation of Peripheral Pulses⁹⁷

Palpable Pulses			Location of Obstruction	Possible Causes
Femoral	Popliteal	Pedal		
–	–	–	Aortoiliac segment	Aortoiliac atherosclerosis; embolus to common iliac bifurcation
+	–	–	Femoral segment	Thrombosis, femoral atherosclerosis; common femoral embolus
+	++	–	Distal popliteal ± tibials	Popliteal aneurysm with embolization
+	+	–	Distal popliteal ± tibials	Popliteal embolus; popliteal/tibial atherosclerosis, diabetes

Table 3 Clinical Categorization of ALI⁴

Category	Findings			Doppler Signals	
	Description/Prognosis	Sensory Loss	Muscle Weakness	Arterial	Venous
I. Viable	Not immediately threatened	None	None	Audible	Audible
IIa. Marginally threatened	Salvageable if promptly treated	Minimal (toes) or none	None	(Often) inaudible	Audible
IIb. Immediately threatened	Salvageable with immediate revascularization	More than toes, associated with rest pain	Mild, moderate	(Usually) inaudible	Audible
III. Irreversible*	Major tissue loss or permanent nerve damage inevitable	Profound, anesthetic	Profound, paralysis (rigor)	Inaudible	Inaudible

*When presenting early, category IIb and category III may be difficult to differentiate.

pressure is then divided by the brachial systolic pressure to yield the ABI. An ABI in the range of 1 is normal; however, the ABI can be falsely elevated if the distal arteries are not compressible. When the ABI falls below 0.6, there is a significant difference in blood pressure between the proximal arterial tree and the distal extremity, which usually denotes an occlusive process. Next, segmental pressures are obtained by placing cuffs at the ankle, below the knee, above the knee, and on the thigh. Systolic blood pressures are measured at each location, and any pressure drop greater than 15 mm Hg is considered significant.

When the venous Doppler signal or hum is lost in addition to the arterial Doppler signal, the ischemia is severe. In addition, when a Doppler signal is present, intervention may be delayed slightly. However, the absence of signals does not always signify an irreversibly threatened limb.

Duplex ultrasonography Duplex scanning can be valuable for localizing the site of occlusion, especially in bypass grafts. Unfortunately, it is not always a practical option in acute circumstances, both because the machine is often unavailable in the emergency setting and because the results of scanning are highly operator dependent. However, in specialized centers where a duplex ultrasound machine is readily available and personnel are experienced in its use, a quick look at the suspected site may yield helpful information.⁵ In stenotic regions, the velocities measured across the lesion are greatly increased.^{6,7} In addition, duplex ultrasonography can be used to visualize plaque morphology, stenoses, dissections, and thrombi. In some centers of excellence, duplex ultrasound technology has obviated the need for lengthy arteriograms and has benefited patients by reducing ischemia time.

Arteriography Arteriography remains the gold standard for diagnosis of ALI and may even be a primary tool in its management. It should not, however, be performed if doing so would keep a critically ischemic leg from receiving prompt surgical therapy. Arteriography should be reserved for patients with viable limbs who can tolerate the additional delay before revascularization.

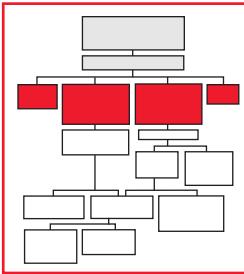

Arteriography should be performed from a site remote from the point of concern. Thus, if lytic therapy is to be administered, entry-site bleeding will be minimized. A complete angiogram that includes the runoff vessels in the foot should be performed to establish the baseline degree of arterial disease and delineate the inflow and outflow anatomy. This information facilitates subsequent planning for revascularization, should this step prove necessary. Digital subtraction angiography is preferred in that it allows a reduced contrast load and lowers the incidence of contrast-associated renal injury.^{8,9} If the patient is allergic to the contrast agent

or has renal insufficiency, CO₂- or gadolinium-based angiography may be performed instead. These two modalities have the advantage of possessing minimal to no nephrotoxicity, but they yield poorer suprainguinal arterial visualization than standard contrast angiography does.^{10,11}

The arteriogram can provide useful clues for differentiating emboli from thrombi. In a patient with arterial embolism, there is often an identifiable source, there is rarely a history of claudication, contralateral and proximal pulses are normal, cutoff is sharp, atherosclerosis is minimal, a few collateral vessels are present, and a discrete clot is clearly visible on contrast studies. In a patient with arterial thrombosis, the thrombus has no identifiable source, there is a history of claudication with evidence of peripheral vascular disease, diffuse atherosclerotic vessel wall disease is present, cutoff is tapered and irregular, and there is ample collateral circulation.

TREATMENT

Until the middle of the 20th century, when revascularization techniques were developed, amputation was the only treatment for acute lower-extremity ischemia [see **6:19 Lower-Extremity Amputation for Ischemia**]. Today, however, the vascular surgeon possesses an immense armamentarium for the treatment of this condition, ranging from emergency bypass to embolectomy to thrombolytic therapy.

The treatment of ALI is an emergency situation. Rapid restoration of flow to the extremity substantially reduces morbidity and mortality. Accordingly, the clinician must be thoroughly familiar with the therapeutic modalities available and capable of making an appropriate choice among them without undue delay. Whichever therapeutic modality is chosen for a given patient, several primary measures should be undertaken to protect and optimize the status of the extremity. Full systemic heparinization should not be delayed. The extremity should be placed in a dependent position, with care taken to avoid extrinsic pressure on the limb. Temperature fluxes should be minimized: cold induces vasoconstriction, and heat increases tissue demand and metabolic and circulatory demands. Finally, tissue oxygenation should be maximized via transfusion, improvement of cardiac function, and restoration of intravascular volume.

Laboratory tests, radiologic studies, and a cardiology evaluation are required. The ABI should be documented. Abnormalities in blood counts, electrolyte concentrations, and coagulation profiles should be corrected. The duration of ischemia should be noted and any comorbid conditions identified so that the examiner can

determine the appropriate degree of monitoring required (e.g., arterial line or pulmonary arterial catheter). Proper and timely preoperative preparation is crucial for preventing rapid deterioration of the patient's condition.

Anticoagulation
