In the 1986 NNIS report, the overall incidence of nosocomial infection was 33.5 per 1,000 discharges; the range extended from 13.3 per 1,000 pediatric discharges to 46.7 per 1,000 surgical discharges. Generally, the rate of infection is highest in large teaching hospitals and lowest in nonteaching hospitals. The higher incidence of infection among surgical patients is largely attributable to SSI. SSIs are the most frequent adverse events reported for hospitalized surgical patients and account for 38% of all nosocomial infections in surgical patients.¹⁵⁷ Two thirds of SSIs are incisional infections, and one third are organ/space infections.^{35,158} Some 38% of all SSIs result in readmission to the hospital.³⁵

Across all services, UTIs are the most common infections, accounting for 38.5% of all nosocomial infections, followed by lower respiratory tract infections (17.8%), surgical wound infections (16.6%), primary bacteremias (7.5%), and cutaneous infections (5.8%). All other categories combined account for 13.8% of nosocomial infections. The total incidence of nosocomial infection from all sites on surgical services ranges from 30.8 to 59.3 per 1,000 discharges. The risk that a surgical patient will acquire any infection varies according to the type of procedure performed as well as to the patient's underlying risk.¹⁵⁹

In the 1993 NNIS report, the most common nosocomial infections for surgical patients after an SSI were UTIs (27%), pneumonias (15%), primary bloodstream infections (7%), and all other sites combined (15%).¹⁵⁹ Of the infected surgical patients, 17% had more than one nosocomial infection, and 9% of surgical patients with nosocomial infections subsequently died; nosocomial infections were reported to have caused or contributed to 60% of the deaths. Of infections related to death, 38% were pneumonias, 21% occurred at the surgical site, and 20% were primary bloodstream infections. The likelihood that a specific infection will be related to death varies with the type of infection [see Table 1].

Urinary Tract Infection

With so many cases of bacteriuria occurring in catheterized patients, it would be easy to become complacent about the problem. Urinary tract catheterization is performed seven to eight million times a year in acute care hospitals in the United States.¹⁶⁰ Approximately 5% to 8% of catheterized, uninfected patients will acquire a urinary tract infection for each day of catheterization, leading to a cumulative infection rate of 40% to 50% after 10 days.¹⁰⁹ However, the great majority of catheterized patients with bacteriuria are asymptomatic.^{109,161} It has been estimated that only 0.7% of catheterized patients will acquire a symptomatic infection and that 8% to 10% of patients will have bacteriuria after the catheter has been removed.¹⁰⁹

In many of these patients, the bacteriuria resolves without specific therapy after the catheter has been removed. However, a

Table 1 Contribution of Nosocomial Infection to Death in Infected Surgical Patients Who Died¹⁵⁹

Type of Nosocomial Infection	Probability That Infection Was Related to Death (%)
Organ/space surgical site infection	89
Primary bloodstream infection	79
Pneumonia	77
Other	48
Incisional surgical site infection	46
Urinary tract infection	22

careful study of more than 1,458 patients clearly demonstrated that mortality is higher in catheterized patients who acquire bacteriuria than in those who do not.¹⁶⁰ In this study, 9% of all catheterized patients acquired catheter-related UTIs; these infections were associated with a threefold increase in deaths occurring during hospitalization, even after correction for other factors (e.g., age, severity of illness, hospital service, duration of catheterization, and renal function). In surgical patients between 50 and 70 years of age with normal renal function and without a fatal underlying disease, a 3% increase in the death rate per patient per hospitalization was associated with the occurrence of a UTI. Of all deaths occurring in catheterized patients, 14% were associated with a UTI.¹⁶⁰ By extrapolation, this mortality suggests that as many as 56,000 deaths a year in the United States may be related to catheter-acquired UTI.

Although the risk of bacteremia is small for any individual patient with bacteriuria, the large number of hospitalized patients with bacteriuria means that many bacteremic episodes are seen in this population. UTI is the most commonly diagnosed source of gram-negative sepsis, and the rate of bacteremia secondary to urinary catheters is estimated to be between 0.7% and 2%.¹⁰⁹ In a case-matched study from 1978, a postoperative UTI was associated with a 2.4-day prolongation of hospital stay and an excess cost of more than \$500.¹⁶² A subsequent study revealed that 2.3% of postoperative patients with UTIs were subsequently diagnosed as having a wound infection caused by the same organism responsible for the UTI.¹⁶³ This finding accounted for 3.4% of the wound infections occurring during the study.

Infection Associated with Intravascular Devices

Nosocomial infection associated with intravascular devices, which are placed for either monitoring or therapeutic purposes, assumed increasing importance during the 1970s and 1980s. In the United States, central venous catheters are in place for approximately 15 million patient-catheter-days per year, resulting in approximately 250,000 catheter-associated bloodstream infections.⁷⁰ Of all cases of nosocomial bacteremia occurring in NNIS hospitals between September 1984 and July 1986, 82% were associated with intravascular devices¹⁶⁴: 27% were associated with parenteral nutrition catheters and 55% with other vascular access devices. Reports from as early as 1963 called attention to the risk of serious systemic infections arising from peripheral I.V. catheters.¹⁶⁵ For ICU patients with bloodstream infections associated with central venous catheters, the attributable mortality is 25% to 35%, and the excess cost for survivors is \$34,000 to \$56,000 per patient, for a total annual cost of \$296 million to \$2.3 billion.⁷⁰

In terms of infection risk, pulmonary arterial catheters are no different from central venous catheters, except for their potential to cause right-side heart lesions that could predispose to right-side endocarditis.¹⁶⁶ Pulmonary arterial catheters can be responsible for bloodstream infection, and they require as much attention during insertion and subsequent care as central venous catheters do.^{68,167}

The arterial catheters used for monitoring purposes in the ICU have been thought to be less frequently associated with infection than central venous catheters are, but it is clear that life-threatening infections can originate with peripheral arterial lines.^{168,169} In early studies of radial artery catheters in which nonquantitative culture techniques were employed, catheter contamination rates of 4% to 39% were recorded, but there were no cases of CRBSI or clinical infection in 605 catheterizations.¹⁷⁰ In these studies, the majority of catheters were removed from patients within 3 days.

Prospective studies of arterial catheters demonstrated that 18% to 35% of the lines were locally infected, as reflected in semiquantitative cultures of at least 15 colonies.¹⁷¹ In one study, five cases of CRBSI occurred, representing an overall incidence of 4% and an incidence of 23% among locally infected catheters.¹⁷¹ The incidence of CRBSI was increased in catheters that were inserted by cutdown rather than by percutaneous puncture and in catheters with signs of local inflammation. In another, the clinical features of bloodstream infection arising from an arterial catheter were indistinguishable from the clinical features of episodes arising from a central venous line, and 12%

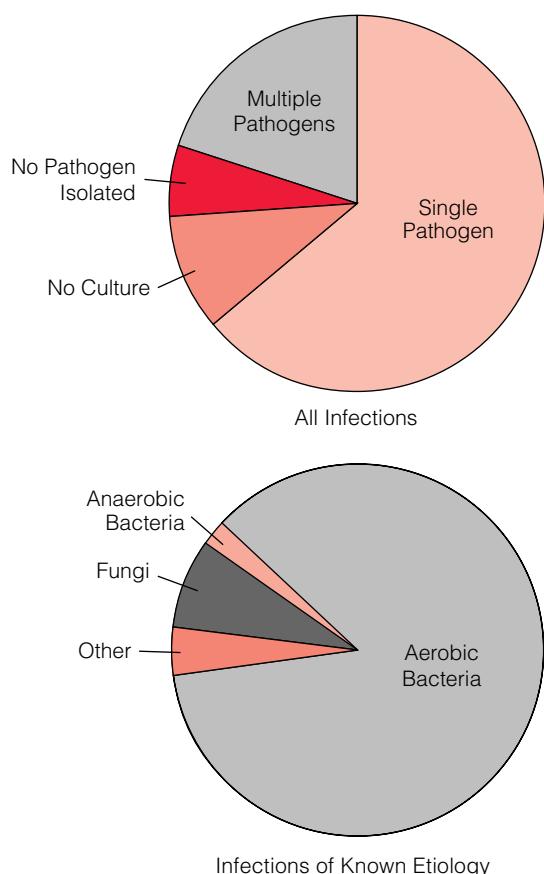

Figure 4 Illustrated is a breakdown of the etiology of 26,965 nosocomial infections from the National Nosocomial Infections Surveillance System.¹⁷³

Table 2 Five Most Common Pathogens Isolated from Surgical Patients and Percentage of Total within Each Site¹⁷³

Infection Site	Organism	Isolates at That Site (%)
Urinary tract infection	<i>Escherichia coli</i>	29
	<i>Pseudomonas aeruginosa</i>	16
	Enterococci	13
	<i>Proteus</i> species	7
	<i>Klebsiella</i> species	7
Surgical wound infection	<i>Staphylococcus aureus</i>	19
	Enterococci	12
	<i>E. coli</i>	12
	<i>P. aeruginosa</i>	10
	Coagulase-negative staphylococci	8
Lower respiratory infection	<i>P. aeruginosa</i>	17
	<i>S. aureus</i>	12
	<i>Enterobacter</i> species	11
	<i>Klebsiella</i> species	11
	<i>Serratia</i> species	7
Bacteremia	Coagulase-negative staphylococci	14
	<i>S. aureus</i>	10
	<i>Enterobacter</i> species	9
	Enterococci	9
	<i>Klebsiella</i> species	8
Cutaneous infections	<i>S. aureus</i>	19
	<i>P. aeruginosa</i>	13
	Enterococci	11
	Coagulase-negative staphylococci	10
	<i>E. coli</i>	8

of all nosocomial bacteremias in the ICU originated from an arterial catheter.¹⁷¹ Clearly, arterial lines as well as venous lines must be considered in the examination of a patient for the source of fever or bloodstream infection in the ICU.^{68,169,171,172} Twelve cases of radial artery rupture after arterial line infection have been reported. All but one were associated with *S. aureus* infection, and nearly all demonstrated systemic signs of infection for 2 days or longer after catheter removal.¹⁶⁹ Although there is no published experience with the use of guide wires to change and culture arterial lines in relation to possible catheter-related infection, the technique can be applied with the same rationale used for central venous catheters.

PATHOGENS

In 1984, the NNIS reported on 26,965 infections. Of these cases, 64% were caused by single pathogens, 20% were caused by multiple pathogens, 6% had no pathogen identified on culture, and 10% were not cultured [see Figure 4].¹⁷³ Of the 84% in which a pathogen was identified, 86% were caused by aerobic bacteria, 2% by anaerobes, and 8% by fungi [see Figure 4 and Table 2]. Overall on the surgical services, the most common pathogen isolated was *E. coli*, followed by *P. aeruginosa*, enterococci, *S. aureus*, *Enterobacter* species, *Klebsiella* species, coagulase-negative staphylococci, *Proteus* species, *Candida* species, and *Serratia* species. These 10 types of pathogens accounted for 84% of all isolates. Gram-negative rods were most common in UTIs

and lower respiratory tract infections, though *S. aureus* was the second most common pathogen isolated in lower respiratory tract infections. *S. aureus* was the most common isolate from surgical wound infections, whereas coagulase-negative staphylococci, followed closely by *S. aureus*, were the pathogens most often responsible for primary bacteremias.

As a consequence of changing hospital practices, hospitalized patients today tend to be more severely ill than was once the case. Large amounts of antibiotics are being used in hospitals, and antibiotic-resistant pathogens have become increasingly problematic. Current NNIS data indicate that the frequency with which antibiotics are administered to hospitalized patients who are not in an ICU is approximately 468 defined daily doses (DDD) per 1,000 patient-days.¹⁷⁴ For hospitalized ICU patients, the frequency is between 800 and 1,031 DDD per 1,000 patient-days. MRSA accounts for 51% of total *S. aureus* isolates in ICU patients, 40% in non-ICU patients, and 24% in outpatients with nosocomial infections; the corresponding figures for quinolone-resistant *P. aeruginosa* in relation to total *P. aeruginosa* isolates are 37%, 27%, and 27%.¹⁷⁴ In 2002, the second clinical isolate of vancomycin-resistant *S. aureus* in the United States was reported.¹⁷⁵

Nosocomial infections with resistant enterococci have become a serious problem. Enterococci were the third most common nosocomial bloodstream isolate reported by NNIS hospitals between 1990 and 1992.¹⁷⁶ The incidence of vancomycin-resistant enterococci (VRE) increased 26-fold between 1989 and 1993, from 0.3% to 7.9%, with a 34-fold rise in ICUs,¹⁷⁷ and the rate has continued to increase. The 2001 NNIS report stated that 13% of enterococci were resistant to vancomycin in ICU patients, 12% in non-ICU patients, and 5% in outpatients.¹⁷⁴ These strains arise from the patient's endogenous flora, but nosocomial spread within the hospital environment is also an important source.^{177,178} The environment around infected patients is heavily contaminated with VRE, and gown and glove isolation techniques are required to stop transmission.¹⁷⁸ Strict application of hand hygiene is also important for reducing the spread of VRE and other nosocomial pathogens. According to the available data and current CDC recommendations, the use of alcohol-based hand-rub solutions is superior to washing with soap and water: it can be performed more rapidly and is less damaging to the skin.¹⁷⁹

VRE are also highly resistant to other available antibiotics. Acquisition of VRE is significantly associated with prior hospitalization and with use of third-generation cephalosporins, vancomycin, or multiple antibiotics.^{180,181} In one study, 16% of stool specimens submitted for testing for *C. difficile* toxin were colonized with VRE, and all surgical patients in that study had the same strain.¹⁸²

High mortality can be associated with VRE infections. In a study comparing the outcome of patients having VRE bacteremia with the outcome of patients having bacteremia caused by vancomycin-sensitive enterococci (VSE), mortality was 2.3 times higher in those with VRE bacteremia, and 89% of patients with VRE bacteremia were colonized or infected with VRE at another site.¹⁸³ Prior treatment with third-generation cephalosporins is another risk factor for increased mortality.¹⁷⁶ Liver transplant patients with VRE bacteremia had a 92% higher mortality than comparable patients with VSE bacteremia, and those with VRE bacteremia also had a higher recurrence rate and greater need for invasive procedures.¹⁸⁴

Current recommendations include decreased—and possibly restricted—use of vancomycin, as well as aggressive infection control measures whenever VRE are isolated in a hospitalized patient.¹⁷⁷ In particular, vancomycin should not be used as pri-

mary treatment for *C. difficile*-associated diarrhea and should be avoided for surgical prophylaxis unless the hospital has a specific problem with MRSA or the patient cannot receive other appropriate antibiotics.

ENTERIC INFECTION

C. difficile is often found in patients with severe antibiotic-associated enteric infections. In one report, 691 (2%) of 32,757 consecutive postoperative patients experienced watery diarrhea significant enough to stimulate a request for *C. difficile* toxin assay.¹⁸⁵ Of this number, 75 (11% of patients with diarrhea) had a positive toxin assay. All cases were associated with antibiotic administration. Approximately 94% of the patients had received a cephalosporin either alone or in combination with other antibiotics; 29% of these responded to cessation of antibiotics and supportive measures, and the remainder were treated with vancomycin, metronidazole, or bacitracin. Six (14%) of the patients who required specific therapy relapsed after initial response to treatment and were subsequently cured with one or more additional courses of treatment. Two patients died, and the overall hospital stay for the remaining patients was prolonged by an average of 50%.

Most patients with mild cases of antibiotic-associated diarrhea do not have either positive cultures for *C. difficile* or positive toxin assays, and the etiologic role of *C. difficile* is unclear. Many hospitalized patients without diarrhea also have *C. difficile* in the stool, with or without toxin production,^{123,186} and the likelihood of isolating this pathogen increases with patients' increasing length of stay.¹¹⁸ A nonpathogenic yeast, *Saccharomyces boulardii*, when administered by mouth to hospitalized patients receiving antibiotics, significantly reduced the occurrence of antibiotic-associated diarrhea without affecting the rate of acquisition of *C. difficile*.¹²³

Some 3% of asymptomatic adults carry *C. difficile* in their stools, but 30% to 40% of healthy neonates may carry the organism. The rate of carriage declines after the age of 1 to 2 years. *C. difficile* can be spread in the hospital and has been isolated from 10% of inanimate objects in the environment of patients with *C. difficile* colonization, compared with 3% in hospital areas with no known cases.¹⁸⁷ In one report,¹⁸⁷ this organism was recovered from the hands of 13% of medical personnel working in a ward with affected patients; in another,¹⁸⁸ it was recovered from 60% of personnel immediately after they had cared for an affected patient. Soap-and-water washing was ineffective in preventing acquisition, but the combination of glove use and chlorhexidine washing was effective. In another medical center,¹⁸⁹ clusters of new nosocomial *C. difficile* diarrhea were prevented by screening all patients with diarrhea by active surveillance (using culture to identify *C. difficile* infection) and by instituting isolation precautions and daily disinfection of infected patients' rooms.

The prevalence of *C. difficile* in the environment is increased when a patient has diarrhea.^{187,188} In one prospectively studied cohort, 21% of patients without *C. difficile* in their stools on admission acquired the organism during hospitalization, and 37% of these patients experienced diarrhea; no cases of colitis occurred.¹⁸⁷ Diarrhea was more common in patients who received antibiotics. The rate of acquisition of *C. difficile* was 73% higher if a patient had a roommate colonized with *C. difficile*.

COST

The cost of nosocomial infections, both in dollars and in morbidity, is high. According to one estimate, 8.7 million extra hospital days and \$4.5 billion in hospital charges were attributable to nosocomial infections in United States hospitals in 1976.¹⁹⁰

Estimates of the number of deaths caused by nosocomial infections run as high as 58,000 a year; 9,700 of these deaths and 36% of all costs attributed to nosocomial infections are due to wound infections.¹⁹⁰ The actual numbers may be even higher. Another study found that 63 of 200 consecutive patients dying in the hospital had nosocomial infections; 18 (29%) of the 63 were judged causal and 26 (41%) contributory.⁸ Most of the causal and contributory infections were of the lower respiratory tract, and deaths were significantly associated with invasive devices (e.g., intra-arterial and central venous pressure monitoring devices and nasogastric tubes). Of the 57 deaths occurring on the surgical service, 27 (47%) were associated with nosocomial infections.

RISK

The risk of acquiring a nosocomial infection is clearly related to the reason for hospitalization as well as to the underlying dis-

ease.^{8,191} Patients admitted to the hospital with a fatal underlying disease have a nosocomial infection rate of 24%, compared with 10% in patients with ultimately fatal disease and 2% in those with nonfatal disease. Among 100 consecutive trauma patients admitted to the ICU at Harborview Medical Center in 1986, 42 acquired 64 nosocomial infections, including 23 lower respiratory tract infections, 17 urinary tract infections, and 6 wound infections.¹⁵² These 100 ICU admissions and 101 consecutive trauma admissions to the general ward were examined together. Of 153 patients admitted with injury severity scores of 25 or less, nosocomial infection occurred in 32 (21%). Of 48 patients with injury severity scores higher than 25, nosocomial infection occurred in 26 (54%).¹⁵² A statewide survey of hospitals in Virginia from 1978 to 1982 found that infections in ICU patients accounted for 25% of all cases of nosocomial infections, although fewer than 10% of the beds were in ICUs.¹⁹²

17 POSTOPERATIVE AND VENTILATOR-ASSOCIATED PNEUMONIA

Craig M. Coopersmith, M.D., F.A.C.S., and Marin H. Kollef, M.D.

Pulmonary complications are common after surgical procedures, accounting for nearly one of every four deaths that occur in the first postoperative week.¹ Overall, pneumonia is the third most common postoperative infection, after urinary tract infection and surgical site infection.² In critically ill patients, however, the respiratory tract is the most common site of nosocomial infection³: in the intensive care unit, pneumonia accounts for 28% to 47% of all nosocomial infections.^{4,5}

In discussing pneumonia occurring in surgical patients after operation, it is useful to distinguish between postoperative pneumonia and ventilator-associated pneumonia (VAP). Throughout this chapter, we make this distinction where appropriate [see Incidence and Risk Factors and Diagnosis, below].

Pathogenesis

Under basal conditions, the lower respiratory tract is sterile. Thus, for pneumonia to develop, bacteria must be introduced into the lungs, typically by being aspirated from either the upper respiratory tract or the gastrointestinal tract. This introduction of bacteria is generally associated with impairment of host defenses, both locally and systemically.

A leading hypothesis regarding the pathogenesis of VAP is that the oropharynx is overgrown by microbes, which subsequently are aspirated into the lungs and colonize the airway.⁶ This hypothesis is supported by the observation that whereas enteric gram-negative bacteria are absent from the oropharynx under basal conditions, they can be detected in the oropharynx in nearly 75% of critically ill patients.⁷ Upper airway colonization by enteric bacteria occurs in 45% to 100% of intubated patients. Besides being colonized by aspirated endogenous flora, the airways may be colonized by exogenous flora as a result of cross-contamination from other ICU patients (through inadvertent transmission by health care workers).

A complementary hypothesis is that the upper GI tract plays a critical role in the pathogenesis of VAP. According to this view, the stomach is a primary site of colonization that may subsequently infect the lung through retrograde movement of bacterial overgrowth, followed by aspiration of organisms from the oropharynx. The small decrease in mortality seen in certain ICU patient populations who undergo selective decontamination of the digestive tract (SDD) supports the possibility that endogenous gut flora plays a role in the pathogenesis of VAP, though this possibility remains controversial.⁸ Chronic infection of biofilms in an endotracheal tube may also play a role in the pathogenesis of VAP.⁹ Either suctioning or performing bronchoscopy in a patient with a biofilm may result in distal embolization of bacteria. The importance of biofilms in this setting, however, remains to be fully determined.

Incidence and Risk Factors

For an accurate assessment of the incidence of and risk factors for pneumonia in postoperative patients, it is helpful to consider postoperative pneumonia separately from VAP. Postoperative VAP, by definition, occurs in a patient who has undergone a surgical procedure and is on mechanical ventilation for longer than 48 to 72 hours; however, not every patient who acquires pneumonia after an operation is on a ventilator or in the ICU. The severity of an episode of pneumonia and its ultimate outcome are at least partially related to the comorbid conditions present; therefore, a surgical ICU patient with multiple organ dysfunction typically has a worse prognosis than a patient who acquires pneumonia while recovering from an operation on the surgical ward.

POSTOPERATIVE PNEUMONIA

A wide-ranging assessment of pneumonia in the postoperative setting was provided by a retrospective review of 160,805 patients who underwent major noncardiac surgical procedures at 100 Veterans Affairs Medical Centers between 1997 and 1999.² Pneumonia was diagnosed in a total of 2,466 (1.5%) of the 160,805 patients. The 30-day mortality was 21% in patients who experienced postoperative pneumonia and 2% in those who did not. Multivariate analysis identified several risk factors that led to an increased risk of postoperative pneumonia, including type of surgery, age, functional status, recent weight loss, chronic obstructive pulmonary disease (COPD), type of anesthesia, impaired sensorium, history of a cerebrovascular accident, blood urea nitrogen (BUN) level, substantial transfusion, emergency surgical intervention, long-term steroid use, recent smoking, and significant recent alcohol use [see Table 1]. This review represents by far the most substantial effort yet made to quantify the incidence and risk factors of postoperative infections. However, it has two major limitations: (1) it was retrospective rather than prospective, and (2) more than 95% of the patients involved in the study were male.

VENTILATOR-ASSOCIATED PNEUMONIA

In contrast to postoperative pneumonia, VAP has been the subject of a good deal of epidemiologic study, though to date, surgical patients have made up only a subset of the patients studied. The reported overall incidence of VAP in ICU patients varies widely among published studies, ranging from 1 to more than 20 cases per 1,000 ventilator days^{4,10}; the average incidence across the various studies is approximately 7 cases per 1,000 ventilator days.⁶ Although VAP can occur in any patient undergoing mechanical ventilation, it is substantially more common in surgical ICU patients than in medical ICU patients, reaching its highest prevalences in trauma, neurosurgical, surgical, and burn ICUs. As an example of how VAP disproportionately affects surgical patients, ventilator usage in trauma ICUs is nearly identical to that in respiratory ICUs (0.58 versus 0.57 ventila-

Table 1 Preoperative Predictors of Postoperative Pneumonia²

Predictor	Odds Ratio (95% CI)
Type of surgical procedure

Current smoker within 1 yr	1.28 (1.17–1.42)
Alcohol intake > 2 drinks/day in past 2 wk	1.24 (1.08–1.42)

tor days/patient days), but VAP develops nearly four times as often in the former as in the latter (15.1 versus 4.2 cases per 1,000 ventilator days).¹¹ It should be remembered, however, that patients in respiratory ICUs may have already had an episode of pneumonia while in the hospital, which may make diagnosis of secondary VAP more difficult in this population.

The single greatest risk factor for VAP is related to the duration of mechanical ventilation. The risk peaks at day 5 on the ventilator, plateaus after day 15, and then declines significantly, with the result that VAP is uncommon in patients on long-term mechanical ventilation.^{6,12} Other risk factors associated with the development of VAP are trauma, thermal injury, male gender, increased age, acute lung injury, and greater severity of illness.^{12,13}

The absolute mortality in VAP patients ranges from 12% to more than 50%, with a substantially lower crude mortality in surgical patients than in medical patients.^{14,15} The attributable mor-

tality associated with VAP has not been determined with certainty: estimates range from no increased risk of death to a relative risk increase of 3.6.^{6,13,15} Attributable mortality is especially difficult to establish in patients with ARDS, though one study of 11 predominantly medical ICUs in France found that mortality in ARDS patients was not appreciably affected by whether they had VAP.¹⁶

Studies that demonstrate an increased relative risk of death with VAP frequently also demonstrate an increased prevalence of resistant organisms (e.g., *Pseudomonas aeruginosa* and *Acinetobacter baumannii*).¹⁷ VAP patients as a group remain in the ICU approximately 6 days longer than comparable patients without VAP and incur more than \$40,000 in additional charges.^{13,15} When the subgroup of surgical patients is considered on its own, however, the increase in length of stay in the ICU is closer to 1 day,¹³ and the increase in hospital charges is almost certainly smaller (though still substantial).

Diagnosis

Pneumonia is commonly defined as distal air-space inflammation caused by microorganisms or products of microorganisms.⁶ Although this definition is simple, diagnosis of pneumonia is often complex, for two reasons. First, it is frequently difficult to isolate microorganisms from the lower respiratory tract, even if the patient has an active infection. Second, in the unlikely circumstance that a patient undergoes an open lung biopsy that demonstrates inflammation, this finding does not indicate that pneumonia is present, because there are a number of noninfectious insults that can result in both local and systemic inflammation.

DIAGNOSTIC CRITERIA

Postoperative Pneumonia

Most postoperative fevers are of noninfectious origin, and even when an elevated temperature and an increased white blood cell (WBC) count result from an infection, pneumonia still is not the most likely diagnosis. It is therefore critical to establish objective criteria for diagnosing pneumonia after a surgical procedure. Of the several different diagnostic approaches that have been formulated, one of the more popular uses a combination of clinical and radiographic criteria to diagnose pneumonia in nonventilated postoperative patients [see Table 2].^{2,18} Typically, in a surgical ward patient, the diagnosis requires either new onset of purulent sputum or a change in the character of the sputum in combination with a worsening chest x-ray that demonstrates either new or progressive infiltrate or consolidation.

Ventilator-Associated Pneumonia

Diagnosing VAP is more complicated than diagnosing postoperative pneumonia in a patient on the surgical ward, though with invasive quantitative cultures, it may be possible to make the diagnosis more accurately in a ventilated patient. In ICU patients, as in surgical ward patients, fever and leukocytosis are very common and are frequently of noninfectious origin. Unlike surgical ward patients, however, ICU patients often have chronically purulent secretions and abnormal chest x-rays that are not representative of pneumonia.¹⁹ There is no absolute gold standard for diagnosing VAP, and attempts to define VAP objectively for surveillance purposes have so far failed to reach any resolution.⁶ In addition to fever, leukocytosis, increased or changed sputum production, and an abnormal chest x-ray, indicators used to diagnose VAP may include sputum culture, the clinical pulmonary infection score (CPIS), and (less commonly) pleural fluid culture or open lung biopsy.^{20,21}

Table 2 Criteria* for Definition of Postoperative Pneumonia²

- Rales or dullness to percussion on physical examination of chest AND any of the following:
- New onset of purulent sputum or change in character of sputum
 - Isolation of organism from blood culture
 - Isolation of pathogen from specimen obtained by transtracheal aspiration, bronchial brushing, or biopsy
- Chest radiography showing new or progressive infiltrate, consolidation, cavitation, or pleural effusion AND any of the following:
- New onset of purulent sputum or change in character of sputum
 - Isolation of organism from blood culture
 - Isolation of pathogen from specimen obtained by transtracheal aspiration, bronchial brushing, or biopsy
 - Isolation of virus or detection of viral antigen in respiratory secretions
 - Diagnostic single antibody titer (IgM) or fourfold increase in paired serum samples (IgG) for pathogen
 - Histopathologic evidence of pneumonia

*Only one criterion need be fulfilled to establish the diagnosis.

INVASIVE AND NONINVASIVE CULTURES

Samples for sputum culture may be obtained either noninvasively, via tracheal aspiration, or invasively, via bronchoscopy with either bronchoalveolar lavage (BAL) or a protected specimen brush (PSB). Tracheal cultures, though commonly employed, overestimate the rate of VAP and fail to diagnose some occurrences of pneumonia documented by postmortem pathologic study of the lung^{20,22}; these failings persist even when quantitative cultures are used. Moreover, the threshold used for documenting VAP with tracheal cultures changes both the sensitivity and the specificity of the test. In one study, reducing this threshold from 10^6 to 10^5 colony-forming units (cfu)/ml increased sensitivity from 55% to 63% while decreasing specificity from 85% to 75%, as determined by comparison with postmortem specimens in a sample of 28 patients who died within 3 days after culture.²³

Invasive sampling is significantly more accurate than tracheal aspiration in diagnosing VAP. Both BAL and PSB have sensitivities and specificities higher than 80% [see Table 3].^{23,24} A study involving 22 patients with suspected VAP who had five samples taken from the same site during the same bronchoscopy procedure found that the two techniques yielded similar results.²⁵ In this study, PSB isolated the same organisms each time, but quantitation with BAL varied within one log 59% of the time, leading to a change in diagnosis (from presence to absence of pneumonia or vice versa) in 13% of cases.

It must be noted that simply placing a bronchoscope through an endotracheal tube or a tracheostomy and obtaining a sample is

still essentially tracheal aspiration, not BAL. As noted (see above), pneumonia is defined as the presence of microorganisms in the distal airways; thus, obtaining a sample from the proximal airways (even if access is obtained with a bronchoscope), though it can provide information about the microbial content of the proximal airways, suffers from the same limitations that obtaining a culture with a catheter placed down the endotracheal tube does.

Techniques for performing BAL vary somewhat among institutions. Generally, however, the bronchoscope is wedged in the most distal airway in the lobe of interest before cultures are obtained, and a 20 or 50 ml aliquot of normal saline is lavaged, returned, and discarded. Another aliquot of normal saline is then lavaged, and the returned fluid is sent off for quantitative culture.

Using invasive sampling techniques to obtain a diagnosis is especially important in trauma patients, who often have fever, leukocytosis, purulent sputum, and radiographic abnormalities as a consequence of the systemic inflammatory response syndrome (SIRS). A study of 43 trauma patients exhibiting all these symptoms and signs who underwent BAL found that 20 had culture results consistent with VAP, whereas 23 had bacterial growth amounting to fewer than 10^5 cfu/ml.²⁶ Antibiotics were stopped after culture results in all patients with low or no bacterial growth (average, 3.3 days); 65% of patients showed improvement after discontinuance of antibiotics, and there was no difference in mortality between the SIRS group and the VAP group. These findings highlight the need to obtain invasive cultures in the trauma setting, in that a high percentage of the patients in this study would have been incorrectly diagnosed as having pneumonia on clinical grounds alone.

Several nonbronchoscopic quantitative sampling techniques are now available, including mini-BAL and blind sampling PSB.^{27,28} These techniques involve blind passage of a catheter or telescoping catheters to a wedged position in the lung.²⁰ Both mini-BAL and blind sampling PSB are slightly less accurate than their bronchoscopic counterparts, with sensitivities ranging from 58% to 100% and specificities ranging from 66% to 100%.⁶ In addition, these techniques may miss unilateral left-side pneumonia, presumably because blind insertion is more likely to result in wedging of the catheter in the right lung.

Regardless of the culture technique used, previous antibiotic therapy can reduce the chances of obtaining a positive culture. The determining factor appears to be the duration of such therapy. Initiation of antibiotic therapy within the preceding 24 hours decreases the chances of obtaining a positive culture and reduces the number of microorganisms recovered, though these effects are less pronounced with BAL than with other diagnostic techniques⁶; however, in patients who have been receiving antibiotics for more than 72 hours, the sensitivity and specificity of BAL and PSB for the diagnosis of pneumonia are largely unaffected.^{29,30} These findings have clear implications for treating pneumonia in postoperative patients. Specifically, cultures should be accurate in a patient who is in the middle of a 1-week antibiotic course for complicated intra-abdominal

Table 3 Diagnostic Techniques Used in Diagnosis of VAP²⁰

Diagnostic Technique	Sensitivity (%)	Specificity (%)	Positive Predictive Value (%)	Negative Predictive Value (%)
PSB cultures ($\geq 10^3$ cfu/ml)	82	89	90	89
BAL cultures ($\geq 10^4$ cfu/ml)	91	78	83	87
Microscopic examination of BAL fluid ($\geq 5\%$ intracellular organisms)	91	89	91	89

nal infection, but starting antibiotic therapy immediately before obtaining a culture for suspected VAP will adversely affect the ability of the surgeon to diagnose this condition.

CLINICAL PULMONARY INFECTION SCORE

The CPIS quantifies a number of clinical findings suggestive of pneumonia—temperature, WBC count, tracheal secretions, tracheal cultures, oxygenation, chest x-rays, and the presence of and progression of infiltrates on x-rays—in an attempt to diagnose pneumonia noninvasively [see Table 4].²¹ A CPIS higher than 6 is associated with a high likelihood of pneumonia, and there is a clear correlation between a high CPIS and a high concentration of bacteria found with invasive culture techniques.³¹ The main use of the CPIS is as a method of defining the probability of pneumonia in a given patient that is more objective than clinical judgment alone. A patient with a low CPIS probably need not be treated for pneumonia, whereas one with a high CPIS is likely to benefit from invasive culturing, followed by rapid institution of broad-spectrum antibiotic therapy. The main drawbacks of the CPIS are (1) that all of its elements are weighted equally (for example, the presence of an infiltrate is given the same weight as a WBC count of 11,000/mm³, even though it is substantially more suggestive of pneumonia) and (2) that assessment of chest x-rays and sputum production is necessarily subjective, meaning that an equivocal CPIS could lead to an inappropriate treatment decision.

OTHER MODALITIES FOR DIAGNOSING VAP

Although the use of invasive culture methods in conjunction with clinical judgment is the most common approach to diagnosing VAP, there are rare circumstances in which other diagnostic modalities may be useful.²⁰ The most likely surgical situation in which pneumonia might be diagnosed without invasive cultures involves a patient with empyema in whom a positive purulent fluid culture is obtained at the time of either chest tube placement or thoracocentesis. Histopathologic examination of tissue obtained at open lung biopsy that demonstrates the presence of both bacteria and inflammation is diagnostic of VAP. Rapid cavitation of a pulmonary infiltrate in a patient who has a negative workup for both cancer and tuberculosis, though extremely uncommon after operation, is likely to represent pneumonia when it does occur in this setting.

Management

IDENTIFICATION OF PATHOGENS

For effective treatment of pneumonia in the postoperative patient, it is critical to know which organism or organisms are causing the disease. Overall, pneumonia in ICU patients is more frequently caused by gram-negative bacteria than by gram-positive bacteria [see Table 5]. The most commonly isolated gram-negative pathogen is *P. aeruginosa*, and the most commonly isolated gram-positive pathogen is *Staphylococcus aureus*.^{13,32}

It is important to note that the microbes isolated in the first 3 to 4 days of an ICU stay are dramatically different from those isolated later.⁶ The pathogens found early (e.g., *S. aureus*, *Haemophilus influenzae*, and *Streptococcus pneumoniae*) are typically sensitive to many classes of antibiotics, whereas the pathogens identified later (e.g., *P. aeruginosa*, *A. baumannii*, methicillin-resistant *S. aureus* [MRSA], and *Stenotrophomonas maltophilia*) are more likely to be resistant. In a large United States database, *S. aureus* was the most commonly isolated organism in patients whose VAP was identified during the first 4 days of mechanical ventilation, *P. aeruginosa* in patients whose VAP was identified after the first 4 days of ventilation (23.7% and 19.7%,

respectively).¹³ In more than 50% of VAP cases, more than one organism is isolated.²⁴ Isolation of an organism, in itself, does not establish the diagnosis of pneumonia, and colonization can occur at any time during the course of mechanical ventilation. It is crucial to distinguish infection from colonization: the former calls for aggressive antimicrobial therapy, and the latter need not be treated at all—in fact, inappropriate use of antibiotics to treat colonization may adversely affect outcome. A study of 26 patients undergoing mechanical ventilation demonstrated that 22 were colonized by at least a single bacterial strain during their ICU stay, with 16 being colonized within 5 days after intubation.³³ Of these 22 patients, 21 were colonized by aerobes and 15 by anaerobes, and five went on to acquire VAP (three with aerobic pathogens, two with anaerobic pathogens).

The role of anaerobes in VAP is controversial^{33,34}: although they may represent as many as 23% of the isolated strains in patients with VAP (typically in early-onset cases in which aspiration was witnessed), their presence is not associated with an increase in mortality,³⁵ and there is no evidence that antianaerobic therapy changes outcomes in patients with VAP.

The role played by so-called commensal bacteria in the normally sterile lower respiratory tract is also unclear. Approximately 50% of isolates from ventilated patients are from bacterial species that are believed to be nonpathogenic except in immunocompromised patients; however, the significance of commensal bacteria in the airways of immunocompetent patients is unknown. The possible importance of commensal bacteria in the lower respiratory tract was highlighted by a study of 369 patients with VAP, a group comprising all patients diagnosed with the disease over a 10-year period in a mixed medical/surgical ICU.³⁶ The investigators iden-

tified 23 cases of VAP (through a combination of PSB and clinical signs) as resulting from a monomicrobial infection involving an organism typically considered to be commensal (most commonly, non-β-hemolytic *Streptococcus*, *Neisseria* species, and coagulase-negative *S. aureus*). Because the idea that commensal bacteria could cause VAP was, and is, controversial, the diagnosis was reported only if agreed on by three independent experts. Mortality in these patients was not different from that in patients without VAP. At present, the importance of commensal bacteria in the pathogenesis of VAP remains undetermined.

ANTIMICROBIAL THERAPY

Importance of Rapid Initial Treatment

The cornerstone of therapy for hospital-acquired pneumonia is rapid institution of an appropriate broad-spectrum antibiotic regimen. Appropriate initial antimicrobial treatment is typically defined as an antibiotic regimen that is known to possess in vitro activity against the identified bacterial species.

The importance of rapid institution of appropriate antibiotic therapy has been highlighted in a number of trials involving post-operative patients. In one such trial, a group of 65 patients in a medical/surgical ICU who had positive BAL cultures and were diagnosed with VAP were retrospectively subdivided into a group that received adequate antibiotic therapy at the time of bronchoscopy and a group that received inadequate therapy.³⁷ Mortality in the adequate-therapy group was 38%, but that in the inadequate-therapy group was 91%. Similar results, albeit with substantially lower mortalities, were obtained in a study from a different medical/surgical ICU involving 113 patients with VAP diagnosed by means of either PSB or BAL.³⁸ Patients receiving inadequate initial antimicrobial therapy had a mortality of 37%, whereas those receiving adequate therapy had a mortality of only 15%.

A link between adequate initial antimicrobial therapy and mortality was also documented in a study of 2,000 consecutive ICU patients, including 793 surgical ICU patients.³⁹ In more than 60% of the 655 patients with documented infections, the respiratory tract was the source of the infection. Of the 655 infected patients, 210 had previously been operated on. Infection-related mortality was 42% in infected patients who initially received inadequate antimicrobial therapy, compared with 18% in those who received adequate therapy. Using a logistic regression model, the investigators found inadequate institution of antibiotic therapy to be the single most important independent determinant of hospital mortality.

At present, there are no data from surgical populations on the impact of delayed initiation of appropriate antimicrobial therapy; however, the findings of one study from a medical ICU suggest that this is not an effective strategy for preventing mortality caused by initial selection of inadequate antibiotics.⁴⁰ In this study, 107 consecutive ICU patients with VAP, all of whom were treated with appropriate antimicrobial therapy, were followed prospectively. Of these patients, 31% experienced delays longer than 24 hours in receiving antimicrobial therapy, almost always because of delays in order writing. The mean time to initiation of antibiotic therapy was 28.6 hours in this group, compared with 12.5 hours in the control group (in whom antimicrobial therapy was initiated in a timely manner). Even though all of the patients in this study received appropriate antimicrobial treatment, mortality differed dramatically between the delayed-initiation group and the control group. VAP-attributable mortality was 39.4% in the former group, compared with 10.8% in the latter. Logistic regression analysis identified delayed initiation of antibiotics as a major independent risk factor for hospital mortality.

Choice of Appropriate Antibiotic

When pneumonia is suspected on the basis of clinical and radiographic signs, there is no way of knowing precisely which bacteria are causing the disease, and culture results usually are not available until 2 to 3 days after a specimen is obtained. In the current era of increasing antibiotic resistance, it is critical to provide broad initial coverage of both sensitive and resistant microorganisms. Because resistance patterns vary among countries, among institutions, and even among ICUs within a single hospital, what constitutes adequate initial antibiotic therapy may be country specific, institution specific, or even ICU specific.

The makeup of the flora causing nosocomial infection tends to evolve as a patient's hospitalization proceeds, with bacterial resistance increasing in the later stages, and this evolution must be taken into account in prescribing the initial antibiotic regimen. Several other factors must be considered as well: (1) the hospital-specific (or, if available, ICU-specific) antibiogram documenting antibiotic resistance, (2) key patient-specific characteristics (for example, an immunosuppressed liver transplant patient may be susceptible to microorganisms that a previously healthy trauma patient would not be), and (3) the efficacy, toxicity, and lung penetration of the antibiotics. If an antibiotic has poor lung penetration (as is the case with vancomycin and the aminoglycosides), a higher dosage may be needed for treatment of VAP than for treatment of other conditions. In addi-

Table 5 Most Common Pathogens Isolated from Pneumonia Patients in Different Types of ICUs³²

Pathogen	Type of ICU

* Dosage recommendations assume normal renal and hepatic function. Initial dosages should be adjusted or streamlined in accordance with microbiologic data and clinical response to therapy.

[†]If an ESBL⁺ strain or *Acinetobacter* is suspected, a carbapenem is recommended.

[‡]If *Legionella* is suspected, a macrolide or a fluoroquinolone is preferable to an aminoglycoside.

[§]Indicated if there are risk factors for MRSA or local incidence of MRSA is high.

[¶]Trough levels should be < 1 µg/ml.

^{||}Trough levels should be < 4–5 µg/ml.

^{**}Trough levels should be 15–20 µg/ml.

ESBL—extended-spectrum β-lactamase MRSA—methicillin-resistant *S. aureus*

tion, when different classes of drugs possess similar efficacy, those with higher side-effect profiles (e.g., aminoglycosides) should not be used as primary monotherapy.

As a rule, initial antibiotic treatment decisions must be tailored to local antibiograms. In 2005, however, the American Thoracic Society and the Infectious Diseases Society of America published consensus recommendations that outlined an evidence-based strategy for initiating antimicrobial therapy in patients with suspected VAP.⁴¹ Patients with early-onset postoperative pneumonia or VAP who have no risk factors for multidrug-resistant pathogens may be treated with ceftriaxone, a quinolone (ciprofloxacin, levofloxacin, or moxifloxacin), ampicillin-sulbactam, or ertapenem. In contrast, patients with late-onset postoperative pneumonia or VAP and those with risk factors for multidrug-resistant organisms must be treated more aggressively. They should be started on combination therapy for gram-negative infections and should receive agents that provide broad coverage of gram-positive infections [see Table 6].

Gram-positive infections The optimal initial antibiotic regimen for gram-positive infections has not been established. A number of antibiotics can effectively treat infections caused by sensitive gram-positive organisms, but the options for treating infections caused by MRSA are limited. Historically, MRSA infection has been treated with vancomycin because no other commonly used antibiotic has been effective. Unfortunately, vancomycin has relatively poor lung penetration. For this reason, linezolid has been proposed as an alternative therapy for nosocomial pneumonia. Two prospective, randomized, multicenter trials comparing vancomycin with linezolid for the treatment of nosocomial pneumonia found the two agents to have similar clinical cure rates and

microbiologic success rates in all of the patients studied, suggesting that these agents will be equally effective in the typical patient with gram-positive nosocomial pneumonia.^{42,43}

Two retrospective analyses pooled patients from the two trials just mentioned (see above), comparing vancomycin to linezolid in a subset of patients with MRSA nosocomial pneumonia⁴⁴ and in a smaller subset comprising patients with VAP from MRSA.⁴⁵ Both analyses demonstrated significantly improved survival and clinical cure rates in patients treated with linezolid. In the 160 patients with MRSA nosocomial pneumonia, treatment with linezolid was associated with an increase in the Kaplan-Meier survival rate from 63.5% to 80.0% and an increase in the clinical cure rate from 35.5% to 59.0%.⁴⁴ In the 91 patients with VAP from MRSA, logistic regression analysis showed that treatment with linezolid was an independent predictor of survival (odds ratio, 4.6) and clinical cure (odds ratio, 20.0). In contrast, a study comparing vancomycin with quinupristin-dalfopristin found the two drugs to have similar cure rates both in nosocomial pneumonia patients as a whole and in a subset of patients with MRSA pneumonia.⁴⁶ Although the favorable linezolid results are obviously limited by the fact that they derive from retrospective analyses of data pooled from two studies, they do raise the question of whether linezolid should be the antibiotic of choice in patients with MRSA pneumonia. If vancomycin is used to treat MRSA, it should be given in an initial dose of 15 mg/kg, and trough levels should be maintained between 15 and 20 µg/ml.⁴¹

Gram-negative infections The optimal initial antibiotic regimen for gram-negative infection involves starting the patient on combination therapy until culture results can be obtained. Options

commonly employed include an antipseudomonal penicillin with a β -lactamase inhibitor, an antipseudomonal cephalosporin, or an antipseudomonal carbapenem combined with either an antipseudomonal fluoroquinolone or an aminoglycoside. If the patient has recently received antimicrobial therapy, the initial antibiotic regimen for VAP should employ a different class of antibiotic so as to avoid the risk of microbial resistance induced by previous antibiotic use.

A prospective study of 156 patients with VAP in two medical/surgical ICUs showed that treatment with antipseudomonal penicillin with β -lactamase inhibitors yielded better outcomes than treatment with cephalosporins, fluoroquinolones, or aminoglycosides (carbapenems were not given as first-line therapy).⁴⁷ The concept that even within the bounds of what constitutes appropriate initial antibiotic therapy there may be a single “most appropriate” antibiotic is intriguing and worthy of further study. At present, however, no single antibiotic class can be recommended over the others as optimal treatment of gram-negative infections.

Rotation of Antibiotics

VAP developing later in a patient’s ICU stay is more likely to be caused by resistant organisms. An increase in resistant organisms is associated with an increased relative risk of death in patients with VAP.¹⁷ Furthermore, patients who are isolated for infection control purposes because of MRSA experience more preventable adverse events and receive less documented care.⁴⁸ Accordingly, scheduled rotation of antibiotics on a protocol basis has been proposed as a technique for hindering the emergence of resistant organisms by manipulating prevailing antibiotic pressures in the hospital environment.^{49,50}

Antibiotic rotation has been studied in both surgical ICUs and surgical wards. A study of 1,456 patients in a surgical ICU compared infection-related mortality during a 1-year period without

an antibiotic protocol with infection-related mortality during a 1-year period in which antibiotics were rotated on a quarterly basis.⁴⁹ Antibiotic rotation reduced infection-related mortality from 9.6 to 2.9 deaths per 100 admissions; in addition, it reduced the rates of resistant gram-positive coccus infection (from 14.6 to 7.8 infections per 100 admissions) and resistant gram-negative bacillus infection (from 7.7 to 2.5 infections per 100 admissions).

A follow-up study examined 2,088 patients both in a surgical ICU and in the ward they were transferred to, using a study design in which ICU patients (but not floor patients) were treated for 1 year without an antibiotic rotation protocol and for 1 year with such a protocol.⁵⁰ In the first quarter of the year, patients received ciprofloxacin with or without clindamycin for pneumonia; in the second, piperacillin-tazobactam; in the third, carbapenem; and in the fourth, cefepime with or without clindamycin. The study demonstrated that the overall number of hospital-acquired infections was decreased on the surgical ward in the year that antibiotic rotation was instituted in the ICU [see Table 7]. Similarly, the incidence of resistant gram-positive and resistant gram-negative infections was reduced on the surgical ward when antibiotic rotation was practiced in the ICU. Perhaps surprisingly, the decrease in resistance came from patients who were not transferred from the ICU.

Although antibiotic cycling has not been definitively proved to be useful in postoperative patients, antibiotic cycling for VAP in the surgical ICU appears to be a strategy that is relatively easy to implement and that may not only decrease the incidence of resistant infection but also, possibly, decrease the overall incidence of infection.

Deescalation of Antibiotic Therapy

Although early initiation of adequate antimicrobial therapy has been demonstrated to reduce mortality in patients with pneumo-

GNB—gram-negative bacillus

nia, it is inappropriate to continue broad-spectrum agents for the entire treatment period. Instead, antibiotic therapy should be reassessed 2 to 3 days after initiation, when culture results become available, and specifically tailored in accordance with these results. If a single pathogen is identified in a culture, all antibiotics may be stopped except for a single agent to which the microbe is sensitive. The exception to this rule is *P. aeruginosa* infection, which many experts recommend treating with two synergistic agents.⁴¹ Although there is little evidence that dual-agent therapy changes outcome, except in cases where VAP is accompanied by bacteremia,⁵¹ the recommendation is made because resistance frequently develops if a patient is treated with a single agent. There is no evidence that maintaining broad-spectrum antibiotic therapy after a positive culture has been obtained improves outcome; however, there is abundant evidence that inappropriate antibiotic use breeds resistant organisms, which are a potential threat not only to the infected patient but also to nearby patients, who may become infected secondarily.

Unfortunately, even invasive quantitative cultures do not identify all pneumonia-causing organisms. How best to tailor antibiotic therapy in a patient with suspected VAP whose cultures are negative remains somewhat controversial. A common approach divides such patients into two broad groups: (1) those whose condition is improving with broad-spectrum therapy and (2) those whose condition is staying the same or becoming worse. In the first group, antibiotic therapy should be tailored to cover gram-negative (and, possibly, sensitive gram-positive) bacteria.

MRSA is fairly easy to culture; thus, if invasive cultures are negative for this organism, vancomycin or linezolid that was started for coverage of resistant gram-positive organisms can be stopped. If there is good evidence of VAP (i.e., CPIS > 6 with both radiographic and sputum evidence of pneumonia), it is reasonable to continue gram-negative coverage for an appropriate period (see below). In the second group, treatment must be individualized. Repeat cultures should be obtained, and a search for nonpulmonary sources of infection, particularly those related to the patient's surgical procedure or to an indwelling central venous catheter, should be initiated. Depending on the clinical situation, all antibiotics may be discontinued, the current antimicrobial regimen may be continued, or a switch to a different class of antibiotic may be made.

Optimal Duration of Antibiotic Therapy

The length of the treatment period for VAP has long been a matter of controversy, thanks largely to the paucity of data on the subject. Historically, 7 to 10 days of treatment has been recommended for sensitive organisms and 14 to 21 days for multiresistant organisms that may be difficult to eradicate from the respiratory tract.^{52,53} Expert opinion also has suggested treating either multilobar or cavitary pneumonia for 14 to 21 days.⁵² To date, few recommendations have been published regarding postoperative pneumonia in surgical patients who are not in an ICU. Given that these patients are healthier than critically ill patients, the duration of antibiotic therapy in this population should be similar to or shorter than that in patients with

VAP, though many surgeons treat any pneumonia for 10 to 14 days, regardless of the initiating organism.

In an attempt to resolve this issue, a prospective, randomized trial was undertaken that assessed mortality in 401 patients (including surgical patients) treated for VAP with antibiotics in 51 different ICUs.⁵⁴ All patients received adequate antimicrobial therapy within 24 hours of the diagnosis of VAP. Antibiotics were withdrawn after either 8 or 15 days, regardless of the patient's clinical condition, except in the case of a documented pneumonia recurrence that occurred before the conclusion of the study. At 28 days, mortality in patients treated with antibiotics for 8 days (18.8%) was comparable to that in patients treated for 15 days (17.2%) [see Table 8]. In addition, the two groups were comparable with respect to the overall recurrent infection rate (28.9% and 26.0%, respectively). The only exception to this latter finding arose in patients with infections caused by nonfermenting gram-negative bacilli (e.g., *P. aeruginosa*), in whom 8-day therapy was associated with a recurrence rate of 40.6%, compared with 25.4% for 15-day therapy; this increase in recurrence was not associated with excess mortality. Overall number of mechanical ventilation-free days and organ failure-free days, length of stay, and 60-day mortality were also similar in the two groups. Not surprisingly, patients receiving 8-day therapy had significantly more antibiotic-free days (13.1) than those receiving 15-day therapy (8.7). This increase was associated with a decrease in resistant organisms in patients who acquired recurrent infections: recurrence was associated with a 42.1% incidence of multiresistant pathogens in the 8-day group but a 62.0% incidence in the 15-day group. Such results are consistent with other observational studies documenting an increase in resistant organisms that is directly related to the duration of antimicrobial therapy.^{55,56}

In another study, 102 consecutive patients with VAP were prospectively evaluated before and after the implementation of a clinical guideline restricting the total duration of antibiotics to 7 days in selected patients who became afebrile under therapy and were neither bacteremic nor neutropenic.⁵⁷ Implementation of the guideline reduced the average duration of antibiotic therapy from 14.8 days to 8.6 days. As in the study mentioned earlier (see above),⁵⁴ no differences in either hospital mortality or length of stay were noted. However, VAP recurrence rates were actually lower in patients restricted to 7 days of antibiotics than in patients receiving physician-directed therapy.

On the basis of the evidence currently available in the literature, it is possible to formulate a treatment approach that is generally appropriate for the treatment of postoperative pneumonia and VAP [see Figure 1].

TREATMENT FAILURE

A 2004 study of 71 patients with ICU-acquired pneumonia in five medical and surgical ICUs found that 62% of patients did not respond 3 days after therapy was initiated.⁵⁸ No cause of treatment failure could be identified in one third of the cases; in the remaining two thirds, the most common causes were inappropriate treatment (23%); concomitant infection (27%); misdiagnosis of infection, with the pulmonary disease being of noninfectious origin (16%); and superinfection (14%). When treatment fails, the patient should be reevaluated to look for a nonpulmonary source of fever, a noninfectious causative condition, or a pneumonia caused by organisms that are resistant to the empirical antibiotic regimen. Aerosolized antibiotics may have a role to play as adjunctive therapy in patients with multidrug-resistant pneumonia who do not respond to I.V. antibiotics.

Discussion

Prevention of Pneumonia after Operation

Before undergoing elective surgical procedures, patients should be instructed about taking deep breaths and ambulating postoperatively (unless there is a medical contraindication to doing so).⁵⁹ Such instruction is especially important in patients who are at high risk for pneumonia after operation. This group includes patients scheduled for abdominal aortic aneurysm repair or thoracic procedures, those older than 60 years, those undergoing general anesthesia, those whose functional status is poor, those with greater than 10% weight loss, those on long-term steroid therapy, those with COPD, smokers, those with abnormally low or high BUN levels, and those receiving more than 4 units of blood preoperatively.^{2,60} Patients who are also at high risk but are not candidates for preoperative respiratory instruction include those undergoing emergency surgical intervention, those with impaired sensoria, and those with a history of cerebrovascular accident with residual neurologic deficit (though, depending on the type of deficit, this patient population may benefit from preoperative teaching as well).

Incentive spirometry is valuable for preventing pneumonia after operation and is a cost-effective adjunct to early ambulation. It benefits a wide range of patients but is especially effective in moderate-risk and high-risk patients, who should receive extra attention in ensuring compliance with this simple intervention.⁶¹ Although chest physiotherapy has been proposed as a means of po-

tentially decreasing postoperative pneumonia, a meta-analysis of 14 published studies assessing the usefulness of this modality after upper abdominal procedures did not support its routine use.⁶²

Like many other infections in critically ill patients, VAP is often preventable.⁶³ Well-designed studies have found numerous interventions to be effective in lowering the incidence of VAP. Some of these interventions are as simple as positioning the patient appropriately or educating health care workers about risk factors for VAP.

HAND HYGIENE

Appropriate hand hygiene is a simple but underutilized method of preventing nosocomial infection [see 1:2 Prevention of Postoperative Infection]. Lack of attention to hand hygiene has been a persistent problem worldwide for decades, and physicians often have the poorest compliance.⁶⁴ The alcohol foams and gels currently available are more effective than handwashing in killing the bacteria present on the hands and take substantially less time to use, improving compliance with hand hygiene in the ICU.⁶⁵ Such preparations now represent the hand hygiene method of choice in most cases and should be readily available throughout the ICU. Hands that are visibly dirty or are soiled with blood or body fluids should still be washed with antimicrobial soap and water, however.⁵⁹ Appropriate hand hygiene practices should be followed both before and after contact with a patient who has an endotracheal tube or tracheostomy in place,

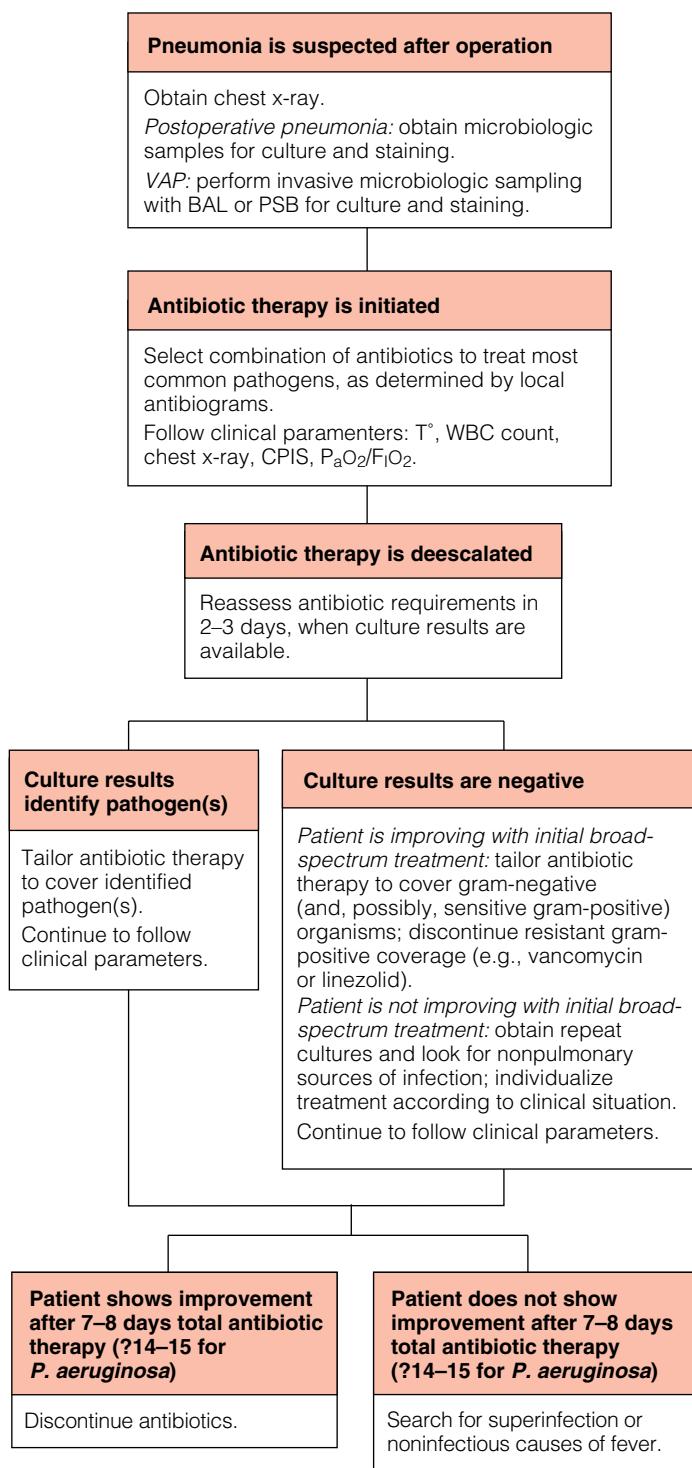

Figure 1 Algorithm outlines recommended approach to antibiotic treatment of suspected pneumonia after operation.⁴⁰

regardless of whether gloves are worn. In addition, hand decontamination is required before and after contact with any respiratory device that is used on a mechanically ventilated patient.⁶⁶

Gloves should be worn for handling respiratory secretions or objects contaminated with such secretions.⁶⁶ They should be changed between contacts with different patients, after handling respiratory secretions. In addition, gloves should be changed between contacts with a contaminated body site and the respi-

tory tract or any portion of the ventilator circuit on the same patient.⁵⁹ Gowns are also recommended when soiling with respiratory secretions is anticipated; they should be removed after the soiling occurs and before any contact with other ICU patients.⁶⁶

PATIENT POSITIONING

Aspiration of upper airway secretions occurs in healthy adults as well as in ill ones. It is, however, a matter of much greater concern in critically ill patients with decreased host defenses, who are at increased risk for VAP. Maneuvers to reduce aspiration of gastric contents therefore have the potential to decrease the incidence of VAP. Because the supine position is associated with an increased risk of aspiration (especially if the patient is receiving tube feedings via a nasoenteric tube), placing the patient in a semirecumbent position—via the simple expedient of raising the head of the bed to an angle of 30° to 45° or greater—is recommended as a means of possibly preventing VAP (if not medically contraindicated).

A prospective, randomized trial involving 86 patients in two ICUs (neither of them surgical) was stopped at the first interim analysis because of the significant difference in the incidence of VAP between semirecumbent patients and supine patients.⁶⁷ The incidence of both clinically suspected VAP and microbiologically proven VAP was drastically reduced in patients positioned with the head of the bed at a 45° angle (from 34% to 8% and from 23% to 5%, respectively). Enteral feeding was also independently associated with the risk of VAP: supine patients receiving enteral feedings had a 50% chance of acquiring VAP.

The supine position has been identified as an independent risk factor for VAP in other observational studies of ICU patients as well.⁶⁸ In addition, patients who require transport from the ICU are at substantially higher risk for VAP than those who do not (24.2% versus 4.4%).⁶⁹ It is possible that the VAP rate is increased because patients requiring transport are sicker at baseline, but it is also possible that the rate is higher in this group partly because patients are supine for much or all of their transport time.

Because static bed rest is known to increase the risk of pulmonary (and nonpulmonary) complications, it has been theorized that postural oscillation and rotation may prevent VAP. Specialized kinetic beds are available that provide continuous movement and are capable of reducing pulmonary complications in surgical patients. A study of 106 blunt trauma patients in a surgical ICU demonstrated a significant decrease in VAP in patients randomly selected to undergo continuous postural oscillation.⁷⁰ A study of 65 surgical patients immobilized because of head injury or traction showed a nonstatistical trend toward a decreased risk of pneumonia in patients treated with kinetic beds.⁷¹ Finally, a study of 69 liver transplant patients randomly assigned to either continuous lateral rotation or a conventional bed found that the incidence of lower respiratory tract infections was decreased in the study group, as was length of time to development of infection; however, duration of mechanical ventilation and length of stay were unchanged.⁷²

Overall, there appears to be a trend toward decreased VAP in surgical patients treated with kinetic beds. In addition, there are various accompanying nonpulmonary complications that can also be prevented by this treatment (e.g., decubitus ulcers). Accordingly, kinetic beds should be used in surgical patients who are expected to have a prolonged ICU course.

CHOICE OF FEEDING ROUTE

Although elevation of the head of the bed reduces aspiration, it does not prevent gastroesophageal reflux.⁷³ Because gastric overdistention is also associated with an increased risk of aspira-

tion, there has been considerable interest in identifying a route of feeding that is associated with a decreased incidence of VAP. This issue is directly relevant to the postoperative setting, in which many patients, as a consequence of the surgical procedure, experience ileus, which is often exacerbated by narcotics given for pain relief. The generally appropriate reluctance to feed a patient with a large gastric residuum in the ICU setting should be balanced against the desire to provide adequate nutrition as soon as is practicable after an operation, as well as against the multiple advantages of enteral feeding over parenteral feeding. Accordingly, the timing for initiating feedings postoperatively must be individualized on the basis of each patient's situation and condition. In addition, whereas feeding a supine patient greatly increases the risk of VAP,⁶⁷ there is no documented benefit to postpyloric feeding or to using smaller nasogastric tubes,^{74,75} and no clear recommendations can be made regarding how best to feed a postoperative patient enterally.

MINIMIZATION OF ENDOTRACHEAL INTUBATION

Extended mechanical ventilation is a major risk factor for VAP; it follows, then, that decreasing or eliminating the need for an endotracheal tube has the potential to lower the incidence of VAP. There are two major strategies by which this goal can be accomplished: (1) earlier extubation (i.e., removing an endotracheal tube when it is no longer needed) and (2) noninvasive ventilation (i.e., continuing ventilatory support without the presence of an endotracheal tube). In addition, the route of intubation (oral versus nasal) can influence the development of pneumonia.⁷⁶

Although the optimal mode of weaning has not been definitively determined, it is clear that many patients are kept intubated even when they no longer require mechanical ventilation. The use of a weaning protocol, a sedation protocol, or both has been shown to reduce the duration of mechanical ventilation.⁶⁹ In addition, daily interruption of sedation until a patient is awake has been demonstrated to decrease the number of ventilator days in a medical ICU population⁷⁷; however, this approach has not been studied in the surgical ICU, where the issue is complicated by the greater need for postoperative narcotics. Regardless of the technique or protocol employed, patients should be assessed daily to determine whether ventilatory support is still necessary. Extubated patients have a substantially lower incidence of postoperative pneumonia than patients with an endotracheal tube in place.

The presence of an endotracheal tube in itself, independent of the need for mechanical ventilation, also appears to be a risk factor for VAP. The tube hinders both airway reflexes and coughing, allowing secretions that accumulate above the tube to enter the airways over time and serve as a nidus of infection. This problem is eliminated in patients who are ventilated noninvasively with bilevel positive airway pressure (BiPAP). Multiple studies have found noninvasive ventilation to be associated with lower pneumonia rates and mortalities than conventional ventilation.^{78,79} However, these studies were done in medical ICUs, predominantly on patients with COPD exacerbations, and it is unclear whether similar results are achievable in patients with postoperative respiratory failure.

Reintubation is also an independent risk factor for the development of VAP.⁸⁰ However, fear of the potential adverse consequences of reintubation should not prevent an awake patient who passes a spontaneous breathing trial from being extubated. Many postoperative patients who are extubated and have unexpected ventilatory problems can be managed without reintubation on BiPAP. In addition, although it is unclear what the correct percentage of extubation attempts that require reintubation would be,

it is clear that the number is not zero. The decision to extubate is, in a way, comparable to the decision to perform an appendectomy. If every patient on whom an appendectomy is done has appendicitis, it is likely that too few operations are being done and that some patients are being allowed to experience a ruptured appendix needlessly. Similarly, if every patient who is extubated postoperatively does well, it is likely that too few extubations are being done and that some patients are being kept intubated inappropriately and thus experiencing preventable morbidity.

Nasal intubation increases the risk of sinusitis, which, even though only 10% of patients with opacified sinuses have recoverable bacteria, is associated with an increased incidence of VAP.⁸¹ It is not clear whether sinusitis causes VAP or merely represents a marker of patients who are at higher risk for pneumonia. In either case, given the association between nasotracheal intubation and increased infection rate and mortality, nasotracheal intubation should not be considered a first-line method of obtaining airway control.

MANAGEMENT OF VENTILATOR

Although in theory, ventilator tubing, suction catheters, and humidification systems could all play a role in the development of pneumonia, none of them have been convincingly shown to have an impact on VAP rates. Condensate in the ventilator tubing can become contaminated, but multiple randomized trials have demonstrated that routinely changing ventilator circuits in patients with respiratory failure does not lower the VAP rate.⁸²⁻⁸⁴ Circuits should be changed when they are visibly soiled with vomit or blood or are malfunctioning. In addition, condensate should periodically be drained and discarded.

Heat moisture exchangers (HMEs) are frequently used instead of heated water humidification systems, because HMEs are relatively inexpensive and require neither electricity nor active heating elements. HMEs minimize the formation of condensate within ventilator circuits, thereby, in theory, potentially decreasing VAP rates. One study found HMEs to yield lower infection rates than humidification systems,⁸⁵ but at present, there is no clear consensus in favor of either type of device.^{8,59}

Either an open single-use catheter system or a closed multiuse catheter system may be used for suctioning. Although open systems are associated with increased environmental contamination, current evidence suggests that the incidence of VAP is not significantly affected by the type of suctioning system used.^{14,86} In addition, when closed systems are used, routine changing of inline suction catheters does not reduce the incidence of VAP,⁸⁷ nor is there convincing evidence that more frequent suctioning prevents VAP.

PREVENTION OF OROPHARYNGEAL COLONIZATION

Oropharyngeal colonization can be decreased by means of either antiseptic therapy or a comprehensive oral hygiene program. Oral chlorhexidine gluconate (0.12%), given before and after cardiac procedures, has proved effective in preventing postoperative pneumonia.⁸⁸ In a prospective, randomized, blinded trial, patients receiving a chlorhexidine rinse, which has documented activity against both aerobes and anaerobes, experienced a 69% decrease in the incidence of postoperative pneumonia. This decrease was not associated with a change in antibiotic resistance patterns after operation and was accompanied by a reduction in postoperative antibiotic use. The effect of a chlorhexidine rinse on the development of postoperative pneumonia in a general surgical population, however, has not yet been adequately studied.

A comprehensive oral hygiene program includes daily oral assessment, frequent tooth brushing, readily available dental care, mouth swabs, and, possibly, a chlorhexidine rinse. These measures

have proved effective in preventing pneumonia in nursing-home patients.⁸⁹ One retrospective study examining the application of a comprehensive oral care protocol in medical/surgical ICU patients demonstrated a decrease in the VAP rate after the initiation of such a program.⁹⁰

DRAINAGE OF SUBGLOTTIC SECRETIONS

Secretions that pool above an inflated endotracheal cuff may be a source of aspirated material that results in VAP. Specially designed endotracheal tubes are available that have a separate opening above the cuff of the tube to allow either continuous suctioning or intermittent irrigation and drainage of secretions that accumulate in the subglottic space.

Three prospective, randomized trials have evaluated the role of subglottic secretion drainage. A study of 190 patients in a medical/surgical ICU demonstrated a decrease in the VAP rate from 39.6 to 19.9 episodes per 1,000 ventilator days.⁹¹ VAP developed later in the subglottic-drainage group (12.0 versus 5.9 days). A study of 150 patients in a general ICU reported similar results, with the VAP rate decreasing from 16% in the control group to 4% in patients receiving intermittent subglottic drainage.⁹² However, continuous aspiration of subglottic secretions does not appear to reduce the VAP rate significantly in cardiac surgical patients. A prospective, randomized trial of 343 cardiac surgical patients demonstrated that pneumonia developed in 5.0% of patients who received subglottic suctioning, compared with 8.2% of control patients.⁹³ As in other studies of subglottic drainage, pneumonia developed later in patients who received the intervention (5.6 days) than in those who did not (2.9 days).

At present, utilization of subglottic secretion drainage is hindered by logistical difficulties. Not only must these specialized tubes and the expertise required to care for them be readily available in the ICU, but the decision to place the tubes must also be made preoperatively and communicated to the anesthesiologist before the patient is intubated.

PHARMACOLOGIC APPROACHES

Widely varying study results and significant infection control concerns have made SDD an extremely controversial practice. The term selective decontamination of the digestive tract is actually a misnomer, in that successful SDD protocols employ a combination of systemic antibiotics and nonabsorbable antibiotics given both orally and via a nasogastric tube. This is an important point: meta-analyses of SDD studies show that SDD is not effective if systemic antibiotics are not included.^{94,95}

A prospective, randomized, unblinded trial of 934 patients in a mixed medical/surgical ICU who received either 4 days of SDD or standard treatment reported that hospital mortality decreased from 31% to 24% in SDD patients.⁸ The treatment protocol consisted of intravenous cefotaxime and oral and enteral polymyxin E, tobramycin, and amphotericin B. The results mirrored those of two meta-analyses that documented decreases in both VAP rate and mortality in patients given SDD,^{94,95} with surgical patients deriving greater benefit than medical patients.⁹⁴

Nearly all of the studies supporting the value of SDD were performed in ICUs with low baseline levels of resistant organisms. The effectiveness of SDD in ICUs where basal antimicrobial resistance is moderate or high is unknown. For instance, a 6-year study of 360 trauma patients receiving SDD reported a moderate increase in the development of resistant organisms.⁹⁶ Owing to infection control concerns, SDD is not widely accepted in the United States. It is noteworthy that routine use of SDD to prevent VAP is not recommended either by the CDC guidelines for preventing health care-associated

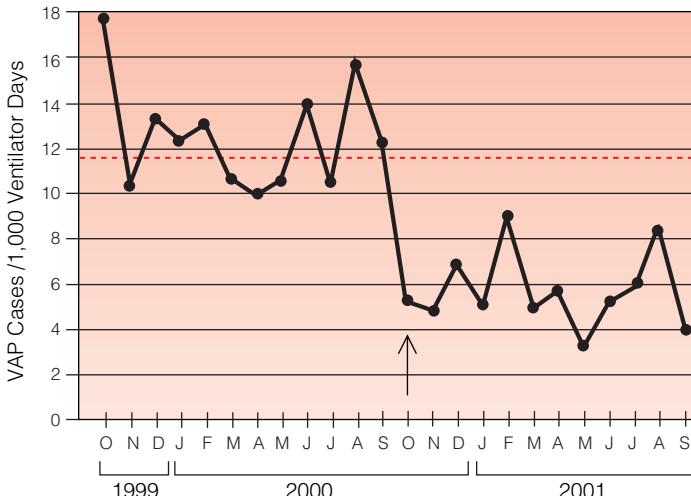

Figure 2 Illustrated is the influence of an education program for health care workers on the monthly rate of VAP per 1,000 ventilator days between October 1999 and 2001.¹⁰⁰ (Dotted line represents the VAP rate cited by the National Nosocomial Infection Surveillance system for ICUs in the United States; arrow represents the point at which the education program was initiated.

ated pneumonia⁵⁹ or by the Fourth International Consensus Conference in Critical Care on ICU-Acquired Pneumonia.⁶

Another pharmacologic approach that has been proposed as a means of preventing VAP is avoidance of drugs that raise stomach pH, on the assumption that these agents may lead to bacterial overgrowth and eventually to VAP. The available data, however, indicate that this assumption is incorrect. A prospective, randomized trial involving 1,200 patients in 16 ICUs that compared the H₂ receptor antagonist ranitidine with sucralfate found no difference in VAP rate between the ranitidine group and the sucralfate group.⁹⁷ Notably, the rate of clinically important GI bleeding was higher in the sucralfate group. On the basis of this definitive study, drugs that raise stomach pH should not be avoided for infection control reasons.

COMPLIANCE WITH EVIDENCE-BASED GUIDELINES FOR PREVENTION

Pneumonia in the postoperative setting cannot be eliminated, but its incidence can be substantially decreased by following evidence-based prevention guidelines. Unfortunately, compliance with such guidelines is far from uniform.

In an attempt to understand why guidelines for preventing VAP are not more widely implemented, a study was performed in which a questionnaire was sent to 110 opinion leaders from 22 countries to ascertain whether 33 practices with the potential to prevent VAP⁶³ were instituted in their ICUs.⁹⁸ If respondents did not follow these practices, they were asked to indicate why not. The overall nonadherence rate among the 62 physicians who returned the survey was 37.0%. For strategies clearly recommended for clinical use, the nonadherence rate was 25.2%; for less effective strategies, the rate rose to 45.6%. Self-reported compliance ranged from 11.7% for continuous subglottic suctioning to 100% for removal of endotracheal tubes as soon as clinically feasible and avoidance of unnecessary reintubation. The most common reasons for nonadherence were disagreement with the interpretation of the clinical trials (35%), unavailability of the necessary resources (31.3%), and high cost (16.9%).

The findings of this study complement those of a separate survey of 103 ICU directors in France and Canada on strategies to

prevent VAP, which cited lack of convincing evidence (e.g., for subglottic secretion drainage) and high cost (e.g., of kinetic beds) as reasons for nonadherence with published recommendations.⁹⁹ Notably, semirecumbent positioning was used more commonly in France than in Canada, and the convenience for the nursing staff was given as the reason for this difference.

EDUCATION OF HEALTH CARE WORKERS

Obviously, to implement interventions that prevent VAP, health care workers must be aware that such interventions exist. Although ICU directors clearly play a major role in the overall direction of care, direct daily care of patients undergoing mechanical ventilation is provided by respiratory therapists and nurses, and it is these professionals who stand to benefit most from educational efforts.

To test the effect of education in reducing VAP rates, a program was initiated that was directed toward respiratory care practitioners and nurses in five ICUs at a single academic center.¹⁰⁰ Initially,

114 respiratory therapists and 146 nurses took a 20-question pretest to determine their level of knowledge about methods of preventing VAP. They then received a 10-page self-study module that provided information about VAP and outlined prevention strategies. Both immediately after the intervention and 6 months later, participants took a posttest that was identical to the original test. Test scores improved at both time points, demonstrating that the information taught was both learned and retained.

In the 12 months before implementation of the education program, 191 episodes of VAP were identified (12.6 per 1,000 ventilator days). In the 12 months following completion of the program, however, only 81 episodes of VAP (5.7 per 1,000 ventilator days) were identified [see Figure 2]. The greatest success in VAP prevention was achieved in the surgical/trauma/burn ICU, where VAP rates decreased from 18.1 to 6.6 per 1,000 ventilator days. These results highlight the importance of disseminating information on VAP prevention to the health care workers who are providing the day-to-day care for patients at risk for VAP.

Recognition and Management of Intra-abdominal Infection

The basic principles of rapid diagnosis, timely physiologic support, and definitive intervention for intra-abdominal infections have remained unchanged over the past century. Specific management of these conditions, however, has been transformed of late as a result of numerous advances in technology. Improved radiologic and laboratory techniques have led to more precise preoperative diagnoses, and newer procedures have led to treatment algorithms that cause less morbidity and permit faster recovery. Whereas the pathophysiology of these infections remains largely unchanged, their management is now marked by an ever-growing complexity. It is no longer true that the diagnosis of intra-abdominal infection, even in association with a perforated viscus, necessitates urgent exploration, but it remains the case that decisions regarding the ultimate course of action for any individual patient are solely the responsibility of the surgeon.

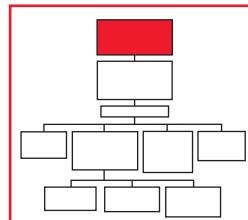

Clinical Evaluation

HISTORY

The general approach to a patient suspected of having an intra-abdominal infection is much like that to a patient with any other acute surgical condition. Specific approaches to various intra-abdominal infections are addressed in more detail elsewhere [see *Infections of the Upper Abdomen and Infections of the Lower Abdomen, below*].

The first step is an accurate history. To begin with, cases of peritonitis are broadly classified as primary, secondary, or tertiary; this classification provides a useful framework for suggesting general approaches to treatment. Primary peritonitis arises spontaneously, without a demonstrable source of contamination, and is generally treated with antibiotics alone; an example is spontaneous bacterial peritonitis in the setting of ascites. Secondary peritonitis is caused by a breach in the GI tract that leads to contamination of a normally sterile space. Control of the source of infection via drainage, resection, diversion, or some combination thereof is imperative for optimizing outcome. Tertiary peritonitis is a poorly defined entity associated with recurrence of intra-abdominal infection after the treatment of secondary peritonitis. It frequently features a diffuse infection in a critically ill patient and may be caused by any of a long list of nosocomial pathogens (e.g., *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Candida albicans*). Management of tertiary peritonitis is complex and must be individualized for each patient.

The acuteness and severity of the presenting symptoms may help localize the origin of the infection. More important, however, they allow appropriate triage of these patients, who are frequently seen in a crowded emergency department. For example, a patient with sudden onset of severe abdominal pain and physiologic derangement must take precedence over almost all other patients,

whereas a stable patient presenting with a chronic complaint can be evaluated in a more deliberate fashion. The specifics of the presenting episode (e.g., the onset, location, and nature of the pain and any changes in bowel habits) are undeniably crucial, but the patient's medical and surgical histories, as well as any previous similar illnesses, are equally critical. Many medical problems and therapies are associated with abdominal pain or discomfort, and an accurate accounting of previous surgical manipulation of the abdomen is vital for refining the differential diagnosis, as well as for prioritizing further tests. The question of whether a patient has presented with similar symptoms before (particularly if those symptoms led to a diagnosis) may be important for determining the timing of any intervention, as well as for putting the current complaint in the context of an ongoing condition. In fact, many patients arrive for medical treatment with a strong (and frequently correct) concept of the nature of their disease.

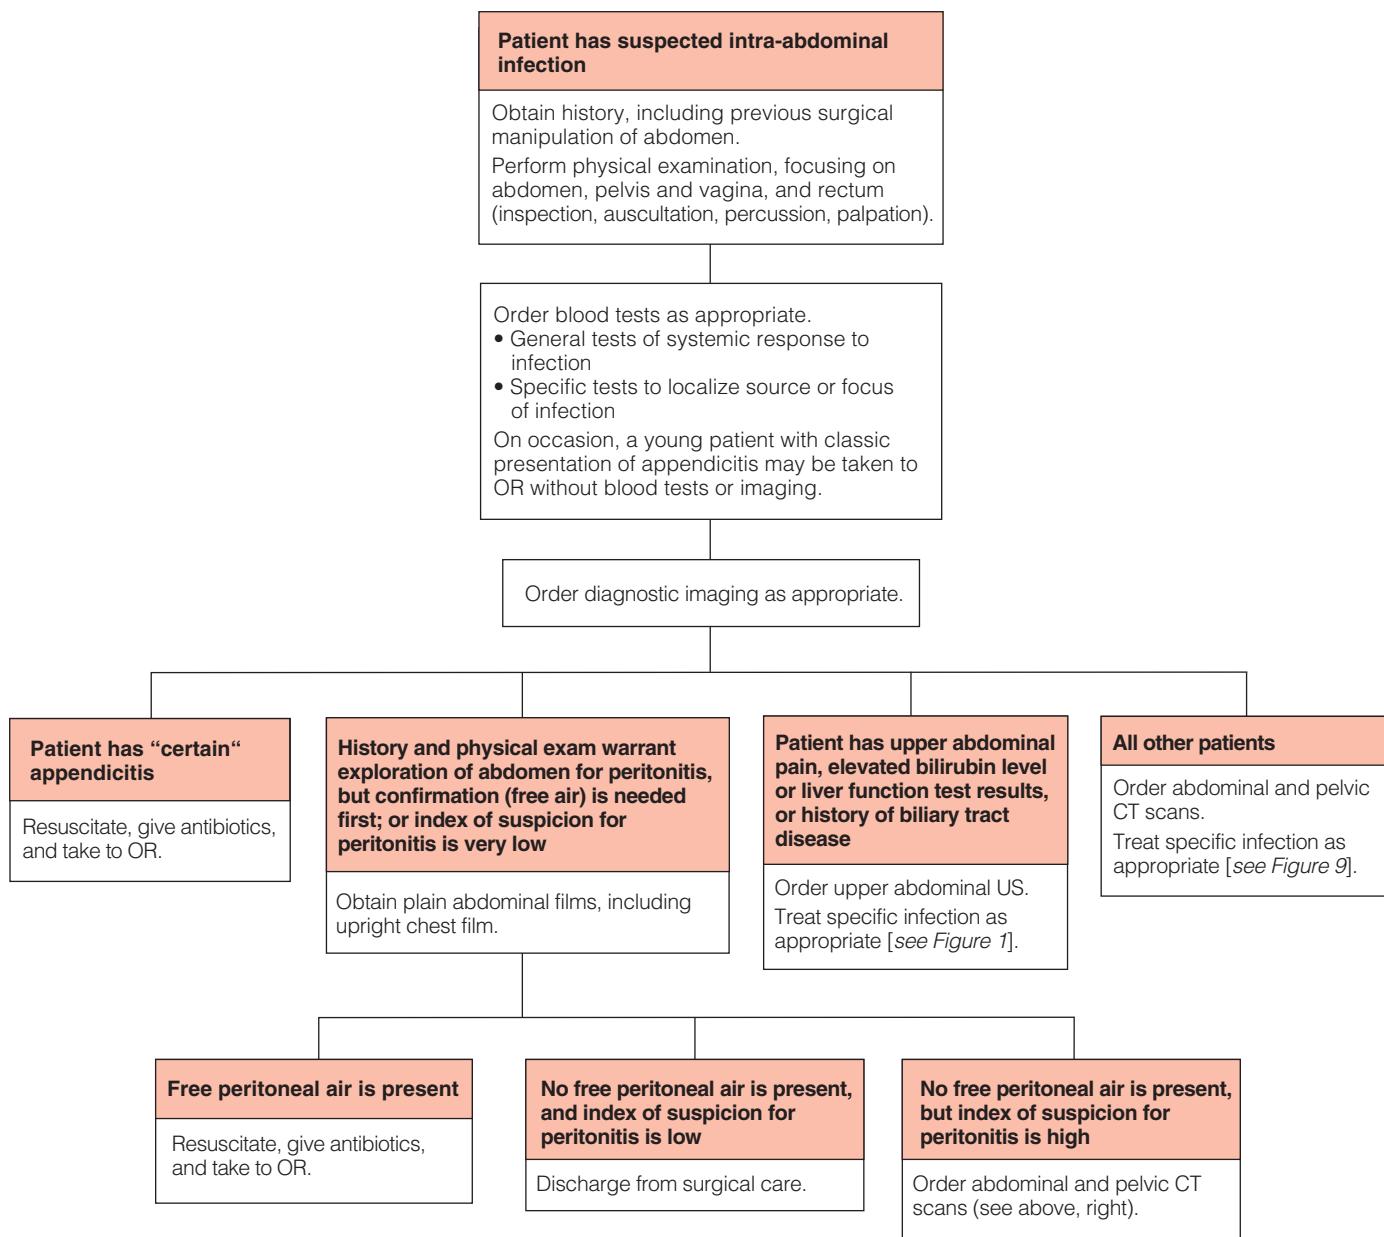

PHYSICAL EXAMINATION

Once the history has been obtained, a thorough physical assessment is performed, with the emphasis on the abdomen, the pelvis (including the vagina), and the rectum. The usual sequence—inspection, auscultation, percussion, and palpation—should be followed as traditionally taught. This sequence need not be extensively reviewed here; however, certain points should be emphasized. With the advent of laparoscopy, inspection must include a careful search for scars indicating previous operations, given that any laparoscopic procedure can be undertaken by way of a variety of trocar sites. Auscultation, though occasionally helpful, is also probably the least specific form of examination. Percussion is valuable for assessing tenderness, as well as for differentiating abdominal distention caused by intraluminal gas or free air (signaled by tympany) from that caused by fluid in the peritoneum, such as ascitic fluid or blood (signaled by dullness).

Proper and humane assessment of the abdomen for tenderness via palpation can be learned only through extensive experience. Gaining the patient's trust is fundamental: an anxious or distressed examinee may respond in a hypersensitive manner, thereby hindering the acquisition of information. An individualized approach is essential as well. Palpation should not be performed in a uniform manner from patient to patient; rather, the amount of tenderness present ought to be judged by the degree of pressure or indentation required to cause a given patient significant discomfort. In the setting of severe abdominal pain, elicitation of rebound tenderness by means of deep palpation followed by rapid release of pressure usually does not improve diagnostic accuracy or alter subsequent evaluation and should therefore be discouraged. Finally, administration of small doses of narcotics to patients with abdominal pain is unlikely to alter an experienced examiner's diagnostic ability for the worse.

Occasionally, a young patient whose history and physical examination (including vital signs) fit the classic clinical picture of appendicitis may be taken to the OR without further assessment.

Recognition and Management of Intra-abdominal Infection

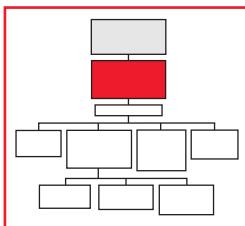

Practically speaking, however, almost all patients with significant intra-abdominal infections undergo blood tests, and most also undergo some sort of radiologic evaluation.

Investigative Studies

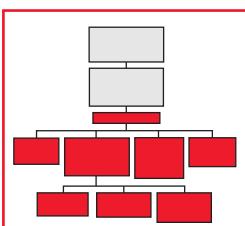

LABORATORY TESTS

Blood work can be divided into two categories: (1) general tests designed to assess the systemic response to infection and (2) specific tests designed to localize the source or site of infection. The former category includes serum chemistries and hematology studies. The latter category commonly includes amylase and lipase concentrations (in patients suspected of having pancreatitis), bilirubin levels and liver function tests (to evaluate hepatic or biliary tract disease), and lactate levels (when an ischemic bowel is suspected). These tests are discussed further elsewhere, in connection with specific infections (see below). Urinalysis, of course, is necessary whenever urinary tract infection or urolithiasis is a possibility.

DIAGNOSTIC IMAGING

The use of various radiologic studies in the diagnosis of intra-abdominal infection continues to evolve rapidly. Outside the setting of trauma, it is now very rare for patients to undergo operations or other major interventions without first undergoing imaging. At one time, plain films of the abdomen (including an upright chest film) were routinely obtained whenever a significant intra-abdominal infection was suspected, principally to detect free peritoneal air, bowel obstruction, or fecaliths. Abdominal plain films proved to lack sensitivity, specificity, and anatomic definition in this setting and consequently have, in many cases, been supplanted by abdominal and pelvic computed tomographic scanning. There are, however, two circumstances in which plain films of the abdomen remain a reasonable first study for a patient with suspected peritonitis: (1) when the surgeon has almost decided, on the basis of the history and physical examination, to explore the patient yet needs confirming evidence of perforation (i.e., free air), and (2) when the index of suspicion for peritonitis is so low that the plain film studies are intended to rule out an unexpected positive finding and will not be followed by an abdominal CT scan if negative.

Ultrasonography for intra-abdominal infection is useful only for focused examination of specific organ systems; it is inferior to CT scanning for generalized surveillance of the abdomen because of the inability of sound waves to penetrate gas in the bowel. By far the best-delineated use of ultrasonography is in the diagnosis of liver and biliary tract disease, for which its ability to demonstrate cholelithiasis makes it superior to CT and for which it should almost always be the first radiologic test in the appropriate circumstances (e.g., a classic history of biliary colic or an elevated serum bilirubin level). Ultrasonography also visualizes the spleen, the kidneys, and the gynecologic pelvic organs well and has the additional benefit of using no ionizing radiation.

The abdominal and pelvic CT scan, appropriately, has become the key diagnostic test for evaluating patients with suspected peritonitis. This modality is widely available throughout much of the world, and newer scanners yield significantly higher resolution than older ones, with reduced scanning times and radiation exposure. CT is highly sensitive for free air, fluid collections, bowel wall

abnormalities, and inflammatory changes. Now that significant intra-abdominal infections—perhaps even in the setting of a perforated viscus—are no longer automatically considered to mandate operative intervention, the ability of CT scanning to identify the source and assess the chronicity of an infection is critical to effective modern management. Multiple common conditions have now been defined for which an adequate CT scan allows nonoperative management either as definitive therapy (e.g., expectant treatment of a simple perforated duodenal ulcer) or as a means of temporizing (e.g., percutaneous drainage of a periappendiceal or peridiverticular abscess). In addition, in experienced hands, a negative CT scan of the abdomen and the pelvis virtually excludes any significant acute surgical illness.

It must be noted, however, that a CT scan is not necessary in all patients with abdominal pain, and the decision whether to obtain one should be made on the basis of predefined guidelines or with the input of a general surgeon. When the need for operative intervention has already been determined, as in a classic case of appendicitis, imaging is unnecessary. In addition, some patients with an intra-abdominal infection amenable to nonoperative management (e.g., simple, mild diverticular disease that can be treated with oral antibiotics on an outpatient basis) do not necessarily benefit from CT scanning.

In selected cases, other forms of imaging may be used. Magnetic resonance imaging, though usually more difficult to obtain in an emergency and logically more complicated than CT scanning, yields excellent tomographic images and has the added benefit of imaging vascular structures and the pancreaticobiliary tree more precisely. Nonetheless, MRI has no significant role in the evaluation of acute peritonitis. Nuclear medicine scans and fluoroscopic studies, though occasionally useful adjuncts for evaluating biliary tract and upper GI disorders, also play no role in the assessment of acute peritonitis.

Options for Intervention

Once an intra-abdominal infection is diagnosed, there are multiple options for intervention. Not infrequently, an approach combining several modalities is warranted. Occasionally, administration of systemic antibiotics is all that is necessary (or practical), as in cases of spontaneous primary bacterial peritonitis or of multiple infected fluid collections that are small but too numerous to drain. Single abscesses, particularly those without thick or particulate contents, can be adequately treated with simple aspiration and a short course of antibiotics. For discrete infected fluid collections in almost any setting, placement of a percutaneous indwelling drain (most commonly under radiologic guidance) is currently the treatment of choice. Operative management, either open or laparoscopic, is employed for resection of damaged or inflamed and unsalvageable organs, diversion of enteric contents, or drainage of collections that are too thick or numerous for percutaneous drainage. Beyond these general guidelines, therapy for specific intra-abdominal infections must be individualized (see below).

Infections of the Upper Abdomen

Biliary tract and pancreatic infections present as a systemic septic response or as infections localized in the upper abdomen [see Figure 1]. Typical findings include abdominal pain, a tender upper abdominal mass, fever and leukocytosis, and jaundice. Various combinations of these symptoms may occur, but it is convenient to consider three common clinical presentations. In each of the presentations, one or two symptoms dominate: (1) upper abdom-

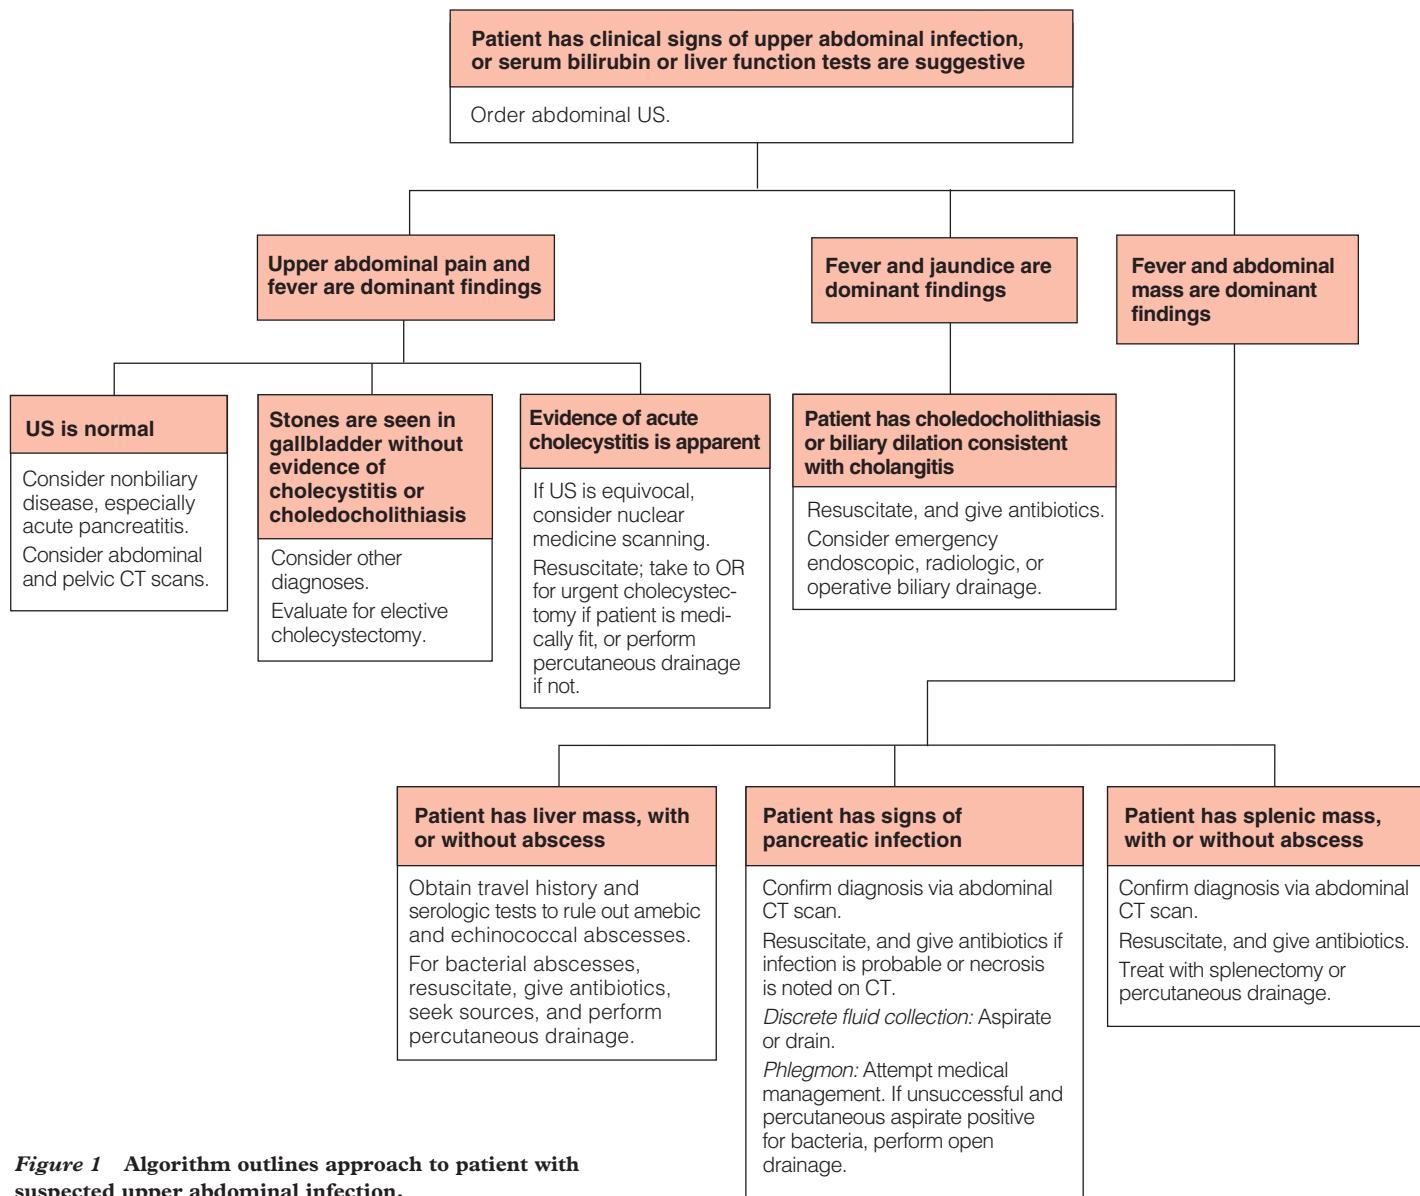

Figure 1 Algorithm outlines approach to patient with suspected upper abdominal infection.

inal pain and fever, (2) fever and jaundice, and (3) an upper abdominal mass and fever. These clinical findings signal the need for a battery of screening tests, including a complete blood count (CBC); routine blood tests of liver function; determination of serum amylase level, prothrombin time (PT), and partial thromboplastin time (PTT); blood culture; chest and abdominal x-rays; and abdominal ultrasonography. When considered together, the clinical findings and the test results allow early differentiation of the three most common disease entities: acute cholecystitis, acute cholangitis, and acute pancreatitis.

UPPER ABDOMINAL PAIN AND FEVER

Patients with upper abdominal sepsis may present with epigastric or right upper quadrant pain and fever. Only two thirds of these patients admitted with a working diagnosis of acute cholecystitis have acute biliary inflammation.¹ In some patients, non-surgical conditions (e.g., pneumonia, acute hepatitis, familial Mediterranean fever, herpes zoster of the intercostal nerves, and gastroenteritis) can be distinguished clinically from biliary disease. The most important screening test for acute biliary infection is the

abdominal ultrasound examination: an abnormal image of the gallbladder or bile ducts supports a biliary etiology [see Figure 2].

The differential diagnosis should include acute cholecystitis, biliary colic, acute pancreatitis, and acute cholangitis, each of which requires specific management [see Table 1]. For example, initial management of biliary colic and mild acute pancreatitis is usually nonoperative, whereas severe acute cholangitis and acute cholecystitis are treated by means of surgical, endoscopic, or radiologic intervention (see below). Clinical features and blood test results, though helpful, may be inconclusive. The abdominal ultrasound may provide specific clues. Stones appear in biliary colic [see Figure 2]; stones and thickening of the gallbladder wall, in acute cholecystitis; gallstones and dilatation of the common bile duct (CBD), in acute cholangitis; and pancreatic enlargement and sonolucency, in pancreatitis.

Pancreatitis

Diagnosis Differentiating acute pancreatitis from acute cholecystitis may be difficult. The serum amylase level lacks specificity, but if the clinical findings suggest acute pancreatitis, an ele-

Figure 2 Abnormal abdominal ultrasound examination shows calculi in gallbladder casting shadows on underlying liver tissue.

vated level of serum amylase clinches the diagnosis. In one study, the initial laboratory results in 100 patients with acute pancreatitis were compared with those in 100 patients with acute abdominal pain caused by acute cholecystitis, perforated peptic ulcer, or acute appendicitis.² The serum amylase concentrations were elevated in 95% of patients with acute pancreatitis but were normal in 95% of patients with acute abdominal pain from other causes. These concentrations peak within the first 48 hours and are almost always elevated in biliary pancreatitis³; in fact, a serum amylase concentration above 1,000 U/L strongly suggests a biliary origin of the pancreatitis.⁴ In addition, determination of serum lipase levels has been shown to be more specific than and at least as sensitive as determination of amylase levels for the detection of

Table 1 Diagnostic Indicators of Upper Abdominal Pain and Fever

	Biliary Colic	Acute Cholecystitis	Acute Pancreatitis
Duration	Short: 40% < 1 hr	Persistent	Persistent
Pathogenesis	Visceral	Somatic	Retroperitoneal
Signs	Tender	Guarding and spasm	Guarding and spasm
Laboratory tests			
Liver function tests	Occasionally abnormal	Abnormal	Abnormal
Serum amylase	Normal	Normal or slightly increased	Increased
Leukocyte counts	Often normal	Increased	Increased

acute pancreatitis.^{5,6} Unless clinical findings and the results of biochemical tests and ultrasonography are unequivocal, a contrast-enhanced spiral abdominal CT scan is usually performed to establish the diagnosis and stage acute pancreatitis. It has been suggested, however, that CT scanning should be reserved for patients with clinically suspected severe acute gallstone pancreatitis, on the grounds that the results would not change the recommended course of action in other patients.⁷ Occasionally, a very mild pancreatitis may give rise to no findings on a CT scan, and a normal technetium-99m (^{99m}Tc)-labeled HIDA (lidofenin) scan may help differentiate this condition from acute cholecystitis.

Treatment Given that pancreatitis encompasses a wide range of diseases with varying degrees of severity, treatment must be individualized for each patient. Possible therapeutic strategies range from outpatient management with temporary dietary modification (for very mild cases) to open debridement and complex intensive care (for severe cases). It is therefore useful to base possible treatment approaches in particular cases on the cause and severity of the pancreatitis.

Gallstone pancreatitis. Standard therapy for gallstone pancreatitis includes I.V. fluids and narcotic analgesics. Nasogastric suction is useful in patients with significant ileus but need not be used routinely.⁸ The use of systemic antibiotics is controversial; they are of benefit in the 10% to 34% of patients who have concomitant cholangitis.⁹ Other treatments suggested previously—including total parenteral nutrition (TPN) and various pharmacologic agents (e.g., cimetidine, somatostatin, glucagon, and insulin)—have not proved useful in all cases of gallstone pancreatitis.¹⁰ Continuous intraduodenal infusion of an elemental diet has reduced exocrine pancreatic secretions in animal experiments.¹¹ Furthermore, enteral feeding has been shown to be beneficial and to decrease disease severity in patients with acute pancreatitis.¹²⁻¹⁴

In clinical practice, the need for further treatment depends on the severity of the acute pancreatitis. Severity determines both the risk of sepsis, which governs outcome, and the risk associated with early cholecystectomy [see 5:21 *Cholecystectomy and Bile Duct*]. The most commonly used clinical prognostic index in North America was developed by Ranson and reliably defines the severity of pancreatitis [see Table 2].² In mild pancreatitis, one or two Ranson signs are present; in more severe pancreatitis, three to five signs are present; and in very severe pancreatitis, more than five signs are present. This distinction serves to stratify further treatment. Other clinical prognostic scores, such as the APACHE-II (Acute Physiology and Chronic Health Evaluation II) and APACHE-III scores and the Balthazar score, have been shown to possess discriminatory value in identifying patients at high risk for complications.^{15,16}

Mild pancreatitis usually subsides within 1 week of onset. Most surgeons defer cholecystectomy until then; urgent operation should be reserved for cases complicated by biliary sepsis, and it may reveal acute cholecystitis in as many as 31% of patients.¹⁷

An attack of acute gallstone pancreatitis is initiated by obstruction at the confluence of the lower end of the CBD and the pancreatic duct by a stone or by edema at the ampulla of Vater resulting from stone migration. These stones may be found and removed in 63% to 78% of patients who undergo operation within 72 hours of admission¹⁷⁻¹⁹ [see 5:22 *Biliary Tract Disease*]; by contrast, they are present in only 3% to 33% of patients explored after the first week.¹⁸⁻²² A randomized trial exploring the optimal timing of surgery for gallstone pancreatitis showed that early surgery (within 48 hours after admission) was not associated with a significant increase in morbidity or mortality in patients with mild pancreatitis but did not change prognosis.²³

Endoscopic retrograde cholangiopancreatography (ERCP). Early ERCP and sphincterotomy [see 5:18 *Gastrointestinal Endoscopy*] has been suggested as an alternative to surgery of the CBD in patients with mild pancreatitis. However, randomized trials comparing endoscopic treatment with conservative treatment within the first 72 hours in patients with mild pancreatitis did not find that urgent endoscopic sphincterotomy improved outcome in this group of patients.^{24,25} Other studies showed that delaying surgery beyond 6 weeks may lead to a 32% to 57% risk of recurrent pancreatitis.^{26,27} Therefore, cholecystectomy and cholangiography should be delayed only until just before patients are discharged from the hospital, 5 to 15 days after the onset of symptoms. Laparoscopic

cholecystectomy has facilitated this approach safely without prolonging hospital stay.

Severe pancreatitis. Patients with three or more Ranson signs are at particular risk for pancreatic sepsis.²⁸ Repeated clinical and radiologic evaluation is required in these patients to ensure early detection of complications, because the outcome of an episode of pancreatitis depends on whether sepsis supervenes. When infection occurs, operative debridement and drainage are required [see Fever and Abdominal Mass, below]. Some surgeons have attempted to alter the course of severe disease by early operation; however, urgent operation is associated with a high mortality in patients with more than three Ranson signs.^{19,21,23,29} To avoid the mortality associated with early operative intervention, some clinicians advocate early diagnosis by ERCP [see Figure 3], followed by biliary decompression by means of endoscopic sphincterotomy and stone extraction. In a randomized trial comparing early ERCP and sphincterotomy with conservative therapy in patients with severe acute pancreatitis, ERCP and sphincterotomy decreased morbidity from 61% to 24% and lowered mortality from 18% to 4%.²⁴ The results of this trial, however, have been the subject of debate, and the success of this approach has been attributed by some authors to the treatment of a concomitant cholangitis rather than of the actual pancreatitis.²⁵ A well-conducted trial that excluded patients with concomitant cholangitis was published in 1997; unfortunately, this trial was unable to answer the question definitively, because too few patients with severe pancreatitis had been recruited.³⁰ It appears that ERCP is warranted mainly in cases of acute pancreatitis complicated by cholangitis and biliary sepsis.^{31,32}

Use of peritoneal lavage in early severe pancreatitis was advocated in one study to decrease morbidity and mortality.³³ Use of standard lavage over a 2-day period did not improve patient outcome, but use of peritoneal lavage for 7 days (long peritoneal lavage) yielded some improvement in outcome.³⁴ Early use of antibiotics and selective decontamination have been proposed as a means of reducing septic complications, but neither has convincingly or reproducibly been shown to improve prognosis.^{35,36} Although prophylactic antibiotics have been shown to decrease the rate of infectious complications in severe acute pancreatitis, they have not clearly been shown to reduce overall disease mortality.^{35,37-40} Attempts have been made to modulate the initial systemic inflammatory response seen in early severe acute pancreatitis to reduce the risk of subsequent infection and improve overall prognosis; somatostatin has exhibited limited success in this regard.^{41,42} Another drug in this category, the platelet-aggregating factor (PAF) inhibitor lexipafant, initially yielded promising results in animal models^{43,44} and in phase II trials⁴⁵; however, a 2001 trial using the same drug did not find it efficacious for treating severe acute pancreatitis.⁴⁶

Acute Cholecystitis

Diagnosis Acute cholecystitis is the most common diagnosis in patients presenting with upper abdominal pain and fever and is characterized by the clinical finding of a midinspiratory arrest on palpation of the right upper quadrant (Murphy's sign). As noted (see above), with the widespread availability of ultrasonography, acute cholecystitis can usually be diagnosed rapidly on the basis of the findings of gallbladder wall thickening, pericholecystic fluid, and stones. Occasionally, more complex cases must be evaluated with nuclear medicine scanning to look for cystic duct obstruction. Concurrent acute obstructive cholangitis must also be considered in all patients with acute cholecystitis. Supportive laboratory data include a high serum bilirubin level and an increased

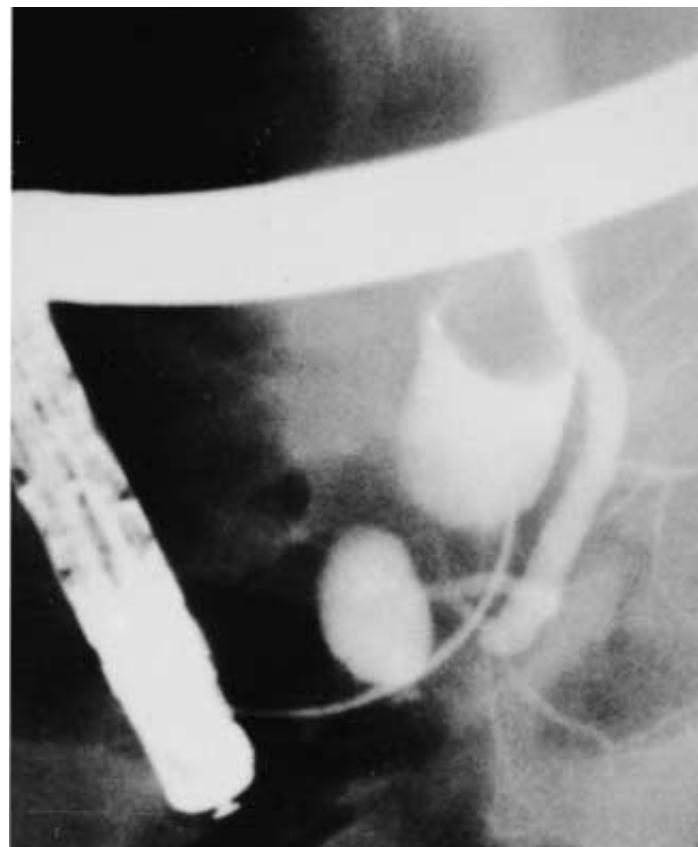

Figure 3 Endoscopic retrograde cholangiopancreatography shows distal CBD stone in acute pancreatitis. Papillotome has been placed through sphincter of Oddi in preparation for endoscopic sphincterotomy.

Figure 4 Air outlines gallbladder and bile ducts in emphysematous cholecystitis.

alkaline phosphatase level. Positive blood cultures and dilated biliary ducts on abdominal ultrasonography usually confirm the diagnosis.

Emphysematous cholecystitis. An uncommon and insidious variant of acute cholecystitis, emphysematous cholecystitis is characterized by gas in the gallbladder lumen or wall or in the pericholecystic soft tissue and biliary ducts secondary to gas-forming bacteria. The key to the diagnosis is the presence of air on abdominal x-ray [see Figure 4] or ultrasound examination. Three stages of emphysematous cholecystitis have been defined: (1) gas is seen only in the lumen of the gallbladder, (2) a ring of gas is identified in the wall of the gallbladder, and (3) gas is seen in the tissues adjacent to the wall. Compared with ordinary acute cholecystitis, emphysematous cholecystitis is associated with a fivefold increase in the risk of gallbladder perforation, as well as a 10-fold increase in mortality in patients younger than 60 years [see Table 3].⁴⁷

Studies from the 1960s noted an increased risk of gangrene and perforation of the acutely inflamed gallbladder in patients with diabetes mellitus.^{48,49} The mortality for acute cholecystitis was also shown to be five to 10 times higher in patients with diabetes than in other patients. Later studies, however, did not show an increased mortality in patients with both diabetes and acute cholecystitis.^{50,51} Nevertheless, one third of patients with emphysematous cholecystitis also have diabetes. This factor, coupled with the current tendency to perform cholecystectomy early in most patients with acute cholecystitis, may account for the disparity between previous studies and later reports.

Acute acalculous cholecystitis. Another variant of acute cholecystitis is acalculous cholecystitis; though still rare, it became more common from the 1950s through the 1990s. This disease was originally described as occurring after surgical treatment of unrelated disease but was subsequently identified in patients with multiple trauma, prolonged critical illness, and sepsis. Predisposing factors include gallbladder ischemia (in patients with shock or trauma) and biliary stasis (in prolonged fasting, hyperalimentation, and

Table 3 Comparison of Acute Cholecystitis and Emphysematous Cholecystitis

	Emphysematous Cholecystitis	Acute Cholecystitis
Gender	70% male	70% female
Stones	70%	90%
Bile culture positive	95%	66%
Clostridia found	46%	1.2%

Perforation of gallbladder	20%	4%
Mortality at age < 60 yr	15%	1.5%
Pathogenesis	Ischemia, obstruction	Obstruction

sustained narcotics therapy). In addition, focal inflammation may cause biliary colonization or may activate coagulation factor XII, thereby causing severe injury to the blood vessels in the gallbladder muscularis and serosa. A high index of suspicion is necessary. Acute acalculous cholecystitis should be considered in any post-operative or acutely ill patient with upper abdominal pain and fever or with unexplained fever and leukocytosis. It is particularly common 2 to 4 weeks after injury. The diagnosis is confirmed by findings on abdominal ultrasound examination [see Figure 5] and ^{99m}Tc-labeled HIDA scanning coupled with infusion of cholecystokinin and morphine.⁵²⁻⁵⁴

Treatment Standard treatment of acute cholecystitis consists of I.V. fluid administration, analgesics, and cholecystectomy. Although the timing of operation is somewhat controversial in ordinary acute cholecystitis, cholecystectomy should be performed at the earliest opportunity [see 5:21 Cholecystectomy/Bile Duct]. This approach has been confirmed by at least one randomized trial comparing early with late laparoscopic cholecystectomy.⁵⁵ The delayed-surgery group had a greater need for conversion to open cholecystectomy (23% versus 11%), as well as a longer

Figure 5 Abnormal abdominal ultrasound examination confirms diagnosis of acute acalculous cholecystitis. When image is compared with that in Figure 2, thickening of gallbladder wall and intraluminal debris are obvious.

average total hospital stay and convalescence. Administration of systemic antibiotics is not required; however, single-dose antibiotic prophylaxis (e.g., cefazolin, 2 g I.V.) can be given at the start of the operation [see 1:2 Prevention of Postoperative Infection].⁵⁶⁻⁵⁸

Some patients with acute cholecystitis are at high risk for gangrene and perforation of the gallbladder. It is crucial to identify these patients and perform cholecystectomy promptly because delay increases morbidity and mortality. Clinically, gangrene and perforation of the gallbladder in this high-risk population are suggested by marked systemic toxicity or by the radiologic demonstration of either emphysematous cholecystitis or acute acalculous cholecystitis.

With ordinary acute cholecystitis, body temperature is slightly increased in most patients—averaging 37.8° C (100.04° F)—but is normal in 20% of patients. By comparison, the risk of gangrene and perforation is reportedly higher in patients with marked systemic toxicity, manifested by a pulse rate greater than 120 beats/min, a body temperature higher than 39° C (102.2° F), and a left shift in the differential white blood cell count, showing more than 90% polymorphonuclear leukocytes. Unfortunately, findings of systemic toxicity are frequently absent in elderly patients.

Patients with acute cholecystitis who have signs of systemic toxicity, emphysematous cholecystitis, or acalculous cholecystitis are at high risk for gallbladder gangrene and perforation and therefore require prompt and aggressive treatment. I.V. antibiotic therapy with a single agent (e.g., ceftriaxone, piperacillin, or a quinolone such as ciprofloxacin or ofloxacin) can be given.^{59,60} Early cholecystectomy is the treatment of choice. Unfortunately, mortality may be as high as 20% to 30% with the traditional surgical approach.⁶¹ If perforation and gangrene are not suspected but medical illness poses a high risk of mortality from operation, nonoperative supportive therapy may suffice. If this fails, another treatment option is cholecystostomy.

Percutaneous transhepatic cholecystostomy has been recommended for these high-risk patients,⁶² particularly where there is a low risk for perforation of the gallbladder.⁶³ To determine the risk of gallbladder perforation, a risk score can be assigned to each of seven findings that may be present on the preoperative abdominal ultrasound examination: pericholecystic fluid, 7 points; distention of the gallbladder, 4 points; intraluminal membrane, 4 points; intraluminal debris, 3 points; round gallbladder, 3 points; sonolucent zone in the gallbladder wall, 2 points; and a thick gallbladder wall (> 3.5 mm), 1 point.⁶³ A patient with a total risk score of 12 or more points requires urgent cholecystectomy; one with a lower score who does not respond to conservative treatment may be treated with percutaneous transhepatic cholecystostomy.

A 1997 review of 59 patients exhibiting the septic response who underwent successful percutaneous radiologic cholecystostomy defined predictors of a successful clinical outcome: localized right upper quadrant tenderness and gallstones, as well as gallstones and pericholecystic fluid on ultrasound examination.⁶⁴ Patients with more equivocal findings may derive greater benefit from more invasive techniques that can simultaneously be used for diagnostic purposes (e.g., laparoscopy, which can even be performed at the ICU bedside⁶⁵).

A few patients with acute cholecystitis will have concurrent acute cholangitis. Cholecystostomy is contraindicated in these patients because of its high mortality; adequate drainage of the CBD is required in such cases [see Fever and Jaundice, below].

FEVER AND JAUNDICE

An alternative presentation of upper abdominal infection includes patients whose predominant symptoms are fever and

jaundice, with pain a less marked component. Jaundice is almost always associated with obstruction of the biliary tree, either intrahepatic or extrahepatic. The combination of fever with jaundice always suggests acute cholangitis, a condition that can have a fulminant and fatal course if not treated promptly.

Acute Cholangitis

Diagnosis If a patient presents with a temperature higher than 38.5° C (101.3° F) in conjunction with jaundice [see 5:3 Jaundice], the possibility of acute cholangitis should always be investigated. If cholangitis is present, laboratory studies will reveal leukocytosis, and blood cultures will often be positive. A finding of gallstones and dilated biliary ducts on abdominal ultrasound examination supports the diagnosis. Reynolds' pentad is present in the full-blown syndrome.⁶⁶ This syndrome includes upper abdominal pain, fever and chills, jaundice, hypotension, and mental status changes. Acute cholangitis is usually related to choledocholithiasis, recent biliary manipulation, or biliary stenting performed for chronic obstruction.

Gallbladder infections. Gallbladder empyema can duplicate most of the findings associated with acute cholangitis. In this condition, acute cholecystitis is complicated by suppuration within the gallbladder, which then becomes the focus of generalized sepsis. The distended gallbladder may be palpable and tender. When jaundice is associated with empyema of the gallbladder, it is less likely to be obstructive than when it is associated with acute cholangitis. True empyema of the gallbladder is rare. Treatment includes administration of I.V. fluids, systemic antibiotic therapy, analgesics, and early cholecystectomy.

In some patients with jaundice and inflammation, a stone impacted in the cystic duct or in Hartmann's pouch may suggest choledocholithiasis, but preoperative diagnosis by ERCP shows an extrinsic compression of the duct known as Mirizzi syndrome. Two types of Mirizzi syndrome exist. In type I, a stone impacted in the cystic duct or Hartmann's pouch compresses the common hepatic duct and causes inflammation, thereby leading to jaundice. Treatment of this type consists of obliteration of the cystic duct and careful partial cholecystectomy, with the neck of the gallbladder left in place. In type II, protrusion of the stone into the hepatic duct erodes the septum between the cystic duct and the hepatic duct and causes a cholecystocholedochal fistula. Treatment of this type involves internal biliary drainage to the wall of the cholecystocholedochal defect, usually with a choledochojejunostomy [see 5:22 Biliary Tract Disease], in addition to cholecystectomy.⁶⁷

Primary sclerosing cholangitis. Patients with primary sclerosing cholangitis, especially those who have undergone internal or external biliary drainage, are at high risk for recurrent bouts of ascending cholangitis. Primary sclerosing cholangitis predominantly affects young males, particularly those with chronic ulcerative colitis. The diagnosis is suggested by the dominant cholestatic biochemical profile—that is, elevation of the serum bilirubin concentration, the serum alkaline phosphatase level, and aspartate aminotransferase activity. Because of the concomitant hepatic scarring, ultrasonography may not reveal the presence of dilated intrahepatic ducts. Definitive diagnosis requires visualization of the beaded appearance of the biliary tree by means of cholangiography. Cholangiocarcinoma and secondary sclerosing cholangitis in patients with Caroli disease or choledochal cysts may mimic these clinical, biochemical, and radiologic features, but this is an unusual occurrence and can be distinguished by careful follow-up of patients.

Currently, magnetic resonance cholangiopancreatography (MRCP) is the imaging modality of choice for elective management of patients with primary sclerosing cholangitis, in that it yields

results comparable to those of ERCP without being invasive.⁶⁸⁻⁷¹

Other causes of cholangitis. An uncommon cause of recurrent cholangitis in North America is Oriental cholangiohepatitis, which is characterized by intrahepatic duct scarring, biliary strictures, and hepatolithiasis, as demonstrated by cholangiography. Irreversible intrahepatic and extrahepatic liver damage may result because of the overwhelming propensity of these patients to form calcium bilirubinate stones.

A few patients with cholangiocarcinoma causing bile duct obstruction or liver metastases causing intrahepatic bile duct obstruction may also present with a clinical picture suggestive of cholangitis. CT followed by MRCP can delineate the diagnosis in most such cases. Treatment consists of I.V. antibiotics and biliary drainage by radiographic or surgical means.

Treatment Once acute cholangitis is diagnosed, resuscitation is started with I.V. fluids and antibiotics, such as fluoroquinolones, mezlocillin, cefoperazone, or piperacillin,^{59,72-75} particularly in patients with marked hyperbilirubinemia, in whom treatment with aminoglycosides may contribute to renal toxicity in up to 33% of cases [see 8:6 Renal Failure].⁷⁶ These antibiotics are required to deal with the various aerobic bacteria, of which *Escherichia coli*, *Klebsiella* species, and enterococci are the most frequently encountered in this setting. Anaerobes may be isolated in 15% to 30% of patients and are particularly likely to be present in diabetics, the elderly, and patients who have previously undergone biliary manipulation. In patients with indwelling catheters, *Enterobacter*, *Pseudomonas*, and *Candida* organisms are being isolated with increasing frequency. Indications of high risk include a serum bilirubin concentration higher than 3 mg/dl.

Approximately 75% of patients with acute cholangitis respond to conservative measures,⁷⁷ and supportive treatment is continued. Subsequent investigations usually include CT followed by MRCP.^{78,79} Because of their invasive nature, ERCP and needle percutaneous transhepatic cholangiography (PTC) are reserved for cases in which a drainage procedure is anticipated or the information from the MRCP is deemed inadequate.

For the 25% of patients who do not respond to conservative treatment, early recognition may improve their prognosis. In one study, patients who did not respond immediately to antibiotics had a mortality of 62%, compared with a mortality of 1.5% in those who improved.⁸⁰ In another study, indicators of high risk were an arterial blood pH less than 7.4, a serum bilirubin concentration above 9 mmol/L, a blood platelet count below 150,000/mm³, and a serum albumin concentration lower than 3 g/dL.¹⁰² These high-risk patients often have systemic hypotension, mental confusion, a temperature higher than 39° C (102.2° F), or hypothermia. Occasionally, acute cholangitis is complicated by disseminated intravascular coagulation (DIC), which manifests itself as a tendency to bruise and bleed or merely as prolongation of the PT and the PTT, together with a fall in the blood platelet count [see 1:4 Bleeding and Transfusion]. If DIC is suspected, the diagnosis should be confirmed and treatment started before biliary decompression.

Patients with refractory cholangitis who do not improve within 24 hours require urgent biliary decompression. Urgent biliary decompression had traditionally been accomplished via surgical exploration of the CBD and T-tube drainage [see 5:22 Biliary Tract Disease]. Cholecystostomy is an inadequate and often fatal option in this context. Rarely, T-tube insertion alone may be life-saving in a desperately ill patient; generally, however, definitive internal decompression is preferable. Unfortunately, any surgical

decompression in these critically ill patients can result in a mortality of 30% to 40%.⁸²⁻⁸⁵ Furthermore, reoperation is required in one third of survivors because important diagnostic information is not available at the initial laparotomy. As a result, nonoperative methods of biliary decompression, including percutaneous transhepatic biliary drainage (PTBD) and endoscopic sphincterotomy at ERCP, have gained favor. PTBD was originally developed for preoperative management of biliary obstruction without cholangitis but has not been found to be beneficial in that setting. At present, it is mainly used for the management of proximal bile duct strictures or for the treatment of cases not amenable to ERCP; its complication rate is less than 10%.⁸⁶

Although PTBD can reduce the mortality associated with initial biliary decompression, many patients still require a definitive operation. Consequently, endoscopic sphincterotomy [see 5:18 Gastrointestinal Endoscopy] has been proposed for decompression of the biliary tree in patients with acute cholangitis from choledocholithiasis [see Figure 6]. In a study of 82 patients with acute cholangitis caused by CBD calculi, early operation was employed in 28 patients, endoscopic sphincterotomy in 43, and antibiotic therapy alone in 11.⁸⁷ Surgical mortality was 21% and morbidity 57%; by comparison, mortality for endoscopic sphincterotomy was 5% and morbidity 28%. Others confirmed these findings.⁸¹ In patients whose gallbladder is still in place, endoscopic sphincterotomy alone, without cholecystectomy, may even be a reasonable long-term option. Of 23 patients whose gallbladders were left in situ,⁸⁷ only two required cholecystectomy in the 1- to 7-year follow-up period: one for empyema of the gallbladder and one for recurrent cholangitis.

An increasingly recognized cause of cholangitis is biliary sepsis after manipulation of the biliary tree with ERCP or PTBD. Treatment includes I.V. fluids and antibiotics. To prevent this complication, prophylactic antibiotics should be administered before every biliary manipulation.⁸⁸

FEVER AND ABDOMINAL MASS

A third group of patients with upper abdominal infection present with fever and an upper abdominal mass identified either by clinical signs or through diagnostic imaging. Even if the mass is only vaguely palpable, the mass effect is demonstrable on ultrasound examination of the abdomen. If the abdominal ultrasound examination is technically unsatisfactory because of intestinal gas, contrast-enhanced CT of the abdomen will facilitate the diagnosis.

The differential diagnosis is aided by the location of the mass. A mass in the right upper quadrant usually indicates acute cholecystitis, though the possibility of a liver abscess must also be considered. A mass in the epigastrium or in the left upper quadrant usually signals a pancreatic infection; in rare instances, a solitary splenic abscess is found. Patients with an intra-abdominal abscess in the subphrenic space or an interloop abscess may also present in this manner.

Liver Abscess

Diagnosis In the setting of acute upper abdominal sepsis, a tender mass in the right upper quadrant is most likely an enlarged, inflamed gallbladder, possibly wrapped with omentum [see Upper Abdominal Pain and Fever, Acute Cholecystitis, above]. The next most common cause of fever and abdominal mass in the right upper quadrant, however, is liver abscess.

Pyogenic abscess. Today, pyogenic liver abscess is most commonly related to biliary tract obstruction from gallstones or malignant disorders (35% of cases), and the ultrasound examination may

Figure 6 Endoscopic sphincterotomy for acute biliary decompression in acute obstructive cholangitis is shown. At left, stone is visible in common hepatic duct, and papillotome has been passed through sphincter of Oddi. At right, stone is held within a Dormia basket before extraction.

reveal both the abscess and the dilated biliary ducts. Previously, portal pyemia from diverticulitis, inflammatory bowel disease (IBD), or perforated appendicitis had been the most common cause; it now accounts for 20% of cases. Even less common is hematogenous spread via the hepatic artery. Approximately 20% of hepatic abscesses are cryptogenic. Ultrasonographic imaging of the liver may demonstrate lesions as small as 2 cm in the liver substance. CT scanning, however, is superior to ultrasonography for evaluating the presence of air and abscesses as small as 0.5 cm in diameter, especially near the hemidiaphragms.⁸⁹ Abdominal CT is also the diagnostic modality of choice in the postoperative patient.⁹⁰ ERCP and PTC are indicated only when gallstone disease or a biliary malignancy is the potential source of the abscess. Most liver abscesses occur in the right lobe: 40% are 1.5 to 5 cm in diameter, 40% are 5 to 8 cm in diameter, and 20% are greater than 8 cm in diameter.

Amebic abscess. Although pyogenic abscesses are commonly multiple, no imaging technique can reliably differentiate them from amebic abscesses. The best indication of a parasitic infection is a history of travel to an endemic area (e.g., Mexico, Central America, or Southeast Asia). However, when a hepatic abscess is detected by an imaging technique, serologic tests should be performed to rule out active amebiasis or echinococcal infection. Examination of stool for amebae is insensitive; consequently,

isoenzyme analysis, *Entamoeba histolytica*-specific antigen detection, or even polymerase chain reaction (PCR) is preferred to confirm the diagnosis of amebiasis.⁹¹

Echinococcal abscess. The diagnosis of echinococcal liver abscess can be confirmed by means of elevated indirect hemagglutination (IHA) titers (> 250). In the late 1980s, a combination of tests that included IHA for *Echinococcus granulosus* and enzyme-linked immunosorbent assay (ELISA) using *E. multilocularis* antigen yielded an 89% species-specific diagnosis of echinococcal disease.⁹² Later work indicated that IgG ELISA and IHA were the best tests for follow-up after resection of the abscess. In patients with a favorable clinical outcome, the specific IgG level decreased toward the end of the first year, though in some cases, a positive serologic result persisted beyond 6 years.⁹³ Diagnostic aspiration is indicated when a diagnosis of pyogenic or amebic abscess is in doubt, but not in echinococcal disease. Aspiration may also be beneficial in patients with left-side abscesses and abscesses greater than 10 cm in diameter. The chest x-ray is abnormal in as many as 50% of cases of amebic abscess, and the plain abdominal x-ray may show calcification of an echinococcal cyst with secondary pyogenic infection.

It is essential to differentiate infected echinococcal cysts from pyogenic abscess: special precautions are required for drainage of echinococcal cysts because of the risk of spillage and anaphylaxis.

Blood cultures are positive in as many as 50% of patients with pyogenic abscess, particularly in those with multiple abscesses; in fact, the presence of *Streptococcus milleri* in the blood suggests a visceral abscess.

Treatment *Pyogenic abscess.* The preferred treatment of pyogenic abscess is closed continuous percutaneous drainage guided by CT or ultrasonography, provided that it is technically feasible and no other indication for laparotomy exists.⁹⁴ More than one catheter may be required for complete drainage. An alternative treatment is repeated percutaneous needle aspiration, the results of which are comparable to those of continuous drainage.⁹⁵ One advantage to repeated needle aspiration is the elimination of cumbersome, painful drainage tubes, which are prone to dislodgment. Although initial studies showed a good response rate with repeated needle aspiration,⁹⁶ the results were not duplicated in a subsequent randomized trial.⁹⁷

The abscess cavity dimensions are followed by serial imaging until the cavity collapses, and the catheter can usually be removed 2 to 3 weeks later. Continuous percutaneous drainage has been associated with a complication rate of 4% and a failure rate of 15%.⁹⁸ However, operative drainage is the treatment of choice in patients with an identified intra-abdominal focus of infection and in patients in whom percutaneous drainage is not feasible or has failed.⁹⁹ Operative drainage, especially via a laparoscopic approach, is a highly effective treatment option that is associated with low mortality and morbidity.¹⁰⁰ In some patients, a limited hepatic resection [see 5.23 *Hepatic Resection*] may be required to eliminate multiple abscesses, particularly when an underlying intrahepatic stricture is the source.¹⁰¹

Treatment of pyogenic liver abscess should include systemic antibiotic therapy. Approximately 70% of pyogenic liver abscesses yield polymicrobial isolates,¹⁰² and 25% to 45% of the organisms are anaerobic.¹⁰³ Multiple anaerobic isolates suggest the colon as a source, whereas a single isolate of *E. coli* suggests a nidus in the biliary tree. Antibiotic treatment should include initial coverage of both aerobes and anaerobes with either a single agent or multiple agents. The need to cover enterococci has been debated, but these organisms clearly are increasingly important nosocomial pathogens. An acceptable initial treatment regimen consists of a single broad-spectrum agent (e.g., ticarcillin-clavulanate or meropenem). It should be noted that significant changes have occurred in the etiology, bacteriology, and treatment of liver abscesses. There is a trend toward a higher incidence of pseudomonas and streptococcal infections, and the frequency of fungal infection is increasing as well.¹⁰⁴ The mortality from this disease remains high, and appropriate antibiotic coverage with drainage is of paramount importance.

The duration of antibiotic therapy is controversial¹⁰⁵; according to one set of guidelines, antibiotics should be continued for 3 to 4 weeks when the abscess has been excised, 4 to 8 weeks when a solitary abscess has been drained, and 6 to 8 weeks when multiple macroscopic abscesses have been drained.¹⁰⁶ Multiple microscopic abscesses usually require that a biliary source also be treated.⁸⁵ The overall prognosis for multiple small hepatic abscesses is not as good as that for solitary abscesses, and the development of a pyogenic abscess in a patient with an underlying hepatobiliary or pancreatic malignancy has been identified as a preterminal event associated with a hospital mortality of 28% and survival of less than 6 months.¹⁰⁷

Amebic abscess. Medical treatment is now the standard approach to management of amebic liver abscesses. Metronidazole, 750 mg orally three times a day for 10 days, is a highly effective regimen.¹⁰⁸ A favorable response to treatment occurs within 4 to 5 days, and

a decrease in the size of the abscess is apparent within 1 week on ultrasonographic examination, though a small residual cavity may persist for as long as 2 years. If the patient's condition does not improve, needle aspiration and culture are indicated. Secondary infection is treated as a pyogenic abscess. Otherwise, oral emetine, 65 mg/day, is added for up to 10 days.

Echinococcal abscess. Symptomatic or secondarily infected echinococcal cysts are best treated by means of surgical excision or marsupialization. The use of oral anthelmintics (e.g., albendazole and mebendazole) has met with limited success. Nevertheless, pre-operative treatment with albendazole or mebendazole for 1 month, combined with postoperative treatment, is indicated to reduce the risk of intraoperative seeding or postoperative recurrence.^{109,110}

Pancreatic Infection

Diagnosis When the mass is located in the epigastrum or the left upper quadrant, a pancreatic source is most likely. Prompt and accurate diagnosis is crucial because severe pancreatic infection is fatal if left untreated. The key to successful treatment is early diagnosis of infected pancreatic necrosis, infected pseudocyst, and pancreatic abscess. A high index of suspicion is required to diagnose these three infectious processes and to differentiate them from a pancreatic inflammatory mass or phlegmon,²⁸ in which pancreatic edema and inflammation are present without necrosis or infection.

Correct diagnosis and treatment of infected pancreatic necrosis, infected pseudocyst, and pancreatic abscess require an understanding of their pathophysiology. It is generally assumed that infected pancreatic necrosis develops as a transmural, transductal, lymphatic, or hematogenous infection of a necrotic region of the pancreas. Infection develops in 40% of cases of pancreatic necrosis, usually in week 2 or 3 after development of the acute pancreatitis.¹¹¹ Surgical debridement is required in these cases to prevent death. Pancreatic abscesses form by liquefaction of infected necrosis. They usually occur after week 5 of pancreatitis, when the acute phase of the disease has subsided.¹¹² Pancreatic abscesses are associated with a lower mortality than infected pancreatic necrosis. Like pancreatic abscesses, infected pancreatic collections and pseudocysts present late in the course of pancreatitis. They are associated with a lower mortality than pancreatic abscesses. Caused by infection in 13% of localized collections resulting from ductal blowout, infected pancreatic collections and pseudocysts may occur in the pancreas itself, in contiguous peripancreatic tissue, or in remote (extrapancreatic) tissue.

Clinical evaluation alone is generally insufficient to diagnose pancreatic infection. A clearly defined upper abdominal mass is palpable in only 50% to 75% of cases.²⁸ In most patients, the screening battery of tests reveals leukocytosis with leukocyte counts greater than 15,000/mm³. Blood cultures are positive in 50% of cases. CT-guided percutaneous aspiration with Gram stain and culture provides the best method of diagnosing pancreatic infection. In one study of 75 patients with clinical toxicity suggestive of pancreatic sepsis, infection was confirmed in only 40%.¹¹³ In another study of 21 patients with pancreatic infection, only five had specific signs on abdominal CT scan.¹¹⁴ CT-guided diagnostic needle aspiration leads to a correct diagnosis within 72 hours in two thirds of patients, and the mortality associated with operative intervention is 19%; however, CT-guided needle aspiration is beneficial only if pancreatic infection is suspected and if the technique is used early in the course of disease.

Several laboratory markers of pancreatic necrosis have been investigated, such as serum methemalbumin, serum ribonuclease, and C-reactive protein. Most of these markers are too insensitive

for routine clinical practice. However, serum levels of C-reactive protein above 10 mg/dl have been reported to be 95% accurate in predicting necrosis.¹¹⁵

Currently, the best indicators of infected pancreatic necrosis or abscess are a combination of Ranson's objective prognostic signs [see Table 2] and dynamic abdominal CT scan findings. In Ranson's series, the pancreatic findings on CT were graded in five categories [see Figure 7]¹¹⁶: (a) normal, (b) pancreatic enlargement alone, (c) inflammation of the pancreas and peripancreatic fat, (d) one peripancreatic fluid collection, and (e) two or more peripancreatic fluid collections. Only category e was associated with a high (61%) incidence of pancreatic abscess. The number of objective prognostic signs present also predicted the subsequent development of an abscess: fewer than three signs, 12.5%; three to five signs, 31.8%; and more than five signs, 80%. However, the value of this method was limited because only five of the 83 patients evaluated had more than five prognostic signs. By combining the objective prognostic signs with positive abdominal CT findings, the investigators identified 30 patients who had three or more objective signs and were graded as category c, d, or e on abdominal CT scan; in these patients, the incidence of pancreatic abscess was 56.7%. By contrast, no patient with fewer than three prognostic signs and graded as category a or b on abdominal CT scan had a pancreatic abscess.

Treatment Once pancreatic infection is diagnosed, supportive measures are initiated, including nasogastric suction, withholding of oral feedings, meticulous attention to respiratory care and fluid and electrolyte balance, systemic antibiotic therapy, and nutritional support. The key to successful treatment, however, is surgical, radiologic, or endoscopic drainage.

Pancreatic necrosis. Sterile pancreatic necrosis alone is not an indication for surgical debridement. In one prospective study, 11 patients with sterile pancreatic necrosis were all followed successfully with conservative treatment.¹¹⁷ However, once infected pancreatic necrosis is confirmed by Gram stain or culture, surgical debridement is required to remove the characteristically thick necrotic material; radiologic or endoscopic methods alone are not as effective for this purpose.

The choice of drainage technique is nevertheless controversial. Many clinicians prefer operative debridement and sump drainage. The mortality associated with extensive operative debridement (so-called necrosectomy) and sump drainage may range from 30% to 40%,¹¹⁸ and this technique may be associated with a 30% to 40% reoperation rate because of sepsis or GI complications.^{28,119}

Open drainage. To reduce the frequency of reoperation and to lower mortality, some clinicians opt for open drainage or marsupialization of the infected pancreas. One modification involves the use of a prosthetic mesh and a zipper to facilitate reexploration in patients with severe intra-abdominal abscess.¹²⁰ A 1991 meta-analysis of published surgical studies on infected pancreatic necrosis found statistically better results with debridement and lavage or debridement and open packing than with extensive debridement and sump drainage.¹²¹ However, surgical treatment should be customized for each patient. In one study, open packing was used for massive necrosis (more than 100 g removed by debridement at operation or CT evidence of at least 50% pancreatic necrosis) or for extrapancreatic necrosis, whereas conventional debridement and sump drainage were used in other cases; the overall mortality in this study was only 14%.¹²²

Pancreatic abscess. Pancreatic abscess resulting from liquefaction of necrosis is also best treated by surgical drainage because residual necrosis may cause failure of treatment by percutaneous methods.¹²³ On the other hand, infected pancreatic fluid collections and

pseudocysts can usually be treated nonoperatively. In one prospective study, percutaneous and surgical drainage were equally successful in treating infected pancreatic fluid collections and pseudocysts.¹²⁴ Clinical signs of progress rather than CT findings are the best indicators of the need for intervention, and nonoperative methods should be attempted before open surgery is planned.

Adjunctive procedures. In the past, debridement and sump drainage were accompanied by the so-called triple ostomy technique, which involved cholecystostomy, gastrostomy, and jejunostomy. The role of these ancillary procedures, however, is controversial at best, and currently, cholecystostomy is employed only if gallstones are detected.

Other operative procedures may be required to manage gastric or colonic complications. Gastric bleeding, gastric outlet obstruction, and gastric fistula necessitating reoperation are relatively infrequent in this setting. By contrast, colonic necrosis and fistula formation are relatively common and occur either spontaneously or as complications of treatment. The usual site of involvement is the splenic flexure or upper descending colon. Treatment consists of colonic resection or a diverting colostomy [see 5.34 Laparoscopic Colostomy].

Antibiotic therapy. The role of systemic antibiotic therapy in the prophylaxis of pancreatic abscess is controversial. Experimental evidence suggests that antibiotics may sometimes decrease the severity of pancreatitis,¹²⁵ and endoscopic cannulation of the pancreatic duct has yielded bacteria in pancreatic secretions of patients with acute pancreatitis.¹²⁶ In patients with pancreatic abscess, bacteriologic cultures are usually polymicrobial, the most common organisms being *E. coli*, enterococci, *Klebsiella pneumoniae*, *P. aeruginosa*, *S. aureus*, *Bacteroides fragilis*, and *Clostridium perfringens*. There is a growing trend toward early use of prophylactic antibiotics in cases of pancreatic necrosis, even though there are no data that convincingly demonstrate a clinical benefit. This trend may be partly responsible for the increasing prevalence of *Candida* species in pancreatitis-related sepsis; a 1996 report stated that *Candida* infection was detected in 21% of patients.¹²⁷

Nutrition. Nutritional support of patients with pancreatic abscesses usually consists of TPN, though small bowel feeding may be attempted occasionally. These patients have high metabolic demands and may experience glucose intolerance or hyperlipidemia. Nevertheless, they generally tolerate I.V. feeding well. A 10-fold increase in mortality (from 2.5% to 21%) was reported in patients in whom a positive nitrogen balance could not be achieved.¹²⁸

Splenic Abscess

Diagnosis A splenic abscess should be considered in patients who present with fever and a left upper quadrant mass, though it remains a rare cause of these symptoms. Most splenic abscesses encountered in clinical practice are solitary; multiple abscesses are usually covert and are typically found at autopsy in patients with disseminated malignancy, collagen vascular disease, or chronic debility.

Because splenic abscess is rare, correct diagnosis requires a high index of suspicion. The main clue is the clinical setting: both bacteremia and local splenic disease are required to produce splenic abscess. In the preantibiotic period, this combination was seen most frequently in patients with bacterial endocarditis and typhoid. Even today, more than three quarters of splenic abscesses occur in patients who already have an infection elsewhere in the body; splenic abscesses can also occur in patients with splenic infarcts, splenic hematomas, or local splenic disease caused by hemoglobinopathies.

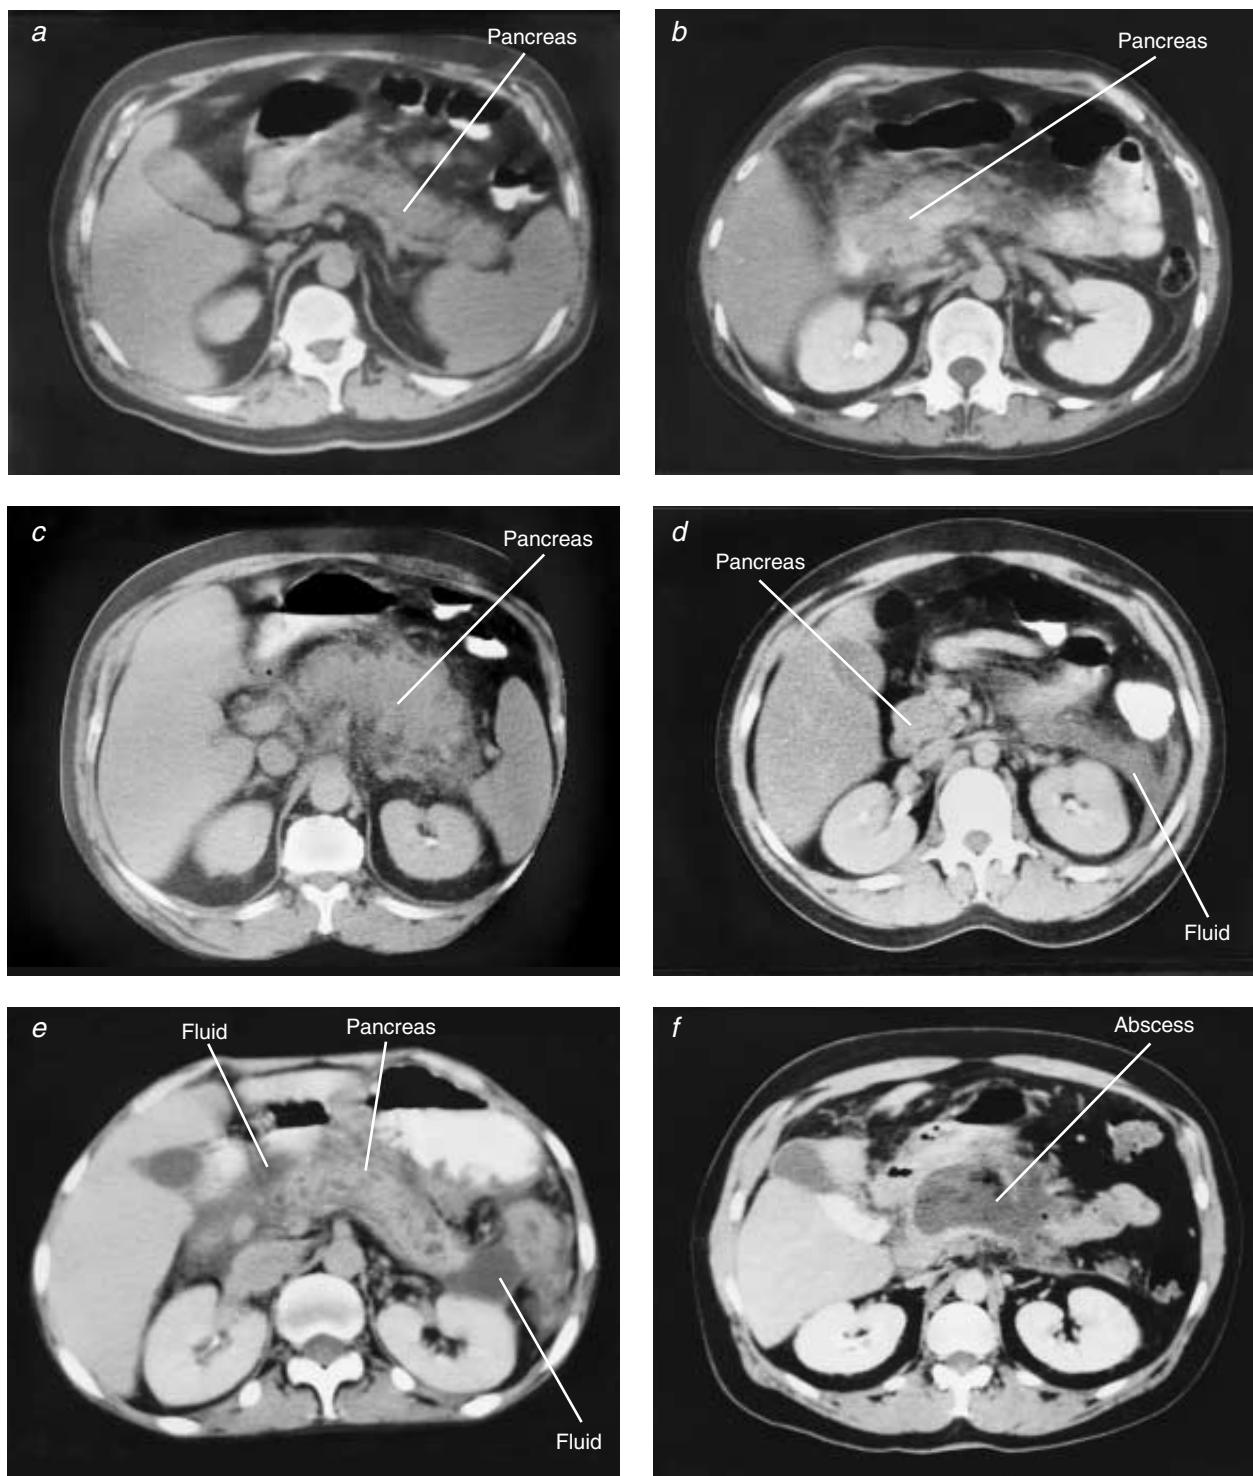

Figure 7 Pancreatic findings on CT scan have been graded by Ranson into five categories: grade A—normal pancreas (a); grade B—diffuse enlargement of pancreas and nonhomogeneous density of gland (b); grade C—diffuse enlargement of pancreas associated with peripancreatic inflammation (c); grade D—high-density fluid collection in left anterior pararenal space (only head of pancreas is visualized at this level) (d); and grade E—diffuse enlargement of pancreas with several intrapancreatic small fluid collections and poorly defined fluid collections adjacent to tail and head of pancreas (e). In final CT scan (f), pancreatic abscess is demonstrated; partially encapsulated fluid collection containing bubbles of air represents large abscess.

The diagnosis of splenic abscess may be supported by indirect radiologic signs, such as an elevated left hemidiaphragm or the finding of a left upper quadrant air-fluid level (mimicking the stomach). To clinch the diagnosis, an abdominal ultrasound examina-

tion or abdominal CT scan is required. The abdominal CT scan, enhanced with I.V. or oral contrast material, is preferred [see Figure 8].¹²⁹ This technique provides a direct image of the spleen, on which abscesses appear as low-density areas that may contain gas.

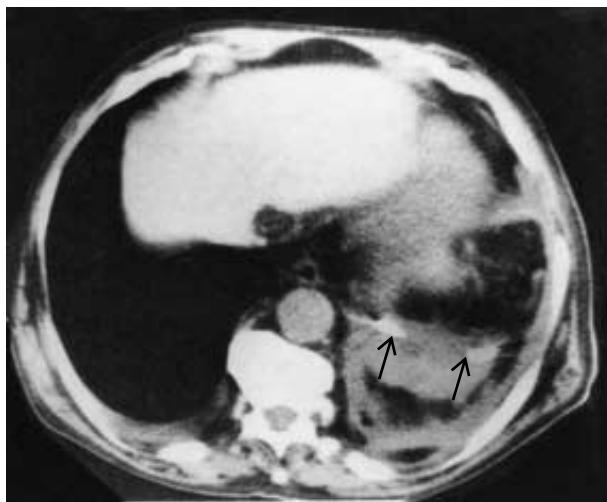

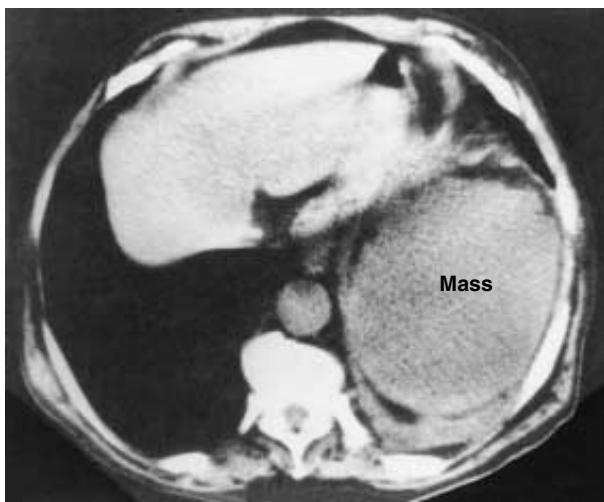

Figure 8 Abdominal CT scan, enhanced by contrast material, confirms diagnosis of splenic abscess.

Treatment Treatment of splenic abscess includes I.V. administration of antibiotics and splenectomy [see 5:25 *Splenectomy*]. The usual pathogenic organisms found are staphylococci and streptococci, though gram-negative bacilli and anaerobes may also be present. When splenic abscesses are not drained, mortality approaches 100%. At one time, splenotomy was the preferred operative treatment, but splenectomy is currently the preferred approach. Percutaneous catheter drainage is being performed with increasing frequency and appears to be as effective as operative drainage.^{8,130,131}

Infections of the Lower Abdomen

Although enteric perforations, like pancreatitis and cholecystitis, present most commonly with pain and fever, their diagnosis differs from that of upper abdominal infections of the solid organs. The pain associated with enteric perforation frequently is not well localized; consequently, CT scanning is used more frequently than ultrasonography because it is superior for evaluating the entire abdomen [see *Figure 9*]. Moreover, a perforated viscus may present more acutely than other forms of infection do, and it is a common indication for emergency exploration. Thus, in the setting of a possible lower

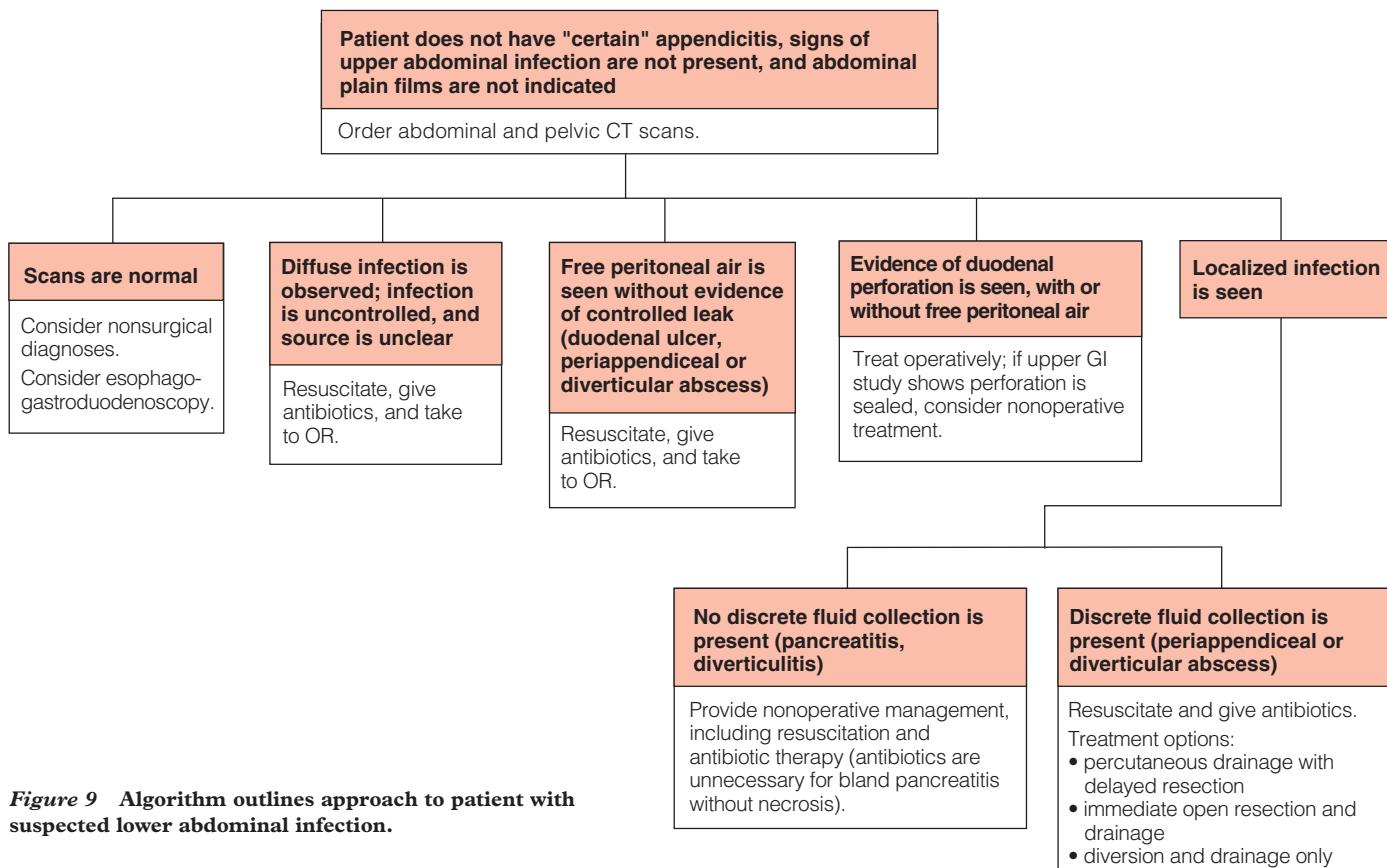

Figure 9 Algorithm outlines approach to patient with suspected lower abdominal infection.

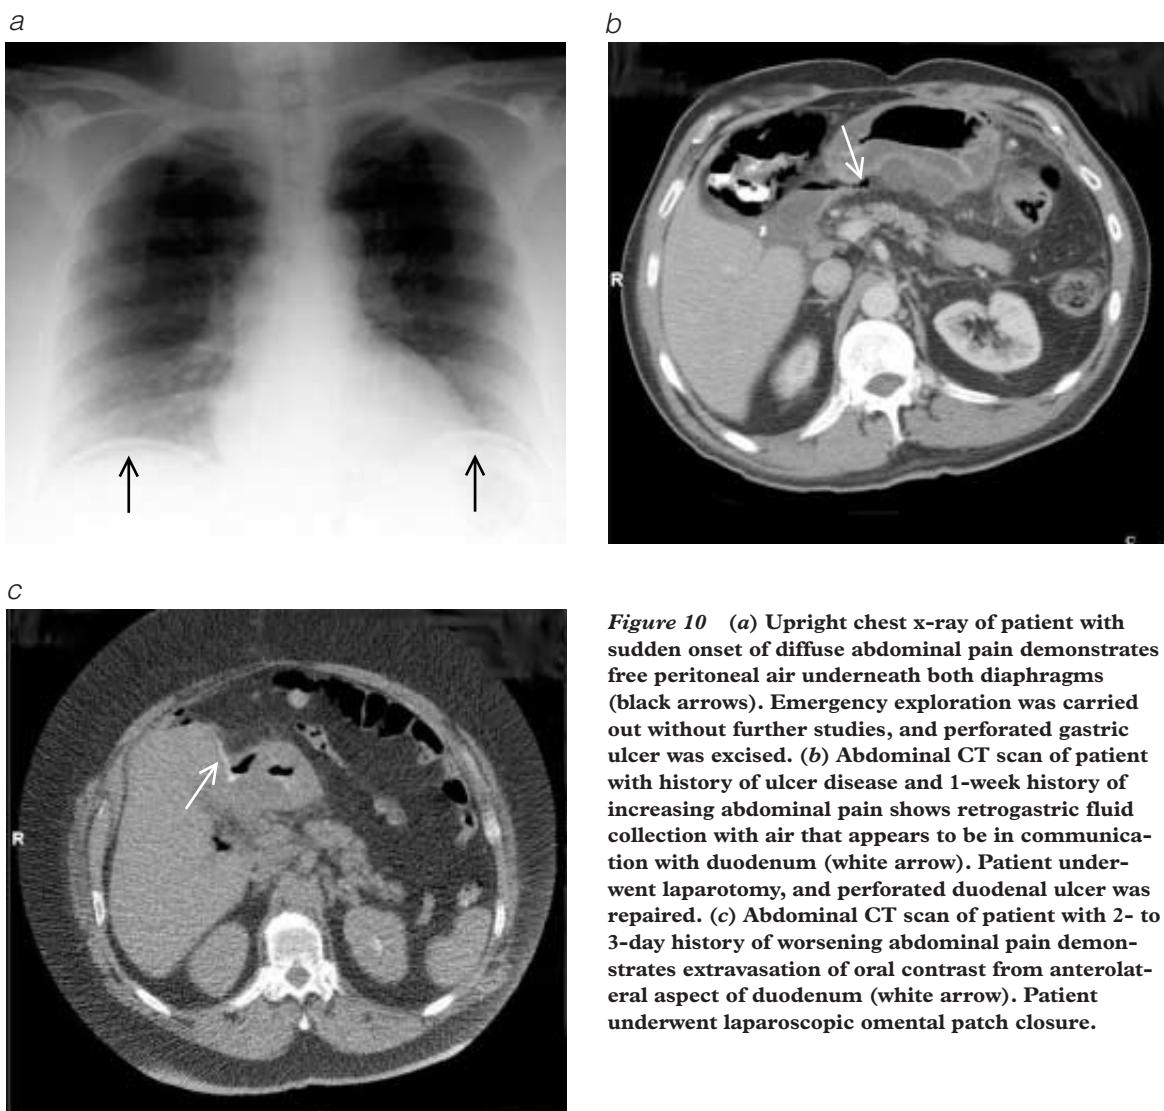

Figure 10 (a) Upright chest x-ray of patient with sudden onset of diffuse abdominal pain demonstrates free peritoneal air underneath both diaphragms (black arrows). Emergency exploration was carried out without further studies, and perforated gastric ulcer was excised. (b) Abdominal CT scan of patient with history of ulcer disease and 1-week history of increasing abdominal pain shows retrogastric fluid collection with air that appears to be in communication with duodenum (white arrow). Patient underwent laparotomy, and perforated duodenal ulcer was repaired. (c) Abdominal CT scan of patient with 2- to 3-day history of worsening abdominal pain demonstrates extravasation of oral contrast from anterolateral aspect of duodenum (white arrow). Patient underwent laparoscopic omental patch closure.

abdominal infection, the diagnostic emphasis is on confirming or ruling out the presence of an acute condition necessitating operation, rather than on fine localization of a more chronic illness.

PEPTIC ULCER PERFORATION

The incidence of peptic ulcer perforation has decreased significantly as a consequence of the changes in disease progression and incidence of intractable ulcers brought about by the advent of H₂ receptor antagonists and proton pump inhibitors (PPIs). Still, a significant percentage of all hospital admissions are secondary to perforated peptic ulcers, and the patient population is becoming older and more evenly balanced between men and women, presumably because of increased use of nonsteroidal anti-inflammatory drugs and cigarettes.¹³²

Several studies found a high (80% to 92%) incidence of *Helicobacter pylori* infection in patients with perforated peptic ulcers.^{133,134} Although the prevalence of *H. pylori* infection in this population is well established, the causal role that such infection plays in peptic ulcer perforations has been questioned.¹³⁵ In a 1999 study involving 50 patients with juxtapyloric perforations related to crack cocaine use who were successfully managed with simple omental patch closure, the investigators found that approximately 80% of the patients who underwent antral mucosal biopsy at the time of closure had a positive urease test, a finding that suggested

a role for *H. pylori* infection in the pathogenesis of these perforations as well.¹³⁶

Diagnosis

A patient with a perforated peptic ulcer will complain of the sudden onset of intense abdominal pain and will often be able to pinpoint the exact time when the symptoms began. If the perforation has not spontaneously sealed or been managed with operative closure, the clinical picture can progress to florid sepsis and shock. Evidence of free air on plain upright and left lateral decubitus radiographs will be seen in as many as 70% of cases [see Figure 10a].¹³⁷ Endoscopy should be avoided in the evaluation of peptic ulcer perforation, but equivocal cases or spontaneously sealed perforations can be evaluated with water-soluble contrast studies. CT scanning can be used to localize an infection to the duodenum, particularly if communication of air or fluid with the duodenum is established [see Figure 10b] or if extravasation of contrast is seen [see Figure 10c].

Treatment

Surgical management centers on control of the site of perforation (via surgical closure or spontaneous sealing), with or without an acid-reducing procedure [see 5:20 Gastrooduodenal Procedures]. Before this is done, I.V. fluids should be given, metabolic derange-

ments corrected, appropriate antibiotics and an H₂ receptor blocker or PPI administered, and a nasogastric tube placed for decompression.

Operative versus conservative management Several studies have shown nonoperative management to be safe and effective for perforations that have sealed spontaneously. A 1989 study evaluated 35 patients with acute duodenal perforations—excluding those with a history of chronic ulcer disease who ultimately went on to primary repair and acid-reducing surgery—who were managed nonoperatively after evidence of a sealed perforation was noted on a water-soluble upper GI study. The investigators reported one death, in a patient with a history of metastatic breast cancer, and one intra-abdominal abscess.¹³⁸ In a 1989 prospective trial of 83 patients with perforated peptic ulcers randomly assigned to either conservative or operative management, the two groups experienced similar morbidity and mortality (~5%), and 73% of the patients in the conservatively managed group experienced full resolution of their symptoms.¹³⁹ The only significant difference between the groups was in the length of hospital stay. It has been suggested that patients with evidence of a sealed perforation confirmed by a Gastrografin upper GI study can be managed conservatively with a low incidence of reperforation and intra-abdominal abscess formation.¹⁴⁰ These patients must undergo repeated clinical examination and receive supportive therapy until clinical symptoms resolve.

Laparoscopic versus open repair A prospective, randomized trial of perforated peptic ulcers to either open or laparoscopic suture omental patch repair concluded that for perforations smaller than 10 mm, laparoscopic repair was associated with reduced operating times, less need for analgesics, fewer postoperative chest infections, earlier return to normal activities, and shorter hospitalizations.¹⁴¹ An earlier study also demonstrated reduced analgesic times and earlier return to normal activities but reported longer operating times.¹⁴² These studies confirm that small perforations can be adequately managed laparoscopically without exacerbation of bacterial sepsis. It must be emphasized, however, that biopsy of perforated gastric ulcers is critical for ruling out malignancies, and laparoscopic repair of the perforation may preclude biopsy.

Simple repair with medical management versus repair with acid-reducing procedure Definitive surgical management of ulcer disease during repair of a perforated peptic ulcer is contraindicated in patients who are hemodynamically unstable, have diffuse peritonitis, have an abscess, or have multiple underlying comorbid conditions.¹⁴³ The significant side effects associated with definitive surgery (dumping and diarrhea) and the success of medical management (PPIs, H₂ receptor blockers, and *H. pylori* eradication) have further contributed to the reduced popularity of proximal vagotomy at the time of repair. Now that fewer acid-reducing operations are being performed, there is some justifiable concern that younger surgeons will not be able to obtain the degree of training they would need to perform a definitive operation (highly selective vagotomy) in an urgent or emergency scenario.

A 1987 study found that simple closure with a Graham patch, without a concurrent operation to reduce ulcer recurrence, resulted in a higher recurrence rate than closure with proximal gastric vagotomy did (52% versus 16%; median follow-up, 54 months).¹⁴⁴ In a subsequent study of patients with acute perforations who were randomly assigned to undergo either simple closure or simple closure with proximal vagotomy, ulcer recurrence rates in the two groups after 2 years were 36.6% and 10.6%, respectively.¹⁴⁵

Both of these studies, however, were performed before PPIs became routinely available.

Some 40% of patients with duodenal perforation treated with simple closure may experience recurrent duodenal ulcer. A 1995 series associated such recurrence with *H. pylori* infection.¹⁴⁶ To further study the role of *H. pylori* eradication in ulcer recurrence after peptic ulcer perforation, a randomized study was done in which patients with perforated duodenal ulcers and *H. pylori* infection after simple closure received either quadruple anti-*H. pylori* therapy (1 week of bismuth, tetracycline, and metronidazole with 4 weeks of omeprazole) or omeprazole alone.¹³³ After 1 year, 38.1% of patients managed with PPIs alone experienced ulcer recurrence, compared with 4.8% of patients managed with PPIs and *H. pylori* eradication. A similar study followed patients with perforated duodenal ulcers for up to 2 years after simple closure and randomization to either short-term H₂ receptor blockers or H₂ blockers with quadruple therapy; ongoing *H. pylori* infection correlated with recurrent ulcers for up to 2 years.¹⁴⁷

On the basis of these findings, definitive acid-reducing procedures should be reserved for (1) patients in whom medical management of peptic ulcers and *H. pylori* fails, (2) patients whose ulcer symptoms have persisted for longer than 3 months, and (3) patients with otherwise complicated ulcers (e.g., lesions that are bleeding or causing obstruction).¹⁴⁸

Antibiotic therapy In fasting persons, gastric juice contains as many as 10³ organisms/ml. These organisms are typically facultative gram-positive salivary bacteria (e.g., lactobacilli and streptococci) and fungi (e.g., *Candida* species). In induced states of achlorhydria (e.g., from treatment with H₂ receptor blockers or PPIs), there is an increase in the total number of organisms, including enterococci and nitrate-reducing organisms. This phenomenon suggests a proliferation of salivary and enteric organisms, but its clinical relevance is unknown.¹⁴⁹

Eradication of *H. pylori* in patients with uncomplicated ulcers and bleeding ulcers is now the standard of care.^{150,151} Infection with this organism is associated with a 1% per year risk of peptic ulcer disease, a level of risk approximately 10 times that seen in uninfected patients. Eradication of *H. pylori* with medical management typically results in resolution of the ulcer, and recurrence is rare. Consequently, acid-reducing procedures are not often required.¹⁵²

SMALL INTESTINAL PERFORATION

Diagnosis

Small intestinal perforation is a very difficult entity to diagnose, in large part because of its relative rarity. There are certain clinical scenarios (e.g., strangulated hernia and Crohn disease) in which the likelihood of this condition is heightened, but in the setting of blunt small intestinal injury, the low incidental occurrence of perforation (~1%¹⁵³) and the complexity of the presentation frequently lead to a delay in diagnosis. Such delay is associated with increases in the morbidity and mortality directly attributable to the injury.¹⁵⁴ The radiographic modality most useful in diagnosis is CT scanning.¹⁵⁵

Treatment

The basics of treatment are the same for small bowel perforation as for all perforations: isolation and control of the source of contamination. In the acute setting, this is accomplished through laparotomy and excision of the disease segment, whether the perforation is the result of ischemic necrosis, of blunt injury, or of IBD. Primary reanastomosis is generally accepted in these patients

[see 5:29 *Intestinal Anastomosis*]. For patients with Crohn disease, perforation (usually presenting as a fistula) is a risk factor for postoperative disease recurrence¹⁵⁶; accordingly, close postoperative follow-up is indicated.

There are two additional issues regarding small bowel perforations that warrant special mention. The first has to do with small bowel perforation secondary to obstruction. When this event occurs, it is important not only that the perforated segment be resected but also that the cause of obstruction be identified to prevent recurrence. The second issue has to do with anastomotic leakage. Not all leaks call for surgical intervention. If the leak is a late complication, it is likely to have walled itself off into an abscess, in which case CT-guided drainage of the abscess is the treatment of choice. Efforts at reducing the luminal transport are also made to improve healing.

Nutritional support plays a major supportive role in the treatment of patients with small bowel perforation. Many of these patients, either because of their underlying pathology (e.g., Crohn disease) or because of their hypermetabolic state (e.g., from trauma), lose some of their innate ability to heal and prevent anastomotic breakdown. The presence of a knowledgeable nutrition staff can dramatically enhance patient recovery in this setting.

Antibiotic therapy The small bowel flora is typically sparse (10^3 to 10^4 /ml), with salivary organisms predominating. In conditions of stasis, obstruction, or impaired motility, however, colonic flora can proliferate, with *E. coli*, enterococci, and obligate anaerobes the dominant organisms. In the distal ileum, there are typically about 10^6 colony-forming units/ml, with an increasing proportion of enteric organisms and anaerobic bacteria, presumably as a result of backwash through the ileocecal valve.¹⁵⁷ Although there are generally far fewer bacteria in the small intestine than in the colon (which contains about 10^{12} organisms/ml), the standard antimicrobial therapy remains broad-spectrum coverage (e.g., fluoroquinolone plus an antianaerobic agent for 5 days).¹⁵⁸

APPENDICITIS

Obstruction of the appendiceal lumen by a fecalith, a hyperplastic lymph node, or a foreign body is typically the inciting event in the pathogenesis of appendicitis. Luminal obstruction with continued secretion results in progressive distention, proliferation of luminal microorganisms, ischemia, gangrene, and subsequent perforation. The clinical history during this evolution is marked by diffuse epigastric pain with anorexia, nausea, and vomiting. The pain typically progresses first to the periumbilical region and then to the right lower quadrant (at McBurney's point). Patients have a low-grade fever and exhibit direct tenderness at McBurney's point but may also manifest rebound tenderness, guarding, rigidity, and marked temperature elevation if the appendix perforates and results in diffuse peritonitis. As the viscera and the omentum localize and sequester the perforation, the symptoms may subside to a degree, with localized pain and a palpable abdominal mass the primary manifestations remaining.

Diagnosis

Classically, the diagnosis of appendicitis has been made primarily through clinical examination, with laboratory tests consistent with inflammation (i.e., an elevated leukocyte count with a left shift and an elevated C-reactive protein level) serving as confirmation. In as many as 20% of patients with appendicitis, however, the incorrect diagnosis is made, and the incidence of removal of a normal appendix can approach 40%.¹⁵⁹⁻¹⁶¹ Early diagnosis of appendicitis can decrease the risk of postoperative complications

Figure 11 Pelvic CT scan of patient with distant history of right lower quadrant abdominal pain with recurrent acute attack demonstrates inflamed and thickened appendix with surrounding fat stranding (white arrow). Gangrenous appendix was removed laparoscopically.

from 39% to 8%, and one retrospective study found that the use of diagnostic CT lowered the rate of misdiagnosis to 7%.¹⁶² CT scanning is reported to be 93% to 98% in diagnosing appendicitis, with significantly improved accuracy achieved by using an appendicitis protocol after retrograde water-soluble contrast administration.¹⁶³ CT findings suggestive of appendicitis [see Figure 11] include enlargement and dilation of the appendix (to > 6 mm), nonfilling of the appendix, and periappendiceal inflammation (fat stranding, abscess, phlegmon, and dependent fluid collections); these findings do not differ significantly between acute appendicitis and chronic, recurrent appendicitis.^{164,165}

Current evidence supports the role of CT scanning in the diagnostic evaluation of patients with suspected appendicitis. Studies have demonstrated decreases both in the incidence of normal appendectomies and in the incidence of prolonged, unnecessary observations.^{166,167} Furthermore, alterations in patient management attributable to diagnostic CT have been shown to decrease overall hospital and patient costs. Nevertheless, the utility of CT in young men whose history, physical examination, and laboratory test results fit the classic picture of appendicitis remains unproven; this subset of patients may be managed without confirmatory CT.¹⁶⁶ On the other hand, CT scanning appears to be quite useful for diagnosing appendicitis in women, in which setting it decreases the incidence of normal appendectomies and facilitates diagnosis of other causes of the symptoms.^{168,169} Preoperative CT scanning assists in planning an operation, identifying a periappendiceal abscess that may delay immediate appendectomy, and recognizing other sources of intra-abdominal pathology.

Treatment

Initial management consists of fluid resuscitation, appropriate prophylactic antibiotics, and preparation for surgery. Currently, acute nonperforated appendicitis, gangrenous appendicitis, and perforated appendicitis without an associated abscess are managed with urgent appendectomy [see 5:26 *Appendectomy*]. The main dilemmas in management center on the appropriate use of

laparoscopic appendectomy and the role of conservative management for periappendiceal masses with interval appendectomy.

Laparoscopic versus open appendectomy In several prospective, randomized clinical trials that compared laparoscopic with open appendectomy, the consensus was that the former was associated with a lower incidence of wound infection, decreased utilization of pain medication, earlier return to normal activities, and reduced cost of hospitalization (though the data were conflicting on this last point).¹⁷⁰⁻¹⁷³ On the other hand, the trials found the laparoscopic approach to be associated with significantly longer operating time, equivalent duration of hospitalization, and a possible increased risk of abscess formation. A retrospective review published in 2000, however, found that when a dedicated laparoscopic service was established for patients with appendicitis, the rates of intra-abdominal abscess formation after laparoscopic appendectomy decreased to levels equivalent to those reported after open appendectomy.¹⁷⁴

Although laparoscopic appendectomy is associated with a higher incidence of intra-abdominal abscess formation in the setting of perforated appendicitis, it is not associated with a higher incidence of wound infection or abscess in patients with gangrenous or nonperforated appendicitis.¹⁷⁵ Furthermore, a prospective, randomized trial found that laparoscopic appendectomy was associated with reduced overall cost of hospitalization, decreased use of pain medication, and earlier return to functional status in patients with uncomplicated appendicitis.¹⁷⁰

Two groups of patients clearly benefit from laparoscopic appendectomy: women and obese patients. In women, laparoscopy aids in the diagnosis of other pelvic pathologic conditions and lowers the incidence of negative appendectomies; in obese patients, it results in less postoperative pain and a shorter recovery time, even though it does not significantly reduce the postoperative complication rate.^{176,177} Patients who present with evidence of perforated or complicated appendicitis may be better managed with the traditional open approach to minimize the risk of postoperative abscess formation.¹⁷⁸ Improvements in laparoscopic techniques, however, may eventually reduce the incidence of this complication to a level comparable to that seen with open management.

Periappendiceal abscess and interval appendectomy

The mainstays of conservative management have been parenteral antibiotics, supportive fluid resuscitation, and percutaneous drainage of radiographically amenable fluid collections. In a 2001 review of 155 patients with periappendiceal abscesses, the complication rate was 36% for patients managed with surgical incision and drainage and appendectomy, compared with 17% for patients managed nonoperatively.¹⁷⁹ The recurrence rate was 8% in the conservatively managed patients, and nonoperative management failed in five patients. Patients with perforated appendicitis and abscess or phlegmon diagnosed by CT scanning but without a palpable mass were safely managed with conservative therapy. In a 2002 study, immediate appendectomy was associated with a higher postoperative complication rate and an increased incidence of more extensive initial operations (e.g., ileocecal resection, right hemicolectomy, and temporary ileostomy).¹⁸⁰

The recurrence rate after conservative management ranges from 10% to 20%. In one study of patients managed with interval appendectomy for periappendiceal mass, histologic evaluation revealed that a significant majority of samples had a patent appendiceal lumen and were at risk for recurrent appendicitis.¹⁸¹ In a 2002 report, 45.8% of interval appendectomy pathologic samples showed evidence of chronic active inflammation.¹⁸² The risk of re-

currence and progression to chronic appendicitis supports the use of interval appendectomy in young patients, but in adults, the decision algorithm must also consider the incidental diagnosis of tumor.

Interval appendectomy is typically performed between 6 weeks and 3 months after percutaneous intervention and clinical resolution [see *Figure 12*]. The risk of recurrence is greatest after the 6-month point in the clinical progression of acute appendicitis managed conservatively.¹⁸³ In several retrospective analyses, interval appendectomy proved to be a safe management plan, but to date, there have been no randomized, prospective trials evaluating its role in management.^{184,185}

Antibiotic therapy The pathogenic organisms recovered in peritoneal cultures derive from the colon and consist of aerobic or facultative bacteria and anaerobes. The most frequently isolated organisms are *E. coli*, enterococci, viridans streptococci, *B. fragilis*, *Lactobacillus* species, *Prevotella melaninogenica*, and *Bilophila wadsworthia*.^{186,187} It is noteworthy that the use of intraoperative peritoneal cultures has not been shown to affect the incidence of wound infection, abscess formation, or small bowel obstruction if patients are presumptively managed with antibiotics that cover gram-negative bacteria and enteric anaerobes.¹⁸⁸

Appropriate coverage can be obtained with any of the following: ampicillin-sulbactam, piperacillin-tazobactam, ticarcillin-clavulanate, cefoxitin, cefotetan, and ciprofloxacin plus metronidazole.¹⁸⁹⁻¹⁹² In a trial involving children with perforated appendicitis, conversion to oral therapy after parenteral therapy was equivalent to parenteral therapy alone.¹⁹³ In a study of patients with acute nonperforated appendicitis, preoperative administration of cefoxitin was superior to placebo in reducing the incidence of wound infection.¹⁹⁰ In a study of children with acute nonperforated appendicitis, prolonged antibiotic administration (5 days) had no advantage over a single preoperative dose with respect to the incidence of wound infection or subsequent abscess formation.¹⁹⁴ The duration and timing of antibiotic administration in patients with nonperforated gangrenous appendicitis have not been shown to correlate with the wound infection rate.¹⁹⁵

COLONIC PERFORATION

Diagnosis

Diagnostic strategies for identifying colon lesions associated with intra-abdominal infection follow the general approach outlined earlier [see *Clinical Evaluation and Investigative Studies, above*]. For unstable patients with generalized peritonitis, there is no need to delay operative intervention to wait for radiologic confirmation: the pathologic condition will be identified in the course of the operation. However, for patients who have localized peritonitis or those who are stable and whose physical examination is not conclusive for peritonitis, radiologic evaluation is pivotal in planning treatment.

Although plain films may reveal free air in the abdomen and prompt surgical intervention, CT scanning may be a more valuable first study because of its ability to delineate the bowel wall and surrounding soft tissues with remarkable accuracy. In a 2002 study comparing abdominal radiography with CT for the evaluation of acute nontraumatic abdominal pain in the ED, the former was not nearly as diagnostically sensitive as the latter (a nonspecific diagnosis in 68%, compared with a specific diagnosis in 80%).¹⁹⁶ The investigators concluded that CT was the initial radiographic modality of choice for patients with acute abdominal pain in the ED. Another study found that CT scans frequently changed physicians' initial diagnoses, increased diagnostic certain-

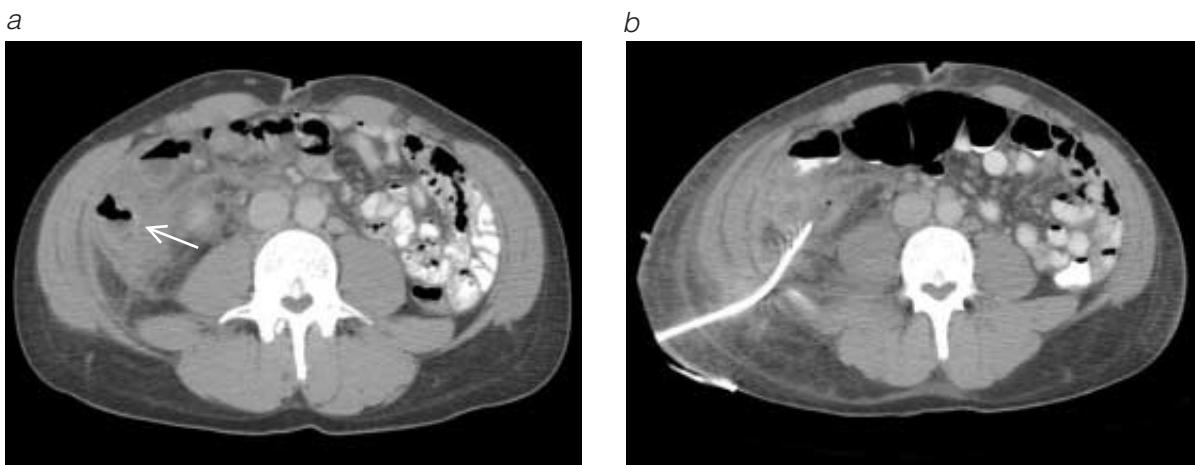

Figure 12 (a) Pelvic CT scan of young patient with a 5-day history of right lower quadrant abdominal pain shows fluid collection containing air adjacent to appendix and consistent with appendiceal perforation and abscess formation (white arrow). (b) Pelvic CT scan of same patient after percutaneous ultrasound-guided placement of drainage catheter shows evacuation of air and much fluid. Patient underwent uneventful interval appendectomy 6 weeks later.

ty, and led to more appropriate treatment in patients with acute abdominal pain in the ED.¹⁹⁷

In view of the relatively high cost of CT scanning, the concomitant radiation exposure, and the use of I.V. contrast agents to enhance the scans, some have suggested using ultrasonography to make diagnoses. However, the well-documented dependency of this modality on the skill of the individual technician makes it less attractive to the broader health care community, where full-time sonographers are not always available. Finally, it should be noted that there is no role for MRI in the acute setting. Although it is both sensitive and specific, the logistic hindrances associated with its use greatly limit its applicability.

Treatment

Diverticulitis Diverticular disease ranges in severity from minor to serious. The focus of our discussion will be on management of complicated (perforated) diverticular disease, for which resection should be considered after only one attack.

In the past, treatment of perforated diverticular disease involved a multistage surgical approach whereby the patient underwent three separate procedures: one for fecal diversion and drainage of the infection, a second for resection of the diseased segment, and a third for closure of the colostomy. This three-stage approach proved to be associated with high morbidities, high cumulative mortalities, and prolonged hospitalizations.¹⁹⁸⁻²⁰⁰ Since then, CT-guided percutaneous drainage, primary resection of the diseased segment, and improved patient selection for resection and primary anastomosis have improved patient outcomes dramatically. Few adequately powered multicenter, prospective, randomized trials evaluating treatment of complicated diverticular disease have been done; accordingly, many of the current treatment standards have been derived by consensus on the basis of thorough review of the literature.

Therapy for perforated diverticular disease depends greatly on the patient's condition at the time of presentation and on the stage of the disease. The Hinchey staging system²⁰¹ [see Table 4] classifies perforated diverticular disease according to the associated inflammatory process and is used to guide and compare treatment options.²⁰²⁻²⁰⁴

In stage I disease, a small pericolic abscess [see Figure 13a] in a stable and otherwise healthy patient may resolve with conservative

management, including broad-spectrum antibiotics and bowel rest. The patient can be evaluated for definitive surgical treatment later, after the episode resolves and the patient is in better condition for surgery. For larger abscesses or stage II disease [see Figure 13b], the standard of care is CT-guided percutaneous abscess drainage, if feasible. After drainage, resuscitation, and bowel preparation, a one-stage colectomy can be done (resection of the diseased segment with primary anastomosis) so as to avoid the potential increased morbidity of a two-stage procedure.²⁰⁵

For patients who have abscesses that are inaccessible to percutaneous drainage or who experience persistent symptoms despite drainage, operative correction is required. If adequate bowel preparation can be carried out, primary anastomosis at the time of surgery should be considered. If adequate bowel preparation is not possible, a two-stage approach, including a Hartmann procedure and subsequent stoma reversal, should be considered. Alternatively, depending on the patient's condition, resection with primary anastomosis may be attempted. There is some evidence that employing intraoperative colonic lavage to reduce the fecal column and thus allow primary anastomosis may reduce morbidity, especially in patients with stage I or II disease.²⁰⁶⁻²⁰⁸ However, the studies supporting this view are not conclusive enough for such a regimen to be considered standard; further investigation is warranted before it is generally accepted. Finally, whether to add a covering stoma to a primary anastomosis is a case-by-case decision that is usually guided by the presence of risk factors such as poor nutritional status, inadequate bowel preparation, blood loss, or intraoperative hypotension.²⁰⁹

Table 4 Hinchey System for Classification of Perforated Diverticulitis²⁰¹

Stage	Description
Stage I	Pericolic or mesenteric abscess
Stage II	Pelvic or retroperitoneal abscess that is walled off
Stage III	Purulent peritonitis
Stage IV	Feculent peritonitis

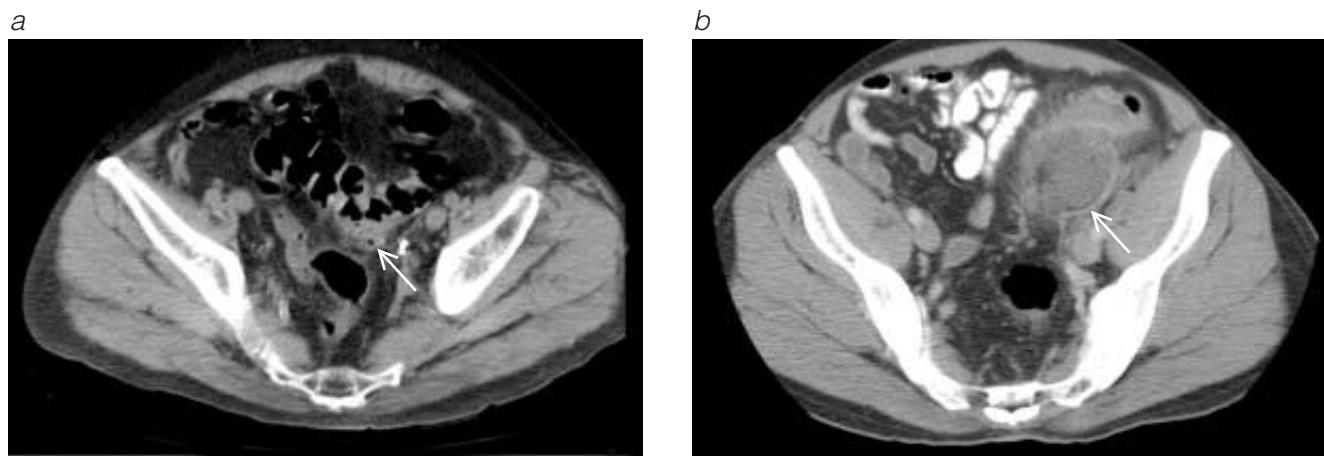

Figure 13 (a) Pelvic CT scan of elderly patient with left lower quadrant abdominal pain of 2 days' duration shows diverticulitis with small amount of extraluminal air (white arrow). Patient was treated acutely with resuscitation and antibiotics alone and was discharged home without complications. (b) Pelvic CT scan of middle-aged patient with 1-week history of constipation and moderate pelvic pain shows left lower quadrant fluid collection consistent with peridiverticular abscess (white arrow). Proximal bowel is seen anterior to abscess, distal bowel posterior. Percutaneous drain was placed, and elective colectomy with primary reanastomosis was performed 12 days later.

Stage III or IV diverticulitis is a surgical emergency that calls for prompt resuscitation and administration of broad-spectrum antibiotics, followed rapidly by surgical treatment. The Hartmann procedure is the most widely accepted operation for this presentation.²¹⁰⁻²¹² It is associated with a substantially lower mortality than drainage followed by colostomy as a separate, delayed procedure (12% versus 28%).²¹³ In certain circumstances, with appropriate patient selection and low feculent contamination, primary anastomosis, with or without a covering stoma, may be feasible.²¹⁴⁻²¹⁶

The goals of resection are to remove the focus of infection and to prevent recurrent attacks. Recurrent diverticulitis after resection is the result of incomplete removal of the diseased segment, especially at the rectosigmoid junction. Therefore, when the diseased segment is resected, the entire sigmoid must be removed, and the distal resection margin must extend below the confluence of the taeniae coli and onto pliable rectum.²¹⁷ Proximally, the colon is mobilized until a margin of uninflamed bowel is identified. It is not, however, necessary to remove the entire colon affected by diverticuli.

Laparoscopy. Laparoscopic treatment of diverticular disease is becoming more common but remains controversial. Many feel that there is no place for laparoscopic-assisted colectomy in the treatment of stage III or IV disease,²⁰² but there is growing acceptance of this approach in the treatment of stage I and II disease. A review of several small studies concluded that laparoscopic colectomy had a high potential for reducing hospitalization time and operative morbidity; however, the cost analysis data were conflicting, and some of the trials reported very high conversion rates.²¹⁸

Right-side disease. Particular mention should be made of right-side diverticulitis. In the past, this condition was often misdiagnosed as appendicitis before exploration, but today, with the increased use of CT scanning, this error is less frequently made. Given that diagnosis is difficult and the disease is surgically curable, some authors suggest that it should be treated with aggressive resection, ranging from simple diverticulectomy to right hemicolectomy.^{219,220} Others argue that the disease is relatively benign in the absence of perforation and suggest leaving the diseased bowel in situ, performing an incidental appendectomy, and then treating the patient conservatively.^{221,222} There is no standard therapy for cecal diverticulitis, mainly because of the small number of patients

it affects annually, which translates into small series reported in the literature. In the course of follow-up, it is important that these patients undergo thorough evaluation for colon cancer.

Antibiotic therapy. Appropriate antibiotic administration is an integral part of standard therapy for diverticular disease and is started at diagnosis. The most frequently isolated organisms are anaerobes, including *Bacteroides*, *Peptostreptococcus*, *Clostridium*, and *Fusobacterium* species. Gram-negative aerobes (predominantly *E. coli*) and facultative gram-positive bacteria (predominantly streptococci) are also associated with these infections.²²³ Parenterally administered broad-spectrum antibiotics are standard. A particularly common regimen is ciprofloxacin plus metronidazole, but there are other regimens that are equally efficacious for treatment. According to a 2002 report from the Surgical Infection Society, the duration of therapy for complicated intra-abdominal infections should be no longer than 5 to 7 days.¹⁵⁸ If ongoing infection is suspected at termination of treatment, investigation into a potential source of infection is warranted.

Other colon lesions associated with perforation and peritonitis A number of colonic conditions besides diverticular disease may be manifested by colonic perforation and secondary peritonitis. Whatever the specific cause, the general goals of therapy remain the same: (1) to identify and control the source of bacterial contamination, (2) to reduce the level of peritoneal contamination, and (3) to prevent recurrent infections.

Colon cancer. After diverticular disease, colon cancer is the next leading cause of colonic perforation in uninjured patients. In general, perforated colon cancer carries a high mortality,^{224,225} and the operative technique of choice is controversial. Perforation typically occurs at the site of the lesion but can also occur proximally (e.g., at the cecum) as a result of luminal obstruction.

Generally, perforations at the site of cancer in the ascending and transverse colon are treated with primary resection and anastomosis, with or without a diverting stoma, regardless of whether localized or diffuse peritonitis is present. When perforations occur at the site of cancer in the descending and sigmoid colon, however, there is some debate over the appropriate surgical approach, with some advocating primary resection and others staged proce-

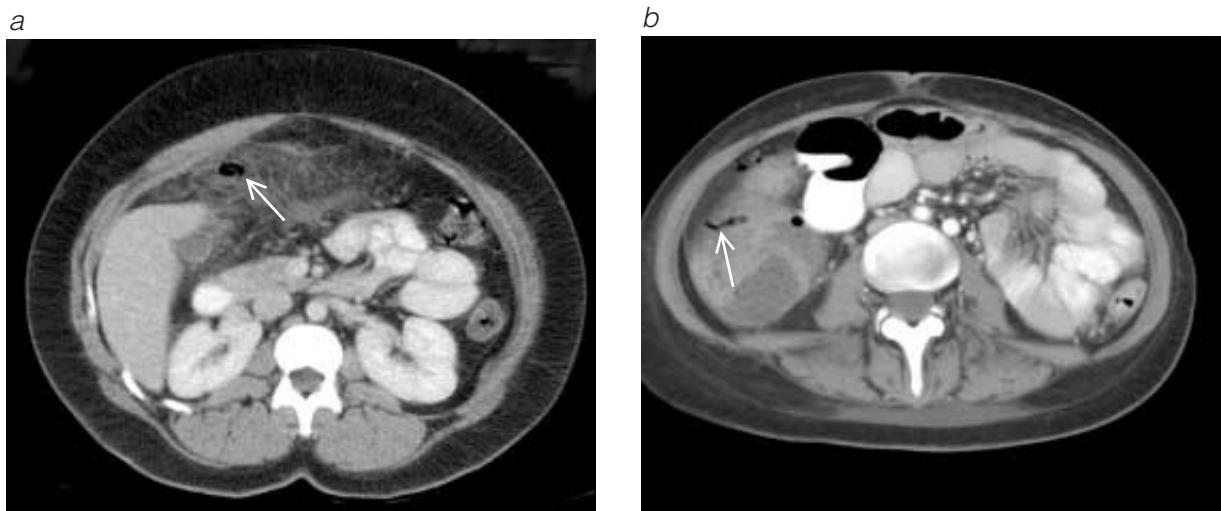

Figure 14 (a) Abdominal CT scan of elderly patient with history of vascular disease and worsening abdominal pain over a 3-day period shows diffuse inflammation and right upper quadrant extraluminal air (white arrow). Patient underwent emergency exploration, and ischemic perforation of cecum was found. Right hemicolectomy and temporary diverting ileostomy were performed. (b) Abdominal CT scan of patient with history of Crohn disease and worsening abdominal pain demonstrates thickening of colonic wall with both intramural and extramural air (white arrow). Patient was treated with emergency total abdominal colectomy for pancolitis with creation of temporary diverting ileostomy.

dures. Two studies from the early 1990s suggested improved long-term mortality after primary resection.^{226,227} A subsequent study, however, suggested that the improved mortality associated with primary resection was secondary to preselection and therefore could not be considered conclusive proof of the superiority of this approach. The authors of this latter study concluded that primary resection was appropriate for a select patient population with minimal comorbidity and that staged resection was beneficial for patients with a high degree of acute illness and comorbidity (e.g., elderly patients).²²⁸

Less common causes of colonic perforation. Other diagnoses associated with colonic perforation and peritonitis (localized or diffuse) are ischemic necrosis as a result of vasculopathology [see Figure 14a] or volvulus, missed traumatic injury, and IBD [see Figure 14b]. Except for IBD, the standard therapy is excision of the affected segment and reanastomosis, with or without a covering stoma. For patients with numerous comorbidities, a high degree of feculent contamination, or very severe illness necessitating an extremely abbreviated operating time, a Hartmann procedure with a mucous fistula or an oversewn distal segment is the primary treatment. Because perforation associated with IBD is typically a self-limited disease, treatment is directed at the underlying pathophysiology and excision of the diseased segment is not always indicated.²²⁹

Other Abdominal Infections

PELVIC INFLAMMATORY DISEASE

Because of the diverse clinical presentations of pelvic inflammatory disease (PID) and the significant sequelae associated with delayed diagnosis, women with this condition can pose a major diagnostic dilemma in the ED. In 2002, the Centers for Disease Control and Prevention (CDC) updated their established diagnostic guidelines for initiating therapy in patients with suspected PID.²³⁰ According to these guidelines, empirical treatment should be started if a young sexually active woman or any woman at risk for sexually transmitted diseases presents with minimal symptoms

[see Table 5] that cannot be attributed to another cause. To reduce undue treatment-associated morbidity, additional criteria are supplied to aid in specifying precisely who should receive treatment.

Treatment of PID, according to the CDC, includes broad-spectrum antibiotics directed toward *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, anaerobes, gram-negative facultative bacteria, and streptococci [see Table 6]. Hospitalization is suggested when surgical emergencies (e.g., appendicitis) cannot be excluded or when the patient is pregnant; does not respond clinically to oral antimicrobial therapy; cannot follow or tolerate an outpatient oral regimen; has severe illness, nausea and vomiting, or high fever; or has a tubo-ovarian abscess. Surgical intervention for PID is generally limited to patients with symptomatic pelvic masses, ruptured

Table 5 CDC Guidelines for Diagnosis of Pelvic Inflammatory Disease²³⁰

Minimal symptoms

Uterine/adnexal tenderness
Cervical motion tenderness

Additional supportive criteria (enhance specificity of minimal symptoms)

Oral temperature >101° F (> 38.3° C)
Abnormal cervical or vaginal mucopurulent discharge
Presence of white blood cells on saline microscopy of vaginal secretions
Elevated erythrocyte sedimentation rate
Elevated C-reactive protein
Laboratory documentation of cervical infection with *Neisseria gonorrhoeae* or *Chlamydia trachomatis*

Most specific criteria

Endometrial biopsy with histopathologic evidence of endometritis
Transvaginal sonography or magnetic resonance imaging techniques showing thickened, fluid-filled tubes with or without free pelvic fluid or tubo-ovarian complex
Laparoscopic abnormalities consistent with PID

Table 6 CDC Guidelines for Antibiotic Treatment of PID²³⁰

Parenteral Regimens	
A	Cefotetan, 2 g I.V. q. 12 hr <i>or</i> Cefoxitin, 2 g I.V. q. 6 hr <i>plus</i> Doxycycline, 100 mg p.o. or I.V. q. 12 hr
B	Clindamycin, 900 mg I.V. q. 8 hr <i>plus</i> Gentamicin, loading dose I.V. or I.M. (2 mg/kg body weight) followed by maintenance dose (1.5 mg/kg) q. 8 hr; single daily dosing may be substituted
Alternative	Ofloxacin, 400 mg I.V. q. 12 hr <i>or</i> Levofloxacin, 500 mg I.V. s.i.d. <i>with or without</i> Metronidazole, 500 mg I.V. q. 8 hr <i>or</i> Ampicillin-sulbactam, 3 g I.V. q. 6 hr <i>plus</i> Doxycycline, 100 mg p.o. or I.V. q. 12 hr
Enteral Regimens	
A	Ofloxacin, 400 mg p.o., b.i.d., for 14 days <i>or</i> Levofloxacin, 500 mg p.o., s.i.d., for 14 days <i>with or without</i> Metronidazole, 500 mg p.o., b.i.d., for 14 days
B	Ceftriaxone, 250 mg I.M. in single dose <i>or</i> Cefoxitin, 2 g I.M. in single dose, and probenecid, 1 g p.o. administered concurrently in a single dose <i>or</i> Other parenteral third-generation cephalosporin (e.g., ceftrizoxime or cefotaxime) <i>plus</i> Doxycycline, 100 mg p.o., b.i.d., for 14 days <i>with or without</i> Metronidazole, 500 mg p.o., b.i.d., for 14 days

tubo-ovarian abscesses, or draining abscesses that do not respond to antibiotic therapy. Aspiration has also been considered as a treatment modality; it may limit morbidity and preserve fertility.²³¹

PYELONEPHRITIS

Pyelonephritis is a complication of urinary tract infection; consequently, it affects women more often than men. The diagnosis is typically made on the basis of systemic symptoms in the setting of a known, bacteriologically confirmed urinary tract infection. Pyelonephritis may be classified as either complicated or uncomplicated, depending on patient factors (e.g., previous transplantation or an anatomic abnormality) and infectious characteristics (e.g., sepsis). The typical pathogen in uncomplicated disease is *E. coli*, and

outpatient treatment with trimethoprim-sulfamethoxazole or a fluoroquinolone usually suffices.²³² Complicated pyelonephritis, however, often is caused by microbes other than *E. coli*, including *Pseudomonas* species and enterococci. Hospitalization is required, and treatment usually involves parenteral administration of ceftriaxone and gentamicin²³³ or piperacillin-tazobactam²³⁴; vancomycin is indicated if the patient is allergic to penicillin. More aggressive therapies, including percutaneous nephrostomy or abscess drainage, may be considered on a case-by-case basis.

SPONTANEOUS BACTERIAL PERITONITIS

In adult patients, primary peritonitis usually accompanies cirrhosis and ascites²³⁵; however, the presentation can be highly variable. To diagnose spontaneous bacterial peritonitis, paracentesis is performed and the fluid sent for Gram stain and culture; pH determination; measurement of glucose, protein, lactate, and lactic dehydrogenase levels; and a cell count with differential. According to a consensus statement from the International Ascites Club, diagnostic paracentesis is recommended for every cirrhotic patient with ascites upon admission to the hospital.²³⁶ Empirical therapy is started if the neutrophil count is higher than 250/mm³, the pH is lower than 7.35, and the lactate concentration is greater than 32 ng/ml. If the results of other studies suggest peritonitis, radiographic evaluation is indicated to rule out potential causes of secondary peritonitis.

Treatment consists of cefotaxime at a minimum dosage of 2 g every 12 hours for 5 days, with follow-up paracentesis scheduled for 48 hours after the start of treatment.^{237,238} If the neutrophil count does not decrease significantly (to < 25% of the pretreatment value), treatment may be assumed to have failed. Surgical intervention is undertaken if the patient is refractory to medical management, the ascitic fluid grows mixed aerobes and anaerobes, or radiographic studies suggest bowel perforation.

PERITONEAL DIALYSIS CATHETER-RELATED INFECTIONS

Peritonitis is a major cause of failure of peritoneal dialysis in long-term studies.²³⁹ Peritonitis is especially difficult to diagnose in dialysis patients because the presentation is usually vague. Accordingly, it is critical to maintain a low threshold for testing. The definition of peritonitis in this population includes satisfaction of two of the following three criteria: (1) a Gram stain demonstrating microorganisms or a positive culture of the dialysis effluent, (2) a dialysate white blood cell count higher than 100/mm³, with at least 50% neutrophils, and (3) peritoneal signs or symptoms.²⁴⁰ The microbes most commonly identified are *S. epidermidis* and *S. aureus* (~60% of isolates), followed by gram-negative bacteria (~30% of isolates); the remaining isolates are largely accounted for by fungi, anaerobes, and mycobacteria.

Treatment usually includes cefazolin and an aminoglycoside, with or without vancomycin (depending on local *S. aureus* resistance patterns). Antibiotics are administered via the catheter and allowed to dwell intraperitoneally. When treatment is complete, the antibiotic effluent is drained via the catheter. If infection continues despite antibiotic treatment, a recurrent infection with the same microbe is likely. If fecal contamination occurs, the catheter must be removed.

Discussion

Controversies and Special Cases

The controversies surrounding the management of intra-abdominal infections are numerous and ongoing, in large part because of the relative lack of well-organized, unbiased clinical evidence. There are several reasons for this information deficit.

First, although in the aggregate, peritonitis is a common problem seen by general surgeons, any given practitioner sees most of the life-threatening forms of the disease (e.g., free perforation from colon cancer) infrequently. Second, advances in nonsurgical medicine and technology (e.g., laparoscopy) have made new forms of treatment available and have improved outcomes from older techniques. As a result, conclusions drawn from older data may no longer be accurate. Third, many forms of intra-abdominal infection routinely present in such a complex and ill patient population (e.g., elderly patients with multiple comorbidities) that randomized studies with multiple exclusion criteria can rarely capture a high percentage of what is a highly heterogeneous group. Fourth, patients presenting with common causes of intra-abdominal infection that occur in relatively healthy and homogeneous populations (e.g., acute appendicitis and cholecystitis) tend to do well no matter what reasonable therapy is applied. Consequently, it is frequently difficult to detect any significant differences between therapeutic modalities. For example, despite multiple randomized trials, it is still unclear whether a laparoscopic approach has any long-term superiority over an open approach in patients with right lower quadrant pain and suspected appendicitis: outcomes are excellent with either method. Finally, for almost any given argument, sufficient supporting data, whether in the form of randomized trials or—equally valuable—of large observational studies performed with statistical rigor, simply do not exist at present. Even simple questions, such as the optimum duration of antibiotic treatment for a patient with a single well-drained liver abscess, lack good answers.

In the end, most controversies in this area are not so much a matter of precisely determining the right or the wrong intervention for a disease as they are a matter of making a judgment about which of many possible interventions is likely to result in the lowest morbidity and mortality. For example, the decision to perform a primary colon reanastomosis in a patient with a perforated colon cancer cannot be considered either universally correct or universally incorrect; rather, it is subject to the surgeon's opinion about the specific patient involved. In what follows, we focus on several controversial decision points and discuss important factors that ought to be considered in attempting to optimize patient care.

NEW CONCEPTS IN PATHOPHYSIOLOGY OF ACUTE BACTERIAL CHOLANGITIS

Longmire's widely accepted classification of acute bacterial cholangitis consists of five categories: acute nonobstructive, acute nonsuppurative, acute suppurative, acute obstructive suppurative, and acute suppurative with intrahepatic abscess. It implies that the severity of disease parallels the degree of obstruction of biliary ducts.²⁴¹ This suggestion is well founded. In acute nonobstructive cholangitis associated with acute cholecystitis, infection ascends along the intrahepatic and extrahepatic lymphatics. In obstructive cholangitis, the bile duct contains bacteria under pressure. When the pressure is at or above the normal secretion pressure (i.e., 200 mm Hg), bacteria pass into the lymphatic system. At a pressure

greater than 250 mm Hg, bacteria may pass directly from the bile ductules through the spaces of Mall and Disse and into the hepatic sinusoids via cholangiovenous reflux.²⁴² One study confirmed the clinical significance of increasing ductal pressure by demonstrating a higher ductal pressure and a higher incidence of bacteremia in patients with proximal ductal obstruction, compared with those with distal malignant biliary obstruction.²⁴³ However, no correlation exists between the degree of suppuration in the duct and the clinical or pathologic severity of obstructive cholangitis.⁸² Therefore, the terms acute nonsuppurative cholangitis and acute suppurative cholangitis are purely descriptive and do not imply differing degrees of severity.

The source of bacteria in acute cholangitis is most often the duodenum. The ease with which organisms reflux from the duodenum depends on the degree of obstruction. Thus, in patients with malignant biliary obstruction, in whom obstruction is usually complete, bile culture is positive in only 10% to 15% of patients²⁴⁴; acute cholangitis is seldom spontaneous in this setting but often follows radiologic intervention.²⁴⁵ By comparison, in patients with ductal stones or benign strictures, in whom biliary obstruction is often incomplete, bile cultures obtained on ERCP are positive in 64% to 87% of cases; in these patients, acute cholangitis occurs frequently, both spontaneously and after ductal manipulation.²⁴⁶

An alternative source of organisms in acute bacterial cholangitis is portal venous blood. In patients who have recurrent pyogenic cholangitis, which occurs frequently in the Far East, a 40% incidence of positive portal blood culture has been reported.²⁴⁷ In studies of rats with ligated bile ducts, bacteria were shown to be effectively transmitted to the bile ducts and the liver through portal blood.²⁴⁸ Finally, in nonobstructive cholangitis and acute cholecystitis, as well as in the early stages of obstructive cholangitis, infection ascends to the liver through the lymphatic system.

CHANGING BACTERIOLOGY OF ACUTE BILIARY INFECTION

Most biliary infections are polymicrobial. The organisms most frequently cultured are *E. coli*, *Klebsiella* species, *Enterobacter* species, and enterococci. Anaerobic bacteria are infrequently implicated in biliary infections. Peptostreptococci and clostridia are found occasionally; clostridia are especially common in patients with emphysematous cholecystitis.⁴⁷ Gram-negative anaerobic bacilli are rarely present in patients with biliary infection. In one study, only two of 28 patients with acute cholangitis had anaerobic bacteria in the bile; another investigator found anaerobic bacteria in 3% to 4% of cultures in similar patients.⁸³ However, a higher incidence of anaerobic bacteria has been reported in patients who have acute cholangitis and acute cholecystitis than in patients who have chronic cholecystitis and cholelithiasis.²⁴⁹

One investigator noted an increased incidence of anaerobic bacteria in biliary infection and suggested that *B. fragilis* may play a more important role in the polymicrobial flora of biliary tract infection than was previously appreciated.²⁵⁰ These findings remain controversial. *Bacteroides* species are generally considered to be of limited importance in biliary tract infections, except in selected groups of patients. These groups include diabetics, the elderly,²⁵¹ and those with acute cholangitis who have previously undergone biliary operation^{252,253}; in particular, malfunctioning biliary-intestinal anastomoses increase the risk of *Bacteroides* infection.²⁵⁴

NECESSITY OF DIVERSION AFTER EMERGENCY COLONIC PROCEDURES

The goal of safely repairing or resecting the colon in an emergency setting without leaving a patient with a temporary or permanent stoma for diversion has been pursued for decades. Through much of the 20th century, largely on the basis of wartime experience, diversion was routinely performed. Today, however, it is apparent that this approach is not always necessary either for trauma or for intrinsic colon disease. Thus, the question is no longer whether primary repair or reanastomosis can be achieved safely but, rather, in which individual patient a given treatment is prudent.

Traditionally, clinical studies have attempted to define patient characteristics associated with complications after attempted primary repair or reanastomosis. Not surprisingly, hypotension, blood loss, delay before treatment, and extensive contamination have all been associated with postoperative complications after primary repair; however, these risk factors are associated with complications after diversion as well. The nature of the colon injury is clearly an important consideration: multiple studies now support a one-step approach to traumatic colon injury in all except the most ill patients, but primary resection and reanastomosis for other causes of perforation (e.g., diverticulitis and cancer) remain controversial. Many nonrandomized studies have demonstrated that for nontraumatic causes of perforation, on-table lavage and primary resection yield outcomes equivalent to those of the Hartmann procedure, which suggests that both approaches are safe and that surgeons are capable of identifying the patients best suited to each one.

Perhaps more important than determining how likely a patient is to experience a complication after a given operation, however, is assessing how well the patient is likely to tolerate that complication in the early postoperative period. Thus, elderly patients with multiple comorbidities might be better off undergoing diversion and thus avoiding the potential significant physiologic stress posed by an anastomotic leak in the early postoperative period, even though they will face the additional risk associated with reoperation if they subsequently choose to have a stoma reversed.

ROLE OF LAPAROSCOPY IN MANAGEMENT OF PERITONITIS

Laparoscopy has altered the surgical landscape by offering a minimally invasive approach that reduces the morbidity associated with a large incision, generally decreasing convalescence time and hastening return to normal activity. Nonetheless, laparoscopic management of intra-abdominal infection is still hindered somewhat by the difficulty of inspecting the entire bowel, the decreased tactile sensation, and the significantly greater expertise required for laparoscopic resection and reanastomosis of the bowel. These obstacles notwithstanding, almost every intra-abdominal procedure used to treat infection has been performed laparoscopically with acceptable results.

The single most important factor in the decision whether to take a laparoscopic approach is the skill and experience of the surgeon. From a theoretical point of view, it is almost always possible to treat a patient with peritonitis laparoscopically; the real question is whether the attending surgeon can perform the procedure most safely and efficiently via an open or a minimally invasive approach. The answer to this question will rely to a large extent on preoperative imaging studies. In addition, even if the surgeon does not plan to complete the operation laparoscopically, initial placement of the scope may aid in planning the most appropriate open incision and procedure by localizing the lesion of interest.

MANAGEMENT OF ANASTOMOTIC LEAKS

Dehiscence of a gastrointestinal anastomosis is a common and too frequently fatal complication of modern GI surgery. Again, there is little debate regarding which therapeutic options are available to surgeons managing this problem. The options include the following: supporting the patient with medical care only, in the case of a tiny radiographically evident but clinically insignificant leak seen on fluoroscopic study; reoperating and performing primary repair and drainage, in the case of a small early leak from an enterostomy with minimal soiling; performing percutaneous drainage, in the case of a moderately symptomatic leak presenting in a delayed manner with an abscess; and reexploring and performing a diverting procedure, in the case of complete disruption of an anastomosis with widespread fecal contamination. The only controversy has to do with which course (or combination of courses) to take in an individual patient.

Some general guidelines for the management of anastomotic dehiscence may be recommended, with the caveat that they have not yet been rigorously tested. Leaks diagnosed in the immediate postoperative period are easily approached because the relevant tissue planes have been dissected free. After 1 to 2 weeks, however, early adhesion formation makes reoperation more difficult, especially if the initial operation was for an infectious or inflammatory process, and increases the risk of complications, particularly inadvertent enterotomy and enterocutaneous fistula formation. Small, contained leaks, if accessible, frequently respond to percutaneous drainage and antibiotics alone, with the small fistula resolving spontaneously. Medical management in such cases generally includes TPN, though enteral nutrition is occasionally feasible if it is shown to have no effect on drain output. Larger leaks, on the other hand, are more likely to call for direct operative repair, resection and reanastomosis, or diversion. Once it is decided that surgical treatment is warranted and is not precluded by the state of the abdomen, definitive management should not be delayed. Exactly which operation is to be performed depends on the health of the bowel, the severity of abdominal contamination, and the level of overall physiologic dysfunction.

MANAGEMENT OF ENDOSCOPIC BOWEL PERFORATION

Large rents in a peritoneal portion of the bowel generally call for operative repair (most commonly to the colon), though it should be noted that simple repair or resection without diversion is almost always all that is required. Extraperitoneal or retroperitoneal perforations, however, can be managed nonoperatively with antibiotics and I.V. fluids if the patient is stable. This situation occurs most frequently after ERCP or with low rectal perforations. Typically, CT scanning demonstrates retroperitoneal air with minimal free peritoneal air. In these circumstances, patients can be safely observed as long as their condition does not deteriorate; oral intake can be restarted after 5 to 7 days. Endoscopic perforations of a normal distal esophagus can also be managed nonoperatively, though a perforation proximal to a tumor or stricture is unlikely to heal and almost always must be treated operatively.

NONOPERATIVE MANAGEMENT OF INFECTED FLUID COLLECTIONS

It is axiomatic that abscesses are best treated with drainage rather than with antibiotics, but there are certain circumstances in which drainage may not be possible. Pyogenic liver abscesses may not be amenable to either percutaneous or open drainage if they are multiple and involve both lobes. In such circumstances, aspiration or drainage of the largest abscess, followed by a long course of antibiotics, is generally successful. It has been argued that this

approach works because of the liver's luxurious dual blood supply.

On the other hand, multiple peritoneal fluid collections (without a natural blood supply) are not infrequently seen even after successful management of diffuse or fecal peritonitis yet can occasionally be managed without drainage. Even if these collections are subsequently proved to be infected, they may be too numerous to approach percutaneously, and ongoing inflammation of the bowel may render an operative approach unsafe. Again, drainage of the largest accessible collection to establish a diagnosis and guide antibiotic management, followed by long-term antibiotic therapy, is the most feasible course. In this case, sampling is imperative because a hospital-acquired intra-abdominal infection is more likely to involve less common but more resistant pathogens, including fungi. Regardless of the situation, though, the optimal duration of antibiotic therapy for small undrained abscesses remains to be established.

ADJUNCTIVE MEDICAL THERAPIES

Until recently, it could be said that advances in surgical therapy for intra-abdominal infection were outpacing other aspects of patient management. Too often, operations were technically successful, yet patients died afterward as a result of their systemic

response to the original insult. Such deaths are still attributed to overwhelming sepsis, to multiple organ dysfunction syndrome, or to any number of other terms used to describe an irreversible sequence of organ failure and death [see 8:13 *Multiple Organ Dysfunction Syndrome*].

Multiple attempts over the years to alter this downward trajectory by using novel therapies to target this generalized inflammatory response proved unsuccessful. In the past few years, however, both recombinant human activated protein C and corticosteroid replacement therapy (for those with sepsis-associated adrenal insufficiency) were shown to improve survival in randomized, placebo-controlled trials involving mixed populations of patients with sepsis. Although the number of patients with intra-abdominal infection was relatively small in each study, there was no indication that these agents would not be similarly effective in this specific subgroup. The overall benefit of each of these treatments appears to be small, but the results of these trials are highly encouraging in that they suggest that related agents might be able to achieve further decreases in mortality. These possibilities, combined with significant improvements in general critical care, portend a future in which significant reductions in mortality may be realized even in the most severely infected patients.

19 FUNGAL INFECTION

Elias J. Anaissie, M.D., Albair B. Bishara, M.D., and Joseph S. Solomkin, M.D.

Approach to the Surgical Patient at Risk for Candidiasis

The infectious diseases that are most commonly encountered by surgeons are acute events in which fever, leukocytosis, and localized signs of inflammation develop in a reasonably healthy host. In this clinical situation, the presence of microorganisms in such normally sterile foci as blood and intra-abdominal sites indicates an infection and the need for antimicrobial chemotherapy.

The clinical setting in which *Candida* species are isolated from various body sites is generally much different. Patients harboring *Candida* infections frequently have had antecedent infections that were treated with antibacterial agents, have received therapy that suppressed their immunologic responses,¹ or have undergone extensive surgery or several operations, especially on the gastrointestinal tract. Such patients are generally long-term residents in acute care hospitals. Previous operative intervention may have left surgical wounds or drainage tracts. These circumstances favor colonization by various opportunistic pathogens, with the resultant risk of overgrowth or invasion by normal enteric microorganisms such as *Candida* species. In this setting, the elements that characterize most infectious processes (i.e., an acute change from wellness to illness and isolation of microorganisms from ordinarily sterile sites) no longer have great diagnostic value.

The problem of defining indications for administration of antifungal therapy in surgical patients is compounded by the limited data available, the difficulty of establishing a diagnosis, and the small number of effective antifungal agents. Although amphotericin B is currently the standard antifungal agent, fluconazole, a newer triazole antifungal that is generally well tolerated, appears to be effective in the treatment of serious *Candida* infections in surgical patients.

Noncandidal fungal infections, although still rare in surgical patients, may cause morbidity and mortality. Because infections such as aspergillosis and mucormycosis may be refractory to standard antifungal therapy, there is an urgent need to define the role of novel antifungal agents in surgical patients.

This chapter summarizes the current understanding of fungal infections, particularly candidiasis, in nonneutropenic surgical patients and provides recommendations for prophylaxis and therapy.

Magnitude of the Problem in the Surgical Patient

Whereas the high mortality associated with bacterial infections in surgical patients has been reduced by the early administration of antibacterial therapy, the incidence of fungal infections, particularly with *Candida* species, has dramatically increased.² In a 1984 nationwide survey of medical and surgical patients, *Candida* species were the eighth most common cause of nosocomial bloodstream infection.³ In a similar survey conducted between October 1986 and December 1990, *Candida* species became the fourth

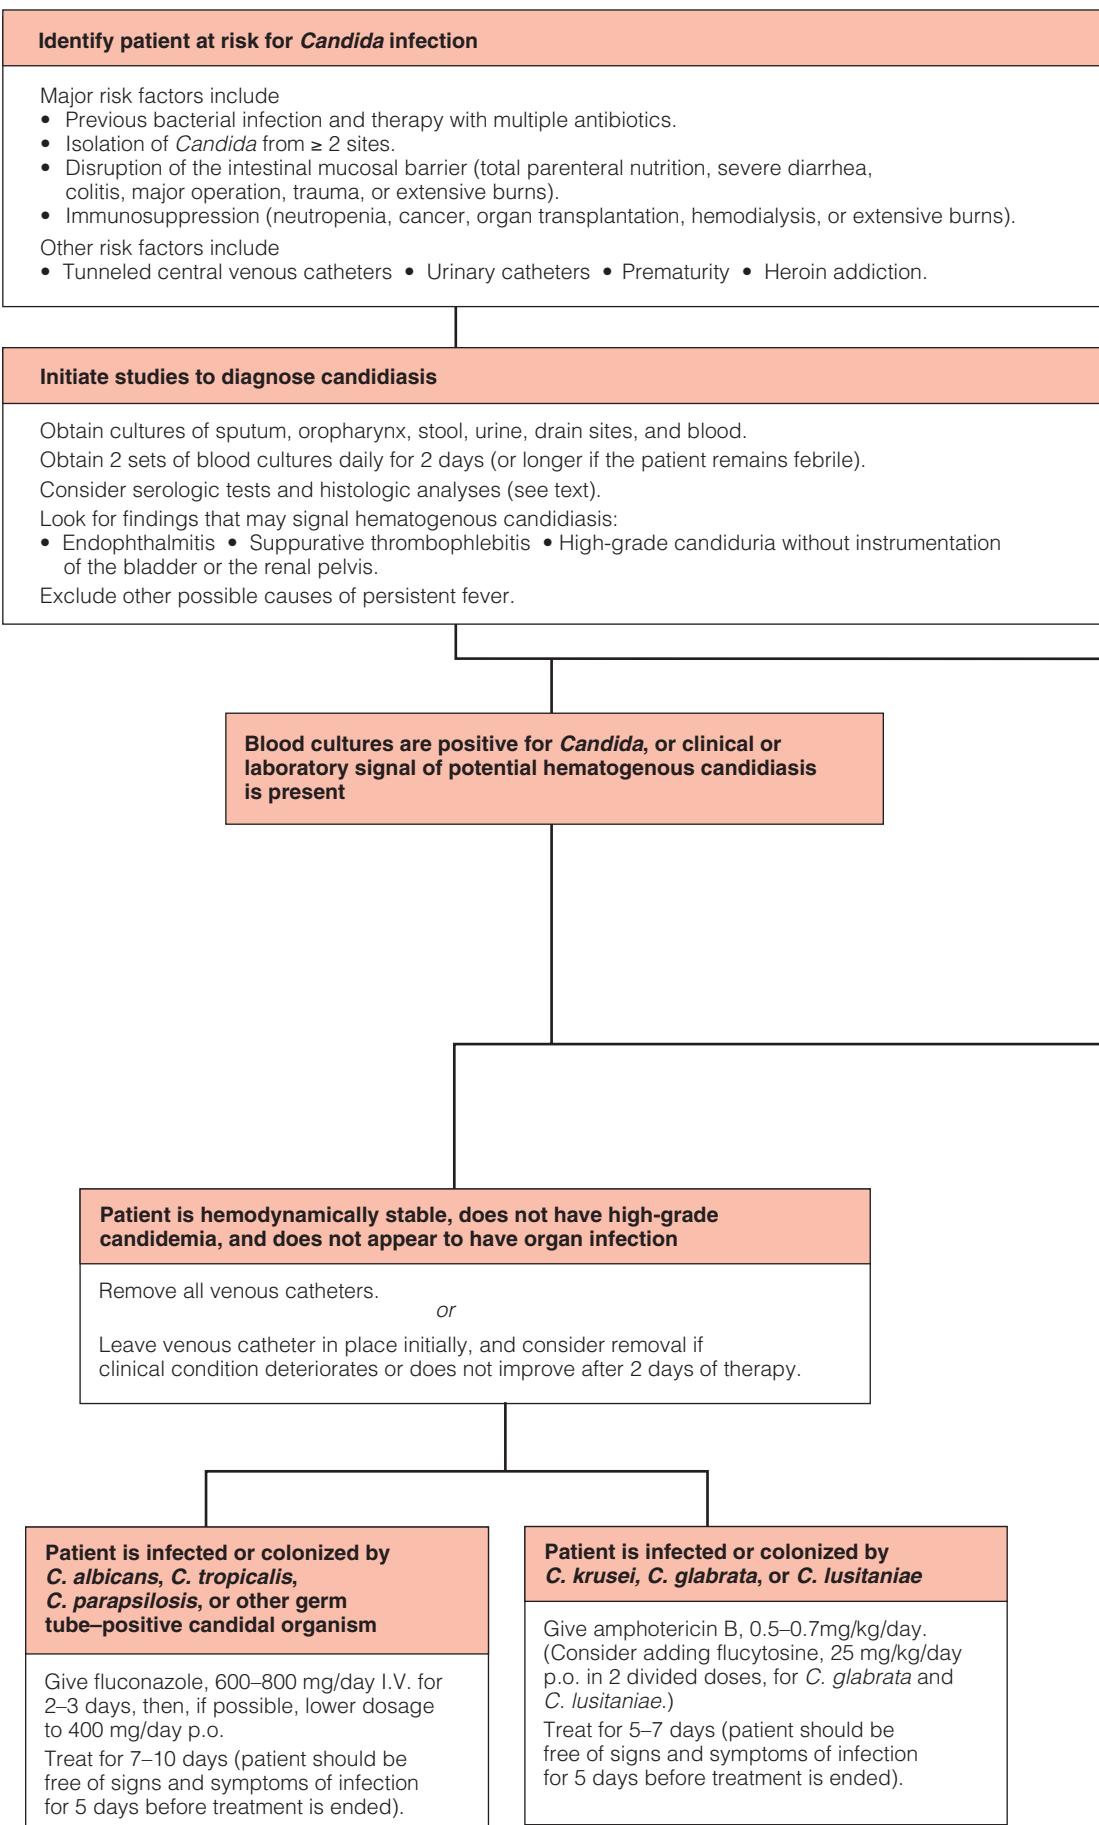

leading cause of nosocomial bloodstream infection, preceded only by coagulase-negative-staphylococci, *Staphylococcus aureus*, and enterococci.³ According to the National Nosocomial Infections Surveillance (NNIS) system, the percentage of nosocomial infections caused by *C. albicans* increased from 2% in 1980 to an average of 5% over the 4-year period from 1986 through 1989.⁴ Data from NNIS hospitals also show that between 1980 and 1989, the incidence of primary bloodstream infections attributable to *Candida* species increased by 487% in large teaching hospitals and by 219% in small (< 200 bed) hospitals.⁵ In addition, the NNIS system reported that the rate of nosocomial fungal infection increased from 2.0 to 3.8 infections per 1,000 patients discharged between 1980 and 1990.⁶ Current data from the SCOPE (Surveillance and Control of Pathogens of Epidemiologic Importance) system confirm that *Candida* species were the fourth leading cause of bloodstream infection.⁷ These data are supported by the Surveillance Network–USA, which compiles information from more than 100 laboratories in the United States. Fungi including *Candida* species were isolated from 17% of 10,038 patients included in a European study of the prevalence of infection in patients in intensive care units.⁸

The most marked increase in candidiasis occurred in surgical patients, particularly in burn and trauma patients followed by cardiac surgery patients and general surgery patients. *Candida* species now account for 78% of all nosocomial fungal infections.⁶

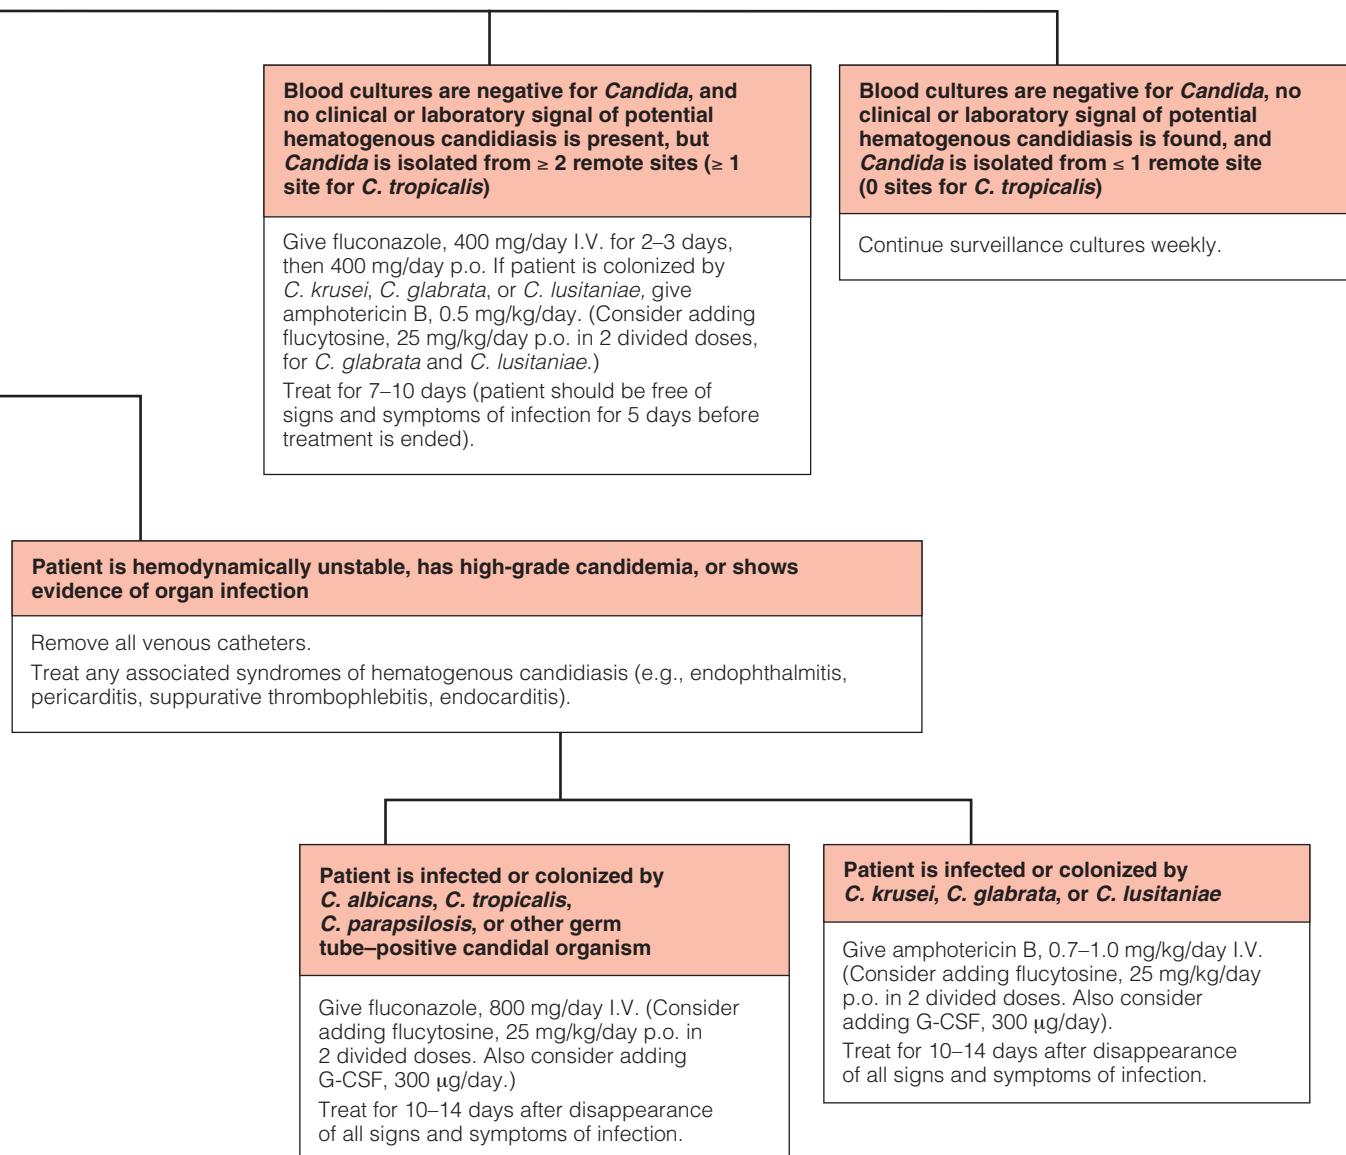

Nosocomial bloodstream infections caused by *Candida* species are an independent predictor of risk of mortality (38% mortality directly attributable to candidiasis) and prolonged hospital stay (30 additional days in comparison with controls).¹ In a more recent prospective study, *Candida* species were the only microorganisms that independently influenced the outcome of nosocomial primary infections of the bloodstream (odds ratio for mortality, 1.84; 95% confidence interval [CI]) and were associated with the highest mortalities (35% at 28 days and 69% at discharge).⁹ In properly conducted multivariate analyses, the most important prognostic factors in patients with hematogenous candidiasis include older age, poor performance status (on Acute Physiology and Chronic Health Evaluation [APACHE] or other measures), the presence and persistence of neutropenia, and dissemination of the infection to noncontiguous organs. Central venous catheter retention appears to play a minimal role.^{8,10}

Definitions of Hematogenous *Candida* Infection Syndromes

In this chapter, the general term hematogenous candidiasis is used to identify all infections involving the bloodstream. Hence,

Approach to the Surgical Patient at Risk for Candidiasis

hematogenous candidiasis refers to candidemia, disseminated candidiasis, or both.

CANDIDEMIA

Candidemia is defined as the isolation of any pathogenic species of *Candida* from at least one blood culture specimen. The recovery of *Candida* species from the bloodstream can be a significant observation in the absence of clinical signs and symptoms, especially if the patient is debilitated or uremic or is receiving adrenal corticosteroid therapy.

CATHETER-ASSOCIATED CANDIDEMIA

Catheter-associated candidemia is candidemia that occurs in a patient with an intravascular catheter and no other obvious origin of infection after careful clinical and laboratory evaluation. Several procedures have been developed to aid in the diagnosis of catheter-associated candidemia. If the catheter is removed, a quantitative culture of the tip should recover at least 15 colony-forming units (CFU) of the same *Candida* species as that found in blood culture by the roll-plate technique (or at least 100 CFU of the same *Candida* species as that found in blood culture by the sonication technique). If the catheter is not removed, a quantitative blood culture collected through a central catheter should contain at least a 10-fold greater concentration of *Candida* species than a simultaneously collected quantitative peripheral blood culture. Routine catheter tip cultures appear to be of no value.

ACUTE DISSEMINATED CANDIDIASIS

Patients who have several noncontiguous organs infected by *Candida* species have a disseminated infection acquired through hematogenous spread. For diagnosis, the organism must be identified by histologic analysis, culture of tissue samples obtained from at least one internal organ, or both; the patient should have radiographic, pathologic, or cultural evidence of infection in at least one other organ. Candidemia associated with *Candida* skin lesions or endophthalmitis consistent with a diagnosis of *Candida* infection also indicates a diagnosis of disseminated candidiasis.¹¹

CHRONIC DISSEMINATED CANDIDIASIS

Chronic disseminated candidiasis, a chronic form of disseminated infection that is also known as hepatosplenic candidiasis, occurs in cancer patients who have been afflicted with protracted neutropenia.¹² This form of hematogenous candidiasis has not yet been described in the nonneutropenic surgical patient.

Characteristics of Surgical Patients at Risk for Candidiasis

Fungal translocation that leads to hematogenous candidiasis is believed to be promoted by (1) colonization of the GI tract by *Candida* species, (2) physical disruption of the intestinal mucosal barrier, and (3) immunosuppression of the host leading to dissemination of the infection in the bloodstream and other organs [see Discussion, below].

Other important risk factors for hematogenous candidiasis include malignancies,¹³ neutropenia and immunosuppressive therapy,¹⁴ use of urinary catheters and diarrhea, prematurity,¹⁵ heroin addiction,¹⁶ abdominal surgery,¹⁷ organ transplantation,¹⁸ and extensive burns.¹⁹

The reported frequency of hematogenous candidiasis in burn patients ranges from 2% to 14%, depending on the reporting center and the study period.¹⁹⁻²¹ Colonization by *Candida* species, hematogenous dissemination, and mortality caused by *Candida* infections have been found to correlate with the amount of body surface area burned and with the extent of full-thickness burn.

The pathogenesis, the incidence, and the microbial etiology of fungal infection vary in different groups of transplant recipients, depending on the organ transplanted, the donor source, the type of surgical procedure performed, and the recipient's age and general condition at the time of the procedure; other influential factors are the conditioning regimen, the type and duration of immunosuppressive therapy, and the presence or absence of organ rejection and graft versus host disease. In heart transplant recipients, for example, *Aspergillus* infection is a major problem, whereas in other organ transplant recipients, most fungal infections are attributable to *Candida*.²² The infection is usually located at the site of the operation (e.g., an intra-abdominal abscess in liver¹⁸ or pancreas²³ transplantation, the mediastinum or the lungs in heart²⁴ or heart-lung²⁵ transplantation, and the urinary tract in kidney²⁶ transplantation); however, dissemination from the primary site is common.

The central venous catheter has been reported as a risk factor in some studies but not in others,¹⁰ particularly with *Candida parapsilosis*. This species, which may become part of the biofilm of intravascular catheters, may not respond to antifungal agents. Alternatively, *Candida* colonization of the catheter may result from gut-derived hematogenous seeding.^{27,28}

Laboratory and Clinical Assessment of Candidiasis

CULTURES

The workup of the surgical patient suspected of having hematogenous candidiasis begins with a complete set of cultures of sputum, oropharynx, stool, urine, all drain sites, and blood [see Table 1]. Candidiasis rarely develops in patients whose cultures show no evidence of *Candida* at some site. Obtaining more than six sets of blood cultures has little value, and there is no evidence to support arterial cultures.

The incidence of positive antemortem blood cultures in patients found to have candidiasis at autopsy is about 30% to 50%, possibly as a result of concomitant bacteremia, which may decrease the recovery of *Candida* species from the bloodstream. Because *Candida* species grow poorly under anaerobic conditions, venting the blood culture bottles is thought to improve the yield. The use of biphasic media also improves recovery of *Candida* species from the blood. Improved sensitivity and time to positivity of fungal blood cultures has been achieved with the development of new media, including biphasic media, automated radiometric and nonradiometric systems, and the lysis-centrifugation technique, a system that allows estimation of the number of *Candida* CFU/ml blood).²⁹ Commercial applications of these techniques include the BACTEC high-blood-volume fungal media system and the BacT/Alert system, both having comparable sensitivity to lysis-centrifugation. There is little evidence, however, that use of these newer methods provides a clinical advantage in the management of patients with hematogenous candidiasis. In a study by Berenguer and colleagues, the sensitivity of the lysis-centrifugation method increased with increasing numbers of involved organs but was still only 58% overall.³⁰

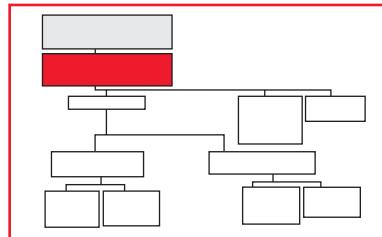

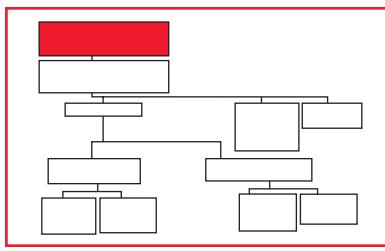

Table 1 Clinical Presentation and Diagnostic Methods for Common Fungal Infections¹³⁹

Host Fungus	Major Clinical Presentations	Diagnostic Methods
Normal host		
<i>Aspergillus</i>	Allergic bronchopulmonary	Serum IgE, precipitins
<i>Blastomycetes</i>	Acute pneumonitis: chronic lung or skin	Culture, tissue
<i>Candida</i>	Vaginitis, thrush, candidemia, I.V. catheter	Culture/smear
<i>Coccidioides</i>	Acute pneumonitis, chronic cavitary, pulmonary nodule	Precipitins, complement fixation, culture
<i>Cryptococcus</i>	Pulmonary, meningitis	Culture, latex agglutination
<i>Histoplasma</i>	Acute pulmonary, progressive dissemination in infants and elderly, chronic cavitary in chronic airway obstruction	Culture, antigen detection
Compromised host		
<i>Diabetes mellitus</i>		
<i>Candida</i>	Disseminated, pyelonephritis, vaginitis	Culture/smear
<i>Torulopsis</i>	Pyelonephritis	Culture
<i>Zygomycetes</i>	Rhinocerebral, paranasal, pulmonary, gastrointestinal, cutaneous	Culture, tissue
Malignancy or corticosteroids		
<i>Aspergillus</i>	Invasive/lung, sinuses, disseminated	Culture, tissue
<i>Candida</i>	Fungemia, acute and chronic disseminated candidiasis	Culture, tissue
<i>Coccidioides</i>	Disseminated	Culture, precipitins, complement fixation
<i>Cryptococcus</i>	Pulmonary, meningeal, disseminated	Culture, latex agglutination, India ink preparation
<i>Dematiaceous fungi</i>	Lung, sinuses, brain, disseminated	Culture, tissue
<i>Fusarium</i>	Lung, sinuses, cellulitis at site of onychomycosis, disseminated	Culture, tissue
<i>Histoplasma</i>	Progressive disseminated	Culture, antigen detection
<i>Torulopsis</i>	Disseminated	Culture, tissue
<i>Trichosporon</i>	Disseminated	Culture, tissue
<i>Zygomycetes</i>	Rhinocerebral, paranasal, pulmonary, gastrointestinal, cutaneous, disseminated	Culture, tissue
Extensive surgery and previous antibiotic therapy		
<i>Candida</i>	Vaginitis, thrush, esophagitis, disseminated	Culture, tissue
<i>Torulopsis</i>	Disseminated	Culture

A rapid and inexpensive test is the germ tube test that can distinguish *C. albicans* (positive test) from other *Candida* species. More than 90% of *C. albicans* isolates produce germ tubes when incubated in serum for 2 to 3 hours at 37° C.

Several newer culture media allow the rapid identification of *C. albicans*. These include Albicans ID (bioMerieux, France), CandiSelect (Sanofi Diagnostics Pasteur, France), CHROMagar *Candida* (Becton Dickinson, USA), Fluoroplate *Candida* (Merck, Germany), Fongiscreen 4H (Sanofi Diagnostics Pasteur), and Murex *Candida albicans* (Murex Diagnostics, USA). CHROMagar and Fongiscreen 4H are also used for detection of other *Candida* species, including *C. glabrata*, *C. tropicalis*, and *C. krusei*. A recent study of 485 isolates (350 of *C. albicans* and 135 of other candidal species) evaluated the presumptive identification of *C. albicans* by comparing results of the germ-tube test to results of these six commercial tests. For *C. albicans*, the sensitivity and specificity of all six tests were greater than 97%. The sensitivity and specificity of the two tests that allow presumptive identification of other candidal species (CHROMagar *Candida* and Fongiscreen 4H) were lower, especially for *C. glabrata* and *C. tropicalis*.

Positive cultures from nonsterile sites (sputum, urine, and wound drainage) need to be interpreted with caution because of the frequent occurrence of *Candida* as a normal commensal of humans. Such cultures are useful mainly as an indication of colonization and, consequently, of the risk of infection in the appropriate setting.

ANTIBODY DETECTION

Previous studies have reported the use of incompletely characterized antigenic extracts of *C. albicans* to detect anticandidal antibod-

ies in human sera. Difficulties with consistent production of uniform materials³¹ have limited the usefulness of these tests. A variety of detection technologies (enzyme-linked immunosorbent assay [ELISA], immunodiffusion, and latex agglutination) have been used in attempts to detect antibodies directed toward defined purified antigen, but the sensitivity and specificity of these methods are low.³² Methods using newly described antigens appear more promising.³³

ANTIGEN DETECTION AND POLYMERASE CHAIN REACTION

Mannan, a polysaccharide component of the *Candida* cell wall, has the disadvantages of a short serum half-life and binding by antimannan antibody.³⁴ Although mannan can be detected by several methods,³⁵ complicated techniques are required to dissociate the mannan-antibody complex.³⁶ The sensitivity of mannan detection is approximately 70%.

A simple test available commercially (CAND-TEC *Candida* detection system, manufactured by Ramco Laboratories, USA) relies on the detection of a heat-labile antigen; however, its low sensitivity (as low as 19%) and specificity have limited its clinical use.³⁷ An antigen studied more recently is an immunodominant 48 kd cytoplasmic protein, *Candida* enolase. Because it is thought that cytoplasmic antigens are released during invasive infection, detection of this antigen may be able to distinguish between colonization and invasive infection.³³ A sensitivity of 54% was demonstrated in a study of 24 patients with invasive candidiasis,³⁸ but the sensitivity increases to 75% with the use of multiple samples. A sensitivity of 65% and a specificity of 97% were shown in a study assessing multiple samples.³⁹ Unfortunately, this test is not commercially available.

A commercial kit (Bichro-latex albicans) using monoclonal antibodies against cell wall extracts of *C. albicans* mannanprotein appears to have high sensitivity and specificity for *C. albicans*.⁴⁰

Another antigen studied is (1-3)- β -D-glucan, an important cell wall constituent of fungi that is not shared with bacteria. Studies of this assay, which indicates the presence of fungi but does not identify the genus causing infection, have been promising in patients with fungal colonization. In these patients, its concentration remains lower than 20 pg/ml.

Amplification of the DNA of *Candida* species appears to be a quick and specific diagnostic tool. Although multiple approaches have been pursued,⁴¹⁻⁴³ several limitations need to be overcome before this method can be used routinely.⁴⁴

METABOLITES

Systems based on the detection of D-arabinitol and mannose release by the fungus have been proposed,⁴⁵ but only those detecting D-arabinitol have been extensively developed. D-Arabinitol, a pentose produced by all of the major *Candida* species except *C. krusei* and *C. glabrata*, is excreted by the kidneys in the same rate as creatinine, and the ratio of D-arabinitol to creatinine must be used to interpret any observed concentration of D-arabinitol. Gas-liquid chromatographic as well as enzymatic methods are available for the detection of D-arabinitol, but gas-liquid chromatography is both technically demanding and expensive; it has been replaced by the recently developed enzymatic assay system. The sensitivity of the serum D-arabinitol-creatinine ratio for the diagnosis of invasive candidiasis, reported in the range of 40% to 83%, rises with repeated sampling.⁴⁶ Sensitivity is highest in patients with fungemia (74% to 83%) and lowest in patients with tissue-invasive *Candida* infections (40% to 44%). The magnitude of the D-arabinitol-creatinine ratio is strongly related to the degree of tissue invasion.^{28,46} Although this assay may produce false positive results in some patients, it offers the promise of earlier detection of invasive candidiasis.⁴⁶

Mannose, the other metabolite of *Candida* species that has been studied, can be detected only by a complicated gas-liquid chromatographic system. Initial estimates of its sensitivity (39%) have limited interest in this technique.⁴⁵

HISTOLOGIC ANALYSES

Fungal smears are relatively insensitive methods of diagnosing candidiasis in otherwise sterile sites (e.g., joint fluid, peritoneal fluid, vitreous humor, or cerebrospinal fluid). Centrifugation of these fluids and examination of the sediment may improve the diagnostic yield. Conventional fungal stains, such as hematoxylin-eosin, periodic acid-Schiff (PAS), and Gomori methenamine-silver (GMS), are useful. The most sensitive stain is calcofluor white, but unfortunately, it requires fluorescent microscopy. Deep tissue biopsy provides a definitive diagnosis of candidiasis.

CLINICAL DIAGNOSIS

Hematogenous candidiasis has no characteristic clinical picture. Three clinical findings that may lead to an early diagnosis of hematogenous candidiasis in the surgical patient are candidal endophthalmitis, suppurative phlebitis, and candiduria in the absence of bladder instrumentation. A careful eye examination to identify the presence of candidal infection should be performed while the results of cultures of various sites are being awaited, and a repeat exam-

ination should be performed after therapy for proven candidemia. Candidal endophthalmitis may remain asymptomatic until late in the course of infection.

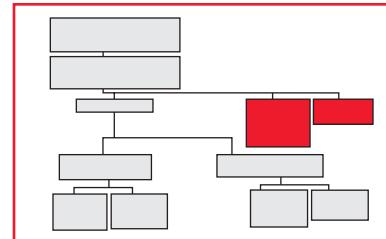

The presence of peripheral suppurative phlebitis that fails to yield bacteria or does not respond to antibacterial agents may be an early clue to the presence of hematogenous candidiasis. Gentle squeezing of the venous catheter exit site may express pus that yields *Candida* species on a smear or culture. Surgical excision of the infected vein usually reveals *Candida* infection in its lumen.

The presence of high-grade candiduria in surgical patients who have not had instrumentation of the renal pelvis or the bladder suggests hematogenous candidiasis and should prompt a workup for this infection. In this setting, candiduria may result from seeding of or filtering through the kidney.

Fever may be the only sign of infection but may be absent in patients who are receiving corticosteroids. Occasionally, a patient with hematogenous candidiasis presents with the systemic inflammatory response syndrome (SIRS) or septic shock. The diagnosis should be seriously considered in high-risk patients who are persistently febrile. Because of the high mortality associated with this infection, empirical antifungal therapy is recommended for early treatment of a clinical occult fungal infection or for the prevention of new fungal infections.

Management of Hematogenous Candidiasis

CANDIDEMIA AND ACUTE DISSEMINATED CANDIDIASIS

During the 1960s and the 1970s, the standard approach to managing candidemia was to classify patients according to degree of risk of disseminated candidiasis and to withhold antifungal treatment from those in whom dissemination appeared to be unlikely. This approach was based on unawareness of the magnitude of the problem in surgical patients and on acute awareness of the toxicities of amphotericin B, which was the only systemic antifungal agent available at the time; eventually, this type of management was found to be associated with a substantial mortality and a high incidence of long-term sequelae (e.g., deep-seated candidiasis presenting with endophthalmitis or other organ infection).¹ Consequently, it is now common practice to treat all candidemic patients except those who are afebrile, asymptomatic, or at low risk for disseminated candidiasis [see Table 2].

Candidates for empirical antifungal therapy are at high risk for candidiasis, colonized by *Candida* species (at one or more sites for *C. tropicalis* or at two or more for other candidal species), and unresponsive to broad-spectrum antibiotics in the absence of any other cause for their fever. Unresponsive patients may be characterized by rapid clinical deterioration, particularly if there is evidence of physical disruption of the intestinal mucosal barrier or immunosuppression.

The role of amphotericin B in the treatment of hematogenous candidiasis in surgical patients has been difficult to determine—first, because most of the studies that evaluated amphotericin B were retrospective trials with small sample sizes, and second, because few of the studies defined hematogenous candidiasis in the same way. In one study, treatment with amphotericin B had no effect on overall outcome in a mixed population of patients; however, the timing of therapy and the dose administered were not clearly stated.⁴⁷ In general, mortality was lower in patients who re-

Table 2 Antimicrobial Agents of Choice for Candidal Infections*

Infection	Agent of Choice	Alternative Agents	Comments
Hematogenous			
Candidemia and acute disseminated candidiasis	Fluconazole, or amphotericin B ± flucytosine	Lipid formulations of amphotericin B	Fluconazole should be given for <i>C. albicans</i> , amphotericin for all other <i>Candida</i> species; a 2-drug regimen should be given to hemodynamically unstable patients with persistent high-grade fungemia
<i>Candida</i> endophthalmitis	Fluconazole	Amphotericin B + flucytosine	Patients with vitral involvement require vitrectomy in addition to antifungal therapy
Suppurative phlebitis	Fluconazole + flucytosine	Amphotericin B + flucytosine	The central venous catheter should be removed and the infected vein excised
Endocarditis	Amphotericin B + flucytosine	—	Surgical replacement or repair of valves is essential to prevent death from embolization or cardiac failure; oral fluconazole should be given after successful completion of a prolonged course of amphotericin B therapy
Pericarditis	Amphotericin B	Fluconazole	—
Prosthetic device-related infection	Fluconazole or amphotericin B	—	Removal of device is required for successful therapy
Arthritis	Fluconazole	—	—
Osteomyelitis	Amphotericin B	Fluconazole	Surgical drainage of pus is required
Meningitis	Amphotericin B + flucytosine	Fluconazole + flucytosine	—
Nonhematogenous			
Oropharyngeal			
Otherwise normal host	Nystatin	Ketoconazole, fluconazole, clotrimazole troches	—
Patients at risk for hematogenous infection (e.g., cancer patients, surgical patients)	Fluconazole	Ketoconazole	—
Deep candidiasis			
Esophagitis and GI candidiasis	Fluconazole	Amphotericin B	Amphotericin B should be reserved for cases of fluconazole failure without endoscopic evidence of other causes of disease
Peritonitis and intra-abdominal	Fluconazole	Amphotericin B	—
Wound	Fluconazole	Amphotericin B	Antifungal therapy should be given to patients who do not respond to antibacterial therapy
Urinary tract			
Cystitis	Fluconazole	Amphotericin B	Fluconazole is preferable because of its high drug concentration in urine and because it is better tolerated
Pyelitis			
Without papillitis	Fluconazole	—	—
With papillitis	Fluconazole + flucytosine	Amphotericin B	—
Pyelonephritis	Fluconazole + flucytosine	Amphotericin B	—

*Therapy is individualized on the basis of the patient's clinical condition and the infecting species.

ceived amphotericin B than in those who did not.⁴⁸ Significant amphotericin B-related nephrotoxicity may occur.

The discovery of the azole antifungal agents has changed the management of *Candida* infections. The first two azoles, clotrimazole and miconazole, were not, however, suitable for systemic use. As for ketoconazole, the lack of a parenteral formulation and the erratic bioavailability of the drug in patients receiving H₂ receptor blockers or antacids have limited its use in the treatment of hematogenous candidiasis in surgical patients.

Fluconazole is a well-tolerated triazole with good activity in hematogenous candidiasis. Data available from several clinical trials suggest that the drug is as effective as and better tolerated than amphotericin B. Overall, four comparative studies have been completed in various patient populations. Two were randomized,^{49,50} one was prospective observational,⁵¹ and one used matched cohorts.⁵⁰ Fluconazole dosages ranged from 200 to 800 mg/day, given orally or intravenously, while intravenous amphotericin B was given at doses of 0.3 to 1.2 mg/kg.

The first prospective, randomized study of fluconazole included 40 surgical patients with hematogenous candidiasis, of whom

20 received 300 mg/day of fluconazole and 20 received 0.5 mg/kg/day of amphotericin B plus flucytosine.⁵² There were no significant differences in outcome between the two study groups.

A matched-pair study compared the outcomes of 45 candidemic cancer patients who were treated with fluconazole with the outcomes of 45 candidemic cancer patients who were treated with amphotericin B;⁵³ in several of the 90 patients, hematogenous candidiasis had developed after operation. This study demonstrated that fluconazole was as effective as and better tolerated than amphotericin B. In one prospective, randomized multicenter study, 164 patients with documented or presumed invasive candidiasis received either amphotericin B, 0.7 mg/kg/day, or fluconazole, 400 mg/day.⁵⁰ The response rate for fluconazole (62%) was virtually identical to that for amphotericin B (63%), and fluconazole was better tolerated. In another prospective, randomized multicenter study, 206 nonimmunocompromised candidemic patients received either amphotericin B or fluconazole.⁴⁹ Once again, the two drugs were comparable in their efficacy, and fluconazole had a better safety profile.

Newer therapeutic options have now become available with the advent of the lipid-associated formulations of amphotericin B,

which are less nephrotoxic than the parent compound.⁵⁴ Thus far, three lipid products of amphotericin B have been marketed in Europe or the United States: Abelcet (amphotericin B lipid complex), Amphocil (amphotericin B colloidal dispersion), and AmBisome (liposomal amphotericin B). A prospective, randomized trial has shown that Abelcet is as efficacious as conventional amphotericin B in hematogenous candidiasis.⁵⁵

All patients with candidemia should receive antifungal therapy. We recommend the administration of fluconazole, 600 to 800 mg/day I.V. for 3 days, particularly if the infecting organism is known to be or is likely to be *C. albicans*. If the patient responds rapidly to this regimen, the dosage may be decreased to 400 mg/day and administered orally. For patients with hematogenous candidiasis who are known to be colonized by *C. glabrata*, *C. krusei*, or *C. lusitaniae*, amphotericin B, 0.5 to 0.7 mg/kg/day, should remain the treatment of choice. For patients who are hemodynamically unstable and for those who have high-grade persistent fungemia, we recommend a two-drug antifungal regimen: the combination of fluconazole and flucytosine or the combination of amphotericin B and flucytosine, depending on the infecting strain.

Clinical data on the effect of itraconazole in hematogenous candidiasis are scant. Given that itraconazole has limited bioavailability in the presence of antacids and H₂ receptor blockers, it should not be used to treat hematogenous candidiasis in the critically ill. However, an I.V. formulation of itraconazole is now available, and it is possible that this formulation may prove effective in patients with hematogenous candidiasis.

Liposomal formulations of amphotericin B offer new therapeutic alternatives. Their substantial cost limits their routine use, but they are appropriate if the patient has renal failure and is infected with an azole-resistant strain. Of the three available formulations, AmBisome is the best tolerated and yields the highest blood levels of amphotericin B.

The duration of therapy depends on the extent and severity of the infection. Therapy can be limited to 7 to 10 days for patients with low-grade fungemia and no evidence of organ involvement or hemodynamic instability. Patients with high-grade fungemia and evidence of organ involvement or hemodynamic instability need to receive antifungal therapy for 10 to 14 days after resolution of all signs and symptoms of infection.

Catheter Management

Controversy remains concerning the role of central venous lines in patients' outcome in hematogenous candidiasis. According to Nguyen and colleagues,⁵¹ patients with catheter-related candidemia had a more favorable prognosis than patients with candidemia from other sources, but the prognosis was worse in patients whose catheters were retained. In contrast, studies by Carroll and colleagues, Nucci and coworkers,⁵⁶ and Anaissie and associates¹⁰ failed to show a major role for retention of central venous catheters in the outcome of hematogenous candidiasis. The study by Anaissie and associates¹⁰ examined the impact of catheter management on outcome in 416 cancer patients with candidemia who had an indwelling catheter at the time of candidal infection. Catheter exchange within 0, 2, or 4 days of the first positive blood culture had no significant effect on outcome. A second analysis, performed in a subset of 363 patients who had a central venous catheter in place and received antifungal therapy, revealed that catheter exchange was associated with improved outcome (80% versus 54%; *P* < 0.001). However, the subset in which the catheter was not exchanged had higher APACHE III scores and were more likely to be neutropenic. By multivariate analysis, catheter retention was not found to significantly affect outcome.

In one study in noncancer patients, Rex and colleagues⁵⁷ showed that replacement of all vascular catheters shortened the duration of candidemia from 5.6 days to 2.6 days. This finding suggests that catheters may play a role in perpetuating infection in nonneutropenic patients. In neutropenic patients, however, the primary source of candidemia is usually the GI tract, not the intravenous catheter, and other factors (e.g., the severity of disease, visceral dissemination, and neutrophil recovery) appear to have more impact on the outcome of neutropenic patients with candidemia.

Given the available data, we recommend that physicians consider the removal of all intravascular catheters in inpatients who have candidemia with persistent fever, persistent or high-grade fungemia, or *C. parapsilosis* (which is more likely to be catheter related than infection with other *Candida* species).

Cytokine Therapy for Opportunistic Infections

Polymorphonuclear leukocytes and macrophages are the predominant host defense against candidal infections. Candidal antigens induce lymphocyte proliferation and cytokine synthesis (interferon gamma and tumor necrosis factor); tumor necrosis factor enhances the candidacidal activity of phagocytes,⁵⁸ probably through increased production of reactive oxygen radicals. Another mechanism by which interferon gamma may augment host defenses against candidal infections is modulation of endothelial cell phagocytosis of *C. albicans*.⁵⁹ Granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) activate phagocytic cells to restrict the growth of *C. albicans*.⁶⁰

Recently, a multicenter, double-blind, randomized phase II trial examined the activity of G-CSF in combination with fluconazole for treatment of hematogenous candidiasis in nonneutropenic patients. Preliminary analysis (Kullberg BJ and associates, unpublished report, 2000) indicated that an increase in the number of circulating neutrophils strongly correlates with accelerated clearance of bloodstream infection and reduced mortality. Additional data are needed to confirm these findings.

Antifungal Prophylaxis

Prophylaxis may be considered in surgical patients at high risk for invasive candidiasis. To date, there have been few trials of antifungal prophylaxis, whether as part of selective bowel decontamination⁶¹ or in the form of low-dose amphotericin B⁶² or liposomal formulations of amphotericin B in surgical transplant recipients.⁶³

Fluconazole prophylaxis has been shown to reduce the rate of superficial and systemic fungal infections in cancer patients undergoing chemotherapy (with or without bone marrow transplantation)^{64,65} and oropharyngeal and esophageal candidiasis in patients infected with HIV.⁶⁶ A recent double-blind randomized trial showed that intravenous fluconazole prophylaxis was effective in preventing candidal colonization and invasive intra-abdominal candidal infections in high-risk surgical patients.⁶⁷

A retrospective study in burn patients reported that topical nystatin in the wound dressing was associated with a significant decrease in yeast acquisitions in burn wounds and fungemia but with an increase in colonization and fungemia caused by nystatin-resistant amphotericin B-susceptible *C. rugosa*.⁶⁸

Invasive fungal infection is one of the most important causes of mortality in organ transplant recipients.⁶⁹ Antifungal prophylaxis has been recommended in organ transplant recipients undergoing immunosuppressive therapy, but there is controversy about which drug is most effective and least toxic. Some physicians use fluconazole prophylactically in organ transplant recipients, but others recommend itraconazole or liposomal amphotericin B.^{1,70,71}

ORGAN INFECTIONS

Candida Endophthalmitis

The diagnosis of candidal endophthalmitis usually implies hematogenous spread to multiple organs and the need for systemic antifungal therapy. Patients with chorioretinitis alone respond better to drug therapy alone than do those with vitreal involvement. Because antifungal drugs do not penetrate the vitreous body as well as the other ocular compartments,⁷² patients with vitreal involvement require early vitrectomy in addition to antifungal therapy. Fluconazole is currently the drug of choice because of its proven efficacy and its higher concentration (20% to 70% of the corresponding plasma level) in ocular tissue, including the vitreous body.⁷³ Thus, we recommend 800 mg/day of fluconazole until a major response is observed, at which time it may be possible to reduce the dose to 400 mg/day. Although endophthalmitis due to *C. albicans* is commonly seen, recent series have reported on the importance of endophthalmitis caused by other candidal species. If the infecting organism (especially *C. krusei*) is potentially resistant to fluconazole, the recommended therapy is amphotericin B, 0.7 to 1.0 mg/kg/day I.V., preferably in conjunction with flucytosine.⁷⁴ Intravitreal injection of amphotericin B is recommended for vitreal infections.

The optimal duration of therapy for endogenous endophthalmitis is unknown, but we recommend that treatment be continued for at least 10 to 14 days after complete resolution of all signs and symptoms of infection. Ophthalmologic consultation is critical in establishing the diagnosis, assessing the patient's response to therapy, detecting complications, and determining whether early vitrectomy is indicated to prevent loss of sight.⁷⁵

Suppurative Thrombophlebitis

A rare but serious consequence of hematogenous candidemia is suppurative thrombophlebitis, which results from infection of a vessel traumatized by prolonged catheterization. Endothelial disruption exposes the basement membrane and leads to thrombus formation and propagation. Suppurative thrombophlebitis is particularly serious because intravascular infection results in a persistent high-density fungemia. Management of this disease consists of high-dose antifungal therapy, removal of the central venous catheter, and excision of the infected vein, when possible.⁷⁶ Typically, blood cultures remain positive for several days; sometimes, they remain positive for as long as 3 to 4 weeks despite appropriate antifungal therapy, if the infected vein is not excised.

Endocarditis

Hematogenous candidiasis may also lead to the establishment of endocarditis, particularly in patients with a prosthetic heart valve or with a previously damaged native valve. Intravenous drug abuse and central intravenous catheterization appear to be predisposing factors. Candidal endocarditis after permanent pacemaker implantation has also been reported. The clinical picture is similar in many respects to that of bacterial endocarditis, although embolic phenomena have been more commonly associated with fungal endocarditis. Transesophageal echocardiography is more sensitive than transthoracic echocardiography in detecting candidal vegetation. Mortality due to *Candida* prosthetic valve endocarditis (PVE) is high, especially when complicated by congestive heart failure and persistent fungemia. For uncomplicated PVE, the mortality for patients receiving antifungal therapy alone (40%) is no worse than that for patients receiving combined medical and surgical therapy (33%).

Candidal endocarditis is very difficult to treat. Surgical replacement or repair of valves is essential to prevent death from embolization or cardiac failure in patients with complicated PVE. Amphotericin B, with or without flucytosine, has been the therapy of choice; however, neither the optimal dosage nor the optimal duration of therapy has been determined. There is anecdotal information on the successful use of fluconazole in this setting, primarily as long-term suppressive therapy after the initial administration of amphotericin B.^{73,77} Because of the high risk of late relapse, long-term maintenance therapy with oral fluconazole should be begun after successful completion of a prolonged course of amphotericin B.

Pericarditis

Candidal pericarditis is a very rare complication of hematogenous candidiasis. The surgical patients at risk for purulent pericarditis caused by *Candida* species are those who have undergone a cardiac operation, those who have a malignancy and whose host defenses are impaired, and those who have a debilitating chronic disease.⁷⁸ High-dose amphotericin B therapy, with or without surgical drainage, is recommended in these cases.

Arthritis

Joint infections with *Candida* species have resulted from hematogenous spread from inadvertent direct inoculation during joint procedures or intra-articular injection of corticosteroids. These infections typically involve a single joint, most frequently the knee, and tend to occur in patients with rheumatoid arthritis or prosthetic joint devices.⁷⁹ Local symptoms of pain on weight bearing or on full extension may be present. Diagnosis is best achieved by visualizing or growing the organisms from the joint fluid. Early diagnosis and systemic antifungal therapy are important to prevent destruction of the cartilage or loosening of the prosthesis. Successful treatment with fluconazole has been reported in several patients with fungal arthritis.⁸⁰ We recommend a dose of 400 to 800 mg/day for 6 months. Fluconazole can be used in acute therapy, alone or in combination with surgery, as well as in long-term suppressive therapy in patients at risk for recurrence or those who cannot undergo surgical debridement.

Osteomyelitis

Except for sternal infections complicating median sternotomy, most cases of candidal osteomyelitis have followed hematogenous spread. Vertebral body involvement is common. Back pain and fever may be followed by radiculopathy. Surgical drainage of pus is essential for a good response; however, surgical debridement of bony lesions may not be needed. Although amphotericin B has been the standard drug of choice, fluconazole offers an alternative in the treatment of these cases.⁸¹

Meningitis

Candidal meningitis may follow hematogenous spread or be a complication of neurosurgery or the implantation of ventriculoperitoneal shunts.⁸² The infection is insidious and may remain undiagnosed. Most patients have recently received antibacterial agents, and half have had antecedent bacterial meningitis. The overall mortality is around 10%. The standard therapy is amphotericin B with flucytosine. The combination of high-dose fluconazole (800 mg/day) and flucytosine (50 mg/kg/day) is a particularly attractive approach because of the high CSF concentrations achieved with both agents. Removal of the infected shunts is recommended when possible.^{51,82} The duration of treatment should be based on clinical response and culture results.

Nonhematogenous Candidiasis**SUPERFICIAL INFECTION**

Oral candidiasis (thrush) appears as a whitish, patchy pseudo-

membrane covering an inflamed oropharynx and commonly involves the tongue, the hard and soft palates, and the tonsillar pillars. Controlled trials have documented the efficacy of nystatin suspension, clotrimazole troches, oral ketoconazole, fluconazole, or itraconazole in eradicating the clinical symptoms of oral candidiasis.^{83,84}

Nystatin should be given as a 10 to 30 ml suspension five times daily, and the patient should be instructed to swish it around the mouth before swallowing; alternatively, the patient may take one or two troches five times daily. Clotrimazole troches are given five times daily as a 10 mg troche that should be held in the mouth until dissolved. In surgical patients at risk for hematogenous infection, systemic therapy with ketoconazole (200 to 400 mg once daily), itraconazole (100 to 200 mg/day), or fluconazole (100 mg once daily) is preferred.⁸⁵ Antifungal therapy should be administered for 1 week, except for fluconazole therapy, which is likely to be effective when given for 2 or 3 days.

DEEP CANDIDIASIS

Esophagitis and Gastrointestinal Candidiasis

Superficial candidiasis involving only mucosal surfaces used to be a common finding at autopsy in surgical patients who had a protracted hospital stay characterized by recurrent sepsis. Such lesions may arise at any site in the GI tract but appear most commonly in the esophagus and the small bowel and may progress to hematogenous infection [see Figure 1].

In a minority of patients, the pathology of infection of the lower GI tract by *Candida* species may change from diarrhea without demonstrable tissue invasion to direct penetration into the submucosa, which eventually leads to pseudomembranous enterocolitis. Direct vascular invasion through the bowel wall has been reported only in patients receiving immunosuppressive chemotherapy.⁸⁶ These patients may have extensive involvement of the GI tract from mouth to anus. Non-neutropenic surgical patients exhibit more localized involvement.

The preferred therapy for esophageal candidiasis is fluconazole or itraconazole, 200 mg daily. In patients who remain symptomatic after 5 days of therapy, endoscopy is needed to rule out other causes of esophagitis. If endoscopy proves that esophagitis is caused by candidal infection, low-dose amphotericin B (0.4 mg/kg/day) should be administered. Therapy for esophageal candidiasis should be continued for at least 4 days after symptoms resolve; immunosuppressed patients generally require more extended therapy to prevent relapse.

Because stool cultures do not differentiate between colonization and infection, candidiasis in the lower gastrointestinal tract is usually a postmortem diagnosis; hence, there are no reliable criteria governing when and how to treat this condition. It has been reported, however, that patients who have diarrhea that can only be caused by heavy colonization with *Candida* species may respond dramatically to 2 to 4 days of nystatin therapy.⁸⁷

Peritonitis and Intra-abdominal Abscess

Perhaps the most controversial aspect of *Candida* infectious syndromes in surgical patients is whether specific systemic therapy is required to eradicate the infection within intra-abdominal abscesses, peritoneal fluid, or fistula drainage. *Candida* is frequently cultured from intra-abdominal infectious foci but should be considered a serious threat only in high-risk patients. Four risk factors for intra-abdominal candidiasis are gastrointestinal perforations, anastomotic leakage, surgery for acute pancreatitis, and splenectomy.⁸⁸

Patients with peritonitis and intra-abdominal abscesses should receive systemic antifungal therapy, usually in combination with antibacterial therapy, given that these infections are almost always polymicrobial in origin. The risk of dissemination is increased by

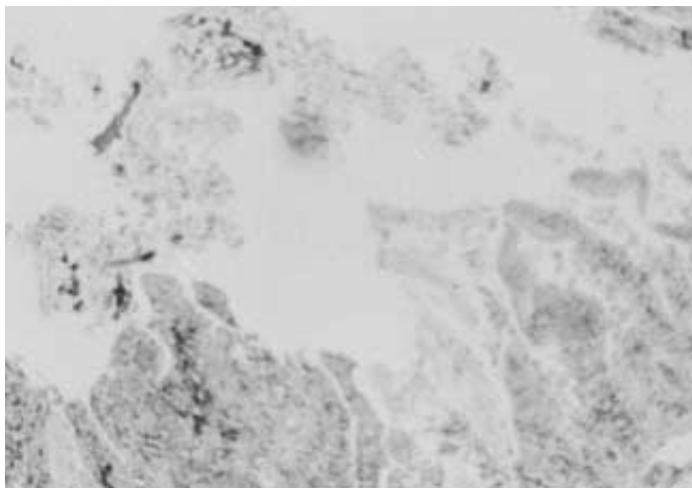

Figure 1 Superficial candidiasis may be found at all levels of the GI tract. Here, the esophagus of a patient found at autopsy to have disseminated candidiasis shows disrupted epithelium, submucosal inflammation, and the presence of yeast in the submucosa.

both the recurrence of intra-abdominal infections and the presence of extensive areas of communication between the abdominal cavity and the external environment via either fistulas or drain tracts.

On rare occasions, candidal peritonitis occurs after long-term ambulatory peritoneal dialysis. In such cases, the infection tends to remain localized and to manifest with low-grade fever and abdominal pain and tenderness. The peritoneal dialysate is usually cloudy and contains more than 100 neutrophils/mm³. Therapy consists of systemic antifungal therapy and removal of the peritoneal catheter. The abdominal pain caused by the addition of amphotericin B to the dialysate has raised concern that chemical peritonitis might give rise to adhesions and thus impair the efficacy of dialysis.

Because fluconazole is very safe and is capable of reaching high concentrations in peritoneal fluid, it is likely to be useful in the management of candidal peritonitis.⁸⁹ Fluconazole should be given at a dosage of 100 to 200 mg/day orally for 2 to 6 weeks. Immediate removal of the peritoneal catheter has been recommended. In one study, however, seven of nine patients treated with oral flucytosine responded to therapy without catheter removal.⁹⁰

A prospective, randomized study in patients on continuous ambulatory dialysis found that successful prophylaxis for *Candida* peritonitis was achieved with oral nystatin (tablets containing 500,000 units given four times a day).⁹¹

Occasionally, *Candida* species may cause cholangitis, biliary tract disease, pancreatic abscess, or liver abscess. This problem is increasingly found in patients with percutaneously placed drainage catheters for malignancy. Such patients must be given systemic therapy for clinical evidence of infection, including candidemia, and the drainage catheter must be changed. Diverticulitis complicated by candidal pylephlebitis has also been reported.

Wound Infections

The diagnosis and treatment of candidal wound infections are problematic. Recovering *Candida* species from drains and wounds does not necessarily mean that this organism is causing tissue infection. Colonization of wounds by *Candida* species should not compel physicians to use systemic antifungal therapy. However, such therapy should be administered to those patients whose wound infections do not respond to appropriate antibacterial therapy, particularly if one *Candida* species is repeatedly isolated from the site and the patient is

at high risk for hematogenous infection. Antifungal therapy should be administered to prevent the establishment of *Candida* osteomyelitis when sternal wound cultures obtained after coronary artery bypass surgery yield *Candida* species.

Urinary Tract and Genital Candidiasis

The recovery of *Candida* species from the urinary tract most commonly results from contamination from the perirectal or the genital area or from colonization of the bladder, which is usually seen in patients who have undergone prolonged catheterization or who have diabetes mellitus or another disease that leads to incomplete bladder emptying. In addition, *Candida* species usually colonize ileal conduits. Persistent candiduria in the surgical intensive care unit may, however, be an early marker of disseminated infection in critically ill high-risk patients.⁹² In a study of 91 pediatric ICU patients who were clinically suspected of having disseminated candidiasis, the isolation of candidal species other than *C. albicans* from the urine was a better indicator of candidemia than was isolation of *C. albicans*; 60% of the patients whose urine contained candidal species other than *C. albicans* had candidemia, versus 33.3% of the patients whose urine contained *C. albicans*.⁹³

Alkalization of the urine with oral potassium-sodium hydrogen citrate is a simple and effective method of treating candiduria in patients with an indwelling catheter.⁹⁴ Replacing or removing the bladder catheter is preferable. If *Candida* colonization persists, particularly if the patient has a risk factor for cystitis (e.g., diabetes mellitus or a disease that leads to incomplete bladder emptying) or for hematogenous dissemination (e.g., immunosuppression or manipulation of the genitourinary system), antifungal therapy should be considered. Amphotericin B bladder irrigation provides only temporary clearance of funguria, and systemic agents (a single I.V. dose of amphotericin B or a 5-day course of oral fluconazole) are usually needed.

The spectrum of urinary tract infection by *Candida* species includes cystitis, pyelitis (i.e., infection of the renal pelvis), fungus ball of the ureter, and renal abscesses. The diagnosis of cystitis is based on the presence of symptoms of cystitis, diffuse erythema or fungal plaques on cystoscopy, candiduria, and pyuria. *Candida* cystitis warrants therapy. If a triple-lumen catheter is in place, bladder irrigation with amphotericin B, 50 mg/L/day for 2 days, may be tried. Fluconazole, 200 mg once daily, is a more attractive approach because of the convenience, lower cost, and very high drug concentrations achieved in the urine.⁹⁵ Flucytosine is excreted in the urine in high concentrations and may be particularly useful against *C. glabrata* infection.

The management of pyelitis depends on whether the renal papillae are invaded or the ureter is obstructed with a fungus ball. Patients with no papillitis and an open ureter usually respond to irrigation with amphotericin B through a ureteral or percutaneous catheter. If papillitis is present, systemic antifungal therapy with fluconazole, 400 mg daily, is recommended. If fungus balls are present, surgical removal should be considered in addition to treatment with antifungal agents.

Hematogenous infections of the kidneys leading to multiple renal abscesses are treated as instances of hematogenous candidiasis. However, because both fluconazole and flucytosine are well tolerated, have good tissue diffusion, and are excreted in the urine in high concentrations, it is reasonable to assume that the combination of these two agents represents the therapy of choice for candidiasis that involves renal parenchyma.

Surgical patients are also at risk for vulvovaginal candidiasis. The diagnosis is based on the clinical findings and on the presence of pseudohyphae on a fungal smear. Various antifungal

agents, including oral azoles and topical medications (suppositories, creams, and vaginal tablets) are effective in more than 80% of uncomplicated infections. Oral agents include fluconazole (150 mg in a single dose), ketoconazole (400 mg daily for 5 days), and itraconazole (200 mg in a single dose). However, women with four or more episodes of vulvovaginal candidiasis during a 12-month period and women with acute severe attacks of candidal vaginitis are less likely to respond to conventional therapy. Preventive measures include control of host factors such as diabetes mellitus, antifungal prophylaxis during the use of antibiotics and under other high-risk conditions, and the avoidance of systematic corticosteroids, oral contraceptives, and antibiotics if possible. Therapy with oral fluconazole, itraconazole, or ketoconazole is recommended for approximately 14 days to ensure clinical remission and negative fungal culture, followed by a maintenance regimen of fluconazole (150 mg once weekly for 6 months). Recurrence of vulvovaginal candidiasis is common, occurring in 30% to 40% of patients after cessation of the maintenance regime.⁹⁶

Other Fungal Infections

ASPERGILLOYSIS

Aspergillosis, a rare infection in the surgical patient, usually occurs in those who are markedly immunosuppressed after undergoing chemotherapy with cytotoxic agents or adrenal corticosteroids. Most cases of nosocomial aspergillosis are acquired via airborne transmission.^{13,97} Colonization of the respiratory tract is followed by invasive disease if these predisposing factors are present. Sources of airborne fungi in microepidemics frequently are associated with construction within the hospital or at adjacent sites. Other modes of transmission of aspergillosis have been reported, including infections associated with foreign bodies, catheters, and bandages.

Acute invasive pulmonary aspergillosis is the most common form of *Aspergillus* infection in immunocompromised surgical patients. The organisms tend to invade blood vessels and cause thrombosis and infarction of the surrounding tissues. The infection may manifest itself in the form of acute vascular events such as pulmonary embolus or, more rarely, myocardial infarction, cerebral hemorrhage, or Budd-Chiari syndrome. Pulmonary *Aspergillus* infections include necrotizing bronchopneumonia and hemorrhagic pulmonary infarction, each accounting for about one third of these infections. Pulmonary aspergillosis may extend to contiguous organs or be disseminated. The rhinocerebral form of aspergillosis occurs less often than pulmonary infection. It originates in the sinuses and progresses through soft tissues, cartilage, and bone, causing lesions in the palate and the nose. Occasionally, the infection progresses through the base of the skull and involves the brain.

Diagnosis of *Aspergillus* infection is difficult and relies on identifying the organism in culture or histopathologic specimens.¹³ The recovery of *Aspergillus* species from the respiratory tract culture of a surgical patient should be considered to represent contamination or colonization unless the patient is symptomatic and severely immunosuppressed. The standard therapy is high-dose amphotericin B (1 mg/kg/day) for a minimum of 2 g.⁹⁸ The addition of flucytosine may be useful. Liposomal formulations of amphotericin B and itraconazole offer additional treatment alternatives; at present, however, clinical experience with these new antifungal agents in patients with aspergillosis is limited.

ZYgomycosis (MUCORMYCOSIS)

Agents of zygomycosis have caused nosocomial infections in the surgical patient. The reservoir, the mode of transmission, the

pathogenesis, and the clinical presentations are similar to those of *Aspergillus* species. In the surgical patient, the major risk factors include diabetic ketoacidosis, immunosuppression after cytotoxic chemotherapy, adrenocorticosteroid therapy, organ transplantation, skin damage (e.g., from adhesive tape, an arm board, or severe burns), and a prolonged postoperative stay.⁹⁹ Zygomycotic infections include rhinocerebral, paranasal, pulmonary, gastrointestinal, cutaneous, and, very rarely, disseminated disease.

Appropriate management of zygomycosis consists of extensive surgical debridement of infected areas, rapid correction of the underlying disease, and high-dose amphotericin B therapy up to a total dose of 2 to 3 g.

EMERGING PATHOGENS

Fungi such as *Fusarium* species, *Curvularia* species, *Alternaria* species, and *Trichosporon beigelii* were once thought to represent contamination or harmless colonization when isolated from tissue specimens. These and other newly recognized fungi have since been clearly shown to be potentially serious pathogens in immunosuppressed surgical patients.¹⁰⁰ In such patients, the recovery of any fungus from any site should prompt an evaluation by an infectious disease specialist to determine the clinical significance of the isolate.

Systemic Antifungal Agents

AMPHOTERICIN B

Amphotericin B is structurally similar to membrane sterols, and its major mechanism of action is believed to be through interaction with membrane sterols and creation of pores in the fungal outer membrane. The clinical usefulness of amphotericin B is believed to be attributable to the greater affinity of amphotericin B for ergosterol (found in fungal cell membranes) than for cholesterol (the principal sterol found in mammalian cell membranes). Oxidation-dependent amphotericin B-induced stimulation of macrophages is another proposed mechanism of action.¹⁰¹ Most species of fungi that cause human infections are susceptible to amphotericin B.

Amphotericin B is supplied as a sterile lyophilized powder in vials containing 50 mg of amphotericin B, deoxycholate, and buffer. The contents are then diluted in 5% dextrose in water at a concentration of 10 mg/dl. Less precipitation occurs in saline solutions. The agent is stable at room temperature for 24 hours and is not sensitive to light. An acute infusion-related reaction, consisting of fever, hypotension, and tachycardia, occurs in about 20% of patients.⁹⁰ Premedication with acetaminophen may blunt this response. If this approach is unsuccessful, premedication with meperidine (25 to 50 mg I.V.) or hydrocortisone (25 to 50 mg I.V.) is recommended. Hypotension, hypertension, hypothermia, and bradycardia are other reported infusion-related toxic effects of amphotericin B deoxycholate. Ventricular arrhythmias have been associated with rapid infusion of amphotericin B deoxycholate and with administration of the agent to patients with severe hypokalemia or renal failure. Through inhibition of erythropoietic production secondary to nephrotoxicity, amphotericin B suppresses the production of red blood cells, causing a normocytic, normochromic anemia.

Common practice is to give a 1 mg test dose and observe the patient for 1 hour in the hope of identifying patients at risk for severe acute reactions. The full dose of the drug (0.6 to 1 mg/kg/day) is then infused over a period of 4 to 6 hours, although there is evidence to suggest that much shorter infusion times (e.g., 1 hour in patients with adequate cardiopulmonary and renal function) may be acceptable. The total dose depends on the extent of the infec-

tion and the patient's condition. Patients must be monitored carefully during the first day of therapy. The infusion should be discontinued if the patient becomes hemodynamically unstable.

If acute reactions limit the amount of drug that can be infused, patients are premedicated with hydrocortisone, 25 to 50 mg I.V., either alone or in combination with meperidine, 25 to 50 mg I.V., 30 minutes before amphotericin B infusion is begun.

The distribution of the drug after I.V. infusion does not directly correlate with the daily dose. This finding is consistent with the unusual pharmacokinetics of amphotericin B. The initial serum half-life of the drug is about 24 hours, and the terminal half-life is about 15 days.

Renal toxicity and hypokalemia are the primary toxicities of amphotericin B [see Table 3]. Amphotericin B-induced nephrotoxicity may be glomerular, characterized by a decrease in glomerular filtration rate and renal blood flow, or tubular, with urinary casts, hypokalemia, hypomagnesemia, renal tubular acidosis, and nephrocalcinosis).¹⁰² All of these abnormalities occur to varying degrees in almost all patients receiving the drug. In most patients, renal dysfunction gradually resolves after discontinuance of therapy. Amphotericin B nephrotoxicity may be minimized by avoiding other agents with synergistic nephrotoxicity (e.g., aminoglycosides, vancomycin, cisplatin, and cyclosporine) and by the administration of sodium supplementation. The latter approach consists of I.V. infusion of 500 ml of 0.9% saline solution 30 minutes before the administration of amphotericin B and a second infusion of the same amount of saline after the amphotericin B infusion is completed.

If the serum creatinine level exceeds 3.5 mg/dl, amphotericin B should be discontinued and the serum creatinine level monitored twice weekly. Administration of amphotericin B may be resumed at 50% to 75% of the original dosage when the serum creatinine level falls below 3 mg/dl.

The combined use of amphotericin B deoxycholate and other nephrotoxic agents, such as cyclosporine, aminoglycosides, and foscarnet, may result in synergistic nephrotoxicity.¹⁰³ Less nephrotoxic lipid formulations of amphotericin B include amphotericin B lipid complex (Abelcet), amphotericin B colloidal dispersion (Amphotec), and liposomal amphotericin B (AmBisome). These preparations differ in the amount of amphotericin B and the type of lipid used as well as in the physical form, pharmacokinetics, and toxicities. Of the three formulations, AmBisome is the one that is best tolerated.

FLUCYTOSINE

Flucytosine can be useful for the treatment of hematogenous candidiasis; however, a high failure rate and secondary emergence of resistance have been reported when flucytosine was used alone, and serious concerns exist regarding its myelosuppressive potential. A review of the literature on the activity of flucytosine in acute disseminated candidiasis and candidemia indicates a good response rate.

The standard dosage for flucytosine is 37.5 mg/kg every 6 hours. On the basis of the pharmacokinetics of flucytosine and the in vitro susceptibility of *Candida* species to the drug, much lower dosages of flucytosine (e.g., 12.5 mg/kg every 12 hours) would probably maintain serum and tissue levels significantly above the minimal inhibitory concentration (MIC) needed for most susceptible strains throughout therapy. For example, giving 25 mg/kg/day at 12-hour intervals would result in peak and trough serum levels of about 25 and 5 µg/ml, respectively, given a steady state and normal kidney function in a 70 kg patient. Because the MIC of flucytosine for most susceptible *Candida* species is usually 1 µg/ml or less, such a dosage schedule will constitute

Table 3 Antifungal Chemotherapy¹⁴⁰

Drug	Indications	Route of Administration	Major Side Effects
Amphotericin B	Hematogenous and deep-seated candidiasis; aspergillosis; blastomycosis; coccidioidomycosis; histoplasmosis; cryptococcosis	Intravenous, intrathecal	Anemia, headache, chills, fever, nausea, renal dysfunction, hypotension, tachypnea, hypokalemia, phlebitis
Clotrimazole	Oropharyngeal candidiasis	Oral	—
Flucytosine	Candidiasis (septicemia, endocarditis, and urinary tract infections); cryptococcosis	Oral	Leukopenia, thrombocytopenia, liver dysfunction, diarrhea
Fluconazole	Oropharyngeal and esophageal candidiasis; hematogenous candidal infection; other candidal infections (e.g., urinary tract infections, peritonitis); meningeal coccidioidomycosis; cryptococcosis	Oral, intravenous	Nausea and vomiting, skin rash, liver dysfunction
Itraconazole	Histoplasmosis; blastomycosis; aspergillosis	Oral	Nausea, vomiting, liver dysfunction
Ketoconazole	Candidiasis (chronic mucocutaneous candidiasis or oropharyngeal candidiasis); candiduria; blastomycosis; coccidioidomycosis; histoplasmosis; chromomycosis; paracoccidioidomycosis	Oral	Hepatotoxicity, nausea or vomiting, occasional suppression of adrenal function

appropriate therapy, given that the drug is used in combination with other antifungals. This approach may decrease the myelosuppressive potential that the drug usually exhibits at levels of 100 µg/ml, and it may lead to the drug's wider use.

Peak serum concentrations should be monitored and the dosage adjusted so as to maintain a peak level of about 25 µg/ml. Flucytosine is removed by hemodialysis and peritoneal dialysis. Patients undergoing hemodialysis should receive a 37.5 mg/kg dose of flucytosine after each dialysis session unless their initial peak serum concentration is higher than 25 µg/ml or their postdialysis concentration is higher than 10 µg/ml. Patients undergoing peritoneal dialysis should receive a single 37.5 mg/kg dose daily.

FLUCONAZOLE

The mechanism of action of fluconazole is preferential inhibition of cytochrome P-450 enzymes in fungal organisms. Fluconazole is active against several *Candida* species, including *C. tropicalis*. *C. krusei*, however, is highly resistant to this agent.⁹⁰ Fluconazole also does not appear to have good clinical activity against *Aspergillus* species. Fluconazole is available in either an oral form or an I.V. form, both of which are rapidly and almost completely absorbed from the GI tract. The serum concentrations after oral administration are almost identical to those achieved when the drug is administered intravenously. A major advantage of fluconazole over ketoconazole is its high degree of GI absorption, which is not affected by gastric acidity or the presence of food. Steady-state serum concentrations of fluconazole are obtained within 5 to 10 days. An initial loading dose that is twice the usual daily dose is recommended. Fluconazole is distributed evenly in body tissues, penetrates into the vitreous humor and the aqueous humor of the eye, and crosses the blood-brain barrier. The drug is excreted largely unchanged in the urine, with only minimal liver metabolism. Consequently, dosage schedules must be adjusted in patients with renal impairment. Hemodialysis significantly reduces the serum concentrations, and the drug appears also to be removed by peritoneal dialysis. A standard dose should be given after each course of dialysis.

The toxicities of fluconazole are similar to those of other azoles and include nausea and vomiting in about 2% of patients, as well as headache, fatigue, abdominal pain, and diarrhea¹⁰⁴; exfoliative dermatitis also occurs, but very rarely. Transient abnormalities of liver function have been observed in 3% of patients receiving fluconazole. In addition, fatal hepatic necrosis developed in two patients who were receiving fluconazole, but it was unclear whether the agent played a causal role in this event. No significant hormonal abnormalities have been reported after administration of fluconazole.

Because fluconazole interacts with warfarin, phenytoin, and cyclosporine when given in a daily dose of 200 mg or more,¹⁰⁴ serum concentrations of these agents should be monitored.

ITRACONAZOLE

Itraconazole is the only available azole that has substantial activity against *Aspergillus* species. It exists in an oral capsule formulation, the bioavailability of which is approximately 55%. Absorption is enhanced by the presence of food in the stomach but is significantly reduced by the presence of antacids or H₂ receptor blockers. A new solution, which has significantly higher bioavailability, may not be well tolerated by patients. When erratic absorption is of concern, use of the I.V. formulation is recommended. The serum elimination half-life, 15 to 25 hours, increases to 34 to 42 hours after weeks of administration and with increasing itraconazole doses.

Metabolized by the liver, itraconazole is excreted as metabolites primarily in the feces (54%) and urine (35%). A hepatic metabolite, hydroxyitraconazole, has an antifungal spectrum similar to that of the parent compound. Because itraconazole is metabolized to a large degree in the liver, the dosage must be adjusted in patients with hepatic failure; however, its pharmacokinetics are not affected by renal impairment or hemodialysis. Serum concentrations of digoxin may increase when this agent is given with itraconazole,¹⁰⁵ and the metabolism of itraconazole may be accelerated when drugs that induce hepatic enzymes are given simultaneously.¹⁰⁶ Serum concentrations of itraconazole should therefore be measured in patients with invasive infections.

Itraconazole is generally well tolerated in dosages of up to 400 mg/day. The most common side effects are nausea, vomiting, diarrhea, and abdominal discomfort. Headaches, rash, pruritus, and dizziness occasionally occur. At higher doses, a mineralocorticoid excess syndrome (hypokalemia, hypertension, and edema) has been described, and hypokalemia develops in as many as 6% of patients who take 400 mg/day for several months.¹⁰⁷

Itraconazole is available in 100 mg capsules and oral suspension (10 mg/ml). Because itraconazole may be teratogenic, it should be avoided in pregnant patients. A large number of drug interactions occur with itraconazole, many related to inhibition of the cytochrome P-450 enzyme system. Care should be taken in prescribing itraconazole with these agents. Itraconazole is currently approved for the treatment of blastomycosis, histoplasmosis, and aspergillosis but is also effective for the treatment of candidiasis and cryptococcosis.

KETOCONAZOLE

Ketoconazole is effective against yeast infections of the skin and the mucous membranes; however, it should not be used to treat hemato-

Table 4 Characteristics of Currently Available Azoles^{*139}

	Ketoconazole	Fluconazole	Itraconazole
Spectrum	Narrow	Expanded	Expanded
Route(s) of administration	Oral	Oral, intravenous	Oral
Bioavailability	Erratic, requires gastric acidity	Excellent	Erratic, requires gastric acidity

CSF penetration	No	Yes	No
Renal excretion	No	Yes	No
Interaction with other drugs	Frequent	Occasional	Frequent

*Intravenous miconazole is also available but offers no advantage over the currently available azoles.

genous candidiasis. Ketoconazole is not available in an intravenous form, and the serum levels it is capable of reaching depend largely on gastric acidity [see Table 4]. The same adverse events and drug-drug interactions observed with itraconazole occur with ketoconazole.

SPECIAL CONSIDERATIONS IN ORGAN TRANSPLANT RECIPIENTS

Intravenous amphotericin B (0.4 to 0.8 mg/kg/day) has been the mainstay of treatment in organ transplant recipients, but concerns have been expressed about increased nephrotoxicity, particularly in patients receiving cyclosporine or tacrolimus. The lipid formulations of amphotericin B (1 to 3 mg/kg/day) are less nephrotoxic, particularly liposomal amphotericin B (AmBisome). Fluconazole has a minimal effect on hepatic microsomal enzymes in comparison with ketoconazole and itraconazole and therefore is the drug of choice in organ transplant recipients who have candidiasis caused by fluconazole-susceptible strains.

Conclusion

Continued progress in supportive care, including the development of antibiotics with increasingly broad spectra of activity, has resulted in an increased incidence of fungal infections, particularly candidiasis. Because of the inadequacy of the available knowledge base, we do not fully understand the pathophysiology of these infections in surgical patients, nor can we be certain precisely when prophylaxis and therapy should be administered.

Despite these limitations, there is now sufficient information available to justify an aggressive therapeutic approach to suspected *Candida* infections. Now that less toxic agents are available (the newer triazoles, particularly fluconazole, and the lipid formulations of amphotericin B), the clinical approach to presumed fungal infections in surgical patients has been made far simpler.

Discussion

Microbiologic Characteristics of Pathogenic *Candida* Species

Candida species multiply by producing buds from ovoid yeast cells. They are differentiated from other yeasts (e.g., *Saccharomyces* species) by their ability to produce pseudohyphae on certain media and, in the case of *C. albicans*, true hyphae in serum [see Figure 2].

VIRULENCE FACTORS

Four virulence factors have been demonstrated for *Candida* species: adherence to mucosal epithelial cells; secretion of proteinases, which degrade connective tissue proteins, thereby allowing yeast to enter beyond connective tissue barriers; ambient pH¹⁰⁸; and resistance to oxidative killing by neutrophils.

For *Candida* species to disseminate, the organisms must be able to adhere to the vascular system (i.e., endothelium, the basement membrane, or both), an ability that is probably receptor mediated.¹⁰⁹ In vitro, however, *Candida* adheres more avidly to the subendothelial extracellular matrix than to endothelial cells. This finding

may explain the increased risk of hematogenous candidiasis in patients receiving cytotoxic chemotherapy. Such therapy causes denudation of endothelium and consequent exposure of the basement membrane, to which *Candida* then readily adheres.

Genetic studies have evaluated the role of various virulence factors for *Candida* species, including ambient pH,¹⁰⁸ adherence mechanisms, and enzyme production. Mechanisms by which *Candida* species lose virulence include the following: gene dysregulation, stopping the switch from budding yeast to filamentous form; disruption of a gene that results in decreased hyphal growth, adherence, and virulence¹¹⁰; deficiency of *C. albicans* in mannosyl transferase, resulting in decreased adherence and virulence; and deletion of the gene that encodes the production of phospholipase leading to decreased cell wall penetration.

CHANGING MICROBIOLOGIC SPECTRUM OF *CANDIDA*

Although there are more than 100 described species of *Candida*, only four are commonly associated with infection: *C. albicans*, *C. tropi-*

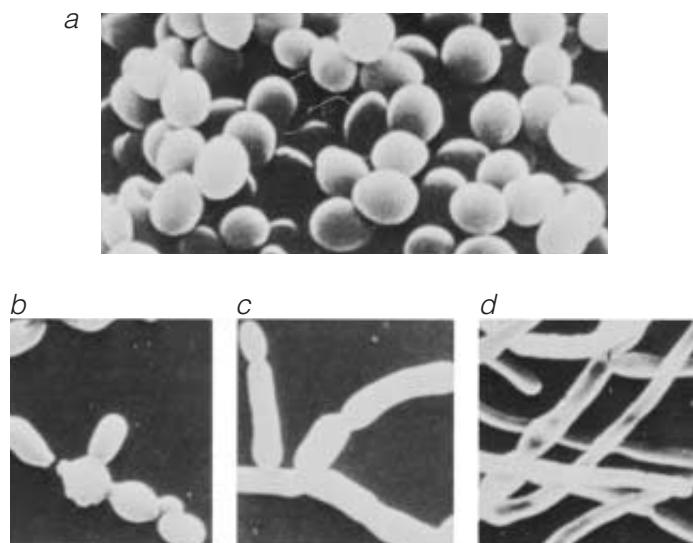

Figure 2 *Candida* takes several forms as it grows. A blastospore is a unicellular form (a). Blastospores divide by budding, a process in which new cellular material grows from a site on the blastospore (b). Nuclear division then occurs, and a septum forms between the two new cells. A hypha is a long tube of several cells divided by septa (c). A mycelium is a cellular aggregate that includes a hypha and its branches (d). A pseudohypha differs from a true hypha in that it is composed of morphologically distinct, elongated blastospores.

calis, *C. parapsilosis*, and *C. glabrata*.¹⁰ Of these, *C. albicans* has been isolated from more than 60% of candidal infections; the other three major species are seen at rates varying from 5% to 20%. Mucosal colonization by *C. tropicalis*, a virulent organism, frequently leads to invasive infection. *C. glabrata* and *C. parapsilosis* appear to be relatively less virulent,¹¹¹ and the latter typically causes infection in association with prosthetic materials (e.g., catheters) or glucose-rich intravenous solutions.¹⁰ Finally, *C. krusei* and *C. lusitaniae* rarely cause disease, being isolated from fewer than 1% of cultures.¹⁰ The epidemiology of candidiasis has changed, with reduced rates of *C. albicans* in favor of other candidal species—in particular, *C. glabrata* and *C. krusei*.¹¹² This change is important because *C. krusei* and several strains of *C. glabrata* are highly resistant to the triazoles such as fluconazole and itraconazole.^{10,112}

A study by the NNIS group evaluated 1,579 bloodstream isolates of *Candida* species obtained from more than 50 hospitals in the United States over a 7-year period (1992–1998) to detect trends in species distribution and susceptibility to fluconazole. *C. albicans* accounted for 52% of isolates, followed by *C. glabrata* (18%), *C. parapsilosis* (15%), *C. tropicalis* (11%), and *C. krusei* (2%). Since 1995, *C. glabrata* has been more prevalent than *C. parapsilosis*. The susceptibility of all *Candida* species to fluconazole has remained stable.¹¹³

Pathogenesis of Candidiasis in the Surgical Patient

COLONIZATION OF THE GUT BY CANDIDA SPECIES

That colonization is a necessary prelude to infection is supported by studies demonstrating (1) that 95% of neutropenic patients and 84% of nonneutropenic patients were infected with the same strains that had previously colonized them and (2) that infection was significantly less likely to develop in patients who were not colonized.^{114,115} In a study investigating the sequence of colonization and candidemia in nonneutropenic patients, Voss and colleagues¹¹⁴ found that the strains recovered from the initial colonized or infected site and from

the bloodstream were identical in patients with disseminated candidiasis; furthermore, nearly every patient was infected with a distinct or unique *Candida* strain. In another study, positive surveillance cultures were found to be highly predictive of systemic infection, whereas negative surveillance cultures correlated with a low risk of candidal dissemination.¹¹⁶ Clinical studies of antifungal prophylaxis in neutropenic cancer patients have also suggested that antifungal regimens effectively prevent hematogenous infection when they can eliminate or reduce colonization by *Candida*.¹¹⁷

The density of colonization appears to be predictive of the risk of hematogenous candidiasis. In two large series of neutropenic cancer patients, hematogenous candidiasis almost never developed in noncolonized patients, compared with an infection rate of more than 30% in patients with multiple colonized sites.^{115,118} In a study of patients with acute lymphocytic leukemia, a relatively high concentration of *Candida* organisms in the stools was found to be a significant risk factor for hematogenous candidiasis.¹¹⁹ In 40 infants of very low birth weight, a value of 8×10^6 *Candida* CFU/g stool was established as a threshold, beyond which GI symptoms (attributed to *Candida*) developed in 50% of the infants and a systemic septic response in 28.5% during 1 to 3 weeks of heavy colonization.¹²⁰ In a prospective study of patients admitted to surgical and neonatal intensive care units, Pittet and coworkers demonstrated that the intensity of *Candida* colonization (as determined by a *Candida* colonization index) was significantly higher in patients who subsequently became infected than in those who did not.¹²¹ Other case-control studies have demonstrated that colonization by *Candida* species at various body sites and exposure to several antibiotics were independent risk factors for candidemia.¹²²

The normal endogenous intestinal flora inhibits GI colonization and overgrowth by potentially pathogenic bacteria and fungi by forming what may be thought of as living wallpaper in the large intestine. Suppression of endogenous microflora as a consequence of antimicrobial administration¹²³ may permit overgrowth of pathogenic strains in the GI tract and selection of resistant strains, which may result in enterocolitis, systemic infection, or the septic response.

PHYSICAL DISRUPTION OF THE INTESTINAL MUCOSAL BARRIER

In humans, as well as in animals, the GI tract is considered to be the most important portal of entry for microorganisms, including yeasts, into the bloodstream. The passage of endogenous fungi from the GI tract to extraintestinal sites can be referred to as fungal translocation (by analogy with bacterial translocation).

Although yeast cells have no intrinsic motility, they are able to translocate from the intestinal lumen within a few hours of ingestion. In a study conducted in the 1960s, two nonpathogenic yeasts were surgically instilled into the rat duodenum and were recovered from the cisterna chyli within 4 hours.¹²⁴ Even in the absence of disease, any marked increase in the intestinal population of *Candida* can lead to fungal translocation and subsequent hematogenous infection. That candidal species can translocate from the gut to the bloodstream was demonstrated in a study in which signs and symptoms of sepsis developed in a healthy volunteer 2 hours after ingestion of a suspension containing 10^{12} *C. albicans* organisms, and blood cultures taken 3 and 6 hours after ingestion were positive for *Candida*.¹²⁵ In addition, autopsy studies conducted in patients with hematogenous candidiasis found involvement of the GI tract and submucosal invasion in almost all patients.⁸⁶

Microbial translocation has been demonstrated in several animal models and has been shown to be enhanced by several factors, including fasting, which induces complex changes in host defenses, and protein deficiency, which results in intestinal microbial overgrowth, increased intestinal absorption of intact proteins, and decreased intracellular killing of bacteria and fungi. In one study involving *C. albicans*, volatile fatty acids and secondary bile salts

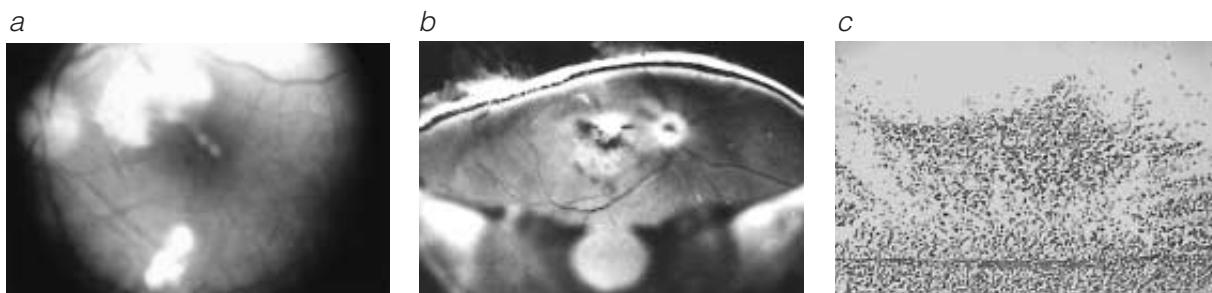

Figure 3 *Candida* endophthalmitis is common in patients with persistent fungemia. On funduscopic examination, a characteristic white, cotton-wool-like exudate can be seen (a). Cut section of an eye shows *Candida* retinitis (b). A microscopic view of *Candida* chorioretinitis is also provided (c).¹³⁸

reduced fungal adhesion to the mucosa, colonization, and dissemination in mice by causing the formation of a dense layer of bacteria in the mucus gel; these bacteria successfully competed with the yeast cells for the same adhesion sites and produced various substances that inhibited fungal growth.¹²⁶ In another animal model, bile duct ligation resulted in bacterial translocation.¹²⁷ In yet another, splanchnic ischemia in guinea pigs increased fungal translocation.¹²⁸ Similar results were obtained in guinea pigs and rats that had burns covering 50% of their total body surface area. After the yeast cells penetrated the lamina propria, the cells were found either free in the lymphatic vessels and in the blood vessels or engulfed by macrophages.¹²⁹

Microbial translocation has been shown to be clinically relevant in humans. Surveillance cultures from patients with leukemia have demonstrated an association between the bacterial biotype or serotype that was most prevalent in the patient's feces and the bacterial biotype or serotype that subsequently caused septicemia. Significant microbial translocation has been demonstrated in patients who underwent operation for colorectal carcinoma, intestinal obstruction, or Crohn disease. In addition, translocation is thought to occur as a result of flattening of the intestinal villi that results from the administration of total parenteral nutrition.¹³⁰

Immunosuppression Leading to Dissemination of Candidiasis

Host defenses against *Candida* infections include T cell immunity, to prevent colonization and superficial invasion, and phagocytic immunity, to prevent deeper tissue invasion and hematogenous dissemination. Any condition that suppresses any of these arms of the immune system puts the patient at increased risk for candidiasis. Phagocytes ingest intestinal microbes. In a patient whose immune system has been compromised, these phagocytes transport microbes out of the intestine, fail to kill them, and finally liberate them in extraintestinal sites. Examples of immunosuppression include hematologic malignancy, bone marrow or organ transplantation, and immunosuppressive therapy such as cancer chemotherapy and corticosteroid therapy. Total parenteral nutrition (TPN) may result in immunosuppression. Transient hyperglycemia in patients receiving TPN causes an acceleration in the nonenzymatic glycosylation of immunoglobulin G, leading to its inactivation and impairment of complement fixation.¹³¹ In a randomized, prospective study,¹³² long-chain triglycerides in TPN significantly decreased the ratio of helper B cells to suppressor T cells. There is evidence that fat emulsions may impair polymorphonuclear and macrophage function.¹³³ In animal models, TPN induced macrophage suppression with decreased peritoneal macrophage superoxide production and *Candida* phagocytosis, associated with bacterial translocation to mesenteric lymph nodes.¹³⁴

Pathology of *Candida* Colonization and Infectious Syndromes

The evolution of *Candida* microabscesses after hematogenous distribution has been studied in animal models. After intravenous infusion in nonneutropenic animals, the liver, the kidneys, the heart, the eyes, the brain, and the skin show a pattern of intracapillary fungi (yeasts and pseudohyphae) with an accumulation of neutrophils. In time, focal areas of necrosis occur, resulting in organ dysfunction that ultimately leads to death.

In nonneutropenic patients who are dying of candidiasis, a similar histologic picture and a similar pattern of organ involvement are seen. The organs most frequently involved are the brain, the heart, the kidneys, and the eyes. *Candida* produces microabscesses and, frequently, noncaseating granulomas. The histologic picture suggests that blood-borne fungi are lodged in the microvasculature, resulting in vasculitis. This multifocal microscopic disease explains the absence of localizing findings despite the progressive cerebral, renal, and cardiac dysfunction seen in infected persons.

The high incidence of cerebral involvement has been underscored by findings in an autopsy study of 41 nonneutropenic patients with tissue-verified deep candidiasis, of whom 26 (63%) had undergone major operations.¹³⁵ Nineteen (46%) were found to have cerebral candidal infections; all 19 individuals had antecedent proven or suspected gram-negative sepsis and had been treated with appropriate antibiotic therapy. In every patient studied, *Candida* organisms were identified at sites outside the brain, including the kidneys (90%) and the heart (80%). Candidiasis produced intracerebral microabscesses and noncaseating granulomas without diffuse leptomeningitis.

In a nearly identical autopsy series, 18 patients with disseminated candidiasis were found to have myocardial involvement.¹³⁶ This mycosis was characterized by myocardial microabscesses with yeasts and pseudohyphal elements. Noncaseating granulomas were seen in only one patient. Eight patients had recognized conduction disturbances, including alterations in both heart rate and heart rhythm.

As in the animal models, ocular involvement is a common finding in patients with disseminated candidiasis and by itself is an indication for systemic therapy. The eye pathology is a chorioretinitis with microabscess formation. Fundoscopic examination, mandatory in patients suspected of having systemic *Candida* infection, reveals patchy, wool-like tufts [see Figure 3].

Despite the frequent finding of *Candida* in sputum cultures, primary *Candida* pneumonitis is extremely uncommon¹³⁷; when it occurs, it usually follows aspiration of oropharyngeal contents. However, pulmonary involvement resulting from hematogenous seeding is common.

20 VIRAL INFECTION

Jennifer W. Janelle, M.D., and Richard J. Howard, M.D., Ph.D.

Approach to Viral Exposure

Compared with primary care physicians, such as internists, family physicians, and pediatricians, surgeons are seldom called on to treat viral infections. Viral infections nonetheless deserve the attention of surgeons because these infections can cause illness in patients after operation, albeit infrequently, and can spread to the hospital staff. Some viral infections (e.g., infections with the hepatitis viruses, HIV, and cytomegalovirus [CMV]) can result from administration of blood or blood products or can be transmitted to hospital personnel through needle-stick injury. Viral infections can also result from organ transplantation or trauma (e.g., rabies, which is transmitted by the bite of an infected animal). Some viruses, especially the herpesviruses, frequently infect immunosuppressed patients, in whom the viruses can cause severe illness and even death. In many surgical practices, there are increasing numbers of immunosuppressed patients, including organ transplant recipients; patients with cancer; patients receiving cancer chemotherapy, steroids, and other immunosuppressive drugs; the elderly; and the malnourished. Some viral infections can cause neoplastic disease for which operation may become necessary. Examples are hepatitis B virus (HBV) and hepatitis C virus (HCV), which are implicated in the etiology of hepatocellular carcinoma; Epstein-Barr virus (EBV), which can cause a lethal lymphoproliferative disorder in immunosuppressed patients; and human T cell lymphotropic virus type I (HTLV-I), which can induce a T cell leukemia. Viral infections very likely can cause other neoplasms as well.

Prevention of Transmission of HIV, Hepatitis B Virus, and Hepatitis C Virus

TRANSMISSION FROM PATIENTS TO HEALTH CARE WORKERS

The Centers for Disease Control and Prevention (CDC) has published extensive recommendations for preventing transmission of HIV, the etiologic agent of AIDS.¹⁻⁵ Applicable to clinical and laboratory staffs,^{3,4} to workers in health care settings [see Table 1]¹ and in other occupational settings,¹ and to health care workers performing invasive procedures,¹⁻⁵ these precautions are appropriate for preventing transmission not only of HIV but also of other blood-borne viruses, including HBV and HCV. The recommendations share the objective of minimizing exposure of personnel to blood and body secretions from infected patients, whether through needle-stick injury or through contamination of mucous membranes or open cuts.

Despite the apparently low risk of such exposure, the CDC recommends enforcement of these as well as other standard infection control precautions, regardless of whether health care workers or

patients are known to be infected with HIV or HBV. The CDC has taken the position that blood and body fluid precautions should be used consistently for all patients because medical history and physical examination cannot reliably identify all patients infected with HIV or other blood-borne pathogens and because in emergencies there may be no time for serologic testing. If these universal precautions are implemented, as the CDC recommends,¹⁻⁵ no additional precautions should be necessary for patients known to be infected with HIV.

The CDC does not recommend routine HIV serologic testing for all patients.¹⁻⁵ HIV serologic testing of patients is recommended for management of health care workers who sustain parenteral or mucous membrane exposure to blood or other body fluids, for patient diagnosis and treatment, and for counseling associated with efforts to prevent and control HIV transmission in the community.¹⁻⁵

Nevertheless, some hospitals and physicians are likely to perform serologic testing of patients if it is possible that health care workers will be exposed to the patients' blood or other body fluids, as would be the case with patients undergoing major operative procedures or receiving treatment in intensive care units. Those who favor routine preoperative testing of patients undergoing invasive procedures maintain that precautions are more likely to be followed and additional steps taken to lower the likelihood of virus transmission from patients to health care workers when it is known which patients are HIV positive.^{6,7} If such policies are adopted, the CDC advocates certain principles: (1) obtain consent for testing, (2) inform patients of results and provide counseling to seropositive patients, (3) ensure confidentiality, (4) ensure that seropositive patients will not receive compromised care, and (5) prospectively evaluate the efficacy of the program in reducing the incidence of exposure of health care workers to blood or body fluids of patients who are infected with HIV.

Although possible acquisition of HIV infection is the major concern for any health care worker who is exposed to blood products in the workplace, acquisition of viral hepatitis is actually much more likely. From a single needle-stick exposure, the estimated average risk of HIV transmission is 0.3%, whereas that of HCV transmission ranges from 0% to 10%.⁸ The risk that HBV will be transmitted from a single needle-stick exposure varies according to the hepatitis B e antigen (HBeAg) status of the source patient, ranging from 1% to 6% for HBeAg-negative patients to 22% to 40% for HBeAg-positive patients.⁹⁻¹¹ That health care workers are at increased risk for hepatitis B is indicated by the seroprevalence of HBV in this population, which is two to four times that in the general United States population (6% to 15% versus < 5%).^{9,12} This seroprevalence is expected to decrease with the availability of the hepatitis B vaccine and the mandate from the Occupational Safety

Table 1 Precautions to Prevent Transmission of HIV¹**Universal Precautions**

1. All health care workers should use appropriate barrier precautions routinely to prevent skin and mucous membrane exposure when contact with blood or other body fluids of any patient is anticipated. Gloves should be worn for touching blood and body fluids, mucous membranes, or nonintact skin of all patients; for handling items or surfaces soiled with blood or body fluids; and for performing venipuncture and other vascular-access procedures. Gloves should be changed after contact with each patient. During procedures that are likely to generate aerosolized droplets of blood or other body fluids, masks and protective eyewear or face shields should be worn to prevent exposure of mucous membranes of the mouth, nose, and eyes. Gowns or aprons should be worn during procedures that are likely to generate splashes of blood or other body fluids.
2. Hands and other skin surfaces should be washed immediately and thoroughly if contaminated with blood or other body fluids. Hands should be washed immediately after gloves are removed.
3. All health care workers should take precautions to prevent injuries caused by needles, scalpels, and other sharp instruments or devices during procedures; when cleaning used instruments; during disposal of used needles; and when handling sharp instruments after procedures. To prevent needle-stick injuries, needles should not be recapped, purposely bent or broken by hand, removed from disposable syringes, or otherwise manipulated by hand. After they are used, disposable syringes and needles, scalpel blades, and other sharp items should be placed in puncture-resistant containers for disposal; the puncture-resistant containers should be located as close as practical to the area of use. Large-bore reusable needles should be placed in a puncture-resistant container for transport to the reprocessing area.
4. Although saliva has not been implicated in HIV transmission, to minimize the need for emergency mouth-to-mouth resuscitation, mouthpieces, re-

suscitation bags, or other ventilation devices should be available for use in areas in which the need for resuscitation is predictable.

5. Health care workers who have exudative lesions or weeping dermatitis should refrain from all direct patient care and from handling patient care equipment until the condition resolves.
6. Pregnant health care workers are not known to be at greater risk for contracting HIV infection than health care workers who are not pregnant; however, if a health care worker acquires HIV infection during pregnancy, the infant is at risk for infection resulting from perinatal transmission. Because of this risk, pregnant health care workers should be especially familiar with and strictly adhere to precautions to minimize the risk of HIV transmission.

Additional Precautions for Invasive Procedures

1. All health care workers who participate in invasive procedures must use appropriate barrier precautions routinely to prevent skin and mucous membrane contact with blood and other body fluids of all patients. Gloves and surgical masks must be worn for all invasive procedures. Protective eyewear or face shields should be worn for procedures that commonly result in the generation of aerosolized droplets, splashing of blood or other body fluids, or the generation of bone chips. Gowns or aprons made of materials that provide an effective barrier should be worn during invasive procedures that are likely to result in the splashing of blood or other body fluids. All health care workers who perform or assist in vaginal or cesarean deliveries should wear gloves and gowns when handling the placenta or the infant until blood and amniotic fluid have been removed from the infant's skin and should wear gloves during postdelivery care of the umbilical cord.
2. If a glove is torn or a needle-stick or other injury occurs, the glove should be removed and a new glove used as promptly as patient safety permits; the needle or instrument involved in the incident should also be removed from the sterile field. In the event of an injury, postexposure evaluation should be sought as soon as possible.

& Health Administration (OSHA) directing that all health care workers potentially exposed to blood or other potentially infectious material either be offered hepatitis B vaccine free of charge, demonstrate immunity to hepatitis B, or formally decline vaccination.¹³ That vaccination has been effective in decreasing the incidence of hepatitis B in health care workers is shown by the decrease in infection rates from 174/100,000 in 1982 to 17/100,000 in 1995.¹⁴ Most series have not found the seroprevalence of HCV to be higher in health care worker groups at risk than in the general population.¹⁴ That hepatitis B and hepatitis C are much more common than HIV in health care workers is a strong argument for using universal precautions in all patients.

One reason why hepatitis B is so much more transmissible than HIV is the greater number of virus particles in the blood of hepatitis B carriers. These persons have blood concentrations of 10^8 to 10^9 virus particles/ml, compared with 10^2 to 10^4 /ml for persons with HIV infection and 10^6 /ml for persons with HCV infection.

The extensive guidelines that have been established by the CDC for the care of patients with HBV infection^{4,15-17} also apply to patients with HIV infection. Patients known to have hepatitis B, hepatitis C, or AIDS need not be put in a private room unless they are fecally incontinent or are shedding virus in body fluids. Health care workers should wear gloves and gowns when they have contact with or may have contact with a patient's blood, feces, or other body fluids. Needles used for drawing blood should be disposed of with special care: they must not be reused, recapped, or removed from the syringe. Hands must be washed before and after direct contact with the patient or with items that have been in contact with the patient's blood, feces, or body fluids.

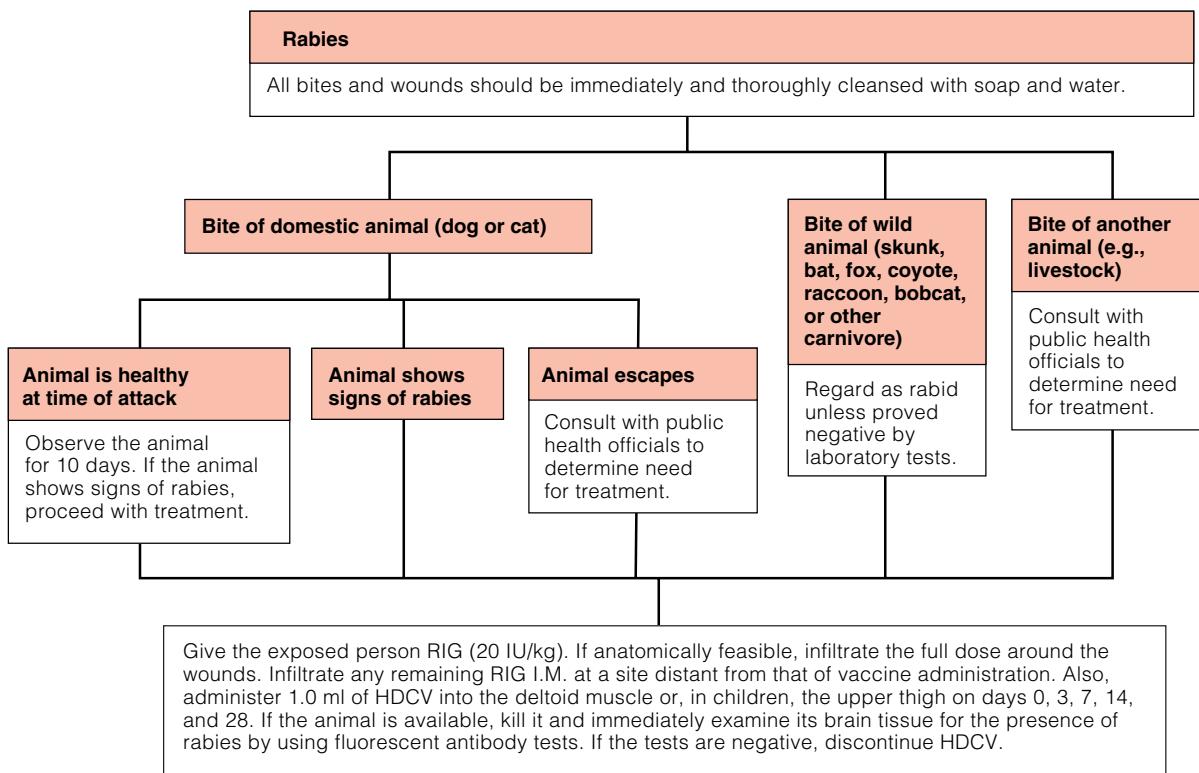

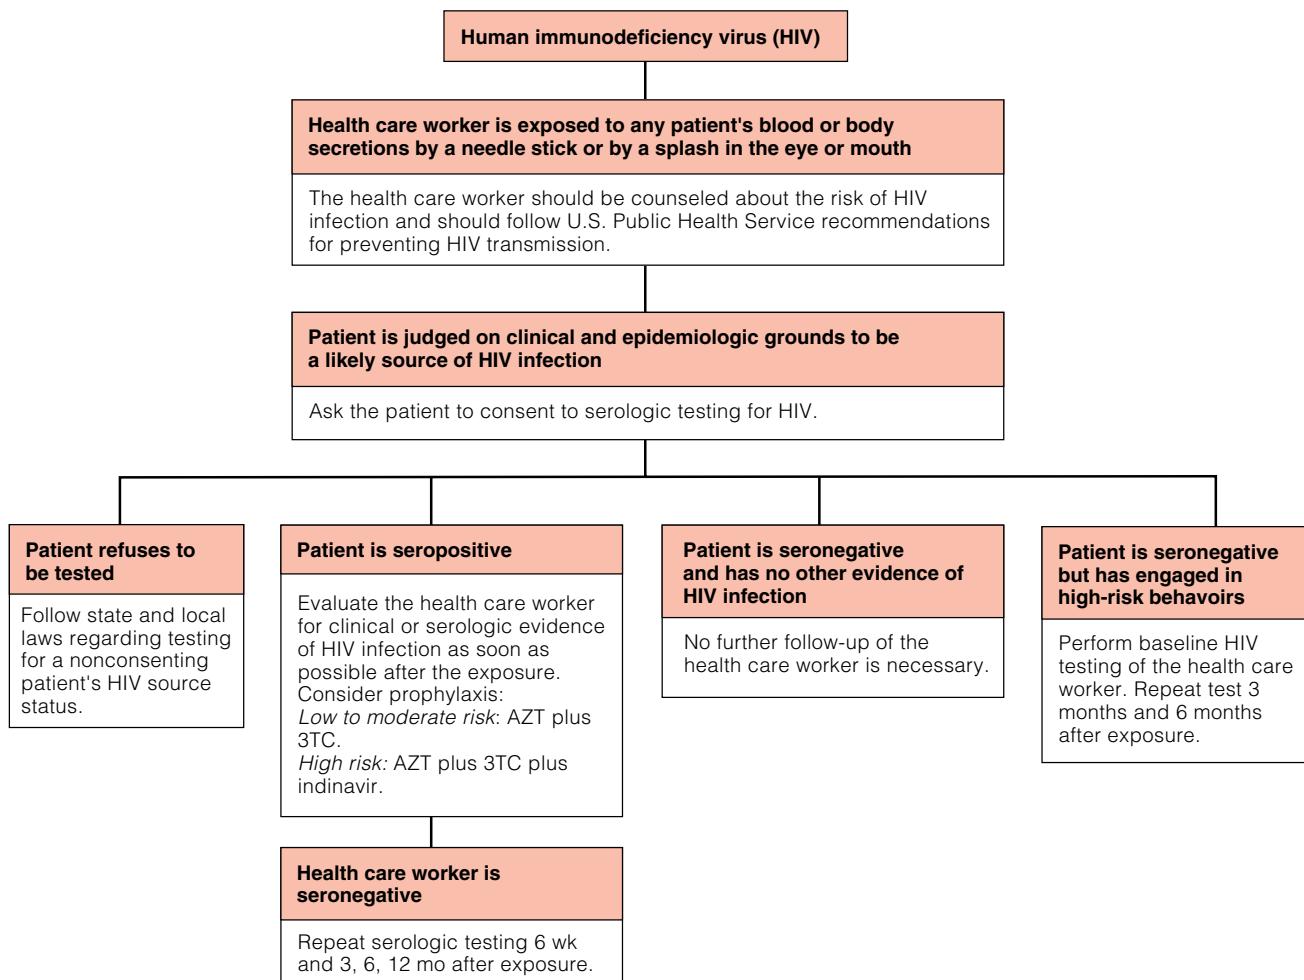

Published recommendations also provide guidelines for health care workers who are not directly involved in patient care (e.g., housekeeping personnel, kitchen staff, and laundry workers).¹⁻⁷

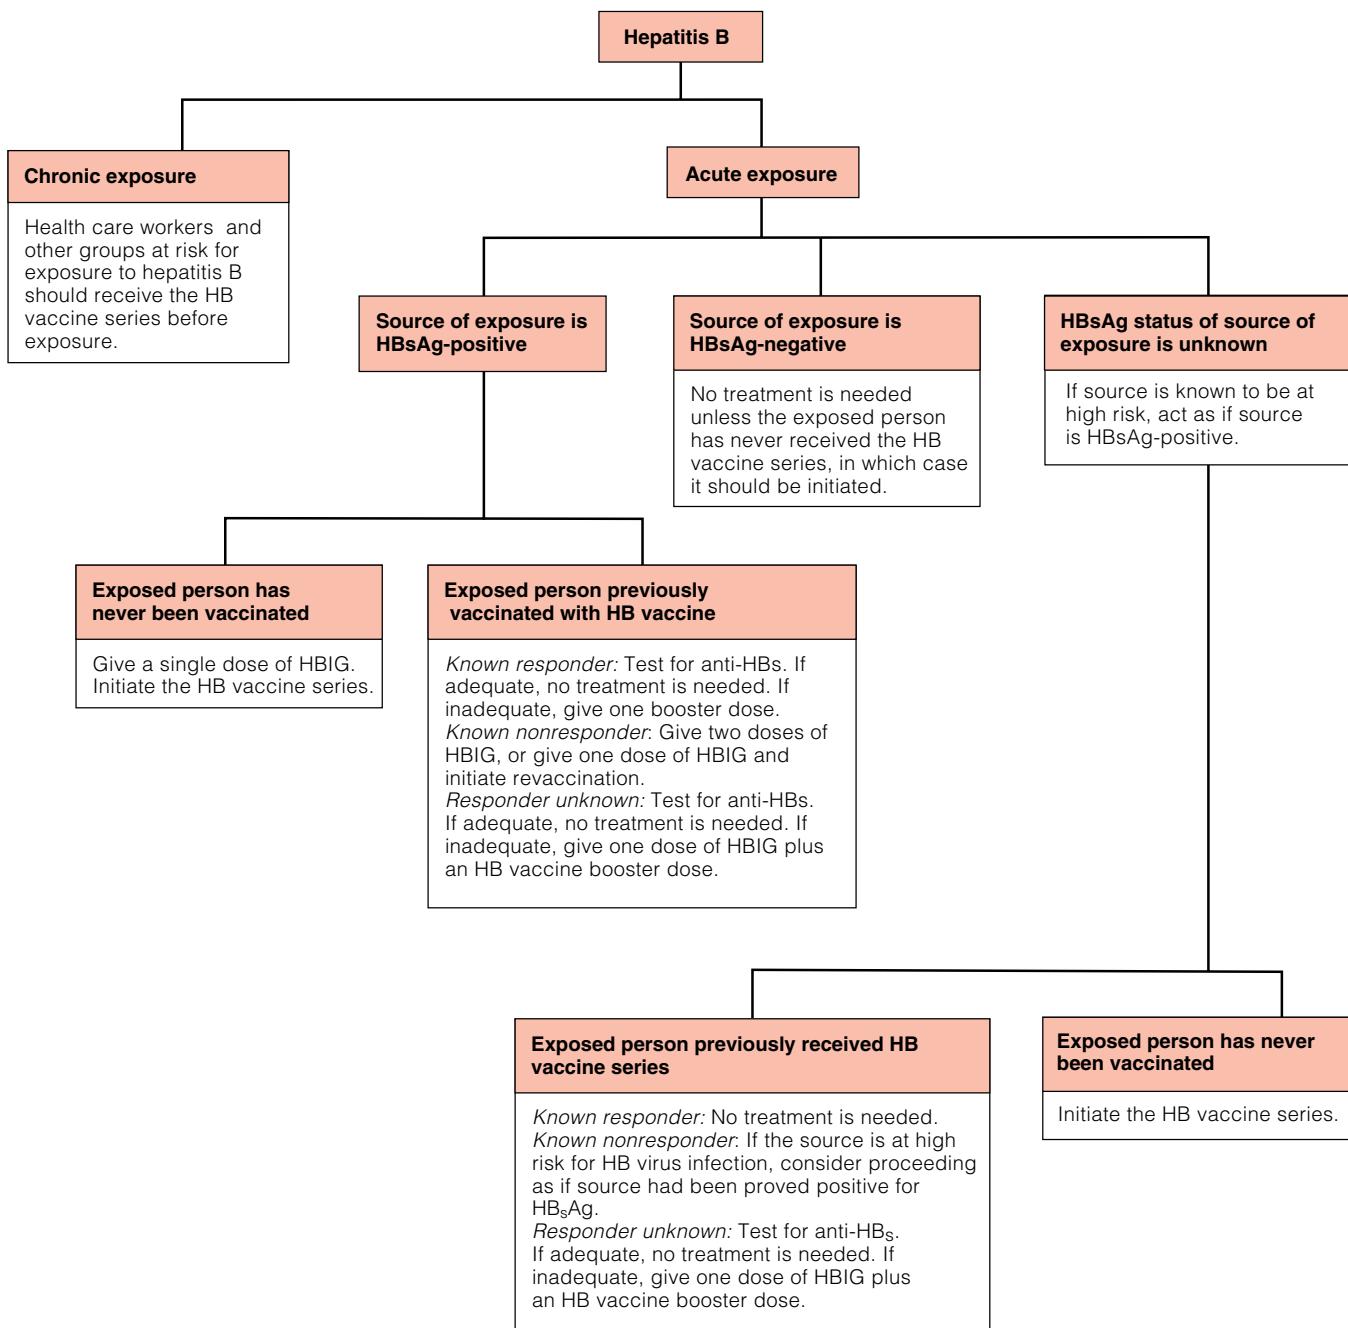

No additional precautions are necessary for these individuals because their risk of acquiring HIV, HCV, or HBV is so low; in fact, transmission to them has not been documented. However, staff should be educated about appropriate procedures. Workers should wear gloves when handling blood and body fluids of all patients and should wear masks in areas where blood may spatter (e.g., the dialysis unit or the obstetrics unit).

TRANSMISSION FROM HEALTH CARE WORKERS TO PATIENTS

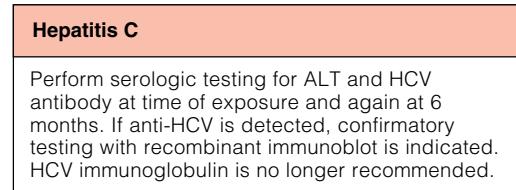

To date, there have been only two reports of HIV transmission from infected health care workers to patients. In one report, DNA sequence analysis linked a Florida dentist with AIDS to HIV infection in six of his patients.¹⁸ In the other, an orthopedic surgeon in France may have transmitted HIV to one of his patients in the course of an operation.¹⁹ Despite extensive investigation, no break in infection control precautions was documented in either case, nor was any clear-cut means of transmission identified.

HBV transmission from health care workers to patients is known to occur. Nineteen case reports have documented physician-to-patient transmission.²⁰⁻³² Eighteen of the 19 physicians were surgeons; seven of the surgeons were gynecologists, three were cardiac surgeons, and one was an orthopedic surgeon. All of the physicians were positive for HBeAg. Three of the gynecologists made a practice of handling needle tips. Of the 135 patients studied, 121 had clinical hepatitis B, and 14 had only serologic evidence of infection. Forty-one of the 135 patients were accounted for by the only nonsurgeon, a family practitioner from rural Switzerland. There are many additional cases of HBV having been transmitted by dentists and oral surgeons. In addition, three patients' relatives, two members of a surgeon's family, and one laboratory technician became infected.

Approach to Viral Exposure

In five studies, patients of 16 health care workers (including two surgeons) who were positive for hepatitis B surface antigen (HBsAg) were prospectively followed for evidence of hepatitis.³³⁻³⁷ A total of 784 patients were followed and were compared with 656 patients cared for by health care workers who were HBsAg negative. None of the patients acquired overt hepatitis or became seropositive for HBsAg. Eight (1.02%) of the 784 patients cared for by HBsAg-positive health care workers developed antibody to HBsAg (anti-HBs), but so did six (0.91%) of the 656 patients cared for by health care workers who were negative for HBsAg. These reports suggest that the likelihood of infected surgeons' or other health care workers' transmitting HIV or HBV to their patients is extremely low. Chronic carriers of HBsAg who are seronegative for HBeAg are much less likely to transmit HBV than persons who are HBeAg positive.

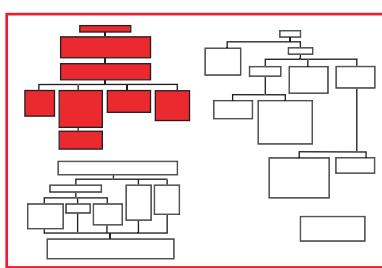

Before the cases of transmission of HIV from the dentist to six of his patients were reported, the CDC had not taken a position on whether HBV- or HIV-infected surgeons should be allowed to continue practicing medicine. After these cases were reported, the CDC held meetings of health care professionals and other interested parties and published its recommendations on July 12, 1991.³⁸ These recommendations called for physicians not to perform "exposure-prone invasive procedures" unless they sought counsel from an expert review panel and were advised under what circumstances, if any, they might be allowed to continue to perform these procedures. Physicians would have to notify prospective patients of their seropositivity. These recommendations were strongly resisted by the medical community because at that time, only one health care worker, the dentist, had been implicated in transmitting HIV to his patients, no mechanism of transmission had been elucidated, no other patients had HIV transmitted by a health care worker, and invasive procedures that were "exposure prone" (exposing the patient to blood of the health care worker) were impossible to define. After subsequent meetings, the CDC abandoned its attempts to define exposure-prone procedures but did not alter its recommendations. Rather, it left it up to the states to define exposure-prone procedures. Subsequently, the President's Commission on AIDS recommended that HIV-infected health care workers should not have to curtail their practices or inform their patients of their infection.

Transmission of HCV from health care workers to patients has been reported. In one such case, a cardiac surgeon transmitted HCV to at least five patients during valve replacement surgery.³⁹ In another, an anesthesiologist in Spain may have infected more than 217 patients by first injecting himself with narcotics, then giving the remainder of the drugs to his patients.⁴⁰ At present, no recommendations exist for restricting the professional activities of health care workers with HCV infection.

Management of Viral Exposure

HIV

The CDC has issued recommendations for the management of potential exposure of health care workers to HIV.^{1,4,41} If a health care worker is exposed by a needle stick or by a splash in the eye or mouth to any patient's blood or other body fluids, and the HIV serostatus of the patient is unknown, the patient should

be informed of the incident and, if consent is obtained, tested for serologic evidence of HIV infection. If consent cannot be obtained, procedures for testing the patient should be followed in accordance with state and local laws. Testing of needles or other sharp instruments associated with exposure to HIV is not recommended, because it is unclear whether the test results would be reliable and how they should be interpreted.⁴¹

Health care workers exposed to HIV should be evaluated for susceptibility to blood-borne infection with baseline testing, including testing for HIV antibody. If the patient who is the source of exposure is seronegative and exhibits no clinical evidence of AIDS or symptoms of HIV infection, further follow-up of the health care worker is usually unnecessary.⁴¹ If the source patient is seropositive or is seronegative but has engaged in high-risk behaviors, baseline and follow-up HIV-antibody testing of the health care worker at 6 weeks, 3 months, and 6 months after exposure should be considered.⁴¹ Seroconversion usually occurs within 6 to 12 weeks of exposure; infrequently, it occurs considerably later. Three cases of delayed HIV seroconversion among health care workers have been reported.⁴²⁻⁴⁴ In all three patients, an HIV antibody test yielded negative results at 6 months but positive results at some point during the following 1 to 7 months. In two cases, coinfection with HCV had occurred and took an unusually severe course. At present, it is unclear whether coinfection with these two viruses directly influences the timing or severity of either infection, but most experts recommend close monitoring for up to 1 year for health care workers exposed to both viruses in whom serologic evidence of HCV infection develops.

Treatment of the exposed health care worker should begin with careful washing of the exposure site with soap and water. Mucous membranes should be flushed with water. There is no evidence that either expressing fluid by squeezing the wound or applying antiseptics is beneficial, though antiseptics are not contraindicated. The use of caustic agents (e.g., bleach) is not recommended.

Any health care worker concerned about exposure to HIV should receive follow-up counseling regarding the risk of HIV transmission, postexposure testing, and medical evaluation, regardless of whether postexposure prophylaxis is given. HIV antibody testing should be performed at specified intervals for at least 6 months after the exposure (e.g., at 6 weeks, 3 months, and 6 months). The risk of HIV transmission is believed to depend on several factors: how much blood is involved in the exposure, whether the blood came from a source patient with terminal AIDS (thought to be attributable to the presence of large quantities of HIV), whether any host factors are present that might affect transmissibility (e.g., abnormal CD4 receptors for HIV), and whether the source patient carries any aggressive HIV viral mutants (e.g., syncytia-inducing strains). Factors indicating exposure to a large quantity of the source patient's blood (and thus a high risk of HIV transmission) include a device visibly contaminated with the patient's blood, a procedure that involved a needle placed directly in a vein or artery, and a deep injury.⁴⁵

During the follow-up period, especially the first 6 to 12 weeks, exposed health care workers should follow the U.S. Public Health Service recommendations for preventing further transmission of HIV.¹⁻⁴ These recommendations include refraining from blood, semen, or organ donation and either abstaining from sexual intercourse or using measures to prevent HIV transmission during intercourse.⁴⁶

The circumstances of the exposure should be recorded in the worker's confidential medical record and should include the following:

Table 2 Recommendations for Hepatitis B Prophylaxis after Percutaneous or Per mucosal Exposure¹⁵

Hepatitis B Vaccination Status of Exposed Person	HBsAg Status of Source of Exposure		
	HBsAg-Positive	HBsAg-Negative	Untested or Unknown
Unvaccinated	Give single dose of HBIG Initiate HB vaccine series	Initiate HB vaccine series	Initiate HB vaccine series
Previously vaccinated Known responder	Test exposed person for anti-HBs If anti-HBs levels are adequate,* no treatment is needed; if they are inadequate, give an HB vaccine booster dose	No treatment is needed	No treatment is needed
	<i>No response to three-dose vaccine series:</i> give two doses of HBIG or one dose of HBIG plus revaccination <i>No response to three-dose vaccine series plus revaccination:</i> give one dose of HBIG as soon as possible and a second dose 1 mo later	No treatment is needed	If source is at high risk for hepatitis B infection, consider proceeding as if source had been demonstrated to be HBsAg-positive
Known nonresponder			
Response unknown	Test exposed person for anti-HBs If anti-HBs levels are adequate,* no treatment is needed; if they are inadequate, give one dose of HBIG plus an HB vaccine booster dose	No treatment is needed	Test exposed person for anti-HBs If anti-HBs levels are adequate,* no treatment is needed; if they are inadequate, initiate revaccination

*An adequate anti-HBs level is ≥ 10 mIU/ml, which is approximately equivalent to 10 sample ratio units (SRU) on radioimmunoassay or a positive result on enzyme immunoassay.

1. The date and time of the exposure.
2. Details of the exposure, including (a) where and how the exposure occurred, (b) the type and amount of fluid or other material involved, and (c) the severity of the exposure (for a percutaneous exposure, this would include the depth of injury and whether fluid was injected; for a skin or mucous membrane exposure, it would include the extent and duration of contact and the condition of the skin—chapped, abraded, or intact).
3. A description of the source of the exposure, including (if known) whether the source material contained HIV or other blood-borne pathogens, whether the source was HIV positive, the stages of any diseases present, whether the patient had previously received antiretroviral therapy, and the viral load.
4. Details about counseling, postexposure management, and follow-up.⁴¹

The data currently available on primary HIV infection indicate that systemic infection does not occur immediately. There may be a brief window of opportunity during which postexposure antiretroviral therapy may modify viral replication. Findings from animal and human studies provide indirect evidence of the efficacy of antiretroviral drugs in postexposure prophylaxis. The majority of these studies included zidovudine (AZT); consequently, all post-exposure prophylaxis regimens now in use include AZT. Combination treatment regimens using nucleoside reverse transcriptase inhibitors and protease inhibitors have proved effective. Accordingly, most experts now recommend dual therapy with two nucleosides (zidovudine and lamivudine) for low- to moderate-risk exposures. For high-risk exposures, most experts would add a protease inhibitor (usually either indinavir or nelfinavir) to the two nucleoside reverse transcriptase inhibitors. These medications should be started as soon as possible after the exposure (within hours rather than days) and should be continued for 4 weeks.

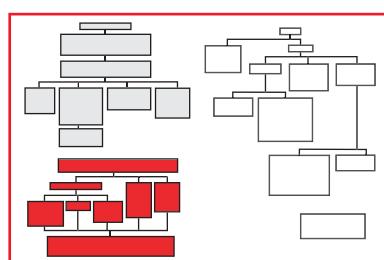

An important component of postexposure care is encouraging and facilitating compliance with the lengthy course of medication. Therefore, careful consideration must be given to the toxicity profiles of the antiretroviral agents chosen. All of these agents have

been associated with side effects, include GI (e.g., nausea or diarrhea), hematologic, endocrine (e.g., diabetes), and urologic effects (e.g., nephrolithiasis with indinavir). According to some early data, 50% to 90% of health care workers receiving combination regimens for postexposure prophylaxis (e.g., zidovudine plus 3TC, with or without a protease inhibitor) reported one or more subjective side effects that were substantial enough to cause 24% to 36% of the workers to discontinue postexposure prophylaxis.⁴⁷⁻⁴⁹

Whether antiretroviral agents should be chosen for postexposure prophylaxis on the basis of the resistance patterns of the source patient's HIV remains unclear. Transmission of resistant strains has been reported⁵⁰⁻⁵²; however, in the perinatal clinical trial that studied vertical transmission of HIV, zidovudine prevented perinatal transmission despite genotypic resistance of HIV to zidovudine in the mother.⁵³ Further study of the significance of genotypic resistance is necessary before definitive recommendations can be made.

HEPATITIS B

Both passive immunization with hepatitis B immune globulin (HBIG) and active immunization with hepatitis B vaccine (HB vaccine) are currently available for prophylaxis against hepatitis B [see Table 2].

Passive Immunoprophylaxis

HBIG is prepared by Cohn ethanol fractionation from plasma selected to contain a high titer of anti-HBs; this process inactivates and eliminates HIV from the final product. In the United States, HBIG has an anti-HBs titer of at least 1:100,000 by radioimmunoassay.⁵⁴ HBIG provides temporary, passive protection. It is indicated after low-volume percutaneous or mucous membrane exposure to HBV; it is not effective for high-

Table 3 Candidates for Hepatitis B Vaccine¹⁵

Preexposure vaccination	Persons with occupational risk (e.g., health care workers, public safety workers)
	Clients and staffs of institutions for the developmentally disabled
	Hemodialysis patients
	Sexually active homosexual men
	Users of illicit injectable drugs
	Recipients of certain blood products (e.g., patients with clotting disorders who receive clotting factor concentrates)
	Household and sexual contacts of HBV carriers
	Adoptees from countries of high HBV endemicity
	Other contacts of HBV carriers (vaccination is usually not required unless there are special circumstances, such as biting or scratching, or medical conditions, such as severe skin disease, that facilitate transmission)
	Populations with high endemicity of HBV infection (e.g., Alaskan natives, Pacific islanders, and refugees from HBV-endemic areas)
	Inmates of long-term correctional facilities
	Sexually active heterosexual persons with multiple sexual partners
	International travelers who spend more than 6 mo in HBV-endemic areas and have close contact with the local population
	All infants born in the United States
	Adolescents 11 to 12 years old who have not previously been vaccinated
Postexposure vaccination	Perinatal exposure (infants born to HBsAg-positive mothers)
	Acute exposure to blood that contains (or might contain) HBsAg
	Sexual partners of persons with acute HBV infections
	Household contacts of persons with acute HBV infections (infants and older persons who have had identifiable blood exposure to the index patient)

volume exposure (e.g., blood transfusion). The recommended dose of HBIG for adults is 0.06 ml/kg I.M. Passive prophylaxis with HBIG should begin as soon as possible after exposure—ideally, within 24 hours.⁵⁴

Active Immunoprophylaxis

Two types of HB vaccine are currently licensed in the United States, plasma-derived vaccine (Heptavax-B) and recombinant vaccine (Recombivax HB and Engerix-B). Heptavax-B contains alum-adsorbed 22 nm HBsAg particles purified from human plasma and processed to inactivate the infectivity of HBV and other viruses. Plasma-derived vaccine is no longer being produced in the United States, but similar vaccines are produced and used in China and other countries. In the United States, use of Heptavax-B is limited to persons allergic to yeast. Recombivax HB and Engerix-B are prepared by recombinant DNA technology in common baker's (or brewer's) yeast, *Saccharomyces cerevisiae*.

For primary vaccination, three I.M. injections (into the deltoid muscle in adults and children and into the anterolateral thigh muscle in infants and neonates) are given, with the second and third doses 1 and 6 months after the first dose.⁵⁴ The dose for Heptavax-B and Engerix-B is 20 µg (volume, 1.0 ml) for persons older than 11 years, and that for Recombivax HB is 10 µg (1.0 ml) for persons

older than 19 years and 5 µg (0.5 ml) for persons 11 to 18 years of age. For immunologically impaired patients, including hemodialysis patients, the dose is 40 µg for all three vaccines. For postexposure prophylaxis with Engerix-B, a regimen of four doses given soon after exposure and 1, 2, and 12 months afterward has been approved.

HB vaccine is more than 90% effective at preventing infection or clinical hepatitis in susceptible persons. Protection is virtually complete in persons who develop adequate antibody. Routine testing for immunity after vaccination is not recommended, but testing should be considered for persons at occupational risk who require postexposure prophylaxis for needle-stick exposure.

Between 30% and 50% of persons who have been vaccinated will cease to have detectable antibody levels within 7 years, but protection against infection and clinical disease appears to persist.^{54,55} The need for booster doses has not been established. Revaccination of individuals who do not respond to the primary series will produce adequate antibody in 15% to 25% of cases after one additional dose and in 30% to 50% after three additional doses.⁵⁶

Although effective HB vaccines have been available since 1982, the incidence of hepatitis B in the United States continued to increase in the first decade of HB vaccine use. In 1991, the Advisory Committee for Immunization Practices (ACIP), citing the safety of the vaccine and the evidence of continuing spread of HBV, recommended universal vaccination of all infants born in the United States.⁵⁷

Recommendations for Exposure to Blood That Contains (or May Contain) HBsAg

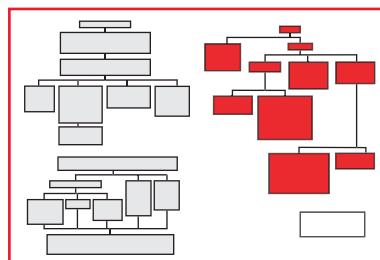

Acute exposure The U.S. Public Health Service has provided recommendations for hepatitis B prophylaxis after accidental percutaneous, mucous membrane, or ocular exposure to blood that contains (or may contain) HBsAg [see Table 2].⁴³ These recommendations are based on consideration of several factors: (1) whether the source of the blood is available, (2) the HBsAg status of the source, and (3) the hepatitis B vaccination and vaccination-response status of the exposed person. After exposure, a blood sample should be obtained from the person who was the source of the exposure and should be tested for HBsAg. The hepatitis B vaccination status and the anti-HBs response status (if known) of the exposed person should be reviewed. Because passive administration of antibody with HBIG does not inhibit the active antibody response to HB vaccine, the two can be given simultaneously.

Chronic exposure The U.S. Public Health Service recommends that persons who are at risk for exposure to HBV receive the HB vaccine series [see Table 3].⁵⁴ Health care workers who are at increased risk for acquiring hepatitis B include all physicians (especially surgeons), dentists, and laboratory and support personnel, such as nurses and technicians who work in the operating room or who have contact with infected patients, blood or blood products, or excreta. Because of their frequent exposure to blood and their high risk of hepatitis B, all surgeons should receive HB vaccine. As of 1994, however, only 50% of surgeons had been vaccinated, despite the proven efficacy and safety of the vaccine and surgeons' increased risk of exposure.⁵⁸ Hospital personnel who do not have frequent contact with blood or blood products (e.g., the janitorial, laundry, and kitchen staffs) need not be vaccinated.

Screening of personnel and patients for anti-HBs before vaccination is indicated only for individuals in high-risk groups; it has not been found to be cost-effective outside these groups.

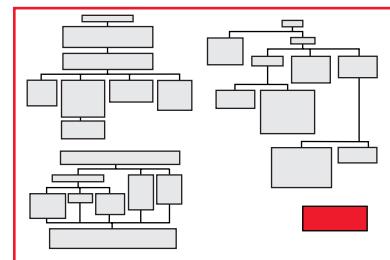

HEPATITIS C

The only tests currently approved by the U.S. Food and Drug Administration for diagnosis of hepatitis C are those that measure antibody to HCV. These tests detect anti-HCV in at least 97% of infected patients, but they cannot distinguish between acute, chronic, and resolved infection.⁵⁹ The positive predictive value of enzyme immunoassay (EIA) for anti-HCV varies depending on the prevalence of the infection in the population. Therefore, supplemental testing of a specimen with a positive EIA result with a more specific assay (e.g., the recombinant immunoblot assay [RIBA]) may detect false positives, especially when asymptomatic persons are being tested. Qualitative polymerase chain reaction (PCR) testing for HCV RNA can also be used to identify HCV. This test can detect HCV at concentrations as low as 100 to 1,000 viral genome copies/ml, and it can detect HCV RNA in serum or plasma within 1 to 2 weeks after viral exposure and weeks before alanine aminotransferase (ALT) levels rise or anti-HCV appears.⁵⁹ Under optimal conditions, the reverse transcriptase PCR assay for HCV can identify 75% to 85% of persons who are anti-HCV-positive and more than 95% of persons with acute or chronic hepatitis C.⁵⁹ Quantitative assays for measuring HCV RNA are also available but are less sensitive and should not be used as primary tests for confirming or excluding the diagnosis of HCV infection or monitoring the end point of treatment.⁵⁹ The data currently available on prevention of HCV infection with immune globulin (IG) indicate that this approach is not effective as postexposure prophylaxis for HCV infection.⁵⁹ Interferon may have a role in the treatment of acute hepatitis C: several studies have shown that interferon may delay or prevent the onset of chronic hepatitis C in patients treated early in the course of acute HCV infection.⁶⁰⁻⁶²

RABIES

The CDC has made recommendations for the prevention of rabies in people bitten by animals [see Table 4].⁶³ Bite wounds should always be thoroughly scrubbed with soap and water. Postexposure antirabies treatment includes both rabies immune globulin (RIG) and human diploid cell (rabies) vaccine (HDCV). The decision to administer such treatment should be based on the following considerations.

*Species and Availability of Biting Animal*

In the United States, rabies is most commonly transmitted by skunks, raccoons, foxes, and bats. Livestock occasionally transmit the virus, but rodents and lagomorphs (i.e., rabbits and hares) are rarely infected.⁶⁴ In different parts of the country, different animals predominate in the transmission of the virus. The likelihood that domestic cats or dogs in the United States will be infected varies from region to region. The chances of rabies transmission by a domestic animal that has been properly immunized are minimal.

Whether an animal is available for observation after biting someone also influences the need for antirabies prophylaxis. In certain cases, an animal that bites a person must be killed and tissue from its brain checked for the presence of rabies by fluorescent antibody tests as soon as possible [see Table 4].

Type of Exposure

Infected animals transmit rabies primarily by biting, although licking may introduce the virus into open cuts in skin or mucous membranes. Transmission occasionally occurs as a result of aerosol exposure: the virus may be excreted in the urine and feces of infected bats, aerosolized during urination and defecation, and then inhaled, for example, by spelunkers exploring caves.

Table 4 Rabies Postexposure Prophylaxis⁶³

Animal Species		Condition of Animal at Time of Attack	Treatment of Exposed Person*
Domestic	Dog, cat	Healthy and available for 10 days of observation	None, unless animal develops rabies [†]
		Rabid or suspected rabid	RIG (20 IU/kg) [‡] and HDCV [§] (five 1.0 ml doses intramuscularly, on days 0, 3, 7, 14, and 28)
		Unknown (escaped)	Consult public health officials. If treatment is indicated, give RIG [‡] and HDCV
Wild	Skunk, bat, fox, coyote, bobcat, raccoon, other carnivores	Regard as rabid unless proved negative by laboratory tests	RIG (20 IU/kg) [‡] and HDCV (five 1.0 ml doses intramuscularly, on days 0, 3, 7, 14, and 28)
Other	Livestock, rodents, lagomorphs (rabbits and hares)		Consider individually. Local and state public health officials should be consulted on questions about the need for rabies prophylaxis. Bites of squirrels, hamsters, guinea pigs, chipmunks, gerbils, rats, mice, other rodents, and lagomorphs almost never call for antirabies prophylaxis.

*All bites and wounds should immediately be thoroughly cleansed with soap and water. If antirabies treatment is indicated, both rabies immune globulin (RIG) and human diploid cell rabies vaccine (HDCV) should be given as soon as possible, regardless of the interval from exposure. (The administration of RIG is the more urgent procedure. If HDCV is not immediately available, start RIG and give HDCV as soon as it is obtained.) Local reactions to vaccines are common and do not contraindicate continuing treatment. Discontinue vaccine if fluorescent antibody tests of the animal are negative.

[†]During the usual holding period of 10 days, begin treatment with RIG and HDCV at first sign of rabies in a dog or cat that has bitten someone. The symptomatic animal should be killed immediately and tested.

[‡]The full dose should be infiltrated around the wounds; any remaining RIG should be given I.M. at a site distant from that of vaccine administration. If RIG is not available, use antirabies serum, equine (ARS). Do not use more than the recommended dosage of RIG or ARS.

[§]HDCV should be administered into the deltoid (not the gluteus) muscle in adults and adolescents. In children, it may be administered into the upper thigh.

^{||}The animal should be killed and tested as soon as possible. Holding for observation is not recommended.

Circumstances of the Bite

An unprovoked attack is more indicative of a rabid animal than is a provoked attack.

If the animal shows signs of rabies or the patient has been bitten by a wild animal that is not captured, the patient should be treated as soon as possible with both RIG and HDCV. The recommended dose of RIG for postexposure prophylaxis is 20 IU/kg.⁶³ If anatomically feasible, the entire dose of RIG should be infiltrated into the area around the wound.^{65,66} Postexposure HDCV should be given I.M. in five 1.0 ml doses on days 0, 3, 7, 14, and 28.⁶³ Those with adequate preexposure immunization should receive two 1.0 ml doses of HDCV I.M. on days 0 and 3 but should receive no RIG. For adults, the vaccine should be administered in the deltoid area. For children, the anterolateral aspect of the thigh is also acceptable. The gluteal area should never be used for HDCV injections, because administration in this area results in lower neutralizing antibody titers.⁶³ HDCV must not be given in the same region as RIG.

The CDC recommends that preexposure immunization be considered for high-risk groups, such as animal handlers, certain labo-

ratory workers and field personnel, and persons planning to stay for more than 1 month in areas where canine rabies is highly prevalent and access to appropriate medical care is limited. The recommended preexposure regimen is 0.1 ml of HDCV on days 0, 7, and 21 or 28.⁶⁷ Testing for adequate antibody response is not necessary for persons at low risk for exposure, but administration of booster doses every 2 to 3 years is recommended for those at high risk for exposure. Postexposure treatment for persons who have received preexposure immunization consists of 1 ml HDCV on days 0 and 3 only, without RIG.⁶⁸

Although only a few cases of clinical rabies occur each year in the United States, approximately 30,000 persons a year are given postexposure prophylaxis. In 1992, 49 states, the District of Columbia, and Puerto Rico collectively reported 8,644 cases of animal rabies and one case of human rabies to the CDC.⁶⁹ The total expense associated with one rabid dog in California was \$105,790, even though no human contracted rabies.⁷⁰ This amount represents the costs of human antirabies treatment, vaccination of other animals, and animal-containment programs.

Discussion

Size and Structure of Viruses

Viruses are among the smallest and simplest of microorganisms. Human viruses can be as small as 18 to 26 nm in diameter (parvoviruses) or as long as 300 nm (vaccinia virus), slightly longer than *Chlamydia* (a bacterium). Viruses do not have the complex enzyme systems required for synthesis of nucleic acid precursors, they lack ribosomes for protein synthesis, and they have no energy-generating mechanism. Consequently, they cannot replicate outside cells.

The core of a virus is made of either RNA or DNA, but never both. The nucleic acid can be either single stranded or double stranded. This nucleic acid core is surrounded by the capsid, which is a protein coat made up of capsomers, repetitive subunits consisting of one protein or at most a few. Because the viral nucleic acid must code for coat proteins, a limitation in the number of capsid proteins conserves viral nucleic acid. The capsid protects the nucleic acid from nucleases in the environment, serves as its vehicle of transmission from one host to another, and plays a role in the attachment of the virus to the receptor sites on susceptible cells. The complete nucleic acid–protein coat complex is termed the nucleocapsid. For many viruses, the nucleocapsid is the complete virus particle, the virion. Other viruses, such as herpesviruses, may acquire an envelope, an additional lipid-containing membrane coat around the nucleocapsid, by budding through a membrane of the host cell [see Figure 1]. Some viruses may also have an enzyme associated with their core that replicates the nucleic acid. Examples are the DNA polymerase of the HBV and the reverse transcriptase of retroviruses.

Classification of Viruses

Viruses, like other organisms, are classified into families, genera, and species, but most viral species do not have formal names and in practice are referred to by common names (e.g., cytomegalovirus, coxsackievirus, Norwalk virus, and varicella-zoster virus). Viruses can also be classified by chemical characteristics and by

structural characteristics determined from electron microscopy (e.g., dimensions and site of assembly). Viruses are categorized into two broad groups depending on whether their nucleic acid is RNA or DNA. These two groups can be subdivided first according to whether the nucleic acid is single stranded or double stranded and then according to the presence or absence of an envelope. Single-stranded RNA viruses that replicate by means of a DNA step (i.e., retroviruses) are grouped separately from those that do not.

Identification of Viruses

Viruses can be identified by means of (1) serologic tests, (2) isolation of virus, (3) histologic examination, (4) detection of viral antigens, (5) detection of viral nucleic acid, and (6) electron microscopy. One or more of these techniques may be applicable to a given viral infection.

Specimens must be handled properly to maximize the likelihood of identifying the virus. If isolation of the virus is desired, blood and tissue samples should be taken promptly to the virology laboratory and inoculated onto the appropriate cell line. Samples obtained at night or on weekends can be placed in a balanced salt solution or tissue culture medium and kept in a refrigerator until taken to the laboratory. If microscopic identification of the virus is planned, specimens must be preserved appropriately. Routine preservation in formalin, for example, permits visualization of viral inclusions by routine staining and light microscopy. For identification of viral antigens by immunofluorescence techniques, the tissue specimen should be immediately frozen, preferably in liquid nitrogen. Specimens to be examined by electron microscopy must be placed in glutaraldehyde or another appropriate fixative.

SEROLOGIC TESTS

The antibody response to viral antigens can be detected in the serum of patients with viral infections. An IgM response usually indicates recent exposure to the virus, whereas the presence of IgG reflects past exposure.

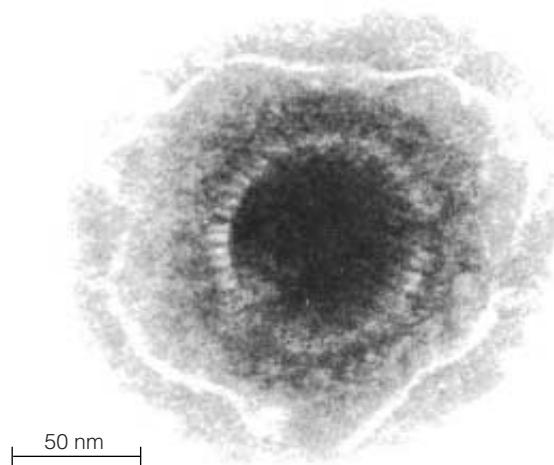

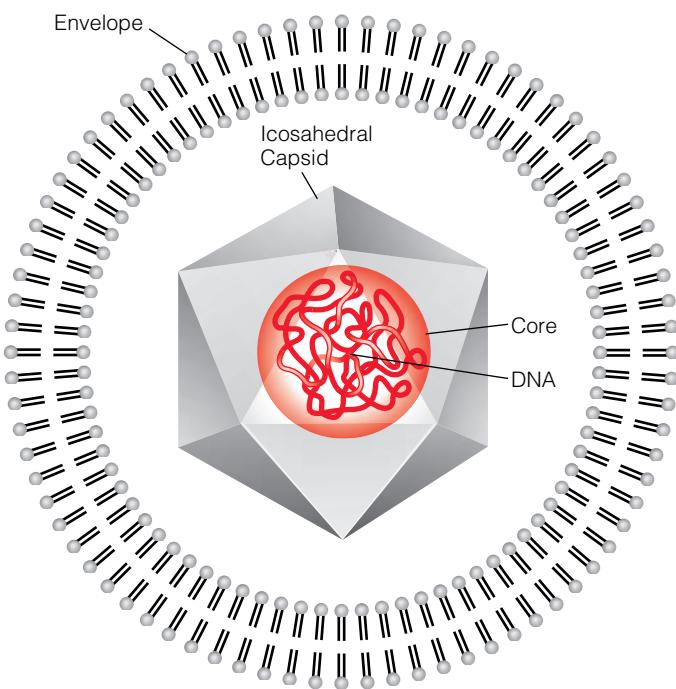

Figure 1 The capsomeres and the irregularly shaped surrounding envelope of a cytomegalovirus are highlighted by negative staining with uranyl acetate (above). A typical herpesvirus (right) consists of a central core containing DNA; an icosahedral capsid, a surrounding layer of protein made up of 162 individual capsomeres; and an envelope, a membrane coat acquired when the virus buds from the nuclear membrane of the host cell.

For most acute primary infections, serum obtained during late recovery or after recovery (convalescent serum) has an increased antibody titer, compared with serum obtained early in the course of the disease (acute serum). Most tests are performed on an initial serum dilution of 1:2 or 1:10 and on serial twofold dilutions thereafter. A fourfold increase in titer (indicated by reactivity of a two-tube dilution) usually represents a significant increase in antibody response and is considered to constitute seroconversion. An immunocompromised host may occasionally fail to mount an antibody response.

Some viruses are so common that patients may already have antibody titers when the disease is first suspected. Herpesviruses are ubiquitous and are present in many healthy people in latent form. At the onset of herpesvirus infections, patients may already have the corresponding antibody. Nevertheless, their antibody titer will almost always increase significantly after recovery.

A variety of serologic tests are available in the clinical laboratory: complement fixation, radioimmunoassay, enzyme-linked immunosorbent assay (ELISA), immunofluorescence, immune precipitation, immune blotting, latex agglutination, virus neutralization, indirect hemagglutination, immune adherence hemagglutination, and hemagglutination inhibition. None of these serologic tests is appropriate for identification of all viruses.

ISOLATION OF VIRUS

The isolation of virus requires appropriate specimen collection and inoculation into animals or onto appropriate cell lines. Blood sent for virus isolation should be unclotted because some viruses, such as herpesviruses, are found primarily in lymphocytes. If cell-associated viruses are suspected, lymphocytes should be inoculated directly onto target cells. Several types of cells are available for growing viruses, and no single cell line is appropriate for all of them. Therefore, it is helpful to the laboratory to know which virus the clinician suspects.

Viruses that grow in cell monolayers in tissue culture have cytopathic effects that can be recognized under the microscope (e.g., rounding, transformation, or death) [see *Figure 2*]. Some viruses, such as rubella, produce no direct cytopathic effects but can be

detected because they inhibit the cytopathic effects of a second test virus. This phenomenon is called viral interference. Other viruses (e.g., myxoviruses) cause changes in the cell membrane so that red blood cells adhere to the cell surface (hemadsorption). The identity of isolated viruses can be confirmed by use of specific antisera that are known to inhibit viral growth.

Tissue suspected of containing an encephalitis or other neurotropic virus can be minced and the extract injected intracerebrally into an infant mouse. If the mouse dies and bacteria cannot be cultured from the brain, the injected material presumably contained such a virus. If antiserum of known specificity neutralizes the virus, the specificity of the antiserum indicates the specific identity of the virus. The criterion for neutralization is that inoculation of neutralized virus will not kill the mouse.

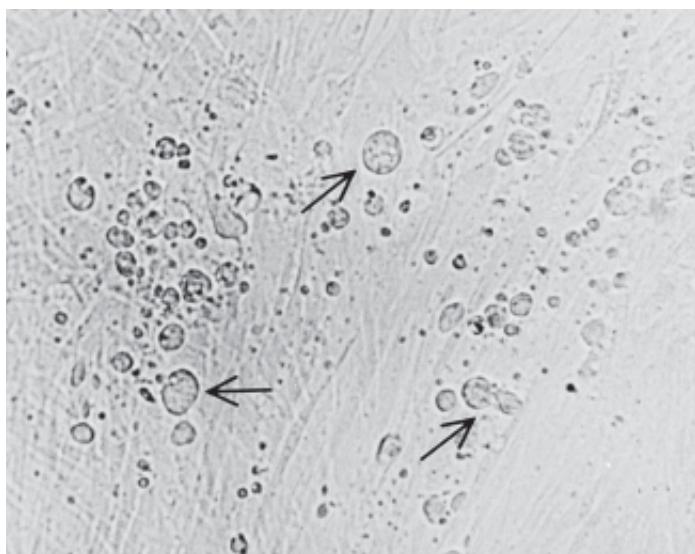

Figure 2 Cells infected with cytomegalovirus become large and round (arrows). Note the uniform appearance of adjacent uninfected cells.

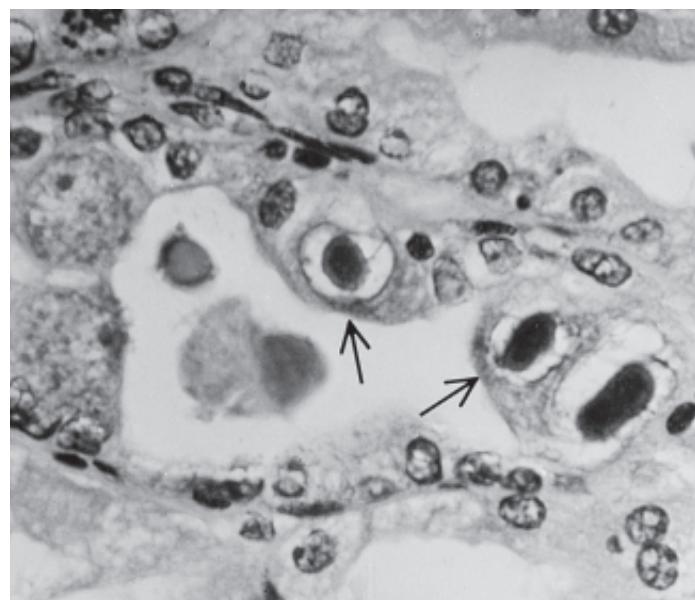

Figure 3 Kidney biopsy shows cytomegalovirus-infected tubular epithelial cells (arrows). In such cells, a dark intranuclear inclusion is surrounded by a clear halo. Inclusions usually indicate sites of previous or current viral replication.

HISTOLOGIC EXAMINATION

Histologic examination of biopsy and autopsy tissues may demonstrate changes that are typical of certain viruses. Members of the herpesvirus group can be characterized by intranuclear inclusions surrounded by a clear halo [see Figure 3]. RNA viruses usually produce inclusions in the cytoplasm; for instance, dark-staining intracytoplasmic inclusions in the brain tissue of animals or patients are diagnostic of rabies infection and are called Negri bodies. Inclusion bodies are either masses of closely packed virus particles or remnants of prior virus replication.

DETECTION OF VIRAL ANTIGENS

Viral antigens can be detected in tissues by techniques employing their corresponding antibodies. If virus is present, these antigens may be visible microscopically under ultraviolet light either by direct immunofluorescence (i.e., in tissue sections stained with fluorescein-labeled antiviral antibody) or by indirect immunofluorescence (i.e., in tissue sections exposed first to antiviral antibody and then to fluorescein-labeled anti- γ -globulin antibody). Fluorescence microscopy requires specimens that are fresh frozen (preferably in liquid nitrogen). Immunofluorescence staining of cells in tissue culture can detect viral antigens before cytopathic effects are evident. Viral antigens in formalin-fixed tissue can be identified by immunohistochemical microscopy (e.g., using peroxidase-labeled antibodies).

DETECTION OF VIRAL NUCLEIC ACID

Viral nucleic acids can be detected in body fluids and tissues at virus concentrations too low to be detected by other means. The PCR permits amplification of even a small number of copies of viral nucleic acid. In theory, even a single copy of a specific DNA can be detected by PCR. Before PCR is performed, DNA can be synthesized from viral RNA by means of reverse transcriptase. The PCR product can be detected by gel electrophoresis and compared with known viral DNA. This test is currently being used to diagnose CMV infection and is more sensitive than current serologic testing for HCV. Nucleic acid hybridization can detect viral nucleic acid in tissue specimens. Epstein-Barr virus genomes

can be detected in this way in EBV-related cancers and lymphoproliferative disorders.

ELECTRON MICROSCOPY

Although seldom used routinely, electron microscopy allows rapid identification (in a matter of hours) of viruses in body fluids, tissues, and tissue extracts. Identification of viruses in body fluids and tissue extracts by this method is easier if the samples are first concentrated by ultracentrifugation, evaporation, or ultrafiltration. HBV has been observed in specimens from hepatitis patients only after ultracentrifugation.

Epidemiology of Viral Infections of Interest to Surgeons

Viral infections are spread to humans via several patterns of transmission: (1) direct transmission from humans with symptomatic infection (e.g., HBV, HCV, herpesviruses, and HIV), (2) transmission from asymptomatic human carriers (e.g., HBV, HCV, HIV, and varicella-zoster virus), (3) transmission from arthropods (e.g., encephalitis and dengue viruses), and (4) transmission from other animals (e.g., rabies virus).

Viral infections are common in immunosuppressed patients in general and especially in recipients of organ transplants, who must take immunosuppressive drugs to prevent rejection. The overwhelming majority of these infections are caused by members of the herpesvirus family (e.g., CMV, herpes simplex viruses, varicella-zoster virus, and EBV); infections with HBV and with papovaviruses (e.g., human papillomavirus, which causes warts, and BK virus) are also frequent.

Because surgical patients are frequently given transfusions of blood or blood products and because hospital staff often incur accidental needle-stick injury, viruses that can be transmitted by these routes are of prime interest to surgeons and their patients. Examples of such viruses are HBV, hepatitis D, HCV, HIV, HTLV-I, and the herpesviruses, including EBV and CMV. These viruses can also be transmitted by organ transplantation either from the cells of the organ itself (e.g., HBV in liver cells or CMV in kidney cells) or from blood that has not been completely removed from the organ. Changes in donor acceptance and screening policies over time have increased the safety of the blood supply and should continue to do so in the future [see Table 5].⁷¹

HIV

Two serotypes of HIV, HIV-1 and HIV-2, have been identified. Both can cause AIDS. HIV-1 accounts for virtually all cases of AIDS in the United States and equatorial Africa. HIV-2 is found almost exclusively in West Africa; only a few cases of HIV-2 infection have occurred in the United States.

Because AIDS patients are immunodepressed, they are susceptible to opportunistic infections and neoplasms, especially non-Hodgkin lymphoma, *Pneumocystis carinii* pneumonia, and Kaposi sarcoma. AIDS is most prevalent in the United States among male homosexuals, abusers of I.V. drugs, and hemophiliacs. Since the implementation of testing for blood-borne HIV and the near-elimination of HIV from blood products, the incidence of HIV infection in the hemophiliac population has diminished markedly; however, in recent years, the incidence in the heterosexual population has been increasing rapidly.

HIV can be transmitted by transfusion of whole blood, packed red cells, plasma, factor VIII concentrates, factor IX concentrates, and platelets. The likelihood that a person will become infected with HIV after receiving a single-donor blood product that tests

Table 5 Changes in Donor Acceptance and Screening Policies Instituted to Reduce the Risk of Transmitting Infectious Diseases⁷¹

Policy	Implementation Date
Screening for HBsAg	July 1972
Voluntary exclusion of persons at high risk for AIDS	March 1983
Redefinition of high-risk behavior to include men who have had sex with more than one man since 1979	December 1984
Testing for antibody to HIV-1	Spring 1985
Redefinition of high-risk behavior to include any man who has had sex with another man since 1977	September 1985
Implementation of a mechanism to allow donors to indicate confidentially that their donations should not be used for transfusion	October 1986
Testing for alanine aminotransferase (ALT, formerly SGPT)	Winter 1986–1987
Testing for anti-HBc	Spring 1987
Testing for antibody to HTLV-1	January 1990
Testing for antibody to HCV	May 1990
Testing for antibody to HIV-2	April 1992
Testing for HIV-1 antigen	March 1996

positive for HIV approaches 100%.⁷²⁻⁷³ Before the advent of serologic testing for HIV in 1985, 0.04% of 1,200,000 blood donations in the United States were estimated to be HIV positive.⁷⁴ AIDS has developed in more than 8,500 recipients of blood transfusions, blood components, or transplanted organs or tissue.

Federal regulations now require that all prospective blood and plasma donors be screened for antibody to HIV by ELISA. Because this test yields a low rate of false positive results, assay by the more sensitive Western blot electrophoresis is always used to confirm positive ELISA results. Routine testing of blood donors has greatly reduced HIV transmission via blood transfusions, but infection can still occur if the donor has been infected with HIV but has not yet developed antibody.⁷⁵ The risk of HIV transmission via transfusion of screened blood that is negative for HIV is estimated to be one in 200,000 to one in 2,000,000 per unit transfused in the United States.⁷⁶ Antibody to HIV usually develops within 4 weeks to 6 months of HIV infection.⁷⁷ From the time of infection until the appearance of antibody, infected individuals will test negative by ELISA or Western blot, and their blood might still be used for transfusion.

HIV and AIDS can also be transmitted by organ transplantation.⁷⁸ So far, only a small number of patients have been found to be infected in this way, but more will undoubtedly be reported. These patients received transplants before HIV testing of potential donors became possible. All prospective organ and tissue donors now should be tested for HIV infection and other blood-borne viral infections.

HIV infection is also a potential problem in health care workers, who are exposed to a large and growing population of AIDS patients. In the United States, an estimated 1.0 to 1.5 million people are infected with HIV but as yet have no symptoms. HIV

transmission from blood, tissue, or other body fluids can occur in the health care setting as a result of percutaneous injury (e.g., from needles or other sharp objects), contamination of mucous membranes or nonintact skin (e.g., skin that is chapped, abraded, or affected by dermatitis), prolonged contact with intact skin, or contamination involving an extensive area.⁷⁹ HIV infection may be contracted through a variety of sources including blood, semen, vaginal secretions, visibly bloody fluids, and a number of other fluids for which the precise risk of transmission is undetermined (e.g., cerebrospinal, synovial, pleural, peritoneal, pericardial, and amniotic fluid). Infection may also be contracted from concentrated HIV used in research settings.⁷⁹ The results of multiple prospective studies quantifying transmission risk associated with a discrete occupational HIV exposure indicate that the average risk of HIV transmission associated with needle punctures or similar percutaneous injuries is approximately 0.3%. The estimated risk of transmission from mucocutaneous exposure to HIV-contaminated material is 0.03%. As of December 1999, the CDC had received reports of 56 U.S. health care workers in whom documented HIV seroconversion was temporally related to occupational HIV exposure. Of these 56, 48 had percutaneous exposures, five mucocutaneous exposures, two both percutaneous and mucous membrane exposures, and one an unknown route of exposure.⁸⁰ Another 138 possible cases of occupational HIV transmission—six involving surgeons—have been reported in persons with no risk factors for HIV transmission other than workplace exposure; however, seroconversion after a specific exposure was not documented. There may be other health care workers who also have acquired HIV infection from needle-stick or mucous membrane exposure but have not been reported, either because they and their patients have not been tested or because they have other risk factors for HIV infection.

The concentration of virus in the blood or serum of antigen-positive individuals is several orders of magnitude less for HIV than for HBV. The number of needle-stick exposures to HIV that have actually led to a positive test result for HIV has been extremely small, whereas hepatitis B occurs in as many as 40% of health care workers exposed to the virus by needle-stick injury. Despite this relatively low infectiousness, AIDS is much more feared than hepatitis B because AIDS is often fatal. Although hepatitis B is usually not fatal and is often of short duration, several health care workers die of hospital-acquired hepatitis B and hepatitis C each year.

Hepatitis

Several viruses can cause hepatitis. Hepatitis A virus (HAV) and HBV cause what were formerly known as infectious hepatitis and serum hepatitis, respectively. HCV is the major cause of parenterally transmitted non-A, non-B hepatitis. Hepatitis E virus is a common cause of epidemic non-A, non-B hepatitis, which is chiefly found in developing countries in Africa and Asia. Hepatitis D virus (HDV, formerly called the delta agent) is defective or incomplete and is pathogenic only in the presence of HBV. The hepatitis viruses are the most common infectious agents to which hospital personnel may be exposed. Herpesviruses can also cause serious and sometimes fatal hepatitis, especially in severely immunocompromised patients, such as recipients of organ or bone marrow transplants and patients receiving intensive chemotherapy for cancer.

HEPATITIS A

HAV is a small (27 nm), single-stranded RNA virus belonging to the enterovirus subgroup of picornaviruses. Its almost exclusive transmission by the fecal-oral route is enhanced by poor personal

hygiene, poor sanitary conditions, and crowding. Transmission can be contained by careful hand washing and the isolation of excretions. Unlike other types of viral hepatitis, hepatitis A is rarely transmitted by blood, blood products, or needle sticks and is rarely transmitted among hemodialysis patients, health care workers, and I.V. drug abusers. The infrequent parenteral transmission of HAV is attributed in part to its lack of an asymptomatic carrier state. Hepatitis A can be transmitted percutaneously only during a brief period of viremia before the onset of symptoms and jaundice. The chance that an infected person will donate blood during this short period is small; also, patients are usually outside the hospital during this period.

HEPATITIS B

HBV is a member of the Hepadnaviridae family of DNA viruses. It is most prevalent in the Far East, the Middle East, Africa, and parts of South America, where as many as 15% of the general population are chronic carriers. Worldwide, the most common mode of transmission is from mother to child during the perinatal period. In the United States, however, sexual or parenteral transmission has been implicated in most infections. The high-risk groups for chronic HBV infection in the United States include I.V. drug users, men who have sex with men, other individuals with multiple sexual partners, household contacts and sexual partners of HBV carriers, health care workers, patients on long-term hemodialysis, and organ transplant recipients.⁸¹

Clinical Course

The clinical course of hepatitis B is extremely variable: infection ranges from the completely asymptomatic to the rapidly fatal. The incubation period averages 75 days but can last from 40 to 180 days. Exposure to HBV has five potential outcomes: (1) no infection occurs; (2) acute hepatitis develops, followed by clearance of infection; (3) acute fulminant infection develops, leading to hepatic necrosis and death; (4) acute hepatitis develops without clearance of infection, and a chronic carrier state ensues; and (5) no acute illness develops, but a chronic carrier state ensues.

Approximately 55% of adults infected with HBV have no symptoms despite serologic documentation of infection (see below), which explains why blood donors who seem to be in good health are capable of transmitting the virus. Other individuals infected with HBV may have such mild symptoms (e.g., slight malaise, fatigability, and loss of appetite) that they do not seek medical attention.

Approximately 45% of people infected with HBV experience typical acute, icteric hepatitis, which is characterized by fatigue, anorexia, nausea, vomiting, and hepatomegaly. In approximately 1% of adults infected with HBV, acute fulminant hepatitis develops. This condition is characterized by progressive hepatocellular destruction, encephalopathy, and deepening coma. Fulminant hepatitis causes death in approximately 80% of affected adults and 30% of affected children.

In approximately 5% to 10% of hepatitis B cases, the infection becomes chronic. Patients with chronic hepatitis may be asymptomatic or may have clinical and histologic evidence of the disease, as well as persistently elevated levels of serum aminotransferases [see Figure 4]. With time, many patients pass to an asymptomatic carrier state, and serum aminotransferase levels fall. The duration of the asymptomatic carrier state appears to be indefinite. Chronic HBV infection can result in hepatocellular carcinoma, which is especially common in China, Southeast Asia, and sub-Saharan Africa.

Because most patients remain asymptomatic until the development of end-stage liver disease, there are no specific clinical

findings that are indicative of chronic HBV infection. There are, however, several clinical syndromes linked to HBV infection that may provide a clue to the presence of chronic HBV infection. These syndromes include polyarteritis nodosa, membranous or membranoproliferative glomerulonephritis, leukocytoclastic vasculitis, erythema nodosum, arthritis, and serum sickness.

Antigens

HBV has a diameter of 42 nm and contains circular, double-stranded DNA. The protein coat on its outer surface is termed hepatitis B surface antigen. HBsAg is made in quantities greatly exceeding the amount required to coat the nucleic acid. The excess surface antigen appears in the serum as spheres 22 nm in diameter or tubules of the same diameter and of varying length. These spheres and tubules contain no nucleic acid and hence are not infectious. They may persist in the serum for prolonged periods, even for life, and in great quantities, up to 10^{12} to 10^{14} surface antigen particles (500 µg protein) per milliliter.⁸²

The hepatitis B virus also has a nucleocapsid core, the outside of which contains the hepatitis B core antigen (HBcAg). HBcAg is not detected in hepatitis B during acute infection, because its antigenic determinants are hidden by the outer surface antigen of the intact virion.

Inside the hepatitis B nucleocapsid is a DNA-dependent DNA polymerase and the hepatitis B e antigen, which is thought to be either an internal component or a degradation product of the core antigen. HBeAg is found only in the serum of individuals whose serum also contains HBsAg, and it appears in the serum of virtually all patients early in the course of HBV infection. The presence of HBeAg in serum is indicative of the presence of large numbers of circulating intact virions: serum containing HBeAg is estimated to be one million times more infectious than serum containing HBsAg but not HBeAg.

Serology

HBsAg can be detected in the serum within a few weeks of viral exposure [see Figure 5]. It usually persists throughout the symptomatic period and does not disappear until after recovery. Anti-HBs appears shortly after the disappearance of HBsAg [see Table 6]. During this window period, neither HBsAg nor anti-HBs is detectable [see Table 7]. Anti-HBs persists for years and is associated with immunity to reinfection. HBV can be differentiated into eight serotypes on the basis of determinants of the surface antigen.

Hepatitis B core antigen (HBcAg) is not found free in the serum, but antibody to HBcAg (anti-HBc) becomes detectable at an early stage in the course of acute infections, 1 to 2 weeks after the appearance of HBsAg. Titers of anti-HBc fall after the disappearance of HBsAg but persist for life. In patients with chronic hepatitis B, HBsAg remains detectable indefinitely, and titers of anti-HBc remain high. Years after infection, titers of anti-HBs may have fallen to undetectable levels, and anti-HBc may be the only marker of previous infection. HBeAg is detectable immediately after the appearance of HBsAg. Antibody to HBeAg (anti-HBe) appears just after HBeAg becomes undetectable (usually before the disappearance of HBsAg) and persists for 1 to 2 years [see Figure 5].

HEPATITIS D

HDV is a defective, 35 to 37 nm RNA virus that can infect only persons who are also infected with HBV, because it uses HBsAg for its structural protein shell. HDV is found worldwide and is especially prevalent in the Amazon basin, central Africa, southern Italy, and the Middle East.⁸³ HDV infection is less common in the United States and Western Europe, where it is generally associat-

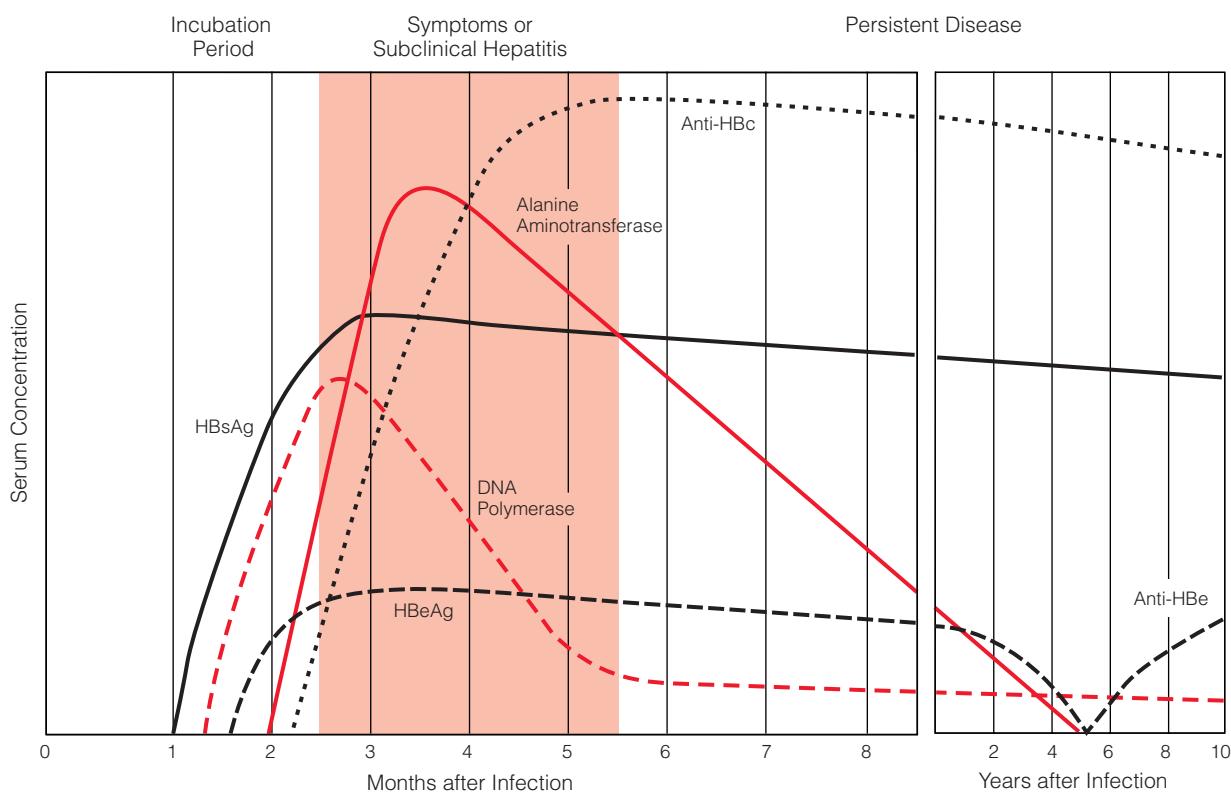

Figure 4 Schematic shows virologic, clinical, and serologic events of a hepatitis B infection that becomes persistent.

ed with parenteral blood exposure, typically in the setting of I.V. drug abuse or multiple transfusions.

Clinically, hepatitis D is found only in association with acute or chronic hepatitis B, and it cannot last longer than hepatitis B does. Depending on the state of the HBV infection, HDV infection appears either as a coinfection or a superinfection. Coinfection occurs when acute HDV infection and acute HBV infection are present simultaneously; superinfection occurs when acute HDV infection is superimposed on chronic HBV infection. Coinfection with HDV is associated with fulminant hepatitis and a mortality of 2% to 20%.⁸⁴ Fewer than 5% of cases of coinfection progress to chronic hepatitis D. In contrast, superinfection with HDV results in chronic HDV hepatitis, often with cirrhosis, in more than 70% of cases. The clinical and biochemical features of HDV infection resemble those of HBV infection alone. Chronic active hepatitis B progresses faster when hepatitis D is also present. Chronic HDV infection is more likely to result in severe morbidity and mortality than chronic HBV or HCV infection alone.

Diagnosis of acute HDV infection may be difficult: HDAg appears in the circulation only briefly and often goes undetected. Antibody to HDAg (anti-HD) of the IgM class subsequently appears in serum in low titers. Because no anti-HD IgG response occurs, no serologic marker of previous HDV infection may remain after recovery. Chronic HDV infection is easier to diagnose: high titers of anti-HD in the serum indicate ongoing HDV infection, and HDV antigen is detectable in the liver by means of immunohistochemical techniques. Moreover, IgM anti-HD remains detectable in serum.⁸³

NON-A, NON-B HEPATITIS: HEPATITIS E AND HEPATITIS C

Non-A, non-B hepatitis is divided into two varieties, an epidemic form (hepatitis E) and a parenterally transmitted form (hepatitis C).⁸⁵ Hepatitis E is an acute, self-limited disease whose

clinical features are similar to those of other types of hepatitis. Hepatitis E virus (HEV) is prevalent in the developing world, where it is spread by the fecal-oral route and has been associated with large outbreaks as well as sporadic cases. Outbreaks have been linked to contaminated water supplies. No cases of HEV infection acquired in the United States have been reported to date, but HEV acquisition has been reported in international travelers.

Hepatitis C is the most common cause of nonalcoholic liver disease in the United States. HCV is an RNA virus of the flavivirus family. It can be transmitted through parenteral exposure (usually in the setting of I.V. drug abuse), sexual contact, or the sharing of a household with an HCV-infected person; however, some persons with HCV infection have none of these risk factors, and there may be other means of transmission that have yet to be elucidated. Before the advent of antibody testing, HCV infection accounted for the majority (75% to 95%) of cases of posttransfusion hepatitis.⁸³ Since the spring of 1990, when a serologic test for HCV became available, all transfused blood has been screened for HCV, and the incidence of transfusion-associated hepatitis C has fallen precipitously. At present, however, I.V. drug use still accounts for a large proportion (60%) of HCV transmission in the United States.⁵⁹

The presence of anti-HCV IgG appears not to be protective: blood donors with anti-HCV antibody can transmit hepatitis.⁶² Surveys of HCV seropositivity indicate that 0.2% to 0.6% of volunteer blood donors carry anti-HCV IgG,⁸³ and the prevalence may be much higher among high-risk populations (e.g., residents of large inner-city communities). The prevalence of anti-HCV IgG is high among I.V. drug users, hemodialysis patients, and hemophiliacs.

Clinical Manifestations

The incubation period of hepatitis C averages 7 to 8 weeks in length but may be as short as 2 weeks or as long as 15. The clin-

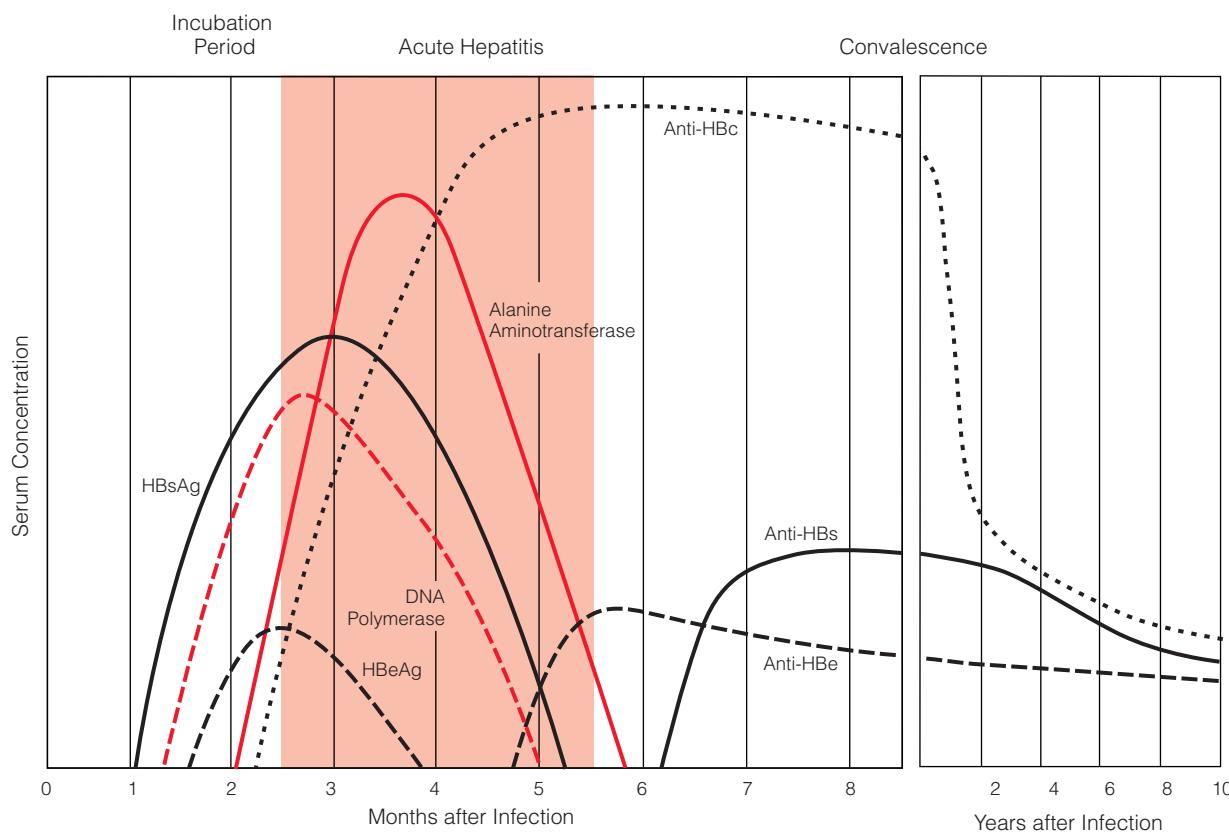

Figure 5 Schematic shows virologic, clinical, and serologic events during acute hepatitis B infection.

cal manifestations and biochemical alterations associated with acute hepatitis C are similar to but milder than those associated with hepatitis B. Serum aminotransferase levels can fluctuate widely; the peak levels are lower than those seen in hepatitis B (10 to 20 times normal as opposed to 20 to 50 times normal). Only about 25% of cases of acute HCV infection are icteric, and the mortality for acute infection is about 1%. Most patients have no acute illness suggestive of HCV infection. Antibody is not always present early in infection, and there are no clinically available assays for detecting IgM antibody to HCV. Thanks to improvements in the immunodetection of HCV, however, the interval before anti-HCV can be detected has decreased from the 6 to 12 months required with the first-generation tests to 8 to 12 weeks with the second-generation assays.⁸³

The most striking feature of HCV infection is its tendency to become chronic in as many as 50% to 75% of cases. One study found that even among the 1% to 10% of individuals with HCV whose bloodstreams had been cleared of HCV according to RT-PCR assay, as many as 90% still had HCV in the liver.⁸⁶ It is estimated that in the United States, nearly four million people are seropositive for HCV, and more than 30% of liver transplantsations are performed to treat end-stage liver disease related to chronic HCV infection. The presence of anti-HCV IgG does not distinguish acute from chronic hepatitis. Within 10 years, cirrhosis may develop in as many as 20% to 25% of patients with active hepatitis⁸⁷; accordingly, these patients must be followed up carefully.

Chronic active hepatitis is characterized by elevated serum aminotransferase levels; however, other test results remain normal, and the patient is usually asymptomatic until end-stage liver disease develops. Liver biopsy shows inflammation around the portal triads. Recombinant interferons have been used to treat

chronic HCV infection, with mixed results: frequently, there is little response to treatment, or viremia returns after treatment. The combination of interferon with ribavirin has shown promise, however. Interferon treatment is generally reserved for patients who have chronic HCV infection and show evidence of active necroinflammatory liver disease with persistent ALT elevations.

HEPATITIS IN HOSPITAL PERSONNEL

Patients with hepatitis can infect hospital personnel with the

Table 6 Serologic Markers of Hepatitis B Infection

HBsAg	Present in acute and chronic infection Indicator that person is infectious
Anti-HBs	Appears 2 to 16 wk after HBsAg disappears from the serum Persists for years Confers immunity
HBcAg	Not present in the serum Found in the hepatocyte
Anti-HBc	Appears in serum with or shortly after HBsAg Persists for years May be only indicator of hepatitis B infection
HBeAg	Appears in the early acute phase Indicates serum is highly infectious Persistence beyond 10 wk suggests progression to chronic carrier state
Anti-HBe	Good prognosis for resolution of infection

virus via needle-stick injuries and other forms of accidental exposure. Conversely, physicians who are chronic carriers of HBV or HCV can infect their patients. According to a nationwide seroepidemiologic survey reported in 1978, approximately 19% of physicians have anti-HBs, compared with 3.5% of healthy volunteer blood donors [see Table 8].⁸⁸ Anti-HBs was found in 28% of surgeons, the highest prevalence in any medical specialty. For physicians, the likelihood of being positive for anti-HBs correlates with age and the number of years in practice. The risk of hepatitis is greatest among medical staff members in renal dialysis units, oncology units, and the clinical laboratory. Since 1978, when these data were reported, HBV vaccination has made it impossible to perform similar, more recent studies, because vaccination rather than previous infection would be responsible for the presence of antibodies.

Physicians and other staff members who care for hemodialysis patients with end-stage renal disease are at greater risk for acquiring HBV because of the high prevalence of hepatitis in such patients [see Table 9].^{89,90} Transmission of HBV decreases in dialysis centers when close attention is paid to hygienic technique. Isolation of patients who are carriers of HBsAg also reduces the incidence of HBV in hemodialysis patients and staff.⁹¹

From 0.28% to 9.3% of health care workers have antibody to HCV.⁹²⁻⁹⁴ In one study from Connecticut, five (12.5%) of 40 surgeons had antibody to HCV.⁹² In another study, from New York City, eight (1.75%) of 456 dentists had anti-HCV antibody.⁹³ The highest prevalence among dentists was found to occur in oral surgeons (9.3%). As use of vaccines for HBV becomes more widespread [see Management of Viral Exposure, Hepatitis B, above], HCV may come to predominate over HBV as the cause of the rare cases of hepatitis transmitted from hospital personnel to patients.

EPIDEMIOLOGY OF POSTTRANSFUSION HEPATITIS

Both HBV and HCV can be transmitted by percutaneous and other routes.⁸⁹ Rare cases of hepatitis have been attributed to the infusion of immune globulin, although its preparation by ethanol fractionization normally destroys hepatitis virus (as well as HIV). Albumin is pasteurized by heating at 60° C for 10 hours, which destroys hepatitis virus.

Because of the current criteria for acceptable blood donors, elimination of payment for blood donation, and serologic testing for HBV and HCV, the risk of contracting hepatitis B from a blood transfusion is now much lower than it once was. In the United States, it is now rare for either HBV or HCV to be transmitted via blood transfusion. According to the latest estimates available, the risk of HCV transmission via this route is approximately 1/103,000 (95% CI, 28,000 to 288,000), and that of HBV transmission is 1/63,000 (95% CI, 31,000 to 147,000).⁹⁵

HDV can also be passed by transfusion. In a study of 262 patients who had posttransfusion hepatitis and whose serum was positive for HBsAg, anti-HD was found in nine patients.⁹⁶ HDV can be detected in 24% of HBsAg-positive drug abusers and in approximately 50% of HBsAg-positive hemophiliacs.

LONG-TERM EFFECTS OF CHRONIC HEPATITIS

Chronic hepatitis can lead to problems requiring surgical intervention. It can cause cirrhosis, which in turn can cause portal hypertension and bleeding varices that necessitate portal systemic shunting. In addition, HBV and HCV predispose to hepatocellular carcinoma, the most prevalent visceral cancer in the world. The condition is especially prevalent in China, Southeast Asia, and sub-Saharan Africa. It is estimated that 25% of chronically infected persons die of cirrhosis or hepatocellular carcinoma.⁹⁷ HBV coinfection

Table 7 Serologic Patterns of Hepatitis B Infection

HBsAg	Anti-HBs	Anti-HBe	Interpretation
+	-	-	Early acute hepatitis B
+	-	+	Late acute hepatitis B
-	-	+	Window period between disappearance of HBsAg and appearance of anti-HBs or Chronic carrier with low HBsAg level or Infection in the remote past

+ = detectable - = not detectable

tion appears to increase the risk of hepatocellular carcinoma in HCV-infected persons. A widespread program of vaccination against HBV could greatly decrease the incidence of hepatocellular carcinoma. Epidemiology, molecular biology, and comparative pathology provide strong circumstantial evidence that hepatitis B is a significant factor in the etiology of hepatocellular carcinoma. The risk of primary hepatocellular carcinoma is more than 250 times greater in carriers of HBV than in noncarriers. HBV markers can be found in 80% to 90% of patients with hepatocellular carcinoma. Perhaps the best epidemiologic data indicating that hepatitis B precedes hepatocellular carcinoma were obtained in Taiwan from male civil servants between 40 and 60 years of age.⁹⁸ Approximately 3,500 HBsAg carriers were matched by age and place of birth (either mainland China or Taiwan) to 3,000 HBsAg-negative men, who served as control subjects. An additional group of 16,000 HBsAg-negative men between 40 and 60 years of age served as unmatched control subjects. After subjects were followed for 2 to 4 years, 50 cases of hepatocellular carcinoma were found, all but one of which occurred in chronic HBsAg carriers.

HCV is also associated with chronic infection in a high percentage (approximately 50%) of cases. In many countries, chronic HBV infection remains the leading factor in the development of hepatocellular carcinoma, whereas in Japan, Korea, and southern Europe, 50% to 75% of cases of hepatocellular carcinoma are

Table 8 Frequency of Antibody to Hepatitis B Surface Antigen (Anti-HBs) by Physician Specialty⁸⁸

Specialty	Number of Patients Tested	Positive Results (%)
Surgery	176	50 (28)
Pathology	37	10 (27)
Pediatrics	63	13 (21)
Internal medicine	259	46 (18)

Table 9 Prevalence of Hepatitis B Virus (HBV) Serologic Markers in Various Populations⁹⁰

Population		Prevalence of Serologic Markers of HBV Infection (%)	
		HBsAg	All Markers
High risk	Immigrants or refugees from areas where HBV is highly endemic	13	70–85
	Clients in institutions for the mentally retarded	10–20	35–80
	Users of illicit parenteral drugs	7	60–80
	Homosexually active men	6	35–80
	Household contacts of HBV carriers	3–6	30–60
	Hemodialysis patients	3–10	20–80
Intermediate risk	Health care workers with frequent blood contact	1–2	15–30
	Prisoners (male)	1–8	10–80
	Staffs of institutions for the mentally retarded	1	10–25
Low risk	Health care workers with no or infrequent blood contact	0.3	3–10
	Healthy adults (first-time volunteer blood donors)	0.3	3–5

associated with chronic HCV infection.⁹⁹ In Japan, mortality from hepatocellular carcinoma increased approximately twofold in the 1980s, a change that may be attributable to a higher incidence of HCV-associated liver cancer.¹⁰⁰

Herpesviruses

CYTOMEGALOVIRUS

CMV is a member of the B herpesvirus family and is the largest virus known to infect humans. In some U.S. cities, the seroprevalence of CMV is 60% to 70%. Like other members of the herpesvirus family, CMV is capable of remaining within its host in a latent state, probably by down-regulating cell surface markers (e.g., HLA-1) and thus avoiding immune destruction. Latent CMV has been found in circulating mononuclear cells, polymorphonuclear cells, vascular endothelium, renal epithelial tissue, and pulmonary secretions. The virus may become reactivated in the setting of immunodeficiency, such as may arise with HIV infection, transplantation, or significant stress from operations or injuries. In non-immunocompromised patients, CMV typically causes a self-limited mononucleosis-like syndrome characterized by fever and mild hepatic transaminase abnormalities. In immunocompromised patients, however, CMV infection can be much more severe and even potentially life threatening, causing myelosuppression, pneumonitis, colitis, and retinopathy.

Posttransfusion Cytomegalovirus Infection (Posttransfusion or Postperfusion Syndrome)

The transmission of CMV by extracorporeal perfusion is responsible for the occasional development of a syndrome similar to mononucleosis in patients who have undergone open-heart operation. The syndrome characteristically appears 3 to 5 weeks after operation; its features are splenomegaly, fever, atypical lymphocytosis, and, occasionally, hepatomegaly, erythematous rash, and eosinophilia.⁸⁹ CMV can be isolated from the blood of virtually all patients with the typi-

cal posttransfusion syndrome and from the urine of half of these patients.⁸⁹ The condition is nonfatal and self-limited, but it may result in prolonged hospitalization and a long, expensive search for the source of fever. Although uncommon in adults 30 years of age and older, the syndrome can occur in as many as 10% of susceptible children and adults younger than 30 years.

This syndrome can also occur in patients who receive transfusions but who do not undergo open-heart operation. Occasional cases that develop postoperatively in patients who did not receive transfusions are thought to be the result of reactivation of latent infection. EBV can sometimes cause the syndrome.

The incidence of posttransfusion CMV infection is related to the kind of blood or blood product transfused. CMV is highly cell associated and is transmitted with leukocytes, which may be present in transfusions of packed red blood cells, platelets, or white blood cells; transmission from transfusion of fresh frozen plasma or cryoprecipitate has not been documented.¹⁴ Therefore, efforts to decrease the number of white blood cells in the transfused blood would be expected to decrease the rate of transfusion-associated CMV infection. Approximately 50% of patients who receive whole blood seroconvert to CMV, whereas only 10% of those who receive washed packed red blood cells seroconvert. The risk of seroconversion to CMV is between 12% and 100% when whole blood, either fresh or stored, is transfused.¹⁰¹ In one study, transfusion of frozen deglycerolized red blood cells resulted in seroconversion in only 3% of patients,⁸⁹ whereas in another, seroconversion occurred in 58% of 36 leukemic patients transfused with lymphocytes.¹⁰²

The risk of posttransfusion CMV infection is also related to the volume of blood received. In one study, 7% of patients receiving a single unit of whole blood seroconverted, whereas anti-CMV antibody titers rose in 21% of patients receiving more than one unit.¹⁰³ The risk of infection per unit of blood transfused is estimated to range between 2.7% and 12%.¹⁰⁴

Preexisting antibody to CMV does not protect transfusion recipients against reinfection. After transfusion of whole blood, titers of antibody to CMV will increase in 10% of recipients (an

indication of reinfection) and in 19% of patients who did not have antibody to CMV before transfusion (an indication of infection). Whereas a seronegative recipient of CMV-positive blood has a 21% chance of seroconversion, the risk of seroconversion from the receipt of one unit of CMV-negative blood is only 2%.⁸⁹ However, the sensitivity of the serologic test for CMV is such that even when blood that tests seronegative is used, there is still a residual 0% to 6% risk of CMV transmission.¹⁰⁵

Because so many patients receive blood transfusions during operation, it is understandable that evidence of posttransfusion CMV infection has been found in many patients postoperatively (e.g., after gynecologic surgery, cholecystectomy, appendectomy, lumbosacral fusion, splenectomy, and transplantation). It has also been found in surgical patients who are victims of trauma or burns.

However, it is surprising that infection with CMV, a ubiquitous virus, does not occur more frequently after transfusion. Between 30% and 54% of the adult population in the United States have antibody to CMV, an indication of previous infection.⁸⁹ Because infection with the virus is probably lifelong, a significant proportion of blood donors harbor the virus. The prevalence of antibody to CMV is 25% in units of blood from donors between 18 and 23 years of age and increases to 89% in blood from donors older than 60 years. The overall prevalence of seropositive blood donors is between 30% and 70%.

Cytomegalovirus in Transplant Recipients

CMV infection occurs not only in patients who have received blood transfusions but also in those who have suffered trauma, those receiving immunosuppressive therapy, and those with neoplastic disease. The groups at highest risk for CMV infection are probably recipients of organ transplants and of bone marrow transplants.¹⁰⁶⁻¹⁰⁸ Numerous studies have documented the high incidence of CMV infection after organ transplantation: the rates range from 26% to 100%.^{89,109,110} Primary CMV infection occurs in patients who do not have antibody to CMV before receiving transplants. Infections are considered to be reactivated if they occur in patients who did have antibody to CMV before receiving transplants. Rates of infection in patients receiving cardiac or bone marrow transplants are similar to those in patients receiving kidney transplants.

The high incidence of CMV infections after transplantation was recognized in the early days of such procedures. At autopsy of patients who died after renal transplantation, the intranuclear inclusions typical of CMV were found in tissue from the lungs, the parotid glands, the lymph nodes, the liver, the pancreas, the parathyroid, and the brain. CMV has been cultured repeatedly from the urine of transplant recipients, and the frequency of seroconversion among them has been high.

Likely sources of the virus are blood, because fresh blood can transmit CMV, and the organ transplant itself, because CMV can grow in renal tubular epithelial cells and can be transmitted as a latent virus. In several studies, recipients of kidney transplants had a much higher incidence of CMV infection when the donors had antibody to CMV than when the donors did not. In one study, 57% of recipients of kidneys from seropositive donors acquired CMV infection after transplantation, compared with 8% of recipients of kidneys from seronegative donors.¹¹¹ Even patients who have antibody to CMV can acquire new CMV infections as a result of transfusion or transplantation because there is more than one antigenic variety of the virus. Also, CMV that is latent in many patients who have antibody before transplantation may be reactivated after transplantation by host versus graft reactions, corticosteroids, or other immunosuppressive drugs. Hospital personnel, family members, and the environment play very small roles in transmission of CMV to transplant recipients.

Several systematic studies have demonstrated that CMV causes clinical illness in renal transplant recipients. In four studies, clinical illness developed in 83% of 76 patients with primary infection, compared with 44% of 268 patients with reactivation of a previous infection.^{89,109,110}

Recipients of renal transplants in whom CMV causes clinical illness most commonly present with fever. Fever occurs in 95% of patients with CMV infection and may be prolonged. Patients with CMV infection also frequently present with anorexia, arthralgias, and leukopenia. Other clinical features of the disease are diffuse pulmonary infiltrates, pancreatitis, transplant malfunction, and systemic bacterial and fungal superinfections. Invasion of the GI tract by CMV may cause gastritis and ulcers in both the duodenum and the colon, which in turn may lead to hemorrhage and perforation. Biopsies demonstrate CMV inclusions at the base of the ulcers. The virus appears to invade the vascular endothelium, and bleeding is possibly a result of vascular occlusion and ischemic necrosis of the overlying tissue.

Lethal CMV disease is characterized by the presence of most of the features listed above. Liver dysfunction is found in 100% of patients with lethal disease but in only 50% to 75% of patients with mild or moderate infection, and CMV viremia occurs in 46% to 48% of patients with severe CMV infection but in only 26% to 28% of patients with mild to moderate infection. Leukopenia and the presence of atypical leukocytes also correlate with the severity of the disease. CMV infection after renal transplantation is also associated with pneumonia, hepatitis, encephalitis, and retinitis.

Whether or not CMV infection causes or leads to graft rejection is uncertain. Both the highest incidence of CMV infection (> 80%)^{89,109,110} and the highest incidence of graft rejection occur within the first 3 months after transplantation. In several studies, young patients and recipients of second kidney transplants were at higher risk for graft loss if they had CMV than if they did not.^{89,109,110} In most studies, however, it is extremely difficult to demonstrate a relation between CMV infection and graft rejection.

Of the multiple factors affecting the risk of CMV infection in transplant recipients, the most important are (1) the familial relation and HLA matching between the kidney donor and the recipient and (2) the CMV serology of both the donor and the recipient. The presence of antibody in transplant recipients before transplantation seems to offer a small amount of protection against fever caused by CMV but does not protect against more serious consequences of the infection, such as leukopenia, graft failure, and death.

CMV infection is also a major problem in liver, heart, and bone marrow transplant recipients.^{106,108} In liver transplant recipients, CMV is a cause of hepatitis and liver dysfunction that can be confused with rejection or other causes of liver malfunction,¹⁰⁶ and it can lead to lethal infection. CMV pneumonitis in bone marrow transplant recipients is the most common life-threatening infectious complication after transplantation. The severity of infection in bone marrow transplant recipients may be attributable to the higher incidence of host versus graft disease in patients with CMV pneumonitis (82%) than in those without CMV pneumonitis (27%).¹¹²

Prevention and Treatment of Cytomegalovirus Infection

Several methods have been proposed to reduce the incidence of CMV infection after transfusion or transplantation. One method is to eliminate as many white blood cells as possible from transfused blood because CMV is almost certainly transmitted solely through these cells. From 90% to 100% of viable leukocytes in blood have been removed from frozen deglycerolized erythrocytes. In one study, transfusion of 24 hemodialyzed patients with leukocyte-free red blood cells from frozen deglycerolized blood prevented subsequent CMV infection.¹⁰⁴

Another approach is to transfuse blood only from CMV-negative donors. Because the majority of posttransfusion CMV infections are asymptomatic, however, the increased cost of performing serologic tests on all donated units might be difficult to justify.

Storage of blood to reduce infectiousness of CMV is another approach, but storage from 48 to 72 hours does not significantly reduce transmission of CMV infection. Irradiating the blood to render the CMV noninfectious is unacceptable because it causes cell transformation in vitro. Furthermore, in one study, administration of leukocytes previously exposed to 1,500 cGy (1,500 rads) of gamma radiation resulted in an increased incidence of CMV infection among recipients of these cells.¹⁰²

Because the incidence of CMV infection is higher in patients who receive kidney transplants from seropositive donors, some centers do not transplant kidneys from seropositive donors into seronegative recipients. However, no published reports indicate that this practice leads to a significant alteration in the outcome of renal transplantation with respect to graft rejection. Moreover, excluding kidneys from seropositive donors makes it more difficult to find kidneys for seronegative recipients.

Many attempts have been made to develop a CMV vaccine for administration before viral exposure by multiple passages of the virus in tissue culture. Two such vaccines have been used in clinical trials, one prepared from the AD169 strain and the other from the Towne 125 strain of the virus. Immunization with these vaccines can elicit both serum antibody and cell-mediated immunity. In one trial, the vaccine prepared from the Towne 125 strain lowered the incidence of clinical disease but not of infection, and the disease tended to be less severe in vaccinated patients than in control subjects who received placebo.¹¹³

Human IgG has been administered after transfusion or transplantation in attempts to prevent associated CMV infection. In one study, it reduced life-threatening infection to a less severe form in most patients, but in other studies, not surprisingly, it provided no consistent benefit.¹¹⁴⁻¹¹⁷ In patients who are already seropositive, the virus is latent inside their cells, where it is probably not accessible to serum antibody. Patients with primary infections may not benefit from antibody treatment, because herpesviruses seem to transfer from cell to cell without ever existing free in serum. Even CMV hyperimmune globulin has no clear benefit in patients with clinical CMV infection.¹¹⁸ It may, however, help control severe infections, such as those seen in bone marrow transplant recipients.

Several antiviral agents have been used in attempts to reduce the incidence or lessen the effect of CMV infection. Among these agents are interferon, transfer factor, immune globulin, and nucleoside derivatives, such as cytarabine, vidarabine, and acyclovir (see below). Immune globulins, acyclovir, and ganciclovir are effective at preventing CMV infection in transplant recipients.^{109,110,114,119,120} Ganciclovir and foscarnet are active against CMV in vitro. Ganciclovir is currently being used to treat CMV and is the most effective agent in organ transplant recipients (see below).^{109,110,119-121}

EPSTEIN-BARR VIRUS

EBV is the herpesvirus responsible for infectious mononucleosis. It can be found in B cells in peripheral blood of infected patients and in tumor cells of patients with Burkitt lymphoma and nasopharyngeal carcinoma. It remains in a latent form in an infected host for years, probably for life. Most posttransfusion EBV infections are asymptomatic. Seroconversion to EBV will develop in approximately 8% of recipients transfused with between two and 14 units of blood. In as many as 5% of patients with preexisting antibody to EBV, significant elevations of antibody titers may develop, beginning

2 weeks after transfusion. These elevations indicate either reinfection or reactivation of a latent infection.⁸⁹ Because EBV is associated with cells and does not exist free in serum to any great extent, antibody to EBV in either donors or recipients is unlikely to provide substantial protection against infection resulting from blood transfusions or organ transplants. Among transfused patients who do not have preexisting antibody to EBV, the prevalence of EBV infection can reach 33% to 46%. In these patients, the absence of preexisting antibody presumably rules out reactivation of latent EBV infection as the source of infection.

EBV occurs worldwide. In the United States, nearly all adults and as many as 65% of persons of all ages have antibody to EBV. Infection is thought to occur in infancy, and as many as 17% of infants have antibody to EBV. By 5 years of age, 72% of children have antibody to EBV, and the prevalence in adults is similar.¹²² Thus, the majority of blood donors in the United States have been previously infected with EBV and probably have latent virus in their leukocytes. Although it is clear that EBV can be transmitted by blood when the transfusion occurs within 3 days of donation, it is not known whether blood stored for longer periods can transmit the virus. Because EBV is predominantly intracellular, plasma and its derivatives do not transmit the virus.

The diagnosis of EBV infection is made serologically. Tests both for IgM antibody to capsid antigens and for IgG antibody to the early antigens of EBV or tests of serial samples for IgG antibody to capsid antigens must be used. The heterophil antibody test (the Paul-Bunnell test) and a rapid slide test that is equivalent (the monospot test) are also used in most clinical studies to screen for EBV infection before more specific diagnostic tests are performed.

In cases of posttransfusion infection, IgG antibody to EBV can be detected at least 10 days before the onset of symptoms, and EBV can be cultured from circulating lymphocytes 11 days before the onset of symptoms. In patients with acute infection, EBV is found in approximately three of every 10⁴ peripheral blood lymphocytes.¹²³ In contrast, all recovered persons with antibodies to EBV are thought to have the virus in one of every 10⁷ circulating lymphocytes.

EBV is strongly implicated in the etiology of a posttransplantation lymphoproliferative disorder (PTLD).^{89,124,125} EBV has been isolated from the tissues of most cases of PTLD, but not all.^{126,127} Non-EBV-related cases of PTLD typically occur later after transplantation, and their etiology has not been elucidated.

PTLD comprises three general clinical presentations: (1) a mononucleosis-like syndrome involving the tonsils and the peripheral lymph nodes, (2) a diffuse polymorphous B-cell infiltration in many visceral organs, and (3) localized extranodal tumors in the GI tract, the neck, the thorax, or other parts of the body. Patients whose disease is limited to a single organ or to lymph nodes often respond to a reduction in immunosuppression or antiviral therapy; however, once the infection becomes widespread, the disease progresses rapidly and is fatal in more than 75% of cases.¹²⁸ In solid organ transplant recipients, PTLD may be limited to the allograft. There is some evidence to suggest that PTLD may have organ-specific features that promote lymphoproliferation: allograft involvement has been reported in 17% of renal transplant recipients, 8.6% of liver transplant recipients, and as many as 60% to 80% of lung or intestinal transplant recipients.¹²⁸

The persons at highest risk for PTLD are EBV-seronegative persons receiving EBV-positive organs or bone marrow. Most infections occur within the first 4 months after transplantation.¹²⁹ Several specific risk factors for the development of PTLD have been identified: a seropositive graft in a seronegative recipient, certain types of organ allografts (with intestinal transplants carrying the highest risk), any type of immunosuppression that blunts cellular immuni-

ty to EBV (with risk increasing as immunosuppression becomes more pronounced), and the presence of other infections (CMV in particular).

The optimal treatment of lymphoproliferative disorders remains unclear. Some early EBV-associated lymphoproliferative disorders in solid organ transplant recipients have regressed completely after reduction of immunosuppression.^{130,131} Early PTLD may respond to antiviral therapy with acyclovir or ganciclovir, which may prevent infection of resting B cells, but such therapy is less likely to be effective in the face of high concentrations of latently infected circulating or tissue-invasive B cells. Some investigators also report resolution of PTLD after treatment with interferon alfa.^{132,133}

Transmission of EBV can occur simultaneously with transmission of CMV or hepatitis virus. Although hepatitis accompanies EBV infections in sporadic cases, EBV alone has not been documented as a cause of posttransfusion hepatitis.

HERPES SIMPLEX VIRUS

Infection or reactivation of infection with herpes simplex virus type 1 (HSV-1) follows renal transplantation in 50% to 75% of patients, most often within 30 days after transplantation. Reactivation of infection is more common than primary infection: only 14% of patients who are seronegative before transplantation become infected, but infection is reactivated in 64% of patients who were already seropositive before transplantation.

Most cases of HSV-1 infection after transplantation are clinically inapparent and are indicated only by a significant rise in titer of antibody to the virus. The most prevalent clinical manifestation is herpes labialis, that is, fever blisters affecting not only the lips but also the mucous membranes of the oral cavity and the skin of the head and neck. Although these lesions are painful and may make eating, drinking, and taking oral medications difficult, they are usually self-limited and heal without treatment or reduction of immunosuppression. However, HSV-1 infection can take a much more malignant course, disseminating to cause pneumonitis, fulminant hepatitis, upper GI hemorrhage, encephalitis, aseptic meningitis, and death.

VARICELLA-ZOSTER VIRUS

Varicella-zoster virus (VZV), another herpesvirus, is the etiologic agent of herpes zoster and chicken pox. This virus resides in the dorsal root ganglia of adults who had primary varicella infection in childhood. Herpes zoster is more common in organ transplant recipients, in patients with cancer (especially those who have leukemia or lymphomas), in burn patients, and in patients receiving immunosuppressive drugs. Serologic evidence of VZV infection occurs in 8% to 16% of renal transplant recipients. The lesions of herpes zoster become evident 12 to 511 days after organ transplantation.

In children or adults who have not already had chicken pox and occasionally even in children who have, VZV can cause disseminated chicken pox in many organs, which may be fatal.

AGENTS EFFECTIVE AGAINST HERPESVIRUSES

Because the essential synthetic activities of viruses depend on the metabolic machinery of their host, it has been difficult to devise specific antiviral agents that interfere with viral replication but are not harmful to host cells.^{134,135} Many antiviral agents are too toxic to be used clinically. In contrast, antibacterial agents that are both toxic to bacteria and safe for human cells are easier to design because the structure and metabolic machinery of bacteria are distinct from those of host cells.

Although intracellular processes unique to viral replication have

been identified and specifically targeted for chemotherapeutic attack, very few agents have been effective against human viruses. Among these is amantadine, which is used for both prophylaxis and treatment of influenza A. Agents that were found to be effective for prophylaxis against smallpox, such as methisazone, now have no use, because the disease has been eradicated.

There are few effective chemotherapeutic agents for hepatitis or most of the other major viral diseases that concern surgeons, but several agents have been used for the treatment of herpesvirus infections, especially in immunocompromised patients [see Table 10]. These agents, derivatives of purines and pyrimidines, interfere with viral nucleic acid synthesis.

Acyclovir and Valacyclovir

Acyclovir (acycloguanosine) is a nucleoside derivative that is used to treat herpesvirus infections, especially herpes simplex and varicella-zoster infections in immunocompromised hosts. Valacyclovir is the L-valyl ester prodrug of acyclovir. In cases of mucocutaneous herpes simplex and herpes zoster, acyclovir can shorten the period of virus shedding, decrease pain, and promote more rapid scabbing and healing of lesions. Acyclovir is also the drug of choice for encephalitis caused by herpes simplex, but it is not effective in patients with established neurologic damage resulting from herpes simplex or varicella-zoster infections or in patients infected with CMV. Acyclovir inhibits the replication of EBV in actively replicating cells but does not affect latent or persistent infection.

The total daily dose of acyclovir is 10 to 25 mg/kg, given by I.V. infusion lasting 60 minutes. The recommended length of parenteral acyclovir therapy ranges from 5 to 10 days, depending on the indication. A major side effect of such therapy is phlebitis at the injection site; rash, leukopenia, and neurotoxicity may also occur. Acyclovir applied topically as a 5% ointment is effective in immunocompromised patients for the treatment of limited cutaneous herpes infections and in patients with normal immunity for the treatment of initial episodes (but not recurrent episodes) of genital herpes simplex infection. Oral acyclovir seems to be effective as prophylaxis against reactivated herpes simplex infection in recipients of bone marrow transplants and in patients immunosuppressed as a result of HIV infection.

Penciclovir and Famciclovir

Penciclovir is a nucleoside analogue that is similar to acyclovir with respect to spectrum of activity and potency against herpesviruses. Famciclovir is the diacetyl ester of penciclovir. Penciclovir requires thymidine kinase (TK) for phosphorylation and thus is inactive against thymidine kinase-deficient strains of HSV or VZV; however, it may be active against some TK-altered or polymerase mutants that are resistant to acyclovir as well as against some foscarnet-resistant HSV isolates. In experimental settings, topical, parenteral, and oral penciclovir and oral famciclovir have been effective against HSV infection.

Vidarabine

Vidarabine (ara-A) is effective against herpes simplex and varicella-zoster viruses as well as poxviruses, oncornaviruses, and rhabdoviruses. It is used mostly to combat herpesvirus infections in immunocompromised patients. In these patients, vidarabine accelerates healing of cutaneous herpes zoster, decreases its rates of cutaneous dissemination and of visceral complications, and shortens the duration of postherpetic neuralgia. For systemic use, a daily dose of 10 to 15 mg/kg of vidarabine is administered I.V. over a period of 12 hours. The duration of therapy for herpes zoster is

Table 10 Antiviral Therapy of Clinical Benefit

Virus	Condition	Regimen
Herpes simplex virus	Keratitis	3% Acyclovir ointment or 1% Trifluridine solution or 3% Vidarabine ointment or 0.5% IDU ointment or 0.1% IDU drops
	Herpes labialis	Treatment usually not indicated; may use 1% penciclovir cream or topical acyclovir q. 2 hr while patient is awake for 4 days
	Genital herpes Primary	Acyclovir, 200 mg p.o. 5 times daily or 400 mg p.o., t.i.d., for 10 days, or Valacyclovir, 500 mg–1 g p.o., b.i.d., for 10–14 days, or Famciclovir, 250 mg p.o., t.i.d., for 10 days*
	Recurrent	Acyclovir, 200 mg p.o. 5 times daily or 400 mg p.o., t.i.d., for 5 days, or Valacyclovir, 500 mg p.o., b.i.d., for 5 days, or Famciclovir, 125 mg p.o., b.i.d., for 5 days
	Prophylaxis	Acyclovir, 400 mg p.o., b.i.d., or Valacyclovir, 500 mg–1 g p.o., q.d., or Famciclovir, 250 mg p.o., b.i.d.
	Encephalitis	Acyclovir, 10 mg/kg t.i.d. I.V. for 14–21 days
	Neonatal HSV	Acyclovir, 10 mg/kg I.V. q. 8 hr for 10–21 days (20 mg/kg I.V. q. 8 hr if neonate is premature)
Varicella-zoster virus	Immunocompetent host Eye infections Shingles	3% Acyclovir ointment Acyclovir, 800 mg p.o. 5 times daily for 7–10 days, or Valacyclovir, 1 g p.o., t.i.d., for 7–10 days, or Famciclovir, 500 mg p.o., t.i.d., for 7–10 days
	Immunocompromised host	Acyclovir, 10–12 mg/kg I.V. q. 8 hr for 7 days (500 mg/m ²)
Cytomegalovirus	Immunocompromised host Retinitis	Ganciclovir, 5 mg/kg I.V. q. 12 hr for 14–21 days, [†] or Foscarnet, 90 mg/kg (adjusted for renal function) I.V. q. 12 hr for 14–21 days, or Cidofovir, 5 mg/kg I.V. weekly for 2 weeks, then every other week Ganciclovir, 2.5 mg/kg I.V. q.d. for 20 days
	CMV pneumonia	

*Not approved by the FDA for this indication.

[†]An intraocular insert is also available.

5 days. Side effects include anorexia, weight loss, nausea, vomiting, weakness, anemia, leukopenia, thrombocytopenia, tremors, and thrombophlebitis at the site of administration.

Iodoxuridine

Iodoxuridine (5-iodo-2'-deoxyuridine) (IUdR, IDU) was the first clinically effective antiviral nucleoside. It is a halogenated pyrimidine that resembles thymidine in structure. Topical application of either a 0.1% solution or a 0.5% ointment of idoxuridine is effective treatment of herpes simplex keratitis but not of recurrent herpes labialis or localized zoster. In the United States, IDU is approved only for topical treatment of HSV keratitis. When combined with dimethyl sulfoxide (DMSO), IDU is active against herpes zoster and recurrent or primary genital HSV infection. In Europe, IDU is available in combination with DMSO for the treatment of herpes labialis, herpes genitalis, and herpes zoster.

Ganciclovir

Ganciclovir (DHPG, 2'-NDG, or BIOLF-62) is an acyclic nucleoside structurally related to acyclovir but with greater activity against CMV in vitro and in vivo. It is effective in treating CMV disease in transplant recipients and AIDS patients. The usual total daily dose of ganciclovir is 7.5 to 10 mg/kg, given in two or three divided doses. The dosage should be adjusted if the patient has decreased renal function. Myelosuppression is the principal dose-limiting toxic side effect.

Foscarnet

Foscarnet (trisodium phosphonoformate) is a pyrophosphate derivative that inhibits herpesvirus DNA polymerases and retroviral reverse transcriptases.^{134–136} In the United States, it has been used for the prevention and treatment of CMV retinitis in patients with AIDS. For patients who have received renal or bone marrow transplants,

foscarnet is given in a bolus injection of 9 mg/kg followed by infusion of 0.015 to 0.090 mg/kg/min I.V. for 7 days. Foscarnet is also used to treat acyclovir-resistant HSV infection. The major toxicity associated with foscarnet is nephrotoxicity; CNS side effects (e.g., headache, tremor, irritability, and seizures) can also occur.

Viral Infections from Animal and Human Bites

Surgeons are frequently called on to treat patients who have been bitten by either an animal or another person. Such bites can transmit several viruses and other infections. Certainly, rabies is the most feared viral infection transmitted in this way. Viruses that are found in saliva, such as HBV, herpesviruses, and possibly HIV, can be transmitted by a human bite, although such cases are most likely rare.

From zero to five cases of human rabies occur each year in the United States. Animal rabies is widespread and is found in every state except Hawaii. In 1992, more than 8,600 cases of animal rabies were reported to the CDC by 49 states, the District of Columbia, and Puerto Rico. The great majority of cases occur in

wild animals.⁶⁹ Before 1950, more than 8,000 cases of rabies in dogs were reported each year in the United States; the number is now fewer than 150 a year.

Rabies proceeds from a prodrome of fever, malaise, and headache, to hyperactivity and diffuse cerebral dysfunction, and then to coma and death. From 5% to 20% of patients may also show progressive paralysis. Occasionally, there is no history of an animal bite. Diagnosis can be confirmed by culture of saliva, cerebrospinal fluid, or brain tissue; demonstration of rabies antigen in the cornea or skin; or measurement of serum antibody to rabies virus. At postmortem examination, typical intracytoplasmic inclusions (Negri bodies) can be seen in the brain cells.

Although the number of cases of human rabies is small, the disease is an important problem because of the large number of animal bites that occur each year. Surgeons may have to consider rabies prophylaxis in patients whom they treat for bite injuries [see Management of Viral Exposure, Rabies, above, and 1:7 Acute Wound Care]. Also, two fatal cases of rabies have occurred in recipients of corneal transplants from a patient whose cause of death was later found to be rabies.¹³⁷

21 ACQUIRED IMMUNODEFICIENCY SYNDROME

Kathleen Casey, M.D., and John Mihran Davis, M.D.

Approach to Human Immunodeficiency Virus Infection

In June 1981, the Centers for Disease Control and Prevention (CDC) published a report of *Pneumocystis carinii* pneumonia (PCP) in five previously healthy homosexual men living in Los Angeles.¹ At that time, the CDC was the sole distributor of pentamidine, the only treatment for this rare pulmonary infection. This outbreak represented a unique cohort for PCP, which until then had been seen only in severely immunosuppressed patients who were receiving chemotherapy for disseminated cancer. Even in this select group, PCP was rare, and *P. carinii* was not considered pathogenic in otherwise healthy adults. The sudden increase in demand for pentamidine in one geographic area raised the prospect of a new disease process. In July 1981, the CDC reported a group of young homosexual men with Kaposi sarcoma.² Like PCP, Kaposi sarcoma was a rare lesion not commonly seen in young adults. Many of these Kaposi sarcoma patients also had severe infections caused by organisms associated with immunodeficiency, including PCP, toxoplasmosis, candidiasis, cryptococcosis, and cytomegalovirus (CMV) infections.

These two accounts represented the first recognition of AIDS. The cause of the severe immunodepression in these patients, who were not otherwise at risk for opportunistic infection, was controversial until late 1983 and early 1984, when the human immunodeficiency virus (HIV) was isolated in AIDS patients.³ This retrovirus—formerly known as human T cell lymphotropic virus (HTLV) type III and lymphadenopathy-associated virus (LAV)—is now recognized as the agent that causes AIDS. Presumably, the patients in the 1981 reports had become infected with HIV at least 3 to 4 years earlier.

In September 1987, the definition of AIDS was expanded to include symptomatic HIV-infected patients suspected of having an opportunistic infection. This new definition precipitated a potentially misleading sudden increase in new cases.⁴ Since 1986, the percentage of homosexual or bisexual AIDS patients has steadily declined, and the percentage of AIDS patients who are I.V. drug abusers or are heterosexual has increased.

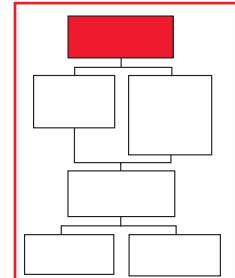

June 1, 2001, marked the 20th anniversary of the AIDS epidemic. Over those 2 decades, more than 20 million people died of AIDS, leaving an estimated 36 million people infected.⁵ No immediate end to the epidemic is in sight, but current therapies have significantly altered the course of the illness. Until the advent of highly active antiretroviral agents (HAART), it was believed that everyone with an opportunistic infection or tumor associated with AIDS (e.g., Kaposi sarcoma or non-Hodgkin lymphoma) would die as a direct result of severe immunosuppression; that is no longer the case.⁶ HIV-infected persons are living longer, are less likely to die of opportunistic infections, and are more likely to present with relatively well-preserved immune function.⁷ With this increase in the prevalence of HIV infection, it is all the more important that surgeons have a basic under-

standing of HIV disease and its treatment and be familiar with prophylaxis after occupational exposure.

Recognition of HIV Infection

PATHOGENESIS

HIV is an oncavirus belonging to the retrovirus family. The potential of retroviruses to cause neoplasia was first recognized in 1911 by the American pathologist Rous, who associated them with certain malignant disorders in animals.⁸ For example, HTLV-I, a retrovirus related to HIV, has been identified as a cause of leukemia in humans.⁹

One of the characteristic features of retroviruses is the presence of an enzyme called reverse transcriptase. This enzyme allows the virus to transcribe viral RNA to DNA. The virus can synthesize double-stranded DNA from single-stranded DNA that has been liberated from the RNA-DNA hybrid. This double-stranded DNA inserts itself into the nucleus of the host cell and serves as a template for viral replication. Thus, whenever the infected host cell divides, new HIV particles are also reproduced. HIV has been isolated in many cell types, but it is thought that helper T cells (CD4⁺ cells) are most frequently infected. It is believed that when an HIV-infected CD4⁺ cell is activated by a secondary infection, the virus is replicated, resulting in the dissemination of mature virions and the death of the cell.

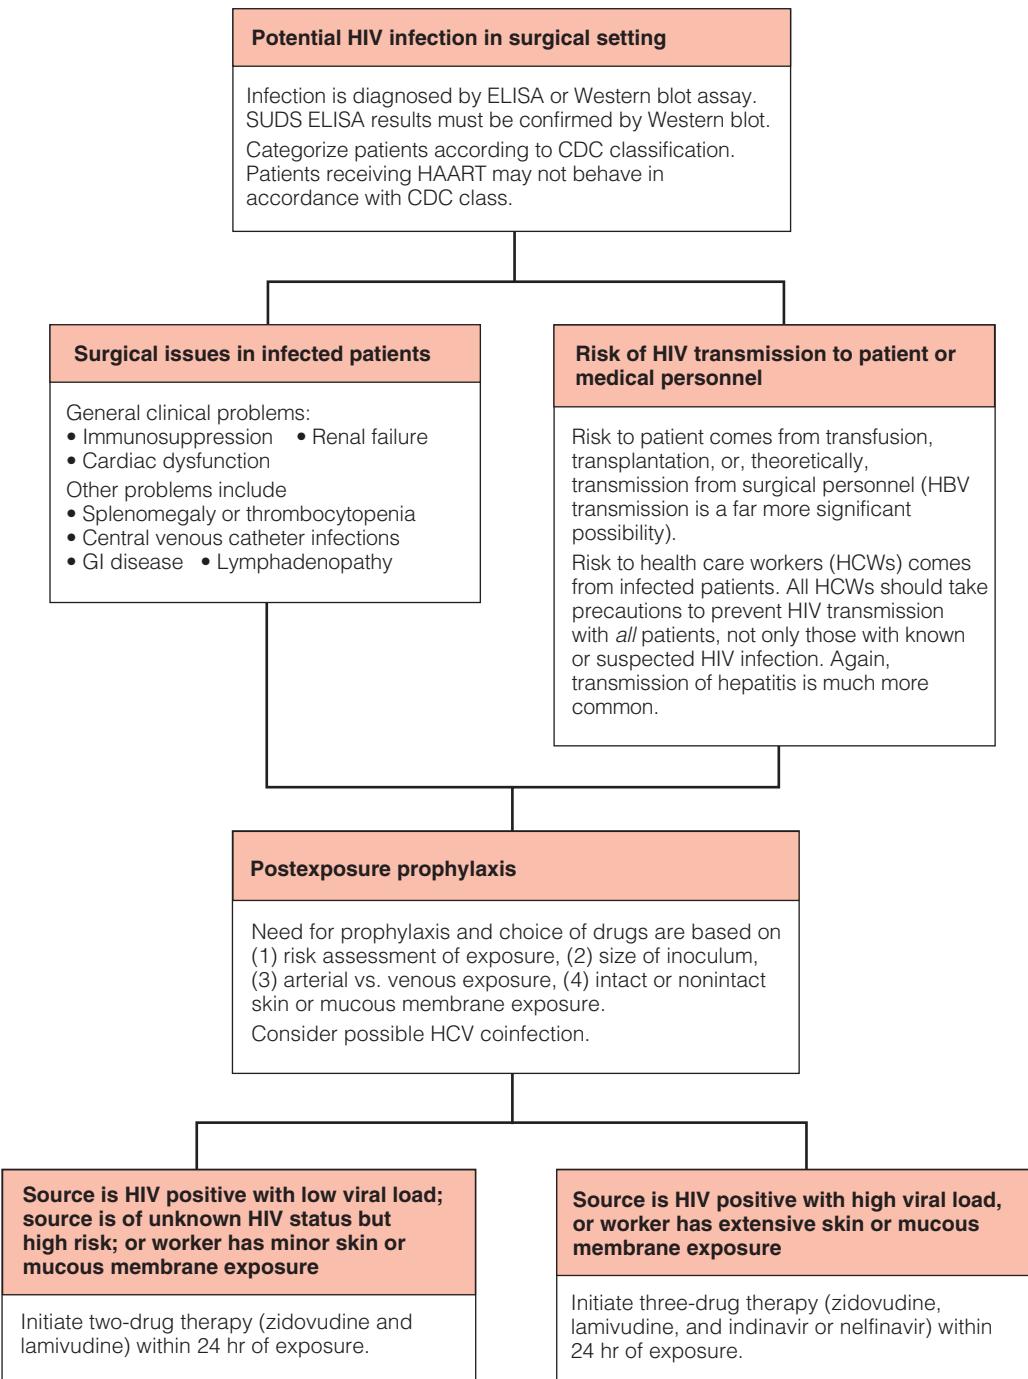

The latency period between acquisition of HIV infection and onset of AIDS has been estimated to be about 5 years. This estimate is probably misleading because it is based on experience with patients in high-risk groups, who are frequently exposed to other infectious challenges. Exposure to these other pathogens activates the T cells that harbor HIV, which promotes dissemination of the virus throughout the host and significant impairment in cellular immunity. Because the incidence of concomitant infections is lower in the general population than in high-risk groups, the latency period of HIV infection is probably longer in the general population.

DIAGNOSTIC TESTS

The enzyme-linked immunosorbent assay (ELISA) and the Western blot assay are designed to detect the presence of HIV antibody in serum. ELISA is considered very sensitive (93% to 100%; i.e., its false negative rate is low). The specificity of a repeatedly reactive ELISA approaches 99%. The weakness of the ELISA is that some persons have antibodies that react with HIV antigens but are not specific for HIV.

The Western blot assay is more specific than ELISA but is cumbersome and less sensitive. It is therefore not a good screen-

Approach to Human Immunodeficiency Virus Infection

ing test; it is used most effectively for confirming ELISA results. However, most blood banks will not use blood that has demonstrated a positive ELISA reaction, even if HIV antibody was not detected by Western blot testing.¹⁰

The Single-Use Diagnostic System (SUDS; Murex Diagnostics, Norcross, Georgia) provides a rapid ELISA technology that can yield a reliable result in 15 minutes. A positive SUDS result must still be confirmed by Western blot assay. SUDS is especially useful in occupational-injury investigation.

There is a window period of 25 days between infection with HIV and seroconversion detectable by ELISA. It has been estimated that since 1985, when all banked blood began to be tested for HIV, 35 persons in the United States have contracted HIV infection from transfusions containing blood collected from an HIV-infected individual during this window period.^{11,12} For that reason, on August 8, 1995, the Food and Drug Administration recommended that all blood donated for transfusion be screened for the p24 antigen (the core structural protein of HIV).¹³ Additional laboratory tests that may help in the diagnosis of patients believed to have HIV infection in whom HIV antibody screening yields negative results include DNA polymerase chain reaction (PCR), antigen testing after immune complex disruption, and RNA reverse transcriptase PCR.¹⁴

In February 2002, the FDA approved a nucleic acid test system that detects ribonucleic acid from HIV and hepatitis C virus (HCV) in whole blood and blood component donors, thus permitting earlier results than tests based on detection of antibodies or antigens (<http://www.fda.gov/cber/approvaltr/hivhcvgen022702L.htm>). Like ELISA, the nucleic acid test has a window period during which the virus can be present but escape detection; however, this window period is substantially shorter than that associated with antibody-based tests (12 versus 22 days, on average, for HIV; 25 versus 82 days, on average, for HCV).

CDC Classification of HIV Infection

In 1993, the CDC revised the classification of the HIV-infected adult and adolescent [see Table 1]. In this classification, a CD4⁺ count below 200 cells/ μ l is considered an indicator of AIDS, regardless of the patient's symptoms. Once classified into a given group, a patient is not reclassified to a more favorable category, even if symptoms resolve or the CD4⁺ cell count rises. However, if the disease progresses or the CD4⁺ count falls, the patient is reclassified into the next less-favorable group. This system allows uniformity in patient classification for research trials and scientific communication and, of particular importance, facilitates formulation of health care policy and strategy.

Table 1 1993 Revised Classification for HIV Infection and Expanded AIDS Surveillance Case Definition for Adolescents and Adults⁸¹

CD4 ⁺ T Cell Categories	Clinical Categories		
	A	B	C
	Asymptomatic, Acute (Primary) HIV, or PGL	Symptomatic, Not A or C Conditions	AIDS Indicator Conditions
≥ 500/ μ l	A1	B1	C1
200–499/ μ l	A2	B2	C2
< 200/ μ l AIDS-indicator T cell count	A3	B3	C3

PGL—persistent generalized lymphadenopathy

Unfortunately, the system does not take into account the immune reconstitution that occurs with HAART. After successful treatment with HAART, patients originally classified as having AIDS (on the basis of their CD4⁺ count or level of immunocompromise) often will no longer have signs and symptoms in accordance with their original CDC classification. A number of studies have now shown that secondary prophylaxis for PCP, CMV retinitis, *Toxoplasma* encephalitis, and cryptococcal meningitis may be safely discontinued in patients whose CD4⁺ counts have risen and remained above 200 cells/ μ l because of HAART.¹⁵ Similarly, recent studies of gynecologic procedures in HIV-infected patients have found that postoperative infection rates correlate only with the current CD4⁺ count. In these studies, a CD4⁺ level below 200 cells/ μ l at the time of the procedure was an independent risk factor for surgical complications, whereas the previous nadir had no influence on outcome.¹⁴

Surgical Issues

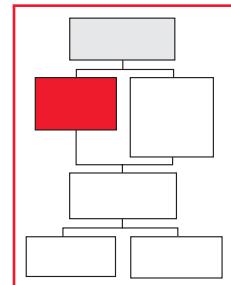

GENERAL

As a group, HIV-infected patients present the surgeon with three notable clinical problems: immunosuppression, renal failure, and cardiac dysfunction. Surgeons need to be aware of the immune status of their HIV-infected patients, because this has the greatest bearing on outcome. For example, in HIV-infected patients with normal CD4⁺ counts, the risk of infectious complications after surgery for a perforated appendix is comparable to the risk in patients without HIV infection. In patients with AIDS (< 200 CD4⁺ cells/ μ l), the risk of infection is higher, though it is from opportunistic organisms associated with severe immunosuppression rather than common pathogens.^{16–20}

Renal failure in HIV-infected patients can be the result of specific HIV-related nephropathy, which occurs in up to 10% of this population.²¹ Another possible cause is drug toxicity from antiviral and antimicrobial medications: pentamidine, foscarnet, and aminoglycosides cause acute tubular necrosis; acyclovir, indinavir, and sulfadiazine cause intratubular obstruction.

Until recently, the risk of cardiac disease in HIV-infected patients had not been as well documented as that of renal failure. With HIV-infected patients living longer, the problems of acquired heart disease have been increasingly appreciated.^{22–24}

In addition, malignancy has been increasingly recognized over the past 2 decades as a consequence of HIV infection. Initially, the occurrence of AIDS-defining tumors, such as B cell lym-

phoma and Kaposi sarcoma, was thought to relate to the immunosuppression of the host. Other tumors have now been associated with HIV infection, including squamous cell cancers of the cervix and anus and lung cancer. It is believed that at some point after infection with HIV, activation of oncogenes and loss of tumor suppressor genes give rise to microsatellite alterations. These are highly pleomorphic segments of DNA associated with the AIDS-defining malignancies.²⁵⁻²⁷

Treatment of patients with AIDS involves multimodal therapy and consultation with oncology and infectious disease specialists. It is beyond the scope of this discussion to describe the specific therapeutic approaches to the complications of HIV infections; however, three principal problems must be addressed. First, any opportunistic infection or secondary malignant disorder must be treated; second, the underlying immunodeficiency must be corrected; and finally, the cause—HIV infection—must be controlled. The role of the surgeon in the management of these chronically ill, and sometimes critically ill, patients includes performing diagnostic biopsies, giving supportive care, and managing complications of malignancy of infection.

SPLEEN

The role of splenectomy in patients with marked splenomegaly or with thrombocytopenia must be individualized. Some experts believe that coinfections such as HCV infection contribute to the development of HIV-related immune thrombocytopenic purpura (ITP). Thrombocytopenia occurs in AIDS patients as a result of the deposition of circulating immune complexes on platelets rather than as a result of a specific antiplatelet antibody.^{28,29} Splenectomy has been extremely effective in the management of AIDS-related ITP, with a success rate of over 90%. Occasionally, patients who have debilitating fevers associated with significantly enlarged spleens experience dramatic palliation after splenectomy. Some data indicate that splenectomy favors a slower progression of HIV dissemination and progression to AIDS.^{30,31} In patients with massive splenomegaly and fever, simple splenomegaly is sometimes difficult to distinguish from abscess or parenchymal necrosis, and splenectomy may be indicated to resolve the uncertainty. In addition, splenectomy may be indicated in instances in which there is merely a likelihood of injury and in those in which a large spleen compresses the stomach, thereby contributing to malnutrition.

IMPLANTABLE VENOUS ACCESS DEVICES

Placement of an indwelling central venous catheter is a request frequently directed to the general surgeon from the primary care physician, infectious disease consultant, or hematologist caring for an AIDS patient. Long-term venous access for treating fungal infections or, occasionally, for providing nutritional support in patients with debilitating diarrheal syndromes can enhance the care of these patients. However, lines are often placed when the patient is febrile, as a result of either the underlying infection or treatment with amphotericin B. Therefore, a close watch should be kept postoperatively to ensure that fevers are not related to a catheter infection. Although catheter-related infection develops in as many as 30% of AIDS patients with implanted lines, these infections do not increase mortality.³² The high rate of infection relates in part to the high incidence of *Staphylococcus* colonization in these patients.

GASTROINTESTINAL DISEASES

Cryptosporidiosis and CMV infection of the biliary tree have been reported to cause both acute cholecystitis and acute chol-

gitis, necessitating emergency surgical interventions.¹² Choledochoenteric bypass is thought to provide the best palliation in these patients. It is not known whether the biliary tree is ever cleared of the pathogens. *Candida* infection and Kaposi sarcoma have also caused cholangitis, necessitating bypass surgery.¹⁷ The gallbladder is infected with unusual pathogens in over 50% of HIV-infected patients with cholangitis; therefore, the gallbladder wall should be sent for culture, and the pathologist should be alerted so that the tissue may be processed with special stains.³³⁻³⁶

Acute perforations of the GI tract from CMV infection, cryptosporidiosis, and candidiasis, as well as from necrotic lymphoma, have been reported in HIV-infected patients.^{18,37,38} Obstruction of the GI tract by Kaposi sarcoma or lymphoma may also be an indication for resection, bypass, or colostomy. One study of AIDS patients requiring a laparotomy identified four distinct clinical syndromes that called for surgical intervention: (1) peritonitis secondary to CMV enterocolitis and perforation; (2) non-Hodgkin lymphoma of the GI tract (usually the terminal ileum), presenting as obstruction or bleeding; (3) Kaposi sarcoma of the GI tract; and (4) mycobacterial infection of the retroperitoneum or the spleen.³⁹

Another GI lesion that has been increasingly associated with homosexual men who are infected with HIV is squamous cell carcinoma of the anus (SCCA). It is estimated that the risk of developing SCCA is nearly 25 times greater in HIV-infected homosexual men than in the general population. The underlying relationship is not well understood, because the development of SCCA is not related to the duration of the HIV infection. Some experts believe that human papillomavirus 16 (HPV-16) and HPV-18 are important cofactors in the evolution of SCCA.^{40,41}

LYMPHADENOPATHY

Another group of HIV-infected patients defined by the CDC comprises those with persistent generalized lymphadenopathy—that is, palpable lymphadenopathy with nodes measuring greater than 1 cm in diameter in at least two extrainguinal sites and persisting for longer than 3 months. Before the introduction of HIV antibody testing, the relationship of such lymphadenopathy to systemic manifestations of immunosuppression (systemic symptoms, neurologic symptoms, secondary infections, or cancers) was not known. It is now clear that lymphadenopathy is part of the general clinical spectrum associated with HIV infection, and that opportunistic infection, Kaposi sarcoma, or large cell lymphoma will develop in some, if not all, patients with lymphadenopathy. The precise reason that lymphadenopathy occurs in some, but not all, patients with HIV infection is not known.

Lymph node biopsy in these patients is only of academic interest because of the development of serologic tests for HIV infection.³⁷ The histologic appearance of a clinically enlarged lymph node has prognostic value (see below); however, when the decision as to whether to perform a lymph node biopsy is being made, the value of the biopsy findings must be weighed against the value of the information that can be obtained by means of clinical staging with the ratio of helper T cells to suppressor T cells and the total lymphocyte count. The total number of helper T cells in the circulation has been correlated with the risk of AIDS in patients with generalized lymphadenopathy^{20,42-44}; the Walter Reed classification provides the most detailed clinical staging system.^{43,45} Should the clinical condition warrant, a lymph node biopsy may help in the diagnosis of an opportunistic infection. Performing a gallium scan to locate the most suspicious node can enhance the yield of the biopsy.

Four basic histologic patterns have been described in persistent generalized lymphadenopathy and have been correlated

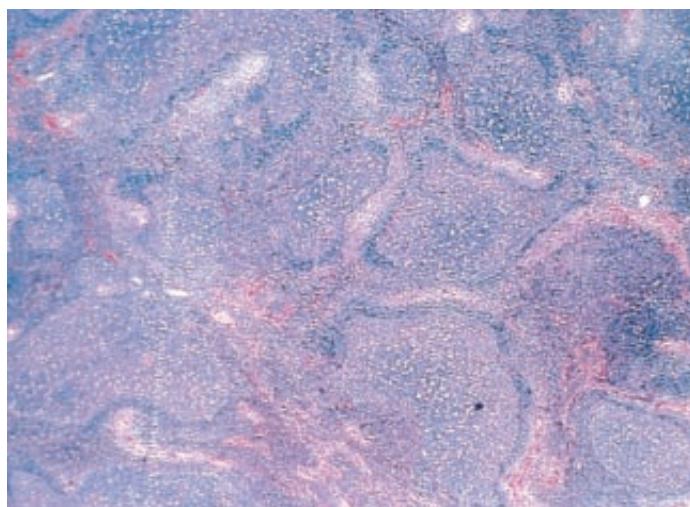

Figure 1 Lymph node viewed under low power exhibits explosive follicular hyperplasia.

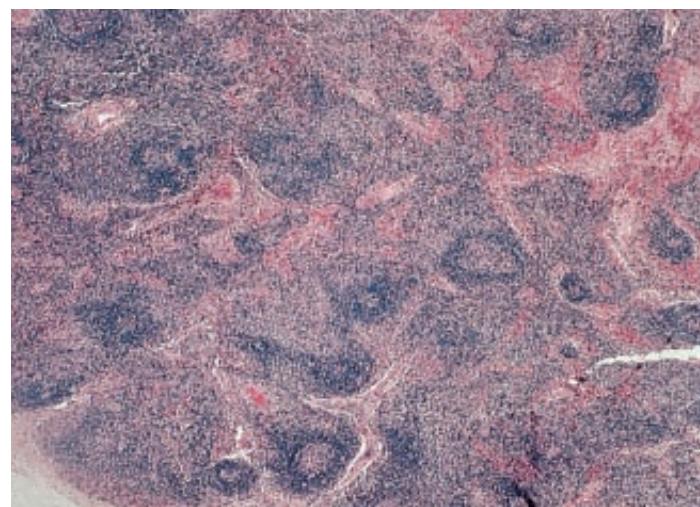

Figure 2 Lymph node viewed under low power exhibits follicular involution.

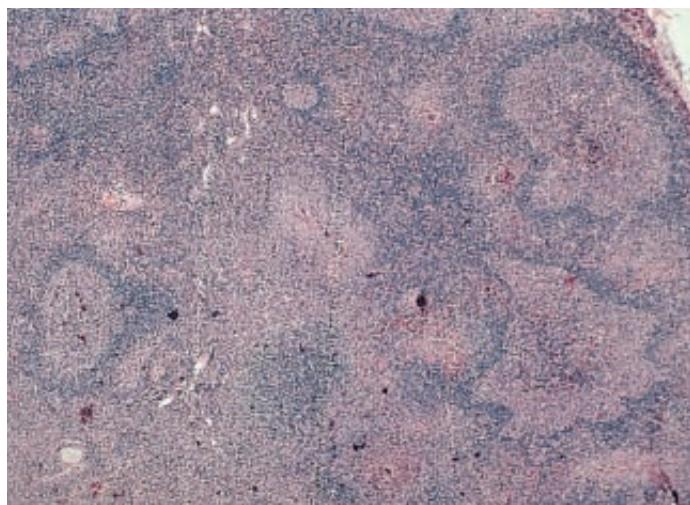

Figure 3 Lymph node viewed under low power exhibits a mixed pattern of both explosive follicular hyperplasia and follicular involution.

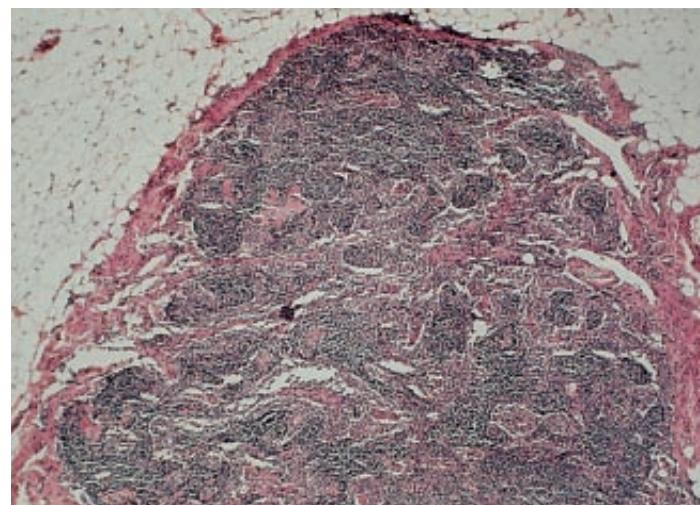

Figure 4 Lymph node viewed under low power exhibits a pattern of lymphocyte depletion.

with prognosis: explosive follicular hyperplasia, follicular involution, a mixed pattern, and a lymphocyte-depleted pattern. Explosive follicular hyperplasia describes a pattern of enlarged confluent follicles with disruption of the medullary zone of the lymph node [see *Figure 1*]. Follicular involution is associated with a hypocellular, frequently hyalinized follicle and with hyperplasia of the paracortical areas [see *Figure 2*]. The mixed pattern contains explosive follicular hyperplasia and follicular involution in the same lymph node [see *Figure 3*]. Finally, the lymphocyte-depleted pattern is characterized by the total absence of follicular and paracortical areas. The loss of lymphocytes in the lymph node is associated with the predominance of histiocytes and plasma cells [see *Figure 4*].

The presence of enlarged follicles is associated with a good immunologic response and slower progression of disease, whereas the presence of involuted, hyalinized follicles is more frequently associated with opportunistic infections, Kaposi sarcoma, and lymphoma. Evidence suggests that patients with either explosive follicular hyperplasia or the mixed pattern of explosive follicular hyperplasia and follicular involution have rather pro-

longed survival, even if they have Kaposi sarcoma. The presence of follicular involution in a lymph node is associated with a survival time of less than 1 year. Lymphocyte depletion was seen as a terminal finding in several autopsy cases, suggesting that the pattern represents the end stage of the hyperplastic process.²⁵ The pathologic findings reflect a progressive loss of the CD4⁺-bearing area of the lymph node.

After a lymph node is removed from an HIV-infected patient and before the tissue is removed from the operative field, representative specimens should be placed in sterile containers for routine bacterial culture, culture and smear for tuberculosis, fungal culture, and viral culture. Tissue from the same lymph node should then be delivered to the pathologist as quickly as possible. It is important that culture material from the same lymph node be examined microscopically, because granulomas or actual organisms may be detected before the culture results are available. Data from the pathologist may aid the microbiology laboratory staff in its handling of the cultures.

The pathologist needs to receive the fresh, gently handled specimen, in saline, as soon after the biopsy as possible, for two

important reasons. First, because the tissue is not in formalin, it will rapidly autolyze if not processed immediately. Second, if the diagnosis is lymphoma, the pathologist must have the tissue when it is fresh to perform lymphocyte marker studies. Because different lymphomas respond to different chemotherapeutic regimens, the cell type of the lymphoma is critical. Most surgical pathology laboratories are equipped to perform membrane marker studies on lymph node tissue.

Prevention of Disease Transmission

GENERAL

A key question for surgeons, operating room committees, infection control committees, and clinicians involved with endoscopy is how to effectively clean instruments, equipment, or other inanimate objects to be used with AIDS patients. Those agents that are effective against mycobacteria, the most resistant group of organisms encountered in this population, are also the agents considered most effective against other bacterial and viral pathogens.⁴⁶ A complete list of agents and their efficacies can be obtained from the Disinfectants Branch of the Office of Pesticides, United States Environmental Protection Agency, 401 M Street, S.W., Washington, DC 20460.

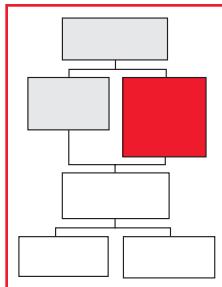

Agents are classified according to whether they are to be used for sterilization, disinfection, or antisepsis.⁴⁷ Agents that sterilize inanimate objects kill all microbial organisms as well as bacterial endospores. Disinfectants are not quite as effective, in that they are not capable of killing bacterial spores. In many cases, an agent may serve as a disinfectant when placed in contact for a short time with the object requiring cleansing and may be capable of sterilizing surgical instruments that are exposed to it for longer periods. Disinfectants are subclassified as having high-level, intermediate-level, or low-level germicidal activity. High-level agents are effective against bacterial spores. Intermediate-level disinfectants are less effective against spores but are mycobactericidal. Low-level disinfectants do not kill *Mycobacteria* and some fungi. Antiseptic agents are used on tissue and therefore must be less toxic than sterilants or disinfectants.

According to current CDC recommendations, agents classified by the United States Environmental Protection Agency as sterilants can be used for sterilization or high-level disinfection, depending on contact time. All instruments entering the bloodstream or other sterile tissues should be sterilized before use. Instruments that contact mucosal surfaces, such as endoscopes, should receive high-level disinfection, which can be achieved with solutions of glutaraldehyde (2%), hydrogen peroxide (3% to 6%), or formaldehyde (1% to 8%).

RISKS TO PATIENTS

Transfusions

Fresh whole blood, packed red blood cells, platelets, plasma, cryoprecipitate, and leukocytes can all carry HIV. In addition, clotting factor concentrates that are not generated by recombinant methods may also carry the virus. Some preparations of γ -globulin can temporarily cause a false positive ELISA result for HIV, but they do not contain the virus or transmit it to recipients. Albumin and plasma extracts (Plasmanate), although prepared from whole blood, do not carry HIV, hepatitis B virus (HBV), or

HCV, because the process by which they are purified inactivates the virus particles. Since adequate antibody testing became available in May 1985, the incidence of undetected HIV in transfused blood has been extremely low, and only anecdotal cases involving contaminated blood have been reported to the CDC. It is currently estimated that the risk of receiving a unit of blood that is contaminated with HIV is one in 150,000 (< 0.0007%).⁴⁸

To minimize the risk of HIV being transmitted by transfusion, patients have increasingly requested the use of predeposited autologous blood donations (PAD) or blood donated by family members or friends (directed donations). This approach has been increasingly discouraged by blood bank and hospital administrators.⁴⁹ Both directed donations and PAD are very expensive methods of preserving homeostasis during surgery. Half of the PAD units of blood are discarded. In addition, the risk of an ABO mismatch error is as great as the risk of HIV transmission in standard bank blood. The use of intraoperative blood salvage and acute normovolemic hemodilution in combination with intravenous iron and erythropoietin provides a reasonable alternative to blood transfusion.⁵⁰

Transplantation

Because it has been shown that HIV can be present in semen, blood, urine, tears, breast milk, cerebrospinal fluid, and saliva and because it is suspected that HIV can be present in all secretions and excretions, as well as all body tissues,⁵¹ potential donors of tissue for transplantation must be tested for serum antibodies to HIV to prevent inadvertent transfer of the virus. Parenthetically, transmission of HIV by artificial insemination has also been documented, so this risk should be considered whenever artificial insemination is planned.⁵²

Transmission from Surgical Personnel

An HIV-infected surgeon could theoretically transmit the virus to his or her patients. Although this concern has been well publicized,⁵³ there have been no documented reports of transmission from surgeon to patient. Furthermore, the CDC has not recommended restricting HIV-positive surgeons from operating.⁵⁴

Unlike surgeon-to-patient transmission of HIV, HBV transmission from surgeon to patient is a significant concern. In a well-documented report involving a nonimmunized cardiac surgeon who acquired HBV infection in the workplace, transmission of the virus occurred in 19 of 122 patients (16%) on whom the surgeon operated over a 12-month period.⁵⁵ The surgeon's blood was positive for hepatitis B e antigen (HBeAg), and sweat from inside his glove was found to contain both HBV antigen and HBV DNA. No deficiencies were found in the surgeon's infection control practice by the CDC, which suggested that the virus might have spread through microperforations in his gloves. This case did not receive the same publicity that cases of HIV transmission have received in the lay press. However, its significance is clear: contact between health care workers who are HBV (HBeAg) positive and patients should be restricted.

RISKS TO HEALTH CARE WORKERS

The CDC now recommends that precautions to prevent HIV transmission be taken with all patients, not only those known to be infected with HIV or at high risk for such infection [see 8:20 *Viral Infection*.]^{18,20,38,39} It is important that any hospital personnel who come in contact with patients, their patients' tissues, or their blood, body fluids, or excreta know of the potential risk in

Table 2 Preventable Exposures to HIV among Health Care Workers*⁴⁹

Circumstances of Preventable Exposure	Number of Health Care Workers (% of 938 Exposed Health Care Workers)
Recapping of needle	152 (16%)
Injury from improper disposal of needle or sharp object	119 (13%)
Contamination of open wound	93 (10%)
Use of needle-cutting device	9 (1%)
Total preventable exposures	373 (40%)

*The total sample under surveillance consisted of 938 health care workers exposed to blood or other body fluids of a patient with AIDS or an AIDS-related illness.

handling materials from these patients and take appropriate precautions. Patients in high-risk groups should be placed on enteric precautions to protect health care workers not only from HIV infection but also from HBV infection (up to 80% of such patients are HBV carriers). As part of any operative procedure on HIV-infected patients, all operating room, nursing, and anesthesia personnel, as well as employees of surgical pathology laboratories and any other laboratories, should employ universal precautions. Employees in ancillary areas, such as housekeeping and dietary services and the venipuncture team, need to be trained in the use of universal precautions.

Exposure to the virus in the workplace is considered to be preventable in many cases.⁵⁶ Most injuries result from carelessness in handling sharp objects, such as needles [see Table 2]. Self-inflicted puncture incurred in the course of recapping used needles is the most common cause of inadvertent exposure to HIV. Consequently, the most important rule to follow when handling used needles is to discard them uncapped in a container that is large enough to accommodate the attached syringe. Tissue specimens, wastes, soiled linen, blood samples, and sharp objects (e.g., surgical instruments, needles, and glassware) must be handled with extreme care. Dressings and other disposable materials should be discarded in specially marked containers and not with the regular hospital refuse.

The use of double gloves has been shown to minimize the possibility of contact with patient blood through small defects in the gloves, and it reduces the likelihood of blood contact with skin when a glove puncture occurs.^{57,58} The following are additional precautions health care workers should take when handling any potentially infectious materials:

1. Wear gloves when handling body fluids.
2. Wear a gown to prevent contamination of clothing.
3. Wash hands after contact with body fluids.
4. Place fluid from a potentially contaminated host in two impervious containers.
5. Clean spills with either a 1:10 dilution of 5.25% sodium hypochlorite in water or with some other type of sterilant.
6. Wear masks and protective eyeglasses when there is a possibility of aerosolization of material.

Even health care workers who do not have exfoliative dermatitis or an open wound should wear gloves during patient care. Evidence suggests that the affinity of HIV for Langerhans cells may permit the virus to invade a host through intact skin or mucous membranes.⁵⁹

RISKS TO SURGEONS

HIV Transmission

The risk that a surgeon will acquire an HIV infection while treating a patient who has undetected AIDS is quite low.^{54,56} The CDC has prospectively evaluated nearly 1,500 health care workers who cared for AIDS patients. Serum samples were taken from these workers when they first began to work with AIDS patients and were stored in anticipation of a test for HIV. Of these workers, 666 were exposed to HIV through needlesticks or through cuts from sharp instruments. When tests were performed on these exposed individuals, none were found to have undergone seroconversion after their exposure to HIV. However, two health care workers for whom no baseline blood sample had been drawn did test positive for antibody to HIV after an injury. Because they did not belong to a known risk group for AIDS, they were believed to have generated antibody to HIV as a result of exposure in the workplace. On the basis of this study, the risk to a health care worker of acquiring HIV infection after an accidental needle-stick exposure was concluded to be 2 divided by 666, or 0.3%. A follow-up study found the rate of infection to be 0.5%.⁶⁰ Subsequent surveillance of health care workers identified 151 individuals who acquired HIV infection in the workplace [see Table 3]; 49 had proven seroconversion, and 102 were HIV positive but had no HIV-negative baseline serum sample.

The CDC conducted a serosurvey of 770 surgeons practicing in two inner-city areas where more than 3,000 cases of AIDS have been reported.⁶¹ Accompanying the assay for HIV, HBV, and HCV was a questionnaire designed to elucidate the practice patterns of the surgeons tested. Of the 770 surgeons, 1 (0.13%) was HIV positive; he had practiced for more than 25 years and had performed more than 300 operations in the past year. The study did not specify how the surgeon acquired HIV, and it was noted that he did not participate in high-risk behavior. To date,

Table 3 Health Care Workers with Documented or Suspected HIV Infection⁹

Health Care Workers	No. of Workers	
	With Documented HIV (%) [*]	With Suspected HIV (%) [†]
Dental	0	7 (7%)
Mortician	0	3 (3%)

*Evidence of seroconversion after occupational exposure to HIV.

[†]HIV seropositivity in health care workers with occupational exposure to HIV who do not have behavioral or transfusion risks for HIV infection.

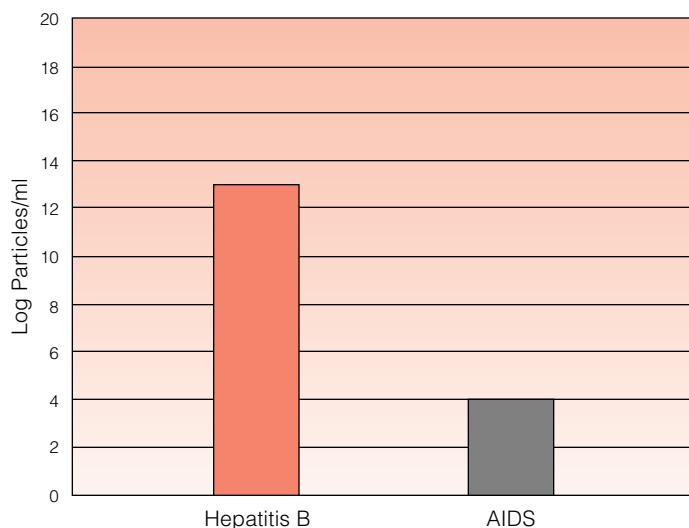

Figure 5 The numbers of infectious viral particles per milliliter of blood in patients with active hepatitis B infections and in AIDS patients are compared.⁶⁷

there has been no documented seroconversion in operating room personnel after a solid-bore needle injury in the OR.

Transmission via skin contact with body fluids was documented in the case of a woman whose infant had received a transfusion from an HIV-infected donor at 3 months of age. The mother was closely involved in the baby's care and took no precautions against contact with the child's blood and body fluids. Seventeen months after the child received the contaminated blood, the mother tested positive on ELISA for HIV. No other risk factors accounted for the change in the mother's HIV antibody titer.⁶²

Exposure to blood in the OR has been of great concern to all operating room personnel since the AIDS epidemic began. The average practicing surgeon has 30 parenteral exposures to blood a year.⁶³ The fact that hollow-bore needles carry more blood than solid-bore needles may be the reason that transmission in the operating room has not yet occurred. Four studies from the early 1990s established a blood-skin exposure rate of approximately 20% and a parenteral exposure rate of approximately 4% during surgical procedures.^{46,64-66} Long operative procedures requiring transfusions are most likely to be associated with blood exposure. Types of procedures that pose a high risk of exposure to blood are cardiac surgery; obstetrics, especially cesarean sections; trauma surgery; and emergency surgery. Special care must be taken to minimize exposure in these procedures; eye protection and use of double gloves are barrier precaution measures that can reduce the likelihood of contact with the patient's blood.

Transmission of HIV to hospital workers is uncommon when compared with transmission of HBV because of the relatively low concentration of HIV in the blood of AIDS patients [see Figure 5]. The concentration of virus particles is estimated to be 10^4 particles/ml in an AIDS patient, whereas it is 10^{13} particles/ml in a patient who has an active HBV infection.⁶⁷

Although HIV transmission is uncommon in the hospital environment, the risk to surgeons is very real. This is evidenced by the fact that even the lower reported rate of transmission by needle stick, 0.3%, is comparable to the 0.4% (1 in 250) rate of transmission by unprotected anal intercourse, which is considered high-risk behavior.^{68,69} Three independent factors are important in determining a surgeon's risk of acquiring HIV infection: (1) the num-

ber of needle sticks or punctures contaminated with the patient's body fluids, (2) the percentage of HIV-infected patients in the surgeon's patient population, and (3) the number of years a surgeon is at risk for acquiring an HIV infection. If the risk of HIV transmission by a contaminated needle is 0.3% to 0.5%, if the HIV-infected population is 10%, if the number of needle sticks averages 30 a year, and if the surgeon has 40 years of exposure, then the lifetime risk of acquiring HIV infection can be as high as 60%.⁷⁰

HEPATITIS TRANSMISSION

The primary health risk to surgeons caring for patients with HIV infection or AIDS is that of acquiring hepatitis B or hepatitis C. The hepatitis D virus (HDV) has been identified as posing an additional risk of death in patients with acute hepatitis; persons who are infected with both HBV and HDV have a higher mortality.⁷¹

The epidemiology of hepatitis B has been well studied because there are numerous antigen and antibody markers of the virus in the blood of chronic carriers. On the basis of data from assays of these markers, it is estimated that more than 200,000 persons in the United States acquire new HBV infections each year.⁷² Of these 200,000, 25% will have symptoms of hepatitis, 5% will require hospitalization for their acute illness, and 1% to 2% of these hospitalized patients will develop fatal fulminant hepatitis [see Figure 6].

Between 5% and 10% of patients infected with HBV become chronic carriers—that is, they do not effectively clear the antigen from their systems, and they have a subclinical hepatic infection for prolonged periods. This group of patients is at risk for cirrhosis, with subsequent hepatic failure or hepatoma. Many chronic hepatitis carriers are unable to clear the infection because of immunosuppression as a result of another disease process, such as advanced HIV infection. AIDS patients are very likely to have had an HBV infection and to be chronic carriers. HIV-infected patients are also less likely to manifest an inflammatory response to hepatic infections. The CDC has estimated that as many as 80% of homosexual men, intravenous drug users, mentally retarded persons, and hemodialysis patients have serologic markers indicating a previous HBV infection.⁷³ Household contact or sexual relations with these high-risk individuals also involves a significant risk of acquiring HBV infection. It is estimated that up to 60% of such contacts have positive serology for HBV.

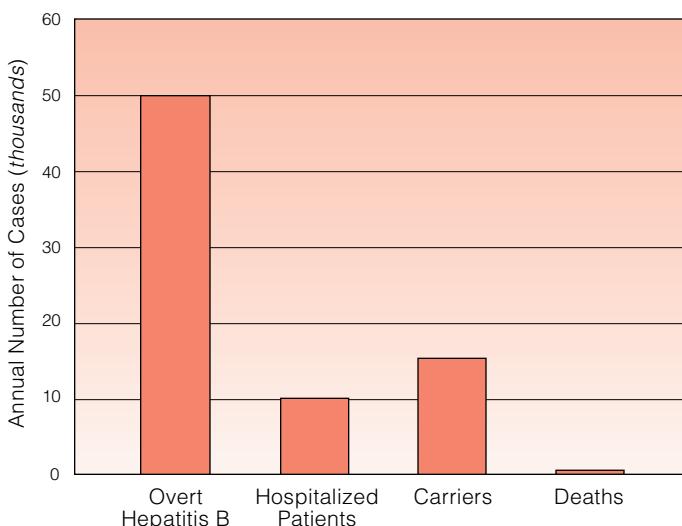

Figure 6 The annual incidence of hepatitis B infection in the United States is 200,000 cases. Various subgroups of hepatitis B patients are shown.⁷²

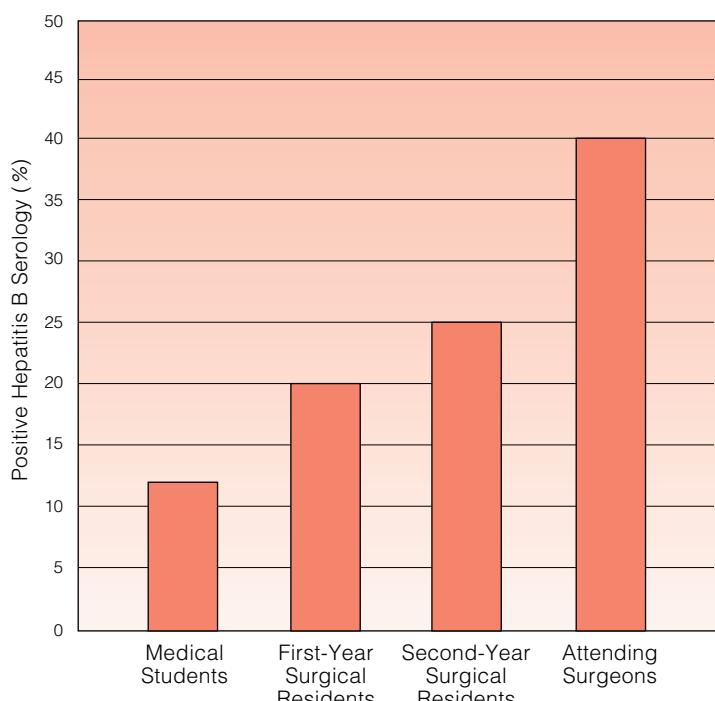

Figure 7 The prevalence of positive serology for hepatitis B increases among individuals in successive stages of a surgical career.⁷²

Exposure to hepatitis carriers is a risk for health care workers, particularly for those who work with blood products [see 8:20 *Viral Infection*]. Physicians involved with direct patient care are at especially high risk.⁷⁴ Those in administrative situations who do not have clinical contact with patients have a relatively low risk of acquiring hepatitis, whereas surgeons, particularly cardiac surgeons and transplant surgeons, are at especially high risk. The risk of hepatitis infection also increases with age.^{71,75} The incidence of positive hepatitis B serology is between 12% and 13% in students in their last year of medical school, nearly 20% in surgical residents at the end of their first year, and about 25% in surgical residents after the second year. During the course of an unimmunized senior surgeon's career, the risk of having hepatitis B approaches 50% [see Figure 7]. These risks are exceedingly high and emphasize the importance of widespread use of the hepatitis B vaccine [see 8:20 *Viral Infection*].

At least two studies have shown that there are numerous unimmunized practicing surgeons who finished medical school, training, or both before the hepatitis B vaccine first became available.^{61,76} These surgeons are at substantial risk for HBV infection and consequently need to be immunized. Surgeons who were immunized 5 or more years ago should have their titers checked; if titers are low, a booster is advisable.

Postexposure Prophylaxis

MANAGEMENT AFTER EXPOSURE TO HIV

If a health care worker is injured by a sharp object that was contaminated by exposure to fluid or tissue from an HIV-positive patient, a series of blood samples should be drawn at the time of injury and again at 6 weeks and 3, 6, and 12 months after the injury to determine whether HIV

infection has occurred. Although administration of antiretroviral therapy is recommended,⁷⁷ to date, no prospective trials have been performed to confirm its effectiveness in humans. A retrospective case-control study published in 1996 supported the post-exposure use of zidovudine.⁷⁸ The current recommendations for prophylaxis after a needle-stick injury are based on the likelihood of transmission from the incident.⁷⁹ In lower-risk situations, the risk of drug toxicity must be carefully weighed against the benefits of protection against HIV transmission.

The average risk of acquiring HIV after a percutaneous exposure is estimated to be 0.3%,⁸⁰ and the risk of acquiring HIV through mucocutaneous exposure approaches approximately 0.09%. It has been shown that the more blood transferred by a hollow-bore needle, the greater the likelihood of transmission. Clearly, patient factors such as viral burden and the presence of syncytia-inducing strains of virus will also influence the likelihood of seroconversion. Host factors such as cytotoxic T cell responses and perhaps T cell C3a/C5a receptors may also influence the outcome. With all this in mind, the CDC has formulated specific recommendations for postexposure prophylaxis (PEP).⁸¹

Because systemic infection after HIV exposure is thought not to occur immediately in primates, prompt initiation of antiretroviral therapy may sufficiently inhibit the initial replication to keep the inoculum of virus low and allow for effective immune clearance. Animal models are imperfect but have suggested that greatest efficacy of PEP was achieved when therapy was instituted within 24 hours of exposure. Overall efficacy of PEP is impossible to ascertain, because the incidence is fortunately low enough not to allow for a prospective study with sufficient statistical power to determine efficacy.

The current recommendations are based partly on the combination of simian studies, the experience with ziduvodine in a retrospective case-control study of health care workers, and collective experience with the prevention of vertical transmission through the use of antiviral prophylaxis. It is also recognized that as HIV-infected patients are increasingly likely to have been treated with a variety of retroviral agents, their likelihood of having multidrug-resistant strains of HIV increases correspondingly. Arbitrary selection of PEP agents may not be optimal; it is possible that knowledge of the patient's antiretroviral history and the results of genotypic antiretroviral resistance studies may need to be taken into account for optimal PEP selection. Whenever possible, physicians familiar with the source patient and local resistance patterns should be consulted on the choice of PEP regimens. However, institution of PEP should never be delayed for consultation, because the regimen can always be altered later if further information is obtained.

The choice of agents is largely empirical, but the need for PEP and the number of drugs to be used should be predicated on (1) the risk assessment of the injury, taking into account the source's HIV status (and, if the patient is HIV positive, the patient's clinical status and viral load); (2) solid-bore versus hollow-bore needle injury (large or small inoculum); (3) whether the source needle was used for arterial or venous puncture; and (4) whether the injury involved intact or nonintact skin or mucous membrane exposure.

A two-drug PEP regimen is probably adequate for situations in which the source is known to be HIV positive but thought to have a relatively low viral load, in which the source's HIV status is unknown but he or she is known to participate in high-risk activity, or in which the worker sustains either a minor percutaneous or mucous membrane exposure. A three-drug regimen would be advised with more severe percutaneous exposure, with

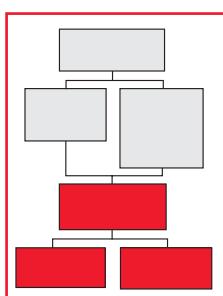

Table 4 Nucleoside Reverse Transcriptase Inhibitors

Agent	Toxicity
Zidovudine	Marrow suppression, myopathy, nausea
Stavudine	Peripheral neuropathy, pancreatitis, increased liver function tests
Lamivudine	Nausea, possible lipodystrophy, especially with concurrent stavudine
Didanosine	Pancreatitis, peripheral neuropathy, diarrhea
Abacavir	Life-threatening hypersensitivity reaction in approximately 5%

extensive exposure of intact skin or mucous membranes, or when the source is thought to have a high viral load. Because all the drugs used for PEP can have significant side effects, even in the short term, the potential risks of two-drug or three-drug therapy should be weighed against the likelihood of acquiring an HIV infection. With cases in which the source patient can be identified but the HIV status is unknown, a rapid HIV test such as the SUDS should be employed. If the results of such testing is negative, PEP should not be given. If rapid testing is not available, PEP can be offered until the source patient is proved to be HIV negative by conventional tests.

For the choice of agents, the 1998 CDC guidelines suggest ziduvudine and lamivudine (3TC) for two-agent therapy, with the addition of indinavir or nelfinavir for three-drug therapy. Zidovudine and 3TC are now available in a combination pill that is taken twice a day, which makes it a more convenient alternative; however, the increasing prevalence of the 184 mutation that confers 3TC resistance makes this less likely to be effective in situations involving patients who have been treated with 3TC. Newer drugs such as efavirenz may offer more tolerable alternatives to adding a protease inhibitor, as was recommended in the past. The 2001 guidelines leave the choice more open to local expertise.

No discussion of occupational exposure is complete without mention of HCV coinfection. Approximately 40% of all HIV-infected patients are coinfected with HCV; in intravenous drug users, the incidence of HCV coinfection can be as high as 90%. Medical personnel exposed to HCV via occupational injury should undergo baseline testing for HCV antibodies and a baseline alanine transaminase (ALT) determination, with repeat testing in 4 to 6 months. There is no prophylactic regimen available, but some authorities recommend early intervention with HCV therapy (interferon alfa and ribavirin) if HCV remains detectable—a finding that would indicate persistence of infection.

TOXICITIES OF HIGHLY ACTIVE ANTIVIRAL THERAPY

Nucleoside Reverse Transcriptase Inhibitors

Long-term exposure to antiretroviral agents has not only improved survival but also introduced a variety of significant toxicities that physicians evaluating an HIV-infected patient must take into account. Nucleoside toxicities became apparent with the introduction of the first nucleoside reverse transcriptase inhibitor, zidovudine, 15 years ago, but a multitude of side effects are now known to be associated with all agents in this class. These agents appear to be toxic primarily through their ability to inhibit mitochondrial DNA synthesis. When critical

levels of mitochondrial depletion are reached, the patient becomes symptomatic [see Table 4]. All the nucleoside transcriptase inhibitors have been associated with hepatotoxicity to some degree. All these agents may also cause increased levels of lactic acid, which may be asymptomatic or present as fulminant lactic acidosis and shock. Patients on combination therapy that includes both didanosine and stavudine seem to be at particular risk for severe lactic acidosis and hepatic steatosis. Patients may present with nausea, vomiting, abdominal pain, and diarrhea and become progressively more acidotic and hypotensive. Lactate levels in excess of 10 mmol/L are associated with multi-organ failure and a mortality of greater than 80%. Symptoms may develop gradually or suddenly and may occur from weeks to years after the start of antiretroviral therapy. Routine monitoring of lactic acid levels is of no benefit, because the results of such monitoring are not predictive of progression to symptomatic lactic acidemia. Once patients become asymptomatic, the keys to survival are early recognition, discontinuance of the offending drugs, and adequate oxygenation of tissues.

Nonnucleoside Reverse Transcriptase Inhibitors

The nonnucleoside reverse transcriptase inhibitors [see Table 5] are increasingly used in triple-drug regimens. They are known to cause rashes and have also been associated with hepatitis. Nevirapine has been implicated in fulminant hepatic failure in the setting of postexposure prophylaxis and in South African women. There is some concern that it may be more hepatotoxic in patients with hepatitis C infection.

Protease Inhibitors

The protease inhibitors [see Table 6] have been more frequently associated with metabolic syndromes involving alterations in fat metabolism, blood glucose, and lipids than with hepatitis or lactic acidemia. Hypercholesterolemia and hypertriglyceridemia have been associated with HAART, especially in regimens that include protease inhibitors. It is well recognized that there is a

Table 5 Nonnucleoside Reverse Transcriptase Inhibitors

Agent	Toxicity
Nevirapine	Rash, fever, hepatitis
Delavirdine	Rash, fever, hepatitis
Efavirenz	Rash, somnolence, insomnia, nightmares

Table 6 Protease Inhibitors

Agent	Toxicity
Indinavir	Nephrolithiasis, elevated bilirubin, fat redistribution, hyperglycemia, dry mouth
Nelfinavir	Diarrhea, abdominal pain
Ritonavir	Femoral numbness, diarrhea, hyperlipidemia
Saquinavir	Diarrhea, liver function abnormalities
Amprenavir	Diarrhea, nausea
Lopinavir/ritonavir	Diarrhea, hyperlipidemia

higher incidence of cardiac disease in HIV-infected patients receiving HAART than in age-matched control patients and that the presence of other traditional risk factors such as smoking and hypertension magnifies the risk. This has led most HIV practitioners to aggressively attempt to correct lipid abnormalities through the use of lipid-lowering agents. The increased risk of premature cardiac disease has also led physicians to consider

tests to attempt to identify occult coronary disease. Patients on protease inhibitors have been found to have insulin resistance even in the absence of overt diabetes, which also contributes to increased risk of coronary artery disease. For that reason, when HIV-infected patients with blood lipid abnormalities are being evaluated for elective surgical procedures, it is prudent to include a cardiac assessment.

22 METABOLIC RESPONSE TO CRITICAL ILLNESS

Palmer Q. Bessey, M.D.

Metabolic Responses in Surgical Patients

Debility commonly accompanies surgical illness. It occurs in varying degrees after elective operations, major trauma, burns, infections, and other critical illnesses. Debility is caused by a variety of factors, including specific biochemical and physiologic alterations that usually occur in response to injury and disease, especially those that persist for a long time. Some aspects of surgical care that are common to almost all patients can also cause debility. This discussion will review these clinical factors and metabolic responses in critically ill surgical patients and will indicate how the clinician can manage them so as to minimize patient debility.

The metabolic responses to critical illness have been studied in a variety of critically ill patients, especially those with trauma, burns, or sepsis. The responses are often grouped into phases on the basis of their temporal relation to the injury or insult. The so-called ebb phase, which is the early phase of the injury response, is characterized by (1) an elevated blood glucose level, (2) normal glucose production, (3) elevated free fatty acid levels, (4) a low insulin concentration, (5) elevated levels of catecholamines and glucagon, (6) an elevated blood lactate level, (7) depressed oxygen consumption, (8) below-normal cardiac output, and (9) below-normal core temperature.¹ The subsequent phase, the so-called flow phase, is characterized by (1) a normal or slightly elevated blood glucose level, (2) increased glucose production, (3) normal or slightly elevated free fatty acid levels, with flux increased, (4) a normal or elevated insulin concentration, (5) high normal or elevated levels of catecholamine and an elevated glucagon level, (6) a normal blood lactate level, (7) elevated oxygen consumption, (8) increased cardiac output, and (9) elevated core temperature.¹

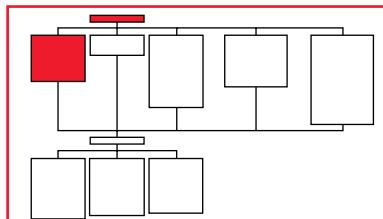

The ebb phase is dominated by cardiovascular instability, alterations in circulating blood volume, impairment of oxygen transport, and heightened autonomic activity. Emergency support of cardio-pulmonary performance is the paramount therapeutic concern. Shock [see 8:3 Shock] is the prototypical clinical manifestation of the ebb phase. After effective resuscitation has been accomplished and restoration of satisfactory oxygen transport has been achieved, the flow phase comes into play. These responses are marked by hyperdynamic circulatory changes, signs of inflammation, glucose intolerance, and muscle wasting. Surgical patients in the ICU usually exhibit these clinical features; these patients and the clinical challenge they pose are the focus of this chapter.

When wounds are closed and infection has resolved, repletion of lean tissue and fat stores and restoration of strength and stamina can begin. This final, anabolic phase often begins near the time of hospital discharge and may persist for months before the patient fully recovers.

Features of Critical Illness That Can Cause Debility

THE WOUND

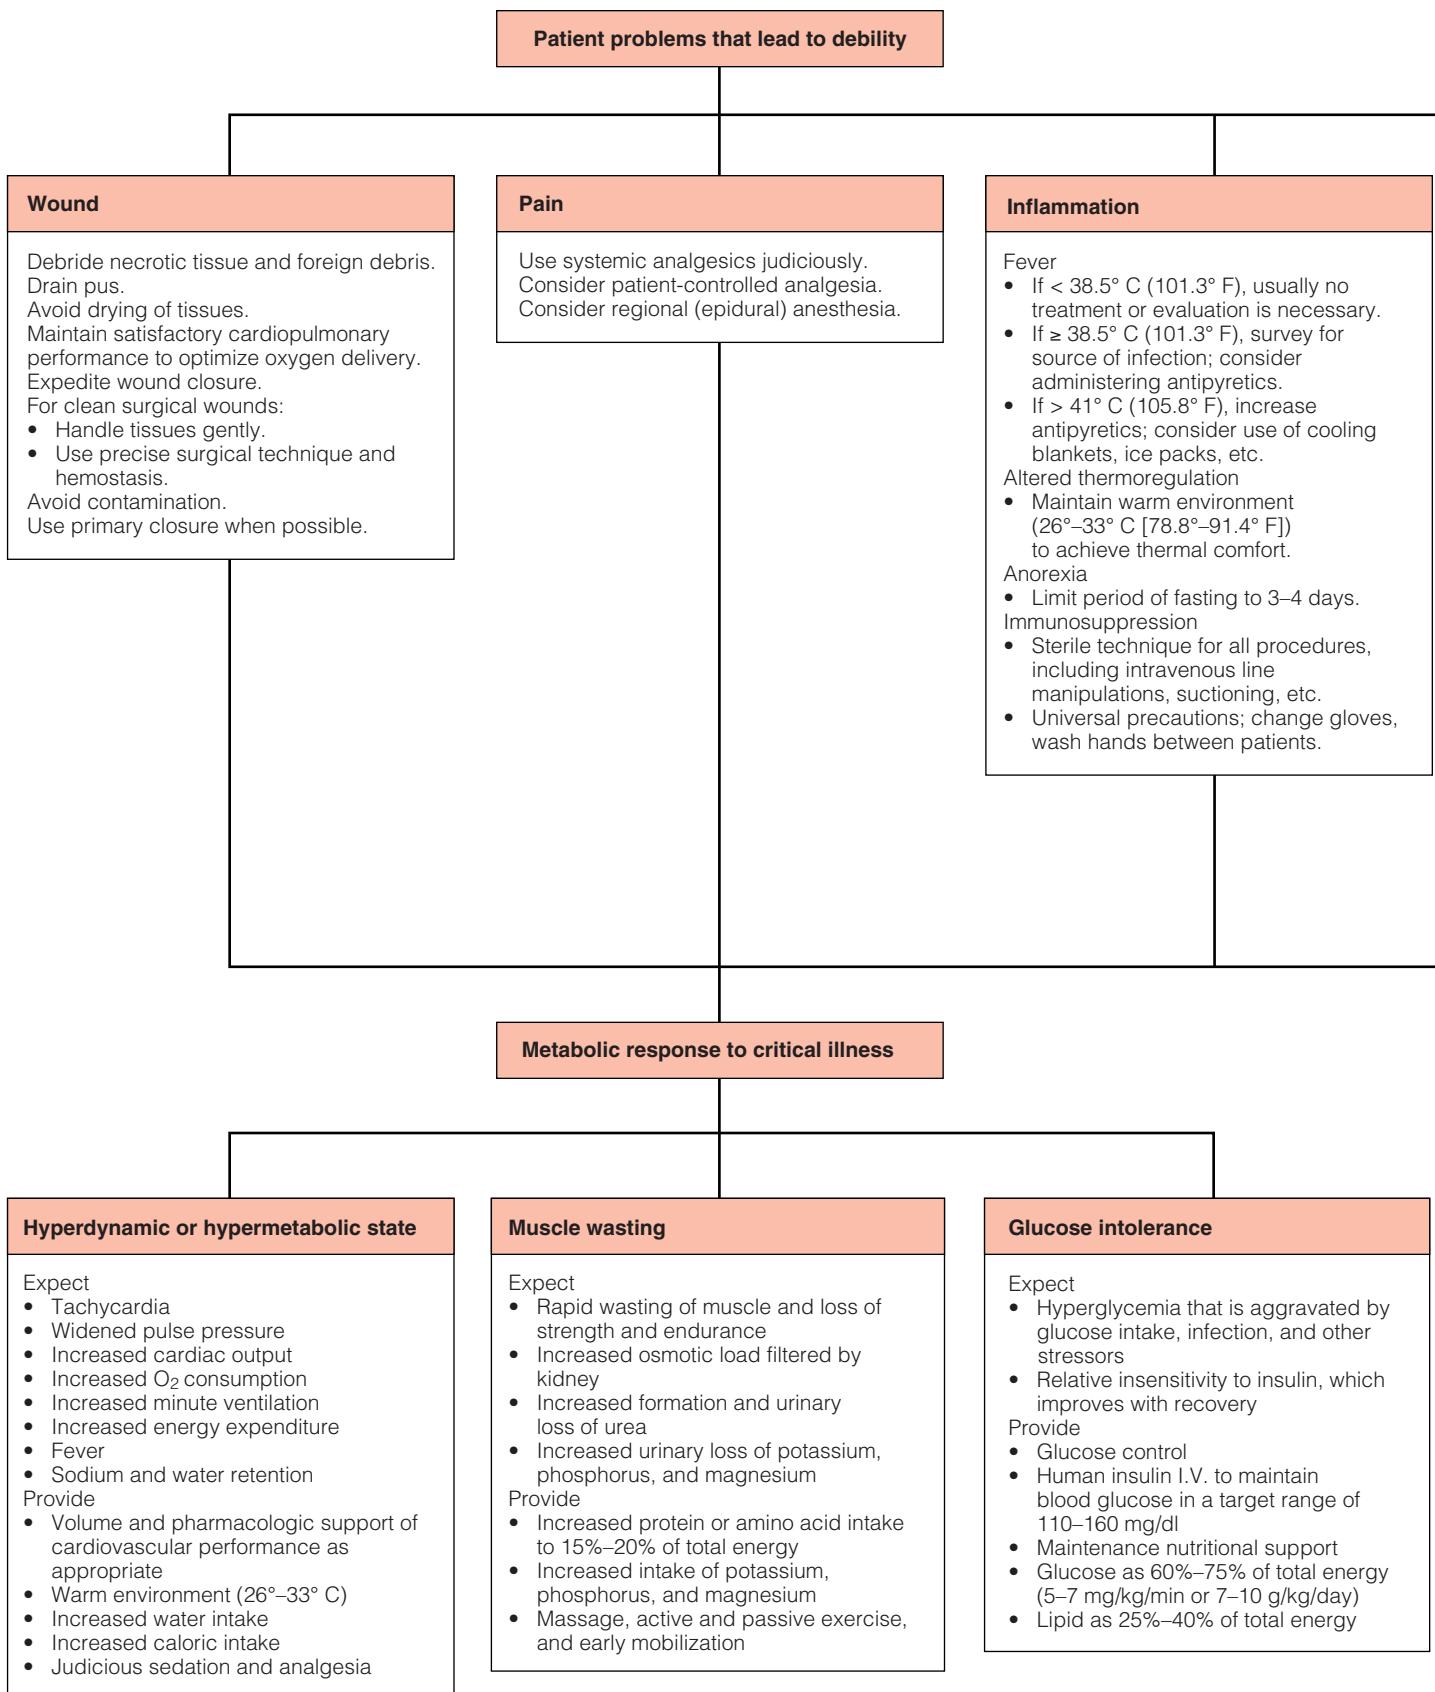

The surgical wound is not only a site of tissue disruption but also a site of inflammation and repair [see

1:7 Acute Wound Care]. After resuscitation, the surgeon's principal task is to expedite and promote wound healing and restore tissue integrity. Because the wound is often the proximate cause of patient debility, providing optimal wound care amounts to providing the best patient care.

Wounds with necrotic or devitalized tissue (e.g., from ischemic necrosis, gangrene, or burns), foreign debris, or grossly contaminated material do not heal readily, if they heal at all. Necrotic tissue and eschar (slough) must be debrided, usually surgically, although application of enzymatic agents to wounds has also been effective in some cases. Foreign material must be removed by either hydrotherapy or debridement. Pus must be drained or removed by irrigation and dressing changes. Contaminated wounds are left open so that they can be repeatedly examined and further necrotic material can be removed. Open wounds should be covered with a dressing to prevent drying (i.e., tissue oxidation) and further tissue slough, to reduce bacterial contamination, and to prevent further mechanical injury. Unfortunately, none of the currently available dressing materials achieve all of these goals. Once it becomes apparent that the wound tissues are viable and uninfected, the wound should be closed primarily if possible or with a skin graft.

The cellular processes involved in wound healing are critically dependent on adequate perfusion and delivery of oxygen, glucose, and other essential nutrients. Inadequate perfusion may result in relative tissue ischemia and delay wound healing. A principal responsibility of the clinician is therefore to ensure adequate tissue perfusion during the entire period of wound healing. For instance, resuscitation from shock should be continued after blood pressure is stabilized and until there is clinical evidence of adequate flow—usually associated with warm extremities, pink nail beds, brisk capillary refilling, full peripheral pulses, urine output greater than 0.5 ml/kg/hr (50 to 70 ml/hr in adults), clear sensorium, and improving metabolic acidosis. Adequate oxygenation must also be ensured. Occasionally, invasive monitoring of cardiopulmonary performance [see 8:26 Cardiopulmonary Monitoring] and tissue oxygenation as well as pharmacologic support may be required to ensure adequate perfusion and oxygen delivery.

Infection	Hospital treatment
<p>Initially diagnose by abrupt changes in fever, leukocytosis, hyperglycemia, pulmonary function, or pulse and blood pressure. Culture appropriately to establish microbiologic diagnosis. Administer broad-spectrum antibiotics empirically to cover likely pathogens if signs of organ system dysfunction and of sepsis develop. Debride necrotic tissue. Establish drainage; remove catheters. Prevent contamination of different sites on same patient. Prevent cross-contamination between patients.</p>	<p>Bed rest:</p> <ul style="list-style-type: none">• Encourage frequent turning, coughing, and deep breathing.• Encourage active, assisted exercise in bed when feasible.• Move to chair as soon as possible.• Use incentive spirometer or similar device.• Practice good hygiene and skin care, and provide massage. <p>Food deprivation:</p> <ul style="list-style-type: none">• Limit period of fasting to 3–4 days.• Begin nutritional support as soon as needed.• Provide enteral feeding when possible. <p>Invasive devices:</p> <ul style="list-style-type: none">• Remove as soon as no longer required.• Remove I.V. lines placed under suboptimal conditions as soon as feasible.• Consider changing I.V. lines or rotating site every 2 or 4 days.• Change I.V. site if redness or inflammation develops. <p>Sleep deprivation:</p> <ul style="list-style-type: none">• Reduce lighting and noise in ICU periodically, especially at night.• Orient patient frequently to time of day and situation.• Use sedation judiciously.

Metabolic Responses in Surgical Patients

Contused tissue, fractures, tissues surrounding an abscess or site of infection, inflammatory sites such as the pancreas in pancreatitis or the lung in acute respiratory distress syndrome (ARDS)—in fact, any mass of inflammatory tissue—can be considered to constitute the patient's wound because resolution of those focal sites of inflammation depends on the same basic cellular processes as does healing of an external wound.

Patients with a large total mass of inflammatory tissue—large wounds—usually are critically ill and clearly manifest most of the metabolic responses associated with critical illness [see Metabolic Responses That Can Cause Debility, below]. In contrast, patients with small wounds do not appear critically ill and are not significantly debilitated. Although elective operations result in wounds, the incisions are made under sterile, controlled conditions; there is minimal direct tissue injury, little contamination, no shock, and limited net loss of blood and fluid. The incisions are closed primarily and most often heal expeditiously. With the current proliferation of minimally invasive surgical techniques, operative incisions are now even more limited, patients recover more rapidly, and the resultant debility is minimal—often little more than a transient indisposition.

PAIN

Virtually all surgical patients experience some pain. Pain usually occurs in association with an incision or with a wound resulting from fracture, burn, contusion, or another type of injury. In addition to creating an unpleasant subjective experience, pain often limits physical activities, such as turning in bed, deep breathing, coughing, and walking, and thereby directly interferes with recovery. A variety of techniques are available for pain management. However, each approach has side effects, the potential for abuse, or other features that limit its application.

Acute pain has traditionally been managed by intermittent parenteral administration of narcotic analgesics when requested by the patient or when the nurse perceives the patient to be in pain. The intravenous route is now preferred, because it does not require a painful injection and avoids potential uptake abnormalities. Intravenous analgesics have a short duration of action and must be given frequently to maintain good, sustained pain control; the dose also must be relatively small to minimize the side effects of sedation and impaired gastric motility. Thus, this approach to pain control is relatively labor intensive. Theoretically, this approach can prevent overuse of narcotics; in practice, it often results in inconsistent pain control and underdosing.

Continuous infusion of narcotic analgesics provides more consistent pain control and is common in the ICU. The dose should be adjusted upward before painful procedures but otherwise should be kept as low as possible to avoid ileus and prolonged sedation. Patient-controlled analgesia (PCA) is an extension of this approach. The patient controls a pump that administers a prescribed dose of the agent when activated; the clinician determines the amount of drug in each dose and the total dose permissible in a given period. This technique has been well accepted by patients who are awake and alert and are capable of controlling the system. One benefit is that the total amount of drug administered for pain relief is usually less than is given in a conventional as-needed dosing schedule.²

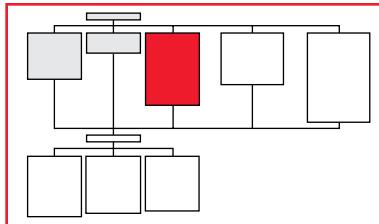

Administration of local anesthetics or narcotics into the epidural space may provide effective local pain relief without the sedating effects of parenteral narcotics. In addition, epidural anesthetics (but not opioids) reduce postoperative ileus.³ Effective epidural analgesia can be maintained for several days and may have a beneficial effect

on pulmonary function in patients with rib fractures or truncal wounds.⁴ This technique requires placement of a catheter in the epidural space.

Patients must be monitored closely, and the dosage schedule must be individualized. This technique is best suited to patients who will be relatively inactive for 24 to 36 hours postoperatively and who can be observed closely, such as patients in the ICU.

INFLAMMATION

Elevation of body temperature above normal, leukocytosis, and other signs of inflammation are common features of critical surgical illness and should be expected. The extent of temperature elevation is generally proportional to the severity of illness. In a patient with a major burn—an extreme example of critical surgical illness—body temperature may be as high as 39° C (102.2° F). The leukocyte count is also typically elevated and may be as high as 20,000 cells/mm³ during satisfactory recovery. A normal or subnormal body temperature or white blood cell count is atypical and may indicate sepsis, drug-induced leukopenia, or limited physiologic reserve. For example, a critically ill elderly patient with a major injury or infection may be afebrile and have a white blood cell count in the normal range.

Fever, however, is also a cardinal sign of infection. It may be difficult to distinguish between a typical postoperative or posttraumatic fever and a fever caused by invasive infection. An acute elevation in rectal temperature of 1.0° to 1.5° C (1.8° to 2.7° F) that occurs within a short period or a rectal temperature higher than 38.5° C (101.3° F) should be considered indicative of infection and should be investigated thoroughly. Sputum, urine, and blood cultures should be obtained, and all wounds should be inspected carefully for signs of inflammation or infection. Devices commonly associated with nosocomial infection—intravenous cannulas, urinary catheters, and endotracheal tubes—should be removed as soon as feasible or else changed (see below).

Because inflammation is such a prominent feature of all critical illness, including that in patients with serious infectious complications of chronic diseases, several clinical syndromes have been defined in an effort to stratify patients according to the severity of their inflammatory responses [see Table 1].⁵ These syndromes are associated with increased mortality, even in the absence of documented infection.⁶ In the remainder of this chapter, I will refer repeatedly to the metabolic responses to critical illness; this term incorporates these inflammatory syndromes and more besides, and its use permits a more comprehensive discussion.

Mild elevation of body temperature is usually well tolerated and requires no specific treatment. However, a higher fever may impose significant stress on the patient, as indicated by pronounced tachycardia, tachypnea, malaise, and, occasionally, restlessness. Thus, a body temperature higher than 39° C (102.2° F) is usually treated with antipyretics (e.g., acetaminophen, aspirin, indomethacin, or ibuprofen).

The fever experienced by critically ill patients is an upward adjustment of the thermoregulatory center in the brain, the central thermostat. A consequence of this adjustment is that the patient usually prefers a warmer environmental temperature than do normal individuals. An ambient temperature in the hospital that is comfortable for the staff is often perceived as cool by the patient, who must generate extra heat to maintain the adjusted body temperature. Thus, patient areas of the hospital should be kept warm, usually in the range of 26° to 33° C (78.8° to 91.4° F). This temperature range will

Table 1 Components of Inflammatory Syndromes⁵

Systemic inflammatory response syndrome (SIRS)—two or more of the following are required:	
Temperature > 38° C (100.4° F) or < 36° C (96.8° F)	
Heart rate > 90 beats/min	
Respirations > 20/min	
WBC > 12,000/mm ³ , < 4,000 mm ³ , or > 10% bands	
Sepsis

Sepsis	
Impaired cardiovascular performance necessitating fluid resuscitation	
Septic shock	
Severe sepsis	
Impaired cardiovascular performance necessitating inotropic support	

promote patient comfort and reduce the physiologic demands of cold stress. When moved into the OR, radiology suite, or other typically cool environments, patients should be insulated, or the room should be warmed.

Attempts to treat a patient with fever by surface cooling (ice packs, alcohol rubs, cooling blankets) are not uncommon. Rather than addressing the altered physiology underlying the fever, however, surface cooling imposes a marked cold stress on an already critically ill and stressed patient. Except in the presence of hyperpyrexia (temperature $\geq 41^{\circ}$ C [105.8° F]), surface cooling should be avoided; antipyretics should be administered first to reduce body temperature.

During acute surgical illness, patients typically have a poor appetite. Even when able to eat, they often do not consume sufficient nutrients even to approximate their needs. Accordingly, the clinician should initiate exogenous nutritional support early in the patient's course, especially if it is likely to be prolonged by the need for additional reparative procedures, such as fracture fixation or delayed wound closure.

Some degree of immunosuppression is also a common feature of inflammation. Thus, critically ill patients are more susceptible than normal to colonization and infection with a variety of microorganisms. Special attention to sterile technique during bedside procedures, the use of universal precautions, and hand washing after each patient encounter by all care providers should help reduce the risk of nosocomial infection.

INFECTION

Infections in hospitalized patients fall into two categories: they may be directly related to the patient's primary disease or injury (e.g., invasive burn wound sepsis, gangrene of an ischemic limb, or intra-abdominal abscess after perforated diverticulitis), or they may develop as a complication of physiologic support (e.g., pneumonia after prolonged mechanical ventilatory support).

Early diagnosis and treatment of infection in surgical patients can minimize debility. Most critically ill surgical patients experience fever, leukocytosis, tachycardia, widened pulse pressure (reduced vascular resistance), glucose intolerance, fluid retention, some impairment

of oxygenation, and other signs associated with the septic response. The challenge for the clinician is to distinguish patients in whom this response is caused by established infection from those in whom it is not the result of an infectious focus. A temperature higher than 38.5° C (101.3° F) or an acute increase in temperature accompanied by an abrupt change in the white blood cell count should prompt investigation for a developing infection [see Figure 1], which would include appropriate cultures and other diagnostic studies. Other signs that suggest underlying infection include relative hypothermia, leukopenia, thrombocytopenia, abrupt elevation or depression of the blood glucose level, restlessness, lassitude, hyperpnea, and failure to progress as expected.

If the presence of infection is suggested by the clinical setting, the magnitude of fever, or any other systemic signs (such as renal or respiratory dysfunction, marked hyperglycemia or hypoglycemia, hypothermia, or hypotension), broad-spectrum antibiotic coverage should be instituted empirically before culture results are available [see 8:14 *Clinical and Laboratory Diagnosis of Infection*]. Specific antimicrobial therapy should be begun once the presence of infection has been confirmed and the microbiologic diagnosis has been established. Other therapeutic measures may also be necessary to treat the infection. Draining an abscess, debriding or excising necrotic tissue, removing indwelling catheters and placing new ones at other sites, performing therapeutic bronchoscopy to ensure drainage of major airways, or creating a tracheostomy in the patient who requires an airway for improved bedside pulmonary toilet may also be advisable.

Because all critically ill patients are at risk for infection, efforts directed at prevention are worthwhile. Medical and nursing personnel can prevent the transmission of organisms from one patient to another by effective hand washing between patient contacts. Gloves used by health care workers for their own protection whenever they have contact with patients must be changed between patients. Of course, sterile techniques should be used during invasive procedures.

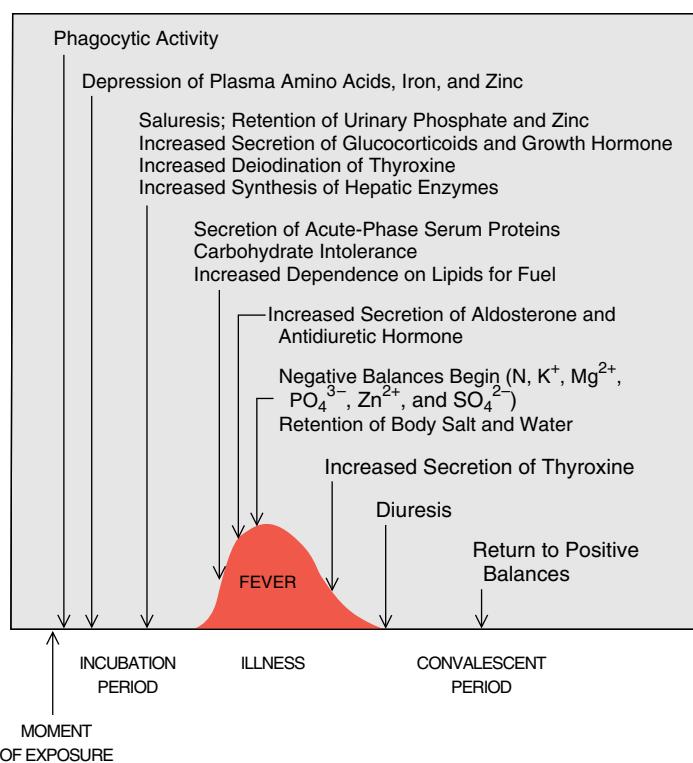

Figure 1 Illustrated is the time course of events that constitute the classic response to bacterial infection.²⁵³

Sites of insertion of intravascular cannulas should be inspected regularly, and the catheters should be moved to a new site if the skin becomes reddened or if pus is observed. Antibiotic-impregnated central venous catheters may reduce the incidence of catheter-related infection and thereby lower the frequency with which lines must be replaced.⁷ The prophylactic use of antibiotics in the ICU is controversial^{8–10} and cannot be encouraged at present.

IATROGENIC FACTORS

Bed Rest

Bed rest and inactivity both contribute to loss of muscle mass and strength. Immobility may result in progressive atelectasis, respiratory insufficiency, and pulmonary sepsis. If immobility is prolonged, open pressure sores may develop over bony prominences. Thus, patients should be turned frequently, and their position should be changed often. Patients who are able to participate actively in repositioning themselves should be encouraged to do so by helping to turn or lift themselves. They should be urged to take deep breaths and cough. An incentive spirometer is inexpensive and is often helpful in this regard. When patients are hemodynamically stable, they should be moved to a chair, provided that no musculoskeletal contraindications are present. This position improves ventilation and helps preserve postural reflexes. Patients should assist in sitting up as much as is feasible. Even simple actions such as standing in place or bearing weight during the transfer may be beneficial. Active and passive range-of-motion exercises can help maintain joint function. Proper positioning of the extremities may be necessary to prevent contractures and to preserve range of motion.

Skin integrity is preserved not only by frequent position changes but also by attention to hygiene. Patients should be bathed regularly, with special attention paid to intertriginous areas. Any soiling with blood, stool, urine, or other material should be removed and the skin thoroughly dried. Massage and application of moisturizing lotions are also helpful. The use of foam or air mattress pads that distribute body weight over a large area or low-air-loss beds may also benefit the patient confined to bed for a prolonged period. However, these devices are no substitute for good nursing care.

Food Deprivation

Food is commonly withheld from the patient before and during various diagnostic and therapeutic procedures as well as before operations or after injury. Starvation for several days appears to be well tolerated by patients who were relatively well nourished before their critical illness. However, if food deprivation is prolonged, the complications of starvation will compound the effects of critical surgical illness. Total starvation should usually be limited to a period no longer than 3 or 4 days. Nutritional support should be instituted via the most effective and safest route possible [see 8:23 *Nutritional Support*].

Invasive Devices

A variety of tubes, catheters, and drains are essential for the proper care and monitoring of critically ill patients. However, each of these devices transgresses a normal barrier to infection, and each is associated with infectious risks and other complications. An invasive device should be removed as soon as it is no longer required. Intravenous lines placed in the emergency room or under less than ideal conditions (e.g., at the scene of an accident or while the patient is en route to the hospital) should be removed as soon as possible and replaced, if necessary, with new devices by means of appropriate sterile

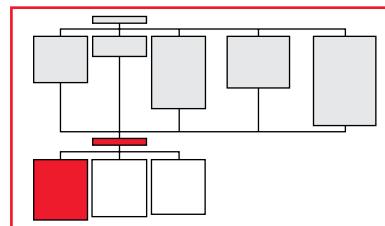

technique. Such lines should also be changed if the puncture site is red, inflamed, or purulent. With most of these devices, the risk of infectious complications increases after 3 or 4 days.¹¹ Regular replacement is commonly practiced, especially if the patient becomes febrile. Catheters impregnated with antibiotics appear not to require such frequent exchanges and may be safely used for longer periods.⁷

Sleep Deprivation

Normal sleep patterns are disturbed in ICU patients, in part because of the constant light and noise in the ICU and because of repetitive stimulation by the ICU staff. Such disturbances, in combination with other stresses associated with illness, often result in confusion, disorientation, anxiety, and, occasionally, frank psychosis. As many efforts as possible should be made to orient the patient, including the use of wall calendars, clocks, and other methods that serve as normal day-night indicators (e.g., turning the lights down at night). Even the personal activities of daily living, such as bathing and shaving, can serve as time cues. Patients should be reassured and reminded about the date, the time, their location, and the reason for their hospitalization. Sedatives and hypnotics may be useful in critically ill patients but occasionally have a paradoxically excitatory effect.

Metabolic Responses That Can Cause Debility

All of the clinical factors of surgical care contribute to or affect various physiologic and biochemical alterations that occur in response to critical illness; these physiologic and biochemical alterations collectively constitute the metabolic response to critical illness. The intensity and duration of this response determine debility. Current critical care management generally supports rather than modifies the response. Three major features of the metabolic response to critical illness affect clinical care: the hyperdynamic or hypermetabolic state, muscle wasting, and glucose intolerance.

HYPERDYNAMIC OR HYPERMETABOLIC STATE

In recovery from critical illness, several organ systems function at an accelerated pace. Principal among these is the cardiovascular system. Tachycardia and a widened pulse pressure are typically present and reflect cardiac output greater than that expected in a resting, healthy individual. The increased blood flow is distributed to most vascular beds, especially to inflammatory tissue or the wound, and supports increased cellular activity in the healing wound. In the kidneys, increased flow is associated with an elevated glomerular filtration rate. Thus, drug excretion may be accelerated, and increased dosages may be required to maintain therapeutic plasma concentrations.

Accompanying the increases in cardiac output and regional blood flow is an increase in oxygen delivery (transport) to the microcirculation. This increase in oxygen delivery supports the enhanced oxygen requirements of several organ systems. Total body oxygen consumption ($\dot{V}O_2$) is greater than normal because of the increased oxidation of body fuels—carbohydrates, fats, and amino acids—needed to provide the energy to drive the cellular machinery at this accelerated pace [see Figure 2]. These reactions produce heat. Heat production, also referred to as energy expenditure or metabolic rate, is increased in critically ill patients, who thus are said to be hypermetabolic.

The increase in $\dot{V}O_2$ is paralleled by increased carbon dioxide production ($\dot{V}CO_2$), which, under normal conditions, stimulates breathing and augments minute ventilation. For patients who require ven-

tulatory assistance, the ventilator should be set to deliver a minute ventilation that is greater than normal.

As discussed earlier, critically ill patients typically have a fever and prefer warmer ambient temperatures than normal individuals. In these patients, metabolic rates increase in part to maintain a higher than normal core temperature. A warm environment may help blunt the patient's increased heat production and energy needs.

Associated with the hyperdynamic state of critical illness is expansion of the extracellular fluid (ECF) compartment. Total body water and total body sodium are increased. This expansion occurs perioperatively or with resuscitation after injury. Short-term changes in body weight reflect alterations in body water and in lean tissue mass. Slow, persistent expansion of the ECF may mask loss of tissue mass. Conversely, spontaneous diuresis of sodium and water during recovery may lead to pronounced weight loss in a patient who otherwise appears to be progressing well.

During critical illness, the daily loss of body water is increased in several ways. Fever accelerates insensible loss of body water, and renal loss may be greater than normal because of the increased osmotic load caused by the breakdown of lean tissue (see below). If there are open wounds, evaporative water loss is markedly increased, in proportion to the size of the open wound. Thus, maintenance water requirements may be greater than normal. It is often necessary to monitor both the intravascular fluid volume, using values for central venous or pulmonary arterial wedge pressures, and the ECF composition or tonicity, as indicated by changes in serum sodium concentrations.

The clinician should provide not only volume and possible pharmacologic support to maintain a hyperdynamic circulation but also an increased amount of calories to meet the patient's elevated energy needs. These needs can often be reliably estimated on the basis of the patient's age, sex, body size, and critical illness. Occasionally, it may be helpful to measure the patient's $\dot{V}O_2$ and $\dot{V}CO_2$ and to use these values to calculate daily caloric requirements.

In addition to providing cardiopulmonary and nutritional support to critically ill, hyperdynamic patients, the clinician should try to neutralize factors that may augment the hyperdynamic response to critical illness. Judicious analgesia and sedation provide metabolic benefits and relieve pain and anxiety. Providing a warm environment mitigates the hyperdynamic response by reducing cold stress. Antipyretics reduce the heart rate during periods of extreme fever.

MUSCLE WASTING

The distinguishing feature of the debility of critical illness is marked muscle wasting and weakness. Wasting is in part a consequence of accelerated muscle protein breakdown, which is generally related to the severity of illness [see Figure 2]. The increased protein breakdown presumably serves to mobilize amino acids for synthesis of new protein in wounds; for proliferation of phagocytes, macrophages, and other cellular components involved in wound healing; and for synthesis of acute-phase proteins and glucose in the liver. The increased synthetic work and processing of amino acids in the liver result in increased production of urea, which is filtered and excreted by the kidneys. In the presence of renal dysfunction, blood urea nitrogen (BUN) may rise rapidly.

To reduce muscle wasting, additional exogenous protein or amino acids are provided through nutritional support. In general, protein needs increase in proportion to caloric requirements. However, for the critically ill surgical patient, it may be beneficial to provide at least

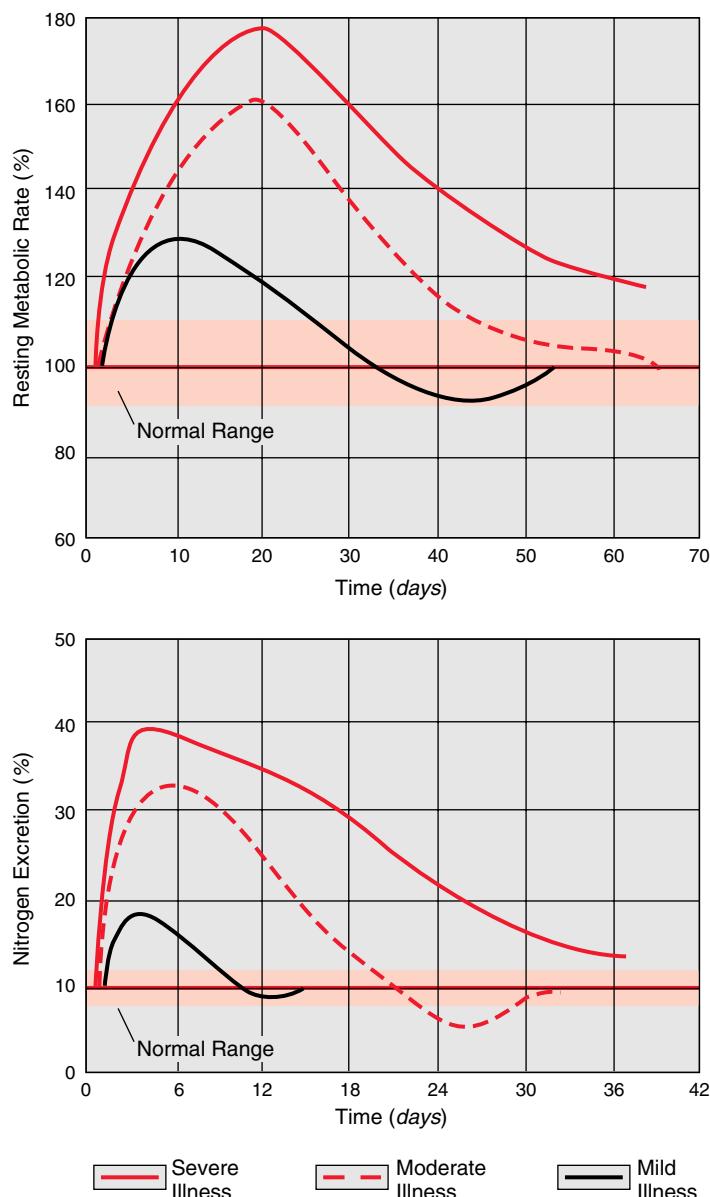

Figure 2 Increased resting metabolic activity (hypermetabolism) and increased nitrogen loss are closely related during critical surgical illness. Both correlate with the severity of illness and return to normal as the patient recovers. Patients with severe illness are represented by the solid red line, those with moderate illness by the broken red line, and those with mild illness by the solid black line; the normal range is shown by the light-red bar.

20% to 25% of total calories as protein or amino acids. BUN may be higher than normal (at least 20 to 30 mg/dL) with this level of amino acid intake, even if renal function is normal.

In addition to amino acids, other intracellular constituents are released by these catabolic processes and subsequently excreted. Thus, metabolic alkalosis often develops, associated with mild hypochloremia and with reduction in total body potassium and magnesium. Repletion with potassium chloride and magnesium sulfate is usually effective. During nutritional support, generous amounts of potassium (≥ 100 mEq/day), magnesium (≥ 30 mEq/day), phosphate (20 to 30 mmol/day), and trace minerals should be provided to promote synthesis and restoration of intracellular proteins and other constituents.

Muscle mass is also lost as a result of disuse. The critically ill patient is usually confined to bed and may be further immobilized because of

Table 2 Blood Glucose and Insulin Concentrations in Burn Patients¹

Group	N	Burn Size (% TBS)	Postburn Day Studied	Fasting Blood Glucose		Basal Insulin (μ U/ml)
				(mmol/L)	(mg/dl)	
Control subjects	12	—	—	3.88 ± 0.11	69.8 ± 1.9	22 ± 3
Resuscitated burn patients	4	71	1	7.77 ± 0.61	139.9 ± 10.9	20 ± 6
Hypermetabolic burn patients	17	42	9	6.27 ± 0.28	112.9 ± 5.0	22 ± 2
Convalescing burn patients	5	56.5	69	4.05 ± 0.33	72.9 ± 5.9	14 ± 1
Septic burn patients	15	71	10	6.43 ± 0.55	115.8 ± 9.9	22 ± 4
Treated septic burn patients	4	72	11	6.11 ± 0.83	110.0 ± 15.9	12 ± 3

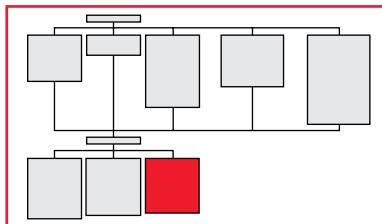

traction, monitoring devices, mechanical ventilation, and sedation. Massage, passive range-of-motion exercises, early mobilization, and limited bed exercises (e.g., moving from bed to chair, use of a trapeze bar to assist with positioning) may be helpful in reducing muscle wasting and debility.

GLUCOSE INTOLERANCE

Critically ill patients usually exhibit glucose intolerance similar to that seen in diabetic patients [see Table 2]. Hyperglycemia during critical illness is a result of both increased production of glucose by the liver and decreased uptake of glucose by insulin-dependent tissues. These processes occur despite normal or exaggerated insulin responses to hyperglycemia.

Hyperglycemia may be marked, especially if the patient is receiving a large glucose load, such as might be provided with nutritional support. Hyperglycemia may exacerbate ventilatory insufficiency, contribute to hepatic dysfunction, and provoke osmotic diuresis, thereby leading to dehydration and a hyperosmolar state. Hyperglycemia has also been associated with an increased risk of postoperative infection, renal failure, increased transfusion requirements, and death in critically ill patients. Vigorous attempts to control the blood glucose concentration are therefore warranted.

The provision of safe amounts of glucose and the administration of exogenous recombinant human insulin are the mainstays of therapy for glucose control. Because insulin resistance is present in patients with critical illness, relatively large quantities of insulin may be required to control the blood glucose level. Intravenous administration of insulin provides rapid control and prevents unpredictable

subcutaneous uptake caused by variations in blood flow. Because of its short half-life, intravenous insulin must be administered either in frequent intermittent doses or by continuous infusion. Both techniques can be used with a reasonable margin of safety. Blood glucose levels may be determined rapidly by using a portable glucose analyzer at the bedside on a small blood sample drawn every 1 or 2 hours. On the basis of the blood glucose value, a predetermined insulin dose may be administered (on a so-called sliding scale) or the infusion rate may be adjusted. Current data suggest that the optimal range for blood glucose values in critically ill surgical patients is 80 to 110 mg/dl (4.4 to 6.1 mmol/L).¹² One half to two thirds of the total insulin dose required to maintain blood glucose in this target range in a 24-hour period may be added to the intravenous feeding regimen on the next day. In this way, the blood glucose level is ultimately maintained in an acceptable range.

The degree of glucose intolerance will vary over the course of the critical illness. Therefore, regular monitoring of blood glucose concentrations is advisable, even after adequate control has been achieved. Further episodes of stress-inducing conditions, especially infection, may exacerbate glucose intolerance; an abrupt rise in blood glucose concentration may be the first indication of impending sepsis. As the patient recovers, glucose tolerance improves and the requirement for insulin decreases. When the patient is transferred from intravenous nutrition to enteral nutrition, insulin requirements often decrease despite similar nutrient intake.

Glucose remains an important fuel during critical illness, especially for healing wounds. However, the ability to utilize glucose effectively appears to be reduced. Most of the total energy administered in nutritional support should be provided by glucose (60% to 75% of total calories). The dose of glucose should, however, be limited if marked hyperglycemia cannot be readily controlled with insulin. The remaining calories can be provided by fat emulsion.

Discussion

The clinical features of all critical illnesses are similar, regardless of the type of insult sustained, be it injury, operation, or infection. Similar responses can be seen in a wide variety of animals that have been injured or challenged by invasive infection.^{13,14} These responses to critical illness presumably evolved because they confer an advantage with respect to survival. In fact, it seems indisputable that when an individual organism acquires an enhanced ability to recover from an injury or infection, the species is thereby benefited. Accordingly, the metabolic responses to critical illness are often considered to be adaptive reactions that serve to promote recovery.

There is a cost for this benefit, however, and that is debility. In addition, the metabolic responses to critical illness can lead to organ system dysfunction. Critically ill patients also typically have

immunologic abnormalities that may make them more susceptible to invasive infection by a variety of microorganisms, including those that are not usually pathogenic. The syndrome of multiorgan failure and sepsis that may develop in association with the metabolic responses to critical illness is often the final route to death [see 8:13 *Multiple Organ Dysfunction Syndrome*]. Thus, in some ways, certain metabolic responses seem maladaptive in that they retard recovery and lead to organ failure and death.

An improved understanding of the metabolic responses to critical illness may benefit patients in two ways. First, it may facilitate the development of improved supportive therapies. Much of current critical care practice is based on our understanding of these processes and has been designed to support them. Second, a better under-

standing of the mechanisms underlying the metabolic responses to critical illness may lead to strategies for altering the responses so as to stimulate those features that are beneficial and promote recovery and to suppress or limit those features that are debilitating or lead to organ system dysfunction.

Integrated Metabolic Response to Critical Illness

The metabolic responses to injury and critical illness occur simultaneously. They primarily involve the liver, skeletal muscle, the gut, the kidneys, and the wound or focus of inflammation [see *Figure 3*]. The heart also plays a major role by providing the motive force for the high rate of blood flow that is required to support increased exchange of nutrients and other substances between organs. The central and autonomic nervous systems and endocrine tissues are mainly involved in regulation of the responses.

The wound, which may include one or more foci of infection and other sites of inflammation in addition to external injuries, plays a principal role. It acts as a large arteriovenous shunt, robbing the host of blood supply and demanding increased cardiovascular work. The wound also induces and controls profound metabolic changes, which subside as the wound heals. Tissues are broken down, presumably to provide substrates for a variety of synthetic and energy-producing processes. The cost to the patient is increased metabolic work, elevated energy requirements, erosion of lean body tissue, and debility.

The healing wound is a site of intense metabolic activity. Dissolution and removal of necrotic tissue, containment and killing of bacteria, collagen synthesis and wound repair, cellular proliferation, and restoration of tissue integrity occur, often simultaneously. These processes require energy and a variety of substrates, particularly amino acids for protein synthesis. The microenvironment of a wound is often relatively hypoxic. However, inflammatory cells have a marked capacity for glycolytic metabolism,¹⁵ in which adenosine triphosphate (ATP) can be generated without the consumption of oxygen. This capacity persists even when oxygen delivery is sufficient. Glucose is thus the principal fuel for the healing wound. It is metabolized to lactate, which is then released into the circulation for transport to the liver.

The liver produces the additional glucose that is required by the wound. It is capable of manufacturing glucose from lactate. In this manner, glucose is recycled between the liver and the wound, and there is no net gain or loss of carbon atoms. The liver also synthesizes glucose from amino acids, principally alanine, which comes from both skeletal muscle and the gut. This mechanism is termed gluconeogenesis. The nitrogen contained in the amino acids is converted to urea and excreted. The liver also synthesizes a variety of circulating proteins in response to inflammation and infection (so-called acute-phase proteins). All of these synthetic processes require energy, produced in part by fat oxidation, and therefore contribute to a general increase in energy utilization, heat production, and metabolic rate.

Skeletal muscle protein breaks down at an accelerated rate after injury and critical illness, releasing a variety of substances into the circulation, including creatine and creatinine, 3-methylhistidine, potassium, magnesium, and amino acids. The amino acids serve as precursors for protein synthesis in the wound and in the liver. The released amino acids do not reflect a simple dissolution of protein. Rather, alanine and glutamine are disproportionately released. Alanine can be readily converted to glucose in the liver. Glutamine serves both as a fuel—especially for the gut and for rapidly proliferating cells, including inflammatory cells and fibroblasts—and as a precursor for renal ammonia production, which is an important mechanism for neutralizing excreted acid loads.

Although muscle tissue in healthy persons is usually quite sensitive to insulin and commonly serves as a site of glucose storage, mus-

cle is resistant to insulin after injury or critical illness, and its capacity for glucose storage is reduced significantly. This response contributes to glucose intolerance and helps direct glucose to the healing wound.

The gut was long considered to be essentially inactive during convalescence, but it now appears to play a central role in the metabolic response to critical illness [see **8:23 Nutritional Support**]. During critical illness, the gut utilizes glutamine as its principal fuel, converting glutamine to alanine, which is transported to the liver by the portal circulation. More important, perhaps, the gut can be a portal of entry for bacteria and bacterial toxins, which can worsen or perpetuate critical illness [**8:13 Multiple Organ Dysfunction Syndrome**].

The kidneys also contribute to the generalized increase in physiologic work and energy requirements that accompanies critical illness. The kidneys must excrete an increased solute load consisting of urea, potassium, magnesium, weak acids, and other intracellular constituents. In addition, many drugs and their metabolites depend on renal excretion. Production of ammonia from glutamine may be increased to neutralize acid loads. Many of these processes require energy.

All of these regional metabolic processes occur simultaneously. The net integrated metabolic response is evident clinically as increased energy expenditure and heat production, fever, accelerated nitrogen excretion and muscle wasting, and glucose intolerance. The wound appears to exert a controlling influence on the intensity and duration of the responses to critical illness or injury: the intensity is proportional to the size of the wound or the mass of inflammatory tissue. The larger the wound, the more intense the metabolic responses. As the wound heals and as inflammation subsides, the heightened metabolic demands abate. Expedited wound closure and definitive treatment of infection are the most effective forms of anticatabolic therapy.

Hypermetabolism

Because humans maintain fairly constant body temperature, the heat generated by the body is equal to the heat lost in biochemical and physiologic processes and is an indicator of overall metabolic activity. This heat ultimately results from the oxidation of organic fuels. The rate of heat production, or metabolic rate (MR), is therefore related to $\dot{V}O_2$ and $\dot{V}CO_2$. It may be measured directly by means of direct calorimetry, or it may be calculated from measurements of $\dot{V}O_2$, $\dot{V}CO_2$, and body surface area (BSA) by means of indirect calorimetry:

$$\text{MR (kcal/m}^2/\text{hr)} = \frac{[(3.9 \times \dot{V}O_2 \text{ [L/min]} + (1.1 \times \dot{V}CO_2 \text{ [L/min]})] \times 60 \text{ (min/hr)}}{\text{BSA (m}^2)}$$

A third term, $-3.3 \times$ urea nitrogen loss (g/time), is sometimes added to account for the heat produced by urea formation. However, it is usually a small factor, adjusting MR by only 2% to 3%.¹⁶

Values determined by direct and indirect calorimetry under steady-state conditions are comparable.¹⁷ When metabolic rates of normal individuals are determined under controlled basal conditions, the values are reproducible and predictable ($\pm 12\%$) on the basis of age, sex, and body size.¹⁸ When metabolic rates of critically ill patients with satisfactory hemodynamic function are determined under similar conditions, the rates are greater than predicted. Thus, patients are said to be hypermetabolic.

The degree of hypermetabolism is proportional to the severity of illness. This phenomenon was most dramatically demonstrated in careful studies of burn patients performed in the 1970s.¹⁹ The increase in resting metabolic rate was proportional to the extent of tissue injury—that is, to the amount of the BSA that was burned. Hypermetabolism has also been demonstrated in a variety of other critically ill patients, but it has usually been less severe than that seen in patients with major burns.²⁰

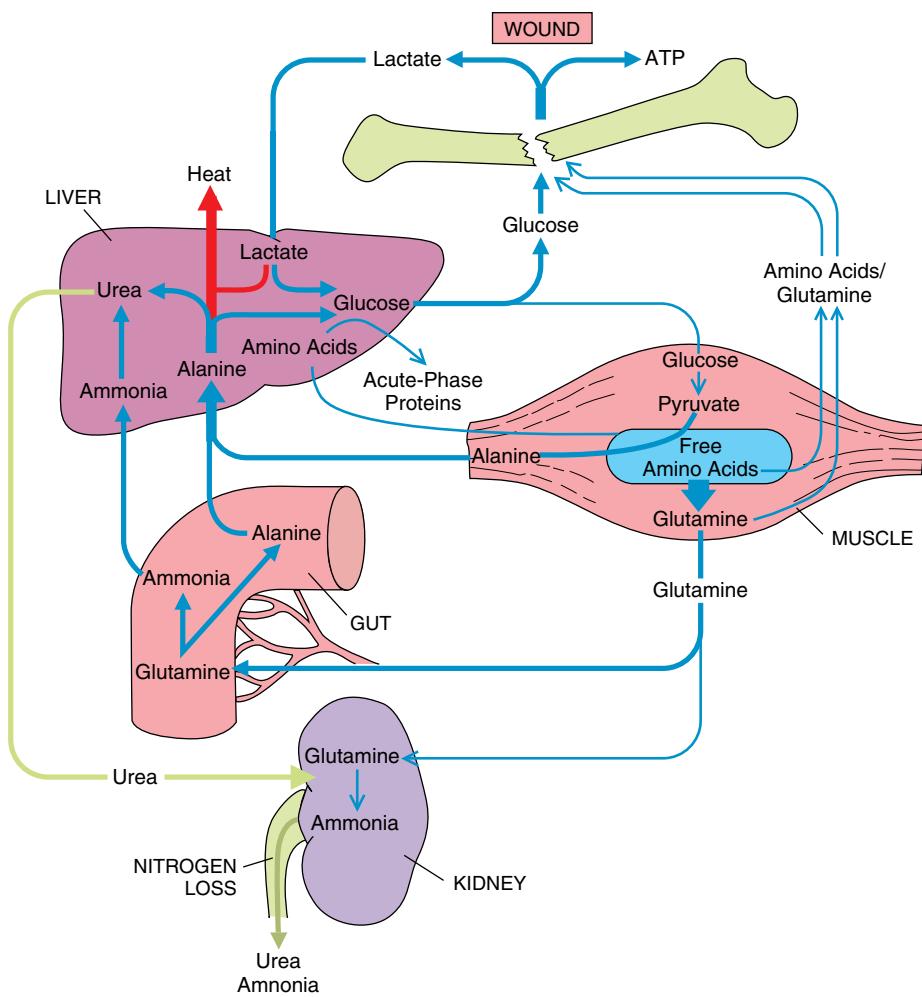

Figure 3 The metabolic response to critical illness includes characteristic alterations in the exchange of substrates between organs. Presumably, these responses occur in support of the healing wound and are facilitated by a hyperdynamic circulation. The wound requires glucose (and probably glutamine) as a primary respiratory fuel. Glucose is converted to lactate; this conversion can occur in an aerobic environment. Lactate is transported to the liver for conversion back into glucose. The recycling of lactate to glucose is a major pathway that requires the input of energy and thereby contributes to increased energy utilization. Most of the glucose required for the healing wound (i.e., inflammatory tissue) is produced by the liver, not only from lactate but also from alanine and other glucogenic amino acids. These reactions require energy and also result in the formation of urea. Muscle is the major source of amino acids, which are used for protein synthesis both in the wound and in the liver. The most abundant amino acids released from muscle are alanine and glutamine. Glutamine serves as a primary fuel for the gut, producing ammonia and other products (e.g., alanine) that are processed by the liver. In addition, glutamine may help buffer filtered acid loads in the kidneys by the formation of ammonia. These metabolic processes contribute to the hypermetabolism, hyperdynamic circulation, increased nitrogen loss, and glucose intolerance that are clinically evident in critically ill patients.

In the burn patients, moreover, there was a limit to the hypermetabolism: metabolic rates of patients with extensive burns were little different from those of patients with burns covering 50% to 60% of BSA.

These observations suggest that there is a limit to the metabolic activity that patients can support in response to critical illness. The difference between this limit and the magnitude of the patient's actual responses defines physiologic reserve [see Figure 4]. Physiologic reserve is presumably also affected by the patient's age and state of health before the critical illness. It reflects the patient's ability to meet additional complicating stresses, such as infection, volume loss, pain, anxiety, and cold ambient temperatures. For example, when patients are exposed to progressively colder ambient temperatures, the metabolic rate generally increases. However, when a group of patients

with very large burns were exposed to cold temperatures, their already high metabolic rates did not increase but actually fell.¹⁹ None of these patients survived the injury, presumably because of inability to respond to new stresses. In another group of burn patients, the inability to increase metabolic rate to facilitate rewarming after skin grafting procedures also identified nonsurvivors.²¹ When patients are cared for in a warm environment, hypermetabolism is reduced and physiologic reserve is increased.

Hypermetabolism refers to an increase in total body oxidative metabolism that is manifested by increases in total body $\dot{V}O_2$, cardiac output, and MR. Regional $\dot{V}O_2$ is generally increased throughout most tissue beds, but regional blood flow is not. The additional total body flow is directed largely to the wound or site of inflammation.

and to the splanchnic circulation, and it appears to supply the wound with increased amounts of glucose and other nutrients. In studies of patients who had sustained a large burn on one leg and no burn on the other, Wilmore and colleagues found that $\dot{V}O_2$ of both limbs was increased in proportion to the total BSA burned and represented a fairly constant 6% of total body $\dot{V}O_2$.²² However, blood flow to the injured extremity was approximately twice that to the uninjured limb. Blood flow was proportional to the extent of the local injury and was directed to the surface wound.²³

Oxygen consumption by the splanchnic and renal circulations also increases in proportion to total body $\dot{V}O_2$ and hence in proportion to total body injury.²⁴ Splanchnic flow increases in proportion to total body flow (cardiac output), and together with the blood flow to the wound, it accounts for a large part of the increase in cardiac output in critically ill patients.²⁵ The increase in renal blood flow correlates with solute load rather than with $\dot{V}O_2$. From these and other studies, it is possible to calculate how oxygen consumption and cardiac output are partitioned among different vascular beds.²⁶

Altered Temperature Regulation

Body temperature is determined by the balance between heat production and heat loss. It is normally closely regulated and maintained within a narrow range. Critically ill patients typically have an elevated body temperature, even in the absence of clinical infection.²⁷ Heat production, as measured by metabolic rate, is increased in the critically ill patient. Heat loss may also be elevated in these patients.

It was once thought that increased evaporative heat loss was the driving force for hypermetabolism, at least in burn patients.^{28,29} Barr and associates tested this assumption.³⁰ Although patients treated in warm, dry air showed substantially increased evaporation of water from the burn wound and more rapid drying of the wound surfaces than did patients exposed to normal ward conditions, they had reduced hypermetabolism and a smaller degree of weight loss.

Several other studies have examined the relation between thermoregulatory factors (evaporative heat loss and ambient temperature) and hypermetabolism. For example, the metabolic rates of burn patients were determined at several ambient temperatures, ranging from 19° to 33° C (66.2° to 91.4° F) [see Table 3].³¹ Metabolic rate decreased as ambient temperature was increased, but core temperature remained elevated at all ambient temperatures, indicating that thermoregulation in these patients occurred in relation to an elevated central reference temperature. When febrile burn patients in another study were allowed to set the ambient temperature to achieve thermal comfort, they invariably preferred higher than normal temperatures, in the range of 30° to 33° C (86.0° to 91.4° F).³² The patients' unburned skin remained relatively vasoconstricted at the higher temperatures as an additional way of maintaining the febrile state. However, even under these conditions of thermal comfort, the patients continued to maintain elevated metabolic rates. Thus, although thermoregulatory factors may influence hypermetabolism, the increased rate of heat production appears to be determined primarily by metabolic factors. Hypermetabolism is temperature sensitive but not temperature dependent.

Altered Protein Metabolism

MUSCLE WASTING, NITROGEN LOSS, AND ACCELERATED PROTEIN BREAKDOWN

One of the most striking features of the metabolic response to critical illness is the marked degree of muscle wasting. This atrophy is associated with increased urinary excretion of nitrogen. Sir David Cuth-

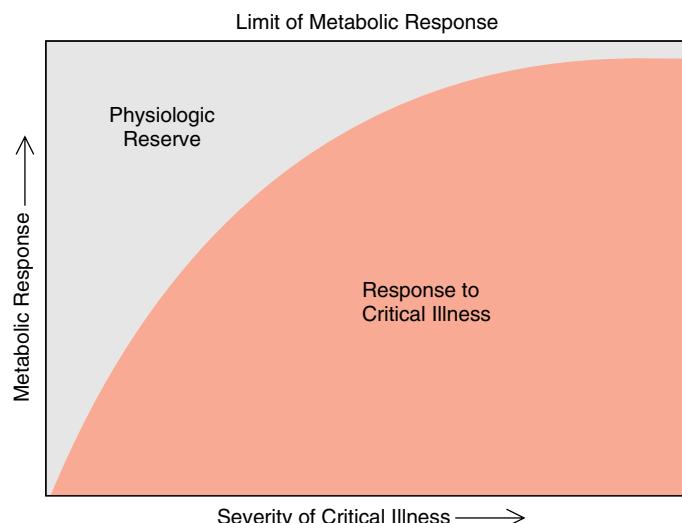

Figure 4 The intensity of the metabolic response to critical surgical illness increases as a function of the severity of illness. In patients with extremely severe critical illness (e.g., patients with burns covering 60% of the body surface area), responses are near maximal, and physiologic reserves, with which patients respond to additional stressors (e.g., infection, hemorrhage, or cold exposure), are limited. Patients may also have limited physiologic reserves because of preexisting disease, starvation, or advanced age. Therapies that attenuate the stressors of critical surgical illness improve physiologic reserve.

bertson first described this phenomenon in patients with long-bone fractures.²⁷ Similar observations were made by Howard and associates in the United States.³³ Cuthbertson concluded that injured and uninjured skeletal muscle was the source of the excreted nitrogen.^{34,35} As skeletal muscle protein is degraded, a variety of markers are released into the circulation and then excreted by the kidneys. Increased excretion of several of these markers^{36,37} has been observed in patients with trauma,^{36,38} burns,³⁹ and infections.⁴⁰

There are other sources of nitrogen loss in critically ill patients, including loss of tissue from slough or excision, loss of blood and exudate, and loss of mucosa from the GI tract. Cuthbertson estimated that in the first 10 days after a burn, the amounts of nitrogen lost as a result of direct tissue injury, wound exudation, generalized catabolism, and atrophy were roughly equivalent.⁴¹ Moore and coworkers measured nitrogen loss in the wound exudate of burn patients. This wound loss accounted for as much as 20% to 30% of total nitrogen loss during the early postburn period.⁴²

The time course of nitrogen excretion during critical illness is

Table 3 Effect of Ambient Temperature on Metabolic Rate and on Core and Skin Temperatures

Ambient Temperature (°C)	N	Core Temperature (°C)	Skin Temperature (°C)	Metabolic Rate (kcal/m²/hr)
Normal subjects				
21	3	36.7	30.0	41.2
25	4	36.8	31.4	35.6
33	4	36.8	34.2	36.3
Burn patients (45% TBS)				
21	9	38.1	32.1	83.7
25	20	38.5	33.1	63.5
33	20	38.0	36.2	62.0

distinctive. Cuthbertson observed that nitrogen excretion peaked several days after injury and gradually returned to normal during a period of several weeks.³⁴ The pattern was similar to that of increased oxygen consumption. Thus, both hypermetabolism and muscle proteolysis peak shortly after the onset of critical illness and gradually return to normal as recovery proceeds. This too appears to be a characteristic feature of the metabolic responses to critical illness [see Figure 2].⁴³⁻⁴⁵

Protein turnover is an indicator of overall protein metabolic activity. It is determined through use of tracers. Both extracellular and intracellular amino acids are considered part of a free amino acid pool. Nitrogen is added to this pool by nitrogen intake (diet) and by protein breakdown. Nitrogen is removed by protein synthesis and by conversion to urea. When a small quantity of a labeled amino acid is infused, the rate of appearance of nitrogen in the free amino acid pool can be determined. Under steady-state conditions, this appearance rate represents protein turnover and matches protein disappearance.⁴⁶ During critical illness, protein turnover is increased.⁴⁷ When nitrogen turnover data are combined with measurements of nitrogen intake and loss, rates of total body protein synthesis and catabolism can be estimated. These estimates indicate that protein catabolism is increased in critically ill patients.⁴⁸ Synthesis rates remain normal during fasting but increase to approach or match catabolic rates when feeding is adequate. Thus, the increase in net nitrogen loss during critical illness appears to result from an increase in protein breakdown. Decreased protein synthesis is less of a factor as long as nutritional intake is satisfactory [see Table 4].

ALTERED AMINO ACID METABOLISM

Protein synthesis and breakdown are processes that occur in cells and involve intracellular amino acids. It has been estimated that skeletal muscle contains as much as 80% of the free amino acid pool.⁴⁹ Intracellular concentrations of free amino acids in skeletal muscle are approximately 30 times greater than plasma concentrations of free amino acids.⁵⁰ Thus, the total muscle mass of a 70 kg man contains approximately 87 g of free amino acids in the intracellular water, whereas the extracellular pool contains only 1.2 g.

The relative amounts of individual free amino acids in cells differ from the proportions found in protein. Glutamine, a nonessential amino acid, accounts for only about 5% to 6% of protein, but it is the most abundant intracellular free amino acid, accounting for about 60% of the total intracellular free amino acid pool. In contrast, the eight essential amino acids together account for only 8.4% of the intracellular pool. The intracellular concentration of glutamine decreases under many catabolic conditions, including starvation, inactivity,⁵¹ elective operation,⁵² trauma,⁵³ and sepsis.⁵⁴ This decrease occurs early in the course of the acute illness, persists until late in convalescence, and appears to be related to the severity of illness.^{55,56} The intracellular concentrations of phenylalanine, tyrosine, alanine, and the branched-chain amino acids (BCAAs)—leucine, isoleucine, and valine—typically increase after trauma and infection.^{51,54} These levels return to normal during convalescence, usually before glutamine levels do.

Plasma concentrations of free amino acids generally decrease after operation, injury, or infection, largely because of a fall in the concentrations of the nonessential amino acids. Changes in extracellular concentrations of specific amino acids have been inconsistent between studies, presumably as a reflection of differences in patient selection, analytic methods, or treatment.⁵⁴

The ECF compartment is important for amino acid transport between organs and between regions of the body. Aulick and Wilmore calculated amino acid release rates from peripheral tissues of burn patients on the basis of measurements of leg blood flow and of femoral arterial and venous plasma concentrations of 10 amino

Table 4 Alterations in Rates of Protein Synthesis and Catabolism That May Affect Hospitalized Patients

	Synthesis	Catabolism
Normal—starvation	↓	0
Normal-fed, bed rest	↓	0
Elective surgical procedure	↓	0
Injury/sepsis—I.V. dextrose	↑↑	↑↑↑
Injury/sepsis—fed	↑↑↑	↑↑↑

↓—decrease ↑—increase 0—no change

acids.⁵⁷ The net release of amino acid nitrogen was five times greater in burn patients than in control subjects. Alanine was the only amino acid whose release rate was significantly elevated (glutamine concentration was not determined). Alanine release was related to total burn size (injury severity) and to total body $\dot{V}O_2$. In related studies, the accelerated peripheral amino acid release was matched by increased uptake across the splanchnic bed.²⁴ Alanine uptake was three to four times control values. This increased release of amino acids from the periphery and transport to splanchnic tissues appears to be another characteristic metabolic response to critical burn injury.

Garber and colleagues observed that glutamine and alanine together constituted as much as 70% of the amino acids released from skeletal muscle in vitro.⁵⁸ Furthermore, the release rates of alanine and glutamine reflected the net rates of formation from other amino acids.⁵⁹ Thus, during critical illness, skeletal muscle protein is broken down into amino acids that are largely converted to glutamine and alanine, which are then released into the ECF for transport. Although all amino acids are required for protein synthesis at remote locations, glutamine and alanine are the major nitrogen carriers from muscle. These two amino acids have other roles as well. Alanine is a precursor of glucose production in the liver. In that process, urea is also formed and subsequently excreted by the kidneys. Although there may be some minor recycling of urea nitrogen under certain conditions,⁶⁰ formation of urea is the final step in the loss of body protein, representing an irreversible loss of nitrogen.

Glutamine is a precursor for production of ammonia in the kidneys, an important buffering mechanism for excreted acid loads. Increased breakdown of intracellular constituents could result in such an acid load, and ammonia excretion is often increased after injury. Intracellular skeletal muscle glutamine may be an important determinant of net skeletal muscle protein breakdown.^{61,62} After a standard operation in an animal model, net amino acid efflux from the hindquarter was increased as the glutamine concentration fell. However, if the intracellular glutamine concentration was maintained by the provision of exogenous glutamine, net efflux was reduced.

Glutamine also appears to be an important respiratory fuel for rapidly dividing cells. Glutamine can be converted to glutamate and then to α -ketoglutarate for participation in the citric acid cycle. The nitrogen of glutamine is used to form ammonia, alanine, and citrulline.⁶³ This process occurs in colonocytes, enterocytes, fibroblasts, and, possibly, inflammatory cells such as macrophages. Phagocytic cells are found in fixed locations in the GI tract, such as Peyer's patches and other regions containing Kupffer's cells, as well as in the wound, at other sites of inflammation, and in the bone marrow. Windmueller measured the nutrient requirements of the rat intestine using an isolated, perfused segment of small bowel.⁶³ The intestinal segment extracted large amounts of glutamine from the recirculated perfusate. Souba and Wilmore measured amino acid uptake by the gut in conscious animals and demonstrated that the consumption of glutamine by the gut was significantly increased after celiotomy, even

though the circulating glutamine concentration was reduced (i.e., glutamine was actively taken up by the intestine).⁶⁴

Dissolution of skeletal muscle protein during critical illness seems to serve many purposes. First, it provides amino acids to support protein synthesis at remote sites such as the wound, other inflammatory foci, and the liver. Proteolysis also provides amino acid precursors for glucose production by the liver and for production of ammonia in the kidneys. Finally, it provides glutamine, which appears to be a specific fuel for the gut and possibly for other tissues with rapid cell turnover, such as the wound, bone marrow, and fixed macrophages of the GI tract. This mobilization of amino acids from muscle protein, however, leads to an irretrievable loss of nitrogen in the form of urea, ammonia, creatinine, uric acid, and other compounds. The cost to the patient is rapid erosion of muscle mass and debility.

Altered Carbohydrate Metabolism

ACCELERATED ENDOGENOUS GLUCOSE PRODUCTION

The liver normally produces sufficient glucose to permit maintenance of the blood glucose concentration within narrow limits, even during periods of fasting. During critical illness, the rate of endogenous glucose production is increased.^{24,65,66} Increased basal glucose production is matched by an increase in glucose uptake, so that glucose levels remain relatively stable. Thus, the mass flow, or turnover, of glucose is increased. In studies of patients with burns, glucose turnover was related to total body $\dot{V}O_2$ and thus to the size of the burn (i.e., to injury severity).⁶⁷ Regional uptake was closely related to regional blood flow and regional lactate release but not to regional $\dot{V}O_2$. Thus, glucose was directed by the circulation to the wound, where it was taken up and converted via glycolysis to lactate, even in the presence of adequate or increased oxygen delivery.

The liver produces glucose by a variety of mechanisms. Hydrolysis of hepatic glycogen mobilizes glucose rapidly to serve as an energy source in times of acute need. This mechanism is most important immediately after injury and during acute stress states, such as shock, fever, pain, and anxiety (ebb-phase responses). Glycogen reserves are limited, however, and glycogen is not the major source of hepatic glucose production during recovery from critical illness.

Glucose can also be formed from lactate and from alanine.⁶⁸ The conversion of lactate to glucose occurs via the Cori cycle in the liver. Lactate is formed from pyruvate, which is the end product of glycolysis. In critically ill patients with adequate oxygen delivery, the wound is a major source of lactate. Adenosine triphosphate (ATP) is formed during glycolysis and provides energy for the wound, but ATP is required to convert lactate back to glucose. The increased mass flow of glucose serves as a fuel for the healing wound. It may also reflect an inefficient biochemical cycle that requires energy but in which there is no net gain or loss of substrate. Accelerated glucose cycling has been documented both in burn patients and in blunt trauma patients.^{69,70} The purpose of these so-called futile cycles is not clear. Because they result in the net generation of heat, they presumably contribute to hypermetabolism. That overall conversion requires net input of ATP and is thus another energy drain for the patient.

GLUCOSE INTOLERANCE AND INSULIN RESISTANCE

When glucose is administered to critically ill patients, hyperglycemia often results. Glucose tolerance tests typically yield abnormal results after injury.⁷¹ During shock, immediately after injury or operation, and in the course of ebb-phase responses, the insulin response to hyperglycemia may be blunted. During the flow phase, however, after resuscitation and stabilization, the response to glucose is normal or even exaggerated.^{72,73} Both glucose and insulin levels are higher in

trauma patients than in control subjects [see Table 5], and the increase in insulin is proportionally greater than the rise in glucose.

Black and associates maintained a fixed level of hyperglycemia in patients recovering from trauma by adjusting a glucose infusion on the basis of bedside glucose readings and a negative-feedback algorithm.⁷⁴ Because the glucose concentration was at steady state, the glucose infusion rate reflected the rate of total body glucose uptake or disposal. Control subjects demonstrated continuously increasing glucose disposal over time; the glucose infusion rate was increased repeatedly to maintain fixed hyperglycemia. Glucose disposal was closely related to insulin concentration, which increased steadily during the 2-hour study. In contrast, glucose disposal in trauma patients was markedly lower than in control subjects, and it did not increase appreciably over time. The insulin concentrations did, however, increase throughout the study and were always greater than corresponding control values. The trauma patients were therefore less responsive (i.e., were resistant) to insulin.

These investigators also infused insulin into trauma patients and control subjects to maintain specific fixed levels of hyperinsulinemia. During these infusions, the glucose concentration was maintained at basal values (i.e., euglycemia). The glucose infusion rate again reflected total body glucose disposal, which was a function of tissue responsiveness to the insulin level. At all insulin levels, glucose disposal was lower in trauma patients than in control subjects. These studies quantitated posttraumatic insulin resistance and suggested that this response was caused by a postreceptor defect. In similar conditions, Brooks and associates demonstrated reduced forearm glucose uptake, indicating that peripheral tissue—principally skeletal muscle—was a major site of insulin resistance⁷⁵ [see Table 6].

ALTERED FUEL METABOLISM

The studies by Black and associates⁷⁴ demonstrated that in recovering trauma patients, there is an upper limit to glucose disposal of 5 to 6 mg/kg/min, despite hyperglycemia and hyperinsulinemia. Additional studies have confirmed that critically ill patients are limited in their ability to utilize glucose as a fuel. Long and coworkers studied the effect of increasing carbohydrate intake on net nitrogen loss in recovering burn patients.⁷⁶ They found that nitrogen loss was reduced as carbohydrate was increased to 60% to 70% of total caloric needs (also approximately 5 to 6 mg/kg/min). Very little additional reduction in nitrogen loss was observed with higher carbohydrate levels. Wolfe and associates used isotope-labeled glucose to measure glucose oxidation in postoperative⁷⁷ and burn patients^{66,78} and found that both groups exhibited an upper limit of glucose oxidation. These studies also suggested that maximum glucose oxidation is inversely related to injury severity.

Lipid metabolism is also affected by critical illness. In an elegant series of kinetic studies performed in blunt trauma patients, Shaw and Wolfe⁷⁰ documented a greater than twofold increase in glycerol turnover, reflecting an accelerated rate of triglyceride hydrolysis to form free fatty acid (FFA) and glycerol. They also demonstrated a doubling of FFA oxidation rate; however, the measured turnover of FFA was only 30% greater than the control value, which suggested that some of the FFA released from triglyceride was oxidized in the

Table 5 Basal Glucose and Insulin Concentrations*

*Mean ± SEM.

cell and did not enter the circulating pool. These studies further demonstrated a high rate of FFA recycling, a phenomenon also described in burn patients.⁶⁹

Askanazi and associates studied the metabolic effects of hypercaloric, glucose-based total parenteral nutrition (TPN) on starved patients.⁷⁰ Patients who were nutritionally depleted but were not critically ill showed an increase in $\dot{V}CO_2$ and an increase in the respiratory quotient (RQ, the ratio of $\dot{V}CO_2$ to \dot{VO}_2) to 1.0 or greater. These findings indicated that these patients were able to meet all of their energy needs with glucose and that fat oxidation was suppressed. Patients who were depleted and also manifested hypermetabolic responses showed an increase not only in $\dot{V}CO_2$ but also in \dot{VO}_2 , and the RQ remained below 1.0; therefore, these critically ill patients could not meet all of their energy needs by oxidation of glucose. Not only was there a limit to the ability of these critically ill patients to use glucose as a metabolic fuel, but the high glucose load intensified hypermetabolism as well. Thus, overfeeding with glucose can aggravate critical illness. The mechanisms of this phenomenon are not clear, but they may involve the futile cycling of glucose via fructose 1,6-diphosphate and its associated heat generation.⁶⁹

In addition to protein, nutritional support of critically ill patients often consists of a mixture of carbohydrate and fat to meet energy requirements. In such a system, exogenous carbohydrate is oxidized directly, but exogenous lipid is added to body fat stores.⁸⁰ Lipid is mobilized from these endogenous stores for oxidation. Such a mixed-fuel preparation should provide sufficient glucose for those tissues that require it (i.e., central nervous system, renal medulla, hematopoietic cells, and inflammatory cells), prevent excessive hyperglycemia, stimulate insulin elaboration, and approach nitrogen equilibrium.

Systemic Mediators

It was once generally thought that the metabolic alterations associated with injury and critical illness were derived from some harmful substance (e.g., a toxin) or dysfunctional process (e.g., a deranged endocrine mechanism). We now appreciate that the regulatory mechanisms affecting these processes are intricate and highly complex and depend on the actions of a myriad of mediators that influence the proliferation, development, and behavior of cells. It is hard to judge which, if any, of these mediators is maladaptive or harmful: those that seem to have harmful effects that exacerbate debility and organ dysfunction in some settings often promote healing and recovery in others.

These mediators may be synthesized by one or many cell types. Some mediators may affect the cell that made them, thus exerting an autocrine effect. Others may affect cells in close proximity, thus exerting a paracrine effect. If they gain access to the ECF, they can be transported via the circulation and affect cells far removed from their site of origin, thus exerting an endocrine effect. Most interact with a specific receptor, usually on the surface of the target cell. This molecular interaction can influence the cell's biology in a number of ways.

First, it may alter the cell membrane, affecting its permeability to certain substances or changing the availability or affinity of other receptors for interaction with their specific mediators. Second, it may alter the structural organization of the cell, making certain intracellular constituents more or less available to exert their effects on cell behavior. Finally, it may initiate one of several intracellular molecular mechanisms that ultimately affect the nucleus, thereby altering gene expression for protein synthesis or DNA replication and cell proliferation.

These mediators have been categorized as endocrine hormones, inflammatory mediators, and growth factors. But as our knowledge about them has grown, it has become apparent that the distinctions are not always clear-cut, and some mediators can fit in more than one category. For example, the hormone insulin exerts definite endocrine metabolic effects that are well known, but it is also an important growth factor. Insulin receptors have been identified in embryos and in plants, and insulin is an important constituent of many cell culture media.⁸¹ Insulin may also affect certain inflammatory responses. In a 2002 study, otherwise normal subjects manifested enhanced and prolonged hemodynamic and cytokine responses to endotoxin under conditions of hyperinsulinemia and euglycemia.⁸²

The metabolic response to critical illness is a clinical phenomenon that dominates the clinical presentation and course of critically ill patients. It involves alterations that affect either the whole body or specific organ systems. In what follows, I discuss several ways in which these clinical events may be regulated.

HORMONES

During critical illness, the concentrations of several hormones are altered. The levels of the counterregulatory or so-called stress hormones—cortisol, glucagon, and the catecholamines epinephrine and norepinephrine—are typically increased. These hormones have several direct and indirect effects and appear to function as important regulating signals in the response to critical illness.

The sympathetic-adrenal axis is one of the major systems by which the body initiates responses to critical illness. It also modifies the elaboration and effects of other hormones and thus serves as a link between the central nervous system and the endocrinologic organs. Many of the changes in vital signs observed during critical illness, such as tachycardia, tachypnea, and widened pulse pressure, are ascribed to adrenergic and catecholamine effects; in addition, many of the signs of shock indicate autonomic overactivity. The catecholamine levels are increased in proportion to the severity of injury.⁸³ During the flow phase of critical illness, concentrations of the catecholamines may be persistently elevated; catecholamine turnover after burn injury is markedly increased.^{44,84} $\dot{V}O_2$ and metabolic rate have been directly related to the excretion of catecholamines. In one study, alpha- and beta-adrenergic blockade significantly reduced the metabolic rate in burn patients, although the rate did not return to control levels.¹⁹ This effect was not produced by alpha-adrenergic blockade alone, which indicates that beta-adrenergic stimulation

Table 6 Glucose Disposal and Forearm Glucose Uptake during Hyperinsulinemia and Euglycemia

Target Dose	N	Plasma Glucose Concentration (mg/dl)	Serum Insulin Concentration (μ U/ml)	Glucose Disposal Rate (mg/kg/min)	Arterial–Deep Venous Glucose Difference (mg/dl)	Forearm Glucose Uptake (mg/dl/min)
Normal subjects 100 μ U/ml 200 μ U/ml	7	92 \pm 2	106 \pm 6	9.32 \pm 1.04	21 \pm 3	0.76 \pm 0.12

predominates in the flow phase of the response to critical illness.

The sympathetic-adrenal axis also affects the endocrine pancreas. Porte and Robertson determined that the insulin response to glucose in normal individuals was reduced substantially with alpha-adrenergic stimulation but was enhanced with beta-adrenergic stimulation.⁸⁵ Catecholamines may also modulate the peripheral action of insulin. When epinephrine was infused into normal individuals at doses low enough to allow beta-adrenergic effects to predominate, insulin resistance was observed in uninjured forearm tissue.⁸⁶ Despite its apparent catabolic effects on metabolic rate and insulin resistance, epinephrine alone reduces the release of amino acid from skeletal muscle in vitro.⁸⁷

Cortisol⁸⁸ and glucagon⁸⁹ levels are elevated after major injury and during critical illness. The degree of elevation appears to be related to the extent or severity of the injury. An increased cortisol level is associated with glucose intolerance.⁹⁰ Patients with Cushing's syndrome manifest reduced muscle mass and loss of protein from the skin. Owen and Cahill administered hydrocortisone to starved obese patients.⁹¹ Although they observed an increase in ammonia excretion and a decrease in urea excretion, there was no net change in total nitrogen loss. Glucagon promotes gluconeogenesis.⁹² This effect may be overcome by increased concentrations of insulin.⁹³ Wolfe and colleagues administered glucagon to fasting normal individuals and observed a slight increase in nitrogen excretion, primarily as urea.⁹⁴ However, net nitrogen loss from peripheral tissues did not increase.

Although injury and critical illness clearly affect hormone levels, it has not been possible to ascribe all of the physiologic responses observed in patients to the known actions of individual hormones. A number of studies, however, have identified interacting effects by altering more than one hormone level simultaneously. For example, when Shamoon and coworkers infused a combination of hydrocortisone, glucagon, and epinephrine, they observed a synergistic effect on glucose production.⁹⁵

Bessey and associates extended these observations.⁹⁶ In an attempt to simulate the endocrine environment of injured patients, they infused the same combination of hormones for 3 days in normal individuals. The infusion maintained elevated catabolic hormone levels, similar to those observed in patients with mild to moderate injury. The investigators monitored a variety of metabolic parameters and compared these results with measurements obtained in a control study of the same individuals, in which the patients received an infusion of saline. The alteration in the hormonal environment increased the resting heart and respiratory rates, widened the pulse pressure, and slightly elevated the rectal temperature. In addition, hypermetabolism, a negative potassium balance, increased endogenous glucose production, insulin resistance, sodium retention, and leukocytosis were observed [see Table 7]. During the control study, the individuals maintained nitrogen equilibrium, but during the triple-hormone infusion, they were in persistently negative nitrogen balance, even though nutritional intake was identical in the two studies. Whole body protein turnover, as measured by ¹⁵N kinetics, was increased in the subjects who received the hormone infusion because of an increase in protein catabolism. These changes, which are typically seen in critically ill patients, occurred in the absence of a wound or inflammatory focus.

The negative nitrogen balance and increased turnover of whole body protein observed during the triple-hormone infusion were also associated with a significant decrease in total intracellular amino acid nitrogen in skeletal muscle.⁹⁷ This decrease was caused primarily by a fall in the intracellular glutamine level. Although these changes suggest that the posttraumatic hormonal environment plays a causative role in increasing net muscle proteolysis, the triple-hormone infusion did not appreciably alter either whole blood amino acid concentra-

tions or amino acid efflux from the forearm. A potential explanation for these findings is that the triple-hormone infusion, particularly the glucagon component, may have affected processing of amino acid by the liver, thereby reducing the net retention of dietary amino acids.⁹⁸

The endocrine environment in critically ill patients, however, is not static. Although catabolic hormone levels may be persistently elevated, insulin is often suppressed during the early phases of critical illness but elevated later, during the flow phase. Bessey and Lowe attempted to simulate this changing hormonal environment in normal subjects by administering a somatostatin analogue during the first 24 hours of a 3-day infusion of catabolic hormones so as to inhibit the elaboration of insulin in response to hyperglycemia.⁹⁹ They compared the findings to those obtained from studies of the same individuals during triple-hormone infusion, when insulin levels were allowed to rise unchecked. Early whole body nitrogen loss was increased in the studies with the somatostatin analogue, but there was no difference in forearm nitrogen release at 24 hours; however, 2 days later, when glucose and insulin concentrations were similar in the two studies, total body nitrogen loss was equivalent, but forearm nitrogen release was increased in the patients receiving the somatostatin analogue. Coadministration of exogenous insulin with somatostatin prevented this acceleration of net muscle protein breakdown (P. Q. Bessey, K. A. Lowe, D. C. Blake; unpublished data). Thus, the interacting effects of multiple hormones and the changing relationships among them over time appear to be capable of inducing, at least qualitatively, most of the metabolic responses to critical illness.

Several investigators have attempted to modulate the catabolic responses of critical illness by altering the endocrine environment. For example, Hulton and colleagues monitored hind-leg amino acid efflux after abdominal operation in an animal model.¹⁰⁰ The accelerated efflux of skeletal muscle amino acids observed postoperatively was attenuated by complete alpha- and beta-adrenergic blockade or by thoracic epidural anesthesia. Both pharmacologic techniques are known to attenuate the hormonal response to operative stress. Brandt and coworkers measured hormonal and protein catabolic responses after abdominal hysterectomy.¹⁰¹ In the patients who underwent epidural anesthesia, concentrations of cortisol and catecholamines were lower and nitrogen loss was less than in patients who received general anesthesia alone. Tsuji and associates reported similar findings.¹⁰² Subsequent studies have shown that perioperative management of patients with high thoracic epidural analgesia and intravenous somatostatin and etomidate to inhibit elaboration of glucagon and cortisol prevents the typical postoperative increases in amino acid clearance and urea synthesis.¹⁰³

In summary, the altered endocrine environment characteristically

Table 7 Effect of Infusion of Cortisol, Glucagon, and Epinephrine on Metabolism

	Saline	Hormones*
Metabolic rate (kcal/m ² /hr)	32.24 ± 1.05	38.42 ± 1.31
Nitrogen balance (g/day)	-0.2 ± 0.4	-3.2 ± 0.4
Protein catabolic rate (g nitrogen/day)	38.4 ± 1.9	46.5 ± 2.5

Insulin-mediated forearm glucose uptake (mg/dl/min)	1.03 ± 0.09	0.48 ± 0.12

*All significantly different from control values.

associated with critical illness and the influence of the sympathoadrenomedullary axis appear to play a major role in mediating the metabolic responses observed in critically ill surgical patients. Simple alteration of the stress hormonal environment in healthy individuals is capable of inducing many of these metabolic changes; however, the magnitude of these changes is generally less than that observed in critically ill patients. Blunting of the stress hormonal changes after operation or injury can modulate acute catabolic responses.

Although changes in stress hormones seem to dominate the clinical picture, characteristic alterations of other endocrine hormones also occur. Levels of thyroxine (T_4) and triiodothyronine (T_3) are typically reduced after critical illness, and levels of an inactive form of T_3 , reverse T_3 (rT_3), are elevated; however, administration of thyroxine to critically ill patients seems to have little clinical effect.¹⁰⁴ Hormones of the gonadal axis are typically suppressed during critical illness. Levels of testosterone are decreased in men, as are levels of luteinizing hormone, follicle-stimulating hormone, and estradiol in women, apparently in proportion to injury severity.¹⁰⁵⁻¹⁰⁷ These changes interrupt the menstrual cycle and decrease libido. Although growth hormone (GH) levels are increased after injury, patients demonstrate muscle wasting and weight loss.¹⁰⁸ The anabolic effects of GH depend on the synthesis and elaboration of insulinlike growth factor-1 (IGF-1), whose activity is affected also by the presence of various IGF-binding proteins (IGFBPs).¹⁰⁹ Despite elevation of circulating GH levels, IGF-1 concentrations are reduced, as are IGFBP-3 levels.

Taken together, all of these endocrine changes (1) mobilize amino acids and fuel substrates to support wound healing, resolution of inflammation, and tissue repair and (2) turn down anabolism and growth in the rest of the body. This response to acute illness would seem to be an adaptive one: wounds heal and patients recover, despite a transient loss of lean tissue. However, patients with protracted critical illnesses, who have been maintained for weeks or months in the ICU, may present a different clinical picture. Despite closure of the wound, drainage of pus, provision of nutrients, and treatment of infection, they remain catabolic and are extremely slow or unable to recover. Current evidence suggests that this syndrome may reflect a different endocrine pattern. Many of the anterior pituitary hormones (e.g., adrenocorticotropic hormone, thyroid-stimulating hormone, and GH) are present in reduced concentrations, or the pattern of their secretion is altered.¹¹⁰ These alterations may reflect a change in hypothalamic function; infusion of various releasing factors can restore normal hormone responsiveness in the thyrotropic, somatotropic, and gonadotrophic axes.¹¹¹

CYTOKINES

A number of cell types appear in a healing wound soon after injury.¹¹² These cells are actively involved in angiogenesis, production and remodeling of collagen, scavenging of necrotic debris, and engulfment and killing of bacteria. Many of them release substances that influence cellular proliferation, development, and function and so regulate local inflammation and wound healing. These substances, collectively known as cytokines, can be produced by and interact with a wide variety of cells in addition to inflammatory cells and appear to be major mediators of multiple cellular responses to injury and infection [see 8:24 *Molecular and Cellular Mediators of the Inflammatory Response*].

Some cytokines primarily stimulate inflammatory responses and thus are known as proinflammatory cytokines, whereas others retard these responses and thus are known as anti-inflammatory cytokines. In addition, specific receptor antagonists have been identified that interfere with the interaction between a cytokine and its cellular receptor. Finally, there are specific soluble receptors, unassociated with a cell, that can effectively neutralize the cytokine before it interacts with

a target cell. Both proinflammatory and anti-inflammatory mechanisms may be stimulated together in acute illness.¹¹³ The balance and interactions between them determine the course of the inflammatory process.

The major proinflammatory cytokines, tumor necrosis factor (TNF), interleukin-1 (IL-1), and IL-6, are closely related in that they are elaborated in a characteristic pattern (or cascade) in response to an inflammatory stimulus, such as trauma¹¹⁴ or endotoxin.¹¹⁵ TNF appears first, followed by IL-1 and then IL-6. The elaboration of TNF and IL-1 is relatively brief, but IL-6 persists longer.

Cytokines appear to regulate cell recruitment, proliferation, development, and other cellular events that occur in the wound, but how and to what extent they exert systemic effects and modulate the metabolic responses to critical illness is less clear. One conceptual model proposes that when local cytokine production is particularly abundant, owing to extensive wounds or uncontrolled infection, certain cytokines spill over into the circulation and then affect tissues at distant sites [see Figure 5]. Although elevated circulating cytokine levels have been detected in critically ill patients, only IL-6 has been consistently associated with severe illness and outcome.^{116,117}

TNF can initiate the cytokine cascade, ultimately producing fever, leukocytosis, and other signs and symptoms of critical illness.¹¹⁸ To characterize the role of TNF in proteolysis associated with endotoxin or sepsis, Michie and coworkers analyzed the responses of both animals and humans during prolonged infusions of TNF.¹¹⁹ Negative nitrogen balance was related to the onset of anorexia and reduced food intake and not to the development of hypermetabolism. Mealy and associates performed adrenalectomies and abrogated the increase in nitrogen loss associated with TNF infusion.¹²⁰ Hall-Angeras and colleagues found that a steroid antagonist prevented the increase in myofibrillar protein breakdown usually seen in an animal model of intra-abdominal sepsis.¹²¹ These observations suggest that even though TNF may be a major initiating signal for a variety of cellular events in critical illness, other mediators are required for the full development of the metabolic responses to injury and infection.

IL-1 was one of the first fever-producing cytokines, or pyrogens, to be identified.^{122,123} Early in vitro studies appeared to present conflicting findings,¹²⁴⁻¹²⁶ but the preponderance of the data currently available indicate that IL-1 can increase proteolysis, especially in intact animals. For example, Zamir and colleagues measured increased muscle protein breakdown in vitro after administration of IL-1 to intact animals.¹²⁷ In another study, they were able to reduce but not prevent the increased proteolysis that followed endotoxin administration by pretreating animals with IL-1 receptor antagonist (IL-1ra).¹²⁸

To characterize the metabolic effects of IL-1 in vivo, Watters and associates gave daily intramuscular injections of etiocholanolone to normal individuals.¹²⁹ (This steroid stimulates the development of an inflammatory focus and the production of IL-1.) The subjects manifested an acute-phase response: fever, leukocytosis, increased concentrations of acute-phase proteins, and hypoferremia. They were not hypermetabolic, however, and they remained in nitrogen equilibrium when fed a standard diet. The concentrations of catabolic hormones were not affected by this treatment. When hydrocortisone, glucagon, and epinephrine were administered in conjunction with etiocholanolone, however, both inflammatory and metabolic responses were observed.¹³⁰ These healthy subjects exhibited the same clinical features as did patients with infection. These findings suggested that both endocrine and cytokine mechanisms influence the responses to critical illness.

IL-6 can induce many of the components of the acute-phase response¹³¹ and may be measured in the blood of patients experiencing trauma,¹³² sepsis,¹³³ pancreatitis,¹³⁴ or other critical illnesses (e.g., myocardial infarction).¹³⁵ Mateo and associates identified IL-6 in

wound fluid from both animals and humans, and they found that the capacity of wound macrophages to produce IL-6 increased with time.¹³⁶ Thus, IL-6 might be one mechanism by which the wound influences critical illness. Persistent measurable levels of IL-6 have been related to mortality in both trauma¹¹⁶ and burn¹¹⁷ patients.

Stouhard and associates infused recombinant IL-6 (rIL-6) into uninjured cancer patients for 4 hours, then measured glucose and lipid kinetics, metabolic rate, and hormonal profiles during the infusion and during a saline control infusion.¹³⁷ IL-6-induced hypermetabolism and energy expenditure increased by 25%. Glucose production, lipolysis, and fatty acid oxidation also increased. Glucose clearance was also increased; serum glucose concentrations were not significantly affected by IL-6 infusion. Tsigos and colleagues administered increasing doses of IL-6 subcutaneously to healthy subjects and demonstrated a dose-response relationship between IL-6 dose and circulating level and glucose concentration.¹³⁸ In both of these studies, IL-6 also induced elevations in circulating stress hormone levels.

IL-6 also affects protein metabolism. Transgenic mice that overexpress IL-6 exhibit retarded growth and muscle atrophy. These observations have been correlated with reduced circulating concentrations of insulinlike growth factor-1 (IGF-1).¹³⁹ In another report, a specific IL-6 receptor antibody administered to the young IL-6 transgenic mice restored muscle growth to normal.¹⁴⁰ The muscle atrophy in these studies was associated with an increase in the synthesis and activity of several enzymes that catalyze muscle protein breakdown, and these changes too were blocked by IL-6 receptor antibody. The effects of IL-6 on long-term protein accretion in humans have not yet been elucidated, but severely burned children who survive after a long period of critical illness often experience growth retardation.¹⁴¹

Both endocrine and inflammatory mediators affect metabolic responses in critically ill patients. In fact, the two systems are closely linked—perhaps inseparably—and probably influence each other.¹³⁰ For example, Bornstein and colleagues identified IL-6 messenger RNA (mRNA) expression in the steroid-producing cells of the adrenal gland, which were located not only in the cortex but also in the medulla, adjacent to catecholamine-producing cells.¹⁴² In a subsequent study, they detected IL-6 and IL-6 receptor expression in adrenal cell cultures, both with macrophages present and with macrophages absent.¹⁴³ They also found that IL-6 stimulated release of steroid hormones, aldosterone, cortisol, and androgens in vitro in a dose-dependent manner; however, these effects developed over a period of 24 hours. These findings indicate not only that IL-6 exerts autocrine and paracrine effects on adrenal cellular synthetic function but also that it is probably involved in the long-term regulation of adrenal steroidogenesis rather than being responsible for acute changes in adrenal function.

On the other hand, glucocorticoids have long been known to exert anti-inflammatory effects. They interfere with the proliferation and function of leukocytes and other immune cells, and they inhibit the synthesis and cellular action of cytokines and other molecules important for cellular responses.¹⁴⁴ In a clinical study, Barber and colleagues demonstrated that glucocorticoid administration led to a dose- and time-dependent reduction in TNF production and symptoms in response to endotoxin.¹⁴⁵

Cytokines and hormones may also affect metabolic responses at the end-organ level via different mechanisms. For example, skeletal muscle protein breakdown can occur via any of at least four intracellular proteolytic systems.¹⁴⁶ One of the major pathways affecting myofibrillar proteins is energy dependent (i.e., ATP-dependent) and involves the cytosolic peptide cofactor ubiquitin. In animals, glucocorticoids stimulate an ATP-dependent proteolytic system and increase the expression of ubiquitin.¹⁴⁷ Zamir and colleagues administered a gluco-

corticoid antagonist to rats with intraperitoneal sepsis and demonstrated that it reduced but did not eliminate the increased muscle proteolysis.¹²⁷ In a subsequent study, they induced accelerated skeletal muscle proteolysis by injecting IL-1 intraperitoneally.¹²⁸ Previous adrenalectomy, which eliminated glucocorticoid elaboration, had little effect on the proteolysis observed.¹⁴⁸ These observations suggest

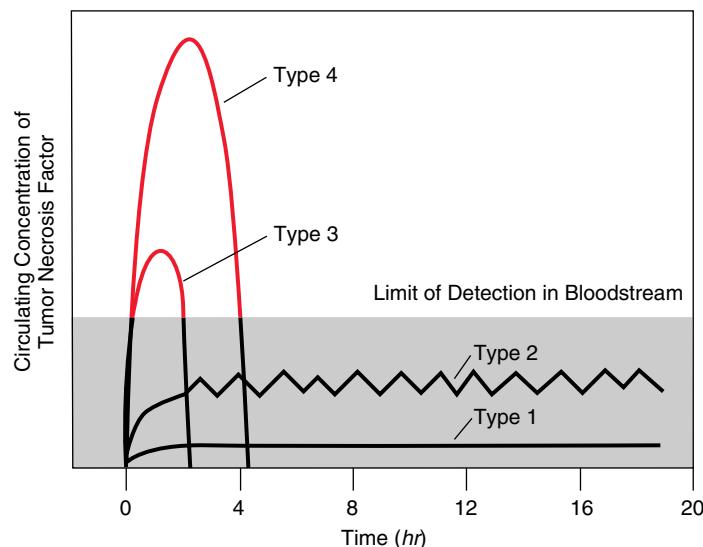

Figure 5 Different infectious states are likely to be associated with different patterns of cytokine release into the circulation.²⁵⁴ Type 1 in this figure could be considered to represent localized cellulitis, such as might be present at an infected intravenous catheter infusion site. Generation of tumor necrosis factor (TNF) and other cytokines occurs locally to produce local responses that aid host defense and tissue repair. Overspill into the circulation is minimal.

The second type might represent the responses ensuing from appendiceal abscess. There is local generation of cytokines, and as bacteria or their endotoxins leak into the circulation, circulating mononuclear cells also elaborate cytokines and give rise to moderate systemic responses. The low level of persistent endotoxemia is reflected in the cytokine response. Because only a small number of cytokine-producing cells are stimulated at any one time, the responses of these cells, although of long duration, are not strong enough to be detectable in the bloodstream. However, this signal is sufficient to generate systemic manifestations of the localized infection.

A third type of infection might be one that follows manipulation of a catheter in the biliary tree or urinary bladder to resolve an obstruction. A few cytokine-producing cells simultaneously elaborate TNF to produce a high-amplitude signal. Because the endotoxemia is transient, both the signal and the host responses are short-lived. Clinical features include a brief episode of hyperpyrexia with rigors and severe symptoms, but the cytokine response is too short and of insufficient amplitude to give rise to life-threatening, irreversible host alterations.

A fourth type of infection might be precipitated by sudden dehiscence of a colonic anastomosis or by meningococcal septicemia. An acute, massive entry of endotoxins into the circulation stimulates virtually every cytokine-producing cell in the body. A very high amplitude signal occurs, but its duration is short, despite the host's continuing exposure to endotoxin. The short duration of the strong signal is caused by the quick disappearance of cytokines from the circulation; their half-life is short, and the cytokine-producing cells become refractory after their simultaneous explosive response to the initial, lethal signal. This high-amplitude signal is misinterpreted by the host, causing the entire body to behave as if it were a massive wound. The entire vascular tree shows increased permeability and vasodilatation, resulting in the clinical state of irreversible shock. These situations have been reversed or prevented by the use of TNF antibodies in animals and occasionally by the use of plasmapheresis in humans.

that both glucocorticoid-dependent and glucocorticoid-independent proteolytic mechanisms can be activated during critical illness.

Role of the Central Nervous System

The CNS plays a major role in the regulation of the metabolic response to critical illness. Hume and Egdaahl were among the first to demonstrate its role in mediating early responses to injury.¹⁴⁹ They measured the rise in 17-hydroxycorticosteroids in adrenal venous blood in response to a burn to the lower limb of an animal under anesthesia. The limb was almost completely separated from the body, so that the only connections between the limb and the rest of the animal were the femoral vessels and the sciatic nerve. The prompt rise in the venous adrenocorticoid concentration after the burn could be prevented by sectioning of the sciatic nerve or of any portion of the CNS up to the level of the midbrain.

To characterize the role of the CNS in the regulation of later hypermetabolic flow-phase responses, Wilmore and associates administered inert gas anesthesia to hypermetabolic burn patients and demonstrated reduced core temperature and metabolic rates.¹⁵⁰ Fried and coworkers studied patients with head injuries during barbiturate coma.^{151,152} Metabolic rate and nitrogen excretion were reduced to basal values during barbiturate administration. Given that its global suppression reduces the intensity of hypermetabolic responses, the CNS appears to be necessary for the full expression of both the ebb phase and the flow phase of the metabolic response to critical illness.

The CNS has long been considered part of a neuroendocrine reflex arc,¹⁵³ a view that has proved useful for explicating underlying regulatory mechanisms. According to this concept, there must be afferent input whereby (1) the body is alerted to an injury or any other threat to its integrity and (2) the wound or inflammatory focus signals its presence, its extent, and its resolution or closure. After reception and interpretation of this input, the CNS generates efferent signals that regulate the regional and systemic metabolic alterations observed clinically. This model is most obviously relevant to the early phase of the response to critical illness (the ebb phase). The hypothalamus, the peripheral and spinal neural pathways, and the adrenals all participate in the classic fright-fight-flight syndrome. Pain, hypovolemia, acidosis, and hypoxia stimulate neural afferent signals to the CNS. The importance of these neural pathways in transmitting afferent signals to the CNS during hypermetabolism is less clear. For example, when lidocaine was applied to burn wounds to anesthetize them, no decrease in hypermetabolism was observed.¹⁵⁴

The CNS may play a role in a variety of immunologic and inflammatory responses.¹⁵⁵ Early studies demonstrated that a small amount of IL-1 injected intrathecally elicited the same increase in body temperature as a much larger dose administered intravenously. This suggested that IL-1 could act centrally and that it might function as an afferent signal from the wound to the CNS.¹⁵⁶ Demonstration of IL-1 immunoreactivity in the hypothalamus of humans lent weight to this suggestion.¹⁵⁷ Later studies, however, showed that astrocytes and microglia could express cytokines and cytokine receptors themselves.^{158,159} In addition, these cells increased expression of IL-1 and IL-6 in vitro in response to hypoxia or endotoxin in vitro,^{160,161} and systemic administration of endotoxin to intact animals increased cytokine expression in the CNS.^{162,163}

Hill and colleagues used an animal model to assess the metabolic effects of IL-1 continuously infused either subcutaneously or into the lateral ventricle for 6 days.¹⁶⁴ Subcutaneous IL-1 was given in different doses, which induced fever, anorexia, increased protein catabolism, and weight loss in a dose-dependent manner. Intracerebroventricular (ICV) IL-1 evoked qualitatively similar responses.

Subcutaneous IL-1, however, resulted in a greater leukocytosis and a more pronounced acute-phase response than did ICV IL-1, even though the other systemic alterations were quantitatively similar. Thus, IL-1 produced in the CNS may not have the same physiologic consequences as IL-1 produced in other anatomic sites.

In another study, Hill and colleagues pair-fed control animals with animals receiving ICV IL-1.¹⁶⁵ They observed that the pair-fed animals also lost weight, but the weight loss was significantly less severe than in the animals receiving ICV IL-1. Long-term ICV IL-1 infusion also caused increased adrenal gland weight and corticosteroid levels in comparison with values in both pair-fed and chow-fed controls. The ICV IL-1-induced catabolic changes were not, however, attenuated by previous adrenalectomy. This finding indicates that the protein-catabolic effects induced by ICV IL-1 may involve not only glucocorticoid-dependent ATP-ubiquitin proteolysis but also systems that are independent of glucocorticoids. Such a conclusion is consistent with the finding by Zamir and associates that intraperitoneal IL-1 increased total and myofibrillar proteolysis in both adrenalectomized animals and sham controls.¹⁴⁸ Thus, the CNS may be able to influence metabolic responses via both endocrine pathways and other mechanisms that do not involve endocrine activation.

Elaboration of IL-6 typically follows elaboration of IL-1, and IL-6 is a potent activator of corticosteroid synthesis and release.^{115,166} Long-term IL-1 infusion leads to increased muscle protein breakdown and nitrogen loss over and above what is attributable to reduced food intake, and it results in elevated circulating levels of IL-6.¹⁶⁷ When Hill and associates infused IL-6 into the CSF of rats, it had no effect, unlike ICV IL-1.¹⁶⁵ Reyes and Coe followed the appearance of IL-6 in CSF in primates after intravenous injection of IL-1 α , IL-1 β , and IL-6.¹⁶⁸ All three cytokines raised the circulating levels of IL-6, IL-1 α , and cortisol, but only IL-1 β raised the CSF level of IL-6. Furthermore, IL-6 appeared in CSF from the lumbar region 2 hours after it peaked in CSF from the cervical region. These data suggest that the IL-6 in the CSF after the appearance of IL-1 in the periphery is elaborated by the brain.

Romero and colleagues gave an ICV injection of IL-1 β to rats and measured IL-6 concentrations in CSF and in blood from the superior or sagittal sinus and the aorta.¹⁶⁹ IL-6 was elevated in all three compartments, and the concentration gradient between the sagittal sinus and the aorta was widened in comparison with the control value. Both adrenergic pathways and adrenal activation are known to be stimulated by IL-1 administration, but the changes observed in this study were not affected by sympathetic blockade. In addition, ICV corticotropin-releasing hormone did not result in alterations in IL-6 levels in CSF or in blood. The investigators concluded that the IL-6 that appeared in both the CSF and the blood was derived from the brain.

Injury and inflammation also appear to affect nerve function. Compounds elaborated by platelets, neutrophils, and other inflammatory cells can alter the phenotype of neurons, affecting their growth, function, and electrical properties.¹⁷⁰ The complex of IL-6 and its receptor can activate specific neuronal signal transduction systems on sensory neurons and so affect gene expression and protein synthesis.¹⁷¹ Sensory nerve injury induces the expression of IL-6 and IL-6 receptor in more central neurons, and this may influence nerve repair.¹⁷² Current studies further suggest that IL-1, IL-6, and other proinflammatory cytokines may play a key role in generating pain syndromes associated with inflammation.¹⁷³ Inflammatory activation of sensory neurons, as opposed to strictly neural mechanisms of activation, also requires the participation of spinal cord astrocytes and microglia. Persistent inflammation, rather than altered neural properties, thus may be the major mechanism responsible for complex re-

gional pain syndromes (e.g., reflex sympathetic dystrophy and causalgia) after injury.¹⁷⁴

Thus, pain, acidosis, hypoxia, and hypovolemia, as well as cytokines and other substances produced by inflammatory cells, generate afferent signals to the CNS through a variety of mechanisms. Some signals may elicit a rapid effector response, whereas others appear to induce mechanisms that result in delayed and more prolonged end-organ functional alterations. The CNS affects both metabolic and inflammatory processes, and it may do so in multiple complementary but largely independent ways. Activation of the hypothalamic-pituitary-adrenal axis is one of these mechanisms, but the CNS also appears to be able to induce catabolic responses without this intervention. The CNS may also be a source of mediators that are released into the circulation for systemic distribution, thus acting as an endocrine organ.

Role of the Gut

Although the idea that endotoxin absorbed from the gut lumen during shock states might result in irreversible critical illness was first proposed more than 40 years ago,^{175,176} most clinicians thought that the gut was inert after operation and injury until recently. It is now generally recognized that the gut plays an important role in augmenting or perpetuating the response to critical illness.¹⁷⁷

Gram-negative pathogens are the predominant infectious organisms in the ICU, and the gut appears to be a major source of contamination. The gut lumen forms a large reservoir for gram-negative enteric bacteria, but the normal GI mucosa protects the host from intraluminal bacteria and their toxins. The maintenance of tight intracellular junctions between epithelial cells prevents the transepithelial migration of bacteria.¹⁷⁸ The GI tract is also richly supplied with macrophages and fixed immune cells. The elaboration of surface immunoglobulins (e.g., IgA) aids in the recognition of foreign antigens.¹⁷⁹ Finally, the liver and the spleen serve as backup systems for trapping bacteria and neutralizing absorbed toxins. The combination of an intact gut mucosa and a normally functioning immune system provides maximal barrier function. Even in immunosuppressed states, the mucosa can still maintain an effective barrier to infection. This suggests that cell-mediated immunity is secondary in importance to an intact intestinal epithelial lining.

When the barrier function of the GI epithelium is impaired, intraluminal bacteria and toxins can invade the host. In one set of experiments in rabbits, fatal endotoxic shock was observed after temporary occlusion of the superior mesenteric artery or a 30% scald burn¹⁸⁰; however, if the enteric flora was reduced, the animals did not die. Endotoxemia has been observed in patients with a variety of critical illnesses.¹⁷⁶ Wellmann and associates reported that whole gut lavage with saline reduced the concentration of circulating endotoxin and improved the clinical outcome in a large group of patients with inflammatory bowel disease that was unresponsive to medical therapy.¹⁸¹ Moreover, bacteremia in portal blood has been observed at the time of operation in as many as 30% of patients with noninflammatory bowel disease.¹⁸² Ambrose and associates cultured both intestinal serosa and mesenteric lymph nodes during abdominal operation.¹⁸³ In patients without inflammatory bowel disease, the incidence of positive cultures was low, but in patients with Crohn disease, the incidence increased markedly, to approximately 30%.

Bacterial translocation is the migration of bacteria across the bowel wall to invade the host. In a review of the available animal and human data on this process, Berg identified three conditions that appear to promote translocation: altered permeability of the intestinal mucosa, decreased host defenses, and an increased number of bacteria within the intestinal lumen.¹⁸⁴ Deitch and colleagues observed this

phenomenon in animals after a variety of insults, including burns,¹⁸⁵ hemorrhagic shock,¹⁸⁶ and endotoxin administration.¹⁸⁰ Malnutrition alone did not lead to translocation, but it made the gut barrier more susceptible to endotoxin.¹⁸⁷

The extent of bacterial translocation in critically ill patients is not well defined. Moore and colleagues obtained both portal venous and systemic venous blood cultures in patients at risk for multiorgan failure after laparotomy for severe trauma.¹⁸⁸ Only 2% of cultures were positive in the first 5 days, which suggests that translocation of bacteria in sufficient quantities to cause portal vein bacteremia is not a major determinant of organ failure soon after injury.

Subsequent studies focused on the gut as a source of cytokines. Even the normal gut contains a large number of intestinal lymphocytes that elaborate proinflammatory cytokines, and these are counteracted by expression of anti-inflammatory cytokines in a state of so-called controlled inflammation.¹⁸⁹ Guy-Grand and colleagues detected measurable levels of TNF, IL-6, and interferon gamma in proximal small bowel secretions in humans.¹⁹⁰ The presence of bacterial overgrowth, especially colonic-type bacteria, however, was associated with increased IL-6 concentrations. Wyble and associates investigated the cytokine response to intestinal ischemia-reperfusion in ex vivo perfused segments of human intestine.¹⁹¹ Concentrations of TNF and IL-1 increased in the venous effluent after reperfusion. The investigators subsequently exposed cultured human endothelial cells to physiologic concentrations of TNF and IL-1 that were lower than those observed after ischemia-reperfusion. The cytokines upregulated expression of E-selectin and intercellular adhesion molecule-1 (ICAM-1), which are thought to mediate the adhesion of neutrophils in the microcirculation and their transmigration across the capillary membrane into tissue, thus initiating tissue inflammation.

Mainous and colleagues produced sterile peritonitis with both a nonlethal and a median lethal dose (LD_{50}) of zymosan.¹⁹² They detected increased IL-6 and TNF in both blood and lymph, but these changes did not correlate with zymosan dose or with bacterial translocation. Thus, the gut appears capable of producing cytokines in response to an inflammatory insult, and this may occur even in the absence of bacterial translocation.

Mochizuki and associates were among the first to demonstrate the importance of enteral feedings in maintaining gut mucosal integrity and modulating catabolic responses in critical illness.¹⁹³ They measured intestinal mucosal weight and several metabolic parameters in experimental animals after a standard burn injury. In one group of animals, feedings were delivered through a gastrostomy tube and were begun soon after the burn injury, whereas in a second group, feedings were oral and were begun after a 72-hour fast. Mucosal weight was preserved in the first group but reduced in the second group. In the animals that fasted, postburn hypermetabolism developed, but this response was attenuated in the ones that received early enteral feedings. Intravenous feeding did not preserve mucosal mass or modify postburn metabolic responses.¹⁹⁴ In an early clinical study, Alexander and colleagues documented improved survival in children with burns who were nourished enterally.¹⁹⁵ Furthermore, Border and associates found that the provision of enteral protein was one of only two factors statistically associated with improved survival in a large group of severely injured patients.¹⁹⁶

Ogle and colleagues extended these observations by comparing intestinal and splenic cytokine expression in animals nourished by parenteral nutrition but allowed no oral intake with cytokine expression in control animals allowed food ad libitum.¹⁹⁷ After 7 days of infusion, mRNA expression for IL-1, IL-6, and TNF was increased in the intestine and decreased in the spleen. Lyouri and associates also reported that protein malnutrition alone enhances intestinal IL-6 expression and acute-phase responses.¹⁹⁸ These findings suggest that

augmented intestinal cytokine production is responsible, in part, for the earlier clinical observations that bowel rest or inadequate enteral protein amplifies the responses to critical illness and may adversely affect outcome.

The presence of food in the gut lumen is known to be a major stimulus for mucosal cell growth. Mucosal atrophy is observed in the absence of enteral nutrition (as occurs during starvation¹⁹⁹ or periods of parenteral nutrition²⁰⁰) and in defunctionalized intestinal segments.²⁰¹ Enteral feeding not only provides nutrients but also stimulates the elaboration of trophic hormones for the intestinal mucosa.^{202,203} In addition to luminal bulk, specific nutrients (e.g., glutamine and butyrate) are important for the growth of gut mucosa. Glutamine is a major respiratory fuel for the gut, especially during critical illness (see above). Colonocytes also utilize butyrate, a short-chain fatty acid that is produced by bacterial fermentation of polysaccharides in the colonic lumen. In solution, glutamine decomposes into toxic substances; it is therefore not included in any commercially available parenteral amino acid solutions or in most enteral nutrition products. When glutamine was added to parenteral nutrition in place of other nonessential amino acids, however, increased mucosal cellularity was observed in the jejunum, ileum, and colon in an animal model.^{204,205} In other studies, the toxic effects of methotrexate were alleviated and mucosal cellularity and nitrogen balance improved when parenteral solutions containing glutamine were used.²⁰⁶

Endotoxin, Bacteria, Inflammation, and Organ Failure

Endotoxin is a lipopolysaccharide component of bacterial cell walls that can reproduce the syndrome of sepsis and shock when given to animals or humans.²⁰⁷ The presence of endotoxin is considered a major determinant of the clinical sequelae of bacterial infection. A low continuous dose of endotoxin in animals produces a hypermetabolic state that exhibits all of the features of the response to critical illness.²⁰⁸

Revhag and associates administered *Escherichia coli* endotoxin to normal individuals under controlled conditions of activity and diet and compared the metabolic responses with those of subjects given only saline.²⁰⁹ About 2 to 4 hours after administration of endotoxin, the subjects experienced headache, chills, malaise, nausea, fever, tachycardia, and an increased respiratory rate. In these and subsequent studies, endotoxin injection was also associated with leukocytosis, mild glucose intolerance, an increased metabolic rate, and elevated concentrations of adrenocorticotrophic hormone, cortisol, catecholamines, and growth hormone.

Michie and colleagues found that the symptoms that followed a single dose of endotoxin in normal subjects were preceded by an abrupt and transient rise in circulating TNF concentration.²¹⁰ The symptoms developing after endotoxin injection were similar to those developing during TNF infusion, but they appeared 60 to 90 minutes after injection, in contrast with the appearance of symptoms 30 minutes after the start of TNF infusion.¹¹⁸ In these studies, IL-1 was not detected, but Fong and associates detected both a peak rise in TNF and a later peak of IL-1 after administration of a lethal dose of bacteria in primates.²¹¹ In those studies, death was prevented by an anti-TNF antibody. Thus, TNF is the first in a characteristic cascade of cytokines that mediate the physiologic responses to endotoxin.

Circulating endotoxin can be detected in patients who have experienced trauma¹¹⁶ or burns¹¹⁷ and even in those who have undergone cardiopulmonary bypass.²¹² In healthy persons, repeated doses of endotoxin result in tolerance. In injured or critically ill patients, however, the responses to sustained or repeated doses of endotoxin have not been well characterized.

O'Dwyer and associates measured intestinal permeability in healthy human volunteers after a single dose of *E. coli* endotoxin or saline.²¹³

Lactulose and mannitol were administered orally as markers of intestinal permeability. (Lactulose is not absorbed to any significant extent under normal conditions.) After endotoxin administration, the urinary excretion of lactulose was increased almost twofold, which indicated that intestinal permeability was markedly altered. This change was closely associated with increases in norepinephrine and cortisol levels, which suggested that these hormonal changes or other systemic responses induced by endotoxin were responsible for the change in permeability. If alteration of the gut barrier led to increased absorption of endotoxin, that could be another mechanism by which the systemic responses to critical illness were amplified and perpetuated.

Patients with infectious disease (e.g., typhoid fever or malaria)^{214,215} manifest many of the clinical features observed in critically ill surgical patients; however, these phenomena are less intense in patients with infectious disease. Surgical patients with uninfected wounds also usually manifest relatively mild responses to injury; those with infected wounds exhibit the most intense metabolic alterations. The infection may be associated with the wound (e.g., surgical site infection, mature abscess, or ARDS and pulmonary sepsis), or it may be remote (e.g., pneumonia in a patient with multiple fractures). Peak catabolic responses in surgical patients often occur several days after operation or injury. This period corresponds to the development of the cellular phase of wound healing¹¹² and to colonization of the wound or another site.

Aulick and colleagues examined the possible contribution of bacteria or bacterial products to the metabolic response to injury in animals.²¹⁶ They measured $\dot{V}O_2$ and core temperature in animals for up to 3 weeks after a standard scald burn. Some of the wounds were seeded with bacteria (virulent and nonvirulent *Pseudomonas aeruginosa* and *Staphylococcus epidermidis*), and some of the infected wounds were treated with topical antibacterial agents. The use of topical antibiotics was associated with a reduction in hypermetabolism. In addition, in animals that became bacteremic, the degree of hypermetabolism was at least twice that in nonbacteremic animals. The metabolic effects of infection thus appear to be proportional to the severity and invasiveness of the infection. In analogous studies, Wilmore and associates examined burn patients with and without bacteremia.²⁴ Although total body $\dot{V}O_2$ and cardiac index were already elevated, the onset of bacteremia resulted in further increases in these parameters. In addition, hepatic glucose production and splanchnic uptake of lactate and alanine were significantly increased in patients with systemic infection. Hypermetabolism decreased, however, once organ failure occurred.

Bacteria are ubiquitous in both health and critical illness. The mechanisms by which bacteria become infective and invade host tissues and produce physiologic responses have yet to be fully elucidated. In part, these involve intracellular regulatory systems that respond to complex reciprocal interactions with the host and that can modify bacterial virulence. Guo and associates investigated the dual peptide system PhoP-PhoQ in *Salmonella*.²¹⁷ PhoP-PhoQ regulates genes required for the synthesis of lipid A, the active component of endotoxin. It is capable of modifying the structure of lipid A, and this structurally modified lipid A can affect the expression both of adhesion molecules by host endothelial cells and of TNF by neighboring monocytes. This capability may be a mechanism by which bacteria can not only increase their chances of survival in host tissues but also affect the character or intensity of host inflammatory responses to the infection. PhoP-PhoQ and other intracellular systems respond to characteristics of the host environment, such as pH, Po_2 , and ionic composition.²¹⁸ Thus, the condition of the patient may influence the virulence characteristics of resident bacteria, and these characteristics, in turn, may modulate the patient's responses to critical illness.

The cellular response to localized injury or other inflammatory stimuli initially consists of the recruitment and proliferation of neutrophils. This process appears to be mediated in part by the expres-

sion of adhesion molecules by endothelial cells. These molecules capture passing circulating neutrophils and facilitate their passage through the capillary wall.²¹⁹ Neutrophils, macrophages, and other inflammatory cells have the capacity to engulf and dispose of necrotic debris and to kill bacteria. These same properties also make them potentially toxic to normal cells. Neutrophil infiltration of specific organs, such as the lung, appears to be a first step in the development of organ failure after shock, endotoxin, and other insults.²²⁰ This finding suggests that neutrophils activated by potent inflammatory stimuli can invade unaffected tissues and so contribute to organ dysfunction in critically ill patients.

Not surprisingly, anti-inflammatory mechanisms exist to limit the intensity and toxicity of inflammatory processes. One such mechanism is apoptosis, or programmed cell death, which is thought to participate in the clearing of inflammatory cells as the wound heals and the inflammatory process subsides. Biffl and colleagues demonstrated that IL-6 inhibited apoptosis in human neutrophils *in vitro*.²²¹ They proposed that circulating IL-6 in critically ill patients retarded neutrophil apoptosis and thus enhanced and prolonged the toxic effects of the neutrophils. This could be another mechanism by which the responses to critical illness could be prolonged and lead to worsening organ failure and death.

Several investigators have sought to understand how neural mechanisms might also influence physiologic responses to infection and inflammation. The vagus nerve has been of particular interest because its fibers are widely distributed, especially in organs that contain large amounts of inflammatory cells (e.g., the liver, the spleen, the lungs, the thymus, the GI tract, and the lymph nodes). Niijima gave varying doses of IL-1 β to rats by portal vein injection.²²² He observed a dose-dependent increase in the afferent activity of the hepatic branch of the vagus nerve. He also detected efferent signals in autonomic nerves to the spleen and the thymus after intraportal administration of IL-1. Because these signals were eliminated by vagotomy, they appeared to be the result of reflex activation. These findings suggested that there may be sensors in the hepatoportal system of vagal origin that can detect IL-1 and other inflammatory mediators and generate neural afferent activity, stimulating the brain to generate signals that affect host defense and other responses.

Maier and colleagues sought also to understand how the vagus nerve might influence the neural and behavioral changes associated with sickness.²²³ Subdiaphragmatic vagotomy blocked or ameliorated many of the responses to intraperitoneal endotoxin or IL-1 β that could be detected physiologically and behaviorally, as well as certain biochemical changes within the brain. Hansen studied the pyrogenic effects of different doses of intraperitoneal IL-1 β .²²⁴ Vagotomy abolished the fever after a low dose, reduced it after a medium dose, and had no effect after a high dose. Circulating IL-1 β levels were increased only after the medium and high doses. Romanovsky also found the vagus nerve to be sensitive to low doses of IL-1 β and suggested that prostaglandins mediated the communication in the periphery.²²⁵ These data support the concept that peripherally elaborated cytokines may signal the brain either via the bloodstream or via the nervous system.

Goehler and associates used a labeled form of IL-1ra to try to identify IL-1 receptors associated with the vagus.²²⁶ There was no specific binding to neural tissue, but there was intense binding to tissues closely surrounding the vagal fibers. These tissues consist primarily of chromaffin tissue and were formerly thought to serve primarily as chemosensors for oxygen and carbon dioxide tension in both the abdomen and the lung. These investigators further demonstrated that endotoxin administration induced IL-1 β expression in dendritic cells and macrophages within the connective tissues associated with the abdominal vagus nerve, which suggested that these cells

were the source of proinflammatory cytokines that could initiate afferent signals to the brain via the vagus.²²⁷

The vagus nerve also contains efferent fibers that are widely distributed. Tracey and colleagues performed bilateral cervical vagotomies in rats and stimulated the distal nerves electrically before and after administering a lethal dose of endotoxin.²²⁸ Stimulation of the distal vagus attenuated endotoxic shock and blunted the rise in circulating TNF. Electrical stimulation also resulted in decreased TNF in homogenates of liver, which suggested that vagal efferent activity diminished hepatic TNF elaboration in response to endotoxin.

These investigators also established primary cultures of human macrophages. These cells, in response to lipopolysaccharide, elaborated IL-1, TNF, and other proinflammatory cytokines, as well as the anti-inflammatory cytokine IL-10. Incubation with the parasympathetic neurotransmitter acetylcholine substantially reduced the endotoxin-stimulated synthesis of the proinflammatory cytokines but not that of IL-10. This group subsequently identified an acetylcholine receptor on human macrophages.²²⁹ Thus, efferent parasympathetic vagal activity appears to dampen inflammation by suppressing elaboration of proinflammatory cytokines by tissue macrophages.

Thus, there is an emerging appreciation of a role for the parasympathetic arm of the autonomic nervous system, especially the vagus. Proinflammatory cytokines produced at the site of the inflammatory process may induce afferent neural activity that directly signals the brain, independent of any change in circulating cytokine levels. If the localized inflammatory response is intense or extensive enough, however, perhaps as a result of invasive infection or systemic bacteremia, locally produced cytokines may spill over into the circulation and also reach the brain via the bloodstream. The afferent branches of the vagus terminate in the nucleus tractus solitarius in the medulla. From there, neural fibers traverse the brain stem, terminating on specific cells in the hypothalamus. Thus, parasympathetic nerves may provide neural circuitry by which a focus of inflammation can signal the brain and activates the hypothalamic-pituitary-adrenal (HPA) axis.

Activation of the HPA axis, whether by neural signaling or by elevation of circulating cytokine levels, may result in sympathetic efferent activity, the characteristic elaboration of classic stress hormones, and alteration of the thyrotropic, somatotropic, and gonadotropin endocrine axes. These neuroendocrine responses induce systemic and metabolic alterations that serve to promote wound healing, such as increased blood flow, mobilization of amino acids from muscle, glucose intolerance, and insulin resistance. In addition, efferent parasympathetic activity may modulate the intensity of the inflammatory processes at specific sites of inflammation. Thus, neural mechanisms enable the CNS and the brain to direct and regulate the physiologic responses to injury, infection, inflammation, and critical illness.

Manipulating the Response to Critical Illness

The metabolic response to critical illness has survival value. Young patients are able to mount more intense hypermetabolic responses than elderly persons and in general have higher survival rates. However, these responses are debilitating in all patients and may be associated with organ failure and death. Many have sought to develop therapeutic strategies that would reduce the debilitating aspects of these responses, accelerate recovery, or both.

The endocrine response to injury or operation has been attenuated by adrenergic blockade or regional anesthesia (see above). These maneuvers are associated with an improved postoperative nitrogen balance^{101,102} and decreased muscle protein breakdown.¹⁰⁰ Herndon and colleagues reported that continuous administration of propranolol to children with burns reduced cardiac work without adversely affecting

mortality, postburn course, or wound healing.²³⁰ This technique may benefit elderly, critically ill patients with limited cardiovascular reserve.

Several studies have evaluated the effectiveness of combined neural and humoral blockade in inhibiting the metabolic responses to operative injury. Schulze and associates compared the responses of patients receiving morphine and acetaminophen for pain control after colonic surgery with those of patients managed with methylprednisolone pretreatment, thoracic epidural analgesia, intrathecal anesthesia, and intravenous indomethacin.²³¹ In the patients receiving combined therapy, postoperative pain and fever were prevented, pulmonary function was improved, and fatigue was reduced. Synthesis of acute-phase proteins and IL-6 was reduced. Similarly, Heindorff and coworkers prevented the typical increases in amino acid clearance and urea synthesis with a combination of intravenous somatostatin and etomidate (to inhibit the elevation of glucagon and cortisol levels) and high thoracic epidural analgesia (to provide neural blockade).¹⁰³

Advances in cell and molecular biology have led to an extraordinary expansion of knowledge about the mechanisms involved in the many local and systemic responses to injury, sepsis, and other critical illness. Developments in technology have also led to the formulation of novel strategies for inhibiting various components of these responses that were thought to be particularly deleterious. Thus, antibodies to endotoxin, IL-1, and TNF were developed and studied in clinical trials, along with receptor antagonists and other compounds designed to interfere with systemic inflammatory responses. None of these demonstrated clinical benefit in controlled trials.²³² Given that the regulatory mechanisms are highly complex and that the same ones that may be harmful in some cases promote recovery in others, it is not surprising that blockade of one component of the response might offer no net benefit.

An alternative strategic approach is to enhance or accelerate those components of the response to critical illness that seem to be primarily restorative and lead to wound healing and recovery.

Nutritional support of critically ill patients is important both for promoting protein synthesis and other anabolic processes essential to recovery and for reducing the net drain on the patient's fuel and protein stores. Enteral nutrition is preferred, but the availability of effective intravenous techniques allows the clinician to provide appropriate nutrition to virtually all patients. Exercise and mobility have clear anticatabolic effects and should be initiated as early as is practicable.

Previously, provision of glutamine to critically ill patients had not been possible; glutamine had not been included in most commercial nutrient preparations because of its instability in aqueous solutions. When added to standard TPN, however, glutamine can promote nitrogen retention in postoperative patients.²³³ Ziegler and associates demonstrated that glutamine-supplemented TPN improved nitrogen balance, diminished clinical infection, and shortened hospital stay in a group of critically ill patients recovering from bone marrow transplantation.²³⁴ Enteral preparations enriched with glutamine are now commercially available.

Kudsk and associates randomly selected patients with moderately severe injuries to receive either an enteral formulation enriched with glutamine, arginine, omega-3 fatty acids, and nucleotides or a standard formula that provided an isonitrogenous, isocaloric diet.²³⁵ In both cases, protein content was moderately high (2 g/kg/day). Infectious complications in patients surviving to recovery were less frequent in those receiving the enhanced formula than in those receiving the standard diet.

Growth hormone, when administered to normal subjects, improves nitrogen balance, even if caloric intake is less than energy expenditure.²³⁶ Jiang and associates administered growth hormone and hypocaloric parenteral nutrition perioperatively to patients undergoing elective abdominal operations.²³⁷ They monitored a variety of metabolic parameters and compared the results with those from a

Table 8 Factors Affecting Metabolic Response to Critical Illness and Patient Outcome

Factors that <i>cannot</i> be directly controlled or influenced at present
Patient's genetic makeup and premorbid state of health
Gene transcription and translation
Expression of hormones, cytokines, and growth factors
Expression of hormone, cytokine, growth factor, and other specific cell receptors
Expression of secondary messengers
Generation of nitric oxide and other reactive oxygen intermediates
Signal transduction mechanisms
Intracellular transporters and other regulatory peptides and organelles
CNS neural pathway traffic and cytokine expression
Futile cycles
Enzymes controlling protein synthesis and breakdown
Bacterial virulence factors
Expression of adhesion molecules
Inflammatory and noninflammatory cell proliferation
Apoptosis
Wound-healing biology
Factors that <i>can</i> be directly controlled or influenced at present
Whole-body oxygenation
Whole-body perfusion
Pain, anxiety
Body temperature
Acid-base balance
ECF electrolyte composition and balance
Nutrient supply
Glucose concentration
Anabolic factors
Gut mucosal integrity
Focal infection and bacteremia
Wound repair and closure

control group of patients receiving parenteral nutrition alone. Growth hormone markedly reduced cumulative nitrogen loss. Although both groups of patients lost weight, those receiving growth hormone lost less. Bioelectric impedance data indicated that most of the weight lost by patients receiving growth hormone came from fat mass and not from the muscle compartment. Growth hormone also preserved muscle strength.

Herndon and colleagues administered growth hormone to severely burned children in a randomized trial.²³⁸ Growth hormone accelerated donor site healing, allowing earlier reharvesting of skin. As a result, the time between skin graft procedures and the total length of time required for the children's recovery were both reduced. Knox and associates gave growth hormone to a group of severely burned adults and compared their outcome with that of a similar group of patients cared for without growth hormone in the immediately preceding years²³⁹; mortality was lower in the growth hormone group.

The favorable results reported in burn patients and patients who have undergone elective abdominal operations have not been duplicated in more diverse groups of surgical patients.

Two large multi-institutional randomized trials were conducted in Europe. They included trauma patients, patients who had undergone cardiac procedures, and patients with other acute surgical illnesses. The combined mortality of the patients receiving growth hormone was 42%, more than twice the 18% mortality in the control subjects. Although the reasons for this adverse outcome have not yet been fully elucidated, the manufacturer of the recombinant product issued a safety statement recommending that recombinant growth hormone not be used in catabolic patients.²⁴⁰

An anabolic steroid, oxandrolone, was introduced over 50 years

ago as an adjunct to restoring weight loss. It has a good margin of safety and may play a beneficial role in critical illness by promoting nitrogen retention and accelerating recovery. Combined with a high-protein diet (2 mg/kg/day), oxandrolone promoted weight gain and functional improvement in a randomized study of burn patients who had recovered sufficiently to enter a rehabilitation program.²⁴¹ Hart and associates demonstrated improved efficiency of protein synthesis in nutritionally depleted burned children who received oxandrolone.²⁴² They observed the same benefit in patients who had received appropriate nutritional support from the time of injury.²⁴³ In this group, oxandrolone was also associated with an improvement in lean body mass and increased expression of genes for several functional muscle proteins.

Insulin attenuates cortisol-induced breakdown of skeletal muscle protein in vitro.²⁴⁴ Incullet and associates demonstrated improved nitrogen utilization in patients receiving TPN and insulin after operation.²⁴⁵ The apparent mild beneficial effects of TPN enriched with branched-chain amino acids may be caused by increased insulin elaboration.²⁴⁶ Bessey and Lowe induced accelerated skeletal muscle protein catabolism in normal subjects by blocking insulin elaboration during the first day of a 3-day infusion of stress hormones,⁹⁹ thereby simulating the typical hormonal profiles of injured patients. When insulin elaboration was allowed to rise unchecked or when exogenous insulin was administered to limit the rise of blood glucose, net muscle protein breakdown did not increase.

Although some degree of hyperglycemia may facilitate glucose uptake by the inflammatory cells in the wound, excessive elevations—in excess of 10 mmol/L (180 mg/dl)—have been associated with a variety of adverse effects, including impaired phagocytosis and immune function, increased CO₂ production and ventilatory requirements, increased vascular tone and reduction of regional blood flow, and altered collagen formation. Gore and associates demonstrated an association between hyperglycemia and increased net breakdown of muscle.²⁴⁷ Thus, close control of blood glucose concentration with insulin therapy may not only prevent these effects but also exert a beneficial effect on net protein loss. The insulin resistance in critically ill patients blunts the hypoglycemic effects of insulin, so that it may be administered continuously and regulated safely at the bedside by means of a standardized algorithm (sliding scale).²⁴⁸ Using two such algorithms, van den Berghe and colleagues administered insulin to a large group of critically ill patients (N = 1,548) to maintain blood glucose either in a normal range (80 to 110 mg/dl) or in a moderately hyperglycemic range (180 to 200 mg/dl).¹² Maintenance of normoglycemia was associated with a reduction in mortality from 8.0% to 4.6%. In a subsequent analysis, the investigators further showed that the benefit was related to the glucose concentration, not to the insulin dose.²⁴⁹ Patients with mild hyperglycemia (110 to 150 mg/dl) had worse outcomes than those maintained in the normal range.

One of the most effective means of manipulating the metabolic response to critical surgical illness, however, remains excellent surgical care. Such care is directed toward reducing, limiting, preventing, or neutralizing the signals that initiate these debilitating responses. Aggressive and prompt resuscitation, restoration of tissue oxygenation, debridement of necrotic tissue, drainage of pus, and wound repair all should have a high priority in the early management of a critically ill patient. Maintenance of effective cardiopulmonary function and tissue oxygenation, provision of a warm environment, preservation of GI tract integrity, and control of infection are clinical objectives of later management.

Over the course of the past few decades, close attention to these details has resulted in improved outcome for critically ill patients. For example, Pruitt and Mason analyzed a population of over 8,000 burn patients treated at the US Army Burn Unit from 1950 through 1991.²⁵⁰ Since the mid-1970s, the burn size associated with a 50% mortality steadily rose from 57% of BSA to 77%. Similarly, Milberg and colleagues demonstrated a reduction in ARDS-related mortality from nearly 70% to 30% between 1983 and 1993.²⁵¹

In a 1995 study, Kelleman and colleagues determined the effect of burn size on resting energy expenditure.²⁵² This study reproduced that of Wilmore done at the same institution almost 20 years before. In the earlier study, the resting metabolic rate increased steadily with burn size and plateaued at about twice the basal level with burns larger than 50% of BSA. Kelleman found that energy expenditure plateaued at only 1.5 times the basal level with burns of about 25% of BSA or more. This dramatic change in the relationship between burn size (injury severity) and metabolic activity (hypermetabolism) probably reflects the combined effects of improvements in all aspects of burn care, including resuscitation, cardiopulmonary and metabolic support, wound care, nursing practice, occupational and physical therapy, and reduced time to excision and grafting and wound closure. Improvements in care have thus reduced the metabolic cost of critical surgical illness.

Conclusion

The physiologic impact of major trauma, burns, intra-abdominal catastrophe, sepsis, or other critical illness reverberates throughout the body and affects all organ systems. Knowledge about the mechanisms that regulate this comprehensive and commanding response is growing at an exponential rate. These mechanisms are intricate, interrelated, and redundant. Where we once looked for a simple, direct answer, we now see dizzying complexity. The critically ill patient is a true example of controlled inflammation, suspended between anabolic and catabolic forces and between inflammatory and anti-inflammatory forces.

Unfortunately, our ability to apply our improved understanding to the care of critically ill patients still lags far behind. When the patient is not progressing well, we lack the ability to make a specific bedside diagnosis that will pinpoint the part of the system that is out of balance. Even if we could make such a diagnosis, however, we still lack the accurately targeted therapies that would allow us to intervene precisely.

Thus, a wide variety of factors and processes, with both beneficial and adverse effects, appear to be involved in the metabolic response to critical illness, but we are unable to affect many of them directly with the means currently available [see Table 8]. We can remove necrotic tissue, repair wounds, and drain pus. We can also usually ensure excellent cardiovascular performance and maintain extracellular electrolyte and nutrient composition and acid-base balance. We can often suppress bacteremia and can treat some infections effectively with antibiotics. We can prevent many additional insults to and stresses on our patients. These measures may seem unsophisticated and clumsy in the light of our contemporary understanding of the biology of convalescence, but they clearly are capable of nudging the metabolic response to critical illness toward a successful outcome. At present, such measures constitute the essentials of excellent comprehensive care of critically ill patients, and they give these patients their best hope for recovery.

23 NUTRITIONAL SUPPORT

Rolando H. Rolandelli, M.D., Dipin Gupta, M.D., and Douglas W. Wilmore, M.D.

Nutritional Management of Hospitalized Patients

Evaluation of the Need for Nutritional Support

INDICATIONS FOR NUTRITIONAL INTERVENTION

Nutritional support is required in patients who fall into one of the following general categories:

1. The patient has been without nutrition for 10 days. In a well-nourished individual, body stores are generally adequate to provide nutrients during shorter periods of stress without compromising physiologic functions, altering resistance to infection, or impairing wound healing. Provision of nutrients becomes more important as body stores become eroded because of inadequate food intake and accelerated catabolism. In general, deficits occur in surgical patients after 7 to 10 days of partial starvation; nutritional intervention should be initiated before this time.
2. The duration of illness is anticipated to be longer than 10 days. In this context, nutritional support should be considered essential care. Thus, individuals with severe peritonitis or pancreatitis, major injury (injury severity score > 15), or extensive burns (> 20% total body surface area) are candidates for nutritional support because of the known duration of their illness.

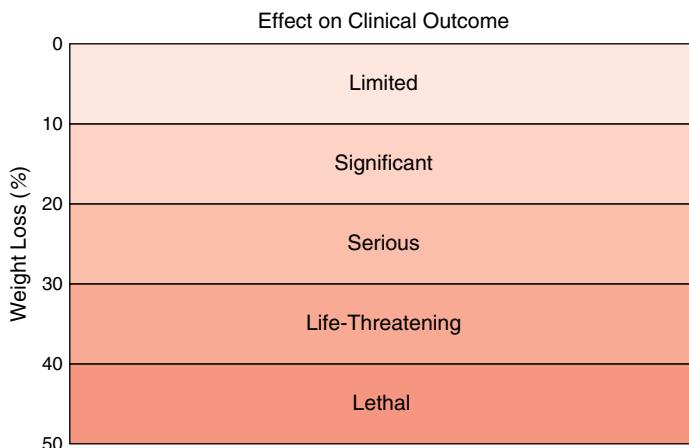

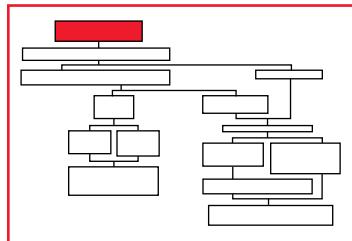

Figure 1 The magnitude of weight loss is a rough predictor of its effect on clinical outcome.

ness. (The duration of illness in chronically malnourished patients also would be expected to exceed 10 days.)

3. The patient is malnourished (loss of > 10% of usual body weight over 3 months). In general, weight loss can be used as an index of nutritional deficiency, and recovery may be compromised in patients who lack adequate body nutrient stores because of an existing nutritional deficit [see Figure 1]. The patient should receive nutritional support when weight loss approaches or exceeds 15% of usual body weight:

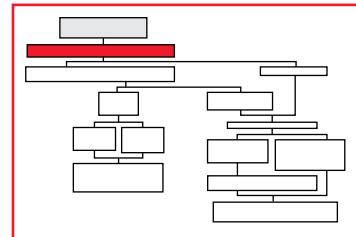

$$\% \text{ Weight loss} = \frac{\text{Usual weight} - \text{present weight}}{\text{Usual weight}} \times 100$$

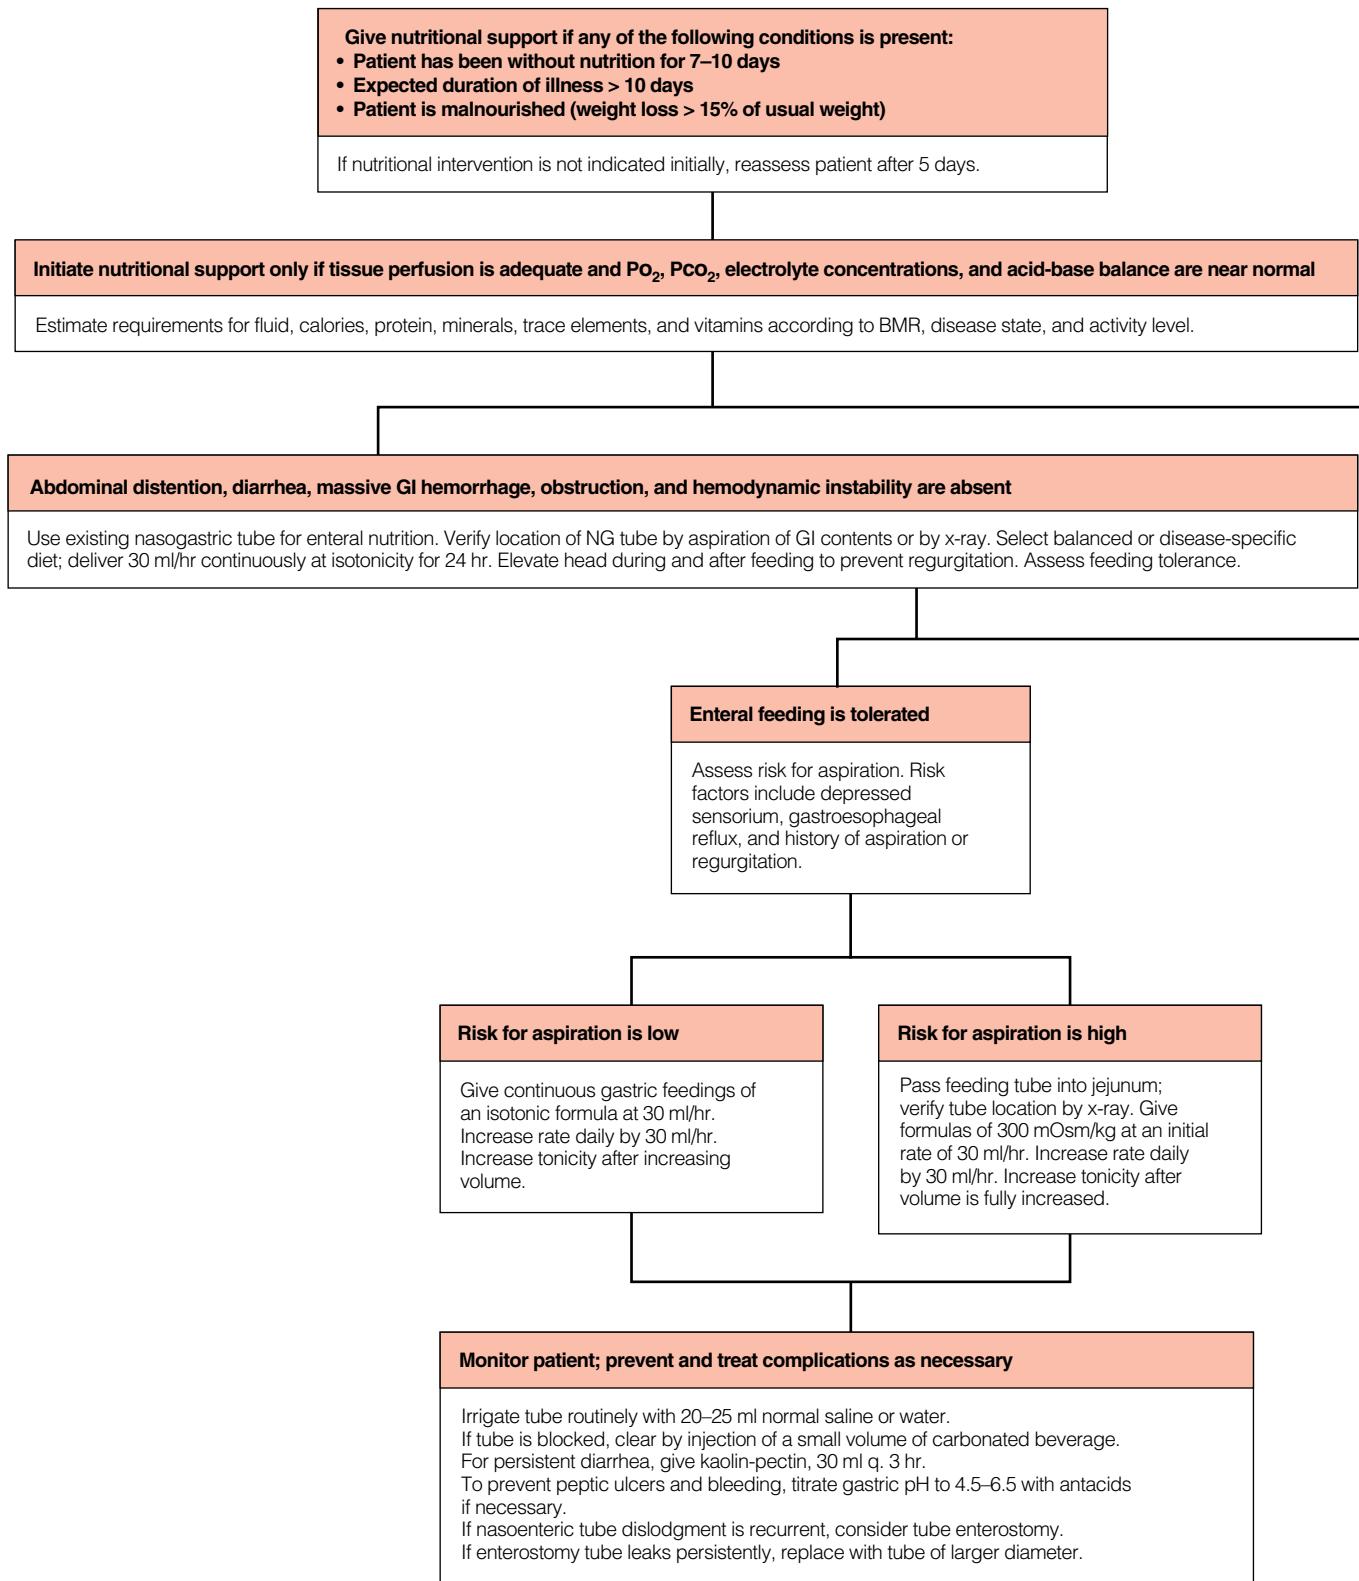

Patients who do not meet one of these three general indications should be reassessed after 7 days to identify individuals in whom complications develop after hospital admission and who require nutritional support. Serum proteins with a short half-life, such as prealbumin, transferrin, or retinol-binding protein, are useful markers for assessing response to therapy.

PRIORITY OF CARDIOPULMONARY FUNCTION

Intensive care unit patients are frequently candidates for nutritional support but often have complex medical and surgical problems that may take precedence. In decreasing order of importance, the priorities are to maintain airway patency, breathing, circulation, tissue oxygenation, acid-base neutrality, normal electrolyte concentrations, and adequate nutrition. The six functions that take priority over nutrition are usually impaired by acute and potentially life-threatening disorders that are often correctable over the short term. To optimize nutrient metabolism, circulation and tissue oxygenation must be adequate. In addition, hydrogen ion and electrolyte concentrations should be near normal in the extracellular fluid compartment, as reflected by blood or serum measurements.

If cardiopulmonary function is abnormal, nutrient administration may create additional problems. For example, in a patient with respiratory insufficiency, infusion of moderate quantities of carbohydrate could increase carbon dioxide tension (PCO_2) and lower serum potassium concentration, thereby potentially initiating a life-threatening cardiac arrhythmia. The need for nutritional support in the ICU patient should always be evaluated with respect to other care problems; acute disorders of cardiorespiratory function, disturbed acid-base status, and altered electrolyte

Nutritional Management of Hospitalized Patients

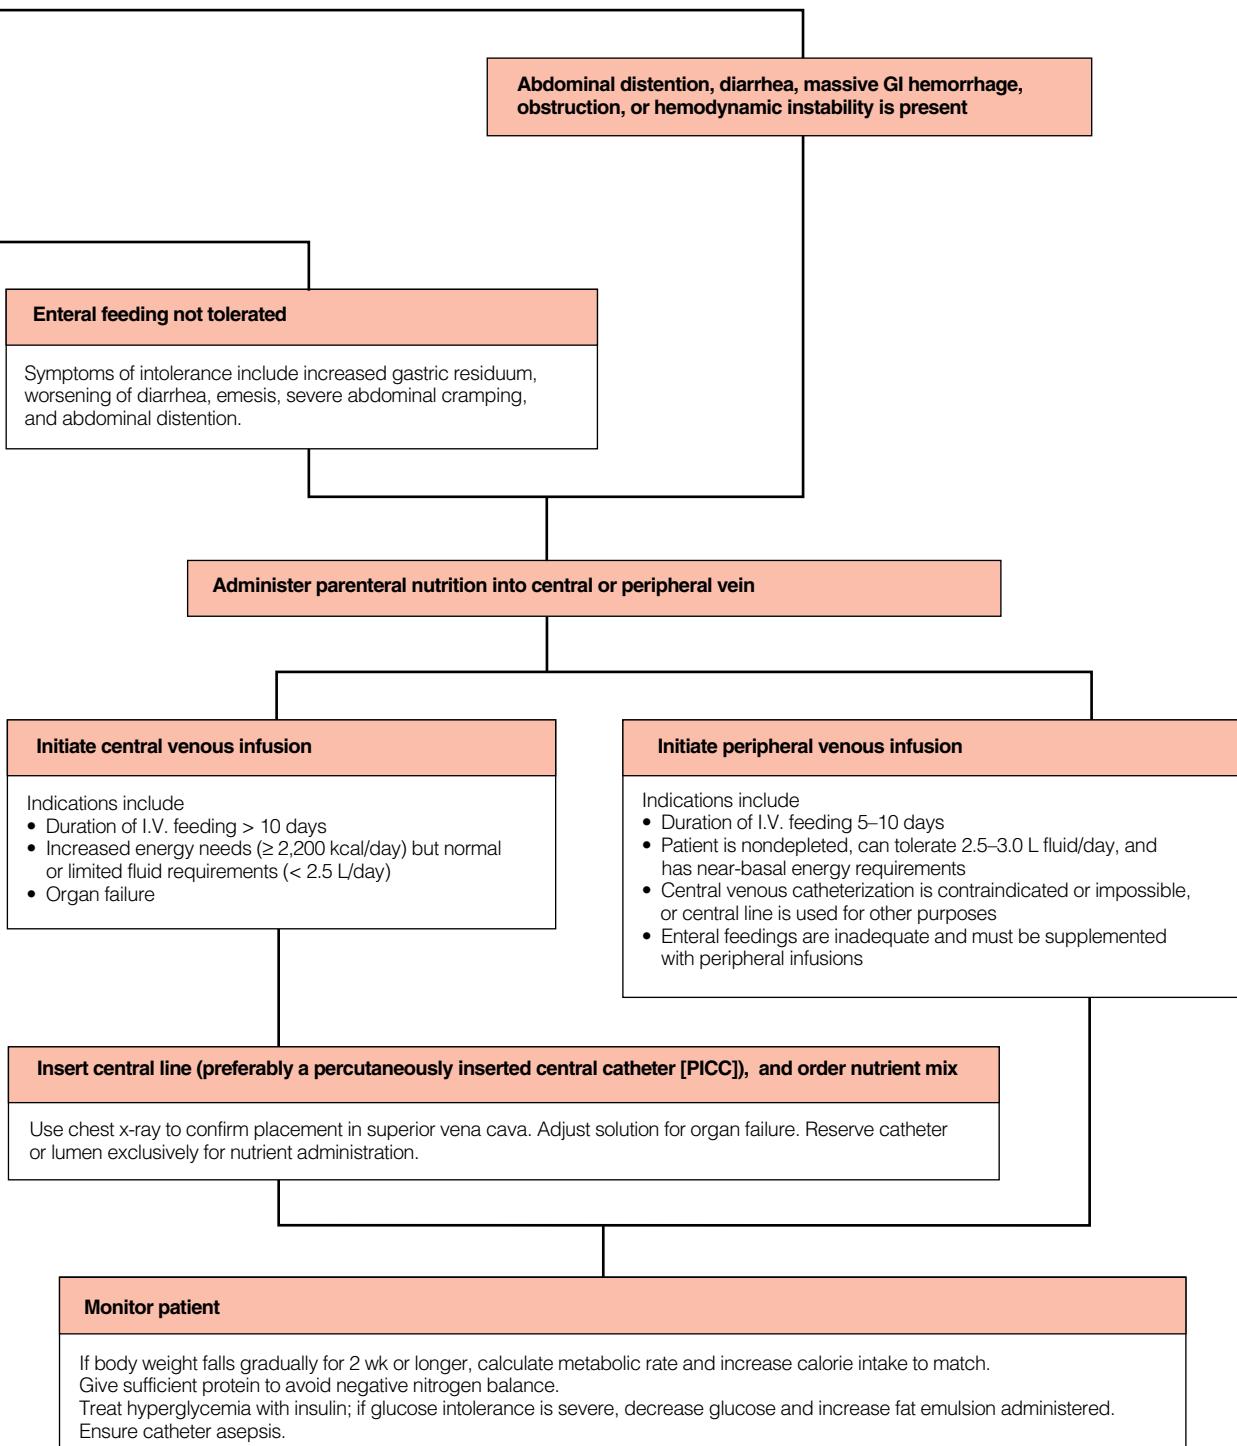

Table 1 Alterations in Metabolic Rate

Patient Condition	Basal Metabolic Rate
No postoperative complications Fistula without infection	Normal
Mild peritonitis Long-bone fracture or mild to moderate injury	25% above normal
Severe injury or infection in ICU patient Multiorgan failure	50% above normal
Burn of 40%–100% of TBS	100% above normal

concentrations should generally be corrected before nutritional support is initiated.

NUTRIENT REQUIREMENTS

Individual energy requirements are primarily related to body size, age, sex, and energy expenditure of activity (muscular work). In hospitalized patients who are generally inactive, the basal metabolic rate (BMR) accounts for the greatest amount of energy expenditure. The BMR in normal individuals is about 25 kcal/kg/day but can be calculated more precisely according to the Harris-Benedict formulas:

$$\text{Males: BMR (kcal/day)} = 66 + (13.7 \times \text{weight [kg]}) + (5 \times \text{height [cm]}) - (6.8 \times \text{age [yr]})$$

$$\text{Females: BMR (kcal/day)} = 665 + (9.6 \times \text{weight [kg]}) + (1.7 \times \text{height [cm]}) - (4.7 \times \text{age [yr]})$$

The BMR is influenced by the disease process. Hypermetabolism occurs in surgical patients with moderate to severe infection or injury, and the magnitude of the increase in the BMR depends on the extent of injury or infection. Patients generally

fall into one of four categories according to their metabolic requirements [see *Table 1*].

Estimates that are based on normal basal metabolic requirements and adjusted only for disease state reflect the energy needs of patients requiring mechanical ventilation or those at bed rest. Further adjustments, however, are necessary for individuals who are out of bed and physically active. To meet the energy needs of such patients, who are in a nonbasal state, calculated requirements should be increased by an additional 15% to 20%. The metabolic response to stress and critical illness is complex and is mediated by interactions between the neuroendocrine system and circulating cytokines. This interaction produces a metabolic milieu in which the body cannot utilize supranormal amounts of nutritional substrates (i.e., hyperalimentation). In fact, administering excessive nutrients in an attempt at acute correction of nutrient deficits is often harmful, leading to an abnormal accumulation of hepatic glycogen, enhancing total energy expenditure, and causing increased urea production and elevation of the blood urea nitrogen (BUN).

Weight gain usually should not be a priority for ICU patients. Complications of nutrient delivery are minimized and nutrient metabolism generally optimized if only the energy necessary for weight maintenance is given. For most general surgical patients admitted to the ICU for non-trauma-related care, this amount is typically no more than 35 kcal/kg body weight/day. With resolution of the disease process, the hormonal environment is altered to favor anabolism. In addition, increases in spontaneous activity and in planned exercise stimulate rebuilding of lean body mass.

Protein

After energy requirements are determined, protein needs are calculated. For most patients, the protein requirement is 0.8 g/kg body weight/day (about 60 to 70 g/day). Critically ill patients, however, may need 1.5 to 2.0 g/kg/day (about 100 to 150 g/day). Most standard enteral and parenteral feeding mixtures provide this increased quantity of protein if enough formula is delivered to meet patients'

Table 2 Vitamin Requirements

Vitamin	Units	Recommended Dietary Allowance (RDA) for Daily Oral Intake	Daily Requirement of the Moderately Injured	Daily Requirement of the Severely Injured	Amount Provided by One Vitamin Pill	Daily Amount Provided by Standard Intravenous Preparations
Vitamin A (retinol)	IU	1,760 (females)–3,300 (males)	5,000	5,000	10,000	3,300 (retinal)

increased caloric requirements. The nitrogen-to-calorie ratio for most feeding formulas prepared for surgical patients is 1:150 (i.e., 1 g of nitrogen for every 150 kcal).

The contraindications to this increased quantity of protein are renal failure before dialysis ($\text{BUN} > 40 \text{ mg/dL}$) and hepatic encephalopathy. Patients with systemic inflammatory response syndrome (SIRS) often require increased quantities of dietary protein [see 8:13 *Multiple Organ Dysfunction Syndrome*]. Nutritional support reduces net nitrogen losses in such patients, but positive or even neutral nitrogen balance is generally not achieved because of the disturbance in metabolism and reduced intake of dietary protein.

Vitamins and Minerals

The requirements for vitamins, minerals, and trace elements are usually met when adequate volumes of balanced nutrient formulas are provided [see Tables 2 and 3]. The requirements for most of the major minerals (sodium, potassium, chloride, phosphorus, magnesium, and zinc) are satisfied by monitoring serum concentrations of these elements and adjusting intake to maintain levels within the normal range. Some minerals and electrolytes are restricted in patients with renal failure. Although serum concentrations may not directly reflect total body deficits, sufficient quantities of these nutrients are available to support normal cellular functions if adequate blood concentrations are maintained. Most premixed enteral formulas provide adequate quantities of these substances if caloric needs are met. Vitamins and trace elements must be added to parenteral solutions.

Pharmacologic recommendations for stress in surgical patients The doses of vitamins given are often not the recommended dietary allowance (RDA) but rather some multiple there-

of; for example, stressed patients usually receive three to 10 times the normal RDA.

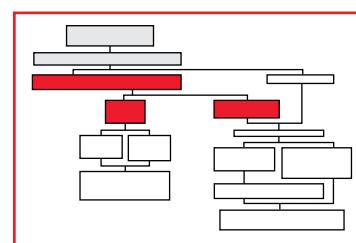

The prescription of vitamins and minerals for therapeutic use should be based on the patient's nutritional history as well as on estimated requirements for the current disease state. These considerations are particularly important for fat-soluble vitamins, which are stored in body fat and thus may become toxic at high levels. Current recommendations stipulate that therapeutic dosages of vitamins should not exceed 10 times the RDA¹; however, it has been suggested that some vitamins may be safe if given at dosages 50 to 100 times the RDA [see Table 4].² Vitamins and minerals are sometimes given in large dosages to exert antioxidant effects. Vitamins A, C, and E and the minerals zinc and selenium can attenuate the tissue-damaging effects of free radicals. One randomized, prospective trial, primarily involving trauma patients, demonstrated a significant reduction in organ failure with the administration of vitamins C (1,000 mg) and E (1,000 IU).³ Many physicians are giving these vitamins and minerals as supplements to injured and infected patients⁴; supplementation with glutamine should also be considered [see Discussion, below].

Electronic Ordering to Optimize Nutritional Support

In hospital settings, nutritional care is often standardized to optimize formula composition and delivery. A useful electronic approach to nutritional prescription is available on the Internet (<http://epen.kumc.edu>).

Enteral Nutrition

Enteral nutrition is the provision of liquid-formula diets by mouth or tube into the GI tract. It is the preferred method of feeding critically ill patients; however, it cannot be used safely in patients who are hemodynamically unstable or who have abdominal distention, intestinal obstruction, or massive GI bleeding [see Table 5]. For those who are able to receive enteral nutrition, either a balanced or a modified diet is selected on the basis of diagnosis and nutritional requirements. An isotonic (approximately 300 mOsm/kg) diet is given continuously for a trial period of 24 hours. If the patient tolerates this regimen but is at increased risk for aspiration, feeding is delivered into the jejunum rather than into the stomach. A standard protocol is helpful in reducing complications.

SAFE USE OF THE GI TRACT FOR FEEDING

Enteral nutrition should be prescribed only if safety and a low complication rate can be ensured. To determine whether enteral

Table 4 Safety Levels of Vitamins²

10 times RDA	Vitamin A Vitamin B ₆ Vitamin D Vitamin K

**Table 5 Indications for Enteral Nutrition
(Partial Listing)**

Considered Routine Care in the Following:

- Protein-calorie malnutrition with inadequate oral intake of nutrients for the previous 5–7 days
- Normal nutritional status but < 50% of required oral intake of nutrients for the previous 7–10 days
- Severe dysphagia
- Major full-thickness burns
- Low-output enterocutaneous fistulas
- Major trauma

Usually Helpful in the Following:

- Radiation therapy
- Mild chemotherapy
- Liver failure and severe renal dysfunction
- Massive small bowel resection (> 50%) in combination with administration of total parenteral nutrition

Of Limited or Undetermined Value in the Following:

- Intensive chemotherapy
- Immediate postoperative period or poststress period
- Acute enteritis
- > 90% resection of small bowel

Contraindicated in the Following:

- Complete mechanical intestinal obstruction
- Abdominal distention
- Ileus or intestinal hypomotility
- Severe diarrhea
- Severe GI bleeding
- High-output external fistulas
- Severe, acute pancreatitis
- Shock
- Case of aggressive nutritional support not desired by the patient or legal guardian and respect of such wish being in accordance with hospital policy and existing law
- Prognosis not warranting aggressive nutritional support

SELECTION OF DIET

Before delivery of enteral nutrition, the appropriate diet must be selected on the basis of the patient's nutrient requirements [*see* Indications for Nutritional Intervention, *above*]. Most liquid-formula diets consist of either a balanced or a modified formula.

Balanced diets contain carbohydrates, proteins, and fats in complex (polymeric) forms in proportions similar to those of a regular Western diet. Frequently, however, the fat content is reduced to 10% to 15% of total calories, and the carbohydrate content is increased. Carbohydrates are present as oligosaccharides, polysaccharides, or maltodextrins; fats consist of medium-chain triglycerides (MCTs) or long-chain triglycerides (LCTs). The nitrogen source is a natural protein, which may be either intact or partially hydrolyzed. In general, balanced diets are isotonic, lactose free, and available in ready-to-use, liquid form. Flavored balanced diets can be used for oral supplementation as well as for enteral tube feeding.

Selection of a balanced diet is based on nutrient and fluid requirements. The caloric density of balanced diets can be 1.0, 1.5, or 2.0 kcal/ml; the largest number of commercially available diets provide 1.0 kcal/ml. Nonprotein caloric content is derived from either carbohydrates or lipids. Balanced diets formulated with carbohydrates as the main caloric source have higher osmolarity than isocaloric diets containing lipids. These carbohydrate-based diets are well tolerated when administered directly into the stomach and may be helpful for patients with steatorrhea. Fat-based balanced diets may be more appropriate for patients with diarrhea caused by diet hyperosmolarity, especially when feedings are infused directly into the small intestine. However, fat malabsorption is common in critically ill patients when the fat content of the diet exceeds 30% of total calories.

In modified formulas (also known as elemental or chemically defined diets), the proportions and types of nutrients differ from those of a regular Western diet. Such diets may be characterized according to the conditions for which they are formulated: stress, immunomodulation, and hepatic, renal, respiratory, or GI dysfunction [*see Table 6*]. Modified diets contain crystalline amino acids or short peptides in compositions that differ from the reference composition of proteins of high biologic value (e.g., egg albumin). The fat-to-carbohydrate ratio of modified diets varies depending on the purpose of the modification. The source of carbohydrate is either dextrose or oligosaccharides; fats are usually in the form of MCTs, essential fatty acids, or both. Because they are not palatable, modified diets are rarely used as oral supplements.

Diets for patients with GI dysfunction have modified nitrogen and fat composition. Transport of dietary nitrogen across the intestinal mucosa is enhanced when nitrogen is provided in the form of short peptides rather than free amino acids. It is also well documented that small bowel mucosa utilizes glutamine as the preferred fuel [*see Discussion, below*]. Consequently, some modified diets contain nitrogen in the form of short peptides, whereas others contain extra glutamine. MCTs are more easily absorbed and metabolized than LCTs are; accordingly, diets modified for improved absorption contain a higher proportion of MCT oil. These diets may be efficacious when used during the transition phase after a period of prolonged bowel rest or when the intestine is inflamed. Controlled trials are necessary to verify their clinical efficacy. Stress formulas are indicated for hypercatabolic patients whose nitrogen balance continues to be negative despite increased intake of a balanced diet; these diets usually contain more nitrogen and frequently have an altered amino acid composition. Little evidence supports the use of diets that provide branched-chain amino acids (BCAAs) in concentrations higher than 20% to 25% of total amino acid content for stressed patients.

nutrition is feasible, a clinical assessment of intestinal function is performed. If GI output—defined as the volume of effluent from a nasogastric tube, an ostomy, or a rectal tube—is less than 600 ml/24 hr, enteral nutrition is likely to be well tolerated. Examples of conditions in critically ill patients that produce excessively high (> 600 ml/24 hr) GI outputs and therefore preclude the use of enteral nutrition are gastroparesis, intestinal obstruction, paralytic ileus, high-output enteric fistulas, antibiotic-induced colitis, severe idiopathic diarrhea, and the initial phase of short bowel syndrome. Selected patients with enteric losses exceeding 600 ml/24 hr may receive enteral nutrition, however, if carefully monitored by an experienced team.

Massive GI bleeding may also cause increased GI output. Conditions that produce bleeding of this magnitude include peptic ulcer disease, esophageal varices, diverticulosis, and angiodysplasia of the colon. Mild bleeding (e.g., that produced by stress gastritis) may actually resolve with the delivery of enteral nutrition into the stomach because the liquid diet buffers gastric acid.⁵ Enteral nutrition does not exacerbate mild lower intestinal bleeding.

Although commonly used at the bedside as indicators of intestinal function, bowel sounds and passage of flatus are nonspecific and are unrelated to the eventual tolerance of enteral nutrition.

In the absence of excessively high GI output, abdominal distention, and massive GI bleeding, a trial of enteral nutrition is warranted to determine if the GI tract can be used safely for feeding.

The fat sources used for enteral diets are primarily omega-6 fatty acids [see 8.24 Molecular and Cellular Mediators of the Inflammatory Response]. Supplementation with omega-3 fatty acids results in the synthesis of eicosanoids that enhance the immune response. Enteral diets may also include other substances believed to have immunomodulatory effects [see Discussion, below].

ASSESSMENT OF FEEDING TOLERANCE

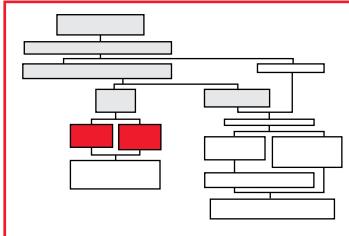

The selected formula is started at isotonicity and delivered continuously at 30 mL/hr for 24 hours. During this initial trial, the formula is delivered via a previously inserted Salem sump or rubber nasogastric (Levin) tube. If a nasogastric tube is not already in place, a soft tube made of either silicone rubber or polyurethane is inserted (see below).

Feeding tolerance is assessed for the first 24 hours. Poor tolerance is indicated by vomiting and severe abdominal cramps, a gastric residuum greater than 50% of the volume administered during the previous 4-hour feeding period, increased abdominal distention (particularly in patients who are comatose or undergoing mechanical ventilation), and worsening diarrhea. If any of these conditions is present, parenteral nutrition is recommended. If there is no evidence of feeding intolerance, the patient is assessed for the aspiration risk.

ASSESSMENT OF RISK OF ASPIRATION

Aspiration is a major complication in patients receiving enteral nutrition. The propensity to aspirate enteral feedings is often related to the patient's primary disease and neurologic status as well as to the site of GI access and the method of delivery.

Important factors in assessing risk of aspiration include depressed sensorium, increased gastroesophageal reflux, and history of previously documented episodes of aspiration. Depressed sensorium in the critical care setting is secondary to organic lesions of the central nervous system, metabolic encephalopathies, or medications. Head trauma, hypoxemia, hepatic and septic encephalopathies, and the use of H₂ receptor blockers are common causes of depressed sensorium in critically ill patients. Increased gastroesophageal reflux may be present in individuals with reduced lower esophageal sphincter (LES) pressure and increased intragastric pressure. Many medications used in the ICU, such as theo-

phylline, anticholinergics, calcium channel blocking agents, beta-adrenergic agonists, and alpha-adrenergic antagonists, cause a reduction in LES pressure. Finally, a history of aspiration places the patient at increased risk for recurrent episodes.

For most enterally fed patients, safety demands that the head be elevated at feeding time and for some period thereafter to prevent regurgitation. If this is not possible, an alternative nutrient delivery site should be considered. Nasogastric intubation, in particular, requires elevation of the head because the tube may render the upper and lower esophageal sphincters incompetent and liable to reflux. Even the presence of a tracheostomy or endotracheal tube does not ensure that regurgitated gastric contents will not be aspirated. Aspiration of liquid formulas can be verified if a bit of food coloring or methylene blue is included in the feeding mixture and subsequently detected in pharyngeal and tracheal secretions.⁶

ACCESS FOR FEEDING

In most general and thoracic surgical patients, access for feeding is most commonly obtained via the stomach or the jejunum. Methods of access for intragastric feedings include nasogastric tubes and feeding gastrostomies placed through a laparotomy or percutaneously with the aid of endoscopy, fluoroscopy, or laparoscopy.

Nasogastric tubes are the most commonly used access method for gastric feeding. Polyurethane or silicone rubber tubes are preferred because they are soft, nonreactive, and generally well tolerated; they are also less corrosive to the nasopharynx than rubber or polyvinyl chloride tubes. This very softness, however, often makes them hard to insert into critically ill patients and precludes checking of gastric residuum. Difficulties of tube passage into the stomach are increased when thin, floppy tubes are inserted into obtunded patients. Useful aids include stylets, judicious use of gravity and positioning, and designation of especially experienced and certified nursing personnel to assist in this task [see Table 7].

Passage of a tube through the pylorus into the jejunum may be necessary if the patient is at increased risk for aspiration (see above). Our practice is to place the tube into the stomach, to position the patient on the right side for several hours once or twice in the next 24 hours, and then to obtain an abdominal roentgenogram. If the tube has not passed, metoclopramide, 10 mg I.V., is given while the patient is still in the radiology department, and the roentgenogram is repeated. If the location of the feeding tube is not evident, a small amount of contrast material can be administered through the tube to verify its position. If the tube still has not passed through the pylorus, the aid of the fluoroscopist is enlisted. Finally, if all else has failed and no alternative route is appropriate, the endoscopist can capture the

Table 7 Procedure for Inserting Nasoenteric Tubes

Provide privacy.
 Explain procedure and its purpose.
 Place patient in sitting position with neck flexed slightly and head of bed elevated to 45°.
 Lubricate stylet and insert into feeding tube.
 Inspect nares and determine optimal patency by having the patient breathe through one nostril while the other is temporarily occluded.
 Estimate the length of tubing required to reach into the stomach by measuring the distance from the tip of the nose to the earlobe and then from the earlobe to the xiphoid process. Add 25 cm to this length for nasoduodenal intubation.
 If the patient seems uncooperative, instill generous amounts of lidocaine jelly into the nares and nasopharynx before tube insertion. Lubricate the end of the tube and pass it posteriorly. Ask a cooperative patient to swallow water to facilitate passage of the tube.
 Once the tube is beyond the nasopharynx, allow the patient to rest.
 Have the patient continue neck flexion and swallowing while the tube is advanced.
 If the patient begins to cough, withdraw the tube into the nasopharynx and then reattempt passage.
 Confirm passage into the stomach by obtaining an abdominal x-ray.
 Remove stylet.
 Secure tube to bridge of nose or upper lip with nonallergenic tape and prevent undue pressure on external nares.

tube tip in the stomach with the biopsy forceps of the flexible endoscope (aided by a suture through the tube end) and guide the tube through the pylorus.

When any type of nasoenteric tube is placed for enteral nutrition, its location must be confirmed before feedings are started. The simplest means of accomplishing this is to aspirate gastric contents, the source of which can be determined by measuring the pH of the aspirate. Because small-bore, soft tubes tend to collapse under high negative pressure, a small syringe should be used to aspirate gastric contents. If gastric contents cannot be aspirated, radiographic confirmation of tube location is mandatory. Because feeding tubes are often radiopaque, a simple plain film of the abdomen may be adequate. If the exact location of the tube is still in doubt, a small amount of contrast material can be injected through the tube. Placement of the distal tip of the tube in the duodenum is usually confirmed by abdominal roentgenogram before transpyloric feedings are started. The tube should be inserted to a length sufficient to permit migration into the proximal jejunum.

Simple insufflation of air into the tube is not sufficient to verify its position. Auscultation over the stomach can detect sound transmitted through a tube that has been inadvertently passed into the bronchial tree. Many of these tubes are small enough to pass through the glottis and the trachea without markedly interfering with phonation or respiration. Enteral formulas delivered into the bronchial tree through a misplaced tube can cause severe pneumonitis and death.

The development of percutaneous techniques for the placement of gastrostomies has been a major contribution to enteral nutrition. Percutaneous endoscopic gastrostomy (PEG) [see 5:18 *Gastrointestinal Endoscopy*] and Witzel techniques for these procedures are well documented.

Concurrent decompression of the stomach and feeding into the small intestine have been used to reduce the risk of aspiration in critically ill patients. This combination of procedures requires either insertion of a multilumen nasojejunal tube, surgical placement of combined gastrojejunal tubes, modification of PEG, or insertion of a nasogastric tube in conjunction with a surgical jejunostomy. Such access to the GI tract also provides a route for

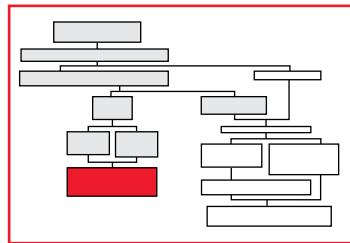

the delivery of crushed medications and the option to provide cyclic nocturnal enteral nutrition with gastric decompression (i.e., the patient receives nutrients by mouth during the day).

FEEDING REGIMENS

If the patient tolerates the initial trial of enteral nutrition, then the delivery site for future feeding is chosen according to the risk of aspiration, and the feeding regimen is gradually intensified. If the risk of aspiration is minimal, intragastric feedings are preferred: they are better tolerated physiologically, easier to administer, and less restrictive for the patient than continuous feeding into the small intestine. Patients fed into the stomach receive an isotonic formula delivered continuously at a rate of 30 ml/hr; the delivery rate is increased daily by 30 ml/hr [see Table 8]. If the risk of aspiration is increased, feedings are delivered via nasoduodenal or nasojejunal tubes. Patients fed into either the duodenum or the jejunum receive formulas of 300 mOsm/kg delivered at an initial rate of 30 ml/hr with the aid of a peristaltic pump; the rate is increased daily by 30 ml/hr [see Table 8]. Only isotonic feedings should be administered into the small bowel: hypertonic formulations have been associated with small bowel injury and necrosis.

MONITORING AND PREVENTION OF COMPLICATIONS

Patients receiving enteral nutrition require careful monitoring similar to that required by patients receiving parenteral nutrition. Particular attention is directed to metabolic status and fluid and electrolyte balance. A protocol should be established and followed to ensure that nutritional goals are met and complications minimized. A standard checklist is helpful and prevents omission of important details [see Table 9].

Four types of complications are related to enteral nutrition: GI, mechanical, metabolic, and infectious. The first two are the most common.

The most frequent GI complication is diarrhea, which may occur in as many as 75% of critically ill patients receiving enteral nutrition. Diarrhea is best defined as stool weight greater than 300 g/24 hr or volume greater than 300 ml/24 hr. Given that such measurements are impractical and difficult to obtain, a more practical definition is more than three loose bowel movements during a 24-hour period. There are many causes of diarrhea in critically ill patients receiving enteral nutrition; the most frequent association is with antibiotic therapy [see Figure 2]. The desired therapeutic approach is to adjust the enteral nutrition regimen as necessary

Table 8 Suggested Starter and Advancement Regimens for Intragastric and Intrajejunal Feeding

Feeding Regimen	Days			
	1	2	3	4
Intragastric mOsm/kg ml/hr	300 30	300 60	300 90	480 90
Intrajejunal mOsm/kg ml/hr	300 30	300 60	300 90	300 90

Table 9 Standard Orders for Enteral Nutrition

- Obtain abdominal x-ray to confirm tube location before feeding.
- Elevate head of bed 45° when feeding into the stomach.
- Record type and strength of diet and rate of infusion.
- Check gastric residuum every 4 hr in patients receiving gastric feedings. Withhold feedings for 4 hr if residuum is 50% greater than ordered volume. Notify physician if two consecutive measurements detect excessive residuum.
- Check for abdominal distention. Check frequency, consistency, and volume of stool output.
- Weigh patient on Monday, Wednesday, and Friday. Record weight on graph.
- Record intake and output daily. For every shift, chart volume of formula administered separately from water or other oral intake.
- Change administration tubing and cleanse feeding bag daily.
- Irrigate feeding tube with 20 ml of water at the completion of each intermittent feeding, when tube is disconnected, after the delivery of crushed medications, or if feeding is stopped for any reason.
- When patient is ingesting oral nutrients, ask the dietitian to provide caloric counts daily for 5 days, then weekly thereafter.
- On a weekly basis, obtain complete blood count with red blood cell indices, SMA-12, serum iron, and serum magnesium.
- Obtain SMA-6 every Monday and Thursday.
- Once a week, collect urine for 24 hours, starting at 8:00 A.M., and analyze for urea nitrogen.

rather than to discontinue it completely. Only one variable of the feeding regimen (i.e., osmolality, volume, rate, or type of diet) should be altered at a time. In our experience, critically ill patients tolerate continuous feeding better than intermittent feeding. If the patient still has diarrhea when receiving 150 to 300 mOsm/kg at 30 ml/hr, antidiarrheal treatment is indicated.

In many instances, antidiarrheal medication is given without a definite diagnosis; therefore, it is essential to select medications with both a wide therapeutic range and a low incidence of side effects. For these reasons, we prefer kaolin-pectin over opiates such as paregoric. Every 3 hours, 30 ml of kaolin-pectin solution is given through the feeding tube, followed by 25 ml of normal saline for irrigation. If this regimen is unsuccessful after 48 hours and opiates are not contraindicated, paregoric is added at a dose of 1 ml/100 ml formula [see Figure 2]. Opiates act by slowing intestinal motility. Because the normal motility pattern is a defense against bacterial growth in the small bowel, administering opiates to patients with a contaminated small bowel can lead to bacterial overgrowth and worsen diarrhea. In addition, opiates are respiratory depressants and are contraindicated in patients with infectious diarrhea.

Several diagnostic methods may help identify the cause of diarrhea associated with enteral nutrition, including the assaying of stool for *Clostridium difficile* enterotoxin, analysis of stool for fat malabsorption, the D-xylose test for carbohydrate malabsorption, and breath H₂ analysis for bacterial overgrowth. The D-xylose test and breath H₂ analysis are more commonly used in non-critically ill patients.

To prevent peptic ulcers and bleeding, gastric acidity is controlled with H₂ receptor blockers in critically ill patients. Although these drugs help control hyperacidity, which is a cause of diarrhea, they also lead to bacterial overgrowth in the intestine.⁷ Therefore, they should not be used in patients who receive intragastric feedings, because the liquid formula in the stomach already provides a physiologic means of buffering acid. If necessary, antacids rather than H₂ receptor blockers should be used to titrate gastric pH to 4.5 to 6.5. Glutamine is also used to prevent or treat ulceration of the upper GI tract.

The most common mechanical complications related to enteral nutrition are tube dislodgment, clogging of the tube, and leakage of enteric contents around the tube's exit site. Tube dislodgment occurs more frequently in agitated patients and hypoxic patients. Inadvertent tube removal can usually be prevented by adequate taping or, in agitated patients, by suturing the tube or using a Velcro abdominal wall binder.

Clogging or plugging of the tube often results from failure to use saline irrigation after intermittent feedings or inadvertent delivery of crushed medications through a small-bore tube. The incidence of this complication is reduced by routine irrigations of 20 to 25 ml of normal saline or water after each intermittent feeding. Liquid medications may also help prevent this complication, though such medications are frequently hyperosmolar and may produce discomfort

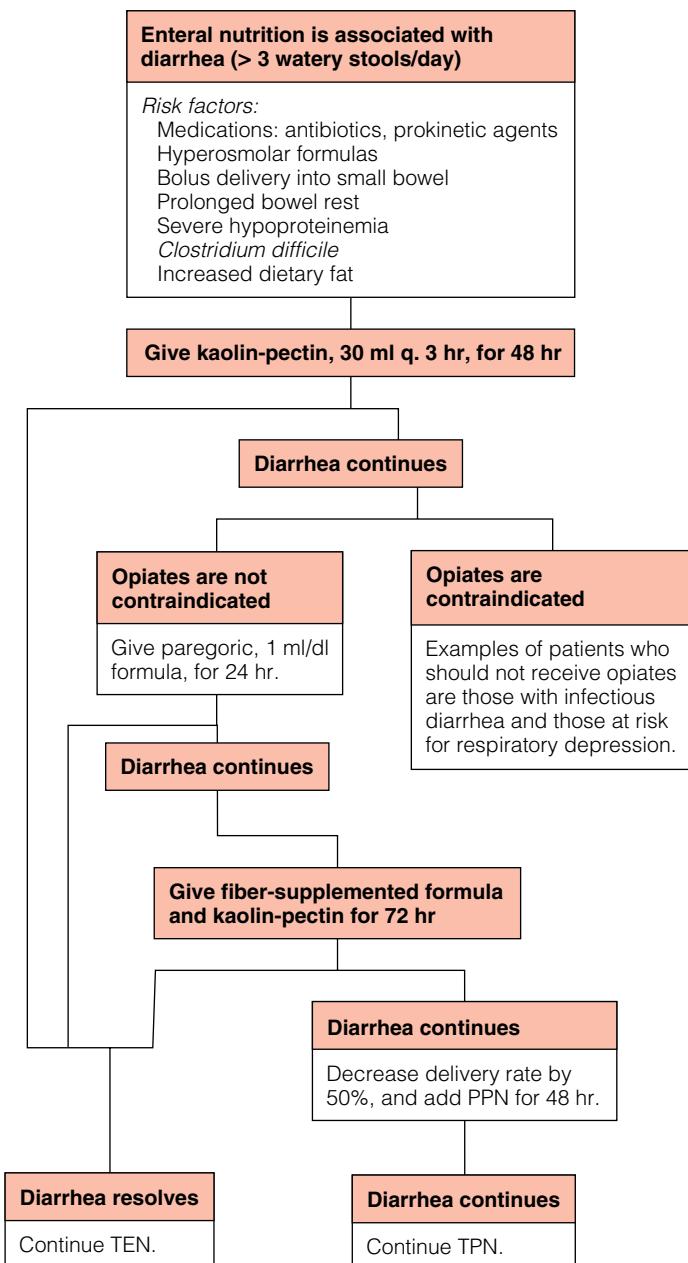

Figure 2 Shown is the decision-making approach for pharmacologic and dietary treatment of diarrhea associated with enteral nutrition.

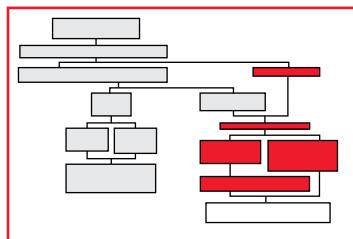

and diarrhea when delivered rapidly into the jejunum. The injection of a small volume of a carbonated beverage into a plugged tube often clears the blockage. Occasionally, a guide wire and the help of the interventional radiologist will be needed.

Leakage of enteric contents onto the skin around the exit site is often uncomfortable for the patient and may produce a moderate amount of skin irritation. One cause of such leakage is inadequate approximation of the end of the tube to the gastric wall. Leakage around a tube is prevented by proper fixation of the end of the tube with a retention disk or bumper at the skin level. The aid of an enterostomal therapist is often useful, as are products such as karaya gum, zinc oxide, Stomahesive, and locally applied antacid. Also problematic is the inappropriate use of urinary catheters for enteral access; these devices were not designed to function as gastrostomy or enterostomy tubes.

Parenteral Nutrition

CENTRAL VENOUS VERSUS PERIPHERAL VENOUS INFUSIONS

Central venous infusions [see **6:22 Vascular and Peritoneal Access**] are indicated in most critically ill patients who receive parenteral nutrition, because (1) patients in the ICU often require increased quantities of energy and cannot tolerate large fluid volumes and (2) solutions of much greater caloric density and tonicity can be infused into central veins than into peripheral veins. Nonetheless, peripheral venous infusions [see *Peripheral Venous Nutrient Infusion, below*] may be indicated in certain situations [see *Table 10*].

CENTRAL VENOUS NUTRIENT INFUSION

Hypertonic nutrient solutions are infused into the superior vena cava, where they are rapidly diluted. Usually, such solutions contain hypertonic glucose (25%), amino acids (5%), and other essential nutrients. Their tonicity ($> 1,900 \text{ mOsm/kg}$) is so great that administration into peripheral veins would cause severe thrombophlebitis and venous sclerosis. These solutions contain at least 1 kcal/ml, and thus, infusion of 2.0 to 2.5 L/day provides 2,000 to 2,500 kcal and all essential nutrients. This calorie load is sufficient to meet energy requirements in more than 90% of surgical patients.

Once positioned, the catheter is used exclusively for administering the hypertonic nutrient solution: drawing blood, monitoring central venous pressure, and administering medication through this dedicated lumen are to be avoided. If a multiple-lumen central venous catheter is used, as is the case in most patients today, at least one port should be devoted solely to the infusion of hypertonic nutrient solutions. Some reports have suggested that the incidence of catheter-related infection is higher with multiple-lumen than with single-lumen feeding catheters^{8,9}; others have not found such differences.¹⁰ It appears that multiple-lumen catheters can be used in the ICU for central venous nutrient infusions if strict protocols are maintained to ensure that one lumen is dedicated to nutrient infusion, that other lumens are handled safely, and that catheters are removed when no longer required.

Occasionally, infusion of a hypertonic nutrient solution may be required in a situation where percutaneous puncture of central veins is impossible or contraindicated. In such cases, catheterization of an antecubital vein and insertion of a peripherally inserted central catheter (PICC) with the tip positioned in the superior vena cava should be considered. These catheters are readily insert-

ed by the interventional radiologist, and they eliminate the complications associated with subclavian and internal jugular vein insertions. The PICC line has become the primary route of central venous access in many institutions.

Silastic catheters have been safely kept in place for extended periods and provide an additional option for central venous access. Catheterization of the femoral vein may provide a route for central venous access in some situations. Because of the high density of skin pathogens in the groin area, these catheters should be replaced every 2 to 3 days. If the catheter tip is positioned in the iliac vein or the inferior vena cava, the concentration of solution infused through the catheter should not exceed 15%. Strict care of the entrance site should be maintained because of the high complication rate associated with lines placed in the groin.

Central Venous Solutions

Central venous solutions are formulated in the hospital pharmacy. They are commonly combinations of 500 ml of 50% dextrose and 500 ml of a 10% amino acid mixture [see *Table 11*] to which electrolytes, vitamins, and trace elements are added (see below). Each day, 2 L of the solution can be infused. Administration of fat emulsion (500 ml, 20%) 1 day each week meets essential fatty acid requirements. Alternatively, the three major nutrients may be mixed together in a 3 L bag (triple mix or three-in-one) and the entire contents of the single bag infused over the 24-hour period [see *Table 11*]. In addition, an automated mixing device may be used to compound various proportions of 70% glucose, 10% amino acids, and 20% fat emulsions into 3 L bags. Such devices allow the hospital pharmacy to manufacture a variety of nutrient combinations with minimal effort. More concentrated solutions can be made, and the computer will generate a label for the bag that allows nurses to verify the order.

Electrolytes and minerals are added to the base formula as required [see *Table 12*]. Sodium and potassium salts are added as chloride or acetate, depending on the acid-base status of the patient. The solution should usually consist of approximately equal quantities of chloride and acetate; if chloride losses from the body are increased, as in a patient requiring nasogastric decompression, the solution should contain proportionately more chloride. Sodium bicarbonate is incompatible with the nutrient solutions; if additional base is re-

Table 10 Indications for Central Venous or Peripheral Venous Infusions

Central Venous Infusions

- To provide adequate intravenous nutritional support for 10 days or more
- To satisfy nutrient requirements in patients with increased energy needs and normal or decreased fluid requirements
- To support the patient with single- or multiple-organ failure by infusing modified nutrient solutions in a limited fluid volume

Peripheral Venous Infusions

- To provide initial feeding (< 5 days) before catheter insertion in a patient who will require central venous feedings
- To infuse less concentrated solutions via a multiuse central catheter (i.e., a line for blood drawing, medication, and nutrients) into an individual in whom other venous access cannot be easily or safely obtained
- To supplement enteral feedings that are inadequate because of gastrointestinal dysfunction
- To satisfy energy requirements that are near basal (1,500–1,800 kcal/day) in a nondepleted patient who can tolerate 2.5–3.0 L I.V. solution each day

Table 11 Composition of Central Venous Solutions

	Standard Solution	Triple-Mix Solution
Volume		
Amino acids 10% (ml)	500	1,000
Dextrose 50% (ml)	500	1,000
Fat emulsion 20% (ml)	—	250
Total (ml)	1,000	2,250
Contents		
Amino acids (g)	50	100
Dextrose (g)	250 (25%)	500
Total nitrogen (g)	8.4	16.8
Total calories (kcal)	1,050	2,600
Ratio of nitrogen to calories	1:125	1:154
Caloric density (kcal/ml)	1.0	1.15
Osmolarity (mOsm/kg)	≈1,970	≈1,900

quired, acetate, which generates bicarbonate when metabolized, is given. Phosphate is usually given as the potassium salt; if potassium phosphate is contraindicated, sodium phosphate is given. Phosphate is also present in fat emulsions.

Commercially available preparations of vitamins, minerals, and trace elements are also added to the nutrient mix for daily administration unless they are contraindicated. A solution containing both fat- and water-soluble vitamins should be added. Vitamin K₁ (phytonadione), 10 mg, is given once a week but is contraindicated in patients receiving warfarin.

Trace elements are given daily. Usual requirements are satisfied by adding commercially available mixtures either to 1 L of standard solution or to the triple-mix bag each day. Trace elements are indicated for all patients receiving central venous nutrient solutions, except those with chronic renal failure or severe liver disease. At especially high risk for zinc deficiency are alcoholics and patients with pancreatic insufficiency with malabsorption, massive small bowel resection, renal failure with dialysis, or nephrotic syn-

drome; at high risk for copper deficiency are patients with short-bowel syndrome, jejunoleal bypass, malabsorptive conditions with severe diarrhea, or nephrotic syndrome. Copper and manganese are excreted primarily via the biliary tract. Therefore, in patients with biliary tract obstruction, excess retention of these elements should be prevented by decreasing intake of these ions, monitoring blood levels, or both. Although the main excretory route for zinc and chromium is via the feces, renal excretion minimizes dangers from modest excesses of these elements. In patients with renal insufficiency, however, daily zinc and chromium administration may be contraindicated. ICU patients usually do not require iron. Iron supports bacterial growth and thus is contraindicated in patients with systemic infection. It may be required to treat iron deficiency anemia, particularly during convalescence from this condition, but rarely does the anemia associated with chronic disease and inflammation respond to iron therapy during its active stages.

Like other invasive therapies, total parenteral nutrition (TPN) is associated with potential complications deriving from either central venous access or the composition of the formula. Most such complications are preventable with appropriate attention to detail [see Table 13].

PERIPHERAL VENOUS NUTRIENT INFUSION

Slightly hypertonic nutrient solutions (approximately 600 to 900 mOsm/kg) can be prepared for peripheral venous infusion from commercially available amino acid mixtures (5%), dextrose solutions (10%), and fat emulsions (20%). These nutrient mixtures have a low caloric density (approximately 0.3 to 0.6 kcal/ml) and thus provide only 1,200 to 2,300 kcal in 2,000 to 3,500 ml of solution. Such solutions are particularly useful in patients whose tube feedings are insufficient and who need additional nutrients.

These dilute nutrient mixtures can be infused through plastic cannulas placed in large-bore peripheral veins. The catheter insertion site and the surrounding tissue should be inspected periodically for signs of phlebitis or infiltration, and the infusion site should be rotated every 48 to 72 hours to prevent thrombophlebitis. Only fat emulsion can be administered simultaneously through the same I.V. site as a peripheral venous solution. The nutrient solution should be temporarily stopped if the catheter is used for administration of antibiotics, chemotherapeutic agents, blood, or blood products. The infusion line should then be flushed with saline and nutrient infusion resumed.

If the fat emulsion is infused in a piggyback manner, administration should take place over a period of 8 to 12 hours and be concluded in the early morning hours (e.g., 3:00 A.M.) to allow clearance of the emulsion from the bloodstream. Blood sampling should be avoided during short-term fat infusion because the associated hypertriglyceridemia will interfere with many of the serum measurements. In patients who are receiving peripheral venous solutions by triple mix, hypertriglyceridemia is rare because the rate of infusion is reduced and infusion extended over a 24-hour period.

Patients receiving peripheral venous feedings should be monitored in much the same fashion as those receiving central venous feedings (see below). Mechanical and infectious complications are uncommon. Fluid imbalances and alterations in serum electrolyte concentrations are similar to those seen with standard I.V. support, and corrections are made by altering the volume of the infusion or adding or omitting electrolytes. Hyperglycemia and glycosuria are rarely observed unless the patient is diabetic.

Table 12 Electrolytes Added to Central Venous Solutions

	Usual Electrolyte Concentration	Usual Range of Electrolyte Concentration
Sodium (mEq/L)	30	0–150
Potassium (mEq/L)	30	0–80
Phosphate (mmol/L)	15	0–20
Magnesium (mEq/L)	5	0–15
Calcium* (mEq/L)	4.7	0–10
Chloride (mEq/L)	50	0–150
Acetate (mEq/L)	70	70–220

Table 13 Diagnosis, Treatment, and Prevention of Potential Mechanical and Metabolic Complications Associated with Total Parenteral Nutrition

	Complications	Diagnosis	Treatment	Prevention
Mechanical	Pneumothorax	Dyspnea, chest x-ray	Tube thoracostomy Observation	Avoid emergency procedures Trendelenburg's position
	Hemothorax	Dyspnea, chest x-ray	Remove catheter Observation	Insert catheter using appropriate technique
	Venous thrombosis	Inability to cannulate	Remove catheter Heparin therapy	Use silicone catheters Add heparin to solution
	Air embolism	Dyspnea, cyanosis, hypotension, tachycardia, precordial murmur	Trendelenburg's position Left lateral decubitus position	Trendelenburg's position Valsalva maneuver Tape intravenous connections
	Catheter embolism	Sheared catheter	Fluoroscopic retrieval	Never withdraw catheter through needle
	Arrhythmias	Catheter tip in right atrium	Withdraw catheter to superior vena cava	Estimate distance to SVC before insertion; confirm position with x-ray
	Subclavian artery injury	Pulsatile red blood	Remove needle Apply pressure Chest x-ray	Review anatomy
	Catheter tip misplacement	Chest x-ray	Redirect with a guide wire	Direct bevel of needle caudally
Metabolic	Hyperglycemic, hyperosmolar, nonketotic coma	Dehydration with osmotic diuresis, disorientation, lethargy, stupor, convulsions, coma, glucose 1,000 mg/dl, osmolarity 350 mOsm/kg	Discontinue TPN; infuse D5 in 0.45% S at 250 ml/hr Insulin 10–20 U/hr Bicarbonate Monitor glucose, potassium, pH	Monitor glucose
	Hypoglycemia	Headache, sweating, thirst, convulsions, disorientation, paresthesias	D50W I.V.	Taper TPN by $\frac{1}{2}$ for 12 hr; then 12 hr of D5W at 100 ml/hr
	CO ₂ retention	Ventilator dependence, high respiratory quotient	Taper glucose	Provide 30%–40% of calories with fat
	Azotemia	Dehydration, elevated BUN	Increase nonprotein calories	Monitor fluid balance
	Hyperammonemia	Lethargy, malaise, coma, seizures	Discontinue amino acid infusions Infuse arginine	Avoid casein or fibrin hydrolysate
	Essential fatty acid deficiency	Xerosis, hepatomegaly, impaired healing, bone changes	Fat administration	Provide 25–200 mg/kg/day of essential fatty acids
	Hypophosphatemia	Lethargy, anorexia, weakness	Supplemental phosphate	Treat causative factors: alkalosis, gram-negative sepsis, vomiting, malabsorption Provide 20 mEq/kcal
	Abnormal liver enzymes	Fatty infiltrate in liver	Evaluate for other causes	Provide balanced TPN solution
	Hypomagnesemia	Weakness, nausea, vomiting, tremors, depression, hyporeflexia	Infuse 10% MgSO ₄	Supply 0.35–0.45 mEq/kg/day
	Hypermagnesemia	Drowsiness, nausea, vomiting, coma, arrhythmia	Dialysis Infuse calcium gluconate	Monitor serum levels

PATIENT MONITORING:
OPTIMIZING NUTRITIONAL SUPPORT, PREVENTING COMPLICATIONS, AND RESOLVING COMMON PROBLEMS

General Measures

Patients receiving central venous feedings should be weighed daily, and accurate intake and output records should be maintained. Blood glucose should be monitored daily. If levels are persistently elevated, a more stringent schedule of monitoring blood glucose should be instituted and specific therapy initiated.

The quantity of energy administered to most ICU patients should minimize the loss of lean body mass and adipose tissues. Thus, variations in body weight usually reflect alterations in fluid balance. If sustained weight loss occurs (as characterized by a gradual fall in body weight over a period of 2 weeks or more), caloric intake may be inadequate. Additional calories (500 to 1,000 kcal/day) should be administered to maintain weight. Alternatively, the metabolic rate can be calculated from oxygen consumption ($\dot{V}O_2$) and calorie intake, then matched to equal energy expenditure:

$$\text{Metabolic rate (kcal/hr)} = \dot{V}O_2 (\text{ml/min}) \times 60 \text{ min/hr} \\ \times 1 \text{ L/1,000 ml} \times 4.83 \text{ kcal/L}$$

This calculation is required in only 5% of our patients.

Sample Calculation of Nitrogen Balance

A 65-year-old man with an infected aortic graft and ileus is receiving 2.2 L triple-mix solution containing 16.8 g nitrogen each day. His UUN is 500 mg/dl, and his urine output is 2,000 ml/day. Is he receiving adequate nitrogen?

$$\begin{aligned} \text{24-hour UUN} &= 500 \text{ mg/dl} \times 2,000 \text{ ml/day} \times 1 \text{ g/1,000 mg} \\ &\quad \times 1 \text{ dl/100 ml} \\ &= 10 \text{ g/day} \end{aligned}$$

$$\begin{aligned} \text{Nitrogen output} \\ &= 24\text{-hr UUN} + (0.20 \times 24\text{-hr UUN}) + 2 \text{ g/day} \\ &= 10 \text{ g/day} + (0.20 \times 10 \text{ g/day}) + 2 \text{ g/day} \\ &= 14 \text{ g/day} \end{aligned}$$

$$\begin{aligned} \text{Nitrogen balance} \\ &= 16.8 \text{ g/day (N intake)} - 14 \text{ g/day (N output)} \\ &= 2.8 \text{ g/day} \end{aligned}$$

The patient is in positive nitrogen balance, retaining approximately 2 to 3 g nitrogen/day. If positive nitrogen balance had not been achieved, his protein and caloric intake would have had to be increased and the nitrogen balance recalculated.

In non-ventilator-dependent patients, oxygen consumption and, in turn, the metabolic rate can be derived from measurements of respiratory gas exchange. In patients with a Swan-Ganz catheter in place, oxygen consumption can be calculated from cardiac output, mixed venous oxygen content ($C_{mv}O_2$), and arterial oxygen content (C_aO_2):

$$\dot{V}O_2 (\text{ml/min}) = \text{cardiac output} (\text{L/min}) \times (C_aO_2 [\text{ml/dl}] - C_{mv}O_2 [\text{ml/dl}]) \times 1 \text{ L}/10 \text{ dl}$$

Another objective of nutritional support in the ICU patient is the maintenance of lean body mass, reflected by nitrogen balance equilibration or positive nitrogen balance. Although complete nitrogen balance determination is a complex and sophisticated study, nitrogen equilibration can be estimated by simply subtracting total nitrogen loss (or output) from total nitrogen intake [see Sidebar Sample Calculation of Nitrogen Balance]. Calculation of total nitrogen loss requires several steps. The urine urea nitrogen (UUN) concentration is multiplied by the total urine output during a given day to yield the 24-hour UUN (i.e., the total amount of urea excreted during that period). Because urea accounts for only approximately 80% of the nitrogen excreted in the urine, the value for the 24-hour UUN is then increased by an additional 20%. This quantity and an additional 2 g/day are added to the value for the 24-hour UUN to account for nonurea nitrogen, stool, and integumentary losses:

$$\begin{aligned} \text{24-hour UUN (g/day)} &= \text{UUN (mg/dl)} \\ &\quad \times \text{urine output (ml/day)} \times 1 \text{ g/1,000 mg} \times 1 \text{ dl/100 ml} \end{aligned}$$

$$\begin{aligned} \text{Total nitrogen loss (g/day)} &= \text{24-hour UUN (g/day)} \\ &\quad + (0.20 \times \text{24-hour UUN [g/day]}) + 2 \text{ g/day} \end{aligned}$$

Metabolic Monitoring

A wide variety of metabolic complications may occur during parenteral feeding [see Table 14]. They are minimized by frequent monitoring [see Table 15] and appropriate adjustment of nutrients in the infusion.

The most common metabolic problems in ICU patients are hyperglycemia and glucosuria. The combination of excessive counterregulatory hormone release and overproduction of tumor necrosis factor (TNF)- α , interleukin (IL)-1, and IL-6 character-

istic of critical illness is a major cause of stress-induced hyperglycemia in nondiabetic hosts.¹¹ Hyperglycemia has been associated with infectious complications,^{12,13} worsened outcome after head injury and stroke,¹⁴ and increased proteolysis.¹⁵ Moreover, prevention of hyperglycemia by means of aggressive insulin treatment has been associated with reduced mortality in ICU patients.¹⁶ Initially, elevated blood glucose levels should be treated by administering insulin (5.0 U s.c. every 4 to 6 hours for glucose 200 to 250 mg/dl; 7.5 U for 250 to 300 mg/dl; 10.0 U for 300 to 350 mg/dl). When the nutritional solution is ordered for the next 24-hour period, half of the quantity of insulin administered subcutaneously is added to the mixture. The initial insulin dose should be least 10 U of regular insulin/L of solution, and in some cases, as much as 40 U/L may be required. If larger doses of insulin are needed (> 100 U/day), a separate insulin infusion or drip should be employed.

In most patients with severe glucose intolerance, the rate of glucose administration should not exceed 5 mg/kg/min (~ 500 g/day). Additional calories should be administered as fat emulsion. The commercially available fat emulsions are all generally well tolerated by critically ill patients. Triglyceride levels should be monitored, and the emulsion should be administered at a reduced rate or temporarily discontinued if levels exceed 500 mg/dl. Fat emulsion should be used with caution in patients with known hypertriglyceridemia or in those with gram-negative bloodstream infection that is associated with hyperlipidemia.

Infusion of excess glucose or lipid may alter pulmonary function and in some patients prevent weaning from a mechanical ventilator. Excessive carbohydrate loads (usually > 500 g/day) increase CO_2 production. If more CO_2 is produced than the lungs can excrete, hypercapnia results. Fat emulsion may also interfere with diffusion of gas across the alveolar membranes. This interference is generally related to the concentration of the emulsion in the bloodstream; hence, it can be minimized by monitoring triglyceride levels and preventing hypertriglyceridemia.

Catheter Care and Catheter Infection

The most serious problem associated with central venous feedings is catheter infection [see 8:18 *Intra-abdominal Infection*]. Primary catheter infection is defined as the signs and symptoms of infection (usually a febrile episode), with the indwelling catheter being the only anatomic infectious focus; after removal of the catheter, the symptoms usually attenuate. Cultures of the catheter tip with semiquantitative techniques yield at least 10^3 organisms,¹⁷ and the organisms are the same as those recovered in blood drawn from a peripheral vein during initial evaluation of the infection. Secondary catheter infection is associated with a primary infectious focus that causes bacteremia and thus seeds or contaminates the catheter; the infection clears after specific treatment of the primary infection. The microorganisms cultured from the catheter tip are similar to those cultured from the primary source.

Primary catheter infection is prevented or at least greatly reduced by following strict protocols governing use and manipulation of the central venous feeding catheter and by employing a systematic method of care and surveillance of the catheter entrance site. Usually, catheter care and its supervision and certification are performed by a nurse with expertise in maintenance of long-term I.V. access. Every 48 to 72 hours, the dressing covering the entrance site of the catheter is removed, the site inspected, the area around the entrance site cleaned, a topical antibiotic or antiseptic ointment applied, and the site redressed with a new sterile dressing. This procedure is documented in the clinical

Table 14 Metabolic Complications of Total Parenteral Nutrition

Problems	Possible Causes	Solutions
Glucose Hyperglycemia, glycosuria, osmotic diuresis, hyperosmolar nonketotic dehydration and coma Ketoacidosis in diabetes mellitus Postinfusion (rebound) hypoglycemia	Excessive total dose or rate of infusion of glucose; inadequate endogenous insulin; increased glucocorticoids; sepsis Inadequate endogenous insulin response; inadequate exogenous insulin therapy Persistence of endogenous insulin production secondary to prolonged stimulation of islet cells by high-carbohydrate infusion	Reduce amount of glucose infused; increase insulin; administer a portion of calories as fat emulsion Give insulin; reduce glucose input Administer 5%–10% glucose before infusate is discontinued
Fat Pyrogenic reaction Altered coagulation Hypertriglyceridemia Impaired liver function Cyanosis Essential fatty acid deficiency	Fat emulsion, other solutions Hyperlipidemia Rapid infusion, decreased clearance May be caused by fat emulsion or by an underlying disease process Altered pulmonary diffusion capacity Inadequate essential fatty acid administration	Exclude other causes of fever Restudy after fat has cleared bloodstream Decrease rate of infusion; allow clearance before blood tests Exclude other causes of hepatic dysfunction Discontinue fat infusion Administer essential fatty acids in the form of one 500 ml bottle of fat emulsion every 2–3 days
Amino Acids Hyperchloremic metabolic acidosis Serum amino acid imbalance Hyperammonemia Prerenal azotemia	Excessive chloride and monohydrochloride content of crystalline amino acid solutions Unphysiologic amino acid profile of the nutrient solution; differential amino acid utilization with various disorders Excessive ammonia in protein hydrolysate solutions; deficiency of arginine, ornithine, aspartic acid, or glutamic acid, or a combination of these deficiencies in amino acid solutions; primary hepatic disorder Excessive amino acid infusion with inadequate calorie administration; inadequate free water intake, dehydration	Administer Na ⁺ and K ⁺ as acetate salts Use experimental solutions if indicated Reduce amino acid intake Reduce amino acid intake; increase glucose calories; increase intake of free water
Calcium and Phosphorus Hypophosphatemia Hypocalcemia Hypercalcemia Vitamin D deficiency; hypervitaminosis D	Inadequate phosphorus administration; redistribution of serum phosphorus into cells or bones, or both Inadequate calcium administration; reciprocal response to phosphorus repletion without simultaneous calcium infusion; hypoalbuminemia Excessive calcium administration with or without high doses of albumin; excessive vitamin D administration Inadequate or excessive vitamin D	Administer phosphorus (\geq 20 mEq potassium dihydrogen phosphate/1,000 I.V. calories); evaluate antacid or calcium administration, or both Administer calcium Decrease calcium or vitamin D Alter vitamin D administration
Miscellaneous Hypokalemia Hyperkalemia Hypomagnesemia Hypermagnesemia Anemia Bleeding Hypervitaminosis A Elevations in AST (formerly SGOT), ALT (formerly SGPT), and serum alkaline phosphatase	Potassium intake inadequate relative to increased requirements for protein anabolism; diuresis Excessive potassium administration, especially in metabolic acidosis; renal failure Inadequate magnesium administration relative to increased requirements for protein anabolism and glucose metabolism; diuresis; cisplatin administration Excessive magnesium administration; renal failure Iron deficiency; folic acid deficiency; vitamin B ₁₂ deficiency; copper deficiency; other deficiencies Vitamin K deficiency Excessive vitamin A administration Enzyme induction secondary to amino acid imbalance or to excessive deposition of glycogen or fat, or both, in the liver	Alter nutrient administration Alter nutrient administration Alter nutrient administration Alter nutrient administration Alter nutrient administration Alter nutrient administration Alter nutrient administration Alter nutrient administration Alter nutrient administration Reevaluate status of patient

record; if drainage or crusting appears at the entrance site, appropriate cultures are taken. In addition, the dressing is changed if it becomes wet or soiled or no longer remains intact. In patients who have either draining wounds in close proximity to the catheter entrance site or tracheostomies, the entire dressing may be covered with a transparent barrier drape to minimize contamination.

If signs and symptoms of infection develop in a recipient of central venous parenteral nutrition, a history should be taken and a physical examination performed [see *Figure 3*]. Appropriate tests (e.g., complete blood count and urinalysis) and diagnostic studies (including roentgenogram) should also be performed. If blood cultures are

needed, samples should be drawn from a peripheral vein. If trained nurses have maintained the catheter and there is no evidence of infection at the exit site, the dressing should not be removed, and the catheter should not be manipulated. Blood cultures should never be taken through the catheter—except, possibly, when the initial presentation of infection is characterized by marked hyperpyrexia or hypotension, in which case, contamination of the catheter is immaterial because the catheter will be removed. If no other infectious focus is identified, the physician may elect to remove all indwelling lines, including the feeding catheter. In addition, either drainage around the catheter or a previous positive culture from the catheter exit site may

Table 15 Variables to Be Monitored during Intravenous Alimentation and Suggested Frequency of Monitoring

Variables	Suggested Monitoring Frequency

also indicate immediate removal. If another primary source of infection is diagnosed, specific therapy should be instituted and parenteral nutrition continued. If no source of infection is identified, the catheter should be removed and the catheter tip cultured [see 8:18 *Intra-abdominal Infection*].

A dilemma arises if another source of infection is identified and if signs and symptoms of infection persist despite what appears to be appropriate therapy. If blood cultures are positive, we favor removal of the catheter to avoid the complications associated with a contaminated indwelling catheter. If, however, peripheral blood cultures are negative, the catheter can be changed over a guide wire and the catheter tip cultured; central venous feeding can be continued during this interval. If the cultured catheter tip is positive ($\geq 10^5$ organisms), the catheter should be removed.

Changing the central venous catheter over a guide wire can aid in the diagnosis of primary catheter infection.¹⁸ Because most ICU patients have multiple potential sources for infection, this technique allows culture of the catheter tip but minimizes the risks associated with reinsertion of a new central catheter. With strict care of catheters, the incidence of catheter infection should be less than 6%.¹⁹ Catheter-related bloodstream infection (CRBSI) is most commonly caused by growth and invasion of organisms along the catheter tract. Occasionally, bacteria are infused through the catheter because of a breach in sterility during care of the infusion

apparatus. The most common bacterial organisms causing catheter sepsis are *Staphylococcus epidermidis*, *S. aureus*, *Klebsiella pneumoniae*, and *Candida albicans*. In some rare cases, the I.V. solutions may be contaminated. Moreover, most patients requiring central venous alimentation are immunocompromised hosts; their resistance is lowered further by disease, severe malnutrition, or treatment or by some combination of these factors. Coexisting conditions such as urinary tract infection, abscess, pneumonia, or mucositis secondary to chemotherapy predispose to bacteremia, which may contaminate the central venous catheter.

Immunosuppressed critically ill patients receiving multiple broad-spectrum antibiotics are also at risk for *Candida* CRBSI. Blood cultures positive for *C. albicans* in an ICU patient are an indication for catheter removal and treatment with fluconazole. An ophthalmologist should examine the eyegrounds of patients with proven candidemia to exclude the possibility of metastatic *Candida* ophthalmitis [see 8:19 *Fungal Infection*].

Home Nutritional Support

HOME PARENTERAL NUTRITION

Home parenteral nutrition is indicated for patients who are unable to eat and absorb enough nutrients for maintenance. Most of the adult surgical patients who require home parenteral nutrition suffer from short-bowel syndrome caused by (1) extensive Crohn disease, (2) mesenteric infarction, or (3) severe abdominal trauma. Pseudo-obstruction, radiation enteritis, carcinomatosis, necrotizing enterocolitis, and intestinal fistulas are other indications for home parenteral nutrition. Patients with these conditions cannot receive adequate nutrition enterally, though sometimes compensatory mucosal growth occurs that may reduce or eventually eliminate the need for continued home parenteral nutrition.

Patients must receive extensive evaluation, teaching, and training during hospitalization if home parenteral nutrition is to prove successful. These services should be provided by a team consisting of a physician, a nurse, a dietitian, a pharmacist, and a social worker. The team's instructions should cover the basic principles of parenteral nutrition as well as provide mechanical guidelines for catheter care, asepsis, and use of infusion pumps. Patients should be objectively evaluated before discharge to ensure that they adequately understand the principles of I.V. nutrition and can carry out home parenteral nutrition properly.

Once a patient is judged to be a suitable candidate for home TPN, a Silastic catheter is placed that is designed for more permanent use than the central venous catheter employed during hospitalization. Typically, the catheter is 90 cm long, with a thin 55 cm intravascular segment that is inserted either by venous cutdown into the internal or external jugular vein or the cephalic vein or by venipuncture directly into the subclavian vein. Its intravascular portion is cut so that the tip will lie at the junction of the superior vena cava and the right atrium.

Catheter placement is done in the OR with the patient under local anesthesia (1% lidocaine) and adequate sedation. The catheter is tunneled subcutaneously from a small incision lateral to the sternum to the site of venous insertion. The exit site is chosen on the basis of the patient's sex, physique, and hand dominance. In women, lower paraxiphoid or upper abdominal exit sites permit a more natural appearance. If coagulation status is abnormal, the cephalic vein is isolated in the deltopectoral groove and tied distally, and the catheter is inserted proximally by means of venotomy; otherwise, it is inserted into the subclavian vein percutaneously. Proper position-

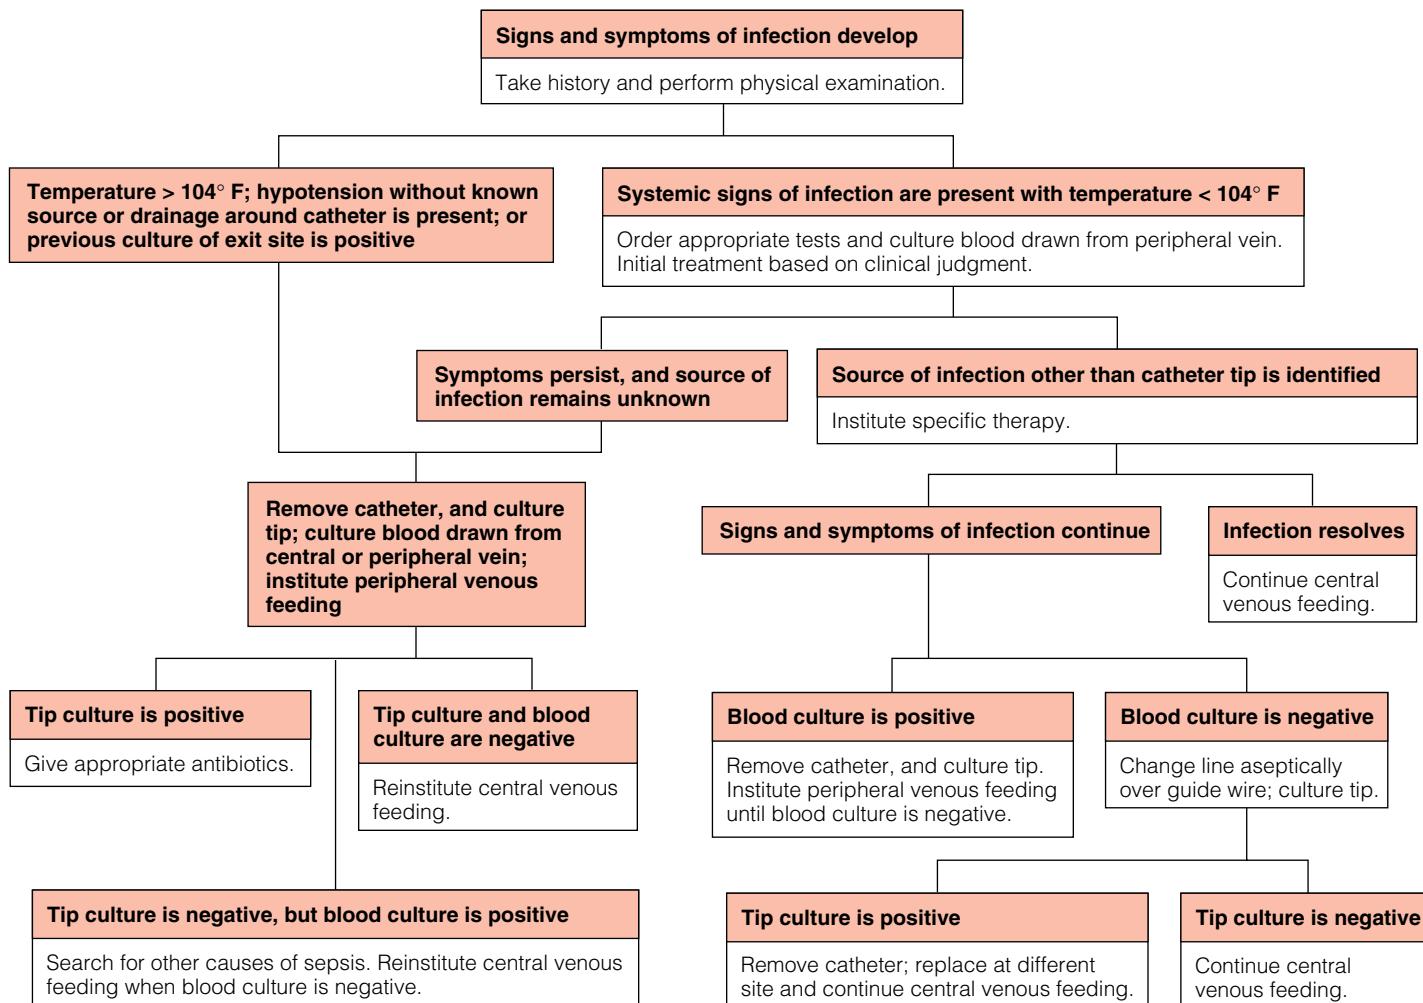

Figure 3 Shown is an algorithm for evaluating a febrile patient receiving central venous parenteral nutrition.

ing of the catheter is confirmed by fluoroscopy, and the incisions are closed with absorbable sutures. The catheter is sutured to the exit site, and the sutures are left attached for at least 2 weeks while tissue ingrowth into the cuff takes place. After the sutures are placed, sterile dressings are applied.

Calorie, protein, and fluid needs are carefully estimated for each patient, and the administration schedule is arranged so that the total volume may be infused nocturnally over 10 to 12 hours. Electrolytes, micronutrients, and trace minerals are added as indicated. Fat emulsions may be given either separately or admixed with glucose and protein and are used to reduce the requirement for dextrose calories and to prevent essential fatty acid deficiency.

The complications of home TPN are much the same as those of in-hospital TPN and may be divided into four categories: mechanical, infectious, metabolic, and psychosocial. Mechanical complications, which are generally easy to remedy, include catheter occlusion and dislodgment and damage to the external portion of the catheter. Infectious complications superficial to the cuff usually respond well to antibiotics. Catheter infections may necessitate removal of the device after the diagnosis is confirmed by blood cultures, but the usual therapeutic approach is to initiate a trial of parenteral antibiotics. Metabolic complications related to individual nutrient deficiencies may be corrected by adding the appropriate substance to the solution. The role of serum levels of trace minerals

and micronutrients in delineating nutrient deficiency states is unclear. In patients receiving insulin, hyperinsulinemia after infusion may be prevented by reducing the rate of administration gradually over the last hour of infusion. Psychosocial complications may vary from slight depression to suicidal tendencies, which must be treated with appropriate counseling.

The costs of a home TPN program may also be divided into four categories: patient training, equipment, supplies, and follow-up. It has been estimated that the average annual cost of home TPN is 70% less than that of in-hospital TPN. The growth of private companies that deliver equipment and supplies to the home, maintain inventory, bill patients, and help with health insurance reimbursement has considerably facilitated home care.

HOME ENTERAL NUTRITION

Home enteral nutrition is frequently used as either the sole source or a partial source of nutritional support. It is the preferred method when GI tract function is adequate. In patients undergoing surgery of the aerodigestive tract for cancer, jejunostomy feedings can supplement oral feedings, especially during adjuvant chemotherapy and radiation treatment. Patients are taught to cycle feedings over 12-hour periods, using an enteral pump system to provide 20 to 30 kcal/kg/day. Use of an appropriate feeding tube and immediate flushing of the tube after use reduce the incidence of clogging at home. If blockage occurs,

proteases or carbonated beverages can be introduced into the tube in an attempt to open it. Jejunostomy feedings reduce the risk of aspiration and help maintain nutritional status during periods of inadequate oral intake. Use of inexpensive nutritionally complete commercial formulas is encouraged. For patients

with more permanent disabilities that prevent adequate oral intake, a gastrostomy (or PEG [see 5:18 *Gastrointestinal Endoscopy*]) may be preferable; this reduces the GI complications of feeding by making use of the reservoir and admixing functions of the stomach.

Discussion

Evidence-Based Nutritional Support

EARLY ORAL FEEDINGS AFTER ELECTIVE OPERATIONS

Anesthetics, prolonged bed rest, and fluid shifts make the intestine susceptible to ileus after most operations, particularly abdominal ones. In the past, patients commonly underwent gastric decompression with a nasogastric tube until they showed obvious signs of bowel function. Over the past 10 years, however, several authors have questioned the necessity of postoperative nasogastric decompression.^{20,21} Others have suggested not only that nasogastric decompression is unnecessary but also that perhaps patients should be fed earlier than is usually done.²²⁻²⁴

The traditional approach to postoperative feeding has been to start with a clear liquid or full liquid diet, continue this until the appearance of consistent flatus or bowel movements, and then switch to a regular diet. There is, however, no evidence that such a stepwise progression is necessary or leads to better outcomes. In fact, a 2002 study found no significant differences in time to diet tolerance, complications, or hospital stay between this approach and one in which postoperative feeding started with a regular diet.²⁵

Use of opioids can have significant deleterious effects on nutrition. Opioid-induced constipation can lead to lower abdominal discomfort, fecal impaction, diarrhea, nausea, and inadequate absorption of oral drugs. The ensuing bowel dysfunction is a consequence both of CNS-mediated alteration of autonomic flow to the gut²⁶ and of a direct local opioid effect on the bowel.²⁷ Opioid receptor antagonists (e.g., naloxone and naltrexone) can reverse these changes, but at the cost of some reduction in analgesia. Newer agents (e.g., methylnaltrexone) are poorly lipid soluble and unable to penetrate the CNS and thus do not antagonize the central effects of opioids.²⁸ A 1996 study suggested, however, that I.V. methylnaltrexone could prevent opioid-induced delay in bowel motility without affecting analgesia.²⁹ Such drugs may be particularly useful as adjuncts, minimizing the side effects of opioids when these agents must be given.

Finally, early feeding has been combined with other therapies to enhance recovery [see CP:6 *Fast Track Surgery*]. Patients who undergo epidural anesthesia, receive early oral feedings, and take part in an active exercise program experience much shorter convalescent recovery periods and require less hospitalization.³⁰

DATA ON NUTRITIONAL SUPPORT IN SPECIFIC SETTINGS

Preoperative TPN

A number of studies have been conducted to evaluate the effect of preoperative TPN; most have involved patients with GI cancer who were considered at least moderately malnourished. A pooled analysis of the data showed that in patients who received preoperative TPN, the complication rate dropped from approximately 40% to 30%; in five studies, the differences reached statistical sig-

nificance.³¹ The pooled analysis found no significant difference in mortality between the TPN groups and the control groups.

Intraoperative TPN

Although not yet tested in clinical trials, intraoperative TPN should be avoided. The stress associated with surgery and anesthesia results in hyperglycemia even without the infusion of dextrose. When infused during surgery the dextrose in the TPN solution can increase blood glucose levels severalfold, and these extreme increases have been associated with impaired immune function. Furthermore, it appears that hypotension or cardiac arrest during concentrated dextrose infusion can result in more irreversible damage to the CNS.

Postoperative TPN

TPN in the immediate postoperative period without preoperative TPN has been evaluated in multiple trials—again, mostly involving GI cancer patients who were considered at least moderately malnourished.³¹ In contrast to the pooled analysis of the preoperative data, a pooled analysis of the postoperative data showed that in patients who received TPN after operation, the complication rate rose from approximately 30% to 40%.

Perioperative Enteral Nutrition

Two studies compared preoperative enteral nutrition with an ad libitum oral diet,^{32,33} and in one,³² postoperative complications were significantly lower in patients who received enteral tube feeding. Other studies compared early postoperative jejunal tube feeding with a standard oral diet that was advanced as tolerated and found no consistent differences in postoperative morbidity or mortality.³⁴⁻³⁷ Yet another evaluated the use of postoperative jejunostomy tube feeding with a special formula enriched with arginine, ribonucleic acids, and omega-3 fatty acids after operation for upper GI tract cancer.³⁸ When only successfully fed patients were evaluated, those who received the enriched formula had fewer complications and a shorter hospital stay than those who received the standard formula.

Nutrition in Cancer Patients

Trials addressing perioperative nutritional support have been conducted in patients undergoing surgery for pancreatic, hepatocellular, and upper GI malignancies. In one, patients undergoing major pancreatic resection were randomly assigned either to a group that received TPN on postoperative day 1 or to a non-TPN group.³⁹ Patients in the TPN group derived no demonstrable benefit and experienced more complications (primarily infectious). It was concluded that routine postoperative TPN could not be recommended for patients undergoing major pancreatic resection for malignancy.

Another trial examined the effects of cyclic versus continuous enteral nutrition on postoperative gastric function after pylorus-preserving pancreaticoduodenectomy.⁴⁰ Patients were evaluated with

respect to gastric emptying, resumption of normal diet, and length of hospital stay. Cyclic nutrition was associated with shorter periods of nasogastric intubation, earlier resumption of normal diet, and reduced hospital stay. It was concluded that cyclic enteral nutrition was clinically efficacious in this selected group of patients.

Nutritional support has been shown to reduce the catabolic response, improve protein synthesis, and enhance liver regeneration. In a 1994 study, 124 patients undergoing hepatectomy for hepatocellular carcinoma were randomly assigned either to a control group or to a group receiving perioperative I.V. nutritional support in addition to their oral diet.⁴¹ The overall postoperative morbidity rate was reduced in the perioperative nutrition group (34% versus 55%), mainly because the rate of infection-related complications was lower (17% versus 37%). These benefits were mainly seen in patients with underlying cirrhosis who underwent major hepatectomy. It was concluded that perioperative nutritional support can reduce complications after major hepatectomy in such patients.

Early Postoperative Enteral Nutrition

In a nonrandomized, uncontrolled study of 38 patients who underwent colorectal surgery over a 3-month period,⁴² the 31 patients who were able to tolerate an early feeding regimen had shorter postoperative stays (5.7 versus 10.6 days); the seven who were not had longer operative procedures and lost more blood intraoperatively (possibly as a result of a more difficult operation, which itself might lead to prolonged recovery and decreased tolerance of early enteral feeding). The investigators concluded (1) that early postoperative feeding is safe and is tolerated by the majority of patients and (2) that if early feeding is tolerated, it shortens hospital stay and may decrease health care costs.

In another study, 28 patients undergoing esophagectomy or pancreaticoduodenectomy received either immediate postoperative enteral feeding via jejunostomy or no feedings during the first 6 days after operation.⁴³ Postoperative vital capacity and forced expiratory volume in 1 second (FEV₁) were consistently lower in the fed group than in the unfed group, but there were no significant differences in grip strength and maximal inspiratory pressure between the two groups. Patients in the fed group were less mobile after operation and tended to recover less rapidly; however, there were no significant differences in fatigue or vigor between the two groups. The investigators concluded that immediate postoperative jejunal feeding is associated with impaired respiratory mechanics and postoperative mobility and does not influence the loss of muscle strength or the increase in fatigue occurring after major surgery; they further concluded that immediate postoperative enteral feeding should not be routine in well-nourished patients who are at low risk for nutrition-related complications.

Another trial evaluated early enteral feeding after resection of upper GI malignancies with the aim of determining whether early postoperative enteral feeding with an immune-enhancing formula supplemented with arginine, RNA, and omega-3 fatty acids could decrease morbidity, mortality, and length of hospital stay.⁴⁴ A total of 195 patients with upper GI cancer were randomly selected to receive either the immune-enhancing formula via jejunostomy or standard I.V. crystalloid solutions. There were no significant differences between the two groups with respect to number of minor, major, or infectious wound complications; length of hospital stay; or mortality.

In yet another trial, 43 patients with nontraumatic intestinal perforation and peritonitis were randomly assigned after laparotomy either to a control group or to a study group that received a feeding jejunostomy, with enteral feeding started 12 hours after operation.⁴⁵ Mortality was high in both the control group and the study group

(18% versus 19%).⁴⁵ The control group had more infectious complications (22 versus 8).

Nutrition in ICU Patients

A meta-analysis of 26 relevant randomized clinical trials involving 2,211 patients cared for in ICUs demonstrated that parenteral nutrition did not reduce morbidity or mortality, though the data did suggest that the most malnourished groups of patients might derive some benefit.⁴⁶ Therefore, use of this expensive therapy in the ICU should be carefully limited to patients who have specific nutritional needs and cannot accept enteral feedings.

Conclusions

Parenteral and enteral nutritional support is a valuable adjunctive—and sometimes lifesaving—therapy in selected surgical patients. It is generally agreed that patients who cannot ingest adequate nutrients for a prolonged period require nutritional therapy. It is not entirely clear, however, precisely how “adequate” and “prolonged” should be defined. In practice, definitions are likely to vary from patient to patient, depending on the amount of body energy stores and lean body mass, the presence or absence of pre-existing medical illnesses, the number and severity of postoperative complications, and the nature of the surgical procedure.

Summation of data from numerous trials suggests that giving nutritional support for 7 days before operation decreases postoperative complications. Severely malnourished patients (defined on the basis of percentage of body weight lost or nutritional risk index score) may derive greater clinical benefit from preoperative nutritional support, but support for this view comes largely from retrospective analysis of prospective data. In addition, certain subsets of patients may derive particular benefit from nutritional support (e.g., patients undergoing hepatic resection for hepatocellular carcinoma and elderly patients with hip fractures). The increased complication rates in patients receiving postoperative TPN and the case reports of small bowel necrosis in patients receiving early postoperative enteral nutrition are evidence that nutritional support has risks and should not be given indiscriminately.

Nutritional Pharmacology and Immunonutrition

The role of nutrient administration to surgical patients has evolved from maintenance of a positive energy and nitrogen balance to modulation of tissue metabolism and organ system function. This new role is referred to as nutrition pharmacotherapy. Like other forms of adjuvant therapy, nutrition pharmacotherapy is usually a multitargeted therapeutic modality. For instance, one form of nutrition pharmacotherapy, immunonutrition, makes use of combinations of specific amino acids, fatty acids, and, in some enteral formulas, nucleotides. Another form, so-called bowel rehabilitation, uses an amino acid (glutamine) in combination with growth hormone and a modified diet. Inclusion of a specific nutrient as part of a plan of nutrition pharmacotherapy is based either on clinical studies or, more often, on extrapolations from experimental observations. In what follows, we discuss each of the nutrients used, or proposed for use, in nutrition pharmacotherapy, with emphasis on chemical characteristics, physiologic effects, available forms for exogenous administration, and, if available, clinical data supporting its use for this purpose.

GLUTAMINE

Glutamine is the most abundant amino acid in the body and appears to be the most versatile. Most free glutamine is synthesized and stored in skeletal muscle.⁴⁷ Skeletal muscle releases net glutamine for

transport to the gut, immune cells, and the kidneys. The cells of the gut and the immune system proliferate rapidly, and glutamine acts as their main fuel source and as a biosynthetic precursor. One of the compounds derived from glutamine is glutathione, a tripeptide with potent antioxidant effects. Finally, glutamine participates in acid-base regulation via release of ammonia, which combines with H⁺ to form NH₄⁺ and is lost in urine.

Catabolism induced by major injury, surgery, sepsis, or burns results in increased release of glutamine from skeletal muscle.⁴⁸ This output of glutamine into the circulation is associated with increased uptake and consumption by the gut, the immune system, the liver, and the kidneys. The net effect is a profound fall in intracellular muscle stores of glutamine. This deficit exceeds all other amino acid deficits and persists even when stores of all other amino acids have already been replenished.⁴⁹

Standard amino acid formulations have always included all of the essential amino acids and most of the nonessential ones. For a long time, glutamine was excluded from parenteral formulations because of its instability in aqueous solutions. However, the pharmaceutical industry has now begun to develop ways of keeping glutamine stable in an aqueous solution. For instance, Glamin (Pharmacia & Upjohn, Sweden), an amino acid formulation that is commercially available in Europe, includes the dipeptide glycyl-L-glutamine, which is readily hydrolyzed to free glutamine in plasma and tissues. These dipeptide formulations are not yet approved for use in the United States.

Several clinical studies of supplementation of parenteral formulas with glutamine have been published. Striking results have been reported in patients undergoing bone marrow transplantation. A randomized, double-blind, controlled study from 1992 investigated the effects of glutamine on metabolic parameters and clinical outcome in 45 adult patients undergoing bone marrow transplantation for hematologic malignancies.⁵⁰ Patients were randomly selected to receive either a formula supplemented with L-glutamine or a standard glutamine-free isonitrogenous formula for an average of 4 weeks after operation. The patients who received the glutamine-supplemented formula had a better nitrogen balance than the control group; more important, they also had a lower incidence of microbial colonization and clinical infection and a shorter hospital stay. These findings were subsequently confirmed by a study performed by a different group of investigators.⁵¹

Equally striking results have been reported in patients with the short-bowel syndrome that develops after massive small bowel resection. Although the advent of parenteral nutrition has improved survival for many patients with this syndrome, it has also created a dependency on such therapy, which in the long term can have life-threatening complications. For this reason, many surgical scientists have searched for ways of augmenting these patients' intestinal absorption capacity so as to reduce or eliminate the need for parenteral nutrition. A growing understanding of the roles of glutamine, dietary fiber, short-chain fatty acids, and growth factors in the process of intestinal adaptation led to clinical trials aimed at evaluating the effects of supplementation of these substances on patients with this syndrome.

In a randomized, double-blind, prospective multicenter trial, 41 patients with short-bowel syndrome were given an optimal diet and then randomly selected to receive oral glutamine, 30 g/day, plus placebo growth hormone; placebo glutamine plus growth hormone (GH), 0.1 mg/kg/day; or the two active agents together.⁵² Patients were weaned from TPN according to standard criteria. At the end of 4 weeks, all subjects had decreased I.V. nutrient requirements, with the glutamine-GH group showing a greater reduction than the GH group, which in turn showed a greater reduction than the glutamine-placebo group.

The studies just cited were all conducted according to research protocols that used L-glutamine, which is not practical for I.V. administration, rather than the dipeptide form now commercially available (in Europe), which is stable in an aqueous solution. A meta-analysis of all the appropriate studies involving I.V. glutamine showed a significant reduction in postoperative infection associated with a decreased length of stay.⁵³ Reduced long-term (6 month) mortality was noted in critically ill patients—a finding that has not been recently associated with the administration of other specific nutrients.

ARGININE

Arginine is a nitrogen-dense amino acid that is considered semiessential because it is required for growth.⁵⁴ Its effect on growth seems to be mediated by its role in polyamine and nucleic acid synthesis. In addition, it is a potent secretagogue of growth hormone, insulin, glucagon, prolactin, and somatostatin⁵⁵⁻⁵⁷; when this effect is abolished by hypophysectomy, the stimulatory effect on wound healing is lost.⁵⁸ Supplemental dietary arginine has thymotropic effects and enhances the responsiveness of thymic lymphocytes to mitogens in rats.⁵⁹ A similar response occurs in peripheral blood mononuclear cells of healthy human volunteers⁶⁰ and postoperative patients,⁶¹ as evidenced by an enhanced response to concanavalin A and phytohemagglutinin.

Arginine enhances cellular immunity, as demonstrated by an increased delayed hypersensitivity response in animals with burns.⁶² Dietary supplementation with arginine improves the response to dinitrofluorobenzene (DNFB) and enhances the survival of guinea pigs with 30% body surface burns. However, in a model of acute peritonitis in guinea pigs, supplemental arginine did not improve DNFB response or survival.⁶³

Studies of arginine in humans have not been conclusive, because this substance is often administered with other active substances (e.g., RNA and omega-3 fatty acids). However, oral arginine supplementation has enhanced markers of wound healing in human volunteers,⁶⁴ and both enteral and parenteral arginine administration have improved immunologic measures.⁶⁵ Although arginine has antitumor properties in animals, the only relevant study done to date in humans found that arginine supplementation stimulated growth of breast cancer.⁶⁶ Because there is now controversy over increased mortality in critically ill patients receiving arginine [see Enteral Formulations to Counteract Immunosuppression, below], careful patient selection and full informed consent are necessary with this agent.

NUCLEOTIDES

Purines and pyrimidines are precursors of DNA and RNA, which are essential for cell proliferation. Purines and pyrimidines are synthesized by the liver de novo from amino acids and reutilized by salvage pathways. Reduction of dietary nucleotides results in suppression of cellular immune responses and prolongation of allograft survival.⁶⁷ The mechanism of this immunosuppression seems to be an inability of T cells to undergo blastogenesis. Dietary supplements containing RNA or uracil (but not adenine) maintain resistance to infection by *C. albicans* or *S. aureus* in rodents.^{68,69} However, they do not enhance the immune response in comparison with a standard control diet.

On the basis of the immunosuppressive effect of dietary nucleotide restriction, it has been postulated that nucleotide supplementation could provide an immunostimulant effect. This postulate has been tested in studies of the RNA–fish oil–arginine formula now available [see Enteral Formulations to Counteract Immunosuppression, below].

FATTY ACIDS

Fatty acids in the systemic circulation can be used in two forms: as fuels to be stored and oxidized as needed by the organism and as precursors for other essential compounds, such as eicosanoids (prostaglandins, leukotrienes, and thromboxanes) [see 8:24 *Molecular and Cellular Mediators of the Inflammatory Response*]. Fatty acids may be classified in several different ways. One classification is based on chain length: short (two to five carbons), medium (six to 11 carbons), and long (12 to 26 carbons). Another classification is based on the presence of double bonds in the carbon chain: those with double bonds are called unsaturated and are further subclassified as either monounsaturated fatty acids or polyunsaturated fatty acids (PUFAs), depending on the number of double bonds. Another classification is the omega classification, which indicates where the first double bond is located when carbons are counted from the noncarboxyl end of the chain (e.g., omega-3, omega-6).

Humans can synthesize only fatty acids with double bonds at position 7 (counting from the noncarboxyl end toward the carboxyl end). Therefore, omega-6 or omega-3 fatty acids must be supplied exogenously. Because linoleic acid and α -linolenic acid can be elongated and desaturated to produce the remaining omega-6 and omega-3 PUFAs, these are considered the essential fatty acids. Requirements for omega-6 PUFAs exceed those for omega-3 PUFAs by a ratio of approximately 5:1. Omega-6 PUFAs are abundant in vegetable oils, whereas omega-3 PUFAs are abundant in fish oils and seed oils.

The availability of 20-carbon PUFAs—arachidonic acid in the omega-6 series and eicosapentaenoic acid in the omega-3 series—is the determining factor for the synthesis of eicosanoids [see 8:24 *Molecular and Cellular Mediators of the Inflammatory Response*]. Cells obtain arachidonic acid and eicosapentaenoic acid from degradation of phospholipids by phospholipase A₂ and phospholipase C or by elongation and desaturation of linoleic acid and α -linolenic acid. Because mature immune cells (e.g., monocytes, macrophages, lymphocytes, and polymorphonuclear cells) lack an enzyme needed for transformation of 18-carbon PUFAs into 20-carbon PUFAs,⁷⁰ availability of precursors for eicosanoid synthesis in such cells is largely dependent on their lipid composition. The lipid composition of immune cells, in turn, is influenced by lipid intake, and thus, the type of PUFAs ingested can affect the immune response.^{71,72}

Eicosanoids, especially prostaglandin E₂ (PGE₂), leukotriene B₄ (LTB₄), 5-hydroxyeicosatetraenoic acid (5-HETE), and 15-hydroxy-eicosatetraenoic acid (15-HETE), are immunomodulatory; when produced in excess (as in posttraumatic states), they are generally immunosuppressive.⁷³ Dietary supplementation with omega-3 PUFAs has improved survival of endotoxic shock in guinea pigs.⁷⁴ Reduced intake of omega-6 PUFAs seems to be as important as increased intake of omega-3 PUFAs. When animals are made deficient in linoleic acid, mortality after endotoxin challenge is only 24%; however, when arachidonic acid is given 2 days before endotoxin challenge, mortality reaches 100%.⁷⁵ Similar results were reported in guinea pigs recovering from flame burns covering 30% of body surface area.⁷⁶ Compared with animals fed dietary safflower oil (74% linoleic acid) or linoleic acid alone, animals fed fish oil had less weight loss, better skeletal muscle mass, lower resting metabolic expenditure, better cell-mediated immune responses, better opsonic indices, higher splenic weight, lower adrenal weight, higher serum transferrin levels, and lower serum C3 levels.

The fat emulsions currently available for I.V. use in the United States are made with LCTs derived either from soybean oil alone or from soybean oil and safflower oil. All of the fatty acids in LCTs are in the form of PUFAs. Intravenously administered LCT emulsions are cleared in part through the reticuloendothelial system (RES).⁷⁷ When such emulsions are used as a calorie source, they

may impair the ability of the RES to clear bacteria if given too rapidly or in excessively large amounts. Moreover, the PUFAs in LCT emulsions require carnitine-mediated transport to cross the mitochondrial membrane for oxidation. During sepsis, urinary excretion of free carnitine rises significantly, and the plasma acylcarnitine level falls.⁷⁸ One way of circumventing these problems is to use emulsions that contain MCTs.

MCT-containing emulsions possess an absorptive advantage over LCT-containing emulsions: whereas LCTs are absorbed via lacteals and the lymphatic system, MCTs are absorbed via the portal system. MCTs are obtained from coconut oil and contain saturated fatty acids (with octanoic acids predominating). Because MCTs are smaller than LCTs, they are more water soluble; they are also poorly bound to albumin and diffuse more easily across body compartments. Several reports on the use of I.V. administered MCT fat emulsions have been published. One study evaluated the effect of a 75% MCT/25% LCT emulsion on RES function as demonstrated by ^{99m}Tc-sulfur colloid (Tc-SC) clearance. Tc-SC clearance was significantly higher after 3 days of MCT/LCT administration than after 3 days of LCT administration.⁷⁹ Another study investigated the metabolic effects of MCT-containing emulsions on surgical patients.⁸⁰ Its main finding was the appearance of β -hydroxybutyrate in association with MCT infusion, which was indicative of a ketogenic effect. A tendency toward improved nitrogen balance was also observed but was not statistically significant.

In summary, specific fatty acids have significant potential for use in nutrition pharmacotherapy. Omega-6 fatty acids are potential immunosuppressants, whereas omega-3 fatty acids are potential immunostimulants. A reduction in the intake of omega-6 PUFAs appears prudent in patients who are immunocompromised or in post-traumatic states. Formulas for nutritional support should include omega-3 PUFAs, though the exact amount of omega-3 PUFAs and the precise ratio of omega-6 to omega-3 remain to be determined.

In the United States, the only emulsions commercially available for I.V. use at present are made of LCTs containing omega-6 PUFAs. MCTs offer some metabolic advantages over LCTs and obviate the side effects resulting from an excess of omega-6 PUFAs. Enteral diets containing omega-3 PUFAs appear to benefit stressed surgical patients, particularly those who are immunosuppressed as a result of therapy for cancer.

ENTERAL FORMULATIONS TO COUNTERACT IMMUNOSUPPRESSION

Impact (Sandoz Nutrition, Minneapolis, MN), a commercially available enteral formula enriched with omega-3 PUFAs, arginine, and RNA, was shown to reduce infectious complications in postoperative patients^{81,82} and in some critically ill patients.⁸³ It was also shown to reduce hospital stay in selected patient groups.⁸⁴ However, concern was raised by the publication of data from a large meta-analysis of studies using this formula, which suggested that its use led to increased mortality.⁸⁵ The investigators suggested that the immunomodulation associated with this diet might be beneficial in some patients (generally the less seriously ill) but harmful in others (generally the more critically ill patients who require nutritional support).⁸⁶ Until this issue is resolved, patient selection is extremely important if this diet is to be administered to surgical patients.

Nutritional Support Guidelines

In 2002, the American Society for Parenteral and Enteral Nutrition (ASPEN) published an updated version of guidelines for use of nutritional support.⁸⁷ These guidelines are also available on the Internet (<http://www.nutritioncare.org/publications/2002guidelines.pdf>).

24 MOLECULAR AND CELLULAR MEDIATORS OF THE INFLAMMATORY RESPONSE

Vivienne M. Gough, M.B., CH.B., Constantinos Kyriakides, M.D., and Herbert B. Hechtman, M.D.

The Inflammatory Response

The inflammatory response to injury is complex, involving not only the area of injury but also systemic tissues. The four cardinal signs of acute inflammation—calor (heat), rubor (redness), dolor (pain), and tumor (swelling)—were first described by Celsus in the first century A.D. Subsequent descriptions added a fifth sign, functio laesa (loss of function). Although the descriptive features of acute inflammation have long been known, there is still no single satisfactory definition of this phenomenon. It is commonly considered to be the reaction of living tissues to all forms of injury and involves vascular, neurogenic, humoral, and cellular responses.

The vascular events associated with inflammation typically involve changes in blood flow and alterations in permeability. In 1924, Lewis first described the so-called triple response, in which drawing a blunt instrument across the skin induced a flush, a flare, and a wheal. Thus, directly after injury, local arteriolar dilatation, preceded by a fleeting interval of vasoconstriction, is the dominant vascular response. Precapillary sphincters dilate, leading to increased flow in already active capillaries as well as to the opening of inactive capillary beds. At the same time, postcapillary venules dilate to cope with the increased flow of blood. The rise in hydrostatic pressure is followed by fluid exudation through the vascular bed, leading to edema (wheal). As the edema increases, the wheal turns pale as a result of the increased interstitial pressure compressing the capillaries. The changes observed in the skin after mechanical trauma are typical of those seen in other organs after various injuries.

In what follows, we focus on humoral and cellular responses to injury, making use of several types of clinically important events (e.g., ischemia-reperfusion and sepsis) to illustrate important inflammatory pathways.

Neutrophil

That leukocytes are involved in inflammation was first demonstrated in 1887 by Metchnikoff, who found that rose thorns inserted into the body of starfish resulted in the local accumulation of leukocytes within hours.¹ Metchnikoff also documented the existence of different types of leukocytes and the ability of these cells to kill and digest bacteria, and he was the first to suggest that products released by white blood cells could damage vessel walls. In 1960, Marchesi and Florey, using electron microscopy to follow the movement of neutrophils across blood vessel walls in rat mesentery, found that neutrophils penetrated vascular endothelium at or near cell junctions and that after their diapedesis, no sign of a passageway could be seen.² Furthermore, they demonstrated that the site at which such diapedesis occurred was the postcapillary venule.

MECHANISM OF NEUTROPHIL-MEDIATED INJURY

Once it was established that neutrophils were invariably present during an acute inflammatory reaction, efforts were launched to explore their role in mediating this response. In the 1960s and 1970s it became clear that during inflammation, neutrophils actively secreted products that were injurious^{3,4}; these products included reactive oxygen metabolites (ROMs) as well as proteases such as elastase and collagenase. The importance of the neutrophil in mediating inflammation was further underscored by the finding that the increased permeability resulting from an injection of the eicosanoid leukotriene B₄ (LTB₄), the complement fragment C5a, or the formylated bacterial peptide formyl-methionyl-leucyl-phenylalanine (fMLP) into the skin was prevented by previous neutrophil depletion. That neutrophil depletion did not affect the release of serotonin, histamine, and bradykinin from mast cells in response to these stimuli suggested that these mast cell-derived agents did not play a major role in mediating permeability.⁵

In the early 1980s, it was shown that neutrophils stimulated with phorbol myristate acetate damaged endothelial cells via a mechanism that could be interrupted by catalase, a hydrogen peroxide scavenger.⁶ Subsequent investigations demonstrated that neutrophil-mediated endothelial damage was also caused by elastase.⁷ The mechanism of injury required further clarification, given that normal plasma was known to contain potent protease inhibitors and superoxide dismutase (SOD), which inactivate circulating proteases and ROMs, respectively. Furthermore, a better understanding of how neutrophils were selectively activated was needed, given that indiscriminate release of proteases and ROMs would clearly be both inefficient and dangerous.

The mechanism by which the neutrophil is currently thought to produce its injurious effects on target cells involves the formation of a protected environment in which there is close contact between cells. This concept, though not proved, has some evidence to support it. Neutrophils lyse substrate protein only when in close contact.⁸ Phorbol myristate acetate-induced lung injury occurs only when neutrophils are in direct contact with the endothelium.⁹ When neutrophils are stimulated with fMLP,⁷ C5a, or endotoxin,¹⁰ they must adhere to the endothelium to cause vascular injury, which is governed by molecules expressed on the surfaces of both cell types.

The normal immune action of the neutrophil is to phagocytose its target cell. This process results in the creation within the neutrophil of a protected microenvironment known as a phagosome, which contains the targets for destruction [see Figure 1]. When the phagosome has been established, the neutrophil releases large quantities of ROMs and proteases into it. Any plasma protease inhibitors gaining access to this restricted space are themselves inhibited by the neutrophil secretory products hydrogen peroxide

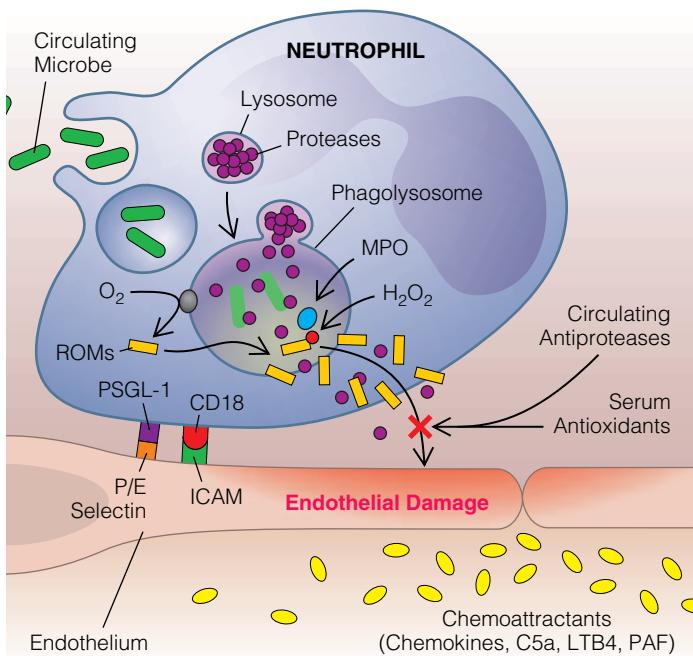

Figure 1 Proteases and ROMs are stored in intracellular lysosomes. These fuse with microbe-containing phagosomes, forming phagolysosomes that initiate destruction of the microbes. Anti-proteases that gain entry to this area, such as serum α_1 -antitrypsin, are inhibited by hydrogen peroxide and myeloperoxidase secreted by neutrophils. The same neutrophil products that cause microbial destruction may also damage surrounding endothelial tissue. Tissue damage is somewhat reduced by natural protective mechanisms, such as ROM scavenging by SOD, catalase, and α_1 -antitrypsin.

and myeloperoxidase, either of which is capable of neutralizing α_1 -antitrypsin, the major protease inhibitor.^{11,12} Furthermore, myeloperoxidase activates other neutrophil proteases, such as collagenase and gelatinase.⁴ Thus, ROMs and proteases act in synergy to digest phagocytosed matter.

In cases of strong neutrophil activation, the cells may release their toxic products in concentrations that overwhelm the body's regulatory defenses, causing substantial damage to surrounding tissues through excess vascular permeability and parenchymal injury.

ROLE IN REPERFUSION INJURY

The importance of neutrophils in the generation of reperfusion injury was first demonstrated in the context of myocardial ischemia.¹³ Histologically, the injury was characterized by an extensive early accumulation of extravasated neutrophils, thus resembling an acute inflammatory process. Depletion of neutrophils by means of an antiserum led to a significant reduction in the size of myocardial infarction after temporary occlusion of the left circumflex coronary artery.¹³ Restoration of blood flow to ischemic skeletal muscle was also associated with significant leukocyte infiltration,¹⁴ whereas leukocyte depletion attenuated the associated increase in microvascular permeability and vascular resistance.¹⁵

Besides enhancing permeability, neutrophils were shown to cause skeletal myocyte injury after ischemia, as evidenced by membrane dysfunction. Such dysfunction was indicated by depolarization of resting skeletal muscle that persisted after restoration of blood flow despite repletion of intracellular high-

energy phosphates; in contrast, such depolarization was limited during hindlimb reperfusion in neutropenic animals.¹⁶

Neutrophils have also been implicated as mediators of the remote lung injury observed to occur as a consequence of skeletal muscle ischemia. Investigators documented leukosequestration and increased lung permeability during reperfusion after hindlimb tourniquet ischemia.¹⁷ Neutropenia, however, was protective in this setting, maintaining normal microvascular permeability and lung histology.

Adhesion Molecules

To patrol the body effectively for infectious organisms and to repair injuries in disparate regions of the body, neutrophils must be able both to circulate as nonadherent particles in blood and lymph and to adhere to and migrate through specific tissue sites where they are needed. Evidence from the past 20 years indicates that inflammatory sites emit signals that activate the adjacent endothelium and circulating phagocytes. Inflammatory events also trigger release of circulating mediators such as cytokines, which produce more generalized activation of endothelial cells and leukocytes, thereby rendering one or both cell types more adhesive.¹⁸ Circulating phagocytes then adhere to endothelium; in response to a chemical chemoattractant gradient across the microvessel, they undergo diapedesis between the junctions of endothelial cells, migrate through the subendothelial matrix, and participate in the parenchymal inflammatory reaction. This phagocyte adherence, though essential to the immune response and the repair of injury, may induce pathologic consequences.

For the first few hours of the inflammatory response, the neutrophil is the predominant leukocyte at inflammatory sites.¹⁹ After 12 to 24 hours, mononuclear phagocytes predominate.²⁰ When injury is extensive and the inflammatory response robust, this second phase may be accompanied by immunomodulation and increased susceptibility to infection.

The importance of leukocyte adhesion to the endothelium in maintaining host defenses against infection is illustrated by the example of patients with a congenital deficiency of CD11/CD18, a family of adhesion-promoting leukocyte surface proteins.²¹ This condition, known as leukocyte adhesion deficiency I (LAD I), results in a profound defect in phagocyte accumulation because the leukocytes, though stimulated, cannot adhere and migrate to extravascular sites.⁷ Patients with LAD I have little or no pus at bacterial infection sites and suffer recurrent life-threatening bacterial infections.²¹ On the other hand, unmoderated leukocyte adhesion to the endothelium can also have pathologic consequences, such as lung failure (i.e., the acute respiratory distress syndrome [ARDS]) or organ transplant rejection.^{22,23} Thus, a better understanding of the mechanism of adhesion may lead to better therapy for a number of disease states. Such therapy will have to balance the benefit of reducing tissue damage caused by leukocyte adhesion against the possible increased risk of infection.

Adhesion molecules on endothelial cells and neutrophils may be classified into three groups: selectins, integrins, and immunoglobulins [see Table 1].

SELECTINS

The selectins are expressed only on cells within the vasculature or the lymphatic system. To date, three selectins have been identified: L-selectin, P-selectin, and E-selectin, or endothelial leukocyte adhesion molecule-1 (ELAM-1). These molecules are also collectively referred to as lectin cell adhesion molecules

Table 1 Adhesion Molecules Involved in Adherence of Leukocytes to Endothelium

Family	Members
Selectins	L-selectin (LAM-1, Mel-14, Leu-8, LECCAM-1) E-selectin (ELAM-1) P-selectin (CD62, GMP-140, PADGEM)
Integrins	LFA-1 (CD11a/CD18) Mac-1 (CD11b/CD18, Mo-1, CR3) gp 150,95 (CD11c/CD18)
Immunoglobulins	ICAM-1 ICAM-2 VCAM-1

(LEC-CAMs). In general, the selectins are responsible for the earliest interaction of circulating cells, setting the stage for integrin-mediated firm adherence. All three help regulate the initial leukocyte rolling on activated endothelium. Without selectins, leukocytes interact poorly with endothelium. Leukocyte adhesion deficiency II (LAD II), a genetic deficiency of glucosyltransferase, prevents formation of sialyl Lewis^x (sLe^x), the key selectin counterreceptor, thereby increasing the risk of infection.

L-selectin, the smallest member of the selectin family, is present on the surface of neutrophils, monocytes, and lymphocytes and binds both constitutive and inducible carbohydrate ligands on the endothelial cell surface. The migration of neutrophils into certain inflammatory sites is significantly attenuated by L-selectin blockade²⁴; however, other molecules play a greater role in neutrophil adhesion than L-selectin does. Where L-selectin plays a dominant role in cell trafficking is in the lymphocyte: L-selectin-deficient knockout mice have small, poorly formed lymph nodes and defective T cell function.²⁵

P-selectin, the largest member of the family, plays a key part in leukocyte rolling.^{26,27} It is constitutively associated with the α -granules of platelets²⁸ and the cytoplasmic Weibel-Palade bodies of endothelial cells²⁹ and is rapidly translocated to the endothelial cell surface after stimulation by histamine or thrombin.²⁹ Expression of P-selectin may also be induced by exposure of the vascular endothelium to free radicals (particularly superoxide),³⁰ C5a, the complement membrane attack complex (C5b-C9),³¹ and tumor necrosis factor- α (TNF- α).³² The extracellular N-terminal domain of the molecule binds to its carbohydrate ligand, sLe^x. An additional P-selectin mechanism of neutrophil-endothelial interaction involves platelets. By adhering to endothelial surfaces, platelets provide a rich surface of exposed P-selectin to which neutrophils can bind. Platelet-endothelial binding may occur via fibrinogen attachment to endothelial intercellular adhesion molecule-1 (ICAM-1) and to platelet GPIIb/IIIa. Platelet endothelial cell adhesion molecule-1 (PECAM-1) can also mediate attachment.

E-selectin, the third member of the selectin family, is a glycoprotein found exclusively on the surface of endothelial cells. Although not expressed on resting endothelium, E-selectin is markedly upregulated in response to the cytokines interleukin-1 (IL-1) and TNF- α as well as to lipopolysaccharide (LPS). E-selectin plays an important role in slightly later leukocyte adhesion to the microvascular endothelium.³³

For all three selectins, P-selectin glycoprotein ligand-1 (PSGL-1), which is rich in sLe^x moieties, is the principal counterreceptor; it is located on the surface of circulating leukocytes and participates in the earliest inflammatory responses.

INTEGRINS

The integrin family comprises a vast number of adhesion molecules that mediate intercellular recognition and cellular binding to the extracellular matrix. These molecules are heterodimeric transmembrane receptors composed of α and β subunits. The β_2 subfamily, collectively known as the leukocyte integrins or leukocyte cell adhesion molecules (LeuCAMs), is expressed exclusively by leukocytes. This subfamily comprises three related heterodimers, each made up of a common β subunit (CD18) complexed with a unique α subunit (CD11a, CD11b, or CD11c).

CD11a/CD18, also known as lymphocyte function-associated antigen-1 (LFA-1), is expressed on all leukocytes and mediates the attachment of unstimulated neutrophils to the vascular endothelium through a specific interaction with ICAM-1 and ICAM-2. CD11b/CD18, previously referred to as complement receptor type 3 (CR3) because of its ability to bind the complement fragment iC3b but now more generally known as Mac-1, is constitutively expressed on the surface of neutrophils, monocytes, and macrophages. It binds to endothelial ICAM-1 at a site distinct from the LFA-1 binding domain.³⁴ In addition to the Mac-1 expressed on the cell surface, an intracellular pool of pre-formed Mac-1 is stored within specific granules in neutrophils. Translocation of Mac-1 from intracellular pools to the neutrophil surface via granule fusion with the plasma membrane is stimulated by chemotaxins, including C5a, LTB₄, IL-8, and platelet-activating factor (PAF).³⁵ Unlike the adhesive interactions between LFA-1 and ICAM-1, which can be demonstrated in both stimulated and unstimulated cells, Mac-1-mediated adherence to endothelial ICAM-1 requires chemotactic activation.³⁶ CD11c/CD18, also referred to as gp150,95, has been identified on the surfaces of neutrophils and monocytes and is believed to play its primary role in monocyte adhesion.

IMMUNOGLOBULINS

Leukocyte integrins bind to endothelial surface receptors belonging to the immunoglobulin supergene family. Members of this superfamily, which includes major histocompatibility complex (MHC) antigens I and II, T cell receptors, ICAM-1, and ICAM-2, share an immunoglobulin domain composed of 90 to 100 amino acids arranged in two sheets of antiparallel β strands stabilized at the center with a disulfide bond. Although constitutively expressed, copies of ICAM-1 are increased after stimulation by TNF- α , IL-1, LPS, lymphotoxin, or interferon gamma (IFN- γ). IL-1-induced upregulation can be observed 30 minutes after incubation, after which time it increases steadily, reaching a peak after 24 hours.³⁷ ICAM-1 is the counterreceptor for CD11a and CD11b.

STUDIES USING ANTIBODIES TO ADHESION MOLECULES

The development of monoclonal antibodies (mAbs) that bind to the functional epitopes of adhesion molecules has yielded useful data on adhesion mechanisms. In addition, a number of studies have aroused clinical interest.

In two trials, survival was significantly increased in rabbits and baboons treated with a CD18 mAb after hemorrhagic shock.^{38,39} In a canine model of myocardial ischemia-reperfusion, treatment with a CD11b mAb led to reduced infarct size and neutrophil sequestration.⁴⁰ In a murine model of liver cell injury induced by LPS and galactosamine, a CD11b mAb reduced liver cell injury by more than 90% (as determined by assessment of alanine aminotransferase levels) but reduced neutrophil sequestration by only 40%.⁴¹ In this setting, it is likely that neutrophils were bound to a large extent by CD11a, which may explain the dis-

crepancy between the degree of protection afforded by the antibody and the reduction in neutrophil sequestration. The beneficial effects of CD11b antibodies may well be related more to the inhibition of neutrophil signaling and function than to sequestration per se.

In another study, treatment with a mAb to ICAM-1 led to a reduction in phorbol myristate acetate-stimulated neutrophil accumulation in rabbit lungs.⁴² This mAb also reduced lymphocyte sequestration and acute graft rejection after renal transplantation in primates.²³ Attempts to modify acute allograft rejection in humans have met with little success. It must be kept in mind, however, that our understanding of the effects of antibodies to adhesion molecules on the immune system is still in its infancy. This rapidly developing field promises to offer powerful tools that may well prove applicable to the control of inflammatory and immunologic reactions.

Cytokines

The term cytokine refers to a diverse group of polypeptides and glycoproteins that are important mediators of inflammation. They are produced by numerous cell types but primarily by leukocytes. Cytokines are potent intercellular messengers that exert most of their actions on immune and inflammatory cells. Taken separately, they have a wide range of effects; considered as a group, their principal functions are to coordinate the immune response to foreign antigens by acting as growth factors and cellular activators and also to moderate this response via various feedback mechanisms.

Cytokines are not stored intracellularly: upon antigenic stimulus of the cell, they are synthesized rapidly by novel mRNA transcription, then quickly released. For example, LPS from bacterial cell walls causes macrophage activation and induces TNF release. The mRNA encoded during this process tends to be unstable, which ensures that cytokine synthesis after cell activation will be brief and self-limiting. Cytokines exert their effects through very high-affinity binding to various receptors on target cells. Thus, as a rule, very small amounts of cytokines suffice to produce their biologic effects. External signals increase the number of receptors on a cell, thereby enhancing the cellular response to a particular cytokine. For example, antigenic stimulation of lymphocytes leads to increased cytokine receptor expression. The cytokine itself can also stimulate cytokine receptor upregulation via a positive feedback mechanism.

Cytokines usually act on cells locally in an autocrine and paracrine fashion, thereby ensuring that the inflammatory response is evoked at the site of infection or injury. When they are produced in very large quantities, they can enter the circulation and exert significant systemic effects. On one hand, a single cytokine may act on more than one cell type, causing a number of different consequences (pleiotropism); on the other, several different cytokines may produce the same functional effects (redundancy). This relative nonspecificity of action limits the clinical usefulness of exogenously administered cytokines: the likelihood is high that such agents will either have unwanted side effects or be functionally useless as a result of compensation by other cytokines.⁴³ Another common feature of cytokines is that they often act in a cascade, with one cytokine leading to the production of another. They may also act synergistically or may antagonize the actions of other cytokines.

Discussion of cytokines is complicated by the often confusing nomenclature. Several of the earliest identified cytokines were

Table 2 General Classification of Cytokines by Primary Activity

Proinflammatory Cytokines	Anti-inflammatory Cytokines
TNF	IL-10
IL-1	IL-4
Chemokines	IL-13
Interferons	TGF- β
IL-2	
CSFs	
IL-6	

discovered in a variety of different settings and consequently bear several different names associated with specific functions. For example, TNF, initially named for its ability to cause tumor necrosis, is also known as cachectin because of its association with cachexia. Current cytokine nomenclature follows a more consistent naming system, in which the term interleukin (IL), referring to a substance that acts between leukocytes, is used in conjunction with a number (e.g., IL-10); however, many of the cytokines are still commonly referred to by their historical (and frequently misleading) names.

The cytokines we address in the following discussion do not constitute an exhaustive list. Such a list would be beyond the scope of this chapter; furthermore, given the rate at which new cytokines are being found and classified, it would be out of date before it was published. Accordingly, we focus on the better-known and more thoroughly studied cytokines.

To facilitate understanding of cytokine function, it may be helpful to classify them on the basis of their primary actions. Various classification systems have been proposed; however, none have proved entirely satisfactory, because these agents, being pleiotropic by nature, often have conflicting actions. In our view, the most useful approach is to categorize the cytokines according to whether they exert primarily proinflammatory or primarily anti-inflammatory effects [see Table 2]. Admittedly, the boundary between the two categories is frequently blurred.

PROINFLAMMATORY CYTOKINES

The general distinction between proinflammatory and anti-inflammatory cytokines is based on the observation that certain cytokines—principally TNF, IL-1, and IL-8—promote the inflammatory response by upregulating expression of genes encoding phospholipase A₂, cyclooxygenase-2 (COX-2), or inducible nitric oxide (NO) synthase, thereby increasing production of the corresponding proinflammatory mediators (PAF, eicosanoids, and NO, respectively). In addition, proinflammatory cytokines mediate neutrophil action, acting as chemoattractants, upregulating expression of leukocyte-endothelial adhesion molecules, causing cell migration into the tissues, and activating neutrophil degranulation—all of which lead to tissue damage.

Tumor Necrosis Factor and Interleukin-1

Although TNF and IL-1 are structurally dissimilar, their functions overlap considerably, and they are known to act synergistically. Originally discovered as a substance causing ischemic necrosis of tumors in rabbits treated with endotoxin, TNF is produced principally by monocytes and macrophages but also by various other immune and endothelial cells. The most potent stimulus for its production is LPS (endotoxin) from gram-nega-

Table 3 Systemic Actions of TNF

Fever
Acute-phase protein synthesis
Cachexia
Myocardial depression
Disseminated intravascular coagulation (DIC)
Hypoglycemia

tive bacteria, but other stressors (e.g., infection, trauma, ischemia, and toxins) can also induce its release.

In small concentrations, TNF acts in an autocrine and paracrine fashion, causing increased expression of endothelial E-selectin and leukocyte integrins and promoting leukocyte adhesion to the endothelium. TNF causes neutrophils to be attracted first, followed by monocytes and lymphocytes, thereby helping to regulate the inflammatory response. It also stimulates endothelial cells to produce a cytokine subset known as the chemokines (e.g., IL-8), which promote leukocyte migration into the tissues, and induces mononuclear phagocytes to produce IL-1. Finally, TNF can cause apoptosis in some cell types, an event that is of unknown physiologic significance.⁴³

In large concentrations, TNF mediates a number of physiologic effects that are well-recognized components of infection. It acts on the hypothalamus via prostaglandin synthesis to cause fever [see Table 3]. It also induces hepatocyte production of some of the acute-phase proteins, the best known of which are C-reactive protein, fibrinogen, serum amyloid A, and α_1 -antitrypsin. Prolonged TNF production also leads to cachexia, probably by reducing appetite. Massive doses of TNF produce the classic symptoms of septic shock. Hypotension results from reduced vascular smooth muscle tone and myocardial depression; disseminated intravascular coagulation (DIC) results from endothelial expression of tissue factor and inhibition of throm-

bomodulin; and profound hypoglycemia results from tissue overutilization of glucose and impaired liver function.⁴³

Like TNF, IL-1 is produced primarily by macrophages and to a lesser extent by other leukocytes and endothelial cells. IL-1 is a primary responder in the inflammatory cascade, and its actions are very similar to those of TNF. It mediates local inflammatory responses at low concentrations and exerts adverse systemic effects at higher concentrations. Unlike TNF, it cannot induce apoptosis. IL-1 also minimizes the perception of posttraumatic pain by causing the release of β -endorphins from the pituitary gland and increasing the number of central opioid receptors. TNF and IL-1 act synergistically to produce the acute innate immune response to invading microorganisms, manifested by neutrophil activation and release of other cytokines that promote further immune activity.

Chemokines

The chemokines are a group of cytokines that regulate migration of leukocytes from blood to other tissues. Chemokines bind to heparan sulfate proteoglycans on endothelium, thus presenting themselves to white blood cells that have become loosely attached to endothelial cells via the action of selectins and that roll along the endothelium. When a white cell interacts with a chemokine, its shape changes rapidly, becoming flatter and more motile. At the same time, surface integrins are exposed, allowing firmer attachment to the endothelium. Chemokines also induce rhythmic contraction of cellular actin filaments, causing cellular migration from the blood vessel at an interendothelial cell junction across a chemokine concentration gradient to the region of tissue injury [see Figure 2].

For the purposes of this discussion, chemokines may be classified into two main subsets, CC and CXC, depending on whether their two terminal cysteine residues are adjacent (CC) or separated (CXC). The CXC group, which includes IL-8 (probably the best known of the chemokines), acts mainly on neutrophils, whereas the CC chemokines act on monocytes, eosinophils, and lymphocytes. Both subsets are produced by leukocytes, endothelial cells, and fibroblasts in response to

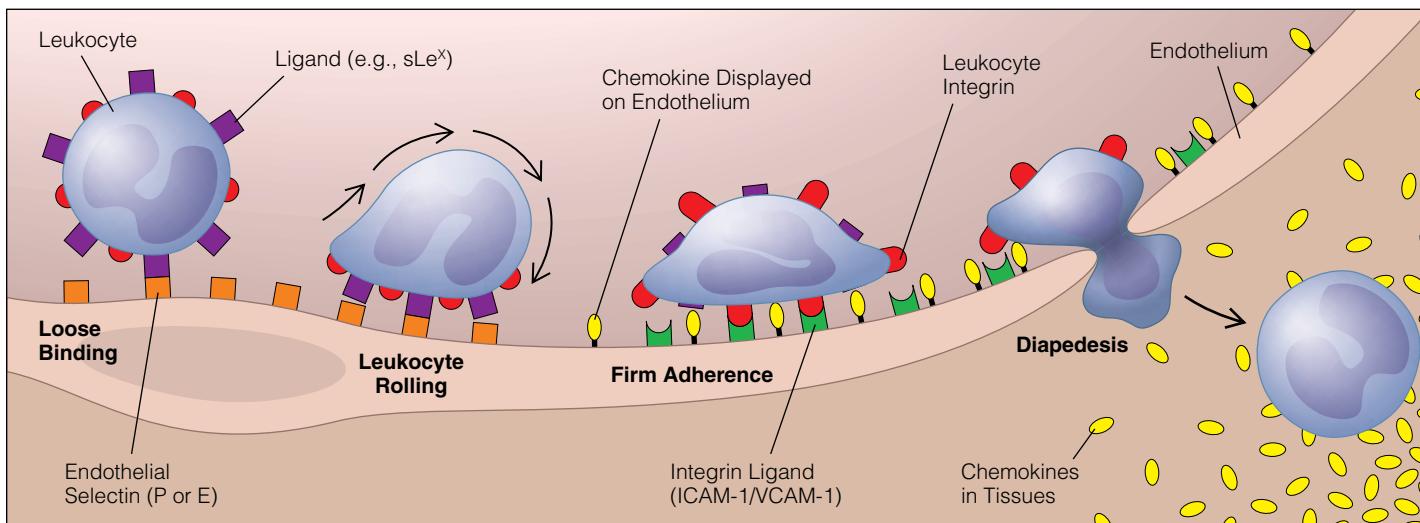

Figure 2 Leukocytes bind loosely to the endothelium via low-affinity interaction between selectins and their ligands. Once loosely bound, they begin rolling slowly along the endothelium. Chemokines cause a conformational change in the leukocyte, exposing the leukocyte integrins that bind to endothelial ICAM-1 and VCAM-1 and thus inducing firm adherence. The leukocyte then undergoes diapedesis into tissues along the chemokine gradient.

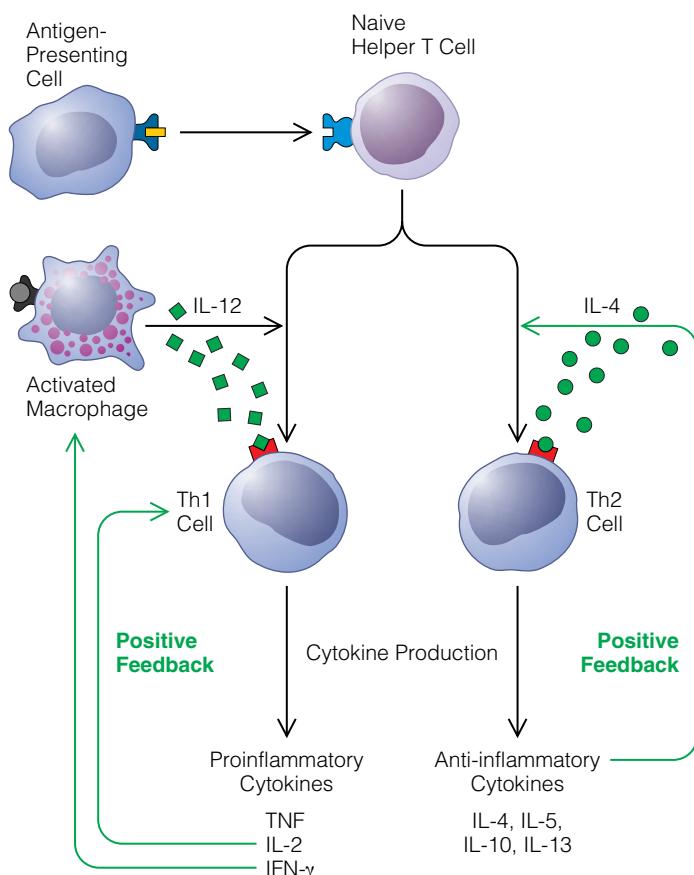

Figure 3 The function of T helper cells is to secrete cytokines in response to antigenic stimulation; these cytokines then act to regulate an appropriate immune response by triggering proliferation and stimulation of T cells, B cells, and other leukocytes. There are two distinct subsets of T helper cells—Th1 and Th2—which are descended from the same precursors, namely, naïve CD4⁺ T cells. The development of Th1 and Th2 subsets occurs in response to naïve T cell stimulation by different cytokines. In turn, each subset secretes a distinct set of cytokines. IL-12 is the major stimulant for Th1 subset development. This subset assists in phagocytose-mediated responses, with IL-12 being produced by phagocytes in response to a variety of antigens (most of which are intracellular). Th1 cells secrete the proinflammatory cytokines, mainly IFN- γ , IL-2, and TNF. IL-2 acts in an autocrine fashion, stimulating further growth of this subset. Th2 cell growth is stimulated by the anti-inflammatory cytokine IL-4. This subset produces the anti-inflammatory cytokines IL-4, IL-5, IL-10, IL-13, and IL-10, with IL-4 acting as an autocrine growth factor through a positive feedback mechanism. These cytokines also mediate the immune response to helminths and allergens.

stimulation by either antigens or other cytokines (e.g., TNF and IL-1). Some are also produced constitutionally by lymphocytes to regulate the flow of these cells through the lymphatic system.

Interleukin-12

When activated by intracellular microbes (e.g., viruses, *Listeria*, and mycobacteria), mononuclear phagocytes and dendritic cells (professional antigen-presenting cells [APCs] located in lymph nodes) produce IL-12, the essential action of which is to mediate the early immune response. The most important single action of IL-12 is to stimulate synthesis and release of IFN- γ by T cells and natural killer (NK) cells (see below).

Interferon Gamma

IFN- γ is produced by T cells and NK cells in response to antigen, an event greatly enhanced by IL-12. It activates macrophages, inducing them to kill microbes by activating enzymes that trigger synthesis of ROMs and NO. In addition, by increasing IL-12 release from the macrophages it activates, IFN- γ increases differentiation of T helper cells into the Th1 cell subset that produces it while inhibiting proliferation of the Th2 subset, which produces anti-inflammatory cytokines [see Figure 3].

Interleukin-6

It is probably most accurate to think of IL-6 as a mixed proinflammatory/anti-inflammatory cytokine. IL-6 is produced by mononuclear phagocytes as well as by endothelial cells and fibroblasts. It acts in a proinflammatory manner by providing a potent stimulus for hepatocyte synthesis of acute-phase proteins. It is also involved in promoting T cell differentiation and maturation and immunoglobulin production and in enhancing NK cell activity.⁴⁴ However, IL-6 also has important anti-inflammatory effects. It has been shown to inhibit production of TNF and IL-1 by mononuclear cells and to reduce release of TNF secondary to endotoxin challenge.⁴⁵ Furthermore, IL-6 leads to reduced plasma concentrations of soluble TNF receptors and IL-1 receptor antagonist (IL-1Ra), which are naturally occurring anticytokines.⁴⁶

Interferon Alfa and Interferon Beta (Type I Interferons)

IFN- α and IFN- β are two functionally similar cytokines that are often jointly referred to as the type I interferons; they are also known as the antiviral interferons because they are produced by antigen-stimulated T cells in response to viral infection. They act in a paracrine fashion to inhibit viral replication, preventing infection of neighboring cells and putting cells into an antiviral state. IFN- α and IFN- β also increase the efficiency of cytotoxic T cell-mediated cell lysis by upregulating expression of MHC class 1 molecules on infected cells. They are frequently used in the clinical setting: IFN- α seems to be effective therapy for viral hepatitis, and IFN- β has been used, with some success, to treat multiple sclerosis.

Interleukin-2

Unlike the cytokines already mentioned, which exert most of their effects via the innate immune system, IL-2 mediates acquired immunity—that is, the proliferation and differentiation of lymphocytes after antigen recognition. Originally known as T cell growth factor, IL-2 acts in an autocrine manner on the T cells that produce it (i.e., T helper cells), upregulating IL-2 receptors and thereby causing preferential proliferation of T cells specific for the stimulating antigen.⁴³ It also promotes growth and differentiation of NK cells.

IL-2 has an immunomodulatory function as well, in that it potentiates apoptosis of antigen-stimulated T cells. This action appears to limit immune responses. It is noteworthy that IL-2 knockout mice experience overproduction of lymphocytes with hyperplasia of lymphoid organs and the development of autoimmune diseases (most strikingly, autoimmune hemolytic anemia and inflammatory bowel disease). These events are probably attributable to loss of the regulatory apoptosis function.

Hematopoietic Cytokines

The hematopoietic cytokines—including the colony-stimulating factors (CSFs), IL-7, and IL-3—are, strictly speaking, proinflammatory, in that they induce the growth and differentiation of

bone marrow progenitor cells; however, this is a normal component of bone marrow hematopoiesis. CSFs are produced by bone marrow stromal cells and act to stimulate the formation of bone marrow cell colonies. There are several different varieties, named according to the type of cell line they promote (e.g., granulocytes [G-CSF], monocytes [M-CSF], or both [GM-CSF]). IL-7 is synthesized by fibroblasts and bone marrow cells and induces the differentiation of B and T cells. IL-3 is also known as multilineage colony-stimulating factor (multi-CSF) because its actions promote the differentiation of bone marrow precursors into all known mature cell types.

ANTI-INFLAMMATORY CYTOKINES

The anti-inflammatory cytokines exert their effects by inhibiting the production of proinflammatory cytokines, countering their actions, or both. In so doing, they reduce gene expression of agents such as TNF, IL-1, and the chemokines, thereby mitigating or preventing their subsequent inflammatory effects.

Interleukin-10

IL-10 is important in the homeostatic control of both innate and acquired immunity. It is produced by activated macrophages and is a potent inhibitor of these cells, regulating them via negative feedback; it is also produced by Th2 cells and B cells. IL-10 antagonizes a broad range of immune functions: it inhibits IL-12 production by activated macrophages, thereby reducing IFN- γ release and, consequently, decreasing macrophage activation. It also inhibits Th1 cells, thereby reducing production of proinflammatory cytokines (e.g., TNF, IFN- γ , and IL-2). However, IL-10 also has proinflammatory effects, stimulating B cell function and enhancing the development of cytotoxic T cells.⁴⁷

The importance of IL-10 in normal regulation of the immune response is demonstrated by studies of IL-10 knockout mice, which experience fatal inflammatory bowel disease and show markedly increased levels of TNF in response to endotoxin challenge.⁴⁸ Administration of recombinant IL-10 before lethal doses of endotoxin reduces TNF release and prevents death.⁴⁹ In humans, it prevents fever, proinflammatory cytokine release, and clotting cascade activation during endotoxin challenge.

Interleukin-4 and Interleukin-13

IL-4 and IL-13 are structurally similar, and both are produced by Th2 cells as well as by mast cells and basophils. They are considered anti-inflammatory cytokines by virtue of their ability to antagonize INF- γ and thereby reduce macrophage activation. Because INF- γ is the major promoter of Th1 cells, these two agents indirectly suppress cytokine production by Th1 cells in much the same way that IL-10 does.

IL-4 is the principal growth factor for Th2 cells, which, in addition to their immune suppressor functions, mediate the immune response to helminths and are responsible for allergic reactions. It is also the major stimulus for production of IgE by B cells.

Transforming Growth Factor- β

Transforming growth factor- β (TGF- β) is produced by a large variety of cells, including activated T cells, phagocytes, and endothelial cells. It has potent anti-inflammatory effects, inhibiting T cell differentiation and proliferation and macrophage activation. It also counteracts the effects of proinflammatory cytokines, causing downregulation of endothelial intercellular adhesion molecules,⁵⁰ downregulation of TNF endothelial receptor expression, and inhibition of chemokine action. TGF- β

knockout mice acquire multifocal inflammatory disease, particularly involving the heart and the lungs.⁵¹

THERAPEUTIC IMPLICATIONS

Interleukin-1 Receptor Antagonist

A naturally occurring cytokine inhibitor is the endogenously secreted protein IL-1Ra, which competitively binds the IL-1 receptor without signaling. IL-1Ra is secreted by mononuclear phagocytes and has nearly the same affinity for the IL-1 receptor as IL-1 itself does.⁵² IL-1Ra is present in high concentrations in the serum of patients with a variety of diseases, often in much higher concentrations than IL-1.⁵³ In patients with sepsis, juvenile rheumatoid arthritis, and inflammatory bowel disease, IL-1Ra levels have been found to correlate with disease severity; presumably, IL-1Ra acts as a natural negative feedback mechanism in inflammatory states. Unfortunately, the results of clinical trials evaluating recombinant IL-1Ra in the setting of septic shock have been largely disappointing.⁵⁴

TNF Antagonists

There are two cell surface receptors for TNF, p55 and p75. These are normally shed after activation and are found in the circulation. In the presence of disease and in response to endotoxin challenge, they circulate in much higher concentrations.⁵⁵ It is thought that p55 and p75 act as carriers for TNF, thereby reducing the amount of TNF available to act on cells. TNF itself induces the production of its soluble receptors. Elevated levels of TNF receptors have been recorded in cancer patients, and these levels correlate well with tumor burden and the extent of metastasis.⁵⁶ Elevated TNF receptor levels in blood or joint fluid have also been recorded in patients with a variety of autoimmune and inflammatory diseases.

In response to such observations, commercial anti-TNF drugs began to be developed. The first such drug to be approved was etanercept, in 1998. This agent, a recombinant TNF p75 receptor, has proved to be effective in treating rheumatoid arthritis and spondyloarthropathies. Infliximab, approved in 1999, is a genetically engineered anti-TNF mAb that is capable of binding to both cell-bound and soluble TNF. It causes lysis of TNF-producing cells via complement- and antibody-dependant cytotoxicity.⁵⁷ Infliximab is approved for use in patients with Crohn disease, in whom it can induce and maintain remissions, bring about endoscopically and histologically demonstrable mucosal healing, reduce the number of perianal fistulae, and decrease inflammation in ileoanal pouches.⁵⁸ Infliximab also shows great promise in the treatment of rheumatoid arthritis, ankylosing spondylitis, and psoriatic arthritis.

Modulation of Cytokine Activity in Sepsis, SIRS, and MODS

Key terms and concepts associated with the systemic activation of the body's inflammatory mechanisms—systemic inflammatory response syndrome (SIRS), sepsis, septic shock, and multiple organ dysfunction syndrome (MODS)—are defined and discussed more fully elsewhere [see 7:14 Clinical and Laboratory Diagnosis of Infection, 7:15 Blood Cultures and Infection in the Patient with the Septic Response, and 7:13 Multiple Organ Dysfunction Syndrome].⁵⁹ The general understanding is that systemic inflammatory activity (i.e., SIRS), which may occur in response to either infectious or noninfectious stimuli, is the fundamental phenomenon; in this view, sepsis may be understood as SIRS occurring specifically in response to microbial invasion. This whole-body inflammatory response can lead ultimately to MODS, which is associated with mortalities higher than 50%.

The role of cytokines in the pathophysiology of SIRS and sepsis was first appreciated when experimental studies demonstrated that antibodies to TNF reduced mortality in animals to which endotoxin had been administered.^{60,61} Further research revealed that the proinflammatory cytokines TNF and IL-1 were both able to evoke a clinical picture mimicking that of sepsis (i.e., hypotension and fever). In addition, TNF activated the coagulation cascade.⁵⁴ Accordingly, it was postulated that SIRS and sepsis were attributable to an overwhelming proinflammatory immune response mediated by TNF and other cytokines. A great deal of research on sepsis has now been carried out in animal and clinical trials, mostly using TNF mAbs and soluble TNF receptors. The initial results were positive, in that TNF amelioration led to increased survival in endotoxin-sensitized animals. Subsequently, however, these findings were countered by the observation that TNF had no significant effect in animal sepsis models of cecal ligation and puncture (which would be more relevant to clinical application in humans). Large-scale clinical trials employing TNF mAbs and receptors or IL-1 ablation with IL-1Ra have met with little success.⁶²

The disappointing clinical results from proinflammatory cytokine ablation have brought into question the thesis that sepsis is entirely understandable in terms of persistent and uncontrolled inflammation. Another view—which is not incompatible with the basic concept of sepsis as a systemic inflammatory response—is that the body also mounts a countering anti-inflammatory reaction to an insult, which then can lead to what is referred to as the compensatory anti-inflammatory response syndrome (CARS).⁶³ According to this hypothesis, when the proinflammatory response to an insult predominates, SIRS and shock result, and when the anti-inflammatory response predominates, CARS, immunosuppression, and increased susceptibility to infection ensue. Homeostasis and return to health reflect a state in which the two responses are in balance. It is likely that in cases of trauma or infection, the body's first response is proinflammatory, and the resulting SIRS is responsible for early mortality. This initial response is followed by an anti-inflammatory response, and the resulting CARS is responsible for late mortality secondary to immunodepression.⁶²

Numerous studies have measured cytokine concentrations in the peripheral vasculature in an effort to identify markers of sepsis, predictors of mortality, and possible clinical interventions. Perhaps surprisingly, levels of the proinflammatory cytokines (TNF, IL-1, IL-12, and IFN- γ) are not consistently correlated with either disease severity or mortality in patients with septic shock. This finding provides some evidence for the CARS hypothesis. It must be remembered, however, that systemic blood sampling is not indicative of tissue cytokine dynamics. In patients with pneumonia, for example, concentrations of TNF, IL-1, and IL-12 were found to be markedly higher in bronchial lavage samples than in serum.⁶⁴ The cytokine for which peripheral blood levels seem to correlate best with disease severity is IL-6; it is unclear why this is so, given that IL-6 certainly does not produce shock. A 1994 study found that circulating levels of the anti-inflammatory cytokine IL-10, which are normally unmeasurable, were detectable in more than 80% of patients with severe sepsis.⁶⁵ A so-called refractory immunologic state developing after infection or trauma has also been described,⁴⁷ characterized by reduced proinflammatory cytokine production by mononuclear cells but increased synthesis of IL-1Ra (which correlates with CARS).

Several studies have examined therapies aimed at promoting cytokines that enhance the proinflammatory response and there-

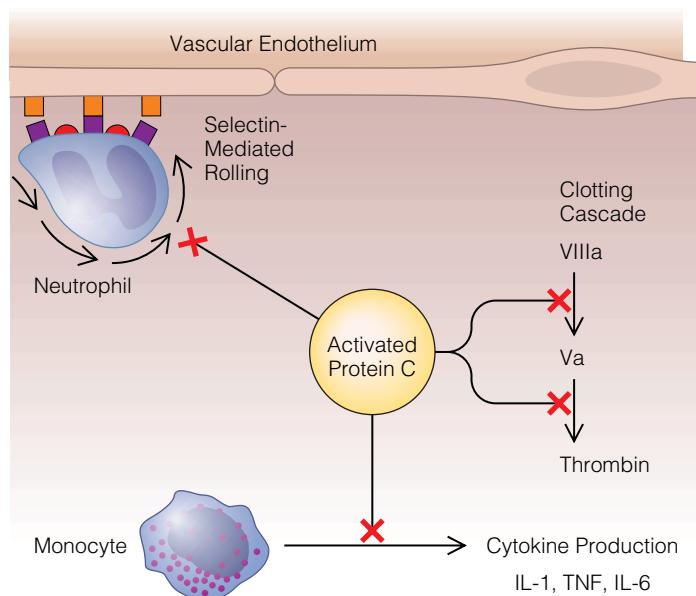

Figure 4 Activated protein C has both anti-inflammatory and antithrombotic actions that make it a valuable antisepsis drug. It reduces cytokine release by mononuclear phagocytes, reduces leukocyte adhesion to the vascular endothelium, and inhibits thrombin formation.

by presumably combat CARS. In one, administration of G-CSF to patients with community-acquired pneumonia resulted in reduced rates of systemic complications and sepsis.⁶² INF- γ was employed in a small clinical study of patients with sepsis and later in a multicenter study of burn patients,⁶⁶ the rationale being that monocyte function had been found to be depressed in severely ill patients. In these settings, the goal of restoring monocyte activity, as defined by HLA-DR expression, was achieved, though no clinical benefit was noted with regard to mortality or incidence of infectious complications.

It is clear that the role of cytokines in sepsis is a complex one: both hypo-inflammation and hyperinflammation occur, and both are major determinants of clinical outcome. To date, no therapy has been found that reliably regulates cytokine activity and reduces sepsis-related mortality. It may be that future treatments will be chosen and given on a patient-to-patient basis, with markers of immune competence (e.g., HLA-DR, IL-6, and TNF) indicating whether a proinflammatory approach or an anti-inflammatory approach is preferable in a specific instance.

Activated Protein C

It has long been recognized that the clotting system plays a major role in inflammation and in the response to invading organisms; DIC is one of the cardinal signs of sepsis. The proinflammatory cytokines TNF, IL-1, and IL-6 are known to trigger activation of the clotting cascade by stimulating the release of tissue factor from monocytes and endothelium, leading to thrombin formation and a fibrin clot. These cytokines also inhibit endogenous fibrinolytic mechanisms by stimulating the release of plasminogen-activator inhibitor-1 (PAI-1) from platelets and endothelium. At the same time, thrombin stimulates many inflammatory pathways and suppresses natural anticoagulant response by activating thrombin-activatable fibrinolysis inhibitor (TAFI).⁶⁷ This procoagulant response leads to microvascular thrombosis and is implicated in the multiple organ failure associated with sepsis.

Protein C is an endogenous anticoagulant that, when activated by thrombin bound to thrombomodulin, reduces the generation of thrombin by inactivating clotting factors Va and VIIIa. It also exerts an anti-inflammatory effect by inhibiting monocyte production of TNF, IL-1, and IL-6 and limiting leukocyte adhesion to endothelium by binding selectins⁶⁸ [see Figure 4]. Activation of protein C is impaired during the inflammatory response because endothelial injury results in reduced levels of thrombomodulin. Decreased circulating levels of activated protein C are usually present in sepsis and are associated with increased mortality.⁶⁹

These observations have led to the investigation of activated protein C as a potential treatment for severe sepsis. A multicenter, placebo-controlled phase III clinical trial comprising 1,690 patients documented a 6.1% reduction in total mortality in patients treated with drotrecogin alpha (the generic name for recombinant human activated protein C).⁶⁷ The only major side effect noted with this agent was an increased risk of serious bleeding: 3.5%, compared with 2% in the placebo group. Drotrecogin is thus the first therapy to have shown a real clinical benefit in sepsis trials, and high hopes are held for its future therapeutic use. The United States Food and Drug Administration has recently approved this agent for treatment of sepsis, and further clinical trials are planned. It is marketed under the brand name Xigris.

Reactive Oxygen Metabolites

Oxygen and its metabolites [see Table 4] are often very toxic, and this toxicity seems to have influenced the early evolution of metabolic pathways to detoxify oxygen and make life possible in an aerobic environment.⁷⁰ Although aerobic organisms are capable of exploiting oxygen's high reactivity for cellular energy, this reactivity also poses a continual assault on living tissues. Whenever the rate of endogenous oxidant generation exceeds the body's endogenous antioxidant capacity, tissue injury ensues. This occurrence is known as oxidative stress.

Free radicals and other ROMs have been implicated in a diverse array of human disease processes, including reperfusion injury, ischemic hepatitis and pancreatitis, inflammatory bowel disease, and ARDS. The common pathway for the tissue injury in these illnesses is the action of free radicals.

CHEMICAL STRUCTURE

The high reactivity of free radicals is a consequence of their chemical structure. Free radicals are molecules that contain one or more unpaired electrons in their outer orbits. As a result, they possess higher energy levels than molecules with full outer orbits and, accordingly, are less stable and more reactive.

The most abundant radical in the biologic system is molecular oxygen itself (O_2), which has two unpaired electrons in its outer orbit. In this ground (i.e., low-energy) state, the two electrons have parallel spins, rendering the molecule relatively unreactive. When the electrons have antiparallel spins, the radical—termed singlet oxygen (1O_2)—is much more reactive. Various oxygen-centered free radicals and ROMs are believed to play important roles in tissue injury. The superoxide anion (O_2^-) and the hydroxyl radical (OH^\bullet) each have one unpaired electron in the outer orbit. The latter is particularly unstable: it reacts within 10^{-6} seconds of its formation and within a distance of 15 nm. Consequently, the hydroxyl radical is not only highly toxic but also very difficult to scavenge effectively.

Some ROMs, technically speaking, are not true radicals but are still quite toxic. For example, much of superoxide's tissue toxicity is actually mediated by its oxidant reduction products.

Table 4 Reactive Oxygen Metabolites and Other Free Radicals

Radicals and Metabolites	Chemical Symbol	Comments
Oxygen-centered free radicals		
Molecular oxygen		
Ground state (triplet) oxygen	3O_2	Constitutes 20% of the atmosphere
Singlet oxygen	1O_2	Much more reactive than 3O_2
Superoxide radical	O_2^-	Initial product of respiratory burst of neutrophils
Hydroxyl radical	OH^\bullet	Highly unstable; extremely toxic
Alkoxy radical	RO^\bullet	Important toxic intermediate of free radical chain reactions
Peroxy radical	ROO^\bullet	Important mediator of DNA damage
Lipoxy radical	LOO^\bullet	Important toxic metabolite of lipid peroxidation
Non-oxygen-centered free radicals		
Nitrogen centered		
Nitric oxide	NO^\bullet	Neurotransmitter
Peroxynitrite	$OONO^\bullet$	Important endogenous toxin
Carbon centered		
Lipid radical	L^\bullet	Important toxic metabolite of lipid peroxidation
Sulfur centered		
Thiyl	$R-S^\bullet$	Metabolites of cysteine and D-penicillamine
Hydrogen centered		
Hydrogen atom	H^\bullet	—
Iron centered		
Perferryl radical	$Fe^{3+}-O_2-Fe^{2+}$	Important final mediator of tissue injury (along with OH^\bullet)
Non-free radical reactive metabolites		
Ozone	O_3	Major air pollutant
Hydroperoxides		
Hydrogen peroxide	H_2O_2	Important endogenous tissue toxin
Lipid peroxide	$LOOH$	Intermediate lipid peroxidation
Hypochlorous acid	$HOCl$	Important mediator of neutrophil toxicity
Chloramines	$R'RNCl$	Important final mediator of neutrophil toxicity

The hydroperoxides constitute an important class of toxic ROMs, with hydrogen peroxide (H_2O_2) playing a particularly important part. Much of the superoxide-initiated tissue damage caused by neutrophils and macrophages can be attributed to halogenated oxidants (e.g., hypochlorous acid [$HOCl$]) and chloramines, which are formed by the secondary reaction of halogenated radical species with nitrogen compounds. This production of toxic ROMs as redox products substantially amplifies the toxicity of free radicals.

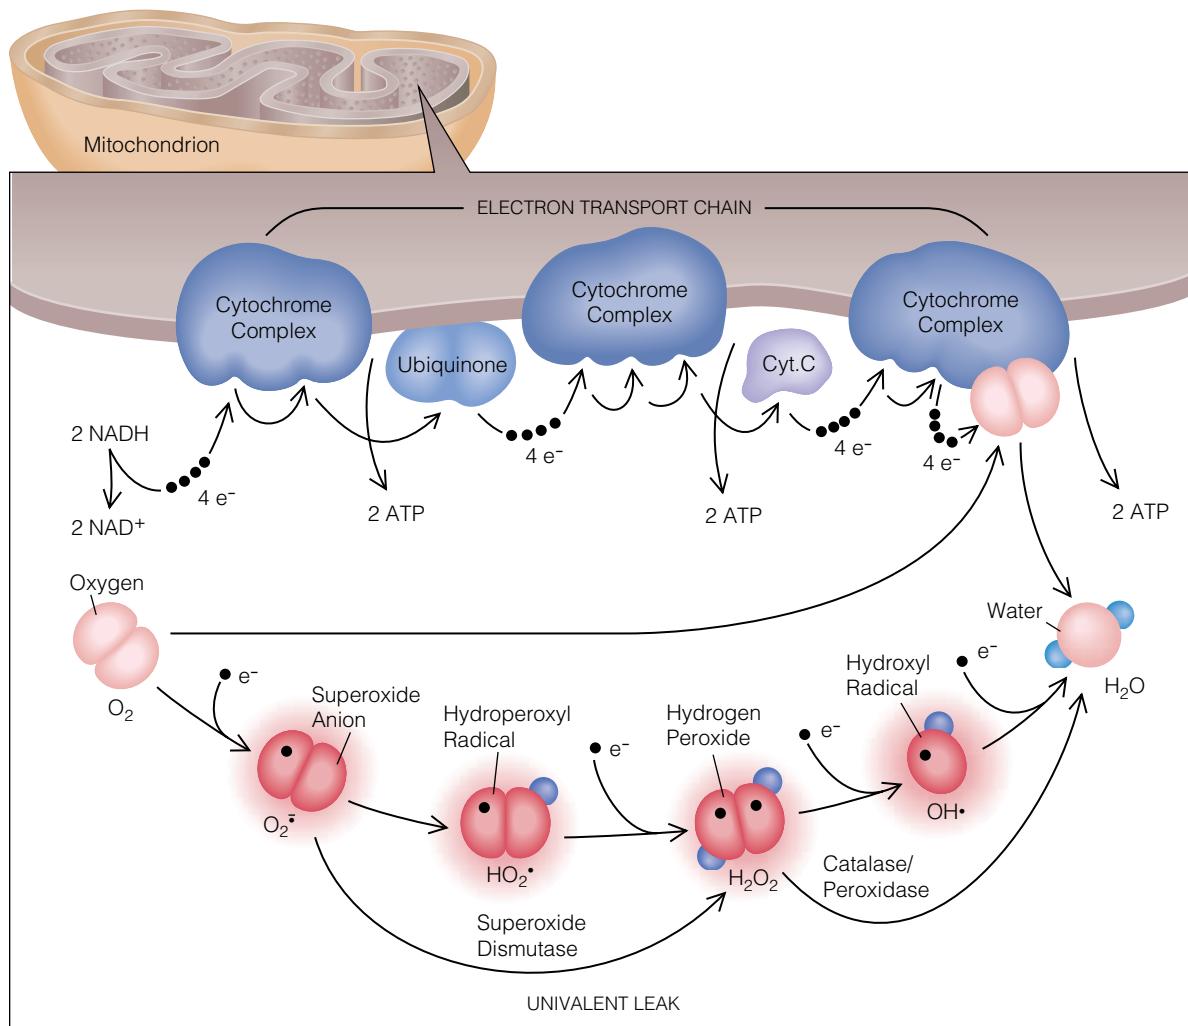

Figure 5 The mitochondrial cytochrome oxidase complex reduces molecular oxygen by the essentially simultaneous addition of four electrons, producing water and generating adenosine triphosphate (ATP) without the production of free reactive oxygen intermediates. However, 1% to 5% of oxygen leaks from this pathway and undergoes stepwise, univalent reduction. The one-electron reduction of molecular oxygen generates the superoxide free radical (superoxide anion). This can subsequently be reduced to hydrogen peroxide (H_2O_2), most commonly in a dismutation reaction catalyzed by SOD. Hydrogen peroxide can be directly reduced to water (by a catalase- or peroxidase-catalyzed reduction), or it can be reduced to the hydroxyl radical (OH^{\cdot}) (usually in an iron-catalyzed reaction). The highly reactive hydroxyl radical can subsequently abstract a hydrogen atom to reduce itself to water. Normally, protective biochemical mechanisms detoxify the toxic intermediates generated by this so-called univalent leak. When increased concentrations of oxygen generate excessive amounts of reactive oxygen metabolites, however, protective mechanisms may be overwhelmed and tissue injury may result.

FORMATION

All cells continuously generate ROMs as normal by-products of metabolism. During oxidative phosphorylation, mitochondrial cytochromes couple the production of adenosine triphosphate (ATP) to the tetravalent reduction of molecular oxygen to water [see Figure 5]. In the course of this process, all four electrons are effectively added to the oxygen molecule at once. No intermediaries are formed, and thus no free radicals are generated. However, about 1% to 5% of the oxygen reduced to water within the mitochondria leaks from this pathway and undergoes a stepwise, noncatalyzed reduction—the so-called univalent leak—that produces a series of toxic intermediaries. These ROMs must then be detoxified by endogenous antioxidants to prevent tissue injury.

ROMs are also formed in many other circumstances. Certain cellular oxidases (e.g., cytochrome P-450, mixed-function oxidase,

and peroxidases) can generate ROMs.⁷¹ The arachidonic acid cascade, which produces eicosanoids [see Eicosanoids, below], also generates peroxy compounds and hydroxyl radicals as by-products.

In inflammatory cells, ROMs are the primary product of a highly specialized NADPH-dependent oxidant system. When activated, they cause reduction of oxygen to the superoxide anion. This process, known as the respiratory burst, may account for more than 90% of the oxygen consumption of an activated neutrophil [see Figure 6].⁷² It is followed by formation of the major toxic product, HOCl, catalyzed by an enzyme (myeloperoxidase [MPO]) that is unique to phagocytes.

MECHANISM OF TISSUE DAMAGE

All biochemical cell components are potentially subject to attack by free radicals; however, lipids, proteins, and nucleic acids are particularly vulnerable. It should also be noted that the

toxic and mutagenic effects of ionizing radiation and those of many toxic chemicals (e.g., carbon tetrachloride [CCl_4]) are in fact mediated by the formation of ROMs. ROMs exert their inflammatory effects in five major ways.

1. Lipid peroxidation. Because ROMs are so reactive, they generally react with the first molecule encountered, which is often a cell membrane lipid. By removing a hydrogen atom from the carbon chain of a polyunsaturated fatty acid, a ROM can form a fatty acid radical (LOO^\bullet), which is then able to react with neighboring lipids, proteins, or nucleic acids, in a chain reaction. Thus, a single free radical can cause the breakdown of several polyunsaturated fatty acids, generating damaged and reactive products along its path. The reaction products include aldehydes, hydrocarbon gases (e.g., pentane, methane, and ethane) and various chemical residues; these agents cause cell edema, influence vascular permeability, give rise to inflammation and chemotaxis, and alter the activity of cell enzymes, including phospholipase. This destructive sequence is terminated only when two of these radicals react together or when the radicals are scavenged by an electron acceptor.

2. Protein denaturation. Both structural and enzymatic proteins are vulnerable to free radical-mediated denaturation. This process can lead to loss of membrane fluidity and structural disintegration, which can cause the destruction of organelles or even entire cells. Calcium adenosine triphosphatase (ATPase) is particularly susceptible to oxidative damage; denaturation of this enzyme results in increased intracellular calcium concentration with subsequent swelling and injury.
3. Nucleic acid denaturation. Free radicals can attack nucleic acids directly, causing base hydroxylation, cross-linking, or scission. Such attacks may be facilitated by the presence of DNA-bound iron acting as a catalyst. Depending on the extent of DNA damage, the effect may be mutagenic or lethal. Ionizing radiation exerts most of its damaging effect by this mechanism.
4. Cell matrix injury. Free radicals also attack extracellular proteins and glycoproteins (e.g., collagen and hyaluronic acid). When these molecules lose their structural integrity, damage to the connective tissue basement membrane and the extracellular matrix may ensue, which can affect vascular permeability and epithelial membrane integrity and can even result in petechiae.⁷³ This process may be the cause of certain con-

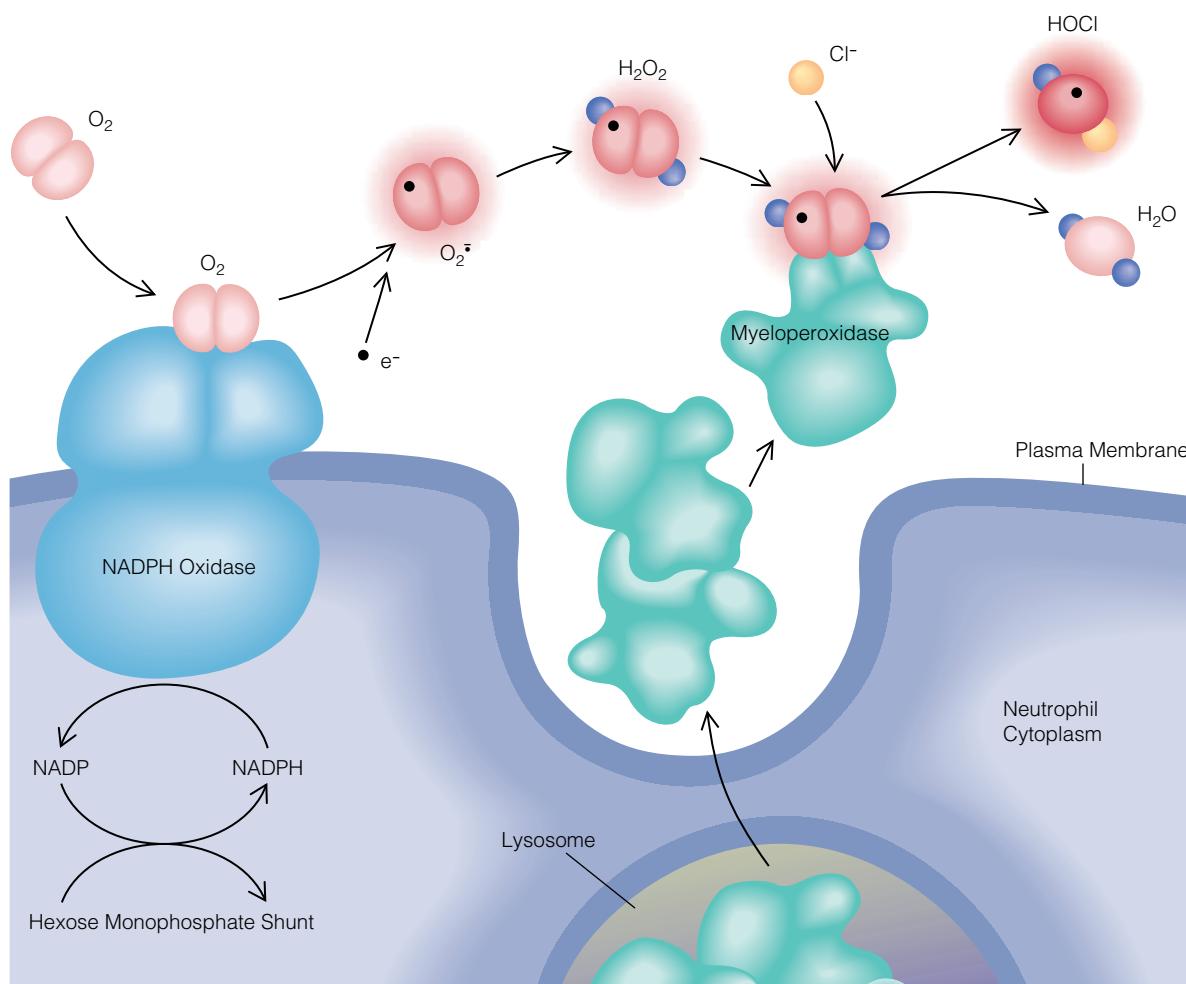

Figure 6 Neutrophils and other phagocytes generate the superoxide radical via the membrane-integrated enzyme NADPH oxidase. On stimulation, more than 90% of the oxygen used by the neutrophil is consumed in this respiratory burst. Although the superoxide radical itself is toxic to many invading microorganisms, the secondary generation of HOCl from hydrogen peroxide and chloride ions, catalyzed by the neutrophil-generated enzyme myeloperoxidase, substantially increases the bactericidal potential of the neutrophil.

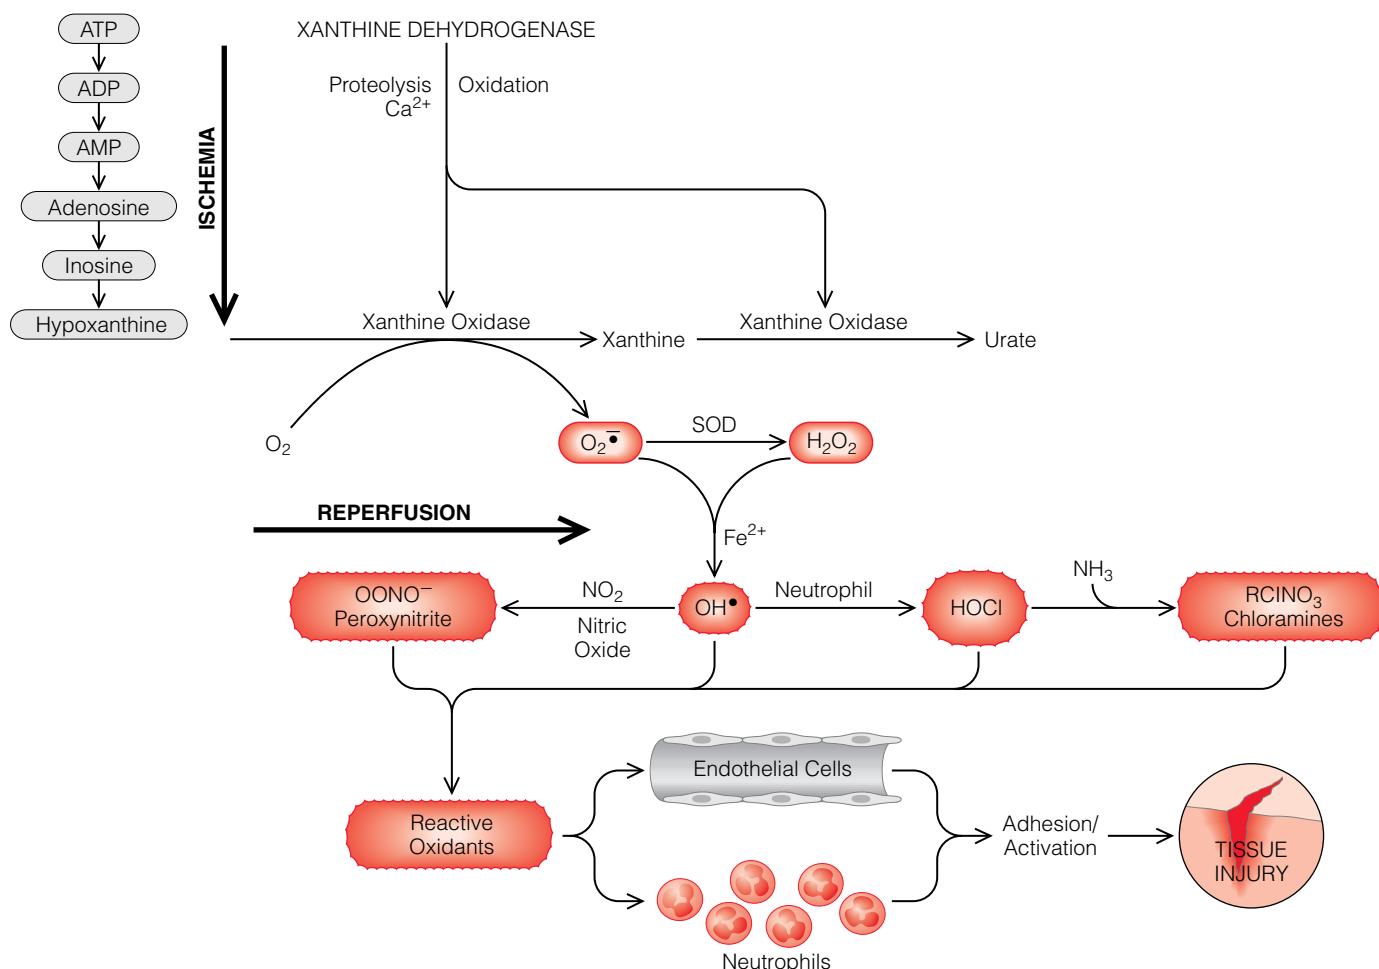

Figure 7 Xanthine oxidase may serve as the initial source of free radical generation in postischemic reperfusion injury. With the onset of ischemia, ATP is degraded to its purine bases (e.g., hypoxanthine), the concentration of which increases. Simultaneously, xanthine dehydrogenase is converted by ischemia to xanthine oxidase. Although the concentrations of substrate and enzyme are high during ischemia, the absence of oxygen prevents purine oxidation until reperfusion. At reperfusion, oxygen becomes available, suddenly and in excess, and the oxidation of hypoxanthine (and xanthine) proceeds rapidly, generating a burst of superoxide radicals as a by-product, probably at or near the endothelial cell surface.

necrotic tissue diseases (e.g., osteoarthritis and rheumatoid arthritis), with inflammatory cells serving as the source of ROMs.

- Apoptosis. Apoptosis, a genetic mechanism that regulates cell numbers, is characterized by cell shrinkage (pyknosis), in contrast with the cell swelling and rupture typical of necrosis. Pyknotic cells are cleared by macrophages with minimal inflammation. Apoptosis is induced by ROMs, acting via diverse mechanisms.

ANTIOXIDANT DEFENSE MECHANISMS

Various endogenous mechanisms have evolved to limit or counteract the tissue damage caused by ROMs. An example is the production and release of enzymatic and nonenzymatic antioxidants such as vitamin E, vitamin C, provitamin A, glutathione, superoxide dismutase (SOD), and glutathione peroxidase, which act by scavenging ROMs. The enzymatic antioxidants require trace metals as cofactors for maximal effect: selenium for glutathione peroxidase; copper, zinc, or manganese for SOD; and iron for catalase.

These endogenous antioxidants are generally present at sites where free radicals are produced, which ensures that scavenging

can occur immediately after formation—a critical point, in view of the short radii of the antioxidants' activity. For example, SOD is located almost exclusively in the mitochondrial matrix, where it scavenges superoxide radicals formed via the univalent leak, and vitamins A and E are found in cell membranes, where they inhibit lipid peroxidation.

ROLE IN REPERFUSION INJURY

Postischemic reperfusion disease provides the classic example of free radical-mediated tissue injury. This phenomenon was first demonstrated in 1981 in the feline small intestine, where administration of SOD near the end of the ischemic period but before reperfusion largely prevented the microvascular and epithelial injury seen after periods of partial ischemia.⁷⁴ Since that initial study, SOD has been shown to attenuate reperfusion injury in many organs, including skeletal muscle⁷⁵ and the heart.⁷⁶ In similar models, injury was ameliorated by (1) scavenging of hydrogen peroxide by catalase,⁷⁷ (2) scavenging of hydroxyl radicals by dimethyl sulfoxide or mannitol,⁷⁸ or (3) prevention of radical formation by chelating iron with transferrin or deferoxamine.⁷⁹ Equivalent protection was provided by inhibiting generation of superoxide by xanthine oxidase through

administration of allopurinol, pterin aldehyde, or tungsten.⁸⁰ These studies suggest that xanthine oxidase, which is known to be present in high concentrations in the intestinal mucosa, is the initial trigger of free radical generation at reperfusion.

In nonischemic tissue, the dehydrogenase form of xanthine oxidoreductase predominates. Ischemia appears to mediate the conversion of xanthine dehydrogenase to xanthine oxidase via a mechanism that remains to be defined. At the same time, catabolism of ATP during ischemia leads to an increased concentration of the purine metabolites, xanthine and hypoxanthine. At reperfusion, oxygen is suddenly reintroduced in excess. The subsequent generation of superoxide by xanthine oxidase triggers a free radical chain reaction and subsequent tissue injury [see Figure 7]. That either scavenging the hydroxyl radical or blocking its generation by an iron-catalyzed reaction has the same protective effect as more proximal blockage of the cascade suggests that the hydroxyl radical, or one of its metabolites, is the final agent of injury.⁷⁷

Reperfusion injury is also known to be mediated by neutrophils, which would seem to suggest that the injury is entirely accounted for by neutrophil superoxide generation. This thesis is unlikely to be true, however: a more plausible thesis is that neutrophils act in concert with ROMs. Thus, in some models of injury, neutrophil depletion fails to ameliorate injuries that are blocked by SOD and catalase. It has been observed that free radical scavengers prevent neutrophil infiltration into postischemic tissue,⁸¹ which has led to the hypothesis that ROMs act primarily as neutrophil chemoattractants.

Clinical Trials

In view of the success achieved in moderating reperfusion injury with antioxidants in animal models, it is perhaps surprising that similar approaches have not met with comparable success in humans. A 1989 study using human recombinant SOD to treat myocardial ischemia-reperfusion injury after angioplasty and renal ischemia failed to demonstrate any benefit.⁸² However, a renal transplant study in which SOD was infused immediately before reperfusion reported reduced rates of acute renal failure in graft recipients who underwent cold ischemia for longer than 30 hours⁸³; graft survival was longer as well.

In general, ROM scavengers are partially effective at best. Despite the enormous amount of data that has been collected, the precise relationship between ROM generation and tissue injury remains unclear.

Nitric Oxide

NO[•] is produced in a variety of tissues (e.g., endothelial cells and platelets) by either a constitutive or an inducible form of NO[•] synthase. In the setting of inflammation, the inducible enzyme is activated by cytokines such as TNF. NO[•] is a potent inhibitor of leukocyte and platelet adhesion, exerting its effects via activation of soluble guanylyl cyclase and generation of cyclic guanosine monophosphate (cGMP).⁸⁴ With regard to platelets, NO[•] has been shown to inhibit the binding of fibrinogen to GPIIb/IIIa and to limit the expression of P-selectin.⁸⁵ Another important anti-inflammatory role of NO[•] is its ability to scavenge superoxide at least as fast as SOD does. Finally, inhaled NO[•] moderately reduces the pulmonary hypertension seen with ARDS; however, it does not increase cardiac output or reduce mortality in these patients.

Moreover, NO[•] acts as a source of potent free radicals when it interacts with superoxide to form peroxynitrite, a strong oxi-

dizing agent. Experimental studies using NO[•] donors and antagonists have not yielded sufficiently consistent results to permit a clear definition of the role of NO[•] in mediating or moderating inflammatory events.

Complement

Complement was discovered in 1889 by Bordet while he was studying the bactericidal action of serum.⁸⁶ Bordet demonstrated that if fresh serum containing an antibacterial antibody was added to the bacteria at physiologic temperature, the bacteria were lysed, but if the serum was heated to a temperature of 56° C or higher, the bacteria were not lysed. Reasoning that the serum's loss of lytic capacity could not have been caused by decay of antibody activity—because antibodies were known to be heat stable, and even heated serum remained capable of agglutinating the bacteria—Bordet concluded that serum must contain another heat-labile component that assisted or complemented the lytic function of antibodies.

COMPLEMENT CASCADE

The complement cascade consists of the classical and alternative pathways, each of which comprises a series of plasma proteins that are known to mediate several aspects of the inflammatory response. This cascade has four principal biologic functions:

1. Osmotic cell lysis, effective in the killing of foreign organisms.
2. Binding of complement proteins to the surfaces of foreign organisms or particles. These opsonins bind to specific counterreceptors on macrophages and leukocytes, facilitating phagocytosis.
3. Augmentation, potentiation, and promotion of the inflammatory response. Complement fragments bring about chemotaxis of inflammatory cells. In addition, C3a and C5a stimulate a neutrophil oxidative burst and mast cell degranulation, which potentiate the inflammatory response.
4. Clearance of immune complexes from the circulation.

The classical pathway and the alternative pathway have different activating mechanisms; however, both result in the formation of the membrane attack complex C5b-C9, which leads to the creation of pores in the cell membrane and consequently to abnormal ion transport, impaired signaling, and potential lysis, particularly of nonnucleated cells. Activation of either pathway leads to production of the biologically active anaphylatoxins C3a and C5a. These peptides are generated via cleavage of native C3 and C5 complement components by C3 convertase and C5 convertase, which are formed at intermediate steps in the process of complement activation. C3a and C5a exert a variety of physiologic effects, including vasodilatation and increased vascular permeability. The effects on neutrophils include chemotaxis, diapedesis, degranulation, and free radical production as well as translocation of intracellular complement receptors to the neutrophil-plasma membrane. In addition, the complement fragments C3b and C4b serve as opsonins, thus facilitating phagocytosis of particles to which they have attached. Inactive C3b (iC3b) is a counterreceptor for the neutrophil CD11b/CD18 (Mac-1) receptor and thus has the ability to enhance neutrophil binding and signaling in response to complement-coated molecules, thereby facilitating their phagocytosis.

The complement cascade has specific features that make it an important effector mechanism in the inflammatory response. Many of its components, once activated, possess enzymatic

activity. As the cascade proceeds, these activated components cause substantial amplifications at each step. In addition to this important positive feedback loop, there are multiple levels at which inhibitory proteins can intervene in the cascade to prevent its accidental or inappropriate generalized activation. Another important property of the complement cascade is that it has both specific and nonspecific activators. Once a specific antibody and antigen have reacted, the classical pathway can be activated by several closely spaced IgG molecules or by a single IgM pentamer. The alternative pathway is triggered by direct binding of components to the surface of foreign organisms. In this way, the alternative pathway participates in nonspecific immunity.

Classical Pathway

The classical pathway [see *Figure 8*] is usually initiated by interaction between C1 and an antigen-antibody complex. It may also be activated by infectious organisms (e.g., *Mycoplasma*) or certain molecules (e.g., DNA, heparin, and chondroitin sulfate).⁸⁷

C1 does not interact with IgG or IgM until the antibody has bound its specific antigen. The subunit of C1 that binds is C1q. C1q attaches either to the C_H3 domain of IgM or to the C_H2 domain of IgG, both of which reside in the Fc portion of the antibody. A single C1q molecule must bind to at least two Fc portions of an immunoglobulin. Because IgM is secreted as a pentamer containing five separate Fc portions, a single molecule is an efficient activator of complement. Because IgG is secreted as a monomer, C1q must bind to two or more adjacent IgG molecules to be activated. C1q is uniquely able to bind these different Fc regions of immunoglobulins because it consists of six identical subunits, each of which has a projecting head.

Once C1q is bound to an immune complex, the other components of C1—C1r and C1s—become operative. A tetramer consisting of two C1r and two C1s molecules is formed and bonded with C1q. This process results in a serum esterase-type enzyme that acts on the next two components in the cascade, C4 and C2. C4, like several other complement proteins, has an internal thioester bond. C4 is split into two parts, C4a and C4b, with the former diffusing away. Generation of C4b results in a reactive molecule called metastable C4b, which possesses an internal thioester. Many C4b molecules react with water at the site of the internal thioester, thereby inactivating the C4 complex; alternatively, some of the C4b thioesters may esterify to cell surface proteins or carbohydrates, thereby stabilizing the C4 complex.

In the presence of magnesium, C2 binds to C4b molecules that in turn are bound to cell surface proteins or carbohydrates. A C1s molecule splits C2, generating C2a and C2b. The latter may diffuse away, whereas the C2a fragment remains complexed with C4b, resulting in C4b2a, which is the C3 convertase of the classical pathway [see *Figure 8*]. In the presence of calcium and magnesium, this C3 convertase binds C3 and cleaves it into C3a and C3b. Like C4b, C3b has an internal thioester, and this thioester may form a covalent bond with C4b2a or be inactivated by reacting with water. The addition of C3b to the preexisting C4b2a complex yields C4b2a3b, which is the C5 convertase of the classical pathway. This C5 convertase cleaves C5 and initiates the common terminal sequence of the complement cascade, which results in the formation of C5b-C9, the membrane attack complex.

Alternative Pathway

The alternative pathway [see *Figure 8*] was so named because it was discovered after the classical pathway was described, but it

seems actually to have evolved before the classical pathway. Both pathways require the production of C3 and C5 convertases to generate the terminal sequence leading to generation of the membrane attack complex; however, each uses a different series of activators and proteins to produce these convertases.

The alternative pathway is in a constant state of low-level activation as a result of spontaneous hydrolysis of the internal thioester bond in the α chain of C3 (the so-called tickover of C3), a process that is believed to be ongoing at a low intensity in the circulation at all times. This hydrolysis leads to the unstable intermediate C3b. (The classical pathway may also initiate the alternative pathway by serving as the source of the first C3b molecules.) C3b is usually hydrolysed by water, but sometimes it reacts with amino or hydroxyl groups of cell surface proteins or polysaccharides to form stable amide or ester bonds. The cell-bound C3b then attaches to factor B, which in turn is proteolytically cleaved by factor D to form C3bBb, the solid-phase alternative pathway C3 convertase, which requires properdin for stabilization.

The C3 convertase then acts on additional C3b to form the C3bBbC3b complex, which is the C5 convertase of the alternative pathway. This C5 convertase initiates hydrolysis of C5, which, as in the classical pathway, eventually results in the formation of the membrane attack complex.

Membrane Attack Complex

Both of the C5 convertases cleave C5 into C5a and C5b. The C5b component binds to C6 and C7, and the resulting C5b67 complex is then inserted into the lipid bilayer of the plasma membrane. Once in place in the membrane, this molecule becomes a receptor for and binds to C8, at which point pore formation, ionic movement, and cell lysis may begin. The C5b678 complex undergoes hydrophilic association within the plasma membrane, weakening it and causing the formation of transmembrane channels. This process may lead to cell death by osmotic lysis because of the cell's inability to maintain critical intra- and extracellular concentration gradients. Because of the amplification mechanisms involved in both pathways, as many as 12 to 15 C9 molecules may be added to the C5b678 complex, resulting in the formation of C5b-C9, the membrane attack complex. Scanning electron microscopy suggests that the membrane attack complex acts as a pore within the cell membrane, allowing the collapse of ionic and osmotic gradients.

Regulation

To prevent inappropriate activation and damage to the host, the complement cascade must be tightly regulated. There are a number of circulating soluble factors that inactivate various aspects of the complement cascade, including C1 inhibitor, C4-binding protein, factor H, and factor I. Molecules that inhibit membrane attack complex formation include homologous restriction factor and the membrane inhibitor of reactive lysis, both of which are thought to play a key role in protecting normal surrounding cells in adjacent areas where complement activation and cell lysis are taking place.

In addition, there are several regulatory proteins that are found within the membranes of most cells of the myeloid line as well as those of platelets and mast cells; these include complement receptor type 1 (CR1), membrane cofactor protein, and decay-accelerating factor. CR1 is present on erythrocytes and in smaller quantities on neutrophils, monocytes, macrophages, eosinophils, and lymphocytes. It has at least three important functions: (1) it can inhibit C3 convertase activity, (2) it enhances the ability of leukocytes to ingest C3b- or C4b-coated

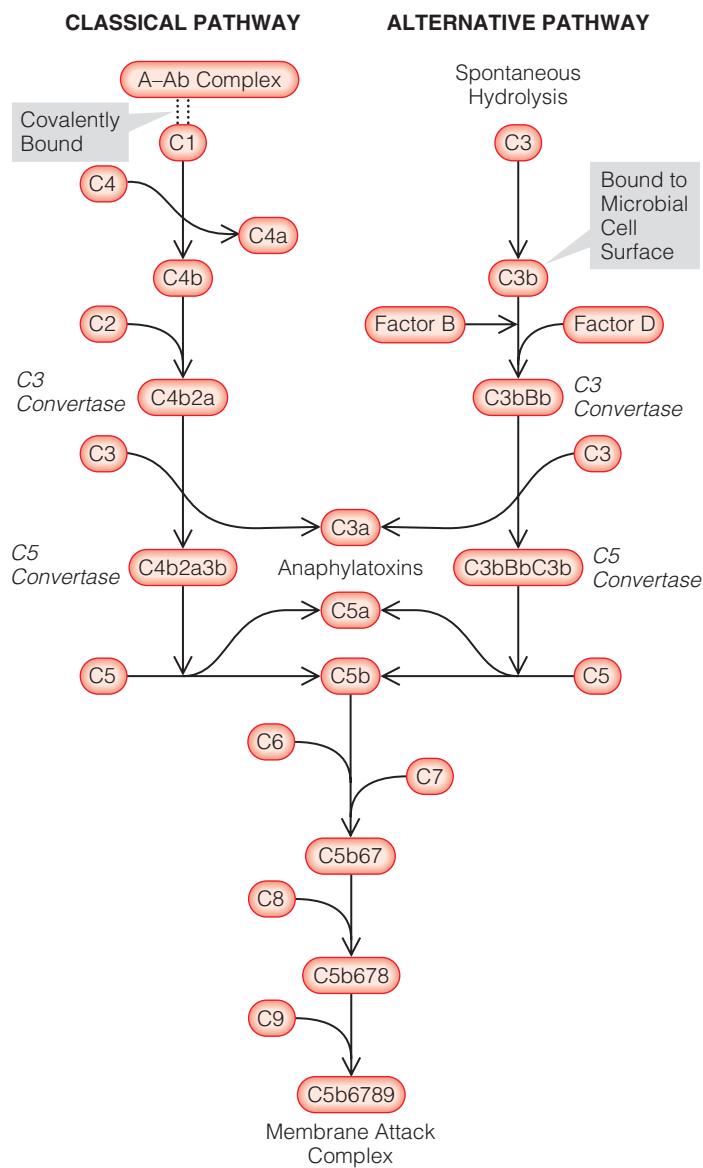

Figure 8 Shown are the classical and alternative pathways of the complement cascade.

particles, and (3) it facilitates clearance of immune complexes from the circulation. CR1 also inhibits the activity of C4b and thus is capable of preventing activation of the classical pathway. This powerful inhibitor of both complement pathways is currently the subject of much attention among researchers. A soluble form of CR1 that lacks the cytoplasmic and transmembrane domains has been engineered from human erythrocytes. This human soluble complement receptor type 1 (sCR1) retains the C3b- and C4b-binding activities of membrane-associated CR1.

ROLE IN REPERFUSION INJURY

The first evidence that complement might play a role in the pathogenesis of ischemia-reperfusion injury was the finding that myocardial ischemia induced complement activation.⁸⁸ It was also reported that mitochondrial fragments in cardiac lymph activated both classical and alternative complement pathways. Later studies using cobra venom factor to deplete complement by triggering its activation demonstrated reductions in myocardial necrosis after coronary artery occlusion.⁸⁹ Researchers

examining therapeutic use of sCR1 in animals documented significant reductions in myocardial infarct size and dramatic reductions in the number of neutrophils sequestered in the myocardium.⁹⁰ Moreover, treatment with sCR1 did not appear to impair healing of the infarcted area. Immunoperoxidase staining for the membrane attack complex demonstrated little or no myocardial deposition of C5b-C9 in the sCR1-treated group in comparison with untreated animals.

Several studies have examined the role of complement in skeletal muscle ischemia-reperfusion injury. In one, concentrations of C3a and C5a were elevated in patients with ischemic limbs.⁹¹ Levels of these anaphylatoxins returned to normal after amputation, which suggested that complement was activated by acute limb ischemia. In another study, there was a significant dose-dependent reduction in muscle permeability with sCR1 treatment after hindlimb ischemia-reperfusion.⁹² Subsequently, it was found that during reperfusion, skeletal muscle permeability was dependent on the presence of IgM natural antibody and on activation of the classical complement pathway. These investigations lend strong support to the thesis that complement is a significant mediator of skeletal muscle injury after ischemia-reperfusion.

In further studies, it was postulated that ischemic injury led to expression or unmasking of a neoantigen. Immunohistochemistry demonstrated colocalization of IgM and C3, indicating the formation of an immune complex in conjunction with complement activation (shown by other techniques to involve the classical pathway). Animals genetically depleted of immunoglobulins—specifically, IgM—were protected from reperfusion injury.

Mast Cell

Although mast cells were first identified more than a century ago, only comparatively recently have major advances been made in understanding their biology. All mast cells are derived from progenitors present in the bone marrow, which migrate to peripheral tissues as immature cells and undergo differentiation *in situ*. Thus, unlike neutrophils, mature mast cells are not found in the circulation but are located throughout the body near blood vessels and nerves, beneath epithelia, and in lymphoid organs.

STRUCTURE AND TYPOLOGY

Mast cells have (1) a mononuclear nucleus, (2) numerous cytoplasmic granules containing mediators (including peptides, proteins, proteoglycans, and amines, and (3) a plicated cell membrane. The cell membrane contains a number of receptors for important regulatory compounds, such as growth factors, activators of secretion (e.g., receptors for the Fc portion of the IgE molecule), and receptors for adhesive molecules that enable the mast cell to attach to certain sites.

Mast cells can be differentiated into two types, those found in mucosa and those found in connective tissue. These two phenotypes are relatively easy to distinguish in rodents because they stain differently, differ in size, and are found in different tissues. GI mucosal mast cells have chondroitin sulfate as their major granule proteoglycan and contain little histamine. In contrast, connective tissue mast cells (found in the lungs and in the serosa of body cavities) have heparin as their major granule proteoglycan and produce large quantities of histamine.

Two techniques have enabled researchers to distinguish between the two types of mast cells in humans. One uses electron microscopy to examine the completeness of the scroll or whorl structure of the granule (only connective tissue mast cells

have a complete scroll). The other uses mAbs to identify mast cell subtypes on the basis of their constituent protease enzymes. All human mast cells contain tryptase, but only connective tissue mast cells contain chymase. Furthermore, there are a number of chymase isotypes that are unique to particular organs, which suggests that the pattern of mediators produced by mast cells might vary with anatomic location.

ACTIVATION

In diseases associated with mast cell activation, increases in the total number of mast cells and variations in the relative abundance of mast cell phenotypes occur at different tissue sites. The best understood immunologic stimulus of mast cell activation is an immune IgE complex. Other important immunologic triggers are cytokines and various histamine-releasing factors generated by neutrophils, platelets, mononuclear leukocytes, and macrophages as a consequence of the immune response.

Numerous nonimmunologic stimuli are also important in mast cell activation associated with wheal-and-flare reactions. Such stimuli include the complement fragments C3a, C4a, and C5a; various neuropeptides, including calcitonin gene-related peptide; substance P; neurotransmitters; and drugs. These nonimmunologic activators are generally more effective on connective tissue mast cells than on mucosal mast cells.

When mast cells are activated, their granules move to the surface, dissolve, and release their contents. Some of these products (e.g., histamine and other low-molecular-weight components) are freely soluble; others (e.g., proteoglycans, enzymes, and larger proteins) are poorly soluble. Differential release of these materials may have a bearing on the mast cell's role in disease.

ROLE IN ACUTE LUNG INJURY

The central role played by mast cells in the immediate hypersensitivity reaction has long been known. In the lung, this reaction is typically manifested either by an asthma attack or by a more generalized systemic hypersensitivity reaction (i.e., anaphylactic shock).

Asthma is characterized by paroxysms of bronchial constriction and increased production of thick mucus, which leads to bronchial obstruction and exacerbation of respiratory distress. The smooth muscle in the airway is often hypertrophied and hyperreactive to constricting stimuli. Anaphylactic shock is characterized by vasodilation and exudation of plasma in vascular beds throughout the body, usually resulting from the presence of a triggering antigen that gains systemic access via injection, an insect sting, or absorption across an epithelial surface (e.g., skin or GI mucosa). The decrease in vascular tone and leakage of plasma lead to a fall in blood pressure that may be fatal. The cardiovascular effects are complicated by constriction of the musculature surrounding the upper and lower airways, increased mucosal reactivity with outpouring of mucus in the gut and the respiratory tract, and urticarial lesions on the skin.

In both asthma and anaphylaxis, mast cell activation takes place in response to an immunologic trigger. Specifically, IgE antibody insertion on mast cell surface Fc ϵ receptors leads to the production and release of inflammatory mediators. Mast cell-derived leukotrienes and PAF are thought to be major mediators of acute airway constriction. In addition, mast cell-derived cytokines (e.g., TNF- α , IL-4, and IL-5) are thought to be the major factors causing sustained airway inflammation via the recruitment of eosinophils and basophils.

Nonimmunologic mechanisms may also play a part in mast cell-mediated lung injury. In one study, when pulmonary alveo-

lar mast cells were exposed to hypoxia, they released their granules, thereby causing lung injury.⁹³ Perivascular mast cells from the hypoxic lungs showed none of the morphologic changes associated with IgE-mediated mast cell degranulation, such as granule swelling, fusion, and exocytosis.

In a murine model of hindlimb ischemia-reperfusion that made use of two congenic animal strains, one mast cell-sufficient and the other mast cell-deficient, it was demonstrated that pulmonary mast cells mediated neutrophil sequestration and pulmonary edema, probably through the production and release of leukotrienes.⁹⁴ Vagal efferent nerves appeared to play an important role in the induction of remote lung injury after hindlimb ischemia; in this setting, bilateral cervical vagotomy limited mast cell degranulation and associated lung injury.⁹⁵

Vagal mechanisms also appear to play a key role in mast cell activation in a murine model of acid aspiration.⁹⁶ Blocking substance P, a neuropeptide released at the end of C-fibers located near mast cells, modified the lung injury; the C-fibers travel with vagal nerves. A similar benefit was obtained by using the chymase antagonist chymostatin, which blocked the effect of a key mast cell secretory product. The reduction in injury achieved with these two approaches was the same as the injury reduction observed in mast cell knockout mice.⁹⁶ This similarity suggested that the final common pathway of lung damage in aspiration was activation of the alternative complement pathway. These data indicate that vagal stimulation with release of substance P leads to release of mast cell-derived chymase that triggers activation of the alternative complement pathway, thereby causing aspiration lung injury.

Eicosanoids

Eicosanoids are vasoactive and immunomodulatory derivatives of membrane fatty acids that can be produced by virtually all cells in the body. They may be divided into three major subgroups: prostaglandins, thromboxanes, and leukotrienes. These agents are not stored but are rapidly synthesized in response to signaling stimuli. After release, they act in an autocrine and paracrine fashion. They have very short half-lives (largely because of their susceptibility to spontaneous hydrolysis or active enzymatic conversion to inactive metabolites) and thus rarely act as circulating hormones.

Prostaglandins were discovered in the 1930s by von Euler when a substance in human semen was found to cause myometrial contraction. The active agent, an acidic lipid, was thought to be a product of the prostate gland and hence was named prostaglandin. The next major observation was the description of the slow-reacting substance of anaphylaxis (SRS-A) in the early 1940s. Thromboxanes were discovered in 1975 and leukotrienes in 1979. In 1980, SRS-A was identified as a combination of the three cysteinyl leukotrienes: LTC₄, LTD₄, and LTE₄.

FORMATION

Liberation of Arachidonic Acid

Arachidonic acid (eicosatetraenoic acid), the major substrate for eicosanoid synthesis, is a long-chain polyunsaturated fatty acid that is incorporated into the phospholipid mammalian cell membrane. It is also present in plasma, but it is tightly bound to plasma proteins and therefore biologically unavailable. The first step in eicosanoid synthesis is liberation of arachidonic acid from the cell membrane. An agonist binds to the membrane receptor, causing activation of the enzyme phospholipase C, which generates

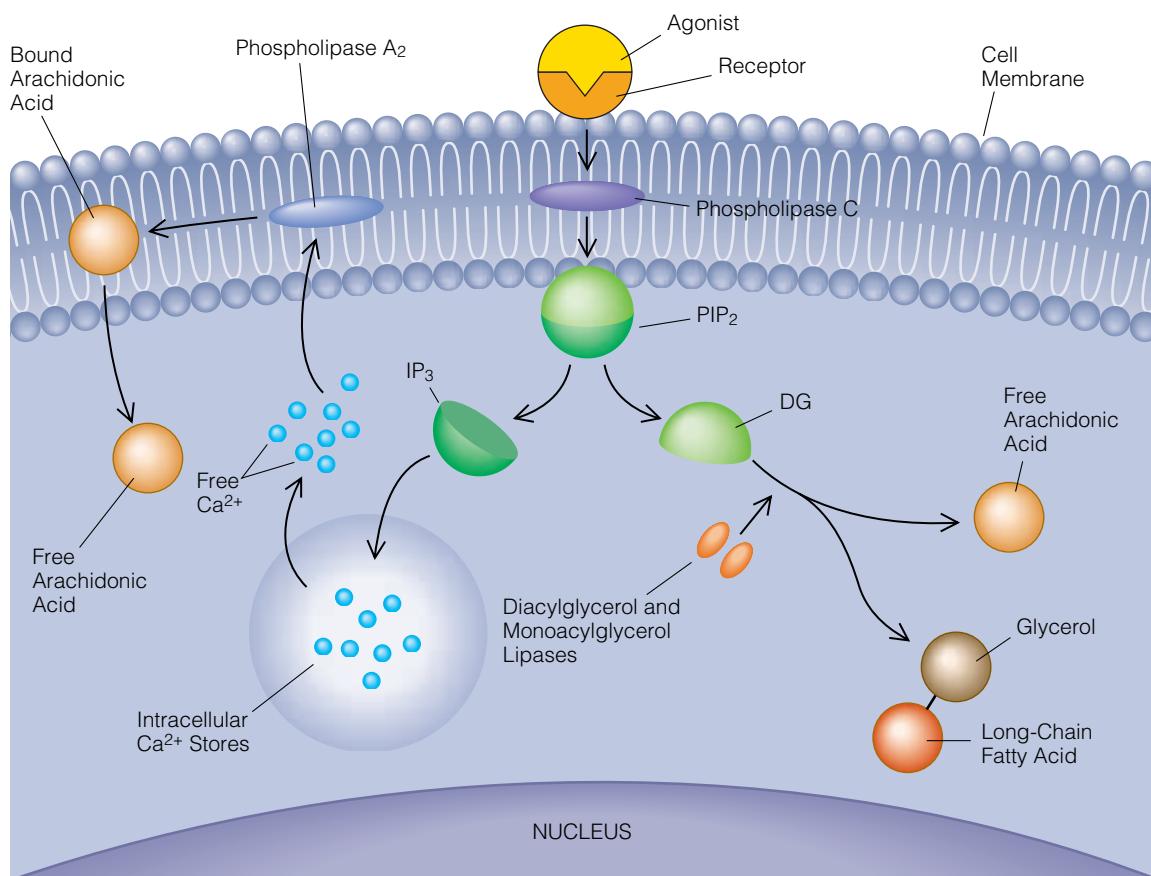

Figure 9 Shown is the production of free arachidonic acid in the cytosol. The binding of an agonist to a receptor activates phospholipase C, which hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP₂) to inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol (DG). From this point, free arachidonic acid can be generated in two ways. First, IP₃, by increasing the intracellular calcium ion concentration, activates phospholipase A₂, which then liberates arachidonic acid from the cell membrane. Second, DG is broken down enzymatically into several products, one of which is arachidonic acid.

free arachidonic acid via the production of the intracellular second messengers inositol triphosphate and diacylglycerol. These messengers, in turn, activate phospholipase A₂ [see Figure 9].

Phospholipase activation is a crucial step in arachidonic acid liberation; in fact, it serves as the rate-limiting step in all eicosanoid production. Once freed, arachidonic acid is metabolized via two pathways. The cyclooxygenase pathway produces prostaglandins and thromboxanes (collectively referred to as prostanoids), and the lipoxygenase pathway, present in cells of myeloid origin, produces leukotrienes.

Cyclooxygenase Pathway

All cells except nonnucleated red cells are capable of generating cyclooxygenase products. Two related but distinct cyclooxygenase isozymes have now been identified, COX-1 and COX-2. COX-1 is constitutively present in cells, and its products are considered to have housekeeping functions (e.g., gastric mucosal protection). COX-2 is an inducible enzyme that is rapidly upregulated in response to various immune and inflammatory mediators (e.g., cytokines, growth factors, and tumor promoters), and its products play a more inflammatory role [see Figure 10]. Admittedly, this polarized view of the functions of COX-1 and COX-2 products is somewhat oversimplified; nevertheless, we believe it is useful for the purposes of general discussion.

Both COX-1 and COX-2 convert arachidonic acid into an endoperoxide, prostaglandin G₂ (PGG₂), which in turn is con-

verted to PGH₂. PGH₂ is then metabolized by different pathways to prostaglandins, prostacyclin (PGI₂), and thromboxanes [see Figure 11].

Cells typically synthesize one or two COX products, depending on the enzymes they express. Platelets, for example, produce thromboxane A₂ (TXA₂) through the action of thromboxane synthetase, whereas endothelial cells primarily produce PGI₂ through the action of prostacyclin synthetase.

Six cyclooxygenase products are currently in widespread use in clinical settings. Alprostadil (PGE₁) is used for its smooth muscle-relaxing effects; misoprostol, a synthetic analogue of PGE₁, is used for gastric cytoprotection; PGE₂ and latanoprost (PGF_{2α}) are used in obstetrics and gynecology; latanoprost is used in ophthalmology, and PGI₂ is used for its properties as a potent vasodilator and a moderate inhibitor of platelet aggregation. At present, however, greater clinical importance is attached to inhibition of the synthesis of cyclooxygenase products by means of nonsteroidal anti-inflammatory drugs (NSAIDs) and selective COX-2 inhibitors, which act as anti-inflammatory and analgesic compounds [see Therapeutic Implications, Cyclooxygenase Inhibition with NSAIDs and COX-2 Antagonists, below].

Lipoxygenase Pathway

There are several differences between the cyclooxygenase and lipoxygenase pathways. Unlike cyclooxygenase, which is ubiquitous, lipoxygenase is present only in inflammatory cells.

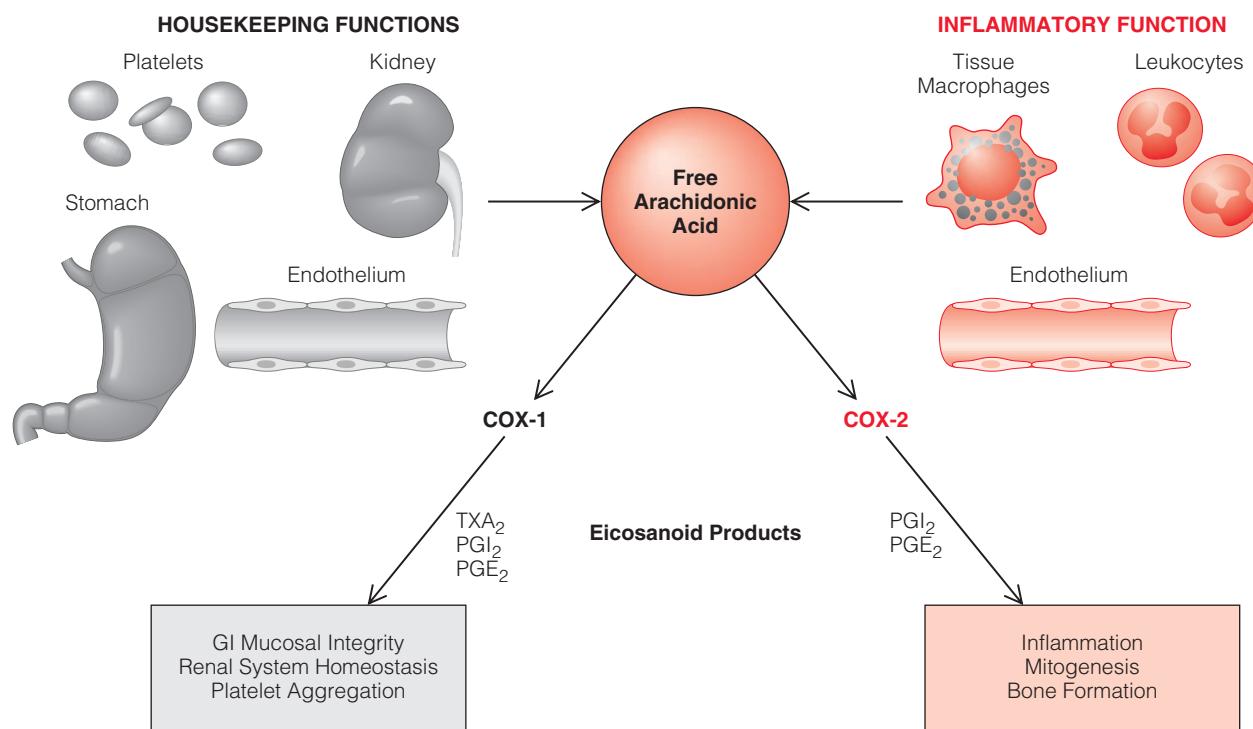

Figure 10 The products of COX-1 tend to have so-called housekeeping functions. This enzyme is constitutively present in cells. In contrast, the COX-2 enzyme is induced in cells in response to inflammatory stimuli. The products of both enzymes tend to cause inflammation.

Furthermore, whereas cyclooxygenase is always active, requiring only the presence of arachidonic acid for endoperoxidase production, lipoxygenase is quiescent and must be activated for leukotriene synthesis to occur. Activating stimuli for the lipoxygenase pathway include GM-CSF, C5a, and fMLP.

In the lipoxygenase pathway, liberated arachidonic acid is converted to 5-hydroperoxyeicosatetraenoic acid (5-HPETE) by 5-lipoxygenase (5-LO). This same enzyme then converts 5-HPETE into LTA₄, which then is either metabolized by LTA₄ hydrolase to LTB₄ or conjugated by LTC₄ synthetase with reduced glutathione to form LTC₄. LTC₄, in turn, is converted into LTD₄ and LTE₄ [see Figure 11].

LTA₄ may diffuse extracellularly and be taken up by cells that possess LTA₄ hydrolase and LTC₄ synthetase (e.g., erythrocytes and endothelium), with the result that leukotrienes may be produced by nonmyeloid cell lines that do not possess 5-LO and thus do not ordinarily generate leukotrienes. This process can amplify the inflammatory response.

PROSTAGLANDINS

There are nine prostaglandin groups: A, B, C, D, E, F, G, H, and I. With some prostaglandins (e.g., PGA₂), the letter refers to the chemical structure of its five-member ring. With others, however, the letter means something else: for example, E originally stood for "ether" and F for "phosphate buffer," which were the substances in which PGE and PGF were most readily soluble. Within a prostaglandin group, the subscript numerals 1, 2, and 3 are used to indicate the number of unsaturated double bonds present in the two side chains. Finally, the subscript Greek letters α and β are used to indicate the spatial orientation of the hydroxyl groups on the side chains in relation to the ring.

Prostaglandins primarily exert their effects on the smooth muscle of the GI tract, the airways, the vasculature, and the

reproductive tract; however, they also play important roles in platelet regulation and in the nervous system. Their main biologic actions may be summarized as follows:

1. Effects on the vasculature. PGI₂ is a vasodilator that is synthesized by both smooth muscle and endothelial cells in response to agents such as bradykinin, thrombin, serotonin, platelet-derived growth factor, and IL-1. Its actions are essentially antagonistic to those of TXA₂: it causes vasodilatation, inhibits platelet aggregation, and is thought to control the release of tissue plasminogen activator. In contrast, PGF_{2 α} is a potent vasoconstrictor.
2. Effects on the nervous system. PGE₁ and PGE₂ are responsible for the increase in body temperature associated with inflammation. Their synthesis in the hypothalamus is promoted by TNF and IL-1 (also known as endogenous pyrogen), which are released by phagocytes in response to viruses, bacteria, fungi, endotoxin, and antigen-antibody complexes. PGE₂ also exerts a strong hyperalgesic effect: it increases sensitivity to a variety of mechanical and chemical pain stimuli, with additive effects occurring over time and with increasing concentration. At high concentrations, PGE₂ can even stimulate nociceptive nerve endings directly.
3. Effects on the renal system. PGE₁, PGE₂, and PGI₂ increase the glomerular filtration rate and moderate renal blood flow by means of local vasodilatation. They also increase sodium and water excretion, though the mechanisms by which they do so are unclear.
4. Effects on the GI tract. Prostaglandins play a central role in gastric epithelial defense and repair and are produced in large amounts by the gastric mucosa. Most of them induce contraction of GI smooth muscle. Specifically, PGE₂ and PGF_{2 α} contract longitudinal smooth muscle, whereas PGI₂ and

- PGF_{2α} contract circular smooth muscle. Administration of these agents causes colicky abdominal pain.
5. Effects on the respiratory tract. PGE₁, PGE₂, and PGI₂ relax respiratory smooth muscle, and PGF_{2α} contracts it.
 6. Effects on the reproductive system. Prostaglandins have potent effects on the uterus and the cervix, moderating uterine contraction during delivery. Although they were originally discovered in semen, their function there remains unknown.

THROMBOXANES

TXA₂, originally called rabbit aortic contracting substance, was identified in 1975 as an agent that contracted vascular smooth muscle and caused platelet aggregation.⁹⁷ In picogram amounts, it exerts five major biologic effects.

1. Vasoconstriction. TXA₂ is one of the most potent naturally occurring constrictors of smooth muscle. It acts on virtually all vascular beds, but its effects are particularly prominent in small arteries and arterioles.
2. Bronchoconstriction. TXA₂ exerts a marked spastic effect on tracheal rings and pulmonary parenchymal strips and causes bronchoconstriction in intact animals.
3. Enhanced platelet aggregation. TXA₂ activates platelets, inducing aggregation with subsequent stimulation to synthesize and release more TXA₂. This autocrine action leads to further platelet activation.
4. Increased membrane permeability. TXA₂ increases vascular endothelial permeability, possibly via restructuring of the endothelial cytoskeleton. It also causes the breakdown of actin microfilaments, leading to increases in intercellular junction size and loss of microvascular barrier function.
5. Neutrophil activation. TXA₂ is both a chemoattractant and chemoactivator of neutrophils; accordingly, it increases neutrophil oxidative activity and diapedesis.

TXA₂ is usually produced at low baseline concentrations; however, there are a number of triggers that can rapidly

increase its synthesis and release from platelets or white blood cells. The presence of thrombin or contact with collagen can stimulate release of TXA₂ from platelets, and cytokines, complement fragments, and PAF all can directly stimulate release of TXA₂ from white blood cells. Thus, clinical situations associated with increased thromboxane production include vascular injury; arteriosclerosis; conditions associated with complement activation, such as sepsis, dialysis, and ischemia; and cytokine production.

TXB₂ is the metabolite of TXA₂, produced via nonenzymatic hydrolysis. Although it is only one tenth as potent as TXA₂, it does have some degree of biologic activity (e.g., enhancement of endothelial permeability, activation of neutrophils, and promotion of neutrophil diapedesis).

LEUKOTRIENES

Leukotrienes derive their name from their origin and their chemical structure: they are products of leukocytes that have a conjugated triene as their common structural feature. They can be divided into two classes on the basis of differing biologic actions: (1) LTB₄ and (2) the cysteinyl leukotrienes (LTC₄, LTD₄, and LTE₄). The most important actions of the leukotrienes have to do with their central role in allergic and inflammatory diseases.

The primary effects of LTB₄ are neutrophil chemotaxis and activation. Neutrophils activated by LTB₄ exhibit increased oxidative activity, granule release, and enhanced integrin expression. LTB₄ is also weakly chemotactic for eosinophils. The primary effects of the cysteinyl leukotrienes are bronchoconstriction and stimulation of mucus secretion. LTC₄ and LTD₄ are 1,000 times more potent than histamine at causing smooth muscle contraction in human bronchi. LTE₄ also causes bronchoconstriction, but it is less potent. All of the cysteinyl leukotrienes are potent mucus secretagogues. They also contribute to plasma extravasation and tissue edema by increasing vascular permeability.

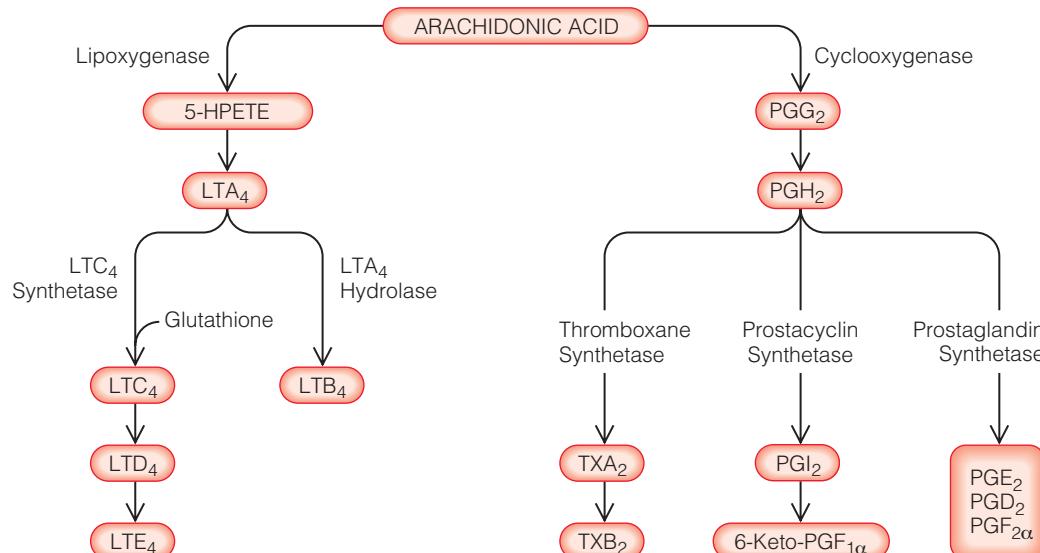

Figure 11 Arachidonic acid is metabolized by two different enzymes, cyclooxygenase (including both COX-1 and COX-2 variants) and lipoxygenase. The products of cyclooxygenase are the prostaglandins and the thromboxanes; the products of lipoxygenase are the leukotrienes.

THERAPEUTIC IMPLICATIONS

Antileukotrienes in Asthma

It is now recognized that the pathogenesis of asthma is more complicated than was previously realized: airway smooth muscle contraction in response to an irritant is only part of a larger overall picture. Asthma has been defined as "a chronic inflammatory disease of the airways,"⁹⁸ in which many cells and cellular elements are involved, particularly mast cells, eosinophils, T cells, neutrophils, and epithelial cells.

Leukotrienes have been shown to play a major role in asthma, producing the characteristic pathophysiologic signs (bronchoconstriction, mucus, airway edema, and cellular infiltration). The clinical manifestations of asthma can be reproduced by administering leukotrienes. Furthermore, increases in bronchoalveolar lavage and urinary leukotriene concentrations have been documented in patients with asthma.⁹⁹

These findings have led to the development of a new class of antiasthma drugs, the antileukotrienes. Two types of antileukotrienes are now in clinical use. The first type, currently exemplified by zafirlukast and montelukast, acts through competitive antagonism of the cysteinyl leukotriene receptor, thereby blocking the action of LTC₄, LTD₄, and LTE₄. The second type, of which zileuton is the only example currently available, competitively inhibits 5-LO, thereby blocking all leukotriene synthesis. Both types are highly effective at moderating asthma: their use leads to improved airway function, less frequent nighttime awakenings, fewer episodes of asthma exacerbation necessitating steroid therapy, and lower required dosages of inhaled steroids. An additional benefit of the antileukotrienes is their ease of use: they are orally administered, are well tolerated, and need be taken only once or twice daily.¹⁰⁰ Routine use of these agents is now recommended as part of the multitiered pharmacologic approach to asthma management.

Whether the antileukotrienes might also be useful in the management of other inflammatory disease states is currently under investigation. Preliminary reports suggest that they might someday play a part in the management of rheumatoid arthritis, systemic lupus erythematosus, urticaria, and atopic dermatitis.

Exogenous Prostaglandins in Obstetric and Gynecologic Settings

Prostaglandins are potent stimulators of myometrial smooth muscle contractility, as are other prostanoids (e.g., TXA₂ and eicosatetraenoic acid). These mediators are thought to play an important—though not yet fully explained—role in normal fetal delivery. Concentrations of certain prostanoids and their metabolites are known to increase before the onset of spontaneous labor and continue to increase during birth. NSAIDs, which inhibit prostanoid synthesis, are known to reduce myometrial contractions and delay or even prevent labor.¹⁰¹ PGE₂ and PGF₂ also induce the cervical ripening that must occur before normal delivery.

Prostaglandin receptors are present on myometrial tissue throughout gestation, unlike many other receptors, such as those for oxytocin, which are only induced in the latter phase of pregnancy. Consequently, therapy with prostaglandins is possible throughout pregnancy. Gemeprost (the methyl ester of PGE₁) and dinoprostone (PGE₂) are currently approved for cervical ripening and labor induction. When given vaginally, they are safe and effective, posing no risk to the fetus even though they cross the placental barrier. These agents are safe in promoting first- and second-trimester terminations, whether used alone or given in combination with mifepristone or methotrexate; moreover,

they are effective for inducing cervical softening before surgical termination of pregnancy.

Cyclooxygenase Inhibition with NSAIDs and COX-2 Antagonists

Management of inflammation Histologically, acute inflammation is characterized by vasodilatation, edema, and early neutrophil accumulation. Production of eicosanoids at the inflammatory site by damaged vessels, leukocytes, and platelets leads to vasodilatation (caused by PGI₂ and PGE₂), increased vascular permeability (caused by TXA₂ and leukotrienes), and neutrophil recruitment and activation (caused by LTB₄ and TXA₂). In addition, LTB₄ is a potent stimulus for production of the proinflammatory cytokines IL-1 and TNF, and PGE₂ gives rise to pain. Eicosanoids have been implicated in the pathophysiology of many inflammatory diseases, including rheumatoid arthritis, ulcerative colitis, Crohn disease, and asthma.

The use of NSAIDs to treat the symptoms of inflammation is a long-standing practice. NSAIDs counteract inflammation by inhibiting cyclooxygenase, thereby decreasing the synthesis of all prostanoids and exerting antipyretic and analgesic effects. NSAIDs are routinely used in the management of chronic inflammatory diseases such as rheumatoid arthritis and are among the most widely prescribed drugs for musculoskeletal conditions and pain. By inhibiting cyclooxygenase, NSAIDs may also effectively redirect arachidonic acid into the lipoxygenase pathway, thus indirectly increasing leukotriene synthesis. This redirection is hypothesized to be the mechanism by which aspirin can trigger asthma in susceptible individuals.

Regulation of blood flow Eicosanoids modulate blood flow to organs and tissues by adjusting local balances between production of vasodilators and production of vasoconstricting components. Loss of these controls, such as occurs when age, diabetes, or atherosclerosis decreases the capacity of the vascular endothelium for PGI₂ production, may impair normal regulatory mechanisms. For example, in occlusive vascular disease, ischemia may cause elevated TXA₂ levels by stimulating the synthesis of TXA₂ by neutrophils and platelets. This would explain why output of TXA₂ is significantly elevated in the clinical settings of unstable angina and acute myocardial infarction and variably elevated after cerebrovascular accidents. Without enhanced PGI₂ production, the resulting vasoconstriction and platelet aggregation may exacerbate ischemia in these settings.

Aspirin, alone among the NSAIDs, causes irreversible methylation of COX-1 and COX-2. It is 50 to 100 times more potent at the COX-1 site than at the COX-2 site. Accordingly, it is capable of permanently eliminating platelets' ability to produce TXA₂, even when given only once daily in low doses; however, to antagonize COX-2, which is largely responsible for inflammation, much higher and more frequent doses are necessary. Platelets, being nonnucleated, are unable to resynthesize COX-1 and COX-2. Because somewhat less than 10% of the platelet population is turned over each day, it takes several days for platelet production of prostanoids to return to normal levels. Nucleated cells, on the other hand, rapidly resynthesize COX-1 and COX-2 enzymes and thus can resume producing prostaglandins a few hours after aspirin administration.

Aspirin, therefore, is antithrombotic when given in small amounts and at wide intervals. When so used, it permits synthesis of vasodilating, antithrombotic prostaglandins while inhibiting platelet synthesis of thromboxane. Accordingly, aspirin has been widely applied to the management of atherosclerotic dis-

ease. One large international trial reported that in patients who took a single 162.5 mg tablet of aspirin daily, starting within 24 hours of a suspected myocardial infarction and continuing for 5 weeks, mortality was reduced by 23%, the incidence of nonfatal reinfarction by 49%, and the incidence of nonfatal stroke by 46%, with no increase in the incidence of either GI bleeding or hemorrhagic stroke.¹⁰² It is now believed that long-term low-dose (75 to 180 mg/day) aspirin therapy may benefit all persons who have unstable angina, have a history of myocardial infarction, or are at risk for ischemic stroke, as well as many other persons at high risk for atherosclerotic events.

Prostaglandins also play an essential role in regulating neonatal circulatory changes. Very soon after birth, the fetal ductus arteriosus starts to contract, thereby reducing the size of the large vascular shunt present in the fetus, which diverts 90% of right ventricular output away from the lungs and into the aorta. In approximately 20% of full-term infants, the ductus arteriosus is functionally closed at 24 hours post partum, and in all, the ductus is closed at 96 hours. The ductus is extremely sensitive to the vasodilatory action of PGE₂. Normally, the high circulating fetal concentration of this prostaglandin decreases after birth; however, in preterm, low-birth-weight infants, this decrease does not occur, and thus the ductus does not close. In these instances, administration of indomethacin is a safe and effective way of promoting duct closure.¹⁰³

There are, however, two groups of patients in whom maintenance of a patent ductus arteriosus is necessary: (1) newborns whose systemic blood flow depends on shunting from the pulmonary artery to the aorta (e.g., those who have an interrupted aortic arch) and (2) newborns whose pulmonary blood flow depends on shunting from the aorta to the pulmonary artery (e.g., those who have pulmonary valve atresia). For both groups, infusions of PGE₁ have proved highly beneficial, enabling resuscitation and stabilization even in the face of major respiratory and electrolyte disturbances.

Prevention of tumors An exciting new potential therapeutic use of NSAIDs derives from epidemiologic studies that document a reduced incidence of colorectal carcinoma in subjects taking aspirin. Of the more than 90 rodent studies of carcinogen-induced and genetically induced colorectal tumors carried out to date, the majority showed definite decreases at all stages of tumorigenesis with NSAID therapy.¹⁰⁴ The results from observational human studies suggest that NSAID therapy is associated with approximately a 40% relative risk reduction with respect to the incidence of colorectal carcinoma. This issue should be clarified further when the results of three ongoing phase III clinical trials of aspirin in colorectal carcinoma prevention become available. COX-2 antagonists have been less well studied, but there is some evidence suggesting that such agents may modify the growth of bladder tumors.

Precisely how NSAIDs exert their antitumor effects is not yet fully understood. Colorectal carcinomas are known to overexpress COX-2 and PGE₂,¹⁰⁵ and it is possible that these agents act to promote cellular proliferation and inhibit cell apoptosis, thereby giving rise to cancer. PGE₂, the eicosanoid most prevalent in GI tissue, has immunosuppressive effects that may reduce tumor surveillance.

Side effects of NSAIDs and development of COX-2 inhibitors The ability of aspirin to cause gastric ulceration and bleeding, originally documented in the first half of the 20th century, is now understood to be attributable to prostaglandin

inhibition. Endogenous prostaglandins play a central role in maintenance of the gastroduodenal mucosal defense barrier by regulating mucosal bicarbonate production, stimulating mucosal blood flow, and modulating epithelial cell proliferation. Oral therapy with misoprostol has proved effective in healing both gastric and duodenal ulcers.

The coxibs, of which rofecoxib and celecoxib are the best-known examples, were developed specifically with the aim of overcoming the ulcerogenic side effects of COX-1 antagonists. The coxibs selectively inhibit COX-2 and thus should be capable of exerting anti-inflammatory effects without interfering with the gastric protection afforded by COX-1 products. To date, they have been at least partially successful in achieving the desired aim. The coxibs are as effective as conventional NSAIDs at treating rheumatoid arthritis and osteoarthritis and reducing pain.¹⁰⁶ In addition, patients receiving coxibs show significantly lower rates of gastric ulceration than patients receiving conventional NSAIDs.¹⁰⁷ Use of coxibs is not, however, without drawbacks. These agents are associated with dyspepsia, though to a lesser degree than conventional NSAIDs are. Moreover, they exert the same delaying effect on ulcer healing that NSAIDs do; this is because both COX-1 products and COX-2 products are necessary for angiogenesis.

Another important side effect of NSAIDs is their nephrotoxicity, which results from interference with prostaglandin-mediated control of local renal vascular flow. PGE₂, PGI₂, and TXA₂ play important roles in regulating the glomerular filtration rate, especially in disease states such as shock, cirrhosis, and congestive heart failure. In these settings, there is a compensatory increase in renal PGE₂ production, leading to improved blood flow. Administration of NSAIDs may cause fluid retention. In addition, NSAIDs are responsible for 20% of cases of drug-induced acute renal failure. To date, the coxibs have not been shown to possess substantial advantages over NSAIDs in regard to nephrotoxicity: they appear to produce the same degree of fluid retention as conventional NSAIDs do, though it is possible that their effect on the glomerular filtration rate is less damaging.

Because TXA₂ is a COX-1 product, the coxibs do not inhibit thromboxane-mediated platelet aggregation. Therefore, it is unlikely that they will be able to reduce the thrombotic complications of vascular disease, as NSAIDs do. Indeed, a recent clinical report indicated that COX-2 inhibitors were associated with a slight but significant increase in myocardial infarction.

Dietary Fatty Acids

The long-chain polyunsaturated fatty acids that are the precursors of eicosanoids cannot be synthesized in the human body and must therefore be supplied through diet. In North America and western Europe, the primary dietary source for eicosanoid synthesis is linoleic acid, the precursor of arachidonic acid. Linoleic acid is found predominantly in vegetable oils. It and its derivatives are termed omega-6 fatty acids because the last of their four double bonds occurs at the sixth carbon atom from the methyl end of the chain. α-Linolenic acid, found in marine fish and to a lesser extent in green vegetables, is the precursor of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), which are also eicosanoid precursors. These substances are termed omega-3 fatty acids because their last double bond occurs at the third carbon atom from the methyl end of the chain.

The relative prevalence of the various fatty acid precursors has important clinical implications, in that higher proportions of one precursor or another will affect which eicosanoid products

are generated. For example, when EPA is the substrate for cyclooxygenase, TXA₃, which is biologically inactive, is produced; EPA also competitively binds cyclooxygenase, thereby reducing TXA₂ synthesis. However, PGI₃ synthesized from omega-3 fatty acids is fully active. In this setting, therefore, with thromboxane activity reduced but prostacyclin activity maintained, the overall effects are to increase platelet survival, to reduce platelet aggregation, and to increase bleeding time.

Interest in the possible clinical use of dietary omega-3 fatty acids came from the observation that Greenland Eskimos had a low incidence of myocardial infarction despite eating a high-fat diet.¹⁰⁸ Their plasma and platelet lipids were found to contain a high proportion of omega-3 long-chain polyunsaturated fatty acids. Furthermore, they had hypoaggregable platelets and increased bleeding times. The same effects were noted in other populations who were fed dietary supplements containing omega-3 fatty acids. The potential long-term benefits of increased omega-3 fatty acid intake were suggested by epidemiologic studies in the Netherlands and Japan that showed a reduced incidence of coronary artery disease in men whose diet contained a large amount of fish supplements.^{109,110} Subsequent randomized, controlled clinical trials demonstrated that dietary supplementation with either fish or fish oil conferred significant benefits on men who had recently had myocardial infarctions, reducing the risk of death and especially of sudden cardiac death. In particular, increased dietary intake of omega-3 fatty acids had a potent antidysrhythmic effect, apparently because incorporation of these substances into the myocyte cell membrane increased the stability and lengthened the refractory period of these cells.

Although the precise mechanisms underlying the protective effect associated with dietary omega-3 fatty acids have not been determined, it is likely that reduced TXA₂ production is a major contributor. Altered leukotriene biochemistry may also play a role: the main leukotriene synthesized from omega-3 fatty acids

is LTB₅, which is less active than LTB₄. Reduced synthesis of LTB₄ by neutrophils may underlie the observation that fish supplements reduce symptom severity in patients with rheumatoid arthritis. It has also been noted that fewer low-birth-weight children are born in northern European populations, who typically consume substantial amounts of fish, than in non-fish-eating populations. In animal studies, experimental subjects that either are deficient in omega-6 fatty acids or have been fed diets high in omega-3 fatty acid exhibit decreased prostaglandin synthesis and longer gestation periods.

It is believed that early hominids evolved on a diet containing roughly equal proportions of omega-3 and omega-6 fatty acids. In contrast, the typical diet in North America and western Europe today, which is high in dairy, meat, and fried foods, contains 10 to 25 times more omega-6 than omega-3 fatty acids. This relative deficiency of omega-3 fatty acids may be a major cause of the high rates of cardiac and inflammatory diseases recorded in the more developed areas of the world.

Conclusion

Inflammation is a highly complex process that involves many interacting systems, which may complement each other, antagonize each other, or both. A degree of redundancy is built in, so that antagonism of one pathway may lead to augmentation of another alternative inflammatory mechanism. Furthermore, simultaneous or sequential production of both proinflammatory and anti-inflammatory signals often occurs. Accordingly, the success of a therapeutic intervention depends not only on the type of injury or insult present but also on the timing of the intervention. Unfortunately, the clinical trials done to date, evaluating a host of anti-inflammatory agents of different classes, have been largely disappointing. For more successful therapies to be developed, much more information regarding the fundamental mechanisms of the inflammatory response will be needed.

The authors would like to acknowledge the work of Drs. Patrick M. Reilly, Susan A. Kelly, Henry J. Schiller, and Gregory B. Bulkley in a chapter entitled "Reactive Oxygen Metabolites," which appeared in previous versions of *ACS Surgery: Principles and Practice*. Some of their work served as the basis for the ROM section of the present chapter.

25 BLOOD CULTURES AND INFECTION IN THE PATIENT WITH THE SEPTIC RESPONSE

Donald E. Fry, M.D.

Approach to Blood Cultures in Patients with the Septic Response

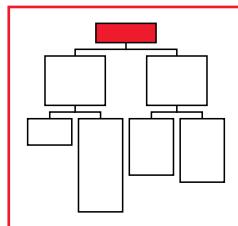

It has been well established that infection and sepsis are distinct events [see 8:14 *Clinical and Laboratory Diagnosis of Infection and Discussion, below*]. Infection is local activation of the human inflammatory response secondary to local proliferation and invasion of tissue by microorganisms. When infection reaches a critical threshold of severity, the inflammatory response may be activated at a systemic level. Systemic activation of inflammation is called the systemic inflammatory response syndrome (SIRS); when infection is the putative agent for SIRS, the resulting state is called sepsis.¹

SIRS secondary to infection occurs when (1) whole microorganisms are disseminated from the primary site of infection, usually via the vascular or lymphatic system (e.g., bacteremia); (2) structural components of the cell wall (e.g., gram-negative endotoxin) or secreted exotoxins are systemically disseminated (as in toxic shock); or (3) normal autocrine and paracrine proinflammatory signals (e.g., tumor necrosis factor [TNF]) from a severe local inflammatory focus reach high systemic concentrations, activating SIRS by virtue of their exaggerated endocrine domain of action.

Although biologic factors other than infection may cause SIRS and provoke a syndrome that is virtually identical to that resulting from invasive infection, infection is the most common cause of SIRS in acutely ill surgical patients. Effective management of infection in these patients requires recognition of the primary site of infection, control of the source of microbial contamination and dissemination (i.e., source control); characterization of the causative microorganism or microorganisms; drainage and debridement of inflammatory exudates and necrotic tissue at the primary site; and antibiotic therapy specific for the pathogen.

Positive Blood Culture with Infection

A positive blood culture in a patient with the septic response identifies the putative cause of the infection [see Table 1].² This identification not only permits institution of appropriate systemic antibiotic therapy [see Figure 1] but also facilitates assessment of potential primary sources of the infection because of the established associations between specific anatomic sites and specific microbial isolates. Although it is not always possible to identify

the microorganism or microorganisms responsible for the septic response, organization of the discussion according to the proven or suspected pathogen that may be recovered in a blood culture is a convenient way of addressing treatment options.

GRAM-POSITIVE COCCI

Staphylococci

The identification of gram-positive organisms from a blood culture immediately arouses suspicion that a *Staphylococcus* species is the likely pathogen. Because staphylococci ordinarily colonize the skin and integument, infection from those sources must be considered responsible for the bacteremia.

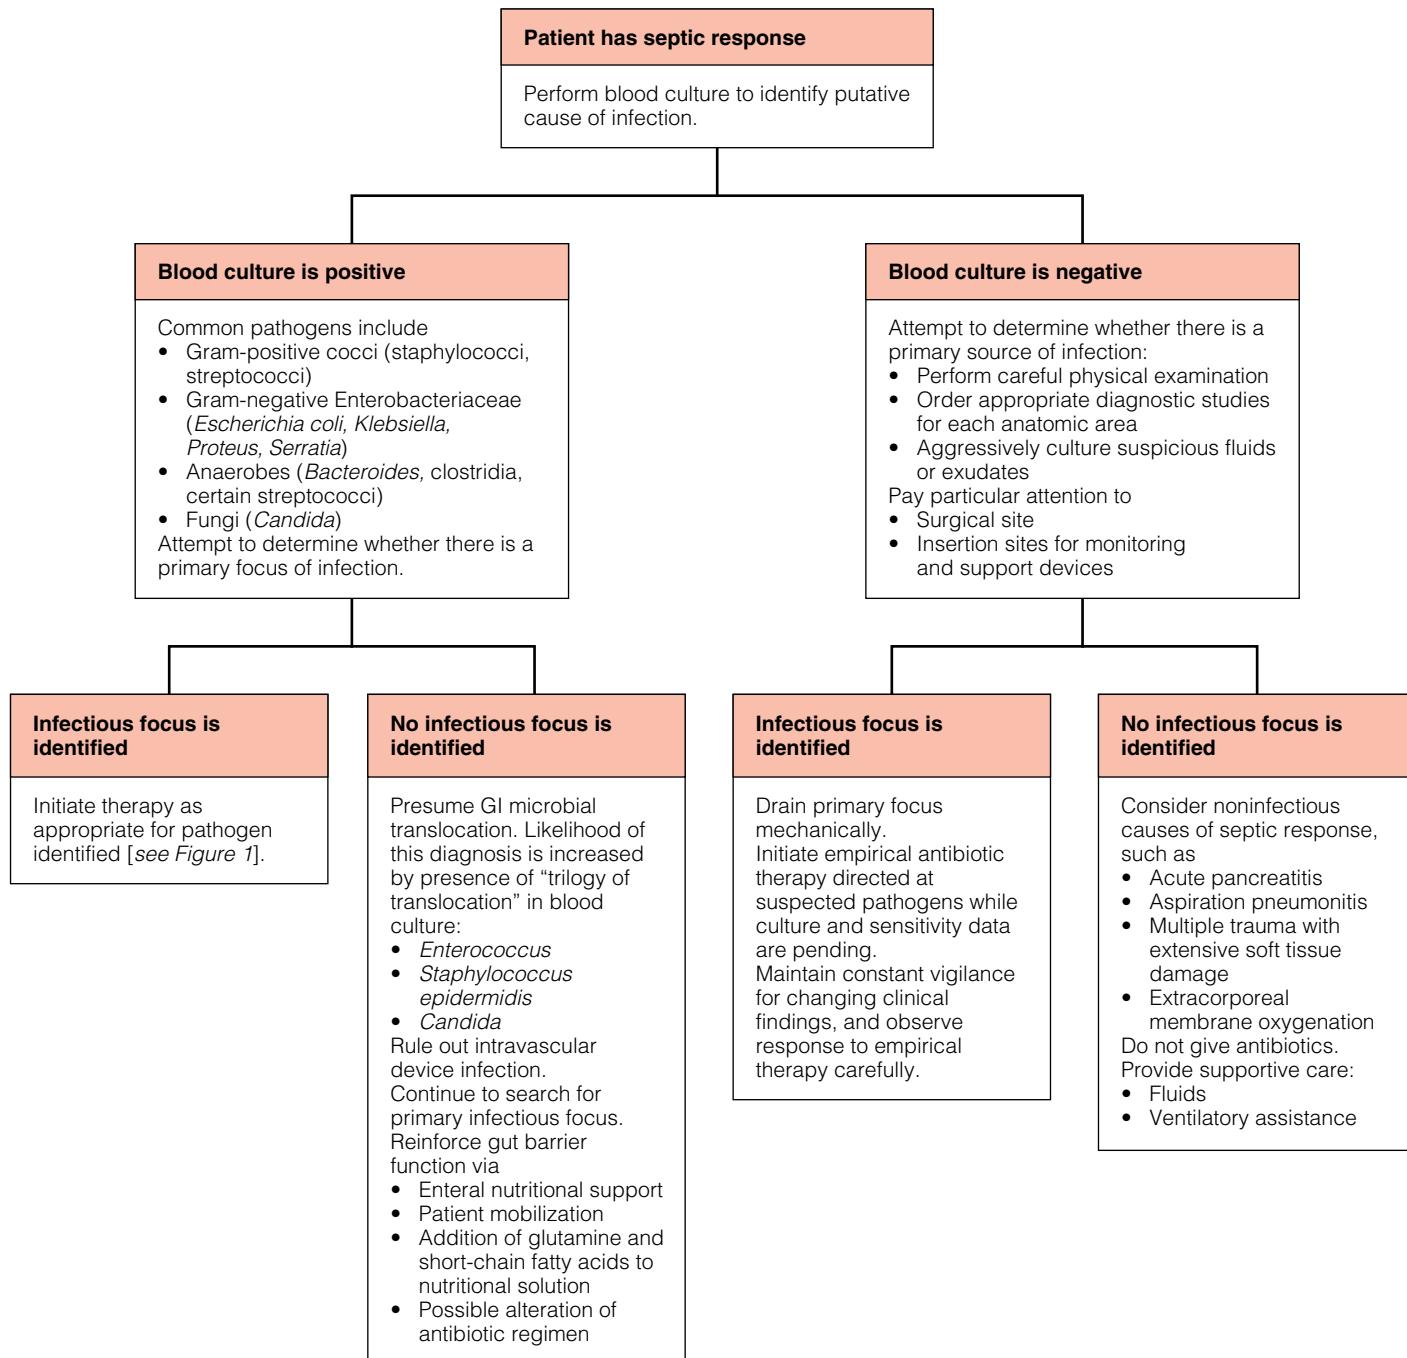

In surgical patients, a blood culture positive for staphylococci must be assumed to indicate infection arising from an intravascular device until proven otherwise [see Table 2].³ Peripheral I.V. catheters, subclavian lines, Swan-Ganz catheters, systemic arterial lines, and even transvenous pacemaker wires are all documented sources of staphylococcal bacteremia [see Table 3]. All lines must be removed and their sites changed. The line and catheter tips should be cultured by semiquantitative methods⁴ to document the role of the device in question [see 8:16 *Nosocomial Infection*]. Although this semiquantitative method uses a count of 15 colony-forming units as the threshold for a positive culture of the catheter, devices responsible for bacteremia will usually demonstrate a solid sheet of bacterial growth on the agar [see Figure 2].

Septic thrombophlebitis may occur at the site of a previously placed device even though the foreign body has been removed.^{5,6} Pus within the vein becomes a source of persistent bacteremia

Table 1 Most Common Nosocomial Bacteremia Pathogens Isolated from All Sites in 12,243 Patients²

Pathogen	Prevalence (%)
Coagulase-negative staphylococci	31.9
<i>Staphylococcus aureus</i>	15.7
<i>Enterococcus</i> species	11.1
<i>Candida</i> species	7.6
<i>Escherichia coli</i>	5.7
<i>Klebsiella</i> species	5.4
<i>Enterobacter</i> species	4.5
<i>Pseudomonas aeruginosa</i>	4.4
<i>Serratia</i> species	1.4

Approach to Blood Cultures in Patients with the Septic Response

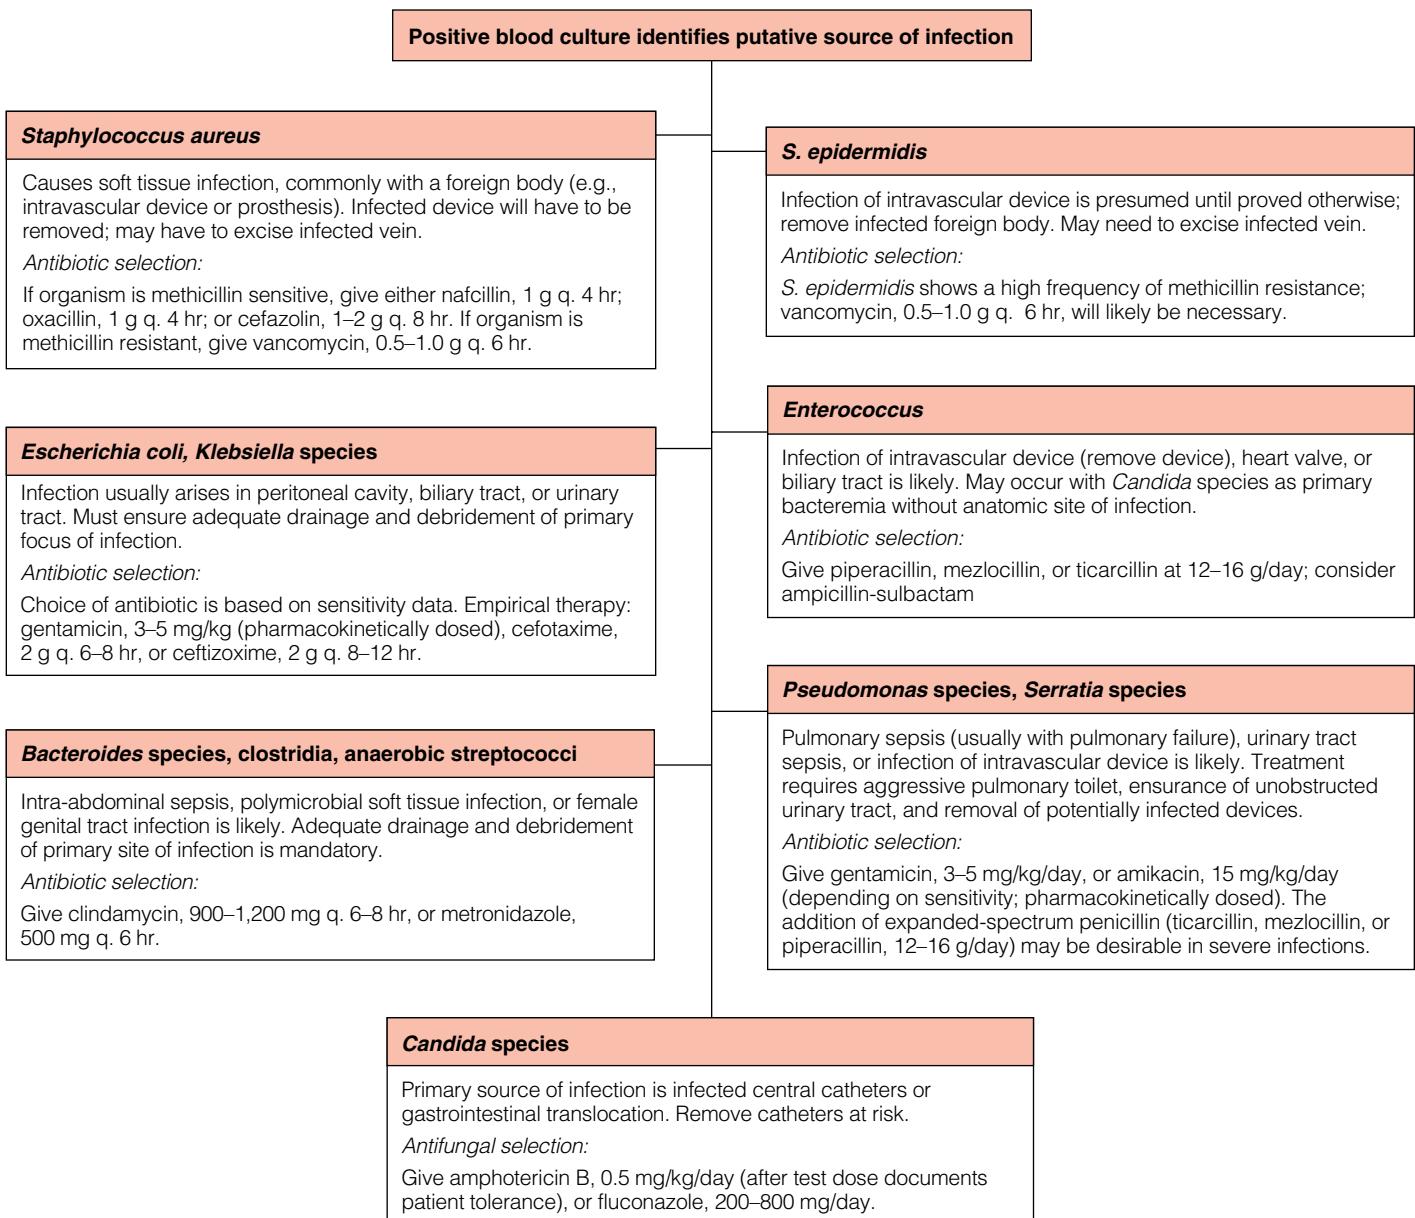

Figure 1 Identification of the putative cause of infection permits institution of appropriate antibiotic therapy.

until appropriate therapy is employed. Persistent evidence of gram-positive bacteremia after removal of all intravascular lines gives rise to a high index of suspicion for suppurative thrombophlebitis. Previous I.V. sites must be examined for evidence of pus; suspicious sites may even have to be explored with the patient under local anesthesia. When identified, the entire length of septic vein must be surgically excised. Although many different species of bacteria may be responsible for suppurative thrombophlebitis, *S. aureus* is decidedly the most common.

The implantable synthetic prosthetic materials that are now such a major part of vascular, cardiac, and orthopedic surgery may become sources of bacteremia secondary to infections resulting from intraoperative contamination. When gram-positive organisms are identified in the blood of a patient at risk, the synthetic implant should be considered the source of blood-borne infection. As the use of synthetic devices has increased, the

delayed nature of some infections, particularly those involving *S. epidermidis*, has become more readily apparent. These indolent infections are consequences of intraoperative contamination but may not be clinically evident for months to years after implantation. Because selected species of *S. epidermidis* produce biofilm,⁷ even culturing the microorganism from the infected prosthesis that has been removed can be very difficult, and recovery of the microorganism from a blood culture is quite uncommon in the period before the infection becomes clinically apparent.⁸

Diagnosis of arterial graft, heart valve, and total-joint arthroplasty infections can be very difficult. Once infection has been established, however, prompt removal of the prosthesis is mandatory. Removal of an actively infected prosthesis is invariably associated with major morbidity because the infection limits the reconstructive options available. Antibiotic therapy alone will not eradicate the infection, and it may lead to a delay in the decision to

Table 2 Pathogens in 159 Cases of Intravascular Device–Associated Bacteremia³

Organism	No. of Isolates

<i>Proteus</i> species	6
Others	6
Total	176*

*The total exceeds 159 because of polymicrobial isolates in several patients.

remove the prosthesis; this can result in arterial graft failure (e.g., thrombosis or pseudoaneurysm), cardiac valvular insufficiency, or extensive arthroplasty infection (e.g., extrusion or osteomyelitis).

Because *S. epidermidis* normally colonizes skin, it is also a potential contaminant in the blood culture process. Accordingly, close attention to proper culturing technique is crucial for minimizing this potential diagnostic artifact. A frequent cause of false positive cultures of *S. epidermidis* is use of the arterial line or the central venous catheter for drawing blood samples instead of a separate and carefully prepared venopuncture site. When more than one culture shows *S. epidermidis* or when cultures taken at separate times show the same organism, however, the clinician must assume that the organism is participating in clinical infection.

Staphylococcal bacteremia is a preventable complication of indwelling devices and implants. Aseptic placement of intravascular devices cannot be compromised. Peripheral I.V. catheters should be changed routinely every 48 to 72 hours. Arterial lines that have been in place for more than 72 hours are at considerable risk for being foci for bacteremia. Catheters devoted to parenteral nutrition must receive ongoing care to prevent septic morbidity [see 8:23 Nutritional Support].

The primary therapy for device-related infection is removal of the infected device. Systemic antibiotics cannot overcome the adjuvant effects of the foreign body in supporting bacterial growth. Antimicrobial therapy thus becomes adjunctive to removal of the primary nidus of infection.

To prevent infection from prosthetic implants, efforts must be made to minimize development of a microenvironment in the wound that favors bacterial proliferation. Meticulous technique, appropriate hemostasis, conservative use of the electrocautery, judicious use of suture ligatures, and antibiotics given immediately before operation will reduce infectious morbidity. Cefazolin, 1 g preoperatively, administered either I.V. (by prefer-

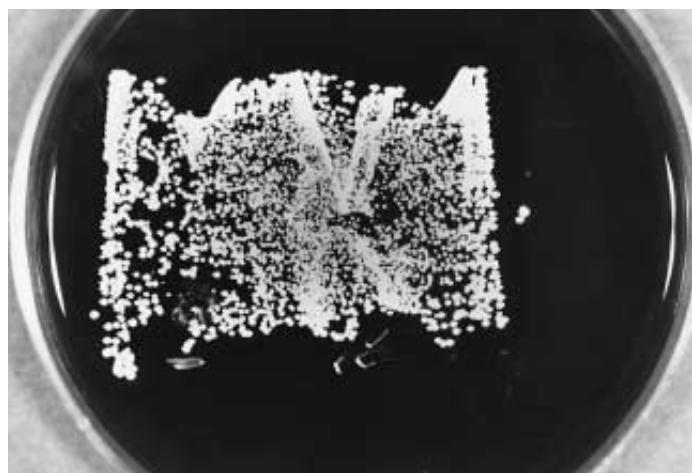

Figure 2 Illustrated is a blood agar plate 24 hours after an infected catheter has been cultured by semiquantitative technique. Although colony counts higher than 15 are associated with a positive culture, the prolific growth shown here is commonly seen.

ence) or intramuscularly, is the agent of choice [see 1:2 Prevention of Postoperative Infection]. With lengthy operations, repeat doses should be given at 4-hour intervals. Prolonged postoperative administration is of no value.

Methicillin-resistant staphylococci are becoming increasingly prevalent; in some series, they account for more than 50% of clinical isolates. Consequently, presumptive antimicrobial therapy for bacteremia arising from an intravascular or implantable device requires vancomycin, 1 g every 8 to 12 hours. If the patient is intolerant of or unresponsive to vancomycin, then either linezolid, 600 mg every 12 hours,⁹ or quinupristin-dalfopristin, 7.5 mg/kg every 8 to 12 hours,¹⁰ may be given instead. The antimicrobial choice may be modified when culture and sensitivity data subsequently become available. If methicillin-resistant species are not a concern, nafcillin, 1 g every 4 hours, is appropriate. Because of the risks of metastatic infectious complications from staphylococcal bacteremia, systemic antibiotics should be continued for a minimum of 7 days.

The toxic-shock syndrome, caused by *S. aureus*, gives the clinical impression of being a bacteremic illness.¹¹ However, positive blood cultures are uncommon with this syndrome because the SIRS is created by the exotoxin produced by the microorganism, not by bacteremia per se. Initially associated with vaginal tampons, the toxic-shock syndrome can be seen wherever body cavities or open wounds are filled with gauze or other packing. Diagnosis of this syndrome requires a high index of suspicion in the septic, hypotensive patient with body packing. Treatment requires removal of the packing, aggressive systemic supportive care of shock and associated organ failure, and systemic administration of suitable antibiotics.

Streptococci

Streptococcal bacteremia occurs less frequently than staphylococcal blood-borne infection, though some areas of the United States have experienced an apparent increase in these infections. Invasive group A streptococcal infections with bacteremia are seen in patients with necrotizing soft tissue infections, invasive pharyngeal infections, bone and joint infections, and severe and rapidly advancing pneumonia. About 20% of bacteremias with group A streptococci are without a primary source of infection¹² and probably arise from the oropharynx.

Table 3 Sites of Intravascular Device–Associated Bacteremia in 159 Patients³

Site	No. of Patients
Peripheral I.V. catheter	72
Central venous catheter	49
Arterial line	18
Subclavian dialysis catheter	12
Swan-Ganz catheter	4
Broviac catheter	3
Transvenous pacemaker wire	1

Necrotizing soft tissue infection is the most common setting for a positive blood culture with group A streptococci. These fulminant infections are seen after seemingly trivial cutaneous injuries but may also complicate chickenpox in children¹³ and may even be seen as complications of elective surgical wounds. The necrotizing infection is characterized by pain, tenderness, and induration around a wound that is out of proportion to the size or mechanism of the injury. The infection dissects along the fascial plane and can evolve from injury to a fatal illness in 24 hours. The diagnosis requires a high index of suspicion in a toxic patient with rapidly advancing cellulitis. The induration of the advancing infection may be palpable in thin patients and serves to distinguish this condition from clostridial gas gangrene. Necrotizing soft tissue infections are associated with a toxic-shock-like syndrome, but unlike patients with true toxic shock, these patients usually have blood cultures that are positive for group A streptococci.¹¹ Unfortunately, the positive blood culture result is not available until the patient's fate has already been dictated by earlier clinical decisions.

Therapy requires aggressive local debridement of necrotic tissue, systemic antibiotic therapy, and systemic supportive therapy for the shock and organ failure characteristic of severe infections. The recommended antibiotic regimen includes both penicillin, 12 to 24 million U/day, and clindamycin, 900 to 1,200 mg every 6 hours in adult patients. The addition of clindamycin is believed to reduce toxin production by inhibiting protein synthesis in the rapidly multiplying bacteria. Another reason why clindamycin is useful is that large inocula of group A streptococci are believed not to express penicillin-binding proteins.¹⁴

α -Hemolytic streptococcal bacteremia is well known in patients with endocarditis and is generally associated with this condition when blood cultures are positive for these organisms. Echocardiographic confirmation of the diagnosis sets the stage for treatment with penicillin. Therapy is continued until there is conclusive evidence that the infection has been eradicated.

Other groups of streptococci may be noted in positive blood cultures, usually reflecting infections secondary to GI contamination. Group B streptococci, long identified as bacteremic pathogens in neonates, are now being seen with greater frequency in adults. In adult bacteremia, group D streptococci are identified in circumstances similar to those associated with group B pathogens. Gut-derived streptococcal pathogens are usually quite sensitive to penicillins.

Enterococci

Although there is disagreement regarding the true virulence and pathogenicity of *Enterococcus* when it is isolated as part of the polymicrobial microflora of a clinical exudate,^{15,16} no one would deny the need for antimicrobial chemotherapy when it is isolated in blood cultures. Mortalities exceeding 40% clearly underscore the severity of enterococcal bacteremia, though it is likely that impaired host status contributes significantly to the poor outcome.

The primary foci of infection in enterococcal bacteremia include intravascular devices and the biliary and GI tracts. Enterococcal bacteremia ordinarily occurs in elderly or chronically ill patients receiving broad-spectrum antibiotics. Cephalosporins in particular have been implicated as favoring enterococcal overgrowth.¹⁷ *Enterococcus* is usually associated with other bacterial species at the primary site of intra-abdominal or soft tissue infection, and a synergistic relation with other organisms may be part of its pathogenic expression.^{18,19}

Therapy for enterococcal bacteremia requires definition of the primary infectious focus. When *Enterococcus* is a solitary isolate in

blood, I.V. devices should be changed and semiquantitatively cultured. Potential biliary sources must be evaluated, with all available clinical data, including those from ultrasound examination of the gallbladder [see 8:18 *Intra-abdominal Infection*], taken into account.

Gangrenous acalculous cholecystitis must be kept in mind because of the type of patient likely to have enterococcal bacteremia.²⁰ Intra-abdominal abscesses and serious soft tissue infections are customarily associated with polymicrobial isolates, which may include *Enterococcus*. The urinary tract, however, appears to be an infrequent cause of enterococcal bacteremia in the absence of anatomic obstruction of urine flow.

Once the primary focus has been identified, removal of the foreign body, drainage and debridement of infected material, and specific antibiotic therapy are indicated. Piperacillintazobactam, 3.375 g every 6 hours, is recommended. Although ampicillin appears to have nearly uniform activity against *Enterococcus* in vitro, the production of β -lactamase by synergistic pathogens in the polymicrobial milieu raises serious questions about the effectiveness of this choice. Addition of sulbactam to ampicillin improves enterococcal coverage in mixed infections.

In about 40% of patients with blood cultures positive for *Enterococcus*, no primary site of infection can be identified.²¹ This observation has led to considerable speculation as to whether this organism is a marker of microbial translocation from the gut [see Positive Blood Culture without Infection, below] or whether the infection derives from a clinically obscure primary focus (e.g., a catheter).

The emergence of vancomycin-resistant enterococci is a matter of great concern,²² and considerable effort has been expended on finding newer agents that are effective against these organisms.²³ Both linezolid, 600 mg every 12 hours,²⁴ and quinupristin-dalfopristin, 7.5 mg/kg every 8 to 12 hours,²⁵ have been successfully used in small treatment groups. The addition of rifampin may enhance the therapeutic effect.²⁶ Vancomycin resistance is mediated by two separate genes, and there is substantial concern in the academic community regarding the possible transfer of these genes into staphylococci or other gram-positive organisms.

GRAM-NEGATIVE ENTEROBACTERIACEAE

The gram-negative Enterobacteriaceae represent a group of facultative bacteria that are associated with infections of the abdominal cavity, the biliary tract, and the genitourinary tract. Infections tend to be monomicrobial when the urinary and biliary tracts are involved^{27,28} but are nearly always polymicrobial with peritonitis and intra-abdominal abscess.²⁹ The common gram-negative Enterobacteriaceae include *Escherichia coli*, *Klebsiella* species, *Enterobacter* species, and *Proteus* species. Because intra-abdominal infection is a polymicrobial process, bacteremia with one of these organisms in patients with such infection represents only the tip of the iceberg, with a polymicrobial flora presumed to be present at the focus [see 8:18 *Intra-abdominal Infection*].

In the surgical patient, eradication of gram-negative bacteremia requires identification of the primary focus. The intra-abdominal compartment must be the primary consideration. Ultrasound examination of the biliary tract may be useful. Abdominal computed tomography is approximately 90% accurate in defining abscess. Urinary cultures may be useful but must be cautiously interpreted because a well-drained urinary tract is an improbable focus for bacteremia. *P. vulgaris* is a urease-producing organism, and its presence in patients with ileal conduits

Table 4 Expanded-Spectrum β-Lactam Antibiotics Effective against Enterobacteriaceae

Drug	Half-life (hr)	Dose Interval (hr)	Total 24-Hr Dose (g)
Cephalosporins			
Cefoxitin	0.7–1.0	4–6	12–18
Cefotetan	3.5	12	2–4
Cefotaxime	1.0	6	8–12
Ceftizoxime	1.5	8	6
Ceftazidime	2.0	8	6

Aztreonam	2.0	8	6
Carbapenems			
Imipenem-cilastatin	1.0	6	2–4
Meropenem	1.0	6	2–4
Ertapenem	4.0	24	1

or staghorn calculi strongly favors a urinary tract source. Gram-negative bacteremia from hospital-acquired pneumonitis is always a possibility but is less common with the Enterobacteriaceae than with *Pseudomonas* or *Serratia* species. In general, bacteremia from nosocomial pneumonia is relatively uncommon in surgical patients. *Klebsiella* and *Enterobacter* species are known pathogens for bacteremia from intravascular devices; appropriate cultures of the primary device are necessary to establish this potential source.

Mechanical treatment is necessary at the primary focus of infection.³⁰ Defects in the GI tract must be managed, pus drained, necrotic tissue debrided, urinary obstruction relieved, and infected catheters removed. Empirical exploration of the abdomen may be necessary in bacteremic patients with a high index of suspicion for an intra-abdominal source, though at present, it is infrequently required, thanks to ongoing improvements in the technology used to visualize the abdominal compartment (i.e., CT).

Considerable latitude surrounds appropriate antibiotic therapy for gram-negative bacteremia, particularly when the bacteremia is secondary to intra-abdominal infection. When the infectious process is community-acquired, an expanded-spectrum β-lactam antibiotic is appropriate [see Table 4]. Although anaerobic coverage is a necessary prerequisite in intra-abdominal infection, the expanded-spectrum β-lactam agents appear to yield results equivalent to those of drug combinations that might appear to have superior anaerobic activity. Furthermore, single-agent treatment with expanded-spectrum β-lactam antibiotics is less expensive than multiple-drug therapy and eliminates the toxicity and pharmacokinetic dosage complexities of the aminoglycoside alternatives.³¹ Ertapenem, a newer carbapenem that can be given once daily, may become a desirable choice in the initial management of peritoneal infection.³²

For patients with bacteremia from infections that are hospital-acquired or represent failures of previous antimicrobial therapy, specific treatment addressed to these more resistant isolates is required. Single antibiotics that may be chosen to cover hospital-acquired gram-negative bacteria include aminoglycosides, expanded-spectrum penicillins, ceftazidime, aztreonam, quinolones, and carbapenems. Even though the isolate may be sensitive

to lesser drugs, a combination of an expanded-spectrum penicillin with an aminoglycoside is commonly chosen [see Table 5] because of the synergism between these two types of agents. Culture and sensitivity data from the primary source of infection are particularly important for guiding modification of drug therapy. Because a complex patient in the surgical ICU typically has an expanded volume of distribution and an altered pattern of antibiotic excretion,³¹ it is essential that aminoglycoside therapy be pharmacokinetically dosed. Considerable interest has been expressed regarding once-daily dosing of aminoglycosides for gram-negative hospital-acquired infections³³; at present, however, there is only testimonial evidence to support this approach for intra-abdominal infection.

Nosocomial gram-negative bacteremia is a significant complication in surgical patients [see 8:16 *Nosocomial Infection*]. The principal sites are usually the respiratory and urinary tracts and intravascular devices; the surgical site is a common locus for nosocomial infection but is only infrequently responsible for the septic response or bacteremia.

ANAEROBES

The anaerobes of particular significance to surgeons as bacteremic pathogens are principally colonists of the human GI tract and the female genital tract. Oral and cutaneous anaerobes (e.g., diphtheroids) are rarely identified as bacteremic pathogens, though diphtheroids are common skin contaminants of the blood-culturing process. *Bacteroides* species, anaerobic streptococci, and *Clostridium* species are the anaerobic pathogens more commonly identified in blood.

Among all anaerobes, *Bacteroides* species, particularly *B. fragilis*, are the preeminent pathogens. They are customarily identified in infections involving distal ileal or colonic contamination. Intra-abdominal infection must be considered the primary focus of *B. fragilis* bacteremia.³⁴ Soft tissue infections may also be the source of *Bacteroides* bacteremia, particularly in the presence of a polymicrobial infection or necrotic tissue and especially in soft tissue infections of the perineum. In one series of patients with *B. fragilis* bacteremia, 80% required operative drainage and debridement as primary treatment.³⁴

Selection of antimicrobial therapy for *B. fragilis* must be based on an understanding of the pathogenesis of anaerobic infections. Anaerobic infection in the abdomen and soft tissues is synergistic in that both anaerobic and aerobic organisms benefit from the polymicrobial environment. The aerobes reduce the oxidation-reduction potential of the environment, thereby optimizing condi-

Table 5 Expanded-Spectrum Penicillins and Aminoglycosides Used in Combination Regimens in Treatment of Nosocomial Gram-Negative Bacteremia

	Drug	Half-life (hr)	Total 24-Hr Dose
Penicillins	Ticarcillin	1.0	16–18 g
	Mezlocillin	1.0	16–18 g
	Piperacillin	1.0	12–18 g
Aminoglycosides*	Gentamicin	2.0	3–5 mg/kg
	Tobramycin	2.0	3–5 mg/kg
	Amikacin	2.0	15–20 mg/kg

*Dosing interval and total dose per day are variable: pharmacokinetic dosing is required to prevent toxicity or underdosing.

tions for anaerobic proliferation. The anaerobes may then elaborate factors that accelerate the aerobes' growth cycle, or they may shed a portion of their capsular polysaccharide into the environment, thereby retarding phagocytosis of all components of the infection.³⁵ The complexity of this synergistic relation may be further compounded by interactions between *Enterococcus* and either the gram-negative rod¹⁸ or the anaerobic organism.¹⁹

Antimicrobial therapy must address both halves of the synergistic pair, with coverage of the aerobic Enterobacteriaceae being a vitally important component of treatment for the anaerobe. The expanded-spectrum β -lactam antibiotics appear to provide adequate polymicrobial coverage. Clindamycin, 900 to 1,200 mg every 6 to 8 hours, or metronidazole, 500 mg every 6 hours, in combination with an aminoglycoside has been the traditional treatment but, as noted, poses special problems. *B. fragilis* bacteremia arising from unusual sites (e.g., endocarditis) or bacteremia in the face of β -lactam antibiotic therapy both call for specific clindamycin or metronidazole therapy. It is of the utmost importance that treatment of anaerobic bacteremia include complete drainage and debridement of the primary focus.

Peptostreptococci and, to a lesser degree, peptococci are anaerobic streptococcal species that may cause bacteremia from infection after GI contamination. More commonly, their presence should arouse suspicion that bacteremia may be arising from the female genital tract. Either of these anaerobes may participate in puerperal sepsis and pelvic inflammatory disease, with common gram-negative Enterobacteriaceae, enterococci, or both acting as synergistic partners in the infection. *Bacteroides* species may also participate in such infections.

Bacteremia with anaerobic streptococci secondary to infection in the female genital tract mandates a search for a drainable primary focus. For puerperal sepsis, dilatation and curettage may be required to eliminate retained products of conception. Pfannenstiel flaps may become sources of surgical site infection (SSI) that may cause bacteremia and thus must be drained and debrided. Pelvic inflammatory disease may be complicated by tubo-ovarian abscess or extrauterine abscess within the pelvis that will have to be drained.

Appropriate antibiotic therapy for anaerobic streptococcal bacteremia remains unclear. Most anaerobic species likely to cause infection in the female genital tract are sensitive to penicillin, with *Bacteroides* species being a notable exception. Therapy with an anaerobe-specific agent (e.g., clindamycin or metronidazole) in combination with an aminoglycoside, however, appears to offer better clinical results in puerperal infection. The role of the expanded-spectrum β -lactam agents remains poorly defined. Because *Enterococcus* is commonly identified in infections involving the female genital tract, ampicillin is frequently added to the antibiotic regimen, but this measure is of unproven value.

Clostridium species are gram-positive anaerobic rods that are relatively uncommon in blood cultures and are ordinarily associated with clostridial myonecrosis or cellulitis. Usually, the fulminant nature of the infection is readily identifiable at the primary soft tissue focus, and blood culture is of little assistance in diagnosis. Therapy consists of radical debridement of the primary site of infection and aggressive administration of penicillin [see 3:2 *Soft Tissue Infection*].

Nonhistotoxic clostridial bacteremia has been identified with increased frequency. In a series of 47 patients with such bacteremia, only 25% had a focus of infection³⁶; the remaining 75% had no clinically identifiable source. The patients in this latter group either were severely, chronically ill or were alcoholics; thus, the presence of a colonic anaerobe in blood may be evi-

dence for primary bacteremia from the GI tract without a primary focus of infection, and nonhistotoxic clostridial bacteremia may be an expression of failed GI barrier function rather than infection in the classic sense.

FUNGI

Candida species are the most common fungal organisms cultured from the blood in surgical patients. Candidemia is typically seen in a severely ill patient who has had or continues to have bacterial infection and is being treated with a prolonged course (more than 7 days) of broad-spectrum antibiotics.^{37,38} Parenteral nutrition and corticosteroid therapy are associated with candidemia. The bacterial microflora becomes suppressed, and colonization of the alimentary tract by *Candida* organisms becomes the reservoir for dissemination.

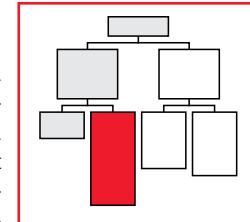

Candidemia appears to occur principally via two mechanisms. In the first, indwelling catheters (particularly central lines) become colonized. Catheter removal and appropriate culture will document the process and likewise be effective treatment. In the second, GI overgrowth with *Candida* leads to impairment of host barrier function and resultant fungemia.³⁸ Although peritonitis and intra-abdominal abscess with *Candida* organisms have been identified,³⁹ translocation of the organisms across the gut barrier is the probable source of contamination.

Prevention of candidemia requires aseptic care of catheters and prompt catheter removal when fungemia is suspected or documented. A reduction in the spectrum and duration of systemic antibiotic therapy is probably the most important method of reducing fungal overgrowth and subsequent risk of dissemination. Oral nystatin, ketoconazole, and fluconazole have been recommended for prophylaxis in patients at risk for candidemia but remain unproven.

Diagnosis and treatment of candidemia are discussed in detail elsewhere [see 8:19 *Fungal Infection*].

Positive Blood Culture without Infection

In the late 1950s, Jacob Fine proposed the theory that acute physiologic perturbations (e.g., hemorrhagic shock) could disrupt GI barrier function to the point where bacteria and their cellular products could escape from the gut reservoir⁴⁰⁻⁴² and contribute to clinical illness. In other words, the septic response could be triggered by bacteria or their products (e.g., endotoxin) in the absence of infection, as it is traditionally understood. Although this theory was discredited in the 1960s in germ-free rat experiments,^{43,44} it enjoyed a considerable resurgence in the late 1980s, as both experimental⁴⁵⁻⁴⁹ and clinical^{50,51} studies demonstrated that GI microbial translocation appears to be a valid biologic event. Consequently, it has been proposed (although not universally accepted⁵²) that some surgical patients may have the septic response secondary to microorganisms while lacking a primary infectious focus.

MECHANISMS OF GUT BARRIER FUNCTION

For microbial translocation to be clinically relevant, gut barrier function must be impaired. At its most distal site, the lumen of the human GI tract may contain as many as 10^{10} bacteria/g colon contents. The biologic partition that prevents microbes from escaping from this reservoir is complex and consists of anatomic, physiologic, and immunologic mechanisms.

The physical barrier of the gut consists of a contiguous layer of enterocytes and colonocytes. An intercellular matrix exists between the cells. Both types of cell appear to obtain a large part of the nutrients they need directly from the gut lumen. Enterocytes have a specific nutrient requirement for glutamine,⁵³ and colonocytes require short-chain fatty acids.⁵⁴ Deficiencies of these critical nutrients lead to atrophy of the gut lining, which results in a defective physical barrier.

The surface of the gut mucosal cells is covered with the glycoprotein mucin,⁵⁵ which is an important component of the gut barrier. The mucin layer has a nonspecific retarding effect on bacterial adherence to mucosal cells; in addition, it has a nonspecific inhibitory effect on bacterial proliferation at the mucosal cell surface, thereby helping prevent invasion by luminal bacteria.

Secretory IgA also prevents the binding of bacteria to mucosal cells.⁵⁶ Presumably produced as nonspecific antibody from submucosal gut lymphocytes, IgA does not fix complement and does not have cytotoxic effects on bacteria. Rather, it is thought to bind to bacteria and impede their binding to the mucosal cell lining. The IgA concentration is highest at the mucosal cell surface.

The normal microflora that colonizes the GI lumen appears to make a significant contribution to normal gut barrier function. Anaerobic bacteria play a positive role by virtue of their species-specific adherence to mucosal cell-binding sites and their ability to prevent more noxious aerobic species from adhering to mucosal cells via competitive inhibition.⁵⁷ This positive role creates a real dilemma for clinicians attempting to formulate antimicrobial regimens for critically ill patients.

Normal GI motility is perhaps the most important of the physiologic components of the gut barrier. Movement of luminal contents distally within the gut keeps intraluminal bacterial concentrations relatively low in the proximal gut and reduces the risk of adherence and translocation. There is, in fact, considerable evidence suggesting that ileus and intestinal obstruction may be important factors in the so-called gut origin septic response.⁵⁸

FACTORS COMPROMISING BARRIER FUNCTION

In critically ill surgical patients, numerous associated clinical factors compromise the various components of barrier function. Critical illness and injury lead to disordered GI motility and ileus. Antibiotic therapy frequently covers the common aerobic and anaerobic members of the normal microflora, which results in overgrowth of the gut with resistant aerobic species. Parenteral nutrient solutions are characteristically deficient in glutamine and short-chain fatty acids, and sustained use of such solutions can cause atrophy of the mucosal barrier. IgA and mucin production may be compromised by the catabolism typical of severe illness. In essence, all of the components of the gut barrier are potentially vulnerable, and microbial translocation (and, subsequently, the systemic septic response) can result from impairment of any or all of them.

RECOGNITION AND MANAGEMENT OF MICROBIAL TRANSLOCATION

The clinical basis for the diagnosis of microbial translocation is imprecise: there is no distinctive clinical marker of this event. Essentially, the diagnosis is one of exclusion. When all conventional infectious sources for a septic response have been excluded by careful clinical evaluation, microbial translocation is considered to be the cause. This clinical diagnosis is a treacherous one and can only be made presumptively. Even when one is convinced that microbial translocation is operative, it is vital to

remain vigilant and continue to search for infectious foci that may be driving the septic response.

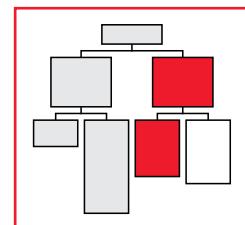

The presence of certain opportunistic microbes in blood cultures strongly implies that GI microbial translocation may have occurred. The organisms making up the so-called trilogy of translocation—namely, *Enterococcus*, *S. epidermidis*, and *Candida* species—are common overgrowth organisms after long-term broad-spectrum antibiotic therapy and are commonly identified together in blood cultures. Obviously, when blood cultures are positive for these organisms, any potential infectious source must be ruled out, particularly bacteremia from intravascular devices.

Fundamental to the prevention and treatment of microbial translocation is reinforcement of the gut barrier. Enteral rather than parenteral nutritional support is always recommended if the clinical circumstances permit [see 8:23 *Nutritional Support*.]⁵⁹ Intraluminal nutrients are delivered directly to the mucosal cells and promote GI motility⁶⁰; moreover, they foster proliferation of a more normal intestinal microflora. Mobilization of the patient from the recumbent position likewise promotes GI motility and is a critical feature of early fixation of long-bone fractures in multiple-trauma patients.^{58,61} Immunonutritional regimens enhanced with glutamine, arginine, omega-3 fatty acids, and nucleotides have yielded encouraging results in prospective clinical trials.⁶²

It is also important to reevaluate patterns of antibiotic use. Although anaerobes act synergistically with aerobes in intra-abdominal and soft tissue infections, the anaerobes in the GI tract are important components of the gut barrier.^{63,64} Because anaerobes are seldom nosocomial pathogens, systemic antibiotics that act against anaerobes should not be used for ICU-acquired infections unless clearly necessary. Some clinicians advocate selective gut decontamination (SGD), in which intraluminal antibiotics are employed to reduce aerobic colonization of the gut while preserving the anaerobic species.^{65,66} One meta-analysis found this technique to improve survival.⁶⁷ In the United States, however, concerns about potential resistance problems from using antibiotics in this way within the critical care environment has limited the use of SGD.

Negative Blood Culture with Infection

A positive blood culture is generally accepted as proof that microbial dissemination has occurred and that this process is the stimulus for the septic response (though, as noted [see Positive Blood Culture without Infection, above], such an assumption is not always warranted). However, most patients who manifest the septic response secondary to severe infection do not have positive blood cultures. In such cases, it is the septic response, rather than the blood culture itself, that is the most useful clinical indicator of a systemic reaction to infection.

REASONS FOR NEGATIVE CULTURE

Patients with the septic response secondary to infection may have negative blood cultures for any of several reasons. First, the septic response may have been activated by disseminated microorganisms that are sensitive to concurrently administered antibiotics. The patient may actually be bacteremic, but the presence of active antibiotic in the blood prevents bacterial growth in the culture. For certain antibiotics, there are laboratory methods for neutralizing the effects of their concurrent administration

Table 6 Common Bacteria Cultured from ICU Patients with Pneumonia: NNIS System Report, 1990–1999⁷⁰

Organism	Type of ICU		
	Cardiothoracic (%)	General Surgery (%)	Trauma (%)
<i>Pseudomonas aeruginosa</i>	13.1	17.2	17.1
<i>Enterobacter</i> species	13.1	12.8	13.4
<i>Staphylococcus aureus</i>	11.3	17.0	18.1
<i>Candida albicans</i>	6.3	3.9	1.5
<i>Klebsiella pneumoniae</i>	5.9	7.2	7.0
<i>Haemophilus influenzae</i>	5.8	4.4	7.4
<i>Escherichia coli</i>	4.8	4.9	4.4
<i>Enterococcus</i> species	2.3	1.8	1.1
All others	37.4	30.9	29.9

(e.g., penicillinase), but for most, this is not the case. Second, it may have been dissemination of bacterial cellular products (most notably, endotoxin) rather than whole, viable microorganisms that activated the septic response. Third, the response may have been activated by systemic distribution of cytokine signals from an intense infectious focus (e.g., severe peritonitis), without dissemination of either bacteria or their products from the focus. Fourth, given that bacteremia is an episodic process and blood culture a random event, the culture sample may simply have been obtained at a time when the patient was temporarily nonbacteremic. The frequency of positive blood cultures in critically ill SICU patients is so low and the value of the occasional positive culture so minimal that several authors have recommended not even drawing blood samples for culture in this population.^{68,69}

EVALUATION AND MANAGEMENT

Nonbacteremic patients who manifest the septic response must still be evaluated just as thoroughly as bacteremic patients would be, with the aim of ascertaining whether there is a primary source of infection. The lungs, the urinary tract, surgical or traumatic wounds, visceral compartments, and I.V. devices must all be sequentially evaluated. Careful physical examination, appropriate diagnostic studies for each anatomic area (e.g., CT scans for the abdomen), and aggressive culturing of suspicious fluids or exudates are indicat-

Table 7 Common Bacteria Cultured from ICU Patients with Urinary Tract Infections: NNIS System Report, 1990–1999⁷⁰

Organism	Type of ICU		
	Cardiothoracic (%)	General Surgery (%)	Trauma (%)
<i>Candida albicans</i>	21.0	16.3	10.8
<i>Pseudomonas aeruginosa</i>	12.6	13.1	13.5
<i>Escherichia coli</i>	12.5	14.6	20.1
<i>Enterococcus</i> species	8.5	14.5	15.5

All others	31.2	26.0	23.9

ed. Special emphasis must be placed on the surgical site and on sites where invasive monitoring devices (e.g., a Foley catheter) or support instruments (e.g., an endotracheal tube) have been introduced into the patient. Nonbacteremic patients may indeed have the septic response without being infected [see *Septic Response without Microorganisms, below*], but this can only be determined after systematic evaluation for a primary infectious focus.

Once a presumptive source of infection has been identified, the primary focus should be drained mechanically, and empirical antimicrobial therapy directed toward the anticipated pathogens should be initiated while culture and sensitivity data are pending. For intra-abdominal infections, the antibiotic regimen must cover both enteric aerobes and anaerobes. For postoperative pulmonary infection, multiresistant gram-negative rods and *S. aureus* are the most common pathogens [see Table 6].⁷⁰ Postoperative urinary tract infections are usually caused by enteric aerobic gram-negative rods, but more and more often, they are being caused by *Candida* species [see Table 7]. Intelligent antibiotic selections for these infections requires a working knowledge of the antibiogram of the ICU.

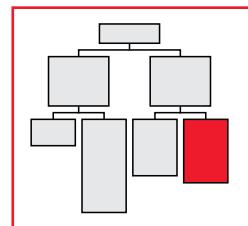

Many critically ill patients who have undergone operation have already received antibiotic therapy at some point during management. Culture and sensitivity information must therefore be continuously obtained because the pathogens found in complex ICU patients with the septic response are often resistant to multiple conventional antibiotics.

Although in many cases the source of the infection and the attendant septic response is readily apparent, in many others the diagnosis can only be presumptive. Constant vigilance for changing clinical findings and careful observation of the response to empirical therapy are essential. For example, if a postoperative patient with the septic response has a urinary tract culture that is positive for *E. coli* at 10^5 colony-forming units/ml, it does not necessarily follow that the urinary tract is the source of the septic response. In my experience, a well-drained urinary tract is seldom the source of a postoperative septic response; other sources must be considered even when a positive urinary tract culture has been obtained.

In the absence of a diagnosis, it is generally difficult to handle either the infection or the septic response effectively; thus, continued intensive surveillance is essential. The objective of management is to control, by mechanical and pharmacologic means, the primary infectious source or sources of the disseminated whole microorganisms, microbial cellular products, or inflammatory cytokines that are responsible for the clinical septic response. Unfortunately, this objective is not equally appropriate for all nonbacteremic septic patients: as is now well established, the septic response can be activated by processes other than clinical infection.

Septic Response without Microorganisms

Traditional assumptions notwithstanding, there is no necessary association between the activation of the septic response and the presence of infection: any physiologic event that can trigger a severe local inflammatory response is potentially capable of activating the septic response.^{71–73} Extreme local tissue inflammation without a microbial component can cause the release of inflammatory cytokines into the circulation in sufficient quantities to evoke the septic response. The clinical manifestations of the septic response are essentially the same

whether it is caused by infection or not; thus, the diagnosis of the septic response secondary to sterile inflammation must be one of suspicion and exclusion.

Of the common clinical entities that can trigger the systemic septic response, perhaps the most notable is acute pancreatitis. The clinical course of severe acute pancreatitis managed with aggressive volume resuscitation includes loss of peripheral vascular resistance, elevated cardiac output, elevated white blood cell counts, and fever. Indeed, Ranson's criteria reflect characteristics of systemic inflammation, including end-organ damage to the lungs, the liver, and the kidneys.⁷⁴ Patients with severe acute pancreatitis often clearly illustrate the rapid physiologic progression from the septic response to the multiple organ dysfunction syndrome (MODS) [see **8:13 Multiple Organ Dysfunction Syndrome**]. Other conditions that can activate the septic response are severe aspiration pneumonitis, which initially is a chemical event that evokes an intense inflammatory response, and multiple trauma with extensive soft tissue injury, necrosis at the injury site, and tissue hematoma. Even extracorporeal membrane oxygenation can be associated with acute activation of the complement cascade and a postoperative septic response leading to end-organ failure, without infection or bacteria being involved at all.

When the septic response occurs in one of these settings, the clinician often is anxious about the possibility of infection and is tempted to initiate antimicrobial therapy, at the very least. However, it is the response itself, rather than any infection, that is the fundamental problem to be dealt with in these patients. Obviously, then, antibiotic therapy will be ineffective in such cases, and specific treatment must be directed toward the septic response.

Effective supportive care is essential to the management of the septic response secondary to sterile inflammation. Volume support to maintain an adequate cardiac output and tissue perfusion is vital. The pulmonary microcirculation is the early target of the septic response; accordingly, support of systemic oxygenation with mechanical ventilation is often necessary.

A vexing problem associated with severe pancreatitis or aspiration pneumonia is that a number of separate stimuli capable of activating the septic response will present themselves during the course of protracted management. In a patient with severe pancreatitis, for example, the primary inflammatory focus gives rise to an initial septic response characterized by pulmonary failure. The patient is effectively resuscitated and appears clinically improved by the fourth or fifth day of hospitalization. By this point, however, an infectious focus, in the form of a pancreatic abscess, has often developed, and this infectious focus evokes a second septic response. Multiple operations and prolonged antibiotic therapy then set the stage for microbial translocation from the gut, which results in candidemia and a third septic response.

What is more, not only may a single pathologic condition give rise to various stimuli that can elicit the septic response, but severely ill surgical patients may also have additional separate inciting causes (which can occur either sequentially or simultaneously) during management, each of which may be associated with one or more septic stimuli. Indeed, a major challenge for the future—perhaps the major challenge—is the necessity of achieving better definition of clinical markers for specific stimuli of the septic response so that treatment can be better directed.

Discussion

Sepsis as Nonspecific Systemic Inflammatory Response

Infection has traditionally been viewed as a local inflammatory response within tissue that is initiated and perpetuated by microorganisms. It is generally agreed that the numerous elements of host defense are designed to both contain and eradicate the microbial provocateurs of this inflammatory process. It is also generally recognized that a threshold exists, the breaching of which results in the dissemination of the infectious process and the elicitation of a systemic inflammatory response. The precise point at which this threshold is passed has not been well defined clinically; however, the clinical expressions of this event are easily recognized [see **8:14 Clinical and Laboratory Diagnosis of Infection**].

There is considerable evidence to support the theory that in the so-called septic patient, there occurs a generalized, systemic activation of the inflammatory cascade. The intricate inflammatory response to injury that is so salutary at the tissue level actually becomes a self-destructive process when activated at the systemic level.⁷⁵ Although these septic events have been associated most often with uncontrolled infection, it is now appreciated that the systemic inflammatory response is in fact a nonspecific host response in the same way that soft tissue inflammation is non-specific.

We can now identify a changing perspective with respect to the stimuli of the septic response in the SICU. Current support technology permits sustained survival of critically ill and severe-

ly injured patients to a biologic point never before reached. As a result, the septic response may now be seen as a consequence of (1) microorganisms in the context of infection, (2) microorganisms in the absence of infection, and (3) inflammatory events not associated with either microorganisms or clinical infection.

Elements of the Septic Response

The septic response represents an evolution of multiple physiologic and metabolic changes. These changes do not constitute an either-or phenomenon but instead take place along an ever-changing continuum. Consequently, it is difficult to determine exactly when a patient ceases to manifest an appropriate stress response and begins to manifest a deleterious septic response. The key physiologic elements of the septic response are (1) reduced peripheral vascular resistance, (2) hyperdynamic cardiac performance, and (3) narrowing of the arteriovenous oxygen content difference. The metabolic features of the septic response are quite complex but can be simplified into five main elements: (1) hypermetabolism, (2) accelerated hepatic gluconeogenesis, (3) accelerated hepatic ureagenesis, (4) increased urinary nitrogen loss, and (5) insulin resistance. These metabolic changes are discussed in greater detail elsewhere [see **8:22 Metabolic Response to Critical Illness**].

Reduced peripheral vascular resistance—contrasting dramatically with the increased resistance associated with hypovolemia and cardiac failure—is the sine qua non of the septic response.

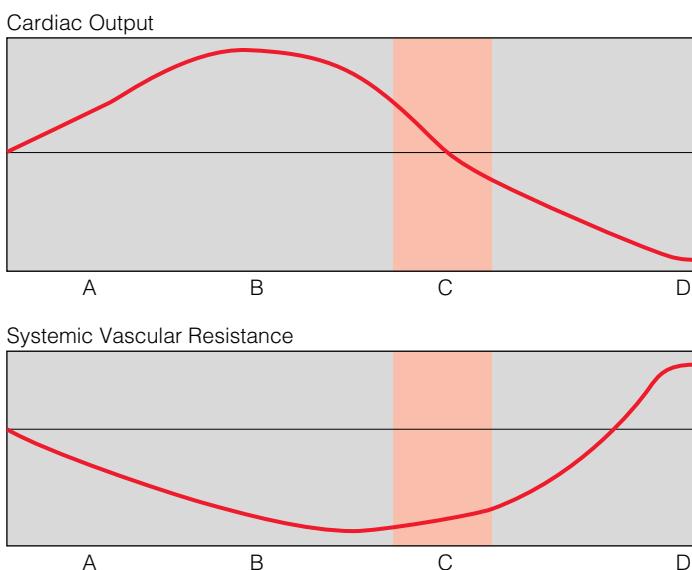

Figure 3 Illustrated is the relation of cardiac output to peripheral vascular resistance during the natural history of the septic response. The areas indicated by the light-red boxes are state C, reflecting the onset of clinical septic shock.

(It must be emphasized that whereas resistance is reduced for the vascular system as a whole, this may not be the case for each individual tissue bed.) The loss of resistance is particularly interesting in light of the elevated catecholamine concentrations that are simultaneously identified in these patients. These elevations reflect the counterregulatory metabolic milieu of the septic response.^{76,77} The alpha-adrenergic effects of the catecholamines are obviously overridden by other peripheral mechanisms.

The systemic vasodilatation appears to be caused primarily by nitric oxide from endothelial cells in the microcirculation.⁷⁸⁻⁸¹ Nitric oxide is a paracrine signal that mediates relaxation of vascular smooth muscle. Its synthesis and release are stimulated by several agonists, including endotoxin, bradykinin, and acetylcholine. Although prostacyclin and histamine are also potential mediators of vasodilatation, at present, nitric oxide appears to be the principal mechanism.

Hyperdynamic cardiac performance is the obligatory response of the left ventricle when peripheral vascular resistance declines. For cardiac output to increase, however, intravascular volume must be replenished, and the myocardium must possess sufficient physiologic reserve. Thus, elderly patients may not be able to meet the physiologic demands imposed by sepsis-induced afterload reduction, and such inability results in the hypodynamic septic shock state. Even in young, healthy patients, sustained hyperdynamism ultimately leads to ventricular failure and low cardiac output.

Narrowing of the arteriovenous oxygen content difference in the hyperdynamic patient is perhaps the most important of the critical mechanisms responsible for the septic response. Oxygen consumption is inadequate to meet the demands of hypermetabolism,^{82,83} and lactate production is the result. When intravascular volume is fully expanded, further increases in cardiac output result in further narrowing of the arteriovenous oxygen content difference. Failure of peripheral oxygen utilization is fundamental to the septic process and underscores that this response is not characterized by inadequate myocardial performance until its very latest stages.

Natural History of the Septic Response

In the predominant view of the natural history of the septic response,⁸⁴ exaggeration of the fundamental stress response is the basis for deterioration of the patient from a compensated state (i.e., the stress response) to a decompensated state (i.e., the septic response). The key element in the natural history of the septic response is the relation between cardiac output and peripheral vascular resistance [see Figure 3].

State A represents the normal adaptive stress response, the first-order response to biologic insults. Cardiac output is modestly elevated, and peripheral vascular resistance is modestly reduced. Systemic oxygen consumption is increased, but lactate concentration is not. State A reflects the postresuscitative physiology of the injured or postoperative patient. The hemodynamic profile progressively returns to normal over several days, provided that there is no intercurrent insult (e.g., infection).

State B represents the exaggerated stress response and marks the transition to the beginning of biologic decompensation. Peripheral vascular resistance is profoundly reduced. A total peripheral vascular resistance lower than 800 dynes-sec/cm⁵ is the commonly recognized threshold for the septic response; resistance may decline to 400 dynes-sec/cm⁵ or even lower. The afterload reduction results in dramatic elevation of cardiac output. An acceptable arterial blood pressure can usually be sustained unless intrinsic myocardial disease or hypovolemia is present. The increased capacitance typical of state B necessitates considerable preload support, which often calls for aggressive fluid administration. Measurement of the pulmonary capillary wedge pressure is often necessary to facilitate the expansion of intravascular volume.

State B is also characterized by accumulation of lactate species in the blood before the evolution of frank clinical hypotension. Blood lactate concentrations reflect net lactate production in selected tissues minus lactate utilization in other tissues. Because not all tissues are necessarily affected equally by the septic response process, oxidation of lactate by selected well-perfused tissues may compensate for production of lactate by others. Lactic acidemia preceding lactic acidosis is usually seen in patients with sustained state B; compensatory mechanisms prevent acidosis until later in the process. These patients are actually in a state of shock, even though their arterial blood pressure is considered normal, because tissue oxygen utilization is clearly impaired.

State C heralds the beginning of septic shock as traditionally defined—that is, as hypotension in a nonhypovolemic patient that is secondary to severe infection. State C patients fulfill this definition: they have mild to severe hypotension, with systolic arterial blood pressure lower than 80 mm Hg. In this setting, however, septic shock is secondary to the severe and exaggerated loss of peripheral vascular resistance; although cardiac output may be normal or slightly increased (8 to 10 L/min), it is insufficient to compensate for this loss.

State C patients are in so-called hot shock. They are warm to the touch and usually show evidence of diaphoresis. Their cutaneous tissues appear well perfused, even though the arterial blood pressure is low. The loss of perfusion pressure acts synergistically with the peripheral defect in oxygen utilization to create a severe peripheral oxygen debt that is clearly reflected in the severe lactic acidosis seen in state C.

State D represents the final phase in the process, in which frank congestive heart failure emerges. Cardiac performance is considerably depressed. Autonomic mechanisms override the vasodilatory influences seen in state C, and peripheral vascular resistance is now increased. In state D, low cardiac output, peripheral vaso-

constriction, and peripheral defects in oxygen utilization work simultaneously to produce profound tissue hypoxemia and lactic acidosis. In the absence of dramatic therapeutic and supportive measures, this is the preagonal period before death.

Pathophysiology of the Septic Response

Fundamental to our understanding of the septic response is the idea that its negative and destructive features are simply the systemic manifestations of what is otherwise a positive and beneficial local inflammatory response to tissue injury. This crucial point can be illustrated by considering the local events that attend soft tissue injury. These events, in essence, are the septic response in microcosm.

LOCAL EVENTS

Soft tissue injury triggers a local inflammatory response that includes disruption of blood vessels, exposure of the collagen matrix, extravasation of red blood cells and plasma proteins, activation of the coagulation cascade, aggregation of platelets, and activation of the complement cascade via the alternative pathway. It is likely that by-products of coagulation and complement activation, among other potential biochemical signals, stimulate mast cells to initiate the first phases of the inflammatory response; the specific cleavage products of complement proteins C3, C4, and C5 (the soluble anaphylatoxins C3a, C4a, and C5a) are known to be the most potent stimuli of mast cell degranulation.⁸⁵⁻⁸⁷ The production of bradykinin from plasma protein precursors occurs via the stimulation of activated factor XII from the coagulation cascade. The activation of these five initiators of inflammation (coagulation cascade, platelets, complement proteins, mast cells, and bradykinin) have the specific effects of (1) local vasodilatation, which increases local flow but reduces flow velocity in the area of injury; (2) increased capillary permeability, which results in extravasation of protein-rich plasma into the injured area, thereby initiating edema formation; and (3) generation of numerous inflammatory enzyme and protein cleavage products, which act as chemoattractants.

Diffusion of the chemoattractant signals from the epicenter of injury begins the process of phagocytic infiltration of the injured area. Chemoattractants bind to specific receptor sites on vascular endothelial cells and initiate the interaction of the endothelial cell with the intravascular neutrophil [see 8:24 Molecular and Cellular Mediators of the Inflammatory Response]. The gradient of chemoattractant signals from the epicenter of the injury then serves as a beacon to direct phagocytic diapedesis toward the site of injury and contamination. The severity of the injury, the extent of necrosis, and the degree of exogenous microbial contamination dictate the intensity of the summed chemoattractant signals that govern the rapidity and the quantity of neutrophil infiltration.

Approximately 24 hours after injury, macrophages infiltrate the area via the same mechanisms for margination and chemotaxis that mobilized the neutrophils. Macrophages orchestrate the severity of the inflammatory response. If necrotic tissue and foreign elements (e.g., bacteria) are minimally present in the area of injury, then the magnitude of the chemoattractant signal is small, macrophages are minimally activated, and the neutrophils proceed with phagocytosis in an orderly fashion. If, however, bacterial contamination is severe and there is considerable necrotic tissue, then the amplitude of chemoattractant effects will be great, which results in full activation of macrophages. Fully activated macrophages elaborate multiple proinflammatory signals that induce the neutrophils to enter a state of accelerated and en-

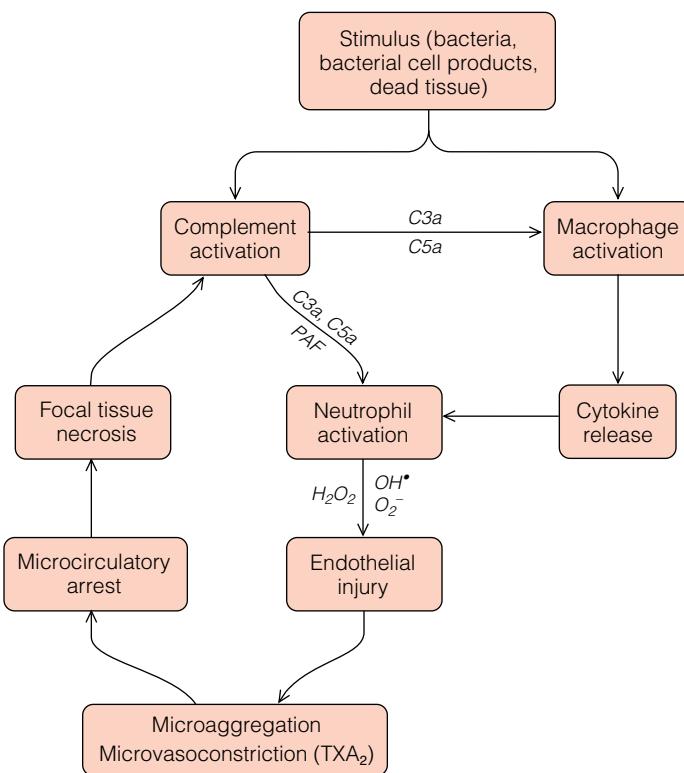

Figure 4 Shown is the self-energized cycle of tissue-level injury that becomes the end-organ consequences of the septic response. Activation of the inflammatory cascade via several different stimuli results in neutrophil activation, which leads to autodestructive inflammation, tissue ischemia, tissue necrosis, and reactivation of the process.

hanced phagocytic activity and elicit the extracellular release of reactive oxygen intermediates and lysosomal enzymes. The accelerated phagocytic activity results in the death of the neutrophils and the formation of pus. Suppuration at the epicenter of the injury is further enhanced when the TNF signal diffuses into the adjacent microcirculation, where marginated neutrophils, recruited into the inflammatory focus, are fully activated, resulting in thrombosis of the adjacent microcirculation. This microcirculatory thrombosis is actually beneficial in that it prevents bacteria or their products from gaining systemic access. Indeed, the ultimate function of the inflammatory response is the containment and subsequent eradication of bacterial contaminants.

SYSTEMIC EVENTS

The systemic septic response comprises the same sequence of events just described, except that the activation of the inflammatory cascade is generalized and lacks the clear directional focus that characterizes the local response. In severe infection, dissemination of bacteria and endotoxins leads to systemic activation of the initiator pathways of inflammation. Systemic activation of coagulation, platelets, complement proteins, mast cells, and bradykinin results in generalized edema, systemic vasodilatation, and a generalized release of chemoattractant signals. Generalized neutrophil margination occurs. The upregulation of the generalized inflammatory response results in full activation of marginated neutrophils. From their intravascular and perivascular positions, the activated neutrophils subsequently release reactive oxygen intermediates and lysosomal enzymes. The resulting inflammatory injury to the microcirculation leads to aggregation of platelets,

damage to the endothelial cells, and release of prostaglandin derivatives that promote vasoconstriction. The consequence of these events is a two-pronged injury comprising the biomechanical blockade caused by the inflammatory aggregate and the vasoconstriction caused by thromboxane A₂.

When an inflammatory focus is sufficiently severe (as, for example, in pancreatitis), it may release sufficient TNF to activate macrophages and neutrophils within the circulation. In these circumstances, *in situ* macrophage cells (e.g., alveolar macrophages and Kupffer's cells) can be activated, and a generalized inflammatory response is the result. The key point in this latter scenario is that this response does not depend on systemic dissemination of the pathogen or its cellular products but can be triggered simply by dissemination of the proinflammatory cytokine signal.

The microcirculatory arrest, in turn, leads to the formation of foci of necrotic tissue,⁸⁸ which evoke a local inflammatory response that eventually reactivates the septic response. A self-energized and futile cycle is created in which an initial injury elicits a local response, the local response expands into a systemic response, and the systemic response finally generates tissue-level injuries that start the whole process all over again [see Figure 4]. The progressive loss of microcirculatory units within the critical organ systems leads to MODS [see 8:13 *Multiple Organ Dysfunction Syndrome*] and ultimately to the death of the host.⁸⁹⁻⁹¹

New Approaches to Management of the Septic Response

It is to be hoped that growing comprehension of the mechanisms involved in the evolution of the septic response and its end-organ effects will lead to new and better therapeutic regimens. Various treatments have already been examined in experimental studies, and a few of them have been used on an investigational basis in humans. These treatments have focused on the following seven basic approaches.

1. Neutralization of activation of inflammation. Efforts to neutralize or inhibit the provocative stimulation of SIRS have principally targeted bacterial endotoxin, a potent activator of the septic response. To this end, antiendotoxin antibody has been given to septic response patients in an attempt to neutralize the effects of endotoxin. Although some clinical studies found that certain patients benefited from administration of polyclonal sera⁹²⁻⁹⁴ or the monoclonal antibody,^{95,96} controversy continues to surround this proposed treatment. Initial favorable reports describing beneficial effects in specific subpopulations were not confirmed by later prospective studies specifically addressed to these same cohorts.^{97,98} Because endotoxin is only one of numerous stimuli of the septic response, routine use of the very expensive monoclonal antiendotoxin antibody for all septic response patients would be difficult to justify. It appears unlikely that this treatment strategy will be generally deployed in clinical practice.
2. Inhibition of initiator signals. Numerous experimental investigations have explored inhibition of the initiators of inflammation: specifically, inhibition of coagulation,⁹⁹ coagulation and platelets,¹⁰⁰⁻¹⁰² bradykinin,¹⁰³ mast cell products,¹⁰⁴ and complement proteins.^{105,106} Few of these approaches have been pursued in prospective clinical trials. A prospective,

multicenter trial of a promising bradykinin antagonist failed to demonstrate any clinical benefit.¹⁰⁷ However, a large prospective trial found that giving recombinant activated protein C (drotrecogin alpha) to septic response patients led to an absolute 6% increase in survival. This result raises hope that significant improvements can be achieved via modulation of the coagulation cascade.¹⁰⁸

3. Inhibition of proinflammatory signals. A third major area of investigation has been the inhibition or alteration of effector mechanisms or consequences of activation of inflammation. Initially, specific neutralization of TNF^{109,110} and receptor blockade of the effects of interleukin-1¹¹¹ were the most promising prospects; however, clinical trials of both failed to demonstrate any meaningful benefit.¹¹²⁻¹¹⁶ Antibodies to prevent neutrophil-endothelial interaction have also been investigated,¹¹⁷ as have platelet-activating factor antagonists.¹¹⁸
4. Neutralization of effector signals. The effector signals are the destructive consequences of the activation of inflammation. Antioxidant therapy aimed at neutralizing the effects of reactive oxygen intermediates has gone from laboratory experimentation to clinical application.¹¹⁹ Experimentally, Lazaroids¹²⁰ and nitrones¹²¹ also appear to have promise as potential treatments.
5. Enhancement of the compensatory anti-inflammatory response syndrome (CARS). The exaggerated inflammatory response results in a counterinflammatory response (i.e., CARS) that modulates inflammatory effects.¹²² Some would argue that SIRS may be understood as the consequence of inadequate CARS. Counterinflammatory signals produced by IL-4,¹²³ IL-10,¹²⁴ IL-13,¹²⁵ transforming growth factor-β,¹²⁶ and prostaglandin E¹²⁷ appear to offset or balance inflammation. Administration of these agents may play a role in future therapy for the septic response.
6. Management of immunosuppression. It has long been recognized that immunosuppression has long been recognized as a consequence of severe injury and sepsis. Accordingly, enhancement of host responses has been explored as a potential therapy for the septic response. Interferon gamma,¹²⁸ levamisole,¹²⁹ muramyl dipeptide,¹³⁰ granulocyte colony-stimulating factor,¹³¹ and granulocyte-monocyte colony-stimulating factor¹³² have all been studied experimentally or clinically.
7. Gene therapy. Experimental studies have explored the use of viral vectors or liposomal delivery systems to enhance endogenous production of counterinflammatory signals,¹³³ antioxidants,¹³⁴ antiproteases,¹³⁵ and heat shock proteins.¹³⁶ Administration of antisense nucleotides to block excessive cellular production of proinflammatory signals has been examined as well.^{137,138}

As the complexity of the host response comes to be better understood, the new knowledge gained generates an ever-increasing number of potential treatments. It is likely that multimodality therapy will receive increased attention in the treatment of sepsis, as such approaches have already done in the treatment of cancer. Balancing proinflammatory signals against counterinflammatory signals may well prove to be the key to modulating this complex human response.

26 CARDIOVASCULAR MONITORING

James W. Holcroft, M.D., F.A.C.S., and John T. Anderson, M.D., F.A.C.S.

Making and interpreting measurements of cardiovascular function in critically ill patients can be a challenge. Invasive monitoring, which is still necessary for many of the measurements, can give rise to complications. Differences among the ICU personnel who make the measurements can raise concerns about accuracy. The measurements, as well as the descriptors of cardiovascular function derived from them, are often abstract and must be interpreted mathematically. Moreover, the measurements are frequently indirect, involving surrogate variables; extrapolating from these surrogate variables back to the primary parameters of interest can be an involved process. Finally, the patient care decisions that are based on these measurements often must be made quickly; thus, one must already have a clear understanding of what the measurements mean. When dealing with problems of metabolism, nutrition, and infection, one usually has time to reflect on how best to proceed, but when dealing with a cardiovascular catastrophe, one may not have this luxury.

Vascular Pressures

PERIPHERAL ARTERIAL PRESSURES AS SURROGATES FOR AORTIC ROOT PRESSURES

The pressures in the aortic root are critical for assessment of tissue perfusion and for estimating the load placed on the left ventricle. The mean aortic root pressure [*see 8:3 Shock*] is the pressure of consequence for the evaluation of perfusion of noncardiac tissues. (This pressure is also close to the pressure that perfuses the coronary arteries, though, admittedly, the mean aortic root diastolic pressure is the better descriptor. In most patients, the two pressures are not very different.) The ventricular end-systolic pressure, which is approximately 90% of the peak systolic pressure in the aortic root, is the most important pressure for estimating myocardial oxygen requirements. The aortic root end-systolic pressure is also the key pressure for assessing afterload [*see 8:3 Shock*].

Direct measurement of the aortic root pressures would be ideal; however, it is impractical. Instead, one must use peripheral arterial pressures—typically, the pressures in a brachial or radial artery—as surrogates for aortic root pressures. This is rarely a problem. Mean pressure decreases ever so slightly as one proceeds distally from the aortic root, unless the arteries between the aortic root and the measurement site in the extremity are in spasm or obstructed. In the absence of spasm or obstruction, the drop in pressure is minimal, and the mean pressure in an artery in an extremity closely approximates the mean pressure in the aortic root. One need only be concerned about the closeness of the approximation if the patient is in severe shock or has obvious obstructive disease—problems that usually are easy to recognize.

The diastolic pressure in the periphery is usually somewhat lower than that in the aortic root, but this too is rarely a problem.¹ The diastolic pressure in the periphery is usually close to the mean pressure distally, which is almost identical to the mean aortic root

pressure. The mean aortic root pressure, in turn, is just slightly larger than the mean aortic root diastolic pressure. Thus, the distal and central diastolic pressures are close to being the same (though not as close to each other as the central and distal mean pressures are).

Using the systolic pressure in the periphery as a surrogate for the systolic pressure in the aorta can, however, be a major problem. The systolic pressure in a peripheral artery is almost always higher than its counterpart in the aortic root, sometimes substantially so. This difference can best be understood by considering that the heart is a pulsatile energy source and that the energy it generates travels to the periphery through a vascular network with complex physical characteristics.^{1,2}

NONINVASIVE MEASUREMENT OF ARTERIAL PRESSURES

In the initial management of a patient with potential cardiovascular instability, arterial pressures must be measured noninvasively and in an extremity. Despite the problems associated with using the systolic pressure in an extremity as a surrogate for the aortic root systolic pressure, it remains true that a great deal of useful information can be obtained from such surrogate measurements. The goal, then, is to make these measurements with the greatest possible accuracy.

In the cuff technique, a blood pressure cuff is applied around the extremity and artery of interest, and a reference point is selected for the pressure measurement. Selection of this point is arbitrary, but most physicians use the right atrium. If the patient is supine, the reference point is placed at the level of the midaxillary line; if upright, the point is situated at the level of the fifth intercostal space in the midaxillary line.³ The cuff is inflated to a pressure that is sufficient to eliminate flow in the underlying artery (e.g., as determined by obliteration of a distal palpable pulse), then gradually deflated while one listens with a stethoscope over the artery at the distal edge of the cuff. When cuff pressure falls below systolic pressure, blood begins to flow again through the artery. Because the artery is still partially compressed, arterial blood flow is turbulent and thus creates sound that is audible through the stethoscope. The pressure in the cuff at the point where this sound first becomes audible is taken to be the peak systolic pressure in the artery encompassed by the cuff.^{4,5}

As deflation continues and the pressure in the cuff falls to levels between the peak systolic pressure and the nadir of the diastolic pressure, the artery becomes less compressed, but some compression remains. Thus, some turbulence and sound remain as well, though their characteristics change. When the pressure in the cuff falls below the nadir of the diastolic pressure in the artery, the vessel becomes widely patent, and turbulence and sound vanish. The pressure in the cuff at the point where sound disappears is taken to be the nadir of the diastolic pressure in the artery.⁴

A stethoscope is generally used to detect the sounds in the artery, but other techniques can also be used to detect distal flow. With all of these techniques, the pressure in the cuff at the point

where flow begins to appear distally is taken to be the peak systolic pressure in the artery. A Doppler device may be used to pick up movement of individual red blood cells in a distal artery; the absence of such movement implies the absence of arterial flow. Arterial flow can also be detected by means of pulse oximetry and evaluated by means of photoplethysmography.⁶ One can even measure volume changes in the distal portion of the extremity as the heart beats: the limb expands during systole as blood is forced into the arteries and veins, and it shrinks during diastole as blood runs out of the vessels. This concept can be used to measure arterial pressure waveforms in the finger. Pressure in a cuff around the finger is regulated to maintain a constant blood volume in the finger; the pressure waveform required to accomplish this reflects the finger arterial pressure waveform.⁷

Sphygmomanometry poses no risk to the patient, and systolic pressures are usually easy to obtain.⁸ Measured pressures can be misleading, however, in that the technique relies on the assumption that the pressures in the cuff are the same as those in the encompassed artery. This condition is usually met, except in diabetic patients with calcified arteries and obese patients, in whom the pressure in the cuff is higher than the pressure in the artery. An additional problem arises when diastolic pressures are measured with a cuff and a stethoscope: the sounds are frequently quite soft, and in a noisy ICU, it is often hard to tell exactly when they vanish. Measurement of diastolic pressure is also difficult if the patient is in shock: flow through the brachial artery can be so minimal that very little turbulence is created and very little sound generated. Only a stethoscope can be used to measure diastolic pressure. Audible Doppler signals in a distal artery change little as a proximal artery goes from partial obstruction to full patency; changes are also minimal if oximetry is used. Finally, the mean pressure cannot be determined with standard sphygmomanometry. Although the mean pressure is commonly approximated as a value that is one third of the way from the diastolic pressure to the systolic pressure, this approximation can be substantially inaccurate [see 8:3 Shock].

The problem of how to determine the mean pressure accurately can be solved by using oscillometric techniques, which have the enormous advantage of being able to measure the mean pressure in an artery in an extremity. Devices that use these techniques sense pulsatility in the volume of the extremity enclosed by the cuff. The point where pulsation amplitudes are maximal corresponds to the mean arterial pressure; various algorithms are used to determine systolic and diastolic arterial pressures.⁹⁻¹¹ Unfortunately, oscillometric methods do not work well in the setting of hypovolemia, which is where they are most often needed, nor are they particularly accurate in determining systolic or diastolic pressures.

Thus, all of these noninvasive methods for measuring arterial pressures have limitations: the inability to measure any pressures accurately in patients who are obese or have calcified arteries, the uncertainty associated with diastolic pressure measurements in all patients, and the difficulty of making measurements in patients in shock.

INVASIVE MEASUREMENT OF ARTERIAL PRESSURES VIA INTRA-ARTERIAL CATHETERS

Except for the problem of using a peripheral systolic arterial pressure as a surrogate for the aortic root systolic pressure, all of the limitations of noninvasive measurement techniques can be overcome by using intra-arterial catheters. In addition, such catheters provide ready access to systemic arterial blood, though not without

a degree of risk.^{12,13} Catheter-related infection can occur, albeit infrequently [see 8:16 Nosocomial Infection and 8:25 Blood Cultures and Infection in the Patient with the Septic Response].¹⁴ Thrombosis associated with insertion and maintenance of indwelling arterial catheters can lead to ischemia and even necrosis distal to the insertion site. Catheters should be inserted in arteries with abundant collateral circulation. The radial artery is safer to use than the brachial artery, and the dorsalis pedis artery is safer than the femoral artery. To reduce the risk of thrombosis, we continuously infuse an isotonic solution through the catheter.^{15,16} If the patient is at high risk for thrombosis, we use a dilute heparin solution for flushing, accepting a slight risk of heparin-induced thrombocytopenia; if not, we use normal saline. Flushing must be done carefully, either as a slow continuous infusion or with boluses no larger than 2 ml. Rapid infusion of large amounts of any solution can lead to retrograde flow. In the case of the radial artery, retrograde flushing can lead to embolization of platelet aggregates or air through the vertebral artery to the brain stem.

The decision whether to use intra-arterial monitoring rests on assessment of the potential risks and benefits. We insert arterial catheters if it appears that blood gases will have to be measured more often than three times daily. We also use them in patients who might bleed suddenly (e.g., those undergoing a major operation), patients whose blood pressure is labile (e.g., those who are in a septic state or require titration of vasoactive or cardiotonic drugs), and patients in whom management of one failing organ system might precipitate failure in another.

Once the decision is made to use intra-arterial monitoring, the artery is cannulated. A pressure transducer is calibrated, then opened to the atmosphere and zeroed at the level of the right atrium.³ The transducer is connected to the cannula with tubing. The pressure waveform from the transducer is displayed on a monitor, along with digital readouts of the running averages (means) of the systolic, diastolic, and mean pressures. These running averages are calculated by computer circuitry in the transducer equipment. To calculate mean peak systolic pressure, for example, the computer might be programmed to sample 10 consecutive heartbeats. It would then detect the peak systolic pressure for each of the 10, add the values, and divide the sum by 10. For the next sampling, it might take the last five values, add these to the next five, and divide the sum by 10. A similar logic is followed for diastolic pressures. The mean pressure is calculated as the area under the tracing divided by the time over which the tracing is sampled (typically, about 10 beats), and a running average is obtained in the same manner as the running averages of systolic and diastolic pressures [see 8:3 Shock]. In all cases, the number of sampled beats is large enough that pressure variations introduced by ventilation are averaged out.

The pressures measured in the transducer are very accurate, and the computer's calculation of the running averages is very sophisticated. A problem remains, however: the displayed pressures represent the pressures in the transducer, not the pressures in the cannulated artery. This is not a major concern with mean pressure. Because there is no net transfer of energy between the catheterized artery and the transducer, the mean pressure in the transducer is the same as that in the artery, as long as the catheter and the tubing are unobstructed. Nor, as a rule, is diastolic pressure a problem. In both the transducer and the artery, mean pressure largely determines diastolic pressure. Because the mean pressures are the same, the diastolic pressures are usually fairly close together.

The peak systolic pressure in the transducer, however, is sometimes substantially different from that in the cannulated artery.

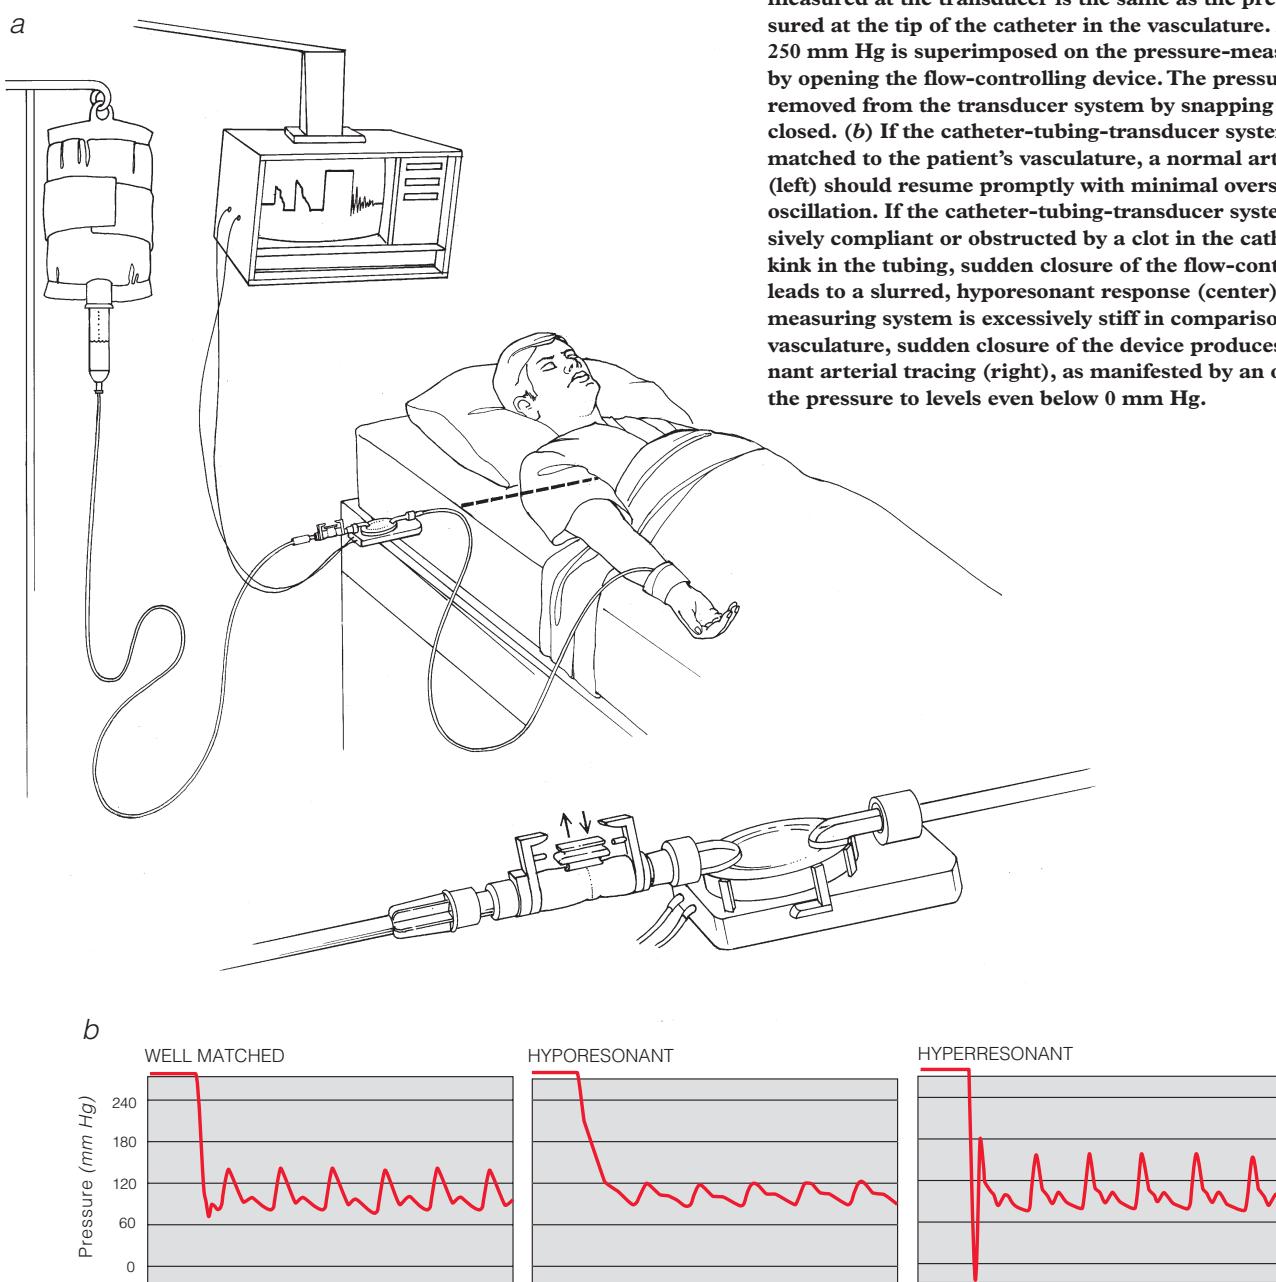

Figure 1 (a) The snap test will indicate whether the pressure measured at the transducer is the same as the pressure measured at the tip of the catheter in the vasculature. A pressure of 250 mm Hg is superimposed on the pressure-measuring system by opening the flow-controlling device. The pressure is abruptly removed from the transducer system by snapping the device closed. (b) If the catheter-tubing-transducer system is well matched to the patient's vasculature, a normal arterial tracing (left) should resume promptly with minimal overshoot and oscillation. If the catheter-tubing-transducer system is excessively compliant or obstructed by a clot in the catheter or by a kink in the tubing, sudden closure of the flow-controlling device leads to a slurred, hyporesonant response (center). When the measuring system is excessively stiff in comparison with the vasculature, sudden closure of the device produces a hyperresonant arterial tracing (right), as manifested by an overshoot of the pressure to levels below 0 mm Hg.

This difference arises because of (1) mismatching between the physical characteristics of the measuring system and those of the artery^{17,18} and (2) catheter whip (or fling).

If the catheter-tubing-transducer system is excessively stiff compared with the vasculature, systolic pressure will be much higher and diastolic pressure somewhat lower in the transducer than in the artery. Conversely, if the measuring system is more compliant than the vasculature, if the vascular catheter is obstructed by a blood clot, or if the tube is too narrow or too long or has a kink, damping at the transducer will be introduced. When such damping occurs, systolic pressure will be lower and diastolic pressure somewhat higher in the transducer than in the artery.

Maintenance of an arterial catheter's patency requires a continuous infusion of fluid, usually from a high-pressure reservoir. A

valve inserted in the circuit between the reservoir and the artery limits the amount of fluid infused. One can take advantage of this arrangement by using the so-called snap test to determine whether the systolic and diastolic pressures in the transducer accurately reflect those in the artery [see Figure 1]. In this test, a square pressure wave is introduced into the catheter-tubing-transducer system by pulling on the tab that allows fluid to flow from the high-pressure bag into the transducer and the artery. The tab is then snapped shut, and the pressure in the system returns abruptly to baseline levels [see Sidebar Snap Test for Detection of Mismatch between Artery and Measuring System].¹⁹ If the system is adequately matched to the vasculature, the pressures in the transducer will abruptly return to baseline with minimal oscillation. If the measuring system is too stiff, the snap test will result in hyperres-

onance, evidenced by prolonged and exaggerated oscillation. If the measuring system is too compliant or if the catheter or tubing is obstructed, the snap test will lead to a slow and slurred descent toward baseline.

To derive the most accurate representation of the arterial pressure from measurements of the pressures in the transducer, the catheter-tubing-transducer system should be set up with the stiffest available tubing, which should be kept as short as is consonant with patient care and should be kept free of compression or clogging. Care should be taken to remove any air bubbles in the tubing or the transducer. Furthermore, the system should be as simple as possible; extraneous connectors and three-way valves should be removed.

If the system ends up with good matching, all of the measured pressures in the transducer can be accepted as accurate reflections of the pressures in the cannulated artery. If the system is hyperresonant, one should make a note of it and keep in mind that systolic and, to a lesser extent, diastolic pressures are not to be trusted. Mean pressures will still be accurate, and in many patients, these are all that is needed. If there is a need to know the systolic and diastolic pressures, any of several commercially available damping devices can be inserted in the transducer-tubing system. If the system is or becomes hyporesonant, an attempt should be made to clear the catheter, both to make the measurements from the catheter more accurate and to prevent propagation of thrombus into the artery from the catheter. If the system continues to be severely damped, it should be replaced and a new catheter inserted, if practicable. None of the measurements from a severely damped system are of any value. In the extreme case of occlusion of the catheter or the tubing, even the mean pressure in the transducer will bear no relation to the mean pressure in the artery.

Another potential problem with using the pressure in the transducer as a surrogate for the pressure in the cannulated artery is catheter whip—that is, movement of the intravascular catheter in the vascular lumen as the heart beats [see *Figure 2*]—which, like mismatch between the artery and the measuring system, can render systolic (and, to a lesser extent, diastolic) pressures unreliable.²⁰ Catheter whip usually is not a problem in the radial artery, where the catheter cannot move around very much, but it can cause difficulties in the femoral artery or the pulmonary artery, where the catheter has ample room for free movement in the lumen. Catheter whip can introduce errors of 20 mm Hg or more in measurements of femoral and pulmonary arterial pressures. Often, distortion introduced by a hyperresonant measuring system looks very much like catheter whip, and the two cannot be distinguished. When this is the case, a device can be added to the catheter-tubing-transducer system to eliminate hyperresonance; any remaining distortion must be the result of catheter whip. Usually, however, it is sufficient just to make a note of possible catheter whip and then refrain from using the systolic or diastolic values in patient management; mean pressures will not be greatly affected and will remain usable.

CENTRAL VENOUS PRESSURE

Central venous pressure is very close to right atrial pressure, which is a critical determinant in the formation of peripheral edema. Right atrial pressure, in turn, is very close to right ventricular end-diastolic pressure (in the absence of tricuspid valvular disease), and end-diastolic pressure gives an idea of end-diastolic volume [see *8:3 Shock*]. Right ventricular end-diastolic volume is a critical determinant of right ventricular stroke volume, end-systolic pressure, and stroke work, which, in turn, are critical determinants of right ventricular oxygen requirements.²¹ Thus, central

Snap Test for Detection of Mismatch between Artery and Measuring System

Clinically, arterial pressures are measured with low-fidelity disposable fluid-filled catheter-tubing-transducer systems. The response of these systems can be characterized by two variables: a damped natural frequency and a damping coefficient.^{17,18} The natural frequency reflects how rapidly the system oscillates in response to a pressure impulse; the damping coefficient reflects how rapidly the system comes to rest after a pressure impulse.

An arterial pressure waveform is made up of various individual harmonic components. The baseline component depends on the heart rate. For example, at a heart rate of 60 beats/min, the first harmonic component is at a frequency of 1 Hz. Adequate representation of an arterial pressure waveform can be obtained from the first several harmonic components. As the frequency of the arterial pressure waveform approaches the natural frequency of the catheter-tubing-transducer system, there will be resonance and amplification of the signal. The measured systolic pressure will be higher than the input arterial pressure, and the measured diastolic pressure will be lower. For an adequate representation of the arterial pressure waveform, the damped natural frequency of the system should be as large as possible—ideally, at least 7.5 to 8 Hz.

In addition, adequate characterization of the arterial pressure waveform requires a certain degree of damping (quantified by the damping coefficient). A completely undamped system will oscillate continuously in response to a pressure input. At the other extreme, an excessively damped system will respond sluggishly to changes in arterial pressures. Ideally, just enough damping should be present to allow minimal overshooting (i.e., a small amount of oscillatory motion).¹⁷ This optimal damping represents a balance between responsiveness and instability.

Measurement of the damped natural frequency and the damping coefficient is readily accomplished by means of the snap test [see *Figure 1*.]^{17,19} This test results in transmission of a square wave impulse to the catheter-tubing-transducer system. Through trial and error, this impulse can be timed to a portion of the arterial waveform that is relatively flat, thereby facilitating evaluation. An arterial pressure waveform strip can generally be printed from a central monitor station. The damped natural frequency is calculated as the inverse of the period of one oscillation. As an approximation, at a standard rate of 25 mm/sec, one oscillatory period should be no longer than three small boxes (0.12 second, corresponding to a frequency of 8.3 Hz). The damping coefficient is reflected by the ratio between the amplitudes of successive oscillations. As the natural frequency of the catheter-tubing-transducer system increases, the range of acceptable damping coefficient values increases as well, while still allowing adequate representation of the arterial pressure waveform. A natural frequency requires a damping coefficient that results in a ratio of roughly 0.15 between successive oscillation amplitudes. Thus, a natural frequency of 10 Hz requires a ratio of 0.1 to 0.25. As the frequency increases to 20 Hz, a ratio ranging from 0.01 to 0.5 would be acceptable.¹⁷

venous pressure can give the clinician substantial insight into the functioning of the right side of the heart.

Quantitative measurement of central venous pressure requires insertion of either a central venous catheter or a pulmonary arterial catheter. Access is usually achieved through either a jugular or a subclavian approach. Certain risks are associated with puncture of these large central veins.²² Penetration of the parietal pleura can produce a pneumothorax. Puncture of the subclavian artery can lead to exsanguination into the pleural cavity. Improper catheter placement can result in intrapleural infusion of fluids. Puncture of one of the major trunks or divisions of the brachial plexus lying near the large veins can permanently impair the extremity. Puncture of the trachea, the esophagus, or the lung can lead to subcutaneous emphysema and mediastinitis. Puncture of the internal

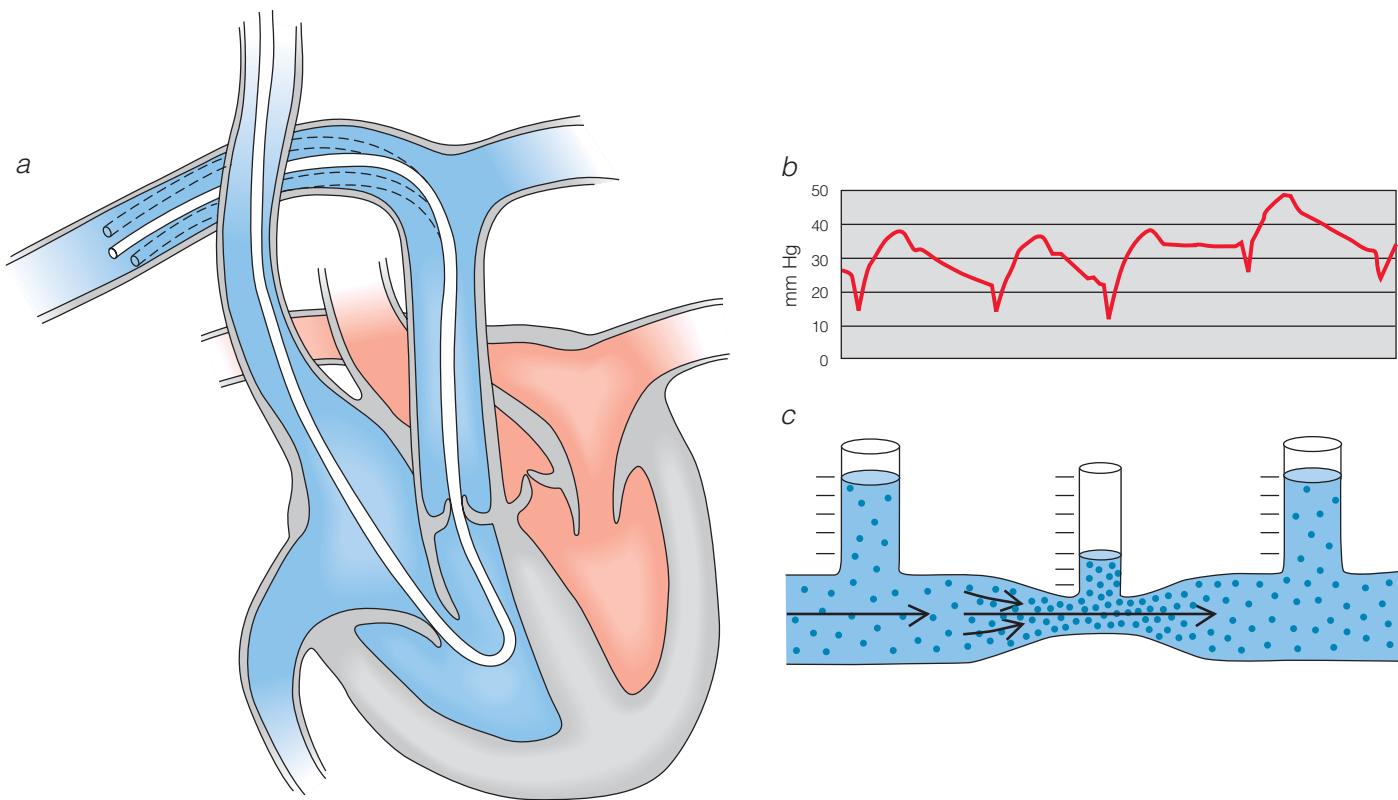

Figure 2 Catheter whip (or fling) results from movement of a catheter within the vasculature (a) that produces hydrostatic pressure changes at the tip of the catheter that are independent of any changes in hydrostatic pressure within the vessel itself. Pressure drops during diastole that are the result of catheter whip could be falsely interpreted as true vascular diastolic pressure. In the pressure tracing shown (b), the true diastolic pressure in the pulmonary artery is 24 mm Hg; catheter fling produces the lower pressure of 12 mm Hg at the tip of the catheter.

The total energy in a hydraulic system, such as the vasculature, is the sum of hydrostatic pressure and kinetic energy. The kinetic energy depends on the square of the velocity of the fluid. The narrower the system (c), the greater the velocity—and, thus, the greater the kinetic energy. The total energy measured at any point in the system is constant; therefore, the hydrostatic pressure must be less in the narrow portion of the tube, where the velocity of flow is higher.

If a femoral or pulmonary arterial catheter moves within the vasculature as the heart beats, the velocity of blood across its orifice will increase; as the velocity increases and the kinetic energy increases, the hydrostatic pressure as measured at the tip will fall. This transient decrease in hydrostatic pressure at the tip of the catheter (as seen in the tracing) does not reflect the true hydrostatic pressure in the artery.

The radial artery catheter is best for determining the total energy in the blood flow. The catheter will not whip, because the artery is small and the catheter has no room to move about, and there will be no kinetic energy component in the blood, because the radial artery catheter is end-on to (i.e., faces into) the direction of the flow; thus, the velocity of the blood as it runs into the end of the catheter is zero. Therefore, the hydrostatic pressure will represent the total energy of the blood at that point of the vasculature. A catheter placed in the ascending aorta will be buffeted by the rapidly accelerating blood in the aorta, and catheter whip will be introduced. A pulmonary arterial catheter potentially has both the problem of catheter whip and the problem that it measures pressure in the direction of flow rather than end-on.

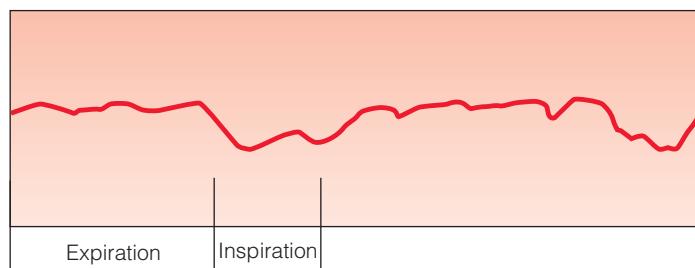

jugular vein on the left side can damage the thoracic duct and lead to a chylothorax. Improper use of the introducing needle can result in shearing of the catheter and catheter emboli. No matter how experienced the person performing the procedure, these complications will occur occasionally; the goal is to keep their incidence to a minimum. The alternative to direct puncture of a central vein is to cannulate a peripheral vein and pass the catheter centrally. This technique, however, carries a very high risk of thrombophlebitis.²³ On balance, it is better to gain direct access to a central vein if this can be accomplished safely.

The central pressures obtained vary with the respiratory cycle. Intracardiac pressures fall during spontaneous inspiration as the lungs pull away from the great veins and cardiac chambers, and they rise during mechanical ventilation as insufflation of the lungs compresses the cardiac chambers. With pressure control or pres-

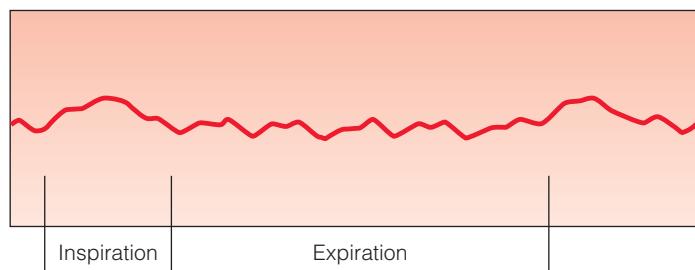

sure support ventilation, end-expiratory pressures will be close to those that would result from spontaneous breathing. Intermittent mandatory ventilation, however, can create a confusing picture, producing augmented vascular pressures when the ventilator gives a mechanical breath but lowered intracardiac pressures when the patient takes a spontaneous breath [see Figure 3].

Substantial pressures can be generated during inspiration with these different modes of ventilation. The intracardiac pressure variations induced by mechanical ventilation can exceed 20 mm Hg. To deal with this problem, some clinicians use end-expiratory values, which can be read from the pressure tracings on the monitor screen. The disadvantage of this approach is that even the most experienced physicians and nurses sometimes find end-expiratory pressure tracings difficult to read.^{24,25} Another approach is to take the patient off the ventilator while making the measure-

SPONTANEOUS VENTILATION

MECHANICAL VENTILATION

INTERMITTENT MANDATORY VENTILATION

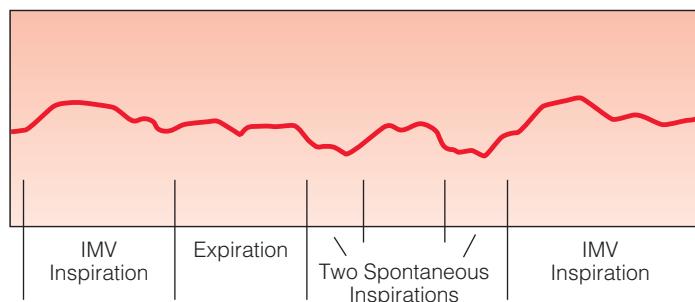

Figure 3 Ventilation can have marked effects on all of the pressures on the right side of the circulation. For example, in a patient breathing spontaneously (top), central venous pressure (or, equivalently, right atrial pressure) falls as the lungs pull away from the intrathoracic great veins and the right atrium. In these patients, the end-expiratory pressure is the highest pressure measured during the ventilatory cycle. During mechanical ventilation (middle), the lungs are pushed against the outside of the heart and the great veins; intracavitary and intravascular pressures are thereby increased during inspiration, and the end-expiratory pressure is the lowest pressure measured during the ventilatory cycle. If intermittent ventilation is used, the problem is made even more complicated (bottom). The machine-generated breaths produce increases in the atrial pressure and spontaneous breaths produce decreases; the end-expiratory pressure is the plateau pressure between the two extremes. The same considerations come into play with measurement of pulmonary arterial pressure and pulmonary arterial wedge pressure. One way to avoid these problems is to take the reading for all of these right-side pressures from the digital display of the monitoring equipment. These values are the running means of the various pressures, taken over a number of breaths.

ments. This approach does make it easier to interpret the pressures. Its disadvantage is that the most significant pressures are the ones prevailing while the patient is being ventilated; removing the patient from the ventilator produces a condition that no longer represents his or her physiologic status.

Currently, most physicians rely on the mean pressure over the entire ventilatory cycle, which is calculated as the integral of the

pressure over time divided by the time during which the area is measured. The computer circuits that govern modern pressure transducers make these calculations routinely and display them in digital form on the monitor screen, along with the pressure tracings. This approach has two advantages: (1) the readings are independent of the person making the measurement, and (2) the measurements reflect the actual conditions to which the patient is exposed. We also use the running means for pulmonary arterial pressure and pulmonary arterial wedge pressure (see below).

PULMONARY ARTERIAL PRESSURES

Monitoring of the pressures in the pulmonary artery of an ICU patient can only be accomplished by means of a Swan-Ganz catheter.²⁶ These pressures, along with other values obtainable from the modern catheter (e.g., cardiac output, right ventricular end-diastolic volume, and mixed venous oxygen levels) can give the clinician an enormous amount of information about a patient's cardiac status.

Pulmonary arterial peak systolic pressure is the same as right ventricular peak systolic pressure. Right ventricular end-systolic pressure can be approximated, as 90% of the peak systolic pressure. This value, along with right ventricular end-diastolic volume, is a critical determinant of right ventricular stroke volume, stroke work, and oxygen requirements.²¹ It is also useful, along with stroke volume, for estimating the hindrance against which the ventricle contracts [see 8:3 Shock]. Mean pulmonary arterial pressure is the most important of the pressures for assessing the perfusion of the pulmonary microvasculature and for filling the left atrium and ventricle during diastole.

Pulmonary arterial wedge pressure can also be measured with a Swan-Ganz catheter. Because there are no valves between the pulmonary arteries and the left atrium, the pressure obtained with occlusion of proximal flow will be the same as the pressure in the left atrium [see Figure 4], provided that there is no significant bronchial blood flow.²⁷⁻²⁹ In the absence of mitral valvular disease, left atrial pressure will be the same as left ventricular end-diastolic pressure.

Knowledge of the pulmonary arterial wedge pressure can help management in two ways. First, it alerts one to possible formation of pulmonary edema. The pulmonary microvascular pressure must lie between the mean pulmonary arterial pressure and the left atrial (or wedge) pressure. If the wedge pressure is high, the pulmonary microvascular pressure must be high as well. A high wedge pressure (≥ 25 mm Hg) is always associated with microvascular pressures that generate at least some interstitial pulmonary edema, even if the microvascular endothelium is intact.³⁰ If the endothelium is disrupted, as in sepsis, pulmonary edema can be produced even with wedge pressures in the midteens.

Second, knowledge of the wedge pressure can facilitate estimation of left ventricular end-diastolic volume, which is one of the prime factors determining left ventricular end-systolic pressure, stroke volume, stroke work, and myocardial oxygen consumption.²¹ As noted (see above), pulmonary arterial wedge pressure, in the absence of mitral valvular disease, is essentially equal to ventricular end-diastolic pressure. End-diastolic pressure can then be extrapolated to derive end-diastolic volume.

A caveat is in order here, however. To make this extrapolation, one must take into account ventricular end-diastolic compliance, which can decrease in the face of myocardial ischemia or hypertrophy or scarring of the ventricular wall.³¹ One must also consider the possibility of external forces that are compressing the heart. A high end-diastolic pressure in a compliant ventricle that is not compressed from the outside will be associated with a large end-diastolic

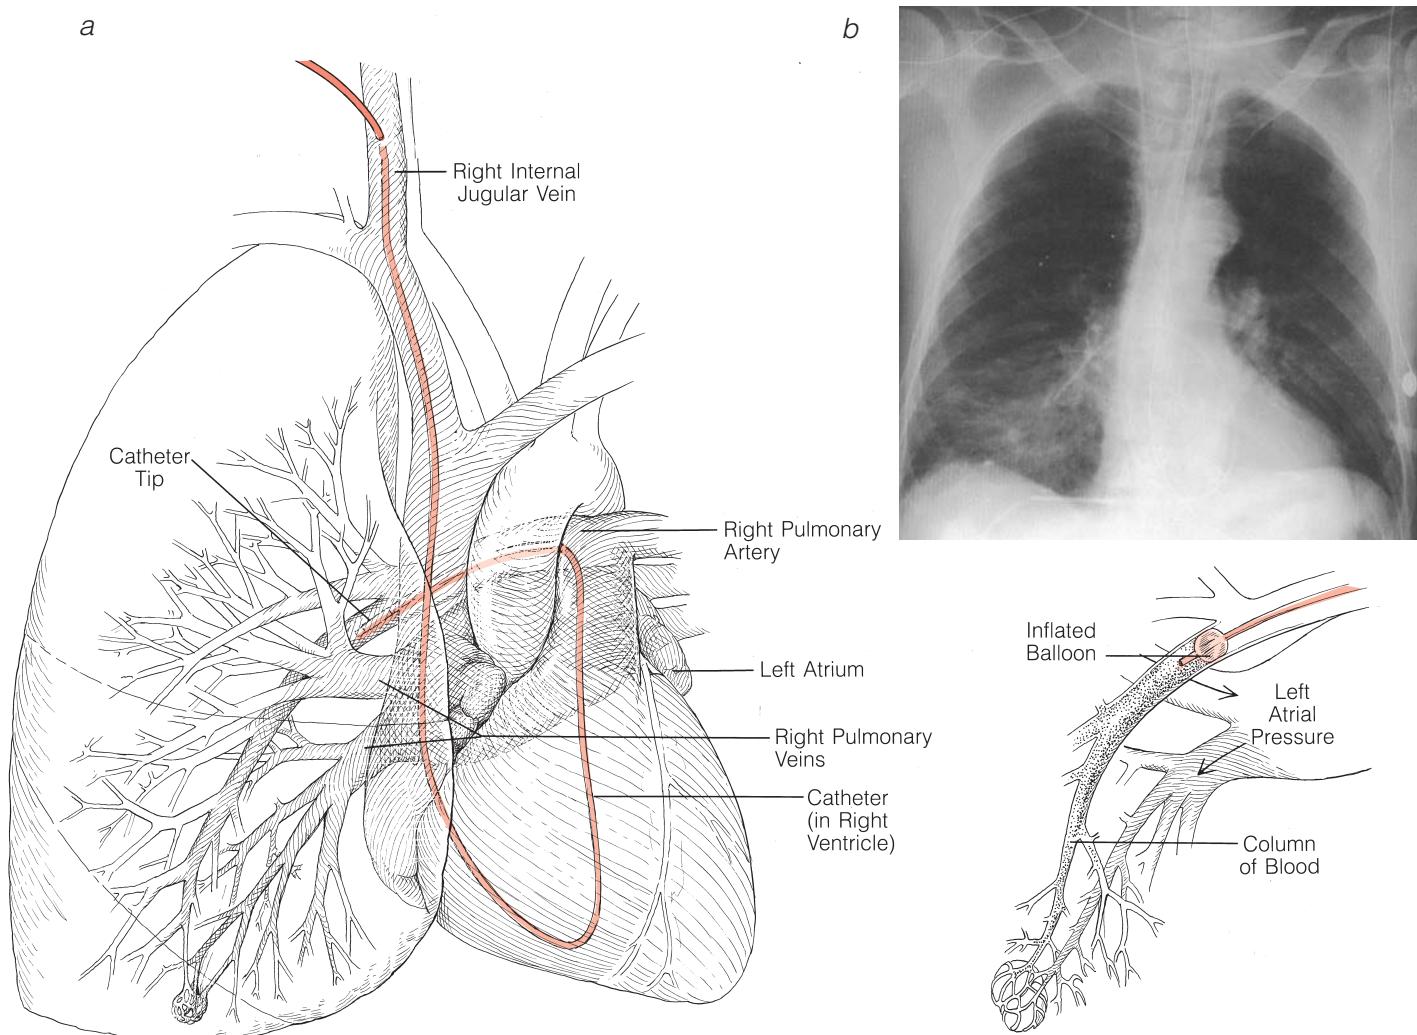

Figure 4 (a) The pulmonary arterial catheter measures pressure in the pulmonary artery when the balloon is deflated. Because flow in the vascular system generates a pressure drop as the blood passes through the microvasculature, the pressure gradually falls as blood flows from the pulmonary artery to the left atrium. When the balloon is inflated, flow in the vasculature distal to the tip is eliminated; therefore, there is no pressure drop. Because there is no pressure drop and because there are no valves between the left atrium and the pulmonary artery, the pressure in the pulmonary artery distal to the point of occlusion must equal the pressure in the left atrium, provided that there is an open column of blood between the end of the catheter and the left atrium. That is, pulmonary arterial wedge pressure will equal left atrial pressure as long as the catheter is in a dependent portion of the lung with a vasculature that remains open during ventilation. Because the catheter is flow directed, it usually will end up in such a dependent, well-perfused area. This is not a certainty, however. If inflated alveoli occlude the microvasculature, wedge pressure will equal alveolar pressure. This inaccuracy might not be easily detected. (b) Verification that the catheter is in the dependent portion of the lung requires a cross-table lateral chest x-ray. We do not routinely obtain these x-rays unless the wedge pressures are absolutely critical for treatment and unless the reliability of the wedge pressure tracing is suspect. Suspicion usually arises when excessively wide pressure swings are evident as the lungs are inflated and deflated.

stolic volume; a similarly high pressure in a ventricle that is stiff or compressed will be associated with a small volume [see 8:3 Shock].

There are other potential pitfalls in interpreting measurements from a Swan-Ganz catheter. As with intra-arterial monitoring of systemic arterial pressures, the pressure in the transducer must be extrapolated to the pressure in the artery. The mean pressures are the same, and the diastolic pressures are nearly the same; but again, the systolic pressures can be misleading because of mismatching and catheter whip. These concerns can be dealt with in the same way as in systemic arterial monitoring.

In contrast with measurement of peripheral systemic arterial pressures and extrapolation back to aortic root pressures, measurement of the pressures at the outflow of the ventricle with the Swan-Ganz catheter is not problematic. The lumen of the catheter used for measuring pulmonary arterial pressure is placed far enough proximally that it gives a direct measurement of the pressure to which the right ventricle is exposed.

Typical pulmonary arterial, left atrial, and left ventricular end-diastolic pressures have been determined [see 8:3 Shock]. Like typical systemic arterial pressures, these values are not necessarily

either ideal or desirable: they merely give an idea of what the cardiovascular system can do when demands are placed on it.

Problems Associated with Swan-Ganz Catheters

In addition to the problems arising from interpretation of measurements made with a Swan-Ganz catheter, there are general problems associated with gaining access to a central vein [see Central Venous Pressure, *above*] and specific problems associated with passage and maintenance of a pulmonary arterial catheter.³²

Ventricular dysrhythmias are common during passage of the catheter, particularly in patients who have suffered recent myocardial infarctions or who have an irritable myocardium (as indicated by a preexisting arrhythmia or conduction defect). For some of these patients, prophylactic administration of lidocaine is indicated. In rare instances, aggressive treatment of such dysrhythmias may be required. Usually, the dysrhythmia subsides when the end of the catheter finally passes through the ventricle and enters the pulmonary artery; sometimes, however, it can be eliminated only by complete removal of the catheter. The balloon on the end of the catheter should be kept inflated during passage to cushion the tip and minimize myocardial irritability.

Passing a Swan-Ganz catheter in a patient with left bundle branch block can be particularly hazardous. The catheter can eliminate conduction through the right ventricle, producing complete heart block. If this condition does not resolve upon prompt withdrawal of the catheter, insertion of a transvenous pacemaker or the use of external pacing may be necessary. The time required to establish a rhythm, however, can be so long that the patient may die first. Therefore, Swan-Ganz catheters should be placed in patients with left bundle branch block only when absolutely necessary.

Lodging of the catheter tip in the trabeculae of the right ventricle is a common problem during catheter passage. On rare occasions, the end of the catheter may puncture the right ventricular wall. The puncture site may not be immediately obvious and may in fact seal by itself; however, it is far more likely to lead to pericardial tamponade and, possibly, death. Measurements from the Swan-Ganz catheter will indicate pericardial tamponade, which mandates emergency operation.

Passage of the catheter through the tricuspid and pulmonic valves can damage them, especially if the device is roughly pulled back through the valves with the balloon inflated. In addition, if the catheter is left in place for more than a few days, valvular damage may result. Besides minimizing long-term use of the catheter, little can be done to prevent this problem.

A problem unique to the Swan-Ganz catheter is intracardiac knotting, which is most likely to develop during placement. The knot can occasionally be untied by manipulating the catheter under fluoroscopic guidance. Passage of a J-wire into the right side of the heart from the groin can also be effective. If these approaches do not work, the catheter must be withdrawn to the site of entry and then removed, usually under direct surgical control.

Swan-Ganz catheters left in place for more than a few days can migrate distally and cut off the blood supply to the pulmonary parenchyma, resulting in pulmonary infarction. This situation is best prevented by continuous monitoring of the pulmonary arterial waveform. Development of a permanently wedged wave pattern is an indication that the catheter should immediately be withdrawn far enough to reestablish a normal pulmonary arterial tracing.

On rare occasions, the catheter can perforate the pulmonary artery. This event typically presents with hemoptysis but may present with acute cardiopulmonary collapse during or immediately after measurement of wedge pressure. Risk factors include

advanced age, pulmonary arterial hypertension, warfarin anticoagulation, clotting deficiencies, distal migration of the catheter into the pulmonary vasculature, and balloon overinflation. Patients with tumors surrounding the pulmonary artery are also at increased risk. The balloon itself may disrupt the pulmonary artery directly, or inflation of the balloon may force the tip of the catheter through the vessel wall. Prevention consists of continuous monitoring of pulmonary arterial pressure tracings. The catheter location should be confirmed by chest x-ray at least once daily. Wedge pressures should be measured only when needed. The degree of balloon inflation necessary to obtain a wedge tracing should be noted and overinflation avoided. The balloon inflation port should be identified so that infusions are not misdirected into the balloon. The catheter should never be left in the wedge position. Rupture associated with mild hemoptysis can be treated by removing the catheter; rupture associated with cardiovascular collapse calls for lobectomy or pneumonectomy, which occasionally permits patient salvage.

Given the limitations of interpreting measurements from the Swan-Ganz catheter and the risks associated with its use, some have asked whether the potential benefits (i.e., increased knowledge of the state of the cardiovascular system) are enough to justify its use, given the concerns that have been expressed about increased risks of morbidity^{33,34} and mortality.³⁵ However, a 2005 meta-analysis of 13 randomized clinical trials that assessed the use of pulmonary arterial catheters in critically ill patients did not find this practice to be either beneficial or detrimental.³⁶ The authors of the meta-analysis pointed out several limitations of the studies evaluated. First, they noted that all of the trials excluded patients whom the treating physicians believed to require a Swan-Ganz catheter. Second, they emphasized that the Swan-Ganz catheter is a diagnostic tool and that any improvement in outcome would require a beneficial therapeutic intervention or change in management that was based on the results of the Swan-Ganz catheter measurements. Third, they observed that only five of the 13 studies evaluated had an outline protocol to achieve specified hemodynamic goals. Fourth, they suggested that the interventions chosen as a result of the Swan-Ganz catheter measurements might be responsible for differences in outcome. For example, they pointed out that vasodilators and inotropes were used more frequently in patients who had a Swan-Ganz catheter in place. In patients with advanced heart failure, some of these agents have been associated with increased morbidity and mortality.^{37,38}

In our view, the question of whether and when to use a Swan-Ganz catheter remains unresolved. There is still a need for a study with a high enrollment rate of eligible patients and with inclusion and exclusion criteria that select a population with an expected mortality confirming severe preexisting illness. We believe that use of the Swan-Ganz catheter is still appropriate and beneficial in selected patients,³⁹⁻⁴¹ provided that the information obtained thereby is employed intelligently^{42,43} and that the associated risks are kept to a minimum.²²

For example, it would seem reasonable to use a Swan-Ganz catheter when myocardial function is severely compromised. The catheter can provide crucial information on the efficacy of pharmacologic support and can aid in the diagnosis of abnormalities such as pericardial tamponade and acute mitral regurgitation. Another reasonable indication would be hypovolemic shock that does not respond readily to volume administration. The catheter may reveal abnormalities of myocardial function or of the pulmonary or systemic vasculature that require specific interventions in addition to volume loading. Pulmonary arterial monitoring

would also seem reasonable in patients with sepsis who have inadequate urine output or who are hypotensive. The catheter can provide valuable information about the adequacy of oxygen consumption and pharmacologic support. Pulmonary disorders, especially those that carry a high probability of associated myocardial dysfunction, might constitute another reasonable indication. Pulmonary arterial catheters might also be useful in patients with good cardiopulmonary function who are undergoing procedures associated with large volume requirements and fluid shifts, as well as in patients with severe preexisting myocardial or pulmonary disease who are undergoing elective procedures. Finally, pulmonary arterial catheterization might be indicated if the patient is experiencing failure of two organs with competing priorities.

Flows, Volumes, and Other Determinants of Cardiovascular Thermodynamics

CARDIAC OUTPUT

Modern pulmonary arterial catheters are equipped to obtain a number of other measurements besides pulmonary arterial pressures. Thermistor-tipped catheters can measure cardiac output by means of thermodilution.⁴⁴ Originally, these values were obtained by injecting a known quantity of a cool solution in the right atrium and analyzing the temperature drop in the pulmonary artery as the cooled blood flowed past the thermistor. Nowadays, a heater coil is used to heat the blood in the right ventricle, and the resulting rise in temperature in the pulmonary artery is used to calculate the output. The temperature pulses are generated randomly. The measured outputs are obtained over the entirety of the respiratory cycle. Commercially available computers make the calculations on the basis of indicator dilution theory.

Methods of measuring cardiac output have also been developed that do not involve placement of pulmonary arterial catheters. The direct Fick method is best used in awake, alert patients.⁴⁵ Transthoracic electrical impedance measurement requires placement of electrodes, which may interfere with surgical procedures.⁴⁶ Doppler ultrasonography probes have been placed at the suprasternal notch and the esophagus for measurement of blood flow velocity and calculation of continuous cardiac output in the ascending aorta, distal to the coronary ostia, and in the descending thoracic aorta, distal to the origin of the left subclavian artery.^{47,48} Suprasternal notch probes require estimation of the diameter of the ascending aorta; esophageal probes require estimation of the diameter of the descending aorta. Expired gas analysis, with rebreathing techniques, has also been used to obtain cardiac output.⁴⁹⁻⁵¹ These methods are currently under clinical evaluation and have not been widely used in clinical settings.

Typical cardiac output values for a well-conditioned person vary under conditions of rest and strenuous exertion [see 8:3 Shock]. Once again, these typical values are to be used as indicators of what the heart can do, not as target values for every critically ill patient.

RIGHT VENTRICULAR END-DIASTOLIC VOLUME

The introduction of fast-response thermistors has allowed development of thermodilution pulmonary arterial catheters that can measure right ventricular end-diastolic volume directly.⁵² The measurements are accurate as long as the patient has a regular rhythm and a heart rate lower than 140 beats/min.

Right ventricular end-diastolic volume varies with cardiovascular condition, total blood volume, positioning, exercise, ventricular

compliance during diastole, pressures applied to the outside of the ventricle, hindrances against which the ventricles contract, and other factors. The right ventricular end-diastolic volume in a resting, supine, well-conditioned 60 kg person is approximately 150 ml. With assumption of an erect position, some of the blood in the thoracic portions of the cardiovascular system pools in the capacitance vessels of the abdominal viscera and the lower extremities. Ventricular end-diastolic volume decreases by perhaps one eighth, to 133 ml. With exercise, muscular contraction in the lower extremities and the abdomen squeezes the capacitance vessels. Blood is redistributed back to the heart and the pulmonary vasculature, raising the end-diastolic volume to perhaps 145 ml. In most 60 kg patients on mechanical ventilation, an end-diastolic volume of 150 ml will be needed to sustain adequate stroke volumes and ventricular pressures.

LEFT VENTRICULAR END-DIASTOLIC VOLUME

Direct measurement of left ventricular end-diastolic volume requires transesophageal echocardiography. This modality is available in most ORs, but it requires the attendance of a physician, usually an anesthesiologist or a cardiologist. This level of physician involvement is not routinely available in most ICUs. Transthoracic imaging can be used for this purpose, but results are frequently misleading in critically ill surgical patients because of bandaging, chest wall edema, and movement of mediastinal structures with mechanical ventilation.

Left ventricular end-diastolic volume can be estimated by measuring the pulmonary arterial wedge pressure and taking into account the factors discussed in relation to pressures in the pulmonary artery [see Pulmonary Arterial Pressures, above, and 8:3 Shock]. A noninvasive and accurate means of determining left ventricular end-diastolic volume would be extremely useful in the management of critically ill patients. Unfortunately, the technology is not yet available.

In a supine, well-conditioned, spontaneously breathing, normal person weighing 60 kg, left ventricular end-diastolic volume is approximately 150 ml. With assumption of an upright position, it decreases by perhaps one eighth; with exercise, it returns to a value close to 150 ml [see 8:3 Shock]. A volume of 150 ml or greater is necessary if the patient is undergoing mechanical ventilation.

VENTRICULAR END-SYSTOLIC VOLUMES

End-systolic volumes can be obtained by subtracting stroke volume from end-diastolic volumes. In a 60 kg person with ventricular end-diastolic volumes of 150 ml and a stroke volume of 100 ml, end-systolic volumes are 50 ml.

Ventricular End-Systolic Unstressed Volumes

The term end-systolic unstressed volume refers to the volume that a ventricle would assume if all of its blood were removed with the ventricle in a fully contracted state. Unstressed volumes cannot be measured routinely in the ICU, but they can be measured during cardiac catheterization. In most patients, unstressed volumes are quite small (~ 6 ml). In those with severe congestive heart failure, however, they can be as large as 50 ml.

AFTERLOAD

The aortic root end-systolic pressure-volume relation can be calculated by dividing left ventricular end-systolic pressure by stroke volume; the pulmonary arterial end-systolic pressure-volume relation can be determined by dividing right ventricular end-systolic pressure by stroke volume. These relations give a good

approximation of the total hindrances or input impedances or afterloads facing the ventricles when they inject their blood into their respective vasculatures [see 8:3 Shock].^{53,54}

Part of the afterload is accounted for by vascular resistance, calculated as pressure divided by flow. To calculate systemic vascular resistance, the difference between mean aortic pressure and right atrial pressure is divided by cardiac output. To calculate pulmonary vascular resistance, the difference between mean pulmonary arterial pressure and pulmonary arterial wedge pressure is divided by cardiac output.³²

Of the two resistances, pulmonary vascular resistance is more difficult to measure and more likely to change under different conditions. Because pulmonary vascular resistance depends on the difference between two relatively small pressures, a slight error in the measurement of either one can result in a large error in the calculation of resistance. For this reason, pulmonary vascular resistance is not, in our view, a reliable descriptor.

In contrast, systemic vascular resistance depends on the difference between a large pressure and a small one. Hence, a slight error in the measurement of either pressure has little effect on the calculation of resistance, and the calculation produces an accurate, reproducible number. In many situations, however, we do not bother to make the calculation, because the general level of resistance is frequently obvious on clinical grounds. A high cardiac output in the face of a low mean arterial pressure—a common finding in inflammatory shock or neurogenic shock—means that the systemic resistance must be low. A low cardiac output with a normal or high pressure—as in obstructive shock or, sometimes, cardiogenic shock—means that the resistance must be high. Furthermore, as noted, the systemic resistance makes up only part of the afterload facing the left ventricle. To assess the total hindrance to outflow from the ventricle, the afterload should be calculated as previously described—that is, as the approximated aortic root end-systolic pressure divided by the stroke volume. On occasion, we do calculate the systemic resistance and use it to direct therapy. If the afterload (or impedance) is high and the resistance is low (a common situation), we direct initial therapy toward reduction of arterial stiffness. If the afterload is high and the resistance is also high, we direct therapy toward both the arteries and the arterioles.

The units used to express vascular resistances vary from hospital to hospital. It is simplest, as well as perfectly acceptable scientifically, to use arbitrary units. We prefer mm Hg · L⁻¹ · min—that is, we use the number obtained through the simple calculation described without making any further corrections. A normal systemic arterial resistance is about 14 mm Hg · L⁻¹ · min in a supine, resting 60 kg person. Some multiply this raw number by 80 to convert the resistances to units in the centimeter-gram-second (CGS) system.

POWER

Power calculations are a useful way of quantifying the energy available for delivery of nutrients to tissues and delivery of energy to the contralateral heart. The total power delivered into the aorta can be calculated by multiplying left ventricular end-systolic pressure by cardiac output.⁵⁵ Steady-flow aortic power is mean arterial pressure multiplied by cardiac output. Oscillatory power is the difference between total power and steady-flow power. Most of the steady-flow power is dissipated as heat in the microvasculature; the amount of heat dissipated can be calculated by subtracting central venous pressure from mean arterial pressure and multiplying the difference by cardiac output. The remaining steady-flow power fills the right atrium and ventricle during diastole. This value can

be calculated by multiplying central venous pressure by cardiac output. The power delivered by the right side of the heart into the pulmonary vasculature can be calculated similarly [see 8:3 Shock].

Summary Measures of Factors Affecting Cardiopulmonary Function

HEMOGLOBIN CONCENTRATION

Although hemoglobin concentration and hematocrit are commonly measured, there is no consensus regarding the values that are desirable in critically ill patients. Normal values vary substantially from person to person, depending on the altitude at which the person lives, physical conditioning, and gender. One might expect these variations to shed light on the question of what constitutes desirable values in the critically ill. There is no reason why humans should evolve to have hemoglobin or hematocrit levels that are not beneficial; on the contrary, there is every reason why humans should evolve to have values that are ideal for the conditions to which they might be exposed.

As an example of how hemoglobin and hematocrit levels in human beings adapt to changing conditions, living at high altitude, not surprisingly, results in high values.

As another example, good cardiovascular conditioning, especially in a warm environment, results in lower hemoglobin and hematocrit levels. Conditioning causes both plasma volume and red cell volume to expand, with the former expanding more than the latter. Consequently, the hematocrit falls, typically by several percentage points. Although it is not known why conditioning results in an anemia, the reason may have to do with the importance of efficient heat dissipation with exercise. Exercise, in some cases, is limited by the oxygen supply to exercising muscles, but it can also be limited by hyperthermia. (For example, in 30 seconds or so of intense running, a cheetah's core temperature can rise above 40° C. The duration of the animal's pursuit of its prey is limited by hyperthermia, not by exhaustion of oxygen supplies.) Heat dissipation is optimized by the lowest possible hematocrit (which decreases viscosity and eases the flow of heated water, either in plasma or red cells, to the skin, where the heat is dissipated to the environment). Oxygen supply is increased by higher hematocrits. We suspect that conditioning generates the hematocrit that best serves these two competing priorities.

As yet another example, hematocrits are lower in women. This difference, too, is probably explainable in terms of heat dissipation. The thicker layer of subcutaneous fat in women has the obvious advantage of improving survival or performance in cold conditions or in situations of limited food supply; however, this fat also makes it more difficult for women to offload heat. Lower hematocrits help alleviate this difficulty.

As a final example, hematocrits are lower in pregnant women. Pregnancy causes both plasma volume and red cell volume to increase, but as with physical conditioning, the former increases more than the latter, leading to a decrease in the hematocrit. This is probably not a surprising result, given the substantial degree of physical conditioning required to carry an increasingly heavy load for the greater part of the day over a period of months. In addition, the lower hematocrit should help the pregnant woman avoid hyperthermia, thereby protecting the fetus from excessively high intrauterine temperatures.

The desirable value for a hematocrit in a critically ill patient depends on many variables, as is discussed in more detail elsewhere [see 8:3 Shock]. We suggest that there can be an advantage

in being anemic, especially in the face of an inflammatory process characterized by increased oxygen consumption and heat production. There are also obvious advantages in higher levels of hemoglobin (see below).

BLOOD LEVELS OF OXYGEN AND CARBON DIOXIDE

The term oxygen saturation (S_{aO_2}) refers to the fraction of hemoglobin occupied by oxygen. Oxygen content (C_{O_2}), or concentration, is the amount of oxygen contained in a given volume of blood. In the United States, it is typically expressed as milliliters of oxygen dissolved in 100 ml (1 dl) of blood. The partial pressure (tension) of oxygen (P_{aO_2}) or carbon dioxide (P_{CO_2}) in blood is the pressure that the dissolved gas exerts on the walls of the blood vessel. Systemic arterial oxygen saturation (S_{aO_2}) can be obtained by means of pulse oximetry. Measurement of blood gases, however, requires blood, usually obtained from indwelling catheters.

Pulse oximeters have proved extremely useful for monitoring S_{aO_2} in the ICU, in that they are noninvasive and easy to use and require minimal calibration. The basic principle is that oxygenated hemoglobin and reduced hemoglobin have different absorption properties for light of known wavelengths. Pulse oximeters measure absorption of selected wavelengths of light from pulsatile (i.e., arterial) blood flow, typically in the nail bed on a finger or toe or in the earlobe. They can be used only in patients who have good perfusion: hypoperfusion and inadequate pulsation of blood in the arterioles make it impossible for the oximeter to distinguish between arteriolar and venular blood.

Oxygen saturations may not give enough information, however. For a more complete clinical assessment, it may be necessary to measure arterial oxygen tension (P_{aO_2}), arterial CO₂ tension (P_{aCO_2}), and pH. Saturation can be approximated from these three measurements, along with temperature. These calculations are typically made by computer in the blood gas laboratory, and the approximated saturation value is returned by the laboratory along with the measured P_{aO_2} , P_{aCO_2} , and pH. Oxygen saturation can also be measured directly on a blood specimen by means of a co-oximeter. This simple and inexpensive device gives a more accurate value because it measures saturation directly. It does require another several milliliters of blood, however, thereby adding to the amount of blood drawn from the patient.

The greatest significance of S_{aO_2} , whether obtained via pulse oximetry or via direct measurement, lies in its role in yielding values for arterial oxygen content (C_{aO_2}), which is the value that usually counts most. C_{aO_2} is a measure of all the oxygen in the blood, including that attached to hemoglobin and that dissolved in plasma, and may be approximated as follows:

$$C_{aO_2} = 1.39 \times [Hb] \times S_{aO_2} + 0.0031 \times P_{aO_2}$$

where [Hb] is the hemoglobin concentration in blood and 0.0031 is the so-called Bunsen coefficient. [Hb] is expressed in g/dl; S_{aO_2} is expressed as a percentage; and P_{aO_2} is expressed in mm Hg.

The amount of oxygen dissolved in plasma is small compared with the amount bound to hemoglobin. As long as P_{aO_2} is less than about 100 mm Hg, the contribution of the oxygen in the plasma to the total oxygen content need not be considered, provided that the hemoglobin concentration is at least 7 g/dl. If the oxygen dissolved in plasma is left out, calculation of C_{aO_2} is even simpler:

$$C_{aO_2} = 1.39 \times [Hb] \times S_{aO_2}$$

Thus, if the hemoglobin concentration is 11.4 g/dl and S_{aO_2} is 97%, the oxygen content of the blood (excluding that dissolved in plasma) is 15.4 ml/dl. If the oxygen dissolved in plasma is added

back in, C_{aO_2} is 15.7 ml/dl, assuming a P_{aO_2} of 97 mm Hg. This is a normal value for a woman who is in good cardiovascular condition or in the late stages of pregnancy, with a hematocrit of 34%.

Although 1.39 is probably the most accurate figure for the purposes of this calculation, other values—some as low as 1.33—have also been reported. Accordingly, the calculation can be simplified yet further by using a value of 4/3 instead of 1.39.

The blood obtained for direct measurement of P_{aO_2} and S_{aO_2} can also be used for measurement of P_{aCO_2} and pH. P_{aCO_2} is a measure of the amount of CO₂ dissolved in the plasma. Arterial CO₂ content (C_{aCO_2}) can be calculated, but it seldom is, because within physiologic ranges of P_{aCO_2} , CO₂ content is almost linearly related to partial pressure. Hydrogen ion concentration is usually expressed as pH and is obtained by direct measurement with ion-sensitive electrodes. It can also be expressed in nmol/L.

Blood drawn for blood gas determinations should be placed on ice immediately to inhibit oxygen consumption by neutrophils. Before being measured in the blood gas apparatus, it is rewarmed to 37° C by a heating element in the cuvette, and P_{aO_2} , P_{aCO_2} , and pH are then determined with the blood at this temperature. The patient's blood, however, may be either warmer or colder than 37° C. If, for example, the patient's blood is 35° C when it is drawn, some of the oxygen and CO₂ will come out of solution when it is warmed to 37° C. Consequently, the partial pressures measured by the apparatus will be higher than the actual pressures in the blood when it was circulating in the patient.

The physician and nurse caring for the patient need not make this temperature correction themselves: the blood gas laboratory typically reports temperature-corrected values for the partial pressures and pH if the patient's temperature is supplied to the laboratory along with the specimen.⁵⁶ An increasing number of clinicians, however, no longer make temperature corrections for blood gases and manage hypothermic and hyperthermic patients with the so-called alpha-stat method.⁵⁷ Treatment based on this method is thought to induce fewer abnormalities in acid-base balance when the patient's temperature returns to normal.

There are several pitfalls in measuring oxygen levels in mixed venous blood. Mixed venous blood, by definition, represents a mixture of all blood returned from all organs. Venous blood from the heart is returned to the right atrium through the coronary sinus. This blood is markedly desaturated. Thus, blood in the right ventricle or in the pulmonary artery is truly mixed venous blood because it includes both the blood from the heart and that from the rest of the body. Blood from the superior vena cava, however, is not mixed venous blood, because it does not include the blood from the heart. Accordingly, blood gas measurements from vena caval blood may be falsely elevated. Measurements of gases in blood obtained from the right atrium may be falsely low if the catheter tip is placed near the coronary sinus.

Two errors in obtaining pulmonary arterial blood can lead to misleading measurements. The first, contamination of the specimen with residual fluid in the lumen of the catheter, is easily avoided by discarding the initial 3 ml of blood drawn through the catheter. The second error is harder to avoid. It arises if the blood sample is withdrawn too forcefully through the catheter. The pulmonary artery may collapse around the end of the catheter, causing the blood to be drawn in a retrograde manner past ventilated alveoli [see Figure 5]. This results in a specimen with very high oxygen levels, which does not accurately reflect desaturated pulmonary arterial blood. The possibility that blood was drawn in a retrograde fashion can be checked by measuring the P_{CO_2} in the specimen. CO₂ tension in true pulmonary arterial blood (P_{mvCO_2}) is typically

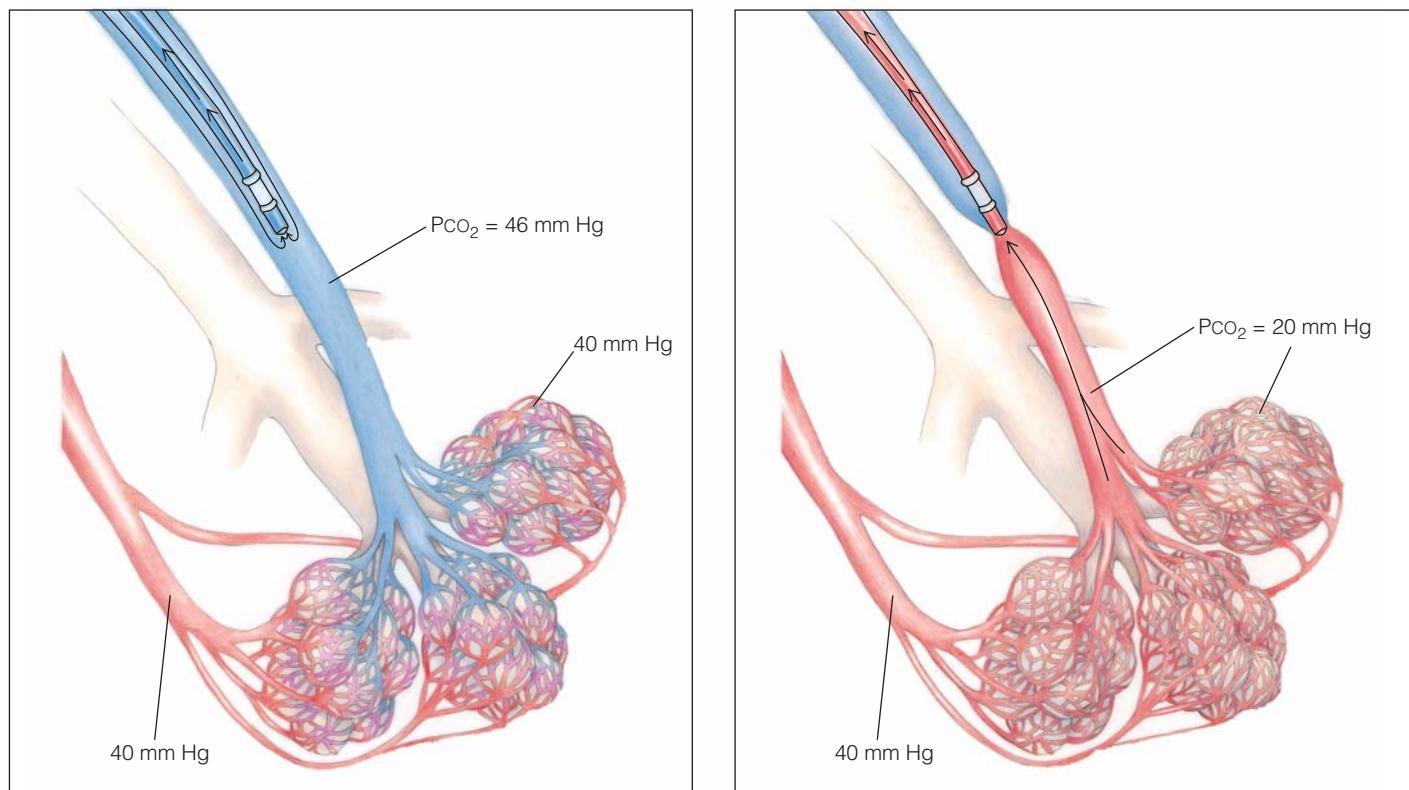

Figure 5 The Swan-Ganz catheter allows collection of mixed venous blood for measurement of $S_{mv}O_2$ and $C_{mv}O_2$ (left). If blood from the pulmonary artery is withdrawn through the catheter too forcefully, however, arterial walls can collapse around the tip of the catheter (right). The sample will in that case consist of blood from the distal pulmonary vasculature that has been pulled back past ventilated alveoli. To determine whether this has happened, the PCO_2 in the sample should be checked. $P_{mv}O_2$ is typically about 5 mm Hg greater than P_aCO_2 . If the arterial walls have collapsed around the catheter, the sample will consist of blood from which much of the CO_2 will already have been excreted into the ventilated alveoli, and the $P_{mv}CO_2$ in the recovered blood may be as much as 20 mm Hg lower than a simultaneously obtained P_aCO_2 . Specimens of this sort should be discarded and new specimens obtained. Taking care in obtaining true mixed venous blood is equally important when using a catheter with an oximeter mounted on its tip. Calibration of the oximeter requires direct measurement of $S_{mv}O_2$ in a correctly obtained specimen.

5 mm Hg higher than that in simultaneously drawn systemic arterial blood.⁵⁸ Blood drawn back past ventilated alveoli will have a very low $P_{mv}CO_2$. If the CO_2 tension in the specimen is equal to or less than that in systemic arterial blood, the specimen should be discarded and another specimen obtained by drawing back on the syringe more slowly. One should rely on the oxygen saturation of the specimen (measured by co-oximetry) rather than on the oxygen tension. Mixed venous partial pressure of oxygen ($P_{mv}O_2$) and oxygen saturation ($S_{mv}O_2$) lie on the steep portion of the oxyhemoglobin dissociation curve. A minor error in measurement of the former can result in a major error in calculation of the latter.

It is frequently worthwhile to monitor $S_{mv}O_2$ continuously with a specially equipped pulmonary arterial catheter that has an oximeter attached to the tip. Calibration of the oximeter requires occasional cross-checking with measurement of $S_{mv}O_2$ in a correctly obtained sample of pulmonary arterial blood. A fall in the $S_{mv}O_2$ can arise from a decline in the cardiac output, a decrease in the hemoglobin concentration, a fall in the S_aO_2 , or an increase in oxygen consumption (including an increase in myocardial oxygen consumption).

It must be kept in mind, however, that even though a falling $S_{mv}O_2$ may be a warning signal, a normal or high value does not guarantee that cardiopulmonary status is satisfactory or that there is adequate oxygen for metabolic demands. In patients with low-output septic shock, for example, well-oxygenated blood is

returned to the heart because blood is functionally shunted away from the tissues. The high $S_{mv}O_2$ in these patients does not indicate that their metabolic needs are being met; rather, it is the result of deranged peripheral metabolic processes characterized by futile metabolic cycling. In patients with high-output septic shock, $S_{mv}O_2$ may be high because large amounts of blood are shunted to the skin so as to attenuate hyperthermia. Because the skin is metabolically inactive, the blood returning from it will have a high oxygen saturation. Similarly, in cirrhotic patients, who have functional arteriovenous shunts, a high $S_{mv}O_2$ is generated in the presence of inadequate metabolic activity.

Mixed venous oxygen content ($C_{mv}O_2$) is easily calculated in the same manner as C_aO_2 . In normal persons, $S_{mv}O_2$ is about 76%. Therefore, if oxygen dissolved in plasma is excluded, $C_{mv}O_2$ is $1.39 \times 11.4 \times 76\%$, or 12.0 ml/dl. If the oxygen in the plasma is added back in, $C_{mv}O_2$ becomes 12.2 ml/dl, on the assumption that $P_{mv}O_2$ is 41 mm Hg.

OXYGEN TRANSPORT

Oxygen transport—the amount of oxygen delivered to the tissues—is calculated by multiplying cardiac output by C_aO_2 . The calculation is simple, though care must be taken to obtain the correct units. Cardiac output is typically expressed in L/min, C_aO_2 in ml/dl. In multiplying the two, it is necessary to introduce a factor of 10 (to convert the liters of blood in cardiac output to the

deciliters of blood in C_aO_2). Thus, in a patient with a normal cardiac output of 6 L/min, a normal hemoglobin concentration of 11.4 g/dl, a normal S_aO_2 of 97%, and a normal P_aO_2 of 97 mm Hg, normal oxygen transport is approximately 940 ml/min:

$$\begin{aligned} O_2 \text{ transport} &= \text{cardiac output} \times C_aO_2 \\ &= 60 \text{ dl/min} \times 15.7 \text{ ml/dl} \\ &= 940 \text{ ml/min} \end{aligned}$$

A reduction in cardiac output, hemoglobin concentration, or S_aO_2 decreases oxygen transport.

OXYGEN RETURN

The amount of oxygen returned to the heart can be calculated by multiplying cardiac output by $C_{mv}O_2$. For a normal cardiac output of 6 L/min and a $C_{mv}O_2$ of 12.2 ml/dl, oxygen return is approximately 730 ml/min.

OXYGEN CONSUMPTION

Oxygen consumption is the difference between oxygen transport and oxygen return. It is therefore calculated by multiplying cardiac output by the difference in oxygen content between systemic arterial blood and mixed venous blood:

$$\text{Oxygen consumption} = \text{cardiac output} \times (C_aO_2 - C_{mv}O_2)$$

Normal oxygen consumption in a resting, supine, well-conditioned woman is 210 ml/min.

Oxygen consumption seems to have even more normal variability than the other parameters already discussed (see above), and it covers a range of values. It is probably easiest to memorize a single normal value, however, rather than a range. As long as the physician recognizes that, for example, an oxygen consumption of 180 ml/min in a 60 kg patient is close to the average of 210, no harm will be done. An oxygen consumption of 150 ml/min, however, would clearly be abnormally low and should prompt investigation to correct a low cardiac output, a low hemoglobin concentration, or a low S_aO_2 .

NONINVASIVE SUMMARY MEASUREMENTS

Three main goals can be identified for cardiovascular monitoring as technology advances. The first is to make as many measurements as possible noninvasively so as to eliminate the risks now associated with monitoring. The second is to find a single measurement that summarizes overall patient status. If this parameter indicates that a patient is doing well, current therapy can be continued; if not, therapy can be reassessed. The third goal—which contradicts the second to some degree but is nonetheless desirable—is to know the status of the individual organs. If a patient is not doing well, one would like to know where to direct therapeutic efforts. Ideally, one could identify the organ at greatest risk, keeping in mind that treating one organ usually comes at the expense of another. If one could monitor the state of all organs at

once, this problem would be close to being solved. Having a feeling for the flows and metabolic activities of individual organ systems, in both baseline and stressful conditions, is a start toward these goals. This knowledge can provide a useful perspective on the measurements available now.

Skin temperature can be monitored on the toe or the thumb with noninvasive devices. It is directly correlated with cutaneous blood flow and can be a sensitive indicator of overall perfusion.⁵⁹ A gradient of less than 2° C between skin temperature and ambient temperature indicates critically low perfusion; a gradient exceeding 2° C suggests that the heart is capable of generating a fairly robust output. Accurate measurements, however, are difficult to obtain unless there is good control of ambient temperatures.

Oxygen tension in soft tissues, which can also be a good indicator of overall perfusion, can be determined by monitoring conjunctival or cutaneous tissues. Conjunctival oxygen tension is measured with a small oxygen sensor placed directly on the conjunctiva. The device is safe, and it does reflect changes in oxygen delivery to the tissue, but it is not commonly used, perhaps because of the potential for damage to the eye. Transcutaneous oxygen tension can be determined by placing a polarographic surface oxygen electrode directly on heated skin; tissue oxygen tension is measured beneath this surface electrode. This value correlates well with P_aO_2 if local tissue perfusion is good.

Urine output is a good indicator of overall status. It is determined primarily by plasma levels of antidiuretic hormone and aldosterone. Stress increases these levels and thereby reduces output. Blood flow to the kidneys is of secondary importance, but it too can contribute to oliguria. The kidneys, however, are rarely at risk solely because of decreased blood flow. In strenuous exercise, for example, blood flow drops to very low levels, but the kidneys fare well. Their metabolic needs are easily met by increased extraction of oxygen from renal arterial blood. Although a low urine output usually reflects stress and perhaps decreased blood flow to the kidneys, an adequate or even high urine output does not necessarily mean that stress is absent or blood flow is more than adequate. For unclear reasons, some patients in inflammatory and even hypovolemic shock continue to produce apparently adequate urine output. Thus, although oliguria can be a warning sign of patient distress, normal urine production is not a guarantee that all is well.

Blood flow to the gastric mucosa can be assessed by means of gastric tonometry.⁶⁰ Low values suggest shock; normal values suggest adequate cardiovascular function. At the same time, blood flow to the gut mucosa and mucosal oxygen consumption can be influenced by other factors, such as body temperature, nutrients in the gut lumen, levels of stress hormones, and underlying individual variations in gastrointestinal physiology. To date, gastric tonometry has been most useful in those ICUs that have a research interest in this measurement technique. Physicians in other ICUs have found it difficult to derive reproducible values from the measurements.

Modern surgical care is dependent on the use of drugs, many of which can be harmful as well as beneficial. Polypharmacy is the norm, and as a result, there is a high potential for adverse interactions between agents. In addition, surgical patients often exhibit abnormalities in drug metabolism, for various reasons. Overall, the incidence of drug-related adverse events in hospitalized patients is difficult to determine precisely because the causality is often unclear. In one review,¹ adverse drug events (defined as injuries caused by the use or nonuse of drugs) or adverse drug reactions (defined as nonpreventable drug reactions resulting from the appropriate use of drugs) occurred in approximately 2% to 6% of hospital admissions. These adverse occurrences increased the duration of hospitalization by 1.2 to 3.8 days and increased hospital costs by \$2,284 to \$5,640. A better understanding of pharmacokinetics and pharmacodynamics can help surgeons minimize the potential for harm associated with the use of pharmacologic agents.

Definitions of Key Terms

Pharmacokinetics may be defined in several ways. The word itself is a combination of the element *pharmaco-*, meaning “related to drugs” (from the Greek word *pharmakon* “drug or poison”), and the word *kinetics*, meaning “the change in one or more variables as a function of time,” as Wagner succinctly put it.² In the discipline of pharmacokinetics, the variables in question relate to the time course and character of the body’s absorption, distribution, metabolism, and excretion of drugs.³ (These four processes are often collectively referred to by the abbreviation ADME.) Pharmacokinetics, then, can be thought of as the study of the actions of the body on a drug administered to it. The body’s pharmacokinetic handling of a drug depends on many factors, including the chemical characteristics of the drug, the dosage, the route of administration, the pharmaceutical formulation, and the physiologic characteristics and disease status of the patient.

Pharmacodynamics can be thought of as the study of the actions of a drug on the body. The variables in question relate to the time course and character of a drug’s effect at its site of action (i.e., at a receptor or another binding site). To ensure adequate patient response and prevent complications during the perioperative period, surgeons should possess a thorough understanding of both pharmacokinetics and pharmacodynamics.

Basic Pharmacokinetic Principles

ABSORPTION

Absorption is defined as the extent to which a substance moves into the systemic circulation from its site of administration. The pharmacokinetic parameter that is generally used to quantify drug absorption is bioavailability—that is, the fraction of an administered dose that becomes systemically available (often abbreviated as F). The bioavail-

ability of a given drug in a given patient depends in large part on its route of administration. Inadequate bioavailability is a not uncommon cause of therapeutic failure.

The absorption of a drug across any membrane or barrier is determined by blood flow to the area of absorption, the molecular size of the drug, and the degree to which the drug is ionized. In critically ill patients, regional blood flow may be abnormal, and diffusion across tissues may be limited by the presence of edema. As molecular weight increases, diffusion decreases exponentially. The ionization of a drug can be estimated by means of the Henderson-Hasselbalch equation:

$$\text{pH} = \text{pK}_a + \log(\text{base form}/\text{acid form})$$

where pH represents the hydrogen ion concentration and pK_a represents the negative logarithm of the acid ionization constant. The ionized form of the drug is not lipid soluble and therefore does not cross cell membranes by diffusion; in some cases, it may be actively transported.

Routes of Drug Delivery

Intravenous Many drugs can be administered directly into the systemic circulation. Intravenous (I.V.) administration, by definition, yields a bioavailability of 100%, thereby rendering the issue of absorption irrelevant. Systemic availability is most rapidly achieved when the drug is administered by I.V. bolus (also referred to as I.V. push). This mode of administration involves injecting small, concentrated volumes of the drug directly into the vein, generally over a period of 1 to 5 minutes (though slower rates are sometimes called for and often preferred). Not surprisingly, there are many drugs that cannot be administered by I.V. bolus, because of the potential for vein irritation and toxicity. With a few exceptions (e.g., propofol, which is given in lipid emulsions), drugs are dissolved in aqueous solutions when administered I.V.

Many drugs that cannot be given in an I.V. bolus can be administered via I.V. infusion. Infusion may be either intermittent or continuous, depending on the drug’s half-life or pharmacologic duration of action. For example, many antibiotics are administered via intermittent I.V. infusion, whereas drugs such as propofol, fentanyl, and dobutamine are typically administered via continuous infusion. Volumes as high as 1 L may be delivered via I.V. infusion; for most drugs, flow rates tend to be in the range of 2 to 3 ml/min. Use of precision infusion pumps is preferred to manual control of the infusion.

Oral Bioavailability is a critical consideration when a drug is being administered orally because the rate and extent of absorption from the gastrointestinal tract will have to be taken into account. The bioavailability of a drug after oral administration depends on three major variables: the fraction of the dose absorbed across the apical cell membrane (i.e., the portion of the membrane bordering the intestinal lumen) into the cellular space of the enterocyte (f_a), the intestinal first-pass extraction of the drug (E_G), and the hepatic first-pass extraction

of the drug (E_H). The relations among these factors may be described by the following equation⁴:

$$F = f_a \times (1 - E_G) \times (1 - E_H)$$

Most drug absorption after oral administration occurs in the small intestine. The value of f_a depends on several factors, including the dissolution rate of the drug formulation (for drugs given in a solid form, such as a tablet or capsule), gastric motility and emptying rate, and the solubility of the drug in GI fluids. Enteral feeding can also affect drug absorption. For example, tube feedings can impair absorption of phenytoin.⁵ Drugs and surgery can affect intestinal motility.

Once a drug molecule is absorbed through the intestinal cell membrane, it may be subject to intestinal first-pass metabolism by enzymes within the cells, as well as by efflux pumps embedded within the apical side of the cell membrane. Both cytochrome P-450 (CYP) and UDP-glucuronosyltransferase (UGT) enzymes are found in the small intestine. These enzymes contribute to the metabolism of certain orally administered drugs before they reach the systemic circulation. Drugs whose oral absorption is significantly affected by the intestinal enzyme CYP3A4 include the immunosuppressive agents cyclosporine, tacrolimus, and sirolimus; the calcium channel blockers; and some HIV protease inhibitors.

P-glycoprotein (P-gp) is a large protein that is the product of the multidrug resistance-1 (*MDR1*) gene. It is found on the apical membrane of enterocytes and acts as an efflux pump to remove exogenous substances.⁶ P-gp is found in many organs, including the kidneys, the brain, the lungs, the liver, and the GI tract.⁷ Many clinically used drugs are P-gp substrates, including tacrolimus, sirolimus, cyclosporine, verapamil, diltiazem, digoxin, dexamethasone, and methylprednisolone; most P-gp substrates are also substrates for CYP3A4.^{8,9} The presence of the P-gp efflux pump keeps these drugs from undergoing enzymatic metabolism within the enterocytes. Some drugs are inhibitors or inducers of P-gp.

After a drug is absorbed into the intestine, it is transported to the liver via the portal vein. At this point, the drug may be subject to hepatic first-pass metabolism by enzymes within the liver. After passage through the liver, the drug, its metabolites, or both pass into the systemic circulation. Drugs that are substrates of CYP2D6 and CYP3A4 are especially vulnerable to hepatic first-pass metabolism.⁵

Intramuscular Drug absorption after I.M. injection is highly variable and depends on the properties of the drug molecule, the formulation, and the injection site. Because muscle is highly vascularized, drugs in aqueous solutions often are absorbed quite rapidly after I.M. administration (albeit more slowly than they are after I.V. administration). Any condition that reduces blood flow to the muscle at the site of injection will decrease the rate and extent of drug absorption after I.M. administration. Drugs in aqueous vehicles are absorbed more rapidly than those in lipid vehicles. In some cases, the slower absorption associated with lipid emulsions constitutes a practical advantage. For example, with certain medications (e.g., penicillin G benzathine, risperidone, and haloperidol), long-acting I.M. formulations are made by suspending the drug in a lipid vehicle specifically for the purpose of extending the duration of the therapeutic effect to as long as 4 weeks.

Subcutaneous In a subcutaneous injection, the drug is injected into the connective tissue that lies underneath the dermal layer of the skin. This tissue is not as well vascularized as muscle. Consequently, a drug typically is absorbed more slowly after subcutaneous administration than after I.M. administration. Drugs commonly given via subcutaneous injection include insulin, heparin (which, unlike most drugs, is rapidly absorbed via this route), and

low-molecular-weight heparins (LMWHs). Generally, no more than 0.5 to 1 ml of a drug may be administered subcutaneously. Peripheral edema or hypoperfusion may limit systemic absorption after subcutaneous injection.

Transdermal Although most topically administered drugs are meant to exert only local effects, some are meant to reach the systemic circulation. To be systemically distributed after topical application, drug molecules must pass through the stratum corneum and the epidermis to reach the blood vessels of the dermis. To traverse these outer layers of the skin, the molecules must be lipophilic, of a low molecular weight, and nonionized. Drugs that are administered transdermally bypass both hepatic and intestinal first-pass metabolism and are absorbed continuously for as long as any available drug remains in the skin. Most transdermal patches are designed so that the rate of drug release is significantly slower than the rate of absorption through the skin, thereby permitting gradual and continuous absorption into the systemic circulation. Sometimes, a loading dose is contained in the adhesive layer (as with the scopolamine patch for motion sickness), allowing more rapid attainment of therapeutic blood levels. Examples of common transdermal formulations include the fentanyl patch, which releases the drug over a 72-hour period, and the clonidine patch, which releases the drug continuously for 7 days.

The main advantage of the transdermal method of administration is that it allows blood levels of a drug to be maintained at a desired level for a relatively long period without I.V. administration. One disadvantage is that after removal of the patch or other formulation, a residual amount of the drug may be left in the skin layer, and this residuum may continue to be absorbed into the systemic circulation even after therapy has been discontinued.

Sublingual and transmucosal Some drugs (in particular, those that are in a nonionized form and that exhibit high lipid solubility) are well enough absorbed via the oral mucosa that they may be given sublingually or simply dissolved in the mouth. This route of administration is especially advantageous for drugs that undergo significant hepatic first-pass metabolism when administered orally (e.g., nitroglycerin) because when a drug is absorbed through the oral mucosa, it passes directly into the systemic circulation. Drugs that are sometimes administered in this manner include buprenorphine and fentanyl.

Rectal Rectal administration of a drug may be convenient in clinical situations where (1) nausea and vomiting is present or oral intake is restricted (e.g., before an operation), (2) I.V. administration is not desirable, and (3) the drug of interest is available in a suppository form. Unfortunately, drug absorption from the rectum is hard to predict and often incomplete. The rectum is drained by both the systemic circulation and the portal circulation. From a pharmacokinetic standpoint, this means that approximately 50% of a rectally administered drug dose will bypass the liver and reach the systemic circulation without undergoing hepatic first-pass metabolism.¹⁰ Drugs available in rectal suppository form that are absorbed systemically include acetaminophen, aspirin, and the antiemetics promethazine and prochlorperazine. In addition, various drugs may be administered rectally with the intention of producing a local or colonic effect (e.g., anesthetic suppositories in patients with hemorrhoids and sucralfate or neomycin retention enemas in patients with hepatic failure).

Vaginal Vaginal administration of drugs is usually intended to produce local effects, except in the case of hormonal treatments (e.g., the vaginal contraceptive ring, the estradiol ring, and estradiol or progesterone creams), which are intended to have at least some

degree of systemic absorption. An important consideration prescribing topical vaginal products (e.g., antifungal agents) is the age of the patient. The pH of the vagina ranges from 3.5 to 4.2 in women of reproductive age, but it is either neutral or slightly basic in postmenopausal women and girls who have not yet reached puberty. These pH changes can alter the ionization state of antifungals such as ketoconazole. At an acidic pH, ketoconazole is protonated, but at a neutral or basic pH, it is nonionized and therefore able to cross the membranes of the vagina, undergoing unwanted systemic absorption and exerting undesired side effects.

Nasal Most drugs that are administered nasally are topical agents employed to produce local effects. However, the nasal mucosa has much the same capacity for systemic absorption that the oral mucosa does: the area is highly vascularized, allowing rapid absorption of lipophilic and nonionized drugs. Currently, only desmopressin acetate (1-deamino-8-D arginine vasopressin, or DDAVP) and calcitonin are administered nasally for systemic therapy, though intranasal formulations of other drugs (e.g., insulin) are now in development. The mucosal membranes of the nose contain a number of drug-metabolizing enzymes, including CYPs, which may result in first-pass metabolism of certain drugs.

Inhalational The large surface area of the lung, the high permeability of the alveolar surfaces, and the highly vascular nature of lung tissue allow rapid systemic absorption of drugs,¹¹ especially those in gaseous form (e.g., inhaled general anesthetics). In terms of the onset of therapeutic effect, however, the partial pressure of these agents in blood and tissue is more important than the actual concentration.¹² Inhalational general anesthetics aside, most inhaled prescription drugs (e.g., beta₂ agonists and corticosteroids for treatment of asthma and amphotericin B and tobramycin for treatment of lung infections) are designed to exert local effects on lung tissue. Systemic absorption does occur, but it is minimal and is partly attributable to swallowing of the drug during inhalation.

At present, the only inhaled drug formulation on the market that is designed for systemic delivery via the lungs is inhaled insulin (Exubera; Pfizer, New York, New York), which was approved by the United States Food and Drug Administration in January 2006. An advantage of this inhaled insulin formulation is that its absorption into the systemic circulation is independent of body mass index (BMI)—in contrast with subcutaneously administered regular insulin, which is absorbed more slowly in obese patients.¹³

The pulmonary route of administration is also particularly effective at ensuring a high spike in drug concentration in the central nervous system. Currently, this property is taken advantage of by cigarette smokers and users of freebase cocaine, crack cocaine, and crystal methamphetamine; in the future, it may be taken advantage of by developers of therapeutic drugs.

Nervous system In some situations, it is desirable to obtain particular drug levels in the cerebrospinal fluid. However, under normal circumstances (i.e., in the absence of conditions such as inflammation and trauma), many drugs, especially those that are water-soluble or ionized, have difficulty penetrating the blood-brain barrier. Even when a drug does cross this barrier and reach the brain, the choroid plexus may secrete it back into the blood, making it difficult to reach the desired drug levels in the CSF. To overcome this difficulty, certain drugs (typically local anesthetics or analgesics) may be injected in or near the spinal canal in the vicinity of the nerve fibers that are to be blocked. Examples of this type of injection include epidural blocks, paravertebral nerve blocks, and spinal nerve blocks. Systemic absorption occurs, but it should be kept to a minimum: it is not necessary

for the therapeutic effect, and it may cause toxicity.¹⁴ The vasoconstrictor epinephrine is often administered along with a local anesthetic during a spinal block because it decreases blood flow around the injection area, thereby reducing systemic absorption and potentiating the effects of the anesthetic. Epinephrine also acts on alpha₂ adrenoceptors on the nerve terminals to enhance the anesthetic effect by inhibiting the release of substance P and reducing nerve firing.

DISTRIBUTION

While a drug is being absorbed into the systemic circulation, it may simultaneously be distributed into other physiologic fluids and tissues, depending on the physiology of the patient and the physiochemical properties of the drug. Patient variables that may affect distribution include body size, fluid distribution within the body, amount of adipose tissue, cardiac output, tissue blood flow, and amount of functional plasma proteins. Drug variables that affect distribution include lipophilicity, molecular weight, and affinity for plasma proteins and tissues. The distribution of a drug beyond the systemic circulation is typically described in terms of volume of distribution (V_d).

Volume of Distribution

V_d is a pharmacokinetic parameter that relates the amount of a given drug in the body to the concentration of the drug in the area from which it was sampled (usually the bloodstream). It is not an actual physical volume; rather, it is estimated by means of pharmacokinetic techniques. There are several types of V_d parameters, the calculation of which depends on the route of administration of the drug and the pharmacokinetic model used to describe its disposition. V_d is usually expressed in liters and may range from a value approximately equivalent to blood volume (5 to 7 L), in the case of a drug such as warfarin, to values as high as 200 L, in the case of digoxin (which is extensively distributed to and readily binds to tissues outside the vasculature). In a clinical setting, V_d may be used to estimate the quantity of drug (A) needed to achieve a desired plasma concentration (C), as follows:

$$A = V_d \times C$$

Plasma Protein Binding

A number of commonly used drugs exhibit significant plasma protein binding [see Table 1]. Of the more than 60 different proteins that are found in plasma,¹⁵ three types are responsible for most instances of drug binding: albumin, α_1 -acid glycoprotein (AAG), and lipoprotein.

Albumin is a 66.3 kd protein that comprises approximately 580 amino acid residues. It is made by the liver and broken down by the liver, the kidneys, the spleen, and the lymph nodes. Its half-life is approximately 19 days, and at any given point, 40% of the body's supply of albumin is circulating in plasma, with the remaining 60% located in interstitial fluid. The albumin molecule possesses two main drug-binding sites. The first site is called the warfarin-binding area, but it also binds other drugs, such as valproic acid, phenytoin, and sulfonamides. The second binding site is called the indole-benzodiazepine-binding area; it binds drugs such as certain penicillins and medium-chain fatty acids. Some drugs, such as the nonsteroidal anti-inflammatory drugs (NSAIDs), bind to both sites. In addition to the main binding sites, separate binding sites for bilirubin, digitoxin, and tamoxifen have been discovered. Albumin binds mainly with weakly acidic (anionic) drugs, though it also binds with certain basic drugs (e.g., benzodiazepines) and some neutral drugs (e.g., dexamethasone).

There are a few rare genetic polymorphisms that are known to affect albumin levels or function. Certain disease states may induce alterations in the concentration or binding ability of albumin, thereby potentially resulting in a higher free fraction of the drug (and thus an

Table 1 Commonly Used Drugs That Are Highly Bound to Plasma Proteins

Bound to Albumin	Bound to AAG	Bound to Albumin and AAG	Bound to Albumin and Lipoproteins	Bound to Albumin, AAG, and Lipoproteins
Ceftriaxone	Diiisopyramide	Alfentanil	Amiodarone	Amphotericin B

Tiagabine				
Valproic acid				
Warfarin				

AAG— α_1 -acid glycoprotein

increased amount of drug available to exert pharmacologic effects) and, often, lower total drug concentrations. In addition, drug displacement interactions may occur when a previously administered drug that is already bound to albumin is followed by a drug that has a higher affinity to albumin. Salicylate and the sulfonamides are examples of drugs with high albumin-binding affinities that are capable of displacing other drugs from albumin binding sites, thereby causing the unbound fraction of the displaced drug to increase. Nevertheless, the majority of displacements from binding sites on the albumin molecule result in the same free concentrations of the drug, though the total concentrations may decrease precipitously. In this situation, if the total concentrations are followed and the dosage increased to achieve a specific total concentration, the increase in the unbound fraction that results from the drug interaction (or from a decreased albumin concentration caused by a disease state) may lead to toxicity. Because albumin levels are frequently low in surgical patients, measurement of free drug levels is recommended if available.

AAG is an acute-phase protein that is both produced and metabolized by the liver. It is somewhat smaller than albumin (38 to 48 kd) and has a half-life of 5 days. Approximately 60% of the body's supply of AAG circulates in plasma, with the remaining 40% in interstitial fluid. AAG tends to bind basic drugs, but it also binds some that are neutral or acidic. There are three known genetic variants of AAG, but it is unclear whether this variation is of any clinical significance. Elevated AAG levels may lead to a decrease in the unbound fraction of a drug and thus to a reduction in the amount of drug available for pharmacologic activity.

The lipoproteins are a diverse group of proteins that vary significantly with respect to molecular weight, lipid content, and drug bind-

ing affinity. Structurally, they comprise a lipid core made up of cholesterol and triglycerides, which is surrounded by an outer layer made up of phospholipids, cholesterol, and apolipoproteins. They are produced by the liver and the intestinal mucosa and are metabolized by the liver, the kidneys, and the intestine. Lipoproteins are classified into four groups: very low-density lipoproteins (VLDLs), low-density lipoproteins (LDLs), intermediate-density lipoproteins (IDLs), and high-density lipoproteins (HDLs). Of these, VLDLs, LDLs, and HDLs account for the bulk of lipoprotein drug binding. The most common mechanism by which drugs attach to lipoproteins is believed to be a nonsaturable partitioning into the lipid core^{15,16}; drugs that appear to exemplify this mechanism include cyclosporine,¹⁷ propranolol, digoxin, and tetracycline.¹⁵ Some drugs, however, such as propranolol and certain tricyclic antidepressants, are believed to bind to specific sites in a saturable manner.^{15,16} Lipoproteins may bind additional drug when albumin binding sites become saturated.¹⁸

The amount of free (unbound) drug in the plasma has pharmacologic implications. Tissue and plasma protein binding influence the apparent volume of distribution of a drug according to the following equation:

$$V_d = V_B + (f_B/f_T)V_T$$

where V_B is blood volume (0.07 L/kg), V_T is tissue volume, f_B is the unbound fraction of drug in the blood, and f_T is the unbound fraction of drug in tissue. For lipophilic drugs, tissue volume is calculated as total body water minus plasma volume (approximately 0.6 L/kg). For hydrophilic drugs, tissue volume is calculated as extracellular fluid minus plasma volume (approximately 0.13 L/kg). The degree of a drug's affinity for plasma proteins as opposed to tissue

components is the main determinant of its volume of distribution. Changes in f_{B_d} , however, lead to changes in V_d only when a drug has a V_d of at least 30 L (i.e., when blood volume constitutes no more than a small fraction the drug's total volume of distribution).¹⁹

Uremia, cirrhosis, nephrotic syndrome, epilepsy, hepatitis, and various other disease states have been shown to decrease protein binding of drugs. Plasma protein binding is also reduced in pregnant women, neonates, and persons who have sustained severe burns. Accordingly, clinicians often assume that pregnant patients, newborns, or burn patients who are taking a highly protein-bound drug are automatically at risk for alterations in the unbound fraction of the drug; however, this assumption is not always valid.¹⁹ As noted (see above), V_d depends on several factors, including f_{B_d} , f_T , V_B , and V_T .

Increased binding of drugs to plasma proteins decreases the amount of drug available for diffusion into tissues, thereby limiting V_d . In contrast, increased binding of drugs to tissue proteins increases the apparent V_d . Increased protein binding also limits drug elimination because for the most part, only unbound drug can be eliminated.

METABOLISM

Hepatic Metabolism

With a few exceptions, drug metabolism (also known as biotransformation) consists of converting a lipophilic drug to a more hydrophilic metabolite, which is then more easily excreted by the kidneys. (The only agents excreted by the pulmonary route are the volatile anesthetic agents.) Metabolic reactions are generally divided into two phases: phase I reactions, which include oxidation, reduction, and hydrolysis; and phase II reactions, which include glucuronidation, sulfation, methylation, acetylation, and amino acid and glutathione conjugation.

From a clinical standpoint, the most important drug-metabolizing enzymes are the CYP enzymes. They are part of the microsomal mixed-function oxidase system and work in combination with CYP reductase, molecular oxygen, and nicotinamide adenine dinucleotide phosphate (NADPH) to perform many of the phase I metabolic reactions. The CYP enzymes also help synthesize and metabolize endogenous substrates (including hormones) and break down nondrug xenobiotics (e.g., environmental pollutants). The liver, as the main metabolic organ of the body, contains more CYP enzymes than any other organ, but CYPs are also found in significant quantities in the small

Table 2 Common Substrates, Inducers, and Inhibitors of Cytochrome P-450

Substrates	Inducers	Inhibitors
Acetaminophen	Carbamazepine	Amiodarone
Caffeine	Cigarette smoke	Cimetidine
Cyclosporine A	Dexamethasone	Ciprofloxacin
Diazepam	Ethanol (in chronic setting)	Diltiazem
Diltiazem	Isoniazid	Ethanol (in acute setting)
Fentanyl	Omeprazole	Fluconazole
Fluoxetine	Phenobarbital	Fluoxetine
Haloperidol	Phenytoin	Metronidazole
Midazolam	Rifampin	omeprazole
Morphine		Propofol
Phenobarbital		
Phenytoin		
Tacrolimus		
Warfarin		

intestine, the colon, the kidneys, the brain, the lungs, the heart, the skin, the nasal mucosa, the heart, and the eyes.

To date, 18 families of CYP enzymes and 42 subfamilies have been identified. These enzymes exhibit many genetic polymorphisms, some of which do not affect function, some of which restrict function, and some of which encode nonfunctional proteins. Particular polymorphisms may alter a person's ability to metabolize drugs. In addition, some persons have gene duplications that give rise to increased enzyme activity. Thus, there is a great deal of interindividual variability with respect to CYP-related metabolic capacity.

A number of common drugs are known to induce, inhibit, or serve as substrates for CYP [see Table 2]. Some of these drugs have multiple effects.

ELIMINATION

Half-life

Half-life ($t_{1/2}$) is a pharmacokinetic parameter that represents the amount of time necessary for the amount or concentration of drug in the body to decrease by 50%. As a general rule, almost all (97%) of a drug will have been eliminated after five half-lives. For a first-order process, half-life is described by the following equation:

$$t_{1/2} = 0.693/k_e$$

where k_e is the elimination rate constant in inverse time units. It is important to remember that half-life should not be used as a measure of hepatic clearance or liver function, because it changes proportionately with clearance only when V_d remains constant.

Clearance of the drug [see Clearance, below] in volume units per unit of time (CL) and V_d are independent (albeit correlated) parameters that are related via k_e , as shown in the following equation:

$$CL = k_e \times V_d$$

Thus, k_e is equivalent to CL/V_d , which means that the equation for half-life (see above) can also be written as follows:

$$t_{1/2} = (0.693 \times V_d)/CL$$

Clearance

Clearance is an independent pharmacokinetic parameter that is defined as the volume of plasma, serum, or blood that is cleared of the drug per unit of time. The liver is the organ primarily responsible for drug clearance. Clearance may be considered the most important of the pharmacokinetic parameters because it determines what the maintenance dose (MD) of a drug should be to achieve a desired steady-state plasma concentration (C_{ps}):

$$MD = C_{ps} \times CL$$

Renal Clearance

Renal clearance of drugs is the result of three processes: tubular secretion, tubular reabsorption, and glomerular filtration. The glomerular filtration rate (GFR) is generally considered the best overall indicator of kidney function. It may be determined through I.V. administration of a substance (e.g., inulin or iothalamate) that is freely filtered at the glomerulus but is not subject to reabsorption or secretion by the tubules. In a routine clinical setting, however, estimation of renal function by direct measurement of the GFR is impractical. A common alternative is to measure creatinine clearance (CrCL), which is generally accepted as a reasonably accurate estimate of the GFR and therefore of renal function. This is done by collecting the patient's urine over a 24-hour period and determining the concentrations of creatinine in serum and urine. CrCL is then calculated according to the following equation:

$\text{CrCL} (\text{ml/min}) = \text{rate of urinary creatinine excretion}/\text{serum creatinine concentration}$

$$\text{CrCL} (\text{ml/min}) = (U_{\text{Cr}} V \times 100)/(S_{\text{Cr}} \times 1,440)$$

where U_{Cr} is the urinary creatinine concentration (mg/ml), V is the volume of urine produced over a 24-hour period (ml), and S_{Cr} is the serum creatinine concentration (mg/dl) measured at the 12th hour (i.e., the midpoint) of the urine collection period.

For practical purposes, CrCL is usually estimated by applying any of a number of commonly accepted equations. The equation most frequently employed to estimate CrCL in patients with stable renal function is that of Cockcroft and Gault, which derives CrCL from the patient's age, ideal body weight (IBW), and S_{Cr} :

$$\text{CrCL} = [(140 - \text{age}) \times \text{IBW}] / (72 \times S_{\text{Cr}})$$

Because women have less muscle mass in relation to their body weight than men do, the value for CrCL in female patients is calculated by multiplying this equation by 0.85. The Cockcroft-Gault equation uses IBW rather than actual body weight because adipose tissue contains little if any muscle and therefore is believed to contribute little to the serum creatinine level; if actual body weight were used, CrCL might be overestimated.

It should be kept in mind that the various methods of estimating CrCL are necessarily imperfect, in that S_{Cr} may be abnormally high or abnormally low for reasons that have nothing to do with kidney function. For example, S_{Cr} may be decreased in elderly, bedridden, or wheelchair-bound patients (because of the loss of muscle mass), and it may be elevated in patients with increased muscle mass, those who have recently undergone strenuous exercise, trauma patients, and even persons who consume high quantities of red meat. Liver dysfunction can affect the accuracy of CrCL estimates by decreasing the conversion of creatine to creatinine.

Unbound drugs of low molecular weight are readily filtered by the glomeruli. The ionized fraction is then excreted. The nonionized fraction, however, is reabsorbed by the tubules and is typically metabolized by the liver to the ionized form. With some drugs, reabsorption is dependent on pH; consequently, when these drugs cause toxicity, manipulation of urinary pH to increase their elimination can be a useful therapeutic measure. Secretion of drugs into the renal tubules is an active process that is not particularly specific.

Thus, drugs may compete with each other or with endogenous substrates, and toxicities may result.

Metrics Reflecting Magnitude of Drug Exposure

AREA UNDER THE CURVE

Area under the curve (AUC) is a pharmacokinetic parameter that reflects the extent of a drug's bioavailability—that is, it reflects the total amount of active drug that reaches the systemic circulation after administration. The AUC is usually calculated from the actual area under a curve generated by plotting plasma concentrations of an administered drug over a period of time (whether from time 0 to infinity or from one dose to the next). For drugs exhibiting linear (i.e., first-order) kinetics, the AUC is proportional to the dose administered. With some drugs, however, this may not be the case at higher dosages, because drug elimination pathways may become saturated.

PEAK PLASMA CONCENTRATION

Peak plasma concentration (C_{max}) is a pharmacokinetic parameter that quantifies the highest level reached in the plasma after administration of a drug. Knowledge of C_{max} may be advantageous in certain situations. For example, some antibiotics (e.g., aminoglycosides) depend on a high C_{max} rather than on sustained drug levels for their bactericidal effects. Other drugs may cause toxicity if C_{max} reaches inappropriately high levels. C_{max} is expressed in units of concentration (e.g., $\mu\text{g}/\text{ml}$ or mg/L). It may be calculated in several ways; which equation is used depends on the route of administration of the drug and the model used to describe its disposition.

TIME OF PEAK PLASMA CONCENTRATION

Time of peak plasma concentration (T_{max}) is simply the time at which the maximum plasma concentration is reached after extravascular drug administration. As such, it is also an indication of the time of peak drug absorption, at which absorption and elimination (expressed in mass units per time unit) are equal. Comparison of T_{max} between two extravascular dosage forms allows determination of relative absorption rates. T_{max} decreases as the absorption rate increases.

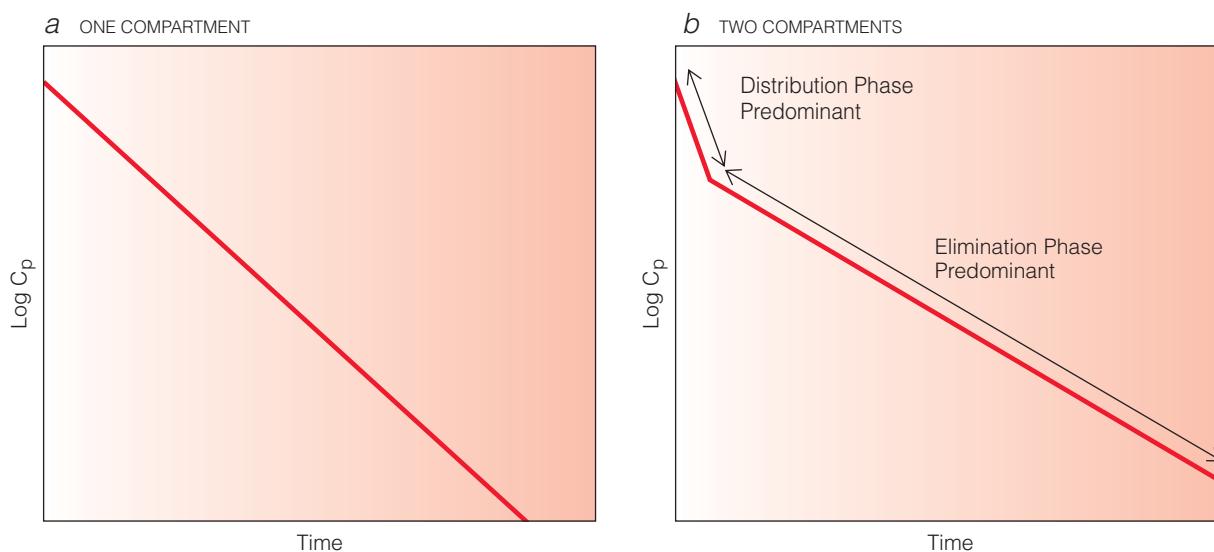

Figure 1 Depicted are (a) one-compartment and (b) two-compartment pharmacokinetic models. (C_p —plasma concentration)

Fundamental Pharmacokinetic Concepts

COMPARTMENTAL PHARMACOKINETIC MODELING

As the study of pharmacokinetics has progressed, various models for the disposition of drugs in the body have been proposed. Many of these models portray the body as a collection of spaces with volumes and elimination rates (clearance rates). These spaces, commonly referred to as compartments, are not actual anatomic realities, though they may have characteristics that are very similar to those of true anatomic spaces. They represent conceptual adaptations of monoexponential or multiexponential concentration-versus-time curves, in which the curves are converted to virtual spaces that have specific finite volumes and elimination rates.

The simplest compartmental model is the one-compartment model. This model assumes that the body is a single homogeneous unit in terms of a particular drug's pharmacokinetic profile. It therefore also assumes that the drug is instantaneously distributed throughout the compartment after administration. Obviously, this assumption is purely theoretical and, from a practical standpoint, impossible. Nevertheless, the one-compartment model adequately describes the disposition of many drugs that are rapidly distributed in the body. A concentration time profile that has a monoexponential character in the decline (see below) is often characterized as a one-compartment model. It is important to remember that the signal characteristic of the one-compartment model is not that the actual drug concentrations are the same in all body tissues as in blood or plasma (which is not necessarily the case) but that the rate at which drug or metabolite levels change is constant throughout the entire body.

Elimination from a compartment may be assumed to be a first-order or linear process. In a static first-order process, a constant proportion of the drug is eliminated over a given unit of time. The first-order elimination rate constant k (or k_e) is a proportionality constant that relates clearance to V_d . It is expressed in reciprocal time units (i.e., hr^{-1} or min^{-1}) because it is derived by dividing a rate (the volume from which all material is removed per unit of time, expressed in L/hr) by a volume (V_d , expressed in liters). The overall clearance of a drug is the sum of the clearances attributable to all of the routes by which the drug may be eliminated (e.g., $\text{CL} = \text{CL}_{\text{renal}} + \text{CL}_{\text{hepatic}} + \text{CL}_{\text{biliary}}$...); the precise value depends on the particular elimination pathways that are open to the drug. If a drug has nonlinear elimination characteristics, clearance will constantly change in conjunction with concentration.

As noted (see above), in a one-compartment model, whereas the rate of change in the drug concentration may be the same in all body tissues, the actual drug concentrations in particular tissues may be different from each other and from those in blood or plasma. The usual assumption, however, is that the ratios between tissue concentrations and plasma concentrations are constant. This assumption then leads to the further assumption that the relation between plasma concentration and the total amount of drug in the body is also constant. The relation between these two factors is represented by the volume of distribution term V_d .

For many drugs, distribution can be more accurately described by employing a multicompartment model, which incorporates both a central compartment (as in the one-compartment model) and one or two (or, in rare cases, more than two) peripheral compartments. These peripheral compartments may represent more poorly perfused tissues of the body that have a different affinity for the drug. Peripheral compartments are hypothetical constructs, in that the actual drug concentrations in tissues are not known, but their presence is often assumed on the basis of plasma concentrations measured over time after an I.V. bolus. When a concentration-time curve is plotted on a semilogarithmic graph after injection of an I.V. bolus, a drug that follows a one-compartment model shows a linear decline [see Figure 1a],

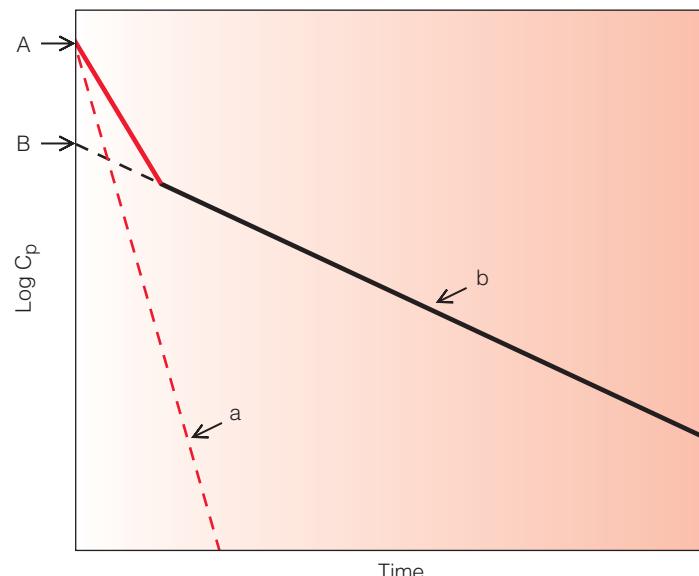

Figure 2 In a two-compartment model of pharmacokinetics, plasma concentration can be estimated by using intercepts A and B and microconstants a and b.

whereas a drug that follows a two-compartment model shows two distinct phases, a distribution phase and an elimination phase [see Figure 1b]. The drug does not switch from one phase to the other in an on-and-off fashion; rather, the two phases predominate at different stages of drug disposition after administration.

The first phase of the two-compartment concentration-time curve, the distribution phase, primarily reflects the distribution of the drug from the rapidly perfused tissues of the central compartment into the more poorly perfused tissues of the peripheral compartment. During this phase, the drug concentration in the peripheral compartment gradually increases until it reaches a maximum. At this maximum peripheral tissue concentration, the rate of drug input into the tissue is equal to the rate of drug output from the tissue, and the portion of drug in the central compartment is in equilibrium with the portion of drug in the peripheral compartment. This point in time is termed distribution equilibrium. After this point, the drug amounts in the central and peripheral compartments decline at similar rates, and the kinetics of the drug begin to resemble those of a one-compartment model.

The second portion of the concentration-time curve, the elimination phase, reflects the passage of the drug from the body. It is usually assumed that drug elimination occurs via the central compartment. This assumption is based on the observation that most drugs are eliminated mainly via the liver or the kidneys, both of which are highly perfused organs that are usually included in the central compartment.

The rate constants describing the rate of transfer between compartments in a two-compartment model are often referred to as microconstants because they cannot be determined by direct measurement; however, they can be estimated from a logarithmic graph of plasma concentration versus time after an I.V. bolus [see Figure 2]. Plasma (or central compartment) drug concentration (C_{central}) may be related to time by means of the following equation:

$$C_{\text{central}} = A e^{-at} + B e^{-bt}$$

where e is the base of the natural system of logarithms, and A and B are intercepts on the y axis for each segment of the concentration-time curve. The hybrid constants A and B have no real physiologic significance, but they are useful for solving this equation as a sum of exponentials. The terms a and b represent the first-order rate constants for

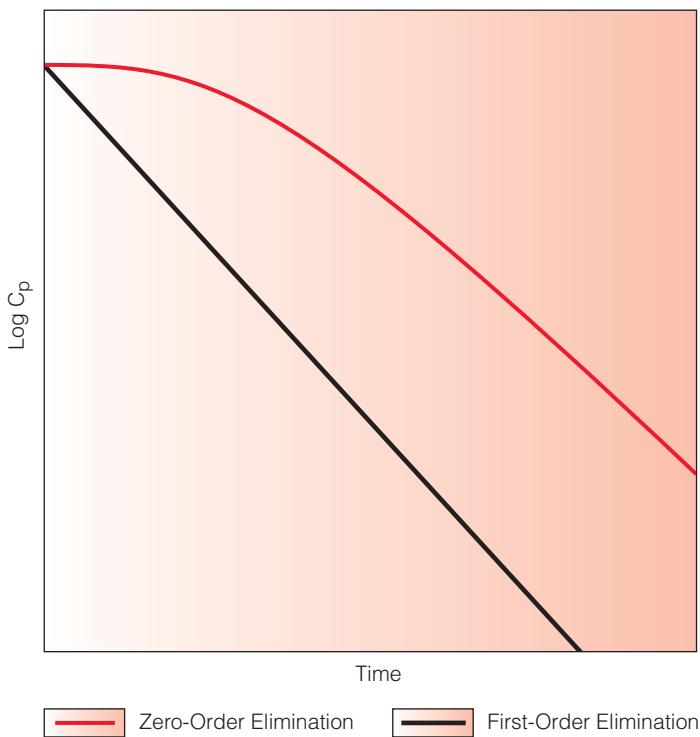

Figure 3 Plotting of plasma concentration against time illustrates the difference between zero-order (saturable) drug elimination and first-order elimination.

the distribution phase and the elimination phase, respectively. As may be seen from the concentration-time curve [see Figure 2], the decline in drug concentration is steeper in the initial (distribution) phase than in the second (elimination) phase.

Many agents are eliminated in a nonlinear manner (so-called zero-order elimination), and their elimination half-life lengthens as the dosage increases [see Figure 3]. This phenomenon is usually attributable to saturation of the enzyme systems responsible for metabolizing the drug. Such saturation can cause changes in the metabolite profile. When there is saturation of elimination, the area under the concentration-time curve ceases to be proportional to drug exposure, and the AUC does not increase linearly with increasing doses (as it does with first-order kinetic processes).

Saturable GI absorption may occur with drugs such as gabapentin, baclofen, and riboflavin, and saturation of intestinal metabolism may occur with propranolol. In addition, saturable plasma protein binding may occur with drugs such as lidocaine, ceftriaxone, warfarin, disopyramide, and phenytoin. Saturable tissue transport may occur with drugs such as methotrexate.¹⁸ The most clinically relevant zero-order processes, however, are those related to hepatic metabolism. Two drugs with narrow therapeutic indices whose metabolism follows zero-order kinetics are the antiepileptic medications phenytoin and valproic acid.

A drug with saturable elimination will, at a large enough dose, demonstrate a disproportionately large increase in AUC with a dose increase once the saturation point of the elimination system is reached. The term Michaelis-Menten kinetics is used to describe elimination of drugs by saturable enzymatic processes. The standard Michaelis-Menten equation for estimating the elimination rate (V) is as follows:

$$V = V_{\max} C_p / (K_m + C_p) = dC_p/dt$$

where V_{\max} is the maximum metabolic rate of the enzymes, C_p is the plasma concentration, and dC_p/dt is the rate at which C_p changes over

time. When V_{\max} is reached, a constant amount of drug is eliminated per unit of time, and elimination is truly a zero-order process. K_m , the so-called Michaelis constant, is a reflection of the metabolizing capacity of the enzyme system. It is equal to the drug concentration in the body when V is one half of V_{\max} . This equation is appropriate at a wide range of drug concentrations because if C_p is much larger than K_m , the enzymatic processes become saturated, K_m can be considered negligible and drops out of the equation, and V is approximately equal to V_{\max} .

PHYSIOLOGICALLY BASED PHARMACOKINETICS

A very useful pharmacokinetic modeling approach that is sometimes employed as an alternative to compartmental modeling is physiologically based pharmacokinetics (PBPK). PBPK is similar to compartmental modeling in that spaces are represented as instantaneous mixing compartments. However, it differs from classical compartmental modeling in that the compartments in a PBPK model are constrained to the actual space occupied by a particular tissue or organ. In addition, tissues are connected not by first-order rate constants or clearances but directly by blood flows originating in the arterial circulation and emptying into the venous system (with the exception of the lungs) [see Figure 4]. Drugs introduced into the vascular system circulate and are delivered to various tissues. Within tissues, any sort of transfer may be specified, from instantaneous transfer with a partition coefficient to linear or nonlinear transfer to or from a tissue space or within tissue subspaces. A great advantage of PBPK is that it permits modeling of tissue-specific concentrations and time courses of concentration changes. This advantage is especially important if the desired drug action depends on exposure within a particular space.

Pharmacodynamics

The discipline of pharmacodynamics aims to define the relation between pharmacokinetics and response to the drug. PBPK modeling is very useful for capturing effect-site concentrations that can be linked to a particular drug effect. Effect-site concentrations are not directly measurable in clinical situations, but estimating such concentrations can help distinguish distributional effects that cause a dissociation between observed plasma concentration and physiologic response from tolerance-type or sensitization-type responses that occur at the site of action. With sensitization, a plasma concentration observed early in the exposure profile evokes a lesser response than the same concentration observed later (i.e., the patient becomes more sensitive to the drug). This development is often seen as a counter-clockwise hysteresis when the drug's concentration is plotted against its effect over time. With tolerance, a concentration observed early in the exposure profile evokes a greater response than the same concentration observed later (i.e., the patient becomes tolerant to the drug). This development is seen as a clockwise hysteresis when concentration is plotted against effect over time.

BASIC PHARMACODYNAMIC MODELS

The linear-response pharmacodynamic model, as its name suggests, describes the relation between drug concentration (whether in plasma, in a particular compartment, or at the biophase) and physiologic response as a linear one [see Figure 5]. The general form of this model is as follows:

$$\text{Response} = \text{baseline} + (\text{concentration} \times \text{response factor})$$

The maximum-response model determines the relation between concentration and response on the basis of the maximum response (E_{\max}), the concentration at which 50% of E_{\max} is observed (EC_{50}), and, optionally, other factors (e.g., exponents applied to both E_{\max} and

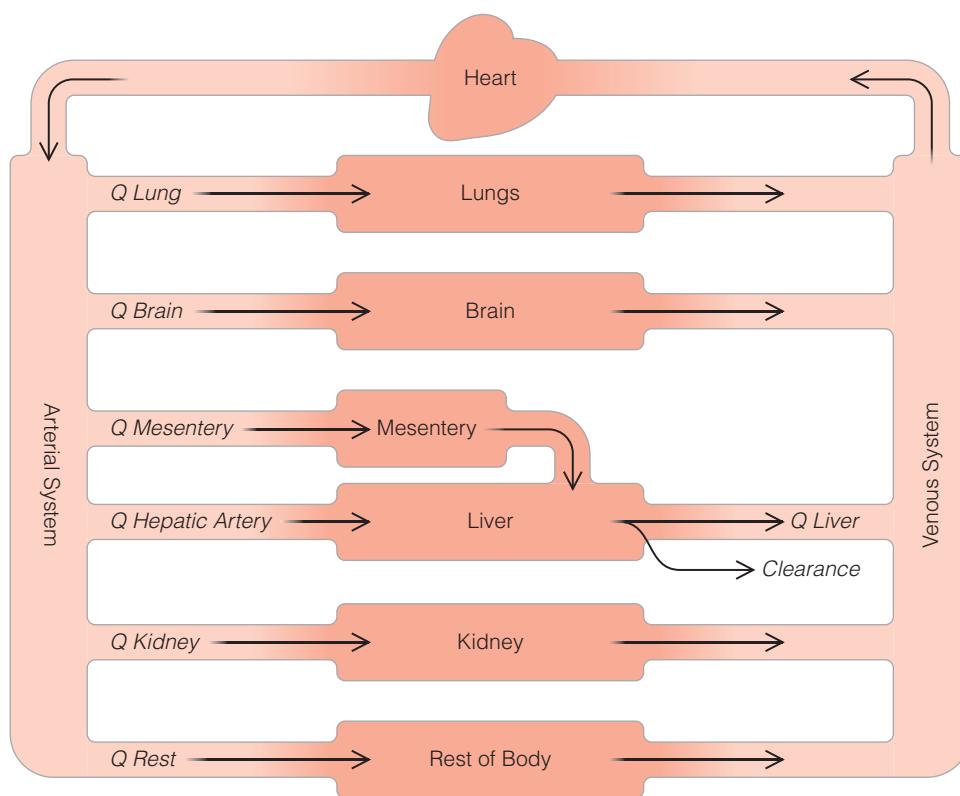

Figure 4 Shown is a schematic structural depiction of physiologically based pharmacokinetics (PBPK). In PBPK, unlike standard one- or two-compartment modeling, the compartments are restricted to the actual spaces occupied by particular tissues or organs. In this example, elimination occurs as clearance from the liver. (Q—blood flow)

EC_{50} that modify the steepness of the response). This model may also be modified to take into account the baseline response [see Figure 6]. The general form of the maximum-response model is as follows:

$$\text{Response} = (\text{E}_{\max} \times \text{concentration}) / (\text{EC}_{50} + \text{concentration})$$

Indirect-response models may be used to describe systems in which there is either constant production or constant elimination of the drug effect. In addition, however, the drug concentrations observed will have an impact on the elimination or production of the drug effect.

Physiologic Factors That Alter Pharmacokinetics and Pharmacodynamics

For the most part, the pharmacokinetic and pharmacodynamic modeling methods used to determine dosing regimens are based on study data from normal subjects. For this reason, they may not be applicable to surgical patients without some modification. Such patients often have significant physiologic derangements that alter drug metabolism. If these physiologic derangements are not taken into account, patients may be at risk not only for drug toxicity and adverse events but also for inadequate drug administration.

ORGAN SYSTEM DYSFUNCTION

Renal

Renal insufficiency, whether acute or chronic, can have pronounced effects on drug disposition, not only because of impaired excretion of drugs and metabolites eliminated by the kidneys but also because of other disease-induced physiologic alterations. The degree of impairment is proportional to the decrease in the GFR. If the

patient becomes oliguric, the GFR is probably less than 10 ml/min. In critically ill patients, renal function may deteriorate rapidly. Because actual measurement of the GFR is usually impractical, estimation of the GFR, based on creatinine level and urine output, should be considered. Besides lowering the GFR, renal failure reduces tubular excretion. The transport systems in the renal tubules may become saturated, further decreasing drug elimination.

Other aspects of renal failure can affect pharmacokinetics. Renal

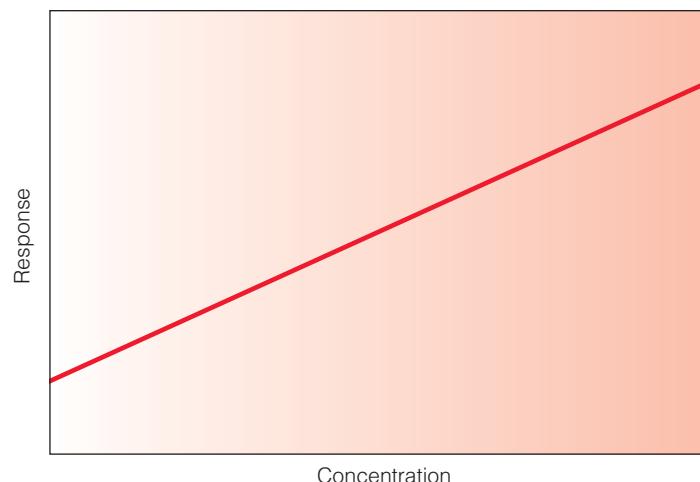

Figure 5 Illustrated is the linear-response pharmacodynamic model, in which the relation between drug concentration and physiologic response is a linear one.

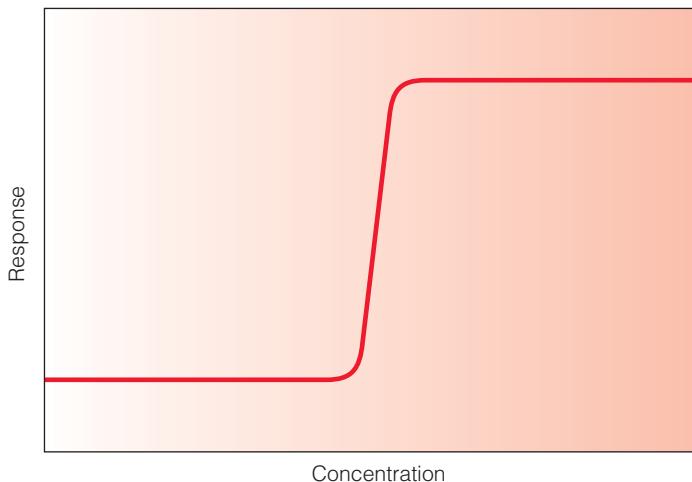

Figure 6 Illustrated is the maximum-response pharmacodynamic model, in which the relation between drug concentration and physiologic response is a nonlinear one that is determined by the maximum response (E_{max}), the concentration at which 50% of E_{max} is observed (EC_{50}), and, sometimes, other factors.

failure may reduce gastric acid secretion, thereby decreasing the absorption of some drugs, and may inhibit hepatic metabolism, thereby decreasing the first-pass effect and increasing systemic drug absorption.

Edema formation and decreased plasma protein levels may have complex effects on V_d and $t_{1/2}$. Although V_d tends to be increased, decreased plasma protein binding may raise unbound drug levels and increase potential toxicity. The higher unbound drug concentrations may actually increase drug excretion, thereby reducing $t_{1/2}$.

Great care should be taken in administering drugs that are mainly excreted by the kidneys and that have significant toxicity or a narrow therapeutic range. Typically, the initial loading dose is appropriate, but subsequent dosing should be based on estimates of the GFR. If possible, drug levels should be monitored. The timing of monitoring depends on the expected $t_{1/2}$. Trough drug levels are often used. Particular caution should be exercised with drugs whose levels or physiologic effects cannot be reliably monitored in a clinical setting (e.g., LMWHs). These drugs should be avoided in patients with significant renal impairment.

For patients who require renal replacement therapy, drug clearance varies from agent to agent. Intermittent hemodialysis and continuous renal replacement therapy can have substantial and varying effects on clearance. Knowledge of clearance rates can greatly facilitate the planning of dosing regimens.

Hepatic

The effects of hepatic dysfunction on pharmacokinetics are complex and difficult to predict. In general, hepatic impairment must be severe to have a significant direct effect on drug metabolism. It must be kept in mind, however, that hepatic dysfunction frequently leads to some degree of renal impairment, even in the absence of overt hepatorenal syndrome.

How hepatic dysfunction affects the metabolism of a given drug is determined by how readily the drug is normally extracted by the liver (i.e., how high the extraction ratio is). For drugs with high extraction ratios (e.g., morphine and labetalol), hepatic removal becomes dependent on hepatic blood flow. If blood flow is limited by end-stage liver disease or portosystemic shunting, bioavailability increases and elimination decreases, leading to a prolonged $t_{1/2}$. For drugs with lower

extraction ratios (e.g., diazepam and warfarin), decreased protein binding and metabolism by hepatic enzymes such as CYP have a greater effect on pharmacokinetics. Decreased protein binding is common in surgical patients, whether from decreases in total proteins (especially albumin), production of abnormal proteins, or displacement of drugs from proteins by endogenous substances or other drugs. The end result of decreased protein binding is an increase in the level of active drug, which leads to an increased potential for toxicity or prolonged effects.

Because there is no readily available method for measuring hepatic function, it is difficult to predict the impact of hepatic dysfunction on the pharmacokinetics of a given drug. Any attempt at such a prediction must begin with a high index of suspicion that hepatic function has deteriorated to the point where it may affect pharmacokinetics. Drug dosing must then be carefully planned on the basis of the estimated severity of the dysfunction. In practice, clinicians often do not consider the possibility that hepatic dysfunction is affecting pharmacokinetics until the patient exhibits signs of decreased drug metabolism (e.g., slow awakening from anesthesia or benzodiazepine infusion).

Cardiac

The major effects of cardiac dysfunction on pharmacokinetics can be attributed to hypoperfusion, venous congestion, or both. Reduced gut perfusion and congestion can hinder absorption of enterally administered drugs. Hypoperfusion can also affect absorption via the intramuscular, subcutaneous, or transcutaneous route; accordingly, to ensure appropriate systemic drug levels, the I.V. route is preferred. With many hydrophilic drugs, congestion and increased total body water can lead to an increase in V_d . With lipophilic drugs, however, V_d may be unaffected or even reduced.

The effects of cardiac dysfunction on renal and hepatic blood flow may result in diminished elimination of drugs. Hepatic congestion may worsen the situation. Congestive heart failure tends to have more severe adverse effects on hepatic function than it does on renal function. It is important to keep this difference in mind when administering drugs that are mainly metabolized by the liver. Hemodynamically active medications (e.g., inotropes, afterload reducers, and vasopressors) or diuretics can have a significant impact on renal and hepatic blood flow and function.

Respiratory

Chronic pulmonary disease with pulmonary hypertension can lead to hepatic congestion. Less commonly, respiratory failure with secondary right heart failure can lead to hypoperfusion of the kidneys and liver. Mechanical ventilation can exacerbate the effects on congestion and hypoperfusion, especially if very high intrathoracic pressures are employed. The resulting hepatic or renal dysfunction can affect drug metabolism.

Systemic inflammatory responses can alter organ blood flow and thereby affect drug metabolism. In addition, if changes in arterial carbon dioxide tension (P_aCO_2) lead to changes in arterial pH, protein binding and drug ionization status can be affected.

AGE

Renal function (specifically, the GFR) varies significantly with age. In neonates, the normal value for the GFR is only 2 to 4 ml/min, compared to a normal adult value of more than 100 ml/min. Over the 6 months following birth, however, the GFR increases to a level approximately twice the normal adult level, then slowly decreases. Consequently, many drugs may have a shorter $t_{1/2}$ in children than in adults. Hepatic function, particularly with regard to drug metabolism, follows a similar pattern in the first few months of life: an increase to supra-adult levels followed by a slow decline.

Gastric emptying is slower in neonates than in adults, and gastric acidity is lower as well; both of these differences may affect absorption of oral medications. In addition, neonates have lower plasma protein levels, which may alter V_d . Common medications whose pharmacokinetics may be different in the pediatric population include antibiotics, narcotics, benzodiazepines, and anticonvulsants.

Increasing age leads to substantial changes in drug pharmacokinetics. Elderly persons have 10% to 15% less total body water than younger persons do, as well as a higher proportion of body fat; they also have 20% to 30% less lean body mass. These changes in body composition can affect V_d . Renal function decreases with age, resulting in decreased clearance of many drugs. Intrinsic hepatic function is usually well preserved, though blood flow to the liver may diminish.

NUTRITIONAL STATUS

Severe malnutrition leads to a relative increase in total body water as fat stores are depleted, as well as to a decrease in plasma protein levels. V_d increases, and the GFR decreases. Hepatic clearance of drugs is reduced, particularly in cases of protein malnutrition. Consequently, $t_{1/2}$ increases, thereby increasing the risk of drug toxicity. These abnormalities resolve with adequate nutritional support.

Obesity also can have significant effects on pharmacokinetics. To assess the potential implications, it is useful to compare total body weight (TBW) to IBW. IBW is calculated as follows:

Men: 50 kg + 2.3 kg for each 1 in. of height over 5 ft

Women: 45.5 kg + 2.3 kg for each 1 in. of height over 5 ft

For persons shorter than 5 ft, 2.3 kg is subtracted for each 1 in. below this height.

Because of the greatly increased amount of body fat in obese patients, lipophilic drugs can be distributed into and sequestered in adipose tissue. This effect becomes more pronounced with increasing lipid solubility. Deposition of drugs in fat increases V_d but also increases $t_{1/2}$. For highly lipophilic drugs (e.g., halothane, enflurane, sufentanil, and various benzodiazepines), the doses required to achieve the desired effect may be quite high. For hydrophilic medications, dosing adjustments generally are not necessary. Some agents, however, are relatively hydrophilic but are still distributed into fat stores to some extent. Ciprofloxacin is an example of such a drug; its partial absorption into fat has led many to recommend that the dose be based on 45% of TBW in addition to IBW. The initial dose of gentamicin should be increased by as much as 40% because of the risk of an increased V_d .

FLUID RESUSCITATION

Aggressive fluid resuscitation, such as is performed after trauma or a major surgical procedure, increases interstitial and intracellular volume, as well as plasma volume, and reduces plasma protein levels. Consequently, V_d is significantly increased for many drugs.²⁰ The concentration of a drug can be estimated on the basis of the relative quantity of fluid sequestration and the size of the reduction in the serum albumin concentration. Underdosing of medications is common in patients who have undergone aggressive fluid resuscitation.

Drug Dosing

INITIAL DOSING

In deciding on the initial dosing of a drug, particularly in the acute care setting, it is essential to strike a balance between the risk of causing toxicity, on one hand, and the risk of failing to achieve therapeutic efficacy because of underdosing, on the other. For example, there is ample evidence that inadequate dosing of antibiotics in patients with

pneumonia can lead to therapeutic failure.²¹ The relative risks for any particular drug can be determined by considering the therapeutic index for that agent. The therapeutic index is approximated as follows:

$$\text{Therapeutic index} = \text{LD}_{50}/\text{ED}_{50}$$

where LD_{50} is the dose that would cause death in 50% of cases and ED_{50} is the dose that would be effective in 50% of cases. If there is any overlap between the range of effective doses and the lowest lethal dose for a given drug (i.e., if the risk of death is substantial even in the drug's therapeutic range), it is worthwhile to consider the drug's standard margin of safety. This parameter is defined as follows:

$$\text{Standard margin of safety} = \text{LD}_1/\text{ED}_{99}$$

where LD_1 is the dose that would cause death in 1% of cases and ED_{99} is the dose that would be effective in 99% of cases. For drugs with a narrow margin of safety, it is critical to monitor their levels whenever possible [see Drug Level Monitoring, below]. These metrics (i.e., standard margin of safety and therapeutic index) are confounded if the slopes of the concentration effect and concentration toxicity relationships are different.

A common way of achieving therapeutic drug levels is to administer a loading dose. The size of the loading dose can be calculated on the basis of volume of distribution, desired plasma concentration, and bioavailability:

$$\text{Loading dose} = (\text{V}_d \times \text{C})/\text{F}$$

As noted (see above), F (i.e., bioavailability) equals 1 if the drug is administered I.V. If there is concern about potential toxicity, the drug dose may be given over a prolonged period (e.g., a phenytoin load over 1 hour) or divided into smaller doses and given over an even longer period (e.g., a digoxin load over 24 hours). The optimal dosing interval for the maintenance doses is often close to the drug's expected $t_{1/2}$.

The goal of maintenance dosing is to achieve a steady-state plasma concentration that is within the therapeutic range. Generally, this goal is reached after five half-lives of the drug. From this point on, the amount of drug administered with each dose is equal to the amount of drug eliminated between doses. The steady-state plasma concentration may be approximately calculated from the drug's bioavailability, the maintenance dose (MD), the clearance rate, and the dosing interval (τ):

$$C_{\text{ps}} = (F \times MD)/(CL \times \tau)$$

C_{ps} may be too low if the MD is too small, if F is too low, if CL is too high, or if τ is too long. Should it prove necessary to adjust the dosing regimen, changes in one or more of these parameters will be indicated. For example, if a higher peak drug level is desired, the maintenance dose can simply be increased. However, if a lower trough level is desired to alleviate concern about toxicity, the dosing interval can be extended, or (depending on the peak level) the maintenance dose can be decreased.

In addition to monitoring drug levels when possible [see Drug Level Monitoring, below], it is crucial to monitor the clinical effect of a drug regimen. At times, this effect may be immediate, as when a vasopressor is administered to a patient in septic shock. At other times, the effect may be delayed, as when a course of antibiotics is administered to a patient with pneumonia. Monitoring the clinical efficacy of a treatment regimen is essential for determining the appropriate timing of discontinuance.

DRUG LEVEL MONITORING

Monitoring of the plasma concentration is most commonly employed with drugs that have a low therapeutic index—that is, drugs for which there is a narrow margin between the level that is therapeu-

tic and the level that causes toxicity. It should be kept in mind, however, that these therapeutic and toxic levels are not absolute indicators of safety or efficacy: they only represent values at which certain percentages of patients are treated effectively or certain percentages experience adverse events. Accordingly, such levels are not infallible guides for drug dosing. As an example, there are circumstances in which a clinician, knowing the drug levels and weighing the various risks and benefits, might elect to push the drug levels toward, or even into, the toxic range; for instance, in a patient with recalcitrant seizures, the plasma phenytoin level might be pushed to 25 µg/ml, which is above the standard therapeutic range. As another example, there are circumstances in which normal therapeutic drug levels are maintained, but the patient still experiences toxicity.

The timing of drug monitoring is important if the results are to be accurately interpreted. The sample for the peak level should be drawn 30 to 60 minutes after a dose is administered; the sample for the trough level should be drawn just before the next dose is to be administered. If there is significant concern about a potentially toxic trough level, the next dose may be held until the level can be determined. The timing of these blood draws should be noted as precisely as possible. Ideally, samples should not be drawn until the drug has been administered for five half-lives. When a patient is critically ill, however, five half-lives may be too long to wait. If so, samples may be drawn before and after the third dose (for trough and peak levels, respectively). In such cases, the levels obtained must be interpreted carefully, first, because a true steady-state may not have been achieved, and second, because these trough and peak levels are not from the same dose.

It should be kept in mind that standard drug level monitoring measures both the bound fraction and the unbound fraction of the drug. In certain circumstances (e.g., a patient with low plasma protein levels), the drug level can be misleading. Phenytoin is an example of a drug that is highly protein bound. If plasma protein levels are low, unbound drug levels can rise significantly even when total drug levels do not. In addition, a number of drugs are metabolized to an active metabolite that may contribute to toxicity. Some such metabolites, (e.g., the procainamide metabolite *N*-acetylprocainamide) can be measured.

Desired peak and trough ranges vary from one drug to another according to the desired effect and the risk of toxicity. With aminoglycosides, for example, toxicity is related to both the peak level (ototoxicity) and the trough level (renal toxicity), whereas efficacy is mostly based on the peak level (concentration-dependent bacterial killing). Once-daily administration of a large dose to achieve a high plasma concentration seems to be advantageous in terms of maximizing the efficacy of aminoglycosides and minimizing their toxicity. (This approach differs from the once-daily dosing that may be necessary in a patient with renal insufficiency.) In contrast, with vancomycin, efficacy depends on maintaining an adequate plasma level for as long as possible. Thus, the trough level is used to determine adequacy of dosing, particularly in situations where higher than normal levels may be

needed for adequate tissue penetration (as, for example, in patients with pneumonia).

Monitoring of the drug's effect is also important. For example, the prothrombin time may be measured in a patient receiving warfarin, or the activated partial thromboplastin time may be measured in a patient receiving heparin.

Drug Interactions

The more drugs a patient is given, the greater the potential for adverse drug interactions. This is particularly true for critically ill patients. Not only do such patients receive multiple medications, but they also are frequently experiencing organ system dysfunction that can affect drug metabolism, and they often have multiple medical issues that may mask the adverse drug effects. Interaction between drugs may lead directly to toxic effects, or it may be indirectly harmful by decreasing the efficacy of one or both agents.

Drug interactions may affect any or all of the four primary pharmacokinetic parameters (i.e., ADMET). Absorption effects are mainly limited to simultaneous administration of enteral medications. Incompatibilities may also arise with I.V. medications, but usually, the only practical consequence is that the two incompatible agents cannot be administered through the same I.V. tubing at the same time. Distributional effects are usually secondary to competition for binding sites on proteins. Once the sites are saturated, the amount of free drug can increase if the metabolism and elimination pathways are intact and unsaturated. Clinically, drugs that compete with warfarin for protein binding sites may significantly increase the level of unbound warfarin, thus increasing the risk of bleeding. Metabolic effects primarily involve induction or inhibition of CYP enzymes [see Table 2]. Elimination effects primarily involve impairment of renal function or competition for tubular secretion pathways.

Pharmacodynamic interactions can either enhance or decrease the efficacy of a drug. For example, two antihypertensive medications from different classes may have additive effects when used together. In contrast, two β-lactam antibiotics may be antagonistic when used together if one induces production of a β-lactamase that subsequently metabolizes the other.

Adverse Effects of Drugs

As noted (see above), critically ill and postoperative patients tend to be experiencing multiple medical issues and to be taking multiple pharmacologic agents, both of which make it difficult to determine what the adverse effects of any single drug may be. Accordingly, a high index of suspicion is critical in these patients. Drugs can cause nephrotoxicity via acute tubular necrosis, interstitial nephritis, or glomerulonephritis. For example, aminoglycosides and amphotericin B can cause acute tubular necrosis, whereas penicillins tend to cause interstitial nephritis through immune responses. Hepatic dysfunction can be caused by direct hepatocellular effects or by cholestasis.

1 THE ELDERLY SURGICAL PATIENT

James M. Watters, M.D., F.A.C.S., Jacqueline C. McClaran, M.D., and Malcolm G. Man-Son-Hing, M.D., F.R.C.P.(C)

Principles of Care

Management of surgical illness in geriatric patients is different from that in younger patients and typically more complex. Assessment of the surgical problems and physiologic status of elderly persons must take into account (1) the marked variability of the changes associated with advancing age, both among individuals and among different organ systems in an individual; (2) changes in the incidence, prevalence, and natural history of certain disease processes; and (3) the increased likelihood of multiple medical diagnoses and polypharmacy.

These factors and others may alter the presentation of surgical illness. Symptoms may be diminished in intensity, nonspecific, indirect, or atypical and therefore may be inappropriately ignored or attributed to advanced age. Patients may postpone seeking medical attention, or physicians may fail to recognize the gravity of an acute surgical condition if pain, fever, and acute-phase responses are blunted [*see Alterations in Clinical Presentation, below*]. Furthermore, it may be difficult to obtain the details of the history if the patient is cognitively impaired (demented or delirious) or suffers from hearing loss. Unfortunately, as a result of this complexity and the increased likelihood of emergency presentation, hospitalized elderly patients are at significantly higher risk for preventable adverse events and their consequences.¹

Both the potential benefits and the risks of surgical treatment are more difficult to assess in older persons. Assumptions about physiologic status and primary treatment goals that are reasonable in younger patients may not be appropriate in older patients. Often, the major concern of elderly patients is whether they will be able to enjoy an independent life after surgery, to at least the extent they did before. Consequently, such patients may find a radical procedure that offers potential cure less desirable than a more conservative procedure (or endoscopic, percutaneous, or nonoperative treatment) that relieves pain or other symptoms, largely restores function, and allows a return to normal surroundings. On the other hand, an early aggressive approach may obviate later procedures and prevent associated morbidity. A thorough knowledge of treatment alternatives and their risks, a close familiarity with the natural history of the disease in relation to life expectancy, and a clear understanding of the patient's goals are paramount in surgical decision making in older persons.

The risks associated with surgical treatment depend on the nature of the proposed procedure and on the patient's physiologic and medical status [*see Preoperative Management, Risk Assessment, below*]. Whereas minor elective procedures done with the patient under local anesthesia can be performed safely regardless of age, emergency thoracotomy and laparotomy are associated with significant mortality in elderly persons. Mortality from emergency procedures is markedly higher than mortality from elective procedures. Elective surgery may therefore be indicated when it can be predicted that complications will develop and emergency

intervention will be necessary. Cardiovascular and pulmonary complications remain important causes of postoperative mortality in elderly patients, much more so than in younger patients.

The elderly population is very heterogeneous. Some elderly persons are wholly independent, have maintained significant levels of physical activity, have preserved lean body mass and cardiopulmonary function, and have physiologic responses similar to those of younger individuals; in these patients, the risks associated with surgical illness and treatment are relatively low. At the opposite extreme, some elderly persons have multiple illnesses, are capable of only limited activity and independence, and suffer from cardiovascular and pulmonary disease; in these patients, surgery-associated risks are substantial. Physiologic status is a more fundamental determinant of risk than age is. As one surgeon put it as long ago as 1907, "In deciding for or [against] operation we depend upon the condition of the heart, the arteries, the lungs, and kidneys, rather more than the number of years the patient has lived."²

No matter how fit, active, and free of comorbidity the elderly individual appears, there is a gradual loss of physiologic reserve in various organ systems associated with aging [*see Table 1*]. This is most obvious in the oldest old but occurs to some extent even in younger old patients. In general, maximal physiologic functions decline, with the result that the ability to increase functions as needed is more and more limited. In addition, sensitivity to deviations from physiologic norms is decreased and mechanisms for reestablishing such norms are less efficient, with the result that homeostatic perturbations tend to be exaggerated.³ These phenomena may be of little consequence in healthy daily life but can be critical to the elderly patient facing the stress of a major operation or acute illness. As a rule, the elderly surgical patient is less able to maintain homeostasis, is at increased risk for complications [*see Figure 1*], and tolerates complications poorly. All aspects of perioperative care must be focused on minimizing the stress of surgery and avoiding the added stresses of complications. The surgical procedure must be carefully chosen and conducted with meticulous technique. Careful attention must be given to drug and fluid and electrolyte therapy. Pain, tubes, and other restraining factors must be kept to a minimum so as to allow prompt resumption of physical activity and minimize the adverse effects of immobility. The potential for delirium (acutely impaired cognitive function) must also be recognized.

Five factors are critical for obtaining the best outcomes from the surgical treatment of elderly patients: (1) careful preoperative preparation of the patient and optimization of medical and physiologic status; (2) minimization of perioperative starvation and inactivity and the stresses of hypothermia, hypoxemia, and pain; (3) meticulous perioperative care, to avoid clinical complications from perturbations of fluid and electrolyte balance, impaired cardiovascular and respiratory function, and inappropriate pharma-

cotherapy; (4) careful surgical judgment and technique to achieve the desired goals and avoid technical complications; and (5) optimization of physical and cognitive function. Accomplishing such care requires thorough preoperative assessment and planning and the involvement of a multidisciplinary clinical team knowledgeable about and interested in the management of the elderly surgical patient.⁴ With a comprehensive approach, major operations can be completed with low risk, a short hospital stay, and a rapid return to full function.⁵

Goals of Therapy

An elderly person with a surgical problem may not place the same emphasis on the various goals of therapy that a younger patient would [see Table 2]. Treatment goals must be carefully elicited and addressed in the treatment plan. Definitive cure of the presenting problem and maximization of longevity may be very reasonable and achievable goals, regardless of age. As the risks of surgical therapy increase in patients with significant comorbid conditions, however, priorities may shift. The major concern of an

Table 1 Physiologic Changes Associated with Aging

	Age-Related Changes	Clinical Consequences	Implications for Care
Respiratory System	<p>Decreased strength and endurance of respiratory muscles</p> <p>Increased stiffness of the chest wall and increased reliance on diaphragm function</p> <p>Decreased vital capacity, FEV₁, maximal inspiratory and expiratory pressures, maximum midexpiratory flow rate, and maximum voluntary ventilation</p> <p>Diminished elastic lung recoil and increased closing volume</p> <p>Increased alveolar-arterial oxygen gradient</p> <p>Decreased arterial oxygen tension</p> <p>Decreased airway sensitivity and efficiency of mucociliary clearance mechanism</p> <p>Decreased compensatory responses to hypoxia or hypercarbia</p> <p>Increased sensitivity to narcotic respiratory depression</p>	<p>Less effective cough</p> <p>Predisposition to aspiration</p> <p>Increased closure of small airways during tidal respiration, especially postoperatively and when supine, leading to increased atelectasis and shunting</p> <p>Predisposition to hypoxemia</p> <p>Tachypnea and increased tidal volume may be less apparent as respiratory failure develops</p>	<p>Encourage early mobilization, assumption of upright rather than supine position</p> <p>Provide effective pain relief to allow mobilization, deep breathing</p> <p>Routinely supply supplemental oxygen in the immediate postoperative period, and then as needed</p> <p>Use nasogastric tubes sparingly</p> <p>Recognize decreased ventilatory responses to hypoxia and hypercarbia</p>
Cardiovascular System	<p>Decreased maximal heart rate, cardiac output, ejection fraction</p> <p>Reliance on increased end-diastolic volume to increase cardiac output</p> <p>Slowed ventricular filling, increased reliance on atrial contribution</p> <p>Decreased inotropic and chronotropic responses to beta-adrenergic stimuli</p> <p>Decreased baroreceptor sensitivity</p> <p>Increased prevalence of coronary artery disease, clinically apparent or occult; may influence cardiac function during acute stress</p>	<p>Greater reliance on ventricular filling and increases in stroke volume (rather than ejection fraction) to achieve increases in cardiac output</p> <p>Intolerance of hypovolemia</p> <p>Intolerance of tachycardia; dysrhythmias, including atrial fibrillation</p>	<p>Employ vigorous fluid resuscitation to achieve optimal ventricular filling</p> <p>Nonvasoconstricting inotropes and afterload reduction may be more effective if pharmacologic support is required</p> <p>Avoid tachycardia; correct significant arrhythmias</p> <p>Recognize potential for preexisting cardiac disease</p>
Renal Function and Fluid-Electrolyte Homeostasis	<p>Decreased sensitivity to fluid and electrolyte perturbations</p> <p>Decreased thirst response</p> <p>Decreased ability to concentrate urine and conserve water and solute</p> <p>Decreased efficiency of solute and water excretion</p> <p>Decreased renal mass, renal blood flow, and glomerular filtration rate</p> <p>Increased renal glucose threshold</p>	<p>Predisposition to hypovolemia</p> <p>Predisposition to extracellular fluid volume expansion, electrolyte disorders (e.g., hyponatremia)</p> <p>Predisposition to hyperglycemia</p> <p>Predisposition to hyperosmolar states</p>	<p>Pay meticulous attention to fluid and electrolyte management</p> <p>Recognize that a "normal" serum creatinine value reflects a decreased creatinine clearance, because muscle mass (i.e., creatinine excretion) is decreased concurrently; estimate creatinine clearance using age-adjusted formulas or measure</p> <p>Select drugs carefully; avoid agents that may be nephrotoxic (e.g., aminoglycosides) or adversely affect renal blood flow (e.g., NSAIDs)</p> <p>Adjust drug dosages as appropriate for altered pharmacokinetics</p>
Body Composition	<p>Significantly decreased muscle mass, accounting for much of the age-related decrease in lean tissue mass</p> <p>Increased fat mass</p>	<p>Erosion of muscle mass during acute illness may result in strength rapidly falling below important clinical threshold (e.g., impaired coughing, decreased mobility, increased risk of venous thrombosis)</p> <p>Altered volumes of drug distribution</p>	<p>Maintain physical function through effective pain relief; avoid tubes, drains, and other "restraints"; encourage early mobilization; and provide assistance with mobilization</p> <p>Minimize fasting, provide early nutritional supplementation or support (both protein-calorie and micronutrient)</p> <p>Adjust drug dosages for volume of distribution</p>
Thermoregulation	<p>Diminished sensitivity to ambient temperature and less efficient mechanisms of heat conservation, production, and dissipation</p> <p>Febrile responses to infection may be blunted in frail or malnourished elderly and those who are extremely old</p>	<p>Predisposition to hypothermia (e.g., decline in body temperature during surgery is more marked unless preventive measures are undertaken)</p> <p>If hypothermic, shivering may result, associated with marked increases in oxygen consumption and cardiopulmonary demands</p> <p>Fever may be absent despite serious infections, especially in frail elderly</p>	<p>Use active measures to maintain normothermia during surgical procedures and to rewarm after trauma: warmed I.V. fluids, humidified gases, warm air</p> <p>Maintaining intraoperative normothermia reduces wound infections, adverse cardiac events, and length of stay</p>

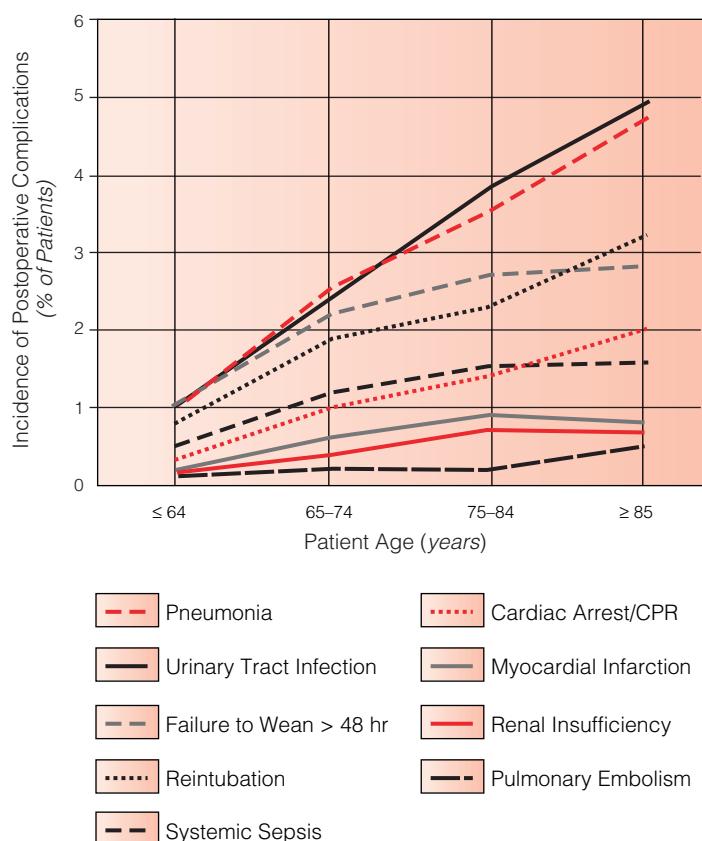

Figure 1 Shown are the incidences of selected postoperative complications in different age groups after major operative procedures.¹

elderly patient may be whether he or she will be able to enjoy the same level of function and independence as before the onset of the problem. Relief of symptoms and maintaining quality of life may be more important than long-term survival. Maintaining reasonable function in the short term may be of special importance, for example, during the last stages of a spouse's illness or in advance of a landmark event in the family. In some circumstances, the

Table 2 Goals in the Care of Elderly Surgical Patients²⁵⁰

Cure presenting surgical problem	Relieve pain and other symptoms
Maximize potential life span	Maintain dignity, autonomy, and self-esteem
Maximize independent function	

elderly patient may be less willing than a younger patient to accept the risks of major surgical interventions, even if such measures are potentially curative, and more likely to pursue alternatives with less immediate risk and more limited goals. It is, of course, essential to recognize those situations in which timely elective intervention carries an acceptable risk and is likely to prevent discomfort, impairment, and the greater risks associated with emergency intervention in the future.

Major surgical procedures to maximize longevity may be entirely appropriate in an elderly patient who is fit from physiologic, functional, and cognitive perspectives. Current average expectations for 70-year-old men and women are an additional 12.5 and 15.3 years of life, respectively; for 85-year-old men and women, an additional 5.3 and 6.3 years, respectively; and for 100-year-old persons, 2 years.⁶ Thus, the absolute gain in life expectancy resulting from even completely effective interventions declines as the age of the patient increases. Patients and clinicians probably recognize this principle intuitively but may find it difficult to quantify. It is based on an understanding of the effects of competing risks—that is, risks to survival from sources other than the condition of interest—and is reflected in the observation that life expectancy curves for normal individuals and for those with various medical conditions typically grow closer together as age increases [see Figure 2]. Competing risks increase progressively with age, decrease the impact of a new condition on life expectancy, and decrease the potential life expectancy gain from therapy.⁷ For example, cancer-specific survival after resection of a colorectal tumor does not vary with age, whereas overall survival declines progressively as age rises.⁸ The implications of competing risks are (1) that interventions carrying minimal risk are reasonable,

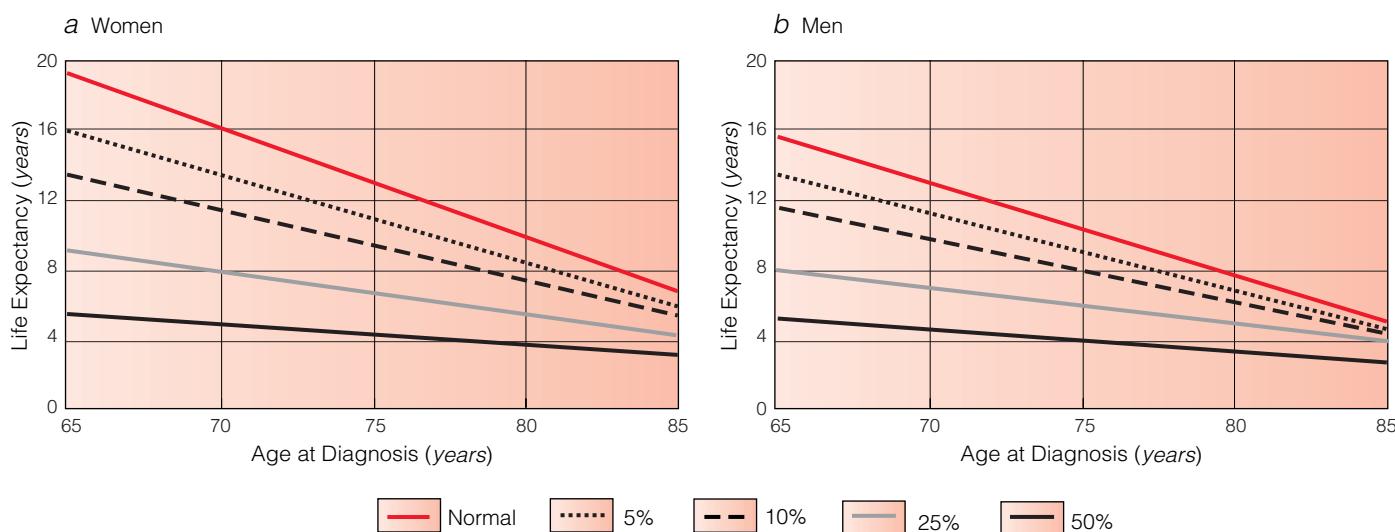

Figure 2 Illustrated is the effect of disease-related mortality (5%, 10%, 25%, and 50%) on remaining life expectancy for women (a) and men (b).⁷ As remaining life expectancy gradually declines with advancing age, the absolute impact of disease on life expectancy diminishes and the curves become closer together.

regardless of age, and (2) that very elderly patients should select interventions that are clearly effective and are associated with a low complication rate when maximizing longevity is their goal. In the oldest old and those with greater than average competing risks (e.g., major comorbid conditions), net gains in longevity can be very modest indeed.

Discussion of the elderly patient's wishes regarding medical care in the event of serious postoperative complications should be encouraged before a major elective procedure, with family members or other possible substitute decision-makers involved as appropriate. Expectations about rehabilitation and convalescence should be discussed, with temporary placement after discharge, home care, and other discharge planning arranged as needed [see Planning of Rehabilitation and Convalescence, *below*]. Patients generally welcome the opportunity to discuss their wishes, and surgeons should not hesitate to raise these issues.

Some elderly patients may be unable to articulate goals and make treatment decisions on their own behalf. In some instances, they have previously expressed their wishes about medical care, perhaps in the form of an advance directive or "living will." (An example of the latter is available from the University of Toronto Joint Centre for Bioethics [http://www.utoronto.ca/jcb/outreach/living_wills.html].) Discussions that patients may have had with their families, their caregivers, or both may be particularly helpful if they were held recently or were relevant to the specific situation at hand. When wishes have not been previously expressed, substitute decision-makers must consider what they know about the patient's values and arrive at a judgment about what the patient would have wished in this situation. Advance directives may provide a context in which to make decisions about limits to treatment, even though they usually apply to conditions that are irreversible or nearly so. In the absence of such information, a decision must be made in the best interests of the patient, taking into account the advantages and disadvantages of the treatment options, likely effects on quality of life, and similar concerns. It should be recognized that individuals may rate their quality of life highly despite significant health impairment and functional problems and that the assessments of physicians and family members may be quite different from those of patients.⁹ In general, the literature suggests that clinicians do not adequately address issues related to the areas of planning, communicating, and implementing advance care preferences.¹⁰

Preserving patients' dignity and autonomy and minimizing distress are important health care goals that often are not met in the treatment of elderly persons.¹¹ Dignity (self-respect and being valued by others) is readily undermined in the health care setting by disrespect for patients' privacy and insensitivity to their needs and desires. Such disrespect and insensitivity may reflect stereotyped, negative attitudes toward older patients on the part of caregivers. Autonomy is inevitably diminished when sufficient information and opportunity to make informed choices about care are not provided.

Alterations in Clinical Presentation

The manifestations of surgical illness in the elderly patients may be considerably different from those in young or middle-aged individuals. Multiple medical disorders are often present, and the symptoms of acute surgical illness may be masked. The central nervous system is particularly sensitive to the effects of drugs and disease, and the presentation of surgical and medical illness may be nonspecific (e.g., lethargy, delirium, or agitation) or indirect (e.g., an unexplained fall). The clinical presentation will tend to

reflect the most vulnerable organ system (often the CNS) in the earliest stages, not necessarily the organ system that is diseased.¹² Relative inactivity may limit the manifestations of important cardiac, pulmonary, or peripheral vascular disease. The patient, the family, or the surgeon may inappropriately attribute symptoms to the supposedly inevitable changes of advancing age. Cognitive or hearing impairment may make it difficult to obtain a reliable history. To ensure effective communication, the surgeon may have to make an extra effort when taking the history and reviewing the medical records.

Elderly patients may have a higher pain threshold than younger individuals. Older patients presenting with acute abdominal pain are more likely than younger individuals to require surgical intervention.¹³ The localization of abdominal pain in patients with peritonitis may not be as reliable; elderly patients with appendicitis are less likely than younger patients to have pain localized to the right lower quadrant.¹⁴ Abdominal pain is a less frequent presentation of colorectal carcinoma in geriatric patients than in younger patients.¹⁵ These observations suggest that pain is a particularly important symptom in elderly patients and that its degree is not necessarily an adequate indication of the gravity of the underlying problem.¹⁶

Although febrile responses are generally intact, fever may be less marked in elderly individuals with infectious or inflammatory processes, particularly those older than 80 years. Hypothermia is more common in elderly patients who are seriously ill than in younger patients [see Discussion, Patterns of Change in Body Composition, Organ System Function, and Integrated Responses, *below*].

The prevalence and natural history of some pathologic processes, as well as their clinical manifestations, may be altered in the geriatric population. For example, elderly patients presenting with appendicitis are more likely to have gangrenous or perforated appendicitis than younger patients are, and elderly patients with perforated diverticulitis are more likely to have generalized peritonitis.¹⁷ It is not clear whether these observations reflect a change in the onset of symptoms, a difference in the evolution of the pathologic process, or a delay in seeking medical attention. Similarly, elderly patients with symptomatic gallstones are more likely than younger patients to present with perforation, empyema, or gangrene of the gallbladder, acute cholecystitis, or cholangitis and are more likely to require urgent operative treatment.¹⁸

Preoperative Management

Preoperative assessment and optimization of cardiovascular, respiratory, nutritional, cognitive, and functional status in the elderly patient are addressed in some detail (see below). Smoking should be stopped as far in advance of surgery as possible, active respiratory infection resolved, airflow obstruction minimized, and exercise tolerance optimized. Strategies for preventing cardiovascular complications continue to evolve [see *Elements of Contemporary Practice: 4 Risk Stratification, Preoperative Testing, and Operative Planning*]. Beta-adrenergic blockade is well tolerated and should be considered in patients undergoing major elective noncardiac procedures who are at increased risk for perioperative ischemic cardiac complications.¹⁹

The importance of micronutrients and compounds with antioxidant properties is being increasingly appreciated. Whether or not preexisting deficits are suspected, preoperative multivitamin supplementation should be considered in elderly patients. The preoperative period is also the optimal time to address protein-calorie deficiencies, using oral supplements in most malnourished

patients, enteral feeding when necessary, and parenteral feeding when it is the only option. The diminished muscle mass, strength, and functional status that tend to accompany aging [see Nutritional Assessment, below] and the demonstrated effects of physical training in elderly nursing home residents raise the possibility that similar programs might minimize the development of muscle weakness and functional impairments after major operations.²⁰ In one randomized trial, patients awaiting coronary bypass grafting who participated in a supervised twice-weekly exercise training plus a broadly based educational program had shorter intensive care unit and hospital stays than control subjects did.²¹ In an observational study, a home-based strength and aerobic training program was associated with increases in 6-minute walking distance, quality of life, strength, and peak oxygen consumption in patients preparing for lung volume reduction procedures.²²

RISK ASSESSMENT

Assessment of risk in elderly patients must consider patient factors, the surgical problem, and the treatment options. Assessment of the elderly patient is typically more challenging and time-consuming, and it more often involves family members, the primary care physician, anesthetists, and other physicians and health care disciplines. Coexisting medical conditions are common and may markedly increase the risks associated with surgical intervention. The physical status scale developed by the American Society of Anesthesiologists (ASA) reflects functional status and comorbidity and is a strong predictor of postoperative and late mortality [see Figure 3].²³

Surgical outcomes depend not only on physical or physiologic fitness but also on cognitive and social factors: a careful assessment must go beyond simply establishing a specific diagnosis and must include all of these elements.²⁴ A rational approach to risk assessment should take into account those specific factors that predict important adverse clinical outcomes, allowing risks and treatment goals to be weighed and preparation for surgery and perioperative care to be planned optimally. Given that aging is a very heterogeneous process, great caution should be exercised in applying generalizations about the elderly population to specific elderly persons. Decisions about surgical care must rest on criteria that are more specific and strongly predictive than chronologic age is.

Approaches to preoperative testing continue to evolve, but there is now considerable evidence that many tests ordered on a routine basis (i.e., without relation to history or clinical findings) do not contribute to preoperative assessment and are sometimes misleading. The value of routine preoperative electrocardiography and blood work was examined in a large randomized trial involving patients undergoing cataract surgery, most of whom were older.²⁵ The addition of routine testing to a careful clinical assessment did not improve the safety of this relatively minor procedure. A systematic review concluded that although the yield of abnormal chest x-rays increases with age, resulting changes in management are infrequent and the effect of such findings on clinical outcomes is unknown.²⁶ Similar conclusions were reached with respect to routine preoperative ECG (in patients undergoing non-cardiac procedures), hematology, and biochemistry. Preoperative hypokalemia, however, has been associated with a higher incidence of perioperative arrhythmia and a greater need for cardiopulmonary resuscitation in patients undergoing elective coronary artery bypass grafting.²⁷ Possibly, older persons represent a population at increased risk for medical problems that are clinically subtle but potentially important after more major operations and that could usefully be identified by means of routine preoperative testing. Additional well-designed studies are needed to

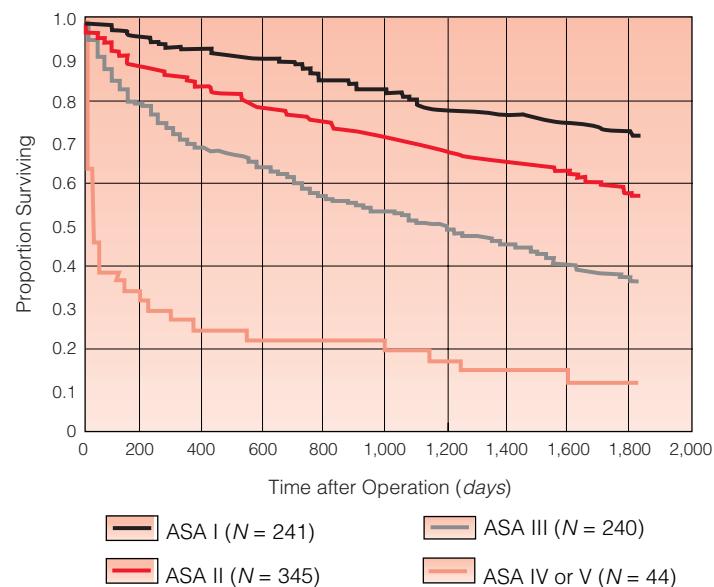

Figure 3 Depicted is correlation between ASA grade and post-operative survival.²³

evaluate routine testing in populations that are at increased risk for postoperative cardiopulmonary and other complications.

RESPIRATORY ASSESSMENT

Respiratory complications are among the most common complications after major surgical procedures and are more frequent in elderly patients [see Figure 1].^{28,29} Postoperative pulmonary complications are considerably more common than cardiac complications and are equally likely to cause postoperative death after abdominal procedures. In a large prospective study of predominantly male patients undergoing major noncardiac procedures, the incidence of postoperative pneumonia was 1.5%, compared with 0.7% for cardiac arrest and 0.4% for myocardial infarction.²⁹ The 30-day mortality was 21% for patients in whom pneumonia developed and 2% for those in whom it did not. The risk of pneumonia was five times greater in patients aged 80 years or older than in those younger than 50 years. In another study, the combination of age 60 years or greater and ASA risk category II or higher identified nearly 90% of patients who experienced respiratory complications after abdominal operations.²⁸ In a systematic review of patients undergoing surgical treatment of colorectal cancer, the incidence of respiratory complications was 5% in patients younger than 65 years, 10% in those 65 to 74 years of age, 12% in those 75 to 84 years of age, and 15% in those 85 years of age or older.⁸ Age-related changes in respiratory function [see Table 1] interact with the changes that occur after operation and during acute surgical illness, to the detriment of the elderly patient [see Postoperative Management, Respiratory Care, below].

Much of the unadjusted risk associated with advanced age is attributable to the presence of comorbid conditions. Significant patient-related risk factors for postoperative pulmonary complications include smoking, poor exercise capacity, chronic obstructive pulmonary disease (COPD), active pulmonary infection, and cognitive impairment.³⁰ Smoking should be stopped as far in advance of operation as possible: cessation of smoking 6 to 8 weeks beforehand significantly reduces cardiopulmonary and wound-related (as well as overall) postoperative complications.³¹ Active respiratory infection should be resolved, even if this means delaying the operation. Airflow obstruction should be treated in

patients with COPD and asthma. The aim should be to optimize respiratory status, as determined by exercise capacity, physical findings, and perhaps spirometry.³⁰ Bronchodilators, inhaled glucocorticoids, and chest physiotherapy may be helpful.

Procedure-related risk factors are also of some relevance. The risk of pulmonary complications is greatest after upper abdominal and thoracic procedures and is lower with laparoscopic procedures than with open procedures. On rare occasions, the risk of respiratory complications is considered so great that the choice of surgical procedure is based on the desire to avoid an abdominal (especially an upper abdominal) or thoracic procedure or general anesthesia. Lengthy surgical procedures (> 3 hours) are also accompanied by increased risk.

A careful history and a thorough physical examination directed at the risk factors discussed are the most important elements of preoperative assessment and should be completed in elderly patients undergoing abdominal and thoracic procedures. Whether routine preoperative chest roentgenography is warranted in healthy elderly patients at low risk for postoperative pulmonary complications is unknown.^{26,32} The value of routine preoperative pulmonary function testing for procedures other than pulmonary resection is not supported by published reports, many of which have methodologic shortcomings.^{30,32,33} Abnormal spirometry results should not be used in isolation to decide against a surgical procedure,³⁰ though they may be helpful in determining whether the status of a patient with known COPD has been optimized. The principles of risk assessment and preoperative optimization of respiratory function are essentially the same, regardless of age [see 7.5 Pulmonary Insufficiency].

CARDIOVASCULAR ASSESSMENT

The presence of coronary artery disease increases with age: significant coronary artery disease is present at autopsy in more than 50% of individuals older than 70 years [see Figure 4]. In unselected patients older than 40 years, the risk of perioperative myocardial infarction or cardiac death has been reported to range from 2.0% to 3.7%, with a pooled average of 2.5%.³⁴ Considerable disparity results from the use of inconsistent diagnostic criteria (e.g., biochemical, electrocardiographic, clinical) in the numerous studies examining this problem.³⁴ In a study of 323 patients 50 years of age or older who had ischemic heart disease and were undergoing noncardiac operations, perioperative myocardial infarction was defined by a predefined combination of criteria.³⁵ Myocardial infarction was identified in 5.6% of patients; it typically occurred early (nearly 80% on the day of surgery or postoperative day 1), was not usually accompanied by chest pain (17%), and was sometimes fatal (17%).

The risk of adverse cardiac events is strongly influenced by the nature of the surgical procedure.³⁶ The risk is very low in low-risk patients undergoing minor surgical procedures.³⁷ For example, in a study of more than 18,000 patients 50 years of age or older who underwent elective cataract surgery, perioperative death and unplanned hospitalization were rare.²⁵ The incidence of myocardial infarction, myocardial ischemia, or congestive heart failure was 1.2 per 1,000 patients. This incidence was not altered by the addition of routine testing (e.g., ECG) to a careful history and physical examination. By contrast, the risk of major cardiac complications (e.g., myocardial infarction, pulmonary edema, and ventricular fibrillation) is relatively high after abdominal, noncardiac thoracic, and suprainguinal vascular procedures in individuals 50 years of age or older.³⁸ In a systematic review of surgical treatment of colorectal cancer, the overall rate of cardiac complications was 2%, with a linear relationship between increasing age

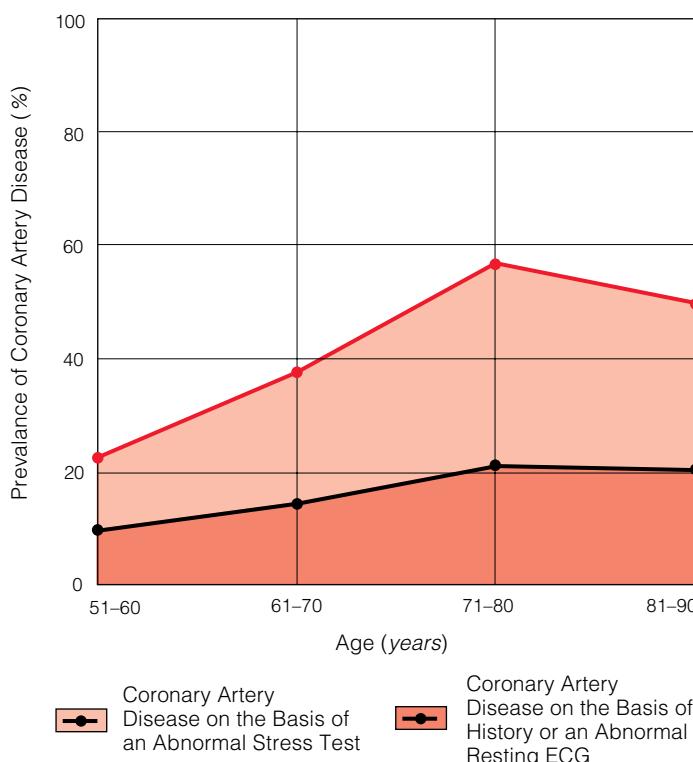

Figure 4 Shown is an estimate of the prevalence of coronary artery disease in men between 51 and 90 years of age.²⁴⁵

and the frequency of such complications.⁸ In another report, the rate of perioperative myocardial infarction or cardiac death was 6.2% in vascular surgical patients (range, 2.2% to 19.0%).³⁴

Even major vascular procedures are accompanied by very low risk when cardiac functional status is good, coronary artery disease is absent, and the multifactorial risk index score is low.³⁹ It is noteworthy that advanced age (i.e., 70 years or older) did not correlate with cardiac complications in the 1999 revision of a widely cited cardiac risk index.³⁸ Presumably, this absence of correlation results, in part, from the inclusion in the index of specific factors (e.g., ischemic heart disease) that are associated with age but are stronger predictors of outcome. It is also noteworthy that cerebrovascular disease, renal insufficiency, and type 1 (insulin-dependent) diabetes are significant predictors of cardiac complications.

The concepts and practical approaches involved in assessing perioperative cardiac risk before major noncardiac procedures are discussed in detail elsewhere [see *Elements of Contemporary Practice: 4 Risk Stratification, Preoperative Testing, and Operative Planning*].

COGNITIVE ASSESSMENT

Preexisting impairment of cognitive function from dementia, delirium, or depression is associated with an increased risk of postoperative complications and worse early and 6-month survival.⁴⁰⁻⁴² For example, the risk of postoperative pulmonary complications after abdominal procedures is increased nearly sixfold in patients with preoperative cognitive dysfunction.⁴³ Patients with end-stage dementia have been reported to have a fourfold higher 6-month mortality (55%) than patients who were cognitively intact (13%).⁴² Such patients were fully dependent in activities of daily living (ADLs) and unable to remember the names of family members. This poor short-term prognosis, which may even be an overestimate, appeared not to have been generally recognized by caregivers and families and was not reflected in differences in care, palliative

measures, or decisions to forgo burdensome interventions or life-sustaining measures. Dementia, delirium, and depression are each associated with increased mortality after hip fracture.⁴⁴ The potential for diagnostic delays in cognitively impaired patients, leading to adverse outcomes, has been identified in patients with general surgical problems.⁴⁰

Advanced age is associated with delirium (acute cognitive impairment) after major operations.⁴⁵⁻⁴⁷ Postoperative delirium is, in turn, a predictor of prolonged hospital stay and functional decline that persists after hospital discharge.^{45,46,48} The incidence of delirium varies with the surgical procedure and may be as high as 15% in general surgical patients and 60% in orthopedic patients.⁴⁹ Other risk factors for postoperative delirium are preexisting dementia, visual impairment, alcohol use, the diagnosis of fracture, and, in hospital, the duration of anesthesia, the occurrence of postoperative infection, the use of narcotics, and the need for a second operation. Late postoperative cognitive function has also been studied.^{47,50,51} Advanced age is associated with cognitive impairment 3 months after major noncardiac operations; this state occurs in approximately 10% of patients but resolves in the major-

ity of patients 1 to 2 years after operation. Complaints about changes in cognitive function do not necessarily correlate well with measured performance. Early cognitive dysfunction after cardiac surgery with cardiopulmonary bypass is well recognized, and the likelihood of long-term dysfunction is considerable.⁵²

The Mini-Mental State Examination (MMSE) is a valid and reliable preoperative screening instrument for cognitive impairment [see Table 3].⁵³ The MMSE requires approximately 10 minutes to complete and is suitable for repeated assessments. A modified "telephone" version requires only verbal responses and yields comparable results.⁵⁴ Alternative instruments are available.⁵⁵ An assessment of cognitive function should be completed as a routine in patients older than 75 years for whom major elective surgery is planned and in patients with existing cognitive impairments or other risk factors for postoperative delirium. A baseline assessment is valuable for assessing risk, implementing preventive strategies, and permitting reliable identification of postoperative cognitive deterioration; such deterioration may be the initial manifestation of a serious postoperative complication.

NUTRITIONAL ASSESSMENT

Elderly persons are at risk for malnutrition for several reasons, even in the absence of acute illness. The dietary range of older persons may be limited by physical and cognitive disabilities, social isolation, lack of awareness of the importance of a balanced diet, poverty, poor dentition, and the effects of medication on appetite, taste, nutrient absorption, and metabolism. The prevalence of overt protein-calorie malnutrition among the community-dwelling older persons is modest, but intakes of specific minerals and vitamins may be inadequate, especially to meet the increased demands of acute illness. Micronutrient (vitamin and trace element) supplementation has been shown to improve immune function and lower the incidence of clinical infections in both healthy community-dwelling and institutionalized elderly persons.^{56,57} Oral protein-calorie and micronutrient supplements should be prescribed before major elective procedures if there is any question about the adequacy of nutrient intake. Malnutrition is more common in elderly residents of nursing homes and other long-term care facilities than in community-dwelling elderly persons. Reported rates vary considerably, ranging from 37% to 85%.⁵⁸⁻⁶⁰ Malnutrition is quite common in hospitalized elderly patients but frequently goes unrecognized.^{61,62} It is consistently associated with adverse outcomes, which intervention studies suggest can be improved by nutritional therapy.^{63,64} Assessment of nutritional status should be routine in elderly patients for whom a major elective procedure is planned or who are admitted to hospital with an acute illness.

There is no single accepted standard for assessment of nutritional status. This is unsurprising, given the range of micronutrients and macronutrients to be considered and the myriad possible structural and functional consequences of what is perceived as malnutrition. Nonetheless, elderly surgical patients should routinely be screened for malnutrition through thoughtful clinical assessment.

Numerous anatomic, biochemical, and functional measures of nutritional status have been used, in some instances combined by means of multivariate statistical techniques.⁶⁵⁻⁶⁸ A structured clinical assessment can be completed rapidly, is reliable, and is among the most useful tools for nutritional assessment in elderly surgical patients. Subjective global assessment (SGA) is one such approach that incorporates relevant features of history and physical examination.⁶⁹ The Mini Nutritional Assessment (<http://www.mna-elderly.com/index.htm>) incorporates brief questions and simple anthropometric measurements in an instrument designed for

Table 3 Mini-Mental State Examination for Cognitive Function⁵³

Maximum Score	Score	Item
5	()	<i>Orientation</i> "What is the date?" Give 1 point each for year, season, date, day, month.
5	()	"Where are we?" Give 1 point each for state, county, town, building, floor or room.
3	()	<i>Registration</i> Name three objects. Take 1 second to say each, then ask patient to name all three. Give 1 point for each correct answer. Repeat until patient learns all three (for later testing).
5		<i>Attention and Calculation</i> Ask patient to subtract serial sevens, starting at 100. Give 1 point for each correct answer. Stop after five answers. (Alternatively, ask patient to spell "world" backward.)
3	()	<i>Recall</i> Ask patient to name the three objects mentioned previously. Give 1 point for each correct answer.
9	()	<i>Language</i> Point to a pencil and a watch and ask patient to name them. Give 1 point for each correct answer. Ask patient to repeat the following: "No ifs, ands, or buts." Give 1 point if successful. Give patient a three-stage command: "Take a paper in your right hand, fold it in half, and put it on the floor." Give 1 point for each correct action. Ask patient to read and obey the following: "Close your eyes." Give 1 point if patient closes eyes. Ask patient to write a sentence. Give 1 point if sentence has a subject and a verb and makes sense. Ask patient to copy a simple design. Give 1 point if drawing is correct.

rapid screening of nutrition status in elderly persons in outpatient, nursing home, and hospital settings.⁷⁰

Decreased muscle mass in older persons is accompanied by decreased strength. Maximal voluntary handgrip strength can be evaluated rapidly and has been reported to be a useful predictor of postoperative complications and length of hospital stay after elective surgery and hip fracture.^{71,72}

ASSESSMENT OF FUNCTION

Assessment of functional level is important at every stage of care of the elderly surgical patient [see Table 4]. Functional assessment is necessary for appropriate surgical decision making, governs perioperative care, and helps set realistic goals for postoperative functional level and quality of life. Tools for functional assessment (e.g., the FIM instrument, available from the Uniform Data System for Medical Rehabilitation, <http://www.udsmr.org>) should address basic ADLs, cognition, mood [see Table 5], health-related quality of life, and instrumental ADLs. Functional level is a rich field for surgical outcomes research.^{24-29,43,73}

PROCEDURE-RELATED FACTORS

The site of the operation and the magnitude of tissue injury and physiologic perturbation are risk factors for postoperative complications. The increased risks of cardiac and pulmonary complications associated with major abdominal or thoracic procedures have been discussed (see above). The risk of perioperative complications is very low after relatively minor procedures, such as cataract surgery and hernia repair under local anesthesia.^{25,74} Laparoscopic procedures appear to be well tolerated by elderly patients and yield the benefits seen in younger patients.⁷⁵ Morbidity and mortality are invariably greater for emergency

Table 4 Functional Level Assessment for Elderly Surgical Candidates

Why

- To individualize and adapt therapy
- To assign patients to particular treatment protocols, clinical guidelines, or critical pathways
- To follow individual patients to determine outcome measures
- To follow groups of patients
- To conduct patient and institutional outcome research
- To identify gaps in service

When

- Preoperative planning period
- Preoperative assessment—immediate for baseline measures for elective patients
- By history for nonelective cases
- "Reflective" history for elective patients with functional compromise related to the condition that will receive surgical intervention (e.g., patient waiting for hip replacement—how long has gait been impaired?)

What

- General function level (e.g., FIM)
- Cognition (e.g., Mini-Mental State Examination) [see Table 3]
- Depression (e.g., Geriatric Depression Scale) [see Table 5]
- Quality of life (e.g., SF-36 or SF-12 v2)
- Capacity for self-care (e.g., CSHA-modified OARS)

FIM—Functional Independence Measure SF-26—Short Form-S6 Health Survey SF-12 v2—Short Form-12, version 2 Health Survey CSHA—Canadian Study of Health and Aging OARS—Older Americans Research Survey

Table 5 Geriatric Depression Scale (Mood Scale) (Short Form)

Patient Name:

Date:

Choose the best answer for how you have felt over the past week:

Give 1 point if answer is:

- | | |
|---|-----|
| 1. Are you basically satisfied with your life? | No |
| 2. Have you dropped many of your activities and interests? | Yes |
| 3. Do you feel that your life is empty? | Yes |
| 4. Do you often get bored? | Yes |
| 5. Are you in good spirits most of the time? | No |
| 6. Are you afraid that something bad is going to happen to you? | Yes |
| 7. Do you feel happy most of the time? | No |
| 8. Do you often feel helpless? | Yes |
| 9. Do you prefer to stay at home, rather than going out and doing new things? | Yes |
| 10. Do you feel you have more problems with memory than most? | Yes |
| 11. Do you think it is wonderful to be alive now? | No |
| 12. Do you feel pretty worthless the way you are now? | Yes |
| 13. Do you feel full of energy? | No |
| 14. Do you feel that your situation is hopeless? | Yes |
| 15. Do you think that most people are better off than you are? | Yes |

Total:

For clinical purposes, a score > 5 points is suggestive of depression and should warrant a follow-up interview. Scores > 10 almost always indicate depression.

operations than for elective ones, presumably because of the greater physiologic disturbance caused by the condition requiring urgent treatment and the limited opportunity to assess and optimize the patient's general medical condition [see Figure 5].^{23,76,77} Mortality for emergency GI procedures, for example, has been reported to be as much as three times higher than that for elective procedures. Elderly surgical patients are less likely than young ones to tolerate the prolonged starvation, pain, immobility, and possible infection that accompany delayed operation and should therefore have a high priority for access to the OR for emergency procedures.⁴ Overall operative mortality in older persons appears to have declined gradually over many years. This decline may be attributable to better preoperative preparation of patients, as well as to improvements in anesthetic and perioperative care and surgical technique.

PSYCHOLOGICAL PREPARATION

Psychological factors are of considerable importance in preparing the elderly patient for elective operation [see Sidebar Establishing Rapport with the Elderly Patient]. Preoperative patient education has been shown to enhance patient confidence and to hasten the resumption of ADLs after operation.⁷⁸ Acute mental stress has been associated with myocardial ischemia in patients with coronary artery disease. Preoperative reassurance and patient education reduce anxiety and the postoperative need for narcotic analgesics. Preoperative teaching probably also improves patient compliance with and the effectiveness of postoperative chest physiotherapy and other respiratory maneuvers.⁷⁹ Postoperative psychological adjustment is enhanced by the physician's caring attitudes, as displayed, for example, in preoperative diagnostic interviews with breast cancer patients, who perceived the actual information given in the interviews as the less important component.⁸⁰

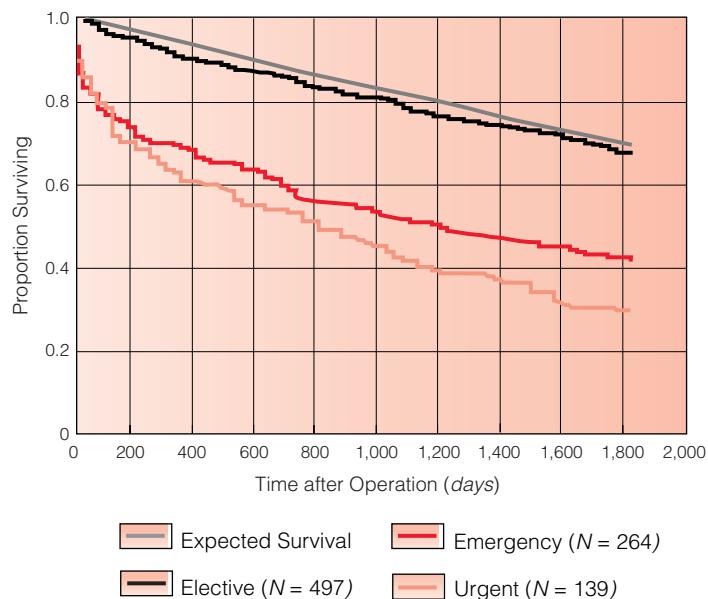

Figure 5 Depicted is the correlation between mode of admission and postoperative survival.²³

PLANNING OF REHABILITATION AND CONVALESCENCE

Rehabilitation and convalescence should be planned before operation, with full consideration given to both the potential impact of the planned procedure on function and the possible duration of functional impairment. Systematic reviews of programs of rehabilitative care after hip fracture and of supported discharge home for geriatric patients suggest that there is value to such interventions (e.g., in terms of hospital stay and the likelihood of returning to independent living) but that considerable uncertainty remains about the populations most likely to benefit and about optimal program design.⁸¹⁻⁸³

The absence of any immediate family contributes not only to long hospital stays for elderly patients but also to the requirement for nursing home placement at discharge. These trends hold true regardless of surgical procedure, surgical service of admission, diagnosis, age, and gender. The adjusted odds ratio for very long hospital stays is 1.85 in patients with no adult child. The adjusted odds ratios for requirement of nursing home placement at discharge are 2.59 in patients with no spouse, 3.27 in patients with no adult child, and 8.47 in patients with neither.⁸⁴

The caretaker is typically a daughter 50 to 70 years of age or an elderly spouse. The caretaker often has a wide range of concerns in addition to the elderly parent or spouse who is the surgical candidate. Such concerns might include holding down a job, supporting her adult children through school, minding her grandchildren, maintaining the traditional homemaker's role, and planning financially for her own retirement. Accordingly, she should plan to do one or more of the following: (1) hire a full-time housekeeper for her parent, (2) miss some work, or (3) arrange for convalescent care for a few weeks after the operation.

If family members are reluctant to participate in planning convalescence or arranging for live-in help or community support, they should be warned that they may eventually need to take as much as 8 weeks off from work to compensate for temporary and minor functional difficulties on the part of the patient. During convalescence, which may go on for weeks after discharge, family members should save their energy for those personal support activities in which they are irreplaceable (e.g., visits and telephone

conversations). They should not spend disproportionate amounts of time and effort on activities that another person could be paid to perform (e.g., washing sheets or delivering provisions). In this way, the family may avoid burnout or family stress, either of which may lead to neglect of the elderly member or to early placement.

The elderly patient should be advised to cultivate healthy habits preoperatively, such as exercising and having regular, balanced meals. Finally, the patient should come to the hospital prepared for an active postoperative period, bringing his or her clothes, jog-

Establishing Rapport with the Elderly Patient

The surgeon's personal rapport with the patient remains an important element of healing. The patient tends to interpret every aspect of preoperative, intraoperative, and postoperative care—including physiotherapy, nursing, and the ward routine as well as the surgical skills and knowledge displayed—as part of the surgeon's treatment. Older patients are often more in awe of physicians than are younger patients and thus may attribute almost shamanic powers to the surgeon. Such beliefs may be a valuable therapeutic aid.

The elderly generations comprise more disparate styles, cultures, vocabularies, and individual differences than any other generational group. It is therefore especially important that the surgeon attempt to understand and empathize with each patient's attitudes, beliefs, concerns, and modes of communication, some of which have been retained from an earlier time. The result will be a more confident patient, and confident elderly patients have been shown to experience fewer complications. Enhanced feelings of control and autonomy on the part of the patient correlate with a shorter hospital stay. These feelings can be promoted by specific behaviors on the part of the surgeon:

- Never call the patient by his or her first name, even if the patient calls you by yours. Never use "dear," "granny," or any other diminutive or familiar name.
- Address the patient, not the accompanying family member.
- When you speak to the patient, keep your expression calm, smile, bring your face close, and do not turn away. Speak slowly and distinctly, but do not raise your voice.
- Pause from time to time to permit the patient to speak. Do not allow the accompanying family member to fill all the pauses.
- To interrupt or to bring the patient back to the subject you want to discuss, touch him or her slowly on the hand or arm and repeat the question.
- Ask the patient if he or she understands what you have said.
- Ask the patient how he or she feels about what you have said, and address any concerns raised.

It is essential to avoid the appearance of haste or carelessness. If the surgeon is calm and supportive, the patient is likely to be calm and confident. Such nonverbal messages are more important to elderly persons than to younger adults and may be perceived as more valuable than the actual information given.

Confused, demented, or depressed elderly patients are not the only ones who benefit from reassuring nonverbal messages. This style of interaction may be used, for instance, with an active 70-year-old CEO who has sandwiched an appointment with the surgeon between a board meeting and a golf game, even if it seems somewhat exaggerated under the circumstances. Later, when the patient feels confused and cold, cannot see, hear, or smile normally, and has just suffered the indignity of a catheter, he or she will remember the respectful healing behaviors, and the surgeon-patient rapport will be enhanced.

Finally, it should be remembered that aged persons are subject to psychological, physical, and financial abuse. The surgeon should ask the patient directly about these potential problems and should, if necessary, request social and psychiatric assessment and legal intervention.

ging suit, shoes, walker or cane, hearing aid, glasses, pictures of loved ones, radio, and calendar.

INFORMED CONSENT AND ASSESSMENT OF COMPETENCE

Inherent in the idea of informed consent is that each patient has both the right to be informed about the therapeutic options available and the right to consent to—or refuse—intervention. Obtaining informed consent can be more complicated with elderly patients than with younger ones for several reasons. First, older patients may be psychologically or physically dependent on someone else; second, they may be overly deferential to (or suspicious of) the surgeon; third, they may be mildly demented but nonetheless competent to accept or reject a surgical choice. Occasionally, an elderly patient is capable in all the usual areas of function but acts incompetently when asked to accept or forgo a surgical intervention. When told that complications are rare, an older patient may believe the risk to be higher than a younger person would.⁸⁵ Older patients may be less interested in obtaining information about complications than younger patients are^{86,87}; however, giving detailed information does not appear to raise their anxiety level.⁸⁸

The term competence, as we use it here, is defined simply as the capacity to understand and appreciate the available options and their consequences and the ability to choose freely among these options.^{89,90} Competence may refer to either clinical status or legal status. It should be remembered that guidelines allowing a parent or guardian to speak for a child or for a mentally challenged person cannot be generalized to apply to an elderly individual whom the surgeon may consider clinically incompetent but who has not yet been determined to be legally incompetent.

To maximize the possibilities for informed consent, the surgeon should arrange to spend some time with the patient, even if the patient seems severely demented. The patient should be asked the following questions:

1. Do you feel comfortable with the idea of surgery?
2. Do you understand what is planned?
3. Do you have any questions for me?

Only after these questions have been answered satisfactorily should the patient be reassured that surgical treatment is in his or her best interests. If the patient is unaccompanied, the surgeon should ask permission to speak with the spouse, a child, or anyone who may be assisting the patient either before or after the surgical procedure. The surgical plan is reviewed with family members and repeated to the patient in the presence of the family. Included in the review should be expectations for the patient's capacity to function in the immediate postoperative period as well as the amount of family support that will be required. Finally, the surgeon should make it very clear to both the patient and the family that although family members can help the patient to understand the available choices, they do not have the right to make the final decision, even if the patient is completely dependent and has dementia, unless there has been a valid formal delegation of responsibility for health care. Definitions and terminology vary among jurisdictions.

When the patient's competence is uncertain, assessment by a psychogeriatrician may be helpful, as may assessments by a geriatrician, a social worker, and the patient's family physician. Some variation of opinion is to be expected because the issue of competence is not a simple one. For example, a patient may be incompetent to manage money but competent to accept operation. Alternatively, a patient may have a borderline status and experience diurnal fluctuations in cognition. In a 1994 study, surgeons performed almost as well as psychiatrists on theoretical issues of

competence but surpassed their psychiatric colleagues in the practical application of competence assessment.⁹¹ The authors concluded that "the common clinical practice of relying on expert medical opinion may introduce bias and produce inaccurate results that undermine patient autonomy." Practical solutions and common sense must prevail. The patient's values, both cultural and personal, must be taken into account.

When the patient is deemed incompetent, the next step is to establish legal incompetence. Most provinces, states, and hospitals require two psychiatric opinions to declare incompetence and to place the patient under legal guardianship. The efforts of a social worker are usually vital to this process, which can be accomplished immediately in urgent situations, usually through the director of professional services. Once declared incompetent, the patient comes under the protection of the state, which may delegate the role of legal representative to the private sector in the form of family guardianship or the so-called committee of the person. These private-sector guardians are then overseen by the state.

It is vital to consult with, to educate, to reassure, and to work with the family when surgical decisions must be made about an elderly patient with dementia. Questions to the family should focus on gathering relevant information, such as what the patient's wishes would probably be if he or she could express them and what the patient's functional and biologic status was before the current surgical problem. The family must understand that such questions constitute a request not for permission but rather for information that will help the surgeon in the management of the patient with dementia.

If the family is the legal representative for health care and refuses operation but the surgeon feels strongly that surgical intervention is in the patient's best interest, legal review should be requested. This request may place the surgeon in a difficult position. In fact, it may relieve some of the burden of decision making carried by the most responsible family member, who may blame himself or herself or be blamed by siblings for everything that goes wrong with the aging parent in the remaining years of life, regardless of whether the problem is related to the surgical intervention.

Rarely, it may happen that even when the patient has been declared legally incompetent, the legal representative for health care has signed the consent form, hospital administrators and the psychogeriatric consultant are supportive of the decision to operate, the family is supportive of the patient, and the patient seems to accept surgical treatment, the patient will adamantly refuse to go to the operating room on the morning of the operation. In such cases, although the surgeon could choose to proceed with the operation, it is probably best to cancel it and reschedule it for the next day. The presence of someone the patient trusts (e.g., an old friend or a minister) through the perioperative period may allow the elderly patient with dementia to tolerate the procedure and the surgical milieu.

Finally, when surgical intervention is considered neither urgent nor life threatening, the surgeon may be frustrated waiting for the courts to appoint a legal representative for health care. If so, the help of other knowledgeable and action-oriented professionals (e.g., the family physician, a psychogeriatrician, or a social worker) may be valuable. Newer, more flexible mechanisms are being explored in various jurisdictions for management of the well-being of the patient who has lost some autonomy. These newer mechanisms include durable power of attorney, health care proxy, living wills, and judicial advisers. The surgeon's consultants should be able to assist in selecting the most appropriate mechanism, depending on the patient's medical status, prognosis, and family support and on local laws.

Intraoperative Management

POSITIONING

Because elderly patients commonly have diminished range of joint motion, particular attention must be paid to how they are positioned for operation. The use of regional or general anesthesia may allow positioning that would be uncomfortable and beyond the usual range of motion were the patient not anesthetized. Postoperative back pain is a well-recognized complication of the lithotomy position in elderly patients. The remarkable prevalence of osteoporosis and the high incidence of related fractures in the geriatric population emphasize the fragility of these patients' bone and the importance of gentleness and care in turning and positioning them, particularly when discomfort and protective musculoskeletal reflexes have been suppressed by anesthesia. In addition, the skin of elderly individuals is easily injured by tape, adhesive electrodes, cautery pads, and warming blankets. Injury to the skin can occur easily by shearing when elderly patients are lifted and moved or when sheets are pulled from underneath them. Careful padding is necessary to prevent localized pressure, which may result in nerve compression and skin injuries, and to maintain appropriate positioning throughout anesthesia. The head and neck should be kept in a position that is comfortable and limits hyperextension so that cerebral blood flow is not compromised.

MAINTENANCE OF CORE TEMPERATURE

Unless effective preventive measures are taken, a fall in core temperature is common in patients undergoing major operative procedures, whether general or neuraxial anesthesia is used.⁹² Elderly patients are less well able to maintain normothermia, and in older studies, the extent and duration of postoperative hypothermia were found to be greater and shivering to be more common in elderly patients.⁹³ Shivering can result in a severalfold increase in oxygen consumption, which imposes a substantial burden on the cardiac and pulmonary systems in the immediate postoperative period.⁹⁴ If the oxygen transport system is unable to meet the increased oxygen demand, myocardial ischemia may result. Maintaining normothermia results in a marked reduction in morbid postoperative cardiac events in patients with cardiac risk factors who have undergone major noncardiac procedures.⁹⁵ The incidence of surgical site infection (SSI) is increased by even mild hypothermia, probably in part because of reduced cutaneous blood flow and tissue oxygen delivery.⁹⁶ Impaired platelet function and decreased activation of the coagulation cascade are believed to contribute to the increased blood loss and the greater need for blood transfusion associated with hypothermia during elective hip arthroplasty.⁹⁷

Hypothermia should be minimized or prevented in the OR by controlling room temperature, minimizing exposure of body surfaces, warming I.V. fluids and ventilator gases, and using active warming devices (e.g., a warming blanket) as needed. The opportunity to restore an appropriate core temperature without excessive metabolic stress and cardiac work is a reason to consider a brief period of mechanical ventilation when hypothermia has developed.

PREVENTION OF SURGICAL SITE INFECTION AND DEEP VEIN THROMBOSIS

Advanced age is well recognized as associated with the development of postoperative deep vein thrombosis (DVT). Prophylaxis of DVT should be considered in elderly surgical patients [see 6:6 *Venous Thromboembolism*]. Advanced age has also been

demonstrated to be associated with an increased incidence of postoperative SSI.⁹⁸ In one report, however, the likelihood of SSI (incision or organ/space) after elective resection of the colon and rectum was not influenced by patient age but was influenced by ASA class, male sex, the presence of a stoma, and other factors.⁹⁹

Postoperative Management

RESPIRATORY CARE

Postoperative respiratory complications, respiratory failure, and inadequate oxygen transport remain important causes of death in the elderly population. Resting arterial oxygen tension and content decrease progressively with advancing age, and the further decrease associated with operation is more marked in elderly patients. In addition, the ventilatory responses to both hypoxia and hypercapnia are blunted in older persons. Postoperative hypothermia is more prominent in older patients, and oxygen demand is markedly increased by postoperative shivering. Abdominal procedures with general anesthesia induce decreases in vital capacity and forced expiratory volume in 1 second (FEV₁) that last as long as 2 weeks after operation¹⁰⁰; similar declines in lung volume accompany aging. The combined result is increased closure of small airways, ventilation-perfusion mismatch, and an increased alveolar-arterial oxygen gradient. Impairment of diaphragmatic function after upper abdominal procedures results in a shift in ventilation away from dependent portions of the lung.¹⁰¹ Because of stiff chest walls and diminished elastic lung recoil, elderly patients are more reliant on diaphragmatic function than younger patients are.¹⁰² Protective airway reflexes are less sensitive in elderly persons, mucociliary transport is less efficient, and coughing is less effective because strength, elastic recoil of the lungs, vital capacity, and maximum expiratory flow rate are all diminished. The use of parenteral narcotics for postoperative analgesia has been associated with striking episodic falls in oxygen tension; the increased sensitivity of older persons to narcotics may further predispose them to such hypoxemia. The presence of coronary artery disease in many older persons underscores the importance of maintaining adequate oxygen delivery and avoiding excessive myocardial oxygen demand in the perioperative period.

Effective regional analgesia is associated with less marked postoperative decreases in vital capacity and functional residual capacity (FRC) and appears to be superior to parenteral narcotic analgesia in this regard.¹⁰⁰ The supine position is accompanied by the closure of small airways in dependent areas of the lung, ventilation-perfusion mismatch, an increased alveolar-arterial oxygen gradient, and hypoxemia. Small airway closure occurs at higher lung volumes in older persons, with the result that these adverse effects are more prominent. Simply changing from the supine position to the sitting position increases FRC and improves gas exchange in patients who have undergone abdominal procedures [see Figure 6].¹⁰³ For this reason, early resumption of physical activity must be encouraged, with appropriate assistance and analgesia provided.

Incentive spirometers, breathing exercises, and intermittent positive-pressure breathing are of some benefit in reducing pulmonary complications after upper abdominal operations and may help shorten the hospital stay.^{104,105} These aids are probably most valuable when used on a regular and frequent basis by patients who are at high risk for pulmonary complications. Supplemental oxygen should be routinely provided to elderly patients who have undergone abdominal or thoracic procedures for a period of several days or until physical mobility is restored—that is, until FRC

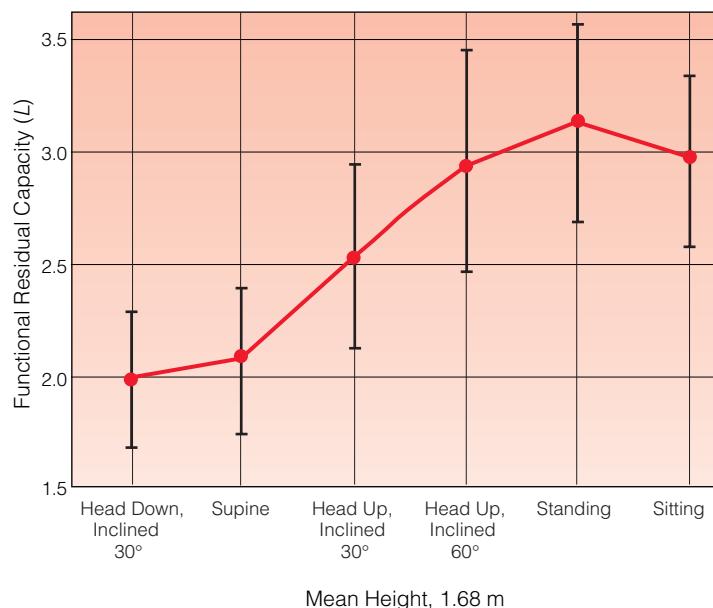

Figure 6 Shown is the functional reserve capacity (FRC) in selected body positions.¹⁰³ Significant improvements in FRC are noted as the patient approaches the upright position.

is close to preoperative values, ventilation and perfusion are better matched, and oxygen delivery is more reliable. Studies in which patients undergoing major elective procedures received an inspired oxygen fraction of either 80% or 30% during operation and for 2 hours afterward found that both the incidence of postoperative nausea and vomiting and that of SSI were lower in those receiving the higher fraction.^{106,107}

RENAL FUNCTION AND FLUID AND ELECTROLYTE MANAGEMENT

A 1999 analysis of postoperative deaths in elderly patients in the United Kingdom identified poor fluid and electrolyte management as an important contributor.⁴ Inadequate monitoring and documentation were common, and the predisposition of elderly patients to fluid and electrolyte imbalances and their clinical importance was not well recognized. Elderly patients are less able to restore and maintain acid-base, fluid, and electrolyte homeostasis during surgical illness. Compensatory mechanisms that can be relied on in younger patients function less rapidly in older ones. Renal handling of salt and water is less efficient, the physiology of aldosterone and vasopressin is altered, and renal and other mechanisms of acid-base regulation are more limited. As a result, elderly patients are less able to maintain the integrity of the extracellular space and other fluid compartments when challenged. Careful management, based on an understanding of physiologic mechanisms, is necessary if extreme abnormalities of fluid, electrolyte, and acid-base status are to be avoided.

The minimum requirement for water is increased in older patients as a result of increased insensible losses through thinned skin and impairment of the concentrating ability of the kidneys. Thirst is an important response to fluid deprivation, but it is known to be diminished in older persons.¹⁰⁸ In one study, thirst after a 24-hour period of water deprivation was less in healthy elderly men (67 to 75 years of age) than in younger patients (20 to 31 years of age) despite higher circulating vasopressin levels and higher plasma osmolality; urine osmolality was lower in the first group as well.¹⁰⁹ Hypothalamic responsiveness to osmotic signals appears to increase with age, as manifested by increased release of

vasopressin from the posterior pituitary.¹¹⁰ Unlike the response to osmotic signals, however, the vasopressin response to volume-pressure changes is blunted in elderly persons. Renin responses to sodium restriction and postural changes are diminished in older patients, and circulating aldosterone levels are decreased as a result of diminished adrenal sensitivity to both renin-angiotensin and local sodium-potassium signals.¹¹¹

Renal blood flow decreases progressively with advancing age, and the glomerular filtration rate (GFR) falls after the fifth or sixth decade. The ability of older persons to conserve or excrete water or solute is further reduced by the diminished efficiency of tubular processes, which is a result of decreased osmotic stratification in the medulla and decreased responsiveness to vasopressin.¹¹² One study found that in response to 12 hours of water deprivation, healthy young patients demonstrated a marked decrease in urine flow and a moderate increase in urine osmolality, whereas healthy elderly patients exhibited no decrease in urine flow or urine osmolality.¹¹³ Sodium conservation is similarly impaired: the half-time to the achievement of sodium equilibrium in the face of sodium restriction is significantly longer in healthy individuals older than 60 years than in younger individuals.¹¹⁴ Thus, inefficient renal conservation of salt and water exacerbates hypovolemic states in the elderly patient, and the onset of oliguria may be delayed.

A fall in the GFR also accounts for the decreased ability of the kidneys in elderly persons to excrete an acute load of salt or water, predisposing to extracellular fluid volume expansion.¹¹⁵ Hyponatremia coupled with water intoxication is a serious disorder in older persons, presenting as anorexia, weakness, lethargy, delirium, and, if severe, seizures or coma. Elderly persons are prone to excessive secretion of antidiuretic hormone (ADH), particularly during the stress of surgical illness; this excessive ADH secretion is accompanied by extracellular fluid expansion, hyponatremia, and inappropriately concentrated (i.e., less than maximally dilute) urine despite normal renal function.¹¹⁵

Although the pH of body fluids is normally only slightly affected by age, the efficiency of acid-base homeostasis is decreased in elderly persons.¹¹² For example, persons 72 to 93 years of age take twice as long to eliminate an acid load as persons 17 to 35 years of age do.¹¹⁶ Maintenance of normal pH depends on chemical buffer systems in body fluids, alterations in ventilation and elimination of carbon dioxide, and renal excretion of excess acid or base. The slight decreases in extracellular volume and in bicarbonate concentration that occur with advancing age may limit the capacity of rapid chemical buffering systems. Similarly, decreased plasma volume and lean body mass and bone demineralization decrease the availability of slower buffers (e.g., plasma and intracellular proteins and hydroxyapatite).¹¹² Bicarbonate buffering depends on the rapid elimination of carbon dioxide by the lungs. Neither arterial carbon dioxide tension (P_aCO_2) nor minute ventilation changes with age: increased physiologic dead space is compensated for by decreases in metabolic rate and carbon dioxide production. Ventilatory responses to hypercapnia are significantly diminished in healthy elderly persons¹¹⁷; however, because ventilation is increased and eucapnia maintained during exercise in older persons,¹¹⁸ physiologic pH buffering by respiratory mechanisms probably is not limited during acute illness except perhaps in the face of a very large acid load.

The progressive decline in renal function that occurs with advancing age has been well described¹¹⁹ and appears to be more consistent than changes in other organ systems [see Table 1]. Because of predictable decreases in skeletal muscle mass—and therefore in creatinine production—the serum creatinine concen-

tration is likely to remain within the laboratory normal range despite the substantial concurrent decreases in GFR [see Figure 7]. Increased serum creatinine concentrations reflect a marked impairment of renal function. Creatinine clearance can be estimated from the assumptions that it is 100 ml/min at age 40 years and declines by 1 ml/min each subsequent year. Another approach to estimating this value is based on age, gender, and serum creatinine level: for males, creatinine clearance in ml/min = [(140 – age in years) × weight in kg] ÷ (72 × serum creatinine in mg/dl); for females, the result is multiplied by 0.85.¹²⁰ Creatinine clearance is most reliably assessed by determining creatinine clearance from 24-hour urine creatinine and serum creatinine concentration.

Nonsteroidal anti-inflammatory drugs (NSAIDs) have a number of potentially detrimental effects on the kidneys of older patients.¹²¹ Inhibition of cyclooxygenase (COX)-catalyzed prostaglandin production by NSAIDs may allow unopposed vasoconstriction and marked decreases in renal blood flow and GFR in hypovolemic states, which may result in acute renal failure. In addition, NSAIDs potentiate hyponatremia and hyperkalemia through their effects on the renin-angiotensin-aldosterone system and may cause acute interstitial nephritis. Selective inhibition of the COX-2 isoform is associated with the therapeutic effects of NSAIDs. However, COX-2 is present in the kidney, and selective COX-2

inhibitors have effects on renal function that resemble those of nonselective NSAIDs.¹²² Both selective and nonselective NSAIDs should be used with caution in elderly surgical patients, especially with preexisting renal impairment and during acute illness.

CARDIOVASCULAR CARE

Cardiovascular complications are a major cause of postoperative death in elderly patients. The assessment of cardiac risk previously described (see above) should be the basis for preventive and monitoring strategies in the perioperative period. Aggressive reduction of coronary risk factors (e.g., smoking and hypertension) should be pursued preoperatively. The effectiveness of perioperative beta blockers in limiting increases in heart rate and blood pressure and reducing myocardial ischemia and cardiac mortality has been suggested in some but not all clinical trials.^{19,123}

It is in the first 48 to 96 hours after operation that the most significant shifts in fluid between body compartments occur, the onset of congestive heart failure is most frequent, and the hemodynamic abnormalities contributing to myocardial ischemia are most readily identified and treated. When invasive hemodynamic monitoring has been initiated in the OR, consideration should be given to continuing it during this period. In studies of patients of varying ages, myocardial infarction and reinfarction have tended to occur in the early postoperative period, often painlessly. Continuous ECG monitoring in the postoperative period may be a sensitive method for detecting myocardial ischemia and determining whether intensive therapy is needed. Many studies suggest the need for frequent clinical assessment and continuous ECG monitoring in elderly patients who are at high risk for cardiac complications (with respect to patient-, diagnosis-, and procedure-related factors) for at least 3 days postoperatively and possibly longer.

MANAGEMENT OF PAIN

Effective analgesia plays a critical role in allowing early resumption of physical activity, increasing lung volumes, and improving respiratory gas exchange after operation. In addition, postoperative pain is itself a stimulus to the elaboration of stress hormones and stress responses. Activation of the sympathoadrenal axis and other mediators results in increases in overall metabolic demand and in myocardial work. These effects serve no beneficial purpose in the postoperative patient and are detrimental from a physiologic perspective, quite apart from the fundamental clinical goal of preventing or relieving suffering.

Alternatives in the management of postoperative pain are discussed in detail elsewhere [see 1:5 Postoperative Pain]. Developments in anesthetic techniques, minimally invasive surgery, and perioperative care allow major procedures to be carried out with a very limited postoperative stress response, minimal pain, decreased organ dysfunction and morbidity, very brief periods of starvation and immobility, and early recovery.¹²⁴ Continuous blockade of neural signals from the operative site for 24 to 48 hours, often with epidural anesthesia, minimizes the stress response to surgery, reducing morbidity substantially and all-cause mortality by one third.¹²⁵ When such techniques are not available or applicable, patient-controlled analgesia may be appropriate for elderly patients who understand and are able to self-administer analgesic medication (usually intravenously).

Of note in elderly patients is the reported CNS stimulation induced by multiple doses of meperidine, which is attributed to accumulation of the metabolite normeperidine; meperidine should therefore be used with caution in these patients. The volume of distribution of morphine is smaller in the elderly patient, plasma and tissue drug levels are greater for a fixed dose, and the

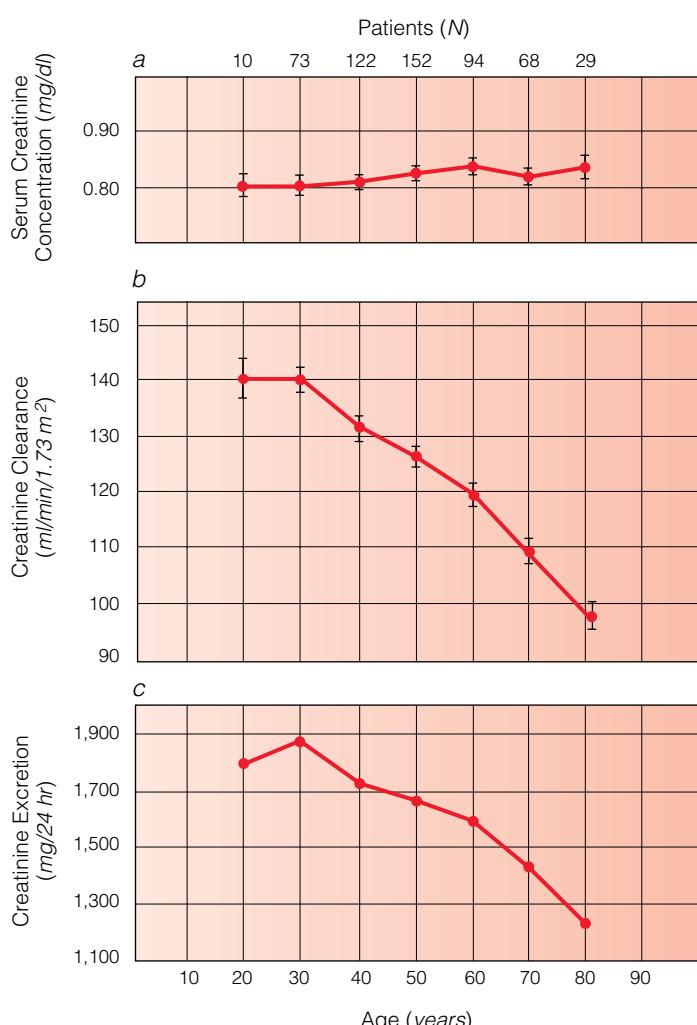

Figure 7 Illustrated are cross-sectional differences in serum creatinine concentration, creatinine clearance, and creatinine excretion.²⁴⁶

Table 6 Stratification of Modified Older Americans Research Survey ADLs and IADLs in Canadian Study of Health and Aging²⁵¹

drug disappears more slowly from CSF; these differences would account for the more marked respiratory depression and other CNS effects observed in older patients. Plasma morphine concentration and morphine clearance also depend on renal function.

Age-related changes in pharmacokinetics and pharmacodynamics are relevant also to the use of fentanyl, sufentanil, and alfentanil.¹²⁶ Elderly patients reportedly obtain greater relief of

pain from constant narcotic doses and show more marked CNS depression at given blood levels of benzodiazepines than younger patients do. Parenteral administration of narcotics can be associated with profound arterial oxygen desaturation, particularly in older patients and particularly during sleep, and may not provide optimal relief of pain.^{127,128}

NSAIDs have been used in combination with narcotics and other analgesics in the management of postoperative pain. Such agents should be used with caution in elderly surgical patients.

MAINTENANCE OF FUNCTION

The goal of postoperative care is maximum function. Achievement of optimal functional level depends on three principal areas—mobility, continence, and cognition—and on how these areas are integrated with the six basic ADLs during hospitalization [see Table 6 and Sidebar Achievement of Optimal Functional Level].

Each patient should have a program designed to enhance independence in performing ADLs at every stage of recovery. Occasionally, postoperative ADL function may exceed preoperative ADL function, either because the operation has direct effects on function or because the patient had been unnecessarily limited (by self, family, or caregivers) preoperatively. All stages of step-down care must be individually tailored and modified when medical conditions are present that might inhibit progress.

Achievement of Optimal Functional Level

Optimal functional level is the goal of all diagnostics, therapeutics, and management in the elderly patient. According to a 1988 statement by the American College of Physicians, "maintenance of the patient's functional well-being is a fundamental goal of medical practice. Assessment of the impact of illness on physical, mental, and psychosocial functioning is an essential element of clinical diagnosis, a major determinant of therapeutic choices, a measure of their efficacy, and a guide in the planning of long-term care for the dependent elderly."²³⁵

Functional level assessment is intrinsic to geriatric care and should be practiced throughout the perioperative period to predict rehabilitation potential, to estimate biologic reserve, to follow progress, to signal complications, to identify appropriate social supports at discharge, and to ensure discharge. Functional level assessment is known to improve diagnostic and therapeutic outcomes.²³⁶ Recognition of functional impairment leads to identification of previously undiagnosed conditions that may be treatable preoperatively or managed perioperatively. Another justification for functional level assessment is that disease states do not correlate as well with severity of impairment in elderly patients as they do in younger adults, even when clinical judgment has provided a reliable estimate of degree of aging and all disease states are known.^{237,238}

The surgical literature reflects a growing awareness of functional outcomes—both specific outcomes related to pathology and surgery and general outcomes related to the patient's day-to-day activities and quality of life.²³⁹⁻²⁴⁴

For assessment of functional level, surgeons need fast, simple tools suitable for all stages of management (preoperative, perioperative, and postoperative) that correlate well with measures of cardiovascular, pulmonary, and renal function and that identify patients who will achieve maximum postoperative function and who need rehabilitation or other community supports at discharge. Unfortunately, no such tool exists; surgeons will probably have to develop one themselves. In the meantime, the ASA scale and other biologic assessments can be complemented with functional assessments borrowed from the medical, psychiatric, and social science literatures.

There are actually hundreds of functional assessment tools, some of which have been validated for use in the geriatric population and some of which were specifically developed for elderly patients. These tools have various goals, ranging from predicting social supports to monitoring deterioration. Most of them address one or more of the following

areas: mobility, falls and balance, continence, cognition, emotional and affective status, nutrition, homeostasis, basic ADLs, instrumental ADLs, environment, and social supports. The various functional level scales cover items ranging from disability, handicap, and incapacity to independence and ranging from ability to self-development and self-realization.

In selecting functional measures, preoperative, perioperative, and postoperative surgical teams may focus on the following domains: basic ADLs (e.g., toilet and nutrition); instrumental ADL (e.g., banking, shopping for and preparing meals, and using public transportation); cognitive function (including memory and language); mood (primarily to validate data available in other domains); and quality of life from the patient's viewpoint [see Table 4].

It is worth remembering that assessments of basic and instrumental ADLs and cognition do not explain why a particular function is impaired but simply describe how well a patient is functioning at a given time. Any functional impairment is a signal that further assessment to identify correctable pathologic conditions is indicated. When areas of compromised function have been identified before an elective procedure, it may be wise to request a period of rehabilitation to maximize functional level before admission. For example, continence training may be provided by a community health nurse, and gait and mobility training may be provided by a geriatric physiotherapist. Complementary assessments by the family physician, a psychiatrist, or a geriatrician may help identify ways of achieving maximal function preoperatively.

In general, it is not expected that a preoperative functional impairment will be improved postoperatively unless the surgical intervention was specifically designed to address the impairment. For example, if mobility is compromised by an inguinal hernia, it is reasonable to expect the patient to resume his or her own banking after herniorrhaphy.

The nursing team should be made aware of the patient's functional deficits in the OR, in recovery, and in the ward afterward. To some degree, they may be able to compensate for disability in the surgical environment and may even prevent additional disability. For example, a patient who is encouraged to wear glasses and a hearing aid in recovery is more cooperative and better oriented and is ready to step down to the ward. Nurses who compensate for patient deafness by ensuring that the patient sees their lips when they speak and by speaking slowly and clearly can report patient level of consciousness more reliably.⁷⁸

Physical Function and Early Mobility

Mobility and appropriate sensory stimulation should be maximized before and after operation. Even healthy elderly patients have lost a good deal of their muscle strength. The continued loss of strength that accompanies immobility may have marked functional consequences. Elderly patients are at increased risk for pulmonary complications after operation, and early mobilization helps minimize their incidence [see Table 7]. Cardiovascular deconditioning occurs regardless of age: the decrease in cardiac output on standing may be considerable after a period of prolonged bed rest and may be accompanied by orthostatic hypotension and tachycardia. Maximum oxygen consumption, cardiac output, and stroke volume at maximum exercise are all lower after prolonged immobilization. Bed rest results in a significant decrease in tissue sensitivity to insulin, exaggerating age-related glucose intolerance. Bed rest is also associated with an increased incidence of DVT. Constipation and fecal impaction are frequent in immobilized patients as a result of alterations in GI motility (related to inactivity and medications), lack of privacy, and the use of bedpans. Pressure ulcers are well-recognized complications of immobility to which elderly patients are predisposed because of diminished subcutaneous fat and decreased skin elasticity.

Expectations about postoperative mobilization, its importance, and the assistance that will be provided should be communicated preoperatively to patients and their families. Postoperatively, effective pain management is essential. Beginning in the immediate postoperative period, full passive range-of-motion exercises of all joints should be undertaken daily, even after the patient is able to sit up in a chair and walk a short distance in the corridor. These interventions not only conserve the patient's capacity for mobility but also help prevent pressure ulcers. The involvement of a phys-

iotherapist is almost invariably required. In addition to passive range-of-motion exercises, active resistance exercises appear feasible for many acutely ill, hospitalized, older patients.¹²⁹

Once awake, the patient who requires glasses or a hearing aid should wear them at all times. As soon as the patient is able to sit in a chair, he or she should wear shoes, preferably solid, comfortable jogging shoes with Velcro closures. The patient should wear regular clothes, preferably a jogging suit, as soon as possible. A walker, a cane, or a wheelchair should be kept at the bedside and used as the physiotherapist advises. The patient should be encouraged to walk 100 m each day. Every effort should be made to minimize I.V. lines, drains, catheters, and other forms of physical restraint. If such devices must be employed, they should not be allowed to prevent planned activities, though they may necessitate accompaniment and assistance. Periods of activity should be systematically alternated with rest periods. The primary nurse is the caregiver best equipped to ensure that this routine is implemented.

These rehabilitation and maintenance efforts must be carried out in the surgical ward. There is no point to sending an elderly person to the physiotherapy/occupational therapy department: the patient will not learn to integrate the new skills into a daily routine. Older persons must work like athletes in the postoperative period. A training effect can be noted in skeletal muscle and in the cardiovascular and pulmonary systems. Accordingly, elderly patients deserve continual encouragement.

Aggressive rehabilitation instituted early will certainly lead to better function at discharge. However, a general surgical ward that properly serves elderly patients may also show a higher incidence of hip fracture and minor injuries. These risks must be accepted by staff, patients, and family.

Cognitive Function

In a dark, soundless, weightless chamber without aural, visual, sensory, or vestibular cues, young, fit adults are known to have a high incidence of transitory psychosis, presumably caused by the intense isolation and lack of stimulation. The elderly hospitalized patient who is medicated, deprived of glasses or a hearing aid, and restrained in a dimly lit room may exhibit a similar response, provoked by isolation and lack of cueing. The sensory deprivation characteristic of even brief confinement in a typical hospital setting may be accompanied by changes in affect, delirium, and perceptual distortions in the elderly patient. All staff members who have contact with older patients, including housekeeping personnel and technicians, should continually provide them with orienting cues, such as the weather, the season, the day of the week, the name of the hospital, and their own name and function. Many of the interventions described in the discussions of physical function, continence, and ADLs have the added advantage of increasing the amount of appropriate sensory stimulation provided to the patient, thereby reducing the incidence of delirium and contributing to improved cognition.

As discussed [see Risk Assessment and Cognitive Assessment, above], early postoperative delirium is relatively common in elderly patients and is best identified by means of an instrument such as the MMSE [see Table 3], especially if a preoperative baseline assessment is available. Postoperative delirium is characterized by an acute onset of fluctuating level of consciousness, shortened attention span, disorientation, cognitive impairment, visual hallucinations, disturbances in the sleep-wake cycle, and psychomotor changes, which may include agitation, retardation, or both. Delirium is much more common in those who have underlying dementia or undergo prolonged procedures. The diagnosis implies an underlying organic cause that must be actively sought and

Table 7 Potential Complications of Immobility²⁵²

Skin	Pressure Sores

Psychological	Sensory deprivation Dementia, delirium Depression

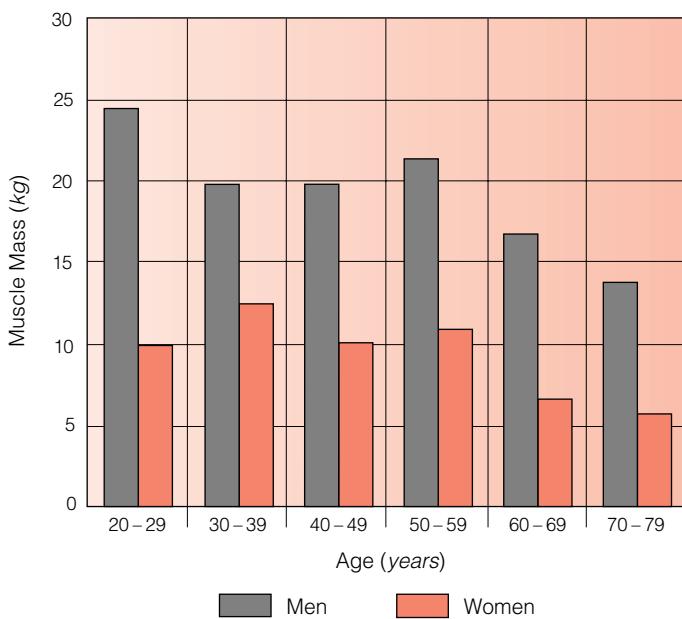

Figure 8 A substantial portion of the muscle mass present in young adulthood is lost by 70 years of age. Age-related declines in muscle strength have been documented as well.¹⁵⁰

corrected. Delirium may be the first manifestation of a postoperative complication such as infection (e.g., pneumonia, SSI, or urinary tract infection) or hypoxemia (e.g., that resulting from congestive heart failure or pulmonary embolism). Medications must be reviewed, especially sedatives, narcotics, and agents with anticholinergic properties. Electrolyte disturbances (especially hyponatremia) are common contributors to delirium. Physical examination should look for potential sources of infection, signs of cardiorespiratory or other organ dysfunction, and focal neurologic deficits. Hematologic tests, blood chemistry, and oxygen saturation or blood gas analysis should be routinely ordered. Chest x-ray, other imaging, ECG, and other investigations should be undertaken as indicated.

Delirious patients require close supervision to ensure that they do not harm themselves. Reassurance and reorientation provided by someone familiar, especially a family member, in a calm, well-lit environment is often the most powerful intervention. If this is not fully effective and the patient is compromising his or her medical care, then judicious use of risperidone or other medications may be necessary. In a 1999 study of elderly general medical patients, a multicomponent intervention strategy was shown to be effective in reducing the incidence of delirium.¹³⁰ The strategy targeted the risk factors of cognitive impairment (orientation), sleep deprivation, immobility, hearing impairment, and dehydration.

Delirium, dementia, and other cognitive deficits are not normal consequences of aging. Their presence is an indication for diagnostic and therapeutic intervention.

Continence

Efforts to help the older patient achieve and maintain continence should begin preoperatively and should be reestablished postoperatively as soon as possible. Systematic toileting (i.e., every 2 hours) should be initiated by the primary nurse. Catheters should be removed as soon as possible: they are sources of infection, impair mobility, and should not be relied on for monitoring of input and output. Nurses should respond promptly to patient requests for toileting. In the postoperative period, narcotics and

immobility often contribute to urinary retention. If urinary incontinence recurs or persists, the postvoid residual volume should be assessed. If the volume is less than 100 ml, the toileting interval should be shortened until continence is achieved, then lengthened. If the volume is 100 ml or greater, potential causes of an acontractile bladder or obstruction should be sought. Stool incontinence (with or without diarrhea) should be considered the result of impaction until proved otherwise, even if there is no fecalith palpable on digital examination. A step-down program for enemas should be started aggressively with osmotic agents (e.g., lactulose) and bulking agents, followed by enemas and stool softeners, with suppositories as needed; toileting should be performed 1 hour after each meal, as well as in response to urge. A behavioral program should be developed with the patient, who should participate in maintaining the toileting schedule and recording performance.

It is worth remembering that incontinence is never a normal consequence of aging. In every case, it should be explained by a specific diagnosis, managed, and treated.

Activities of Daily Living

Patients should take on the task of grooming and dressing themselves entirely (including putting on aids and prostheses) as soon as they are able. Self-medication should be introduced gradually, starting as soon as possible after recovery, and should be reviewed twice daily by the nursing staff. Dosette boxes and calendars are useful. Unit-dose pharmacy management has no place in geriatric care because it systematically teaches dependence.

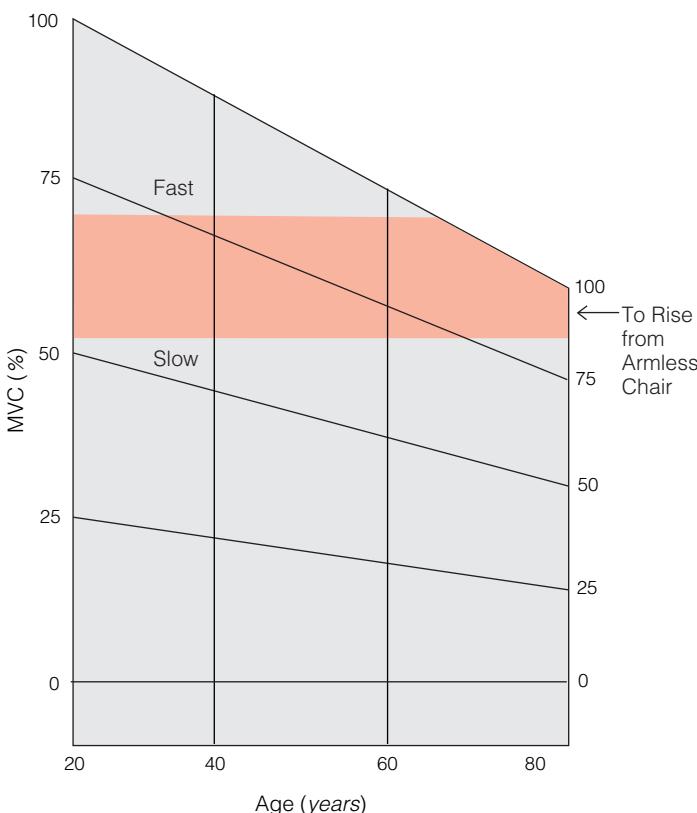

Figure 9 Depicted is the effect of age on muscle strength in relation to the strength required to rise from a low, armless chair.¹³² An elderly person may well be close to the strength threshold even before the onset of an acute illness. (MVC—maximal voluntary contraction)

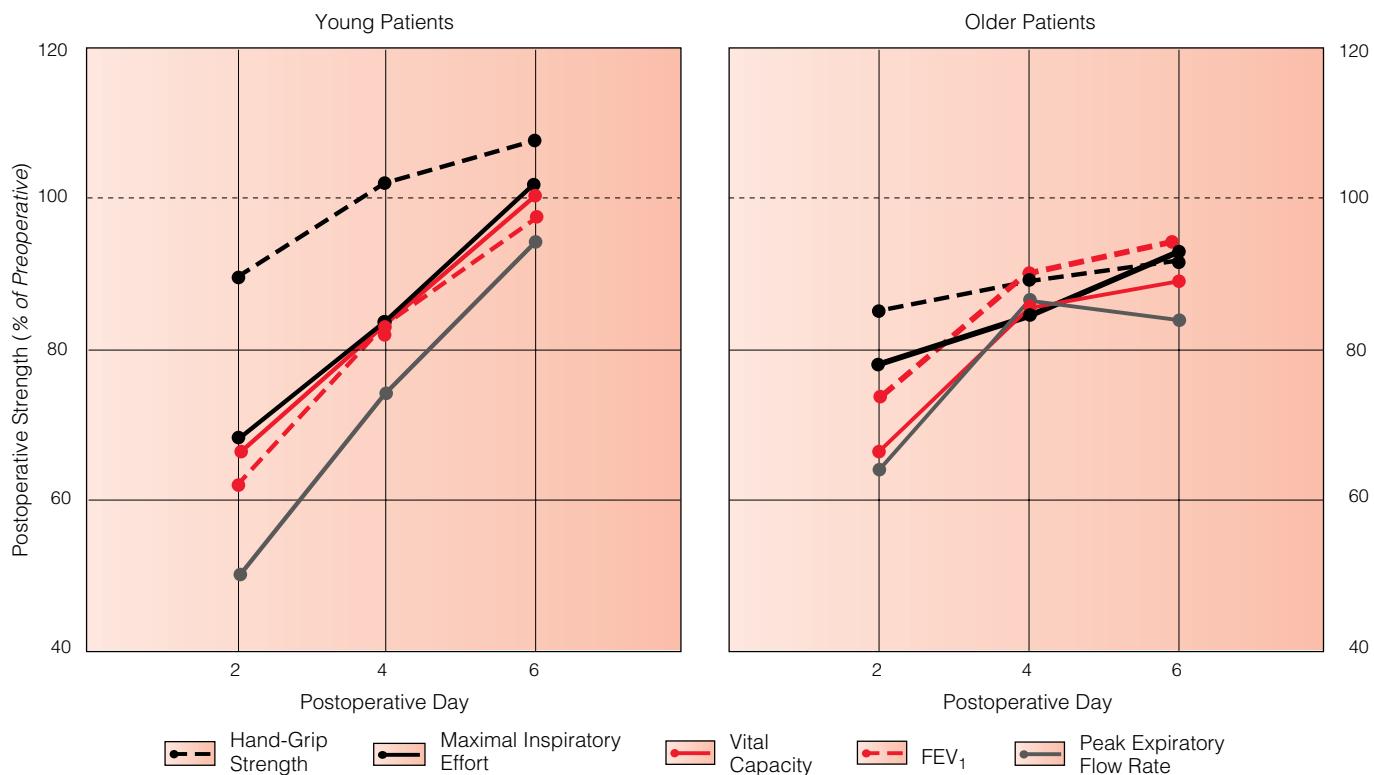

Figure 10 Illustrated is the recovery of postoperative strength (assessed with respect to five variables) in younger and older patients.¹³³

The independence of the hospitalized elderly patient is continually undermined. To begin with, insisting on patient independence takes extra nursing time: it is quicker and easier to do things for patients than it is to instruct them. In addition, patients themselves may sabotage nurses' efforts to foster independence, arguing that because they are old and sick they should not be expected to do much for themselves. Consequently, nurses who encourage self-care sometimes have patients who feel neglected and who may even become resentful and uncooperative; in some cases, an unhappy family may even complain to the administration.

Families are not naturally helpful in mobilization. Instead, they often insist on doing things for geriatric patients even while scolding them for not doing more for themselves. Families must be taught by nurses and physiotherapists exactly how elderly persons are to get out of a chair and how far and how often they are to walk.

Persistent stepwise encouragement to regain autonomy is perhaps the most beneficial service nurses can offer elderly surgical patients in the postoperative period. A word from the surgeon to the patient and the family may gain the nurse and physiotherapist the patient's cooperation. If behavioral problems persist, a behaviorist, a psychiatrist, a geriatrician, or the patient's family physician should be consulted.

Summary

The surgeon should not make the mistake of assuming that paying attention to the patient's functional level in basic ADLs is the responsibility solely of the rehabilitation or convalescent unit. Orientation, mobility, and ADLs all are significantly and systematically compromised in the traditional surgical ward in just a few days. Once function is lost, even long-term rehabilitation cannot ensure that it will be recaptured. Immobility, inadequate nutrition, and sensory deprivation and other features of the usual acute

care hospital environment will contribute to a "cascade to dependency" in vulnerable elderly patients unless actively addressed by a multidisciplinary clinical team.¹³¹

Other patient skills to be demonstrated before discharge should match the environment to which the patient is going. Occupational and physical therapists should routinely follow geriatric surgical patients and integrate their management strategies with those of the nursing staff. Elderly patients are less likely than younger patients to integrate the skills demonstrated during rehabilitation in a traditional occupational/physical therapy work area or gymnasium into the performance of ADLs on the ward and, later, at home. Home visits by the occupational and physical therapists are often useful components of assessment and rehabilitation.

NUTRITIONAL CARE

Preexisting malnutrition is relatively common in elderly persons (see above) and is exacerbated in hospital by the periods of fasting that are commonplace and by the rapid erosion of skeletal muscle that accompanies the stress of major surgery and acute surgical illness. Such losses of muscle protein may be uniquely detrimental in elderly patients. Lean body mass and body cell mass both decrease considerably with normal aging, largely because of declining muscle mass: a loss of 40% of muscle mass or more is typical between young adulthood and the age of 80 years and is accompanied by a comparable decrease in strength [see Figure 8]. For example, the average 80-year-old woman is at the threshold of quadriceps strength necessary to rise from a low, armless chair [see Figure 9].¹³² Thus, during prolonged or severe illness, the rapid erosion of muscle mass may reduce an elderly patient's muscle strength below that required for moving about in bed, sitting, and coughing effectively. Moreover, recovery of strength is impaired in older surgical patients compared with younger patients [see Figure 10].¹³³

The typical diets followed by older persons may provide ade-

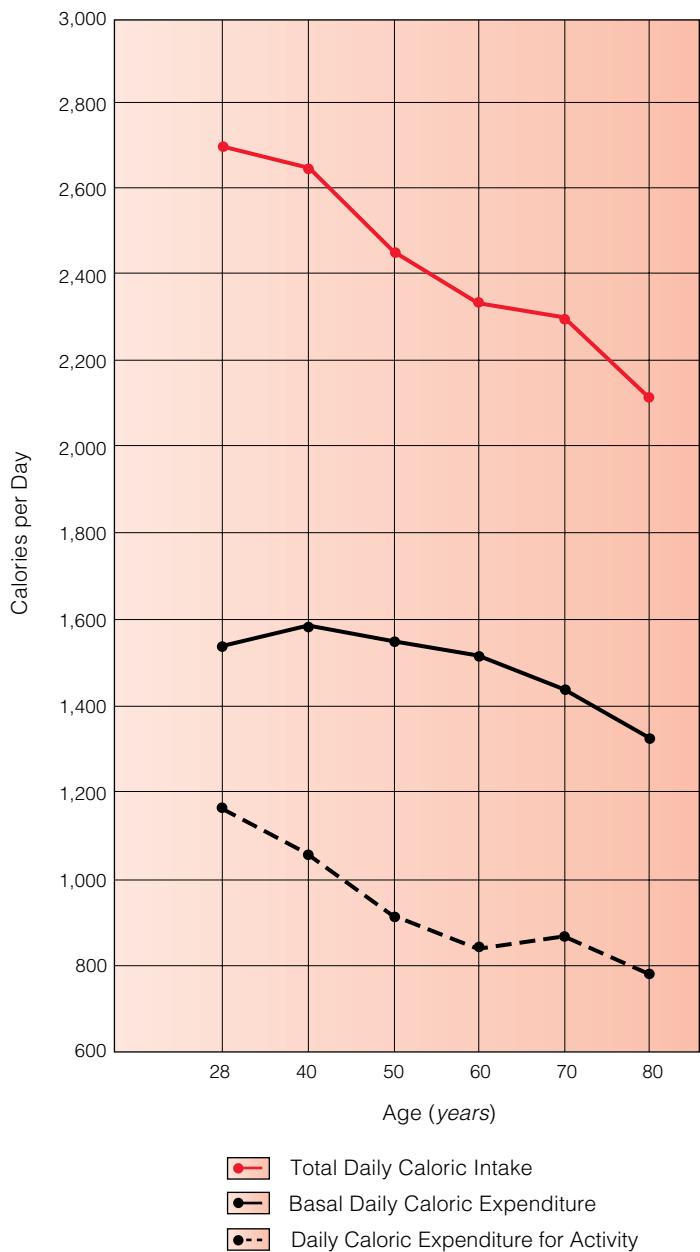

Figure 11 Depicted are the daily intake and expenditure of calories in normal males of various age groups.¹³⁹

quate vitamins and trace minerals in the absence of stress, though it is worth remembering that there is a general lack of information about specific requirements in older persons. Body stores may be limited, however, and deficiencies may arise during illness. For example, plasma zinc concentration decreases after injury and other stresses, partly as a result of increased urinary losses. Zinc deficiency has been associated with impaired wound healing and depressed immune function. Skeletal muscle holds the largest store of zinc. The decrease in muscle bulk in the elderly persons, coupled with the inadequate zinc intake and impaired absorption reported in this age group, suggests that zinc supplementation may play an important role in the nutritional support of these patients. Decreased serum levels of a number of vitamins have been observed after burn injury, and increased requirements for several vitamins and minerals that may affect immune function, wound healing, and antioxidant defenses have been demon-

strated during acute stress states.¹³⁴ Daily supplementation of the diets of healthy elderly persons with physiologic amounts of various vitamins and trace elements has been shown to enhance immune function and reduce the rate of clinical infection.⁵⁶ Early vitamin and trace element supplementation (i.e., within the first 24 to 48 hours) should be considered in all elderly patients, particularly in nonelective settings.

Volitional food intake is often inadequate in hospitalized elderly patients. Fortified meals and between-meal snacks have been shown to improve elderly patients' energy and protein intake.¹³⁵ Early provision of nutritional supplements or enteral or parenteral support should be considered in elderly patients who are not consuming sufficient nutrients in the form of a regular diet. Some, but not all, studies have suggested that protein-calorie supplementation has a beneficial effect on clinical outcomes after hip fracture.¹³⁶⁻¹³⁸ Improvements in hospital stay, complications, and rehabilitation appear to be most apparent in malnourished patients, though methodologic limitations in published trials preclude definitive conclusions. Oral supplements are usually well tolerated and do not necessarily lead to a decrease in volitional intake.

Enteral feeding should be initiated promptly in any elderly patient whose voluntary intake is not adequate. Parenteral feeding can be used alone or as an adjunct when enteral feeding is being established or when prescribed nutrients cannot be fully administered via the enteral route. In healthy persons, energy intake and expenditure tend to decrease with advancing age as a result of diminished metabolic body size (i.e., body cell mass) and reduced activity [see Figure 11].¹³⁹ These changes must be considered in estimating the number of calories to be provided to elderly surgical patients. Protein intake should normally be 1 to 2 g/kg/day, depending on the severity of the primary illness and the nature of the associated disease states. Provision of nutritional support via enteral and parenteral routes is discussed in detail elsewhere [see 8:23 *Nutritional Support*].

Whereas the need for nutritional support appears to be greater in elderly patients, such support may be less efficacious and less well tolerated because of the combined influences of aging and acute illness on intermediary metabolism. Glucose tolerance decreases with normal aging, and enteral or parenteral feeding may result in marked hyperglycemia, particularly when coupled with the insulin resistance that accompanies trauma and critical illness.¹⁴⁰ Additionally, insulin responses to glucose loads are markedly diminished in older persons after injury [see Figure 12]. Decreased serum growth hormone and insulinlike growth factor-1 (IGF-1) responses to feeding have also been described in older trauma patients.^{141,142} Renal clearance of glucose is normally an important defense against hyperglycemia; however, a reduced GFR and an increased renal threshold for glucose make elderly patients even more prone to hyperglycemia. Uncontrolled hyperglycemia resulting from either an enteral or a parenteral glucose load may give rise to hyperosmolar nonketotic coma, in which serum osmolarity and glucose are markedly elevated in association with a solute diuresis, dehydration, coma, and inappropriately low insulin and ketone levels. This condition is corrected by rehydration and insulin administration. In a trial involving patients admitted to a surgical ICU and given parenteral nutrition, intensive insulin therapy and control of blood glucose levels resulted in less frequent sepsis and organ dysfunction and improved survival.¹⁴³

Even when insulin is used, hyperglycemia may limit the administration of calories in the form of glucose to the elderly patient. Fat emulsion may be used as an alternative energy source in parenteral feeding, but plasma triglyceride levels should be moni-

tored because they tend to increase with age and because lipid clearance may be altered. Because of age-related decreases in GFR, protein loads that might be well tolerated in young patients can lead to uremia in elderly patients. Blood urea values should be monitored.

Nutritional support of the elderly patient should begin early, should take into account age-related changes in body composition, should include appropriate micronutrients, and should anticipate diminished tolerance of substrate and fluid loads.

CLINICAL PHARMACOLOGY

Use of both prescription and nonprescription drugs is heavy in the geriatric population, and a careful history of drug use must be obtained, if necessary by contacting family and pharmacist and examining the drug containers themselves. Noncompliance with drug prescriptions occurs but is probably no more frequent in elderly patients than in younger ones. Most instances of noncompliance may actually be underadherence, which can be an appropriate response to adverse drug effects. A knowledge of how aging affects clinical pharmacology is important because drugs and doses that would not normally cause toxicity in younger patients can do so in older ones.¹² Consequently, the incidence of adverse drug reactions increases substantially with age, and drug reactions are an important cause of hospital admission, morbidity, and mortality.¹⁴⁴⁻¹⁴⁶ This increase may reflect the greater use of drugs by older patients (particularly drugs with a low therapeutic index, such as digoxin), polypharmacy and resultant interactions, the presence of multiple and more severe comorbidities in elderly patients, and aging-associated alterations in pharmacokinetics and pharmacodynamics [see Table 8].

The term pharmacokinetics refers to the absorption, distribution, protein binding, metabolism, and excretion of drugs and their

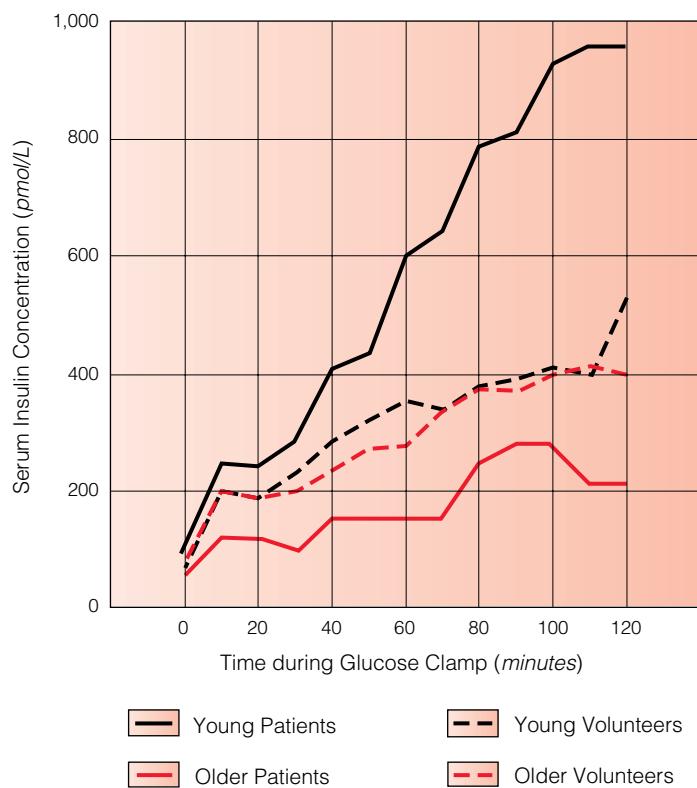

Figure 12 Shown are serum insulin responses to glucose loading (during glucose clamp).²⁴⁷

Table 8 Age-Related Changes with Potential Relevance to Pharmacology²⁵³

Pharmacologic Parameter	Age-Related Changes
Absorption	Decreased absorptive surface, splanchnic blood flow, and gastric acidity Altered gastrointestinal motility
Distribution	Decreased total body water, lean body mass, and serum albumin Increased body fat Altered protein binding
Metabolism	Decreased liver blood flow, enzyme activity, and enzyme inducibility
Excretion	Decreased renal blood flow, glomerular filtration rate, and tubular secretory function
Tissue sensitivity	Altered receptor number, receptor affinity, second-messenger function, and cellular and nuclear responses

metabolites (drug disposition), whereas the term pharmacodynamics refers to the interaction of drugs with receptors and the resulting desired or undesired physiologic responses (drug response). Alterations in both pharmacokinetics and pharmacodynamics are predictable to a degree and must be taken into account whenever a drug is given to an elderly patient.

Most clinically relevant drugs given orally are absorbed by passive diffusion across the very extensive surface area of the proximal small bowel. Absorption of these drugs is unimpaired in older persons, though gastric acid secretion may be decreased and the rate of gastric emptying diminished. Changes in body composition—specifically, an increase in the proportion of body fat and a decrease in the proportion of lean tissue [see Discussion, Patterns of Change in Body Composition, Organ System Function, and Integrated Responses, below]—may influence the distribution of drugs: the volume of distribution of relatively water-soluble drugs tends to decrease, and that of more fat-soluble drugs tends to increase. Altered distribution influences the elimination half-life of drugs, but it does not affect steady-state blood levels with multiple dosing if hepatic and renal drug clearances are unchanged.

Clearance of drugs primarily excreted by the kidneys declines predictably with advancing age and the concomitant decrease in GFR. Creatinine clearance is a much more reliable marker of the GFR than serum creatinine concentration, which depends on muscle mass. Drugs for which the dosage may require adjustment according to the patient's level of renal function include aminoglycosides, vancomycin, penicillins, cephalosporins, imipenem-cilastatin, metronidazole, digoxin, low-molecular-weight heparins, bisphosphonates, and procainamide. Age-related differences in the pharmacokinetics of renally excreted drugs, including the aminoglycosides, are unlikely when the creatinine clearance is greater than 80 ml/min/1.73 m². Drug levels should be monitored, particularly when drugs with a low therapeutic index are used.

Clearance of drugs by the liver depends on the delivery of the drug (i.e., on hepatic blood flow) and on the activity of biotransforming enzymes. Clearance of drugs that are metabolized relatively slowly is dependent on the function of hepatic enzymes; given that hepatic mass decreases with age, clearance of such drugs tends to be reduced.¹⁴⁷ Hepatic blood flow also decreases

with age: it is 40% to 45% less in elderly persons than in young adults, and this decrease results in diminished flow-dependent clearance.¹⁴⁷ Age-related reductions in the clearance of diazepam, chlordiazepoxide, theophylline, and propranolol have been suggested on the basis of decreased hepatic biotransformation (whether dependent on blood flow or on enzyme function). Such reductions may be more pronounced in men. Plasma levels of drugs cleared in a flow-dependent fashion may be higher when hepatic blood flow is further decreased, as it is in conditions such

as congestive heart failure or chronic liver disease.

The effects of age on the actions of drugs at target sites have not been extensively studied. A reduction in the sensitivity of beta-adrenergic receptors may contribute to the diminished effectiveness of sympathetic agonists in older persons. Synthesis of vitamin K-dependent clotting factors may be more strongly inhibited in older patients at a given plasma warfarin concentration.¹⁴⁸ Elderly persons also exhibit more marked CNS depression at given blood levels of benzodiazepines.¹⁴⁹

Discussion

Patterns of Change in Body Composition, Organ System Function, and Integrated Responses

BODY COMPOSITION

Specific changes in body composition are characteristic of advancing age, though they are not inevitable. Whereas weight remains more or less stable, fat mass tends to increase and lean body mass tends to decrease.¹⁵⁰ The increase in total fat mass may be obscured by a reduction in subcutaneous fat and a concurrent increase in intra-abdominal fat.¹⁵¹ Lean body mass comprises body cell mass—defined as the “component of body composition containing the oxygen-consuming, potassium-rich, glucose-oxidizing, work-performing tissue”¹⁵²—and extracellular mass. Body cell mass decreases by an average of 23% in men and 25% in women from the third to the eighth decade.¹⁵⁰ Besides decreasing in absolute terms, body cell mass declines as a proportion of lean body mass; this decline is largely accounted for by diminished skeletal muscle mass [see *Figure 8*]. On average, about 40% to 45% of the muscle mass present in young adulthood is lost by the time a person reaches 70 years of age.¹⁵⁰ At the same time, muscle strength and function are lost as well.^{153,154} Reductions in FEV₁ and maximal midexpiratory flow rate occur with advancing age; these reductions are partially attributable to a decrease in the strength of the respiratory musculature.¹⁵⁵ Together with decreased physical activity, changes in body composition contribute to decreased resting energy expenditure and therefore to decreased requirements for calories. Food intake decreases with aging in relation to alterations in GI physiology, endocrine function, and cytokine elaboration.¹⁵⁶

The changes in body composition and muscle function appear to be at least partially determined by the level of habitual physical activity. For example, body weight and proportion of fat were constant in a cross-sectional study of lumberjacks 20 to 70 years of age, in contrast to the gradual increase in weight and body fat seen in men with sedentary occupations.¹⁵⁷ Another study found that the body composition of male endurance athletes 50 to 75 years of age was very similar to that of younger athletes, whereas both untrained individuals and visually matched lean older individuals had significantly higher levels of body fat.¹⁵⁸ One group of investigators demonstrated increased muscle strength and a modest but significant decrease in body fat in elderly men who underwent 6 weeks of training; significant increases in minute ventilation during exercise and vital capacity were also observed.¹⁵⁹ Another group experienced a 10% increase in lean tissue, a 17% decrease in skinfold thickness, a 4% to 5% increase in body potassium, and an apparent halting of age-related decreases in bone calcium during a 1-year physical-training program in individuals in their seventh decade.¹⁶⁰ Another investigator, who studied age-related muscle fiber atrophy in men 25 to 65 years of age, found that mus-

cle fiber size and strength increased after twice-weekly exercise for 15 weeks, particularly in the older subjects.¹⁶¹

ORGAN SYSTEM FUNCTION

Aging is associated with a variety of predictable morphologic, functional, and pathologic changes in major organ systems. Such changes have been best described for cardiovascular, respiratory, and renal systems, which are also the systems most relevant to perioperative care [see *Table 1*].

INTEGRATED RESPONSES AND FUNCTIONS

Oxygen Transport

The earliest physiologic responses to tissue injury are directed at restoring and maintaining the perfusion of vital organs. These responses rely on rapid activation of the sympathoadrenal axis by signals from the site of injury and from baroreceptors and chemoreceptors. Blood flow to the skin and skeletal muscle is decreased by peripheral vasoconstriction, and cardiac output is redistributed to vital tissues. With advancing age, however, the efficiency of many of these critical responses is diminished, even in healthy individuals. Baroreflex sensitivity is decreased in older persons, presumably as a result of reduced arterial distensibility.¹⁶² Vasoconstrictor responses are also reduced, probably because of alterations in autonomic neural pathways.¹⁶³ In addition, an age-associated decline in the inotropic and chronotropic effects of beta-adrenergic stimulation has been well described.¹⁶⁴ Thus, diminished arterial compliance, impaired vasoconstriction, altered autonomic function and sensitivity to catecholamines, and decreased baroreflex sensitivity all may limit the maintenance of cardiovascular homeostasis.

Delivery of oxygen to the tissues may be impaired in older persons at every step of the oxygen transport pathway and may be inadequate when oxygen demands are increased.^{112,165} Ventilatory responses to both hypoxia and hypercapnia are diminished. The alveolar-arterial oxygen gradient increases, and arterial oxygen tension (P_aO₂) progressively declines. There is substantial variation in most cardiac variables among older individuals, reflecting aging, atherosclerosis and other diseases, and various lifestyle factors that interact and influence cardiovascular function in ways that are often difficult to disentangle.¹⁶⁴ In unselected individuals, cardiac output declines approximately 1% each year, beginning in the fourth decade.¹¹² Progressive decreases in resting stroke volume and cardiac output with increasing age have been observed in individuals without clinical evidence of cardiovascular disease, both at rest and during exercise^{166,167}; in addition, older persons have had larger arteriovenous oxygen differences and increased arterial lactate concentrations. However, the older individuals in such studies may well have had clinically occult cardiovascular disease or deconditioning

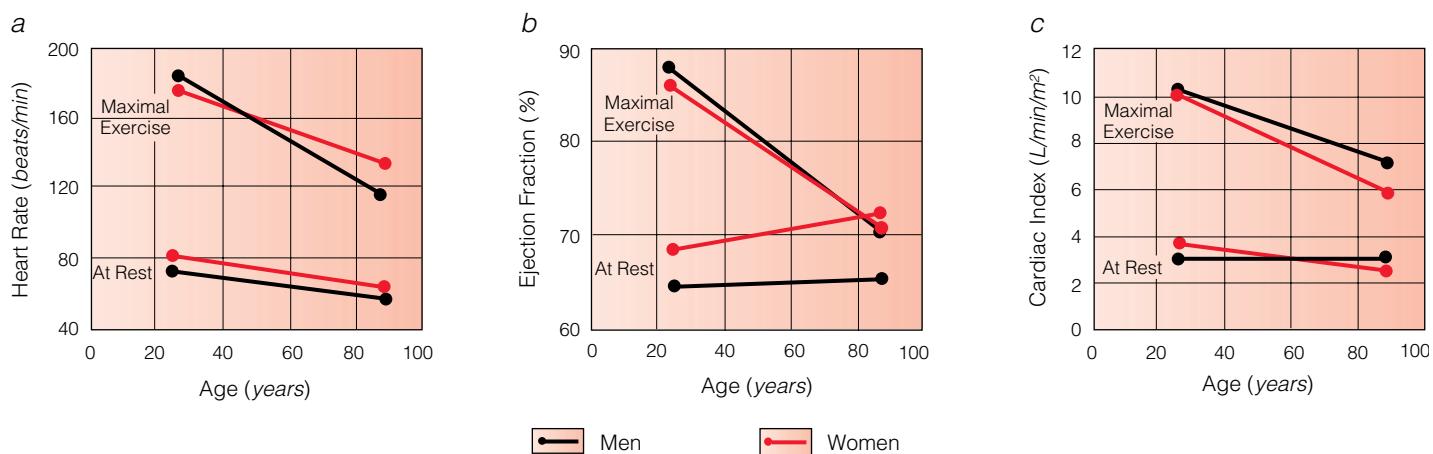

Figure 13 Shown are linear regressions on age of (a) heart rate, (b) ejection fraction, and (c) cardiac index at rest and during maximal cycle ergometry in healthy, sedentary male and female volunteers who had been screened to exclude clinical hypertension and occult coronary artery disease.²⁴⁸

resulting from long-standing limitations of physical activity (e.g., from time spent in nursing homes), and the use of invasive measurement techniques may have influenced observations.

Later studies of nonsedentary individuals who were screened with resting and stress ECG and dipyridamole-thallium scanning have demonstrated that older individuals, assessed noninvasively, maintain resting cardiac output, heart rate, stroke volume, and ejection fraction [see Figure 13].¹⁶⁴ Stiffening of the aorta and of more peripheral vessels tends to be associated with increased peripheral vascular resistance. A normal modest increase in left ventricular wall thickness with aging is exaggerated in persons with hypertension and coronary artery disease. Myocardial relaxation is typically prolonged, and early diastolic filling is slowed and delayed with advancing age.^{164,168} Left ventricular end-diastolic volume at rest tends to be increased, with more rapid filling later in diastole; this tendency is associated with left atrial enlargement and an enhanced contribution to filling from atrial contraction.¹⁶⁹ Resting pulmonary arterial pressure and pul-

monary vascular resistance increase moderately.¹⁷⁰

Cardiovascular responses to exercise have been studied in detail and provide insight into the responses associated with acute surgical illness. The maximal heart rate achieved during exercise diminishes consistently with age, and maximum cardiac index tends to decline.¹⁶⁴ Older persons who are free of cardiovascular disease rely more on increases in stroke volume to achieve increases in their cardiac index during exercise than younger persons do.¹⁷¹ Thus, end-diastolic volume index tends to increase in older persons; decreases in end-systolic volume index and increases in ejection fraction are less prominent than in young individuals [see Figure 14].^{164,172} In one study of generally healthy persons who were not extensively screened, the likelihood of ventricular wall motion abnormalities during exercise rose consistently with age.¹⁷² In an older study of persons with varying levels of habitual activity, the incidence of ECG abnormalities during and after maximal exercise rose with age and was much higher than the incidence at rest.¹⁶⁶

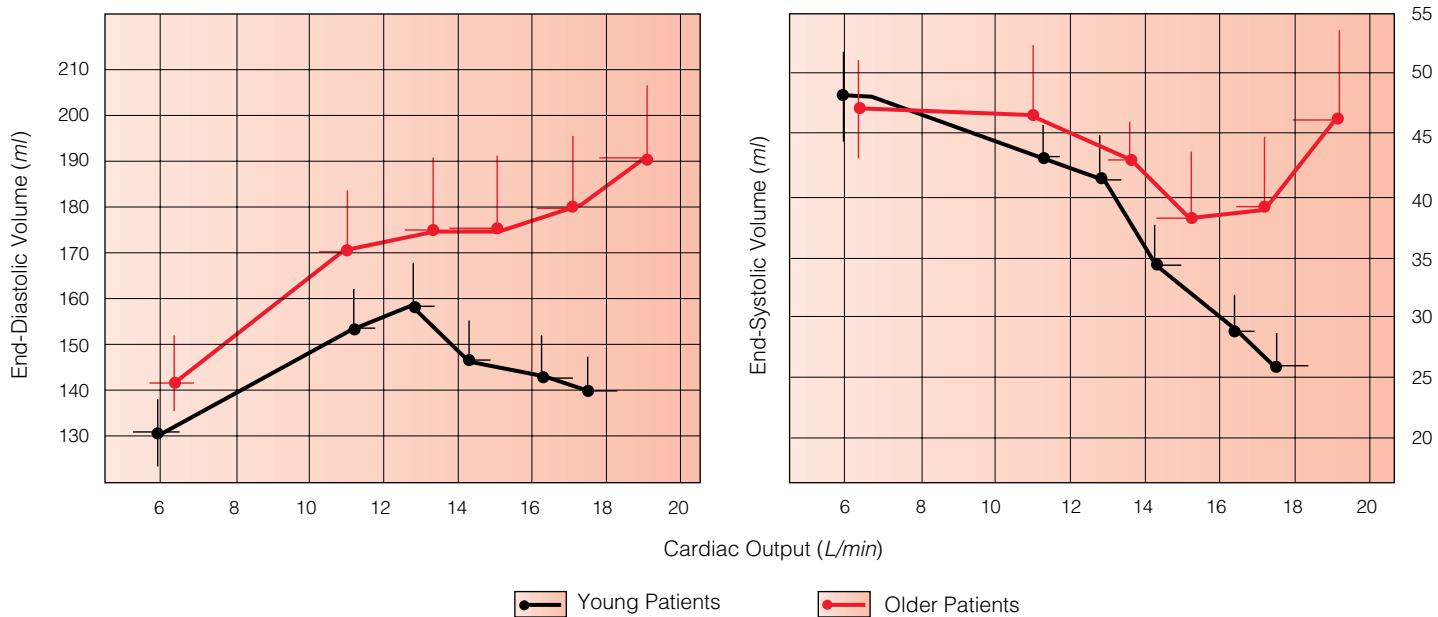

Figure 14 Depicted are relations between end-diastolic volume, end-systolic volume, and cardiac output in young and older patients at rest and during graded upright bicycle exercise.²⁴⁹

The response of healthy older individuals to an increase in cardiac afterload differs from that of young persons: significant left ventricular dilatation occurs, and contraction begins from a greater preload, presumably as a reflection of a diminished contractile reserve in the older persons.¹⁷³ Diminution of the inotropic, chronotropic, and arterial vasodilating effects of beta-adrenergic stimulation with advancing age may contribute to many age-related changes in cardiovascular function.¹⁶⁴ Isoproterenol infusion results in lesser increases in heart rate, left ventricular ejection fraction, and cardiac index in older persons than in younger ones.¹⁷⁴ Dobutamine augments cardiac output and stroke volume to a much lesser extent in elderly patients with decompensated congestive heart failure than in younger patients and provides no additional hemodynamic benefit at infusion rates higher than 5 mg/kg/min.¹⁷⁵

Thus, older patients are predisposed to hemodynamic compromise related to tachyarrhythmias, atrial fibrillation, increased afterload, and coronary artery disease. Increased end-diastolic volume and stroke volume are compensatory mechanisms that maintain cardiac output in the face of other limitations, and appropriate filling volumes must be achieved. Inotropic drugs may be less beneficial in elderly patients, and agents that are non-vasoconstricting (e.g., dobutamine) or have nonadrenergic mechanisms of action (e.g., amrinone) may be useful. Agents that reduce afterload (e.g., angiotensin-converting enzyme inhibitors) may also play a greater role in older patients. Elderly patients are less able to increase oxygen delivery in the face of increased demand and, with a high prevalence of coronary artery disease, are at risk for myocardial ischemia if demands are excessive. It is probably not appropriate to arbitrarily set supranormal goals for cardiac index and oxygen delivery in elderly patients. In addition, every effort must be made to minimize unnecessary stresses that increase metabolic demands, such as hypothermia, shivering, exposure to a cool ambient environment, hypovolemia, acidosis, pain, and inappropriate weaning from ventilatory support. The principles of physiologic and invasive hemodynamic monitoring are the same in elderly patients as in the young; however, such monitoring is perhaps even more important in older persons when the direction of therapy is unclear because of the limitations in cardiopulmonary function and homeostatic mechanisms.

Age-associated changes in blood flow to (and, to a lesser extent, oxygen consumption in) specific organs have been investigated. The kidneys receive a diminishing proportion of cardiac output in elderly persons: renal plasma flow decreases by about 10% each decade after 40 years of age and decreases in relation to renal mass. Liver volume decreases by more than one third, apparent liver blood flow by one half, and liver perfusion by one fifth from age 24 to age 91.¹⁴⁷ Cerebral blood flow, blood volume, and oxygen consumption decrease by about 0.5% a year in pure gray- and white-matter regions, whereas the oxygen extraction ratio does not change or changes only to a minor degree.¹⁷⁶ Skeletal muscle blood flow at rest appears to be unaffected by age, but maximal blood flow after exercise is diminished in older subjects.^{173,177} Average skin blood flow decreases by 30% to 40% from age 20 to age 70.¹⁷⁸

Thermoregulation

The endogenous temperature set point is typically elevated after operation or injury and during sepsis, and ambient temperature is often kept inappropriately low in hospitals. Alterations in vasomotor activity are normally relied on in the range of temperatures between those that elicit shivering and those that cause sweating. When the core temperature is lower than the ther-

moregulatory set point and heat conservation is inadequate, shivering is initiated to generate heat. Shivering may be accompanied by a severalfold increase in oxygen consumption, which would constitute a substantial metabolic load. When the core temperature falls below 34° C (93.2° F), thermoregulation becomes impaired, metabolic activity slows, and further decreases in temperature are more rapid. The hypothermic myocardium is prone to intractable arrhythmias that may be triggered by minimal stimulation. Conditions that are associated with secondary hypothermia, such as hypothyroidism and diabetes mellitus, may be more frequent (or more frequently undiagnosed) in elderly persons.

Elderly persons, particularly those older than 80 years, are less sensitive to alterations in environmental temperature and less able to maintain thermal homeostasis.¹⁷⁹ These limitations result in a higher incidence of hypothermia and heatstroke, a lower maximum body temperature during febrile illness, and more marked and prolonged falls in body temperature with surgery.^{93,94,179}

Mechanisms of heat conservation, production, and offloading are less efficient in elderly persons. Sensitivity to changes in ambient temperature is less precise, and behavioral responses are delayed. Vasoconstrictor responses to a cold stimulus are depressed in some elderly individuals, and shivering is delayed.¹⁸⁰ Moreover, the capacity for metabolic heat production by shivering is limited by the reduced muscle mass characteristic of the aged. With decreased blood flow in the skin, reduced sweat gland density, and delayed and diminished sweating responses, older patients are less able to offload heat and reduce body temperature than younger individuals are.¹¹²

Malnutrition may predispose to hypothermia and accidental injury. In a study of 744 elderly women with fractures of the neck of the femur, most of those who were very thin had a core temperature lower than 35° C (95.0° F) on admission, whereas most of those who were well nourished had a temperature higher than 36° C (96.8° F).¹⁸¹ The increase in the incidence of fractures in cold weather was greatest among the very thin; the finding that most injuries occurred indoors suggested that impaired thermoregulation in the malnourished individuals resulted in hypothermia, lack of coordination, and subsequent injury. In a study of elderly patients exposed to a range of ambient temperatures after femur fracture, vasoconstrictor responses were generally maintained; however, whereas patients who were well nourished could increase metabolic heat production appropriately, those who were undernourished (by anthropometric measurements) could not.¹⁸²

Wound Healing

Advanced age is cited as a risk factor for impaired wound healing, though not consistently. Any association is probably attributable primarily to a higher prevalence of specific risk factors in elderly persons, such as malnutrition, malignancy, uremia, diabetes mellitus, and atherosclerosis. Studies of healthy, well-nourished volunteers have shown minor delays in the epithelialization of split-thickness skin wounds in older persons; collagen synthesis in subcutaneous implants was similar in young persons and older ones, whereas accumulation of noncollagenous protein was decreased in the latter.¹⁸³ In a 2000 study of surgical patients, collagen deposition in subcutaneous implants decreased as a function of age in men but not in women.¹⁸⁴ Anastomotic leak rates after resection of colorectal cancer are not greater in elderly patients.⁸ Outcome after abdominal wound dehiscence may be worse in elderly patients.¹⁸⁵

Immune Function

There is abundant evidence that changes in immune function occur with advancing age and that these changes may predispose to infectious, neoplastic, and perhaps vascular disease.¹⁸⁶ However, there is considerable variability among studies in the age definition of elderly persons, consideration of comorbidity, and the immune functions examined [see Studies of Aging and Aged Populations, *below*]. A 2000 report suggests that many immune functions are relatively well preserved in healthy, independent-living, elderly persons.¹⁸⁷

The delayed-type hypersensitivity (DTH) response to intradermal challenge with common antigens can be used as a global measure of immune function. For a normal response (i.e., erythema and induration), intact antigen processing and stimulation of lymphocytes, release of soluble mediators, and migration of macrophages to the injection site are necessary. The likelihood of diminished or absent DTH responses to common antigens increases after the eighth decade of life, and the probability of achieving primary sensitization to an antigen to which the individual had not previously been exposed is diminished after 70 years of age.^{188,189} Aging-associated changes in cell-mediated and humoral immune responses have been well reviewed elsewhere.^{186,187} Overall, responses to foreign antigens are diminished and responses to autologous antigens may be increased. The limited information available on phagocytic responses suggests that polymorphonuclear leukocyte function may decrease with age.

Specific Clinical Concerns

Much of the material we have presented to this point is relevant to the care of elderly surgical patients in general and of elderly patients undergoing major elective procedures specifically. In what follows, we discuss the clinical considerations that arise for elderly patients who have specific surgical problems or who have significant comorbidities and functional limitations.

TRAUMA

The management of trauma is typically more complex and challenging in elderly patients than in younger ones. The prevalence of preexisting medical conditions increases with age, and such conditions are associated with longer hospital stays and higher mortality after injury.^{190,191} Mechanisms of injury change in relative frequency with age, as do the types of injuries that result from a given physical insult and the outcomes that follow a given injury. In the Major Trauma Outcome Study (MTOS), for example, falls were the predominant mechanism of injury in patients 65 years of age or older, but they were relatively infrequent in younger patients.¹⁹²

Motor vehicle crashes are the most common mechanism of injury in younger patients and remain the second most common in older patients. Once involved in a crash, older persons are more likely to die than younger persons. The circumstances and nature of motor vehicle crashes tend to differ in elderly persons. Crashes involving older drivers occur mainly in daytime and close to home and result more often from errors of judgment or perception than from high speed, aggressive driving, loss of vehicle control, or the use of alcohol.¹⁹³ Older drivers are more likely to be in crashes involving right-of-way conflicts, improper turning or starting, and failure to recognize or obey traffic signals.¹⁹⁴ Older drivers are also more likely to be involved in multi-vehicle side-impact collisions.^{193,195}

The direction of impact influences both the pattern of injuries sustained and mortality.¹⁹³ In one study, injuries to the face and

the lower extremities were significantly more common in drivers involved in frontal collisions, whereas injuries to the chest, the abdomen, and the pelvis were more frequent in left lateral impacts;¹⁹³ Mortality was nearly doubled in left lateral impacts; this increase was independent of both Injury Severity Score and driver age.

The pattern of injuries resulting from a given physical insult also seems to differ to some extent in elderly persons: older drivers have a higher incidence of chest injuries, specifically rib and sternal fractures.¹⁹⁶ Greater chest wall stiffness and osteoporotic changes may predispose older persons to rib fractures after relatively minor trauma. Rib fractures or even flail chest may sometimes occur in elderly persons without the significant underlying pulmonary contusion that would be anticipated in a younger patient.^{197,198} Striking age-related increases in fractures of the vertebrae, the hip, and the distal forearm have been documented, and the pivotal role of osteoporosis in such fractures is well recognized.¹⁹⁹ Patients who have major injuries despite an apparently insignificant mechanism of injury (e.g., a low-level fall) are more likely to be older than 55 years.²⁰⁰ Burn injuries are more common in older persons, and these injuries tend to be more severe in terms of both surface area and depth; moreover, inhalation injury is more likely.²⁰¹ As a consequence, mortality is higher and hospital stay longer. The increased risk of burn injury in elderly patients may be attributable to a diminished sense of smell, impaired hearing or vision, or reduced mobility and reaction time. The tendency to more severe thermal injury may be attributable to age-related changes in skin morphology.

Elderly persons are, in general, less sensitive to deviations from physiologic norms and less able to maintain homeostasis.²⁰² They are less able to maintain adequate perfusion of vital organs after injury than younger patients are,²⁰³ and they are more likely to arrive in the emergency department hypotensive, cold, and in shock after a given injury. Presumably, reduced homeostatic capacity contributes to the overrepresentation of older persons with regard to immediate and early trauma deaths, as well as late deaths related to infection and multiple organ dysfunction syndrome (MODS). Resuscitative measures, though identical in principle to those taken in younger patients, must be carried out with an eye to their physiologic limitations, particularly the need for volume loading to achieve increases in cardiac output. Preexisting medical conditions must be identified rapidly via history-taking, physical examination, and investigative studies as needed, and information about previous medication use should be obtained. Because thermoregulatory mechanisms are less efficient in elderly patients, measures should be taken to minimize ongoing heat loss from exposure and administration of cool fluids and to prevent the adverse effects of hypothermia.

Unfortunately, even an apparently good physiologic status in the ED (at least as reflected in the Trauma Score [TS] or the Revised Trauma Score [RTS]) does not guarantee survival for the elderly trauma patient: mortality in elderly patients with high TS or RTS is many times higher than that in younger patients with comparable scores.^{192,204,205} MTOS data demonstrate that case-fatality rates are uniformly higher in patients 65 years of age or older than in younger patients for every injury mechanism for which sufficient data were available.²⁰⁶ Mortality was consistently higher for each range of Injury Severity Scores and for each injury severity-body region combination. Patients 65 years of age or older accounted for 30% of the deaths that were unexpected according to Trauma and Injury Severity Score (TRISS) projections despite representing only 8% of the MTOS study population.

tion. Complications (pulmonary, cardiovascular, and infectious) were also more common in the older patients^{192,206}; the difference was most striking in patients with mild to moderate injury. Others have noted the high incidence in elderly patients of respiratory complications (including pneumonia), as well as cardiac complications that are relatively uncommon in younger patients.^{207,208}

Elderly patients are less likely to survive their injuries and be discharged from hospital than younger patients, but several reports indicate that many older survivors return to a satisfactory level of function and independence.^{197,207-211} In subsequent studies, however, prolonged and profound functional limitations have been identified after major trauma when sophisticated assessments of long-term functional, psychological, and quality-of-life outcomes have been undertaken.²¹² Variations in functional recovery and placement status result from a number of factors besides the specific mechanism and nature of the injury. For example, family and social support systems have been shown to be important for achieving discharge-to-home and optimal functional recovery in patients with isolated hip fracture, and some authors have reached similar conclusions with reference to trauma in older persons in general.²¹³ Very advanced age, preinjury placement, preinjury functional status, and preexisting medical conditions are also likely to influence postinjury rehabilitation. Injury-causing falls may, in some instances, be a reflection of important underlying problems, such as dementia or a poor physical state. The adverse impact of serious head injury on early and delayed mortality has been reported in a number of studies.^{205,207,209-211} Admission to an ICU, even if the stay is longer than 2 weeks and even if mechanical ventilation is necessary, does not preclude a very good functional recovery in survivors.^{197,207-209}

CANCER

The incidence of most cancers increases with age. One half of new cases of lung and colorectal cancer now occur in persons 70 years of age or older, as do nearly two thirds of new cases of prostate cancer and one third of new cases of breast cancer.²¹⁴ The importance of cancer as a cause of surgical illness in older persons is further indicated by the high proportion of surgical procedures related to malignancy and its frequency as a cause of death in surgical patients.²¹⁵

The principles of cancer care are similar in elderly patients, and surgeons play a central role in determining the application of those principles. There is evidence, however, that in practice, the use of diagnostic modalities, the choice of surgical treatment, and other forms of cancer care differ in elderly patients.^{8,216-220} This difference may be an appropriate response to the increased prevalence of comorbidity or to age-related differences in treatment goals, or it may reflect an inappropriate bias. Older cancer patients may assign greater importance to outcomes other than the traditional ones (survival, response rates, and disease-free intervals) than younger patients do.^{218,221} They also appear more concerned about the effects of treatment and may be less willing to trade current health-related quality of life for potential survival advantage.^{216,222}

Comorbidity in the elderly population may limit potential gains in life expectancy, alter treatment goals, and reduce the ability to tolerate major surgical procedures and other forms of therapy. Yet adjustments for measured comorbidity do not fully account for age-related differences in care.^{223,224} The elderly population is very diverse and includes individuals who are physiologically very fit, as well as ones who are not. There is evidence that nondefinitive care is associated with poorer clinical outcomes.²²⁵ Thus, it is inappropriate to generalize cancer care simply on the basis of chronologic age.

Older persons have been underrepresented in cancer clinical trials, with the result that our perceptions of the efficacy and safety of many therapies in this population must be based on inference rather than knowledge and may therefore be inaccurate.²²⁶ The development of multidimensional assessment tools for the geriatric cancer patient should allow appropriate enrollment and stratification in clinical trials and permit identification of patients who can expect the most benefit from aggressive therapy.^{227,228} There is considerable uncertainty about cancer screening in older populations, for the reasons discussed. A framework for making decisions about screening has been proposed, incorporating quantitative estimates of risks and benefits in relation to individual preferences and values.²²⁹ When life expectancy is less than 5 years, cancer screening is unlikely to provide any survival benefit.

SIGNIFICANT COMORBIDITY AND FUNCTIONAL LIMITATION

Most elderly individuals live independently and function well. Nonetheless, elderly persons in nursing homes or similar facilities often have significant comorbid conditions and functional limitations and usually have a limited life expectancy. They experience a range of orthopedic, general surgical, vascular, and other surgical problems that may be relatively advanced and that commonly present as emergencies or in atypical or nonspecific ways.⁴¹ Dementia and other cognitive impairments predict increased mortality [see Cognitive Assessment, *above*], presumably because of delays in presentation and diagnosis and the comorbidities that are frequently present. Many elderly patients manifest the limited mobility, weakness, relative inactivity, weight loss, and diminished physiologic reserves suggested by the term frail and thus are highly vulnerable to the stresses of acute surgical illness and hospitalization.²³⁰ The term frail, however, has a number of distinct connotations within and among different health care disciplines and should therefore be used with due caution.

For elderly persons with significant comorbid conditions and functional limitations, the goals of surgical therapy are usually modest: to correct immediately life-threatening conditions or to address problems related to quality of life. Comfort, function, and dignity—rather than major gains in survival—are more often the primary goals. How well we achieve these goals with current surgical care is uncertain. Precise diagnosis is usually the most satisfactory basis for relieving suffering and achieving the other goals of importance to the elderly patient. However, it must be kept in mind that precise diagnosis is just one means to that end and that pathologic states of various kinds can almost always be identified in such individuals, whether relevant or not.²³¹

Advance decisions to limit the use of specific therapies have been made and documented by some elderly individuals. Surgical care should not be precluded for patients for whom a do-not-resuscitate (DNR) order has been established. Outcomes in such patients are not necessarily worse than in other older patients. Agreement to rescind the DNR order temporarily in the immediate perioperative period should be sought because the causes of cardiopulmonary arrest during that period may be rapidly and readily correctible.

Surgical problems in nursing home patients should be addressed actively because they can often be managed more easily and safely when elective than when they have evolved into more difficult, high-risk, emergency conditions. The elective setting also provides more opportunity for informed decision-making and treatment planning and the development of consensus among those involved. The care of such patients is especially challenging and should be undertaken by surgeons who are interested in and knowledgeable about the problems that arise, who are prepared to

deal with the complexities of comorbidity and cognitive and functional impairment, and who will educate their colleagues, patients, and families about the full range of therapies available for surgical conditions.⁴¹

THE OLDER ORTHOPEDIC PATIENT

The high prevalence of osteoporosis, combined with an increased predisposition to falls, leads to a high incidence of fractures (especially of the hips, the vertebrae, and the wrists) in older persons. The surgeon's role in the management of these patients should include a careful search for the cause of the fall. Loss of consciousness during the fall may signal that seizures, cardiac disease (e.g., dysrhythmias and aortic stenosis) or postural hypotension are contributors. Medications, including sedatives, narcotics, and anticholinergic agents, may also be implicated. Evidence of neurologic conditions (e.g., Parkinson disease and peripheral neuropathy) should be sought. Surgeons should also consider the need for medications to reduce bone fragility (e.g., calcium, vitamin D, and bisphosphonates). Involving a geriatrician often facilitates management of osteoporosis and falls.

For elderly hip fracture patients, the choice of type of surgical procedure performed must consider the need to avoid prolonged immobility and its resultant complications [see Table 7]. Fully 25% of patients with hip fractures die within 1 year as a consequence of complications of immobility. Therefore, the choice of procedure should allow full weight bearing as soon as possible postoperatively. Appropriate selection of procedures gives elderly patients the best chance of returning to their premorbid functional status.

Studies of Aging and Aged Populations

Age is often associated with adverse clinical outcomes. However, two related concepts must be considered in reviewing studies that are concerned with elderly patients and aged populations or in which age may be a significant variable. First, although age has obvious chronologic meaning, it is a surrogate for a range of biologic, clinical, social, and other variables. Some of the variables that we often recognize as changing in association with age are maximal organ system function (physiologic reserve), the prevalence of comorbidity, functional status, patterns of illness (e.g., a preponderance of perforated appendicitis in older persons), and disease incidence (e.g., cancer). A knowledge of age-related variables in the population being reported on is important in that it can help determine the extent to which findings can be generalized to one's own patients. Age-related variables must be excluded as fully as possible when basic disease mechanisms or causal relationships are being examined.

Second, the method by which elderly research subjects are selected greatly influences the findings of clinical studies. Aging is a highly variable process, both among individual and among different organ systems within an individual. Studies of institutionalized elderly persons who have multiple comorbidities and functional impairments will give very different results from studies of active, healthy, community-dwelling individuals. Again, such age-associated variables must be addressed to allow proper interpretation of study findings. It must also be remembered that aging is a continuous process. For example, a 65-year-old person and an

85-year-old person, each in good health, could well be very different with respect to physiologic and functional status, even though they would often be grouped together into a single "elderly" category.

Two basic study designs are employed in clinical studies of elderly and aged populations: cross-sectional and longitudinal. In cross-sectional studies, subjects of various ages are assembled, and observations are made at one point in time. Such studies are easier and less expensive to conduct than longitudinal studies, but they are subject to bias and confounding variables. For example, elderly patients, when younger, may have been very different from the young patients with whom they are being compared; that is, changes may occur in the population as a whole over time. In addition, elderly individuals (particularly those older than 75 years) make up what may be thought of as a biologically superior group in that they have been selected by the very fact of their survival from a larger group, many of whose members have died. Cross-sectional studies thus may demonstrate differences between current age groups rather than changes that occur with aging. Bias may also arise in relation to referral for surgical care or to particular institutions or from a wide range of other potential sources. A clear description of the source of the data and the basis on which the subjects came to be studied allows others to make judgments about bias and the generalizability of research findings.

In longitudinal studies, a cohort is assembled and followed prospectively, with observations made at planned intervals. Longitudinal studies require a stable, dedicated population observed over a prolonged period and are particularly sensitive to subtle alterations in methods. Among the most comprehensive and widely cited longitudinal studies is the Baltimore Longitudinal Study of Aging, conducted using carefully screened, community-residing, independent adults.²³²

Because research subjects cannot be randomized to an age group, prospective clinical studies of aging and of aged populations are necessarily observational in design. As a result, study groups that differ in age, by design, also unavoidably differ in terms of other variables (covariates), such as those already described. For this reason, although observational studies are very useful for descriptive and prognostic purposes, they are less satisfactory for examining causal relationships. Several strategies for study design and analysis are useful for minimizing or adjusting for imbalances in covariates between groups.²³³

Advanced age has, in the past, been a common exclusion criterion for research studies, with the result that there is a paucity of information pertaining specifically to older persons in certain important clinical areas.²²⁶ Inferences about age effects on diseases and responses to therapy must then be made, exposing elderly patients to the risks of inaccuracy. In addition, outcomes that are likely to be of particular interest to elderly persons (e.g., quality of life) may not be well addressed when studies are designed with a focus on younger patients.²³⁴ The unique problems and questions of the elderly population must be addressed in surgical research. Concerns about vulnerability and exploitation may sometimes arise, but they do not negate the obligation to conduct research in these individuals; to continue to exclude elderly patients would be to deny the potential benefits of research to a population that has great need of them.

2 THE PEDIATRIC SURGICAL PATIENT

Andreas H. Meier, M.D., Robert E. Cilley, M.D., F.A.C.S., Peter W. Dillon, M.D., F.A.C.S., and Arnold G. Coran, M.D., F.A.C.S.

Surgical care of neonates, infants, and children differs in many respects from that of adults.¹ Accordingly, it is essential that surgeons caring for preadult patients be capable of recognizing and managing certain clinical problems that occur frequently in this population. To this end, we begin this chapter by discussing several basic considerations related to pediatric physiology, which is markedly different from adult physiology. With this general discussion as a background, we then provide an overview of specific surgical problems commonly encountered in pediatric patients.

Physiologic Considerations

HOMEOSTASIS

Fluids and Electrolytes

Management of fluids and electrolytes in neonates and infants requires a thorough understanding of the changes in body fluid compartments that occur during development [see Figure 1].²⁻⁷ At birth, total body water accounts for roughly 75% of total body weight (TBW), but this percentage decreases rapidly in the first few days, falling slowly toward 60% over the first year. Similarly, extracellular fluid volume accounts for 45% of TBW at birth but only 20% by the end of the first year. Newborns have lower glomerular filtration rates and reduced renal concentrating ability^{8,9}; consequently, they tolerate dehydration poorly and cannot excrete a water load as effectively as older persons with mature kidneys can. For this reason, adequate fluid management is especially challenging in these patients.

Measurement of urine output is a useful guide to fluid management, provided that accurate urine collections can be obtained. In critically ill infants and children, a urinary catheter should be inserted to ensure accurate urine collections. Catheterization of male neonates and infants carries a significant risk of trauma to the small urethra; in these patients, the use of properly secured collection bags may allow accurate measurement of urine output without the need for catheter insertion. An appropriate urine output is 1 to 2 ml/kg/hr.

Insensible water loss results from continuous evaporative loss of water through the respiratory tract and the skin.¹⁰ In premature infants, a large proportion of insensible water loss occurs transcutaneously. Insensible water loss from the skin can be minimized by using incubators in the neonatal intensive care unit (NICU) and extremity coverings in the operating room. Insensible water loss from the lungs can be decreased by humidifying the inspired gases.

In general, the maintenance fluid requirement of a neonate is considered to be 70 ml/kg/24 hr initially; this figure rises to 100 ml/kg/24 hr after a few days of life. Neonates with surgical problems may require dramatically increased amounts of fluid.

The sodium requirement of a full-term infant is, on average, 2 mEq/kg/24 hr. Conditions such as intestinal obstruction [see Com-

mon Surgical Problems in Newborns, Obstruction of the Gastrointestinal Tract, below] and peritonitis increase sodium loss and therefore increase sodium requirements. Although full-term infants can retain sodium as well as adults do in the face of a sodium deficit, they are unable to excrete excess sodium as effectively. As a result, excessive infusion of sodium can rapidly result in hypernatremia.

The generally accepted potassium requirement is 2 mEq/kg/24 hr after the first 2 to 3 days of life. However, the need for potassium replacement can be significant in the first few days of life as well, especially after a major surgical intervention. Thus, potassium should be administered in the first 1 or 2 days of life after an operation once urine output has been established.

In view of the various fluid and electrolyte requirements of neonates and infants, the initial fluid used in surgical management of these patients, both preoperatively and postoperatively, should be 5% or 10% dextrose in 0.2% saline at a dosage of 100 to 150 ml/kg/24 hr [see Table 1].

Acid-Base Status

Metabolic alkalosis caused by loss of electrolytes (specifically, chloride) may occur with prolonged gastric suction or vomiting; usually, it is easily corrected by replacing the lost electrolytes (e.g., by administering potassium chloride). Metabolic acidosis, on the other hand, is usually the result of poor tissue perfusion and lactic acidosis; it is best corrected by treating the underlying cause of the

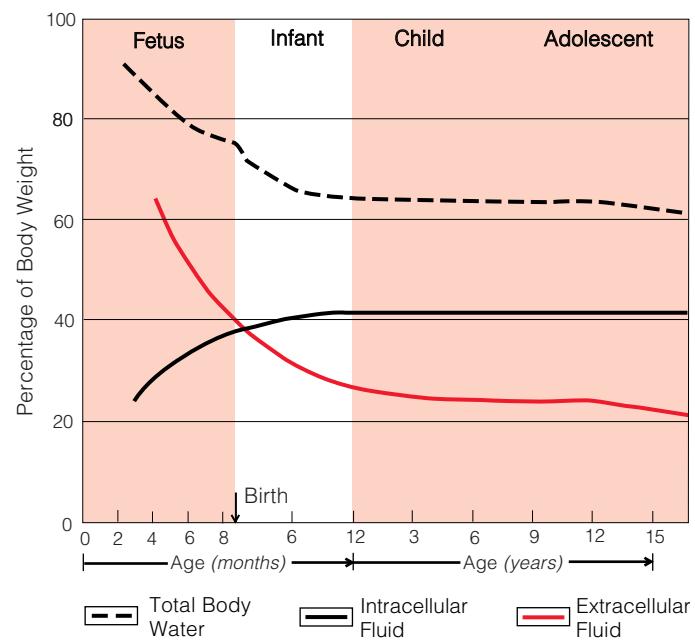

Figure 1 Total body water (TBW) and extracellular fluid (ECF) decrease between fetal life and adulthood, and intracellular fluid (ICF) increases.

Table 1 Daily Fluid Requirements for Neonates and Infants

Weight	Fluid Requirements*
Premature < 1.5 kg	150 ml/kg
Neonates and infants 1.5–10 kg	100 ml/kg
Infants and children 10–20 kg	1,000 ml + 50 ml/kg over 10 kg
Children > 20 kg	1,500 ml + 20 ml/kg over 20 kg

*Maintenance Na⁺ and K⁺ requirements range from 2 to 4 mEq/kg; solution can generally be given as 0.2% saline, with 5% or 10% dextrose and K⁺ added.

poor perfusion and by temporarily administering buffers (e.g., sodium bicarbonate). It should be noted that standard sodium bicarbonate solutions are extremely hypertonic and should be diluted before administration, especially when they are being given to neonates.

Temperature

In neonates, strict regulation of the environmental temperature is critical for preventing hypothermia. Compared with older children and adults, infants have a higher ratio of body surface area to weight, less subcutaneous fat (and therefore poorer thermal insulation), and less lean body mass (which is required for generating and retaining heat).

Maintaining the body temperature of neonates and young infants is critical both in the NICU and in the OR. In the NICU, the infant may be placed in an incubator (which is designed to reduce airflow across the skin and provide a tightly regulated, thermally neutral environment) or on a bed with an overhead radiant heater. In the OR, the ambient room temperature may be raised, overhead radiant warmers may be used, circulatory warm air blankets may be applied, and the head and extremities may be wrapped in plastic. Ventilatory gases are warmed and humidified, and warm intravenous and irrigation fluids are used.

NUTRITION

Whereas the nutritional requirements of children and teenagers do not differ significantly from those of adults [see 8:23 *Nutritional Support*], the requirements of infants do. Not only must the metabolic demands that a major illness or operation imposes on all patients be taken into account, but special consideration must also be given to the smaller body size of infants, their rapid growth, their highly variable fluid requirements, and the immaturity of certain of their organ systems. These characteristics, coupled with the low caloric reserves present if the infant is premature or sick, make adequate nutritional intake particularly important. Consequently, infants whose nutritional needs are not met as the result of a functional or organic disorder of the gastrointestinal tract can rapidly acquire protein-calorie malnutrition. Even a relatively short period of inadequate nutrition can lead to impaired host resistance, an increased risk of infection, and poor wound healing, all of which contribute appreciably to morbidity and mortality in infants and children with surgical disease.

Nutritional Requirements

Infants have higher weight-adjusted caloric requirements than older children and adults do [see Table 2], and these requirements are further increased by periods of active growth and extreme physical activity.^{11,12} Major illness or surgical trauma may raise caloric requirements even further. However, measured energy expenditures do not appear to be elevated in neonatal surgical

patients and critically ill premature infants.^{13–15} In general, calories should be provided in the proportions found in a well-balanced diet: 50% carbohydrate, 35% fat, and 15% protein.

The protein needs of infants are based on the combined requirements for maintenance and growth. Most of the increase in body protein occurs during the first year of life, which explains why protein requirements are highest in infancy and decrease with age. Of the 20 amino acids from which proteins are synthesized, eight are essential in adults, but it is believed that in addition, histidine is essential in infants and cysteine and tyrosine in premature infants.

In general, infants require more vitamins and minerals than adults do. Increased amounts of calcium and phosphorus are particularly important because of the rapid growth rate of the infant's skeleton.

Nutritional Assessment

In many cases, a sick infant's history and overall appearance provide sufficient grounds for initiating nutritional support. For example, a preterm infant with respiratory distress who is small for his or her gestational age clearly requires parenteral nutrition, as does a newborn with gastroschisis. Physical variables that should be considered in nutritional assessment include weight, length, head circumference, chest circumference, and triceps skinfold thickness. No blood test reflects changes in the patient's nutritional status with ideal accuracy, but serum albumin, prealbumin, and transferrin levels are frequently used as markers.

Enteral Nutrition

The type of nutritional support to be employed depends on the disease affecting the patient and on the patient's overall health status. From a physiologic standpoint, enteral nutrition is preferable and is the first choice for patients whose GI tract is functioning adequately.¹⁶ For infants younger than 1 year, breast milk or a standard infant formula is delivered orally or via a tube.¹⁷ For older children who are unable or unwilling to eat, a liquid diet consisting of either blenderized food or liquid formula may be employed. A number of nutritionally complete liquid formulas are commercially available. Specialized formulas are available for use in patients who have lactose intolerance or protein sensitivity or who are experiencing renal or hepatic failure.

The use of predigested or elemental diets may allow patients with injured intestine or inadequate intestinal length to absorb enteral feedings. In children who cannot manage oral feedings, nasogastric and nasojejunal tubes are used. If the child's condition necessitates long-term tube feeding, a gastrostomy may be necessary.

Table 2 Daily Kilocalorie and Protein Requirements for Infants and Children

Age (yr)	Kilocalorie Requirements* (kcal/kg)	Protein Requirements (g/kg)
0–1	90–120	2.0–3.5
1–7	75–90	2.0–2.5
7–12	60–75	2.0
12–18	30–60	1.5
18+	25–30	1.0

*These numbers represent volume administered when 1 kcal/ml solutions are used. Growth can be maintained with 10% to 20% fewer calories if parenteral nutrition is employed.

Table 3 Normal Values for Vital Signs in Children¹⁴²

Age (yr)	Pulse Rate (beats/min)	Systolic BP (mm Hg)	Respirations (breaths/min)	Urinary Output (ml/kg/hr)
0–1	< 160	> 60	< 60	2.0
1–3	< 150	> 70	< 40	1.5
3–5	< 140	> 75	< 35	1.0
6–12	< 120	> 80	< 30	1.0
> 12	< 100	> 90	< 30	0.5

Postoperative Feeding

Infants have more difficulty in feeding during the early months of life. This is especially true of premature infants, in whom the complex physiology of sucking and swallowing is not yet fully developed. In addition, the work of feeding accounts for most of an infant's caloric expenditure in the early months, and a stressed infant tires easily. For this reason, gavage or gastrostomy tube feedings are generally employed for the early stages of postoperative feeding in infants. Feeding is begun after the resolution of postoperative ileus has been demonstrated by the passage of meconium or stool. Further evidence that the bowel is beginning to function is the disappearance of the bilious green color of the gastric aspirate and the decrease in the volume of the aspirate from the nasogastric or gastrostomy tube. Initially, small volumes of rehydration fluid are given orally or via a gastrostomy tube. If these are tolerated, the feedings are increased incrementally until the nutritional goals for the patient have been reached.

Infants tolerate increases in volume more readily than increases in osmolarity. Accordingly, it is often best to start with diluted formulas (three-quarter-strength, half-strength, or quarter-strength), then, as nutritional requirements grow, increase the volume first and subsequently increase the concentration as necessary to supply the required amount of calories.

Elemental or chemically defined diets require a minimum of digestive work and are free of residual bulk. They may be accepted by infants if given orally; however, they are unpalatable and thus are usually given by tube. Because of the high osmolality of these diets, constant infusion with a pump may be necessary to prevent the development of dumping syndrome. The ease of GI absorption and the minimal residue make elemental diets useful as an intermediate step between parenteral nutrition and regular feedings. In infants, whenever possible, oral feedings or oral stimulation should accompany tube feedings.

Parenteral Nutrition

The concept of total parenteral nutrition (TPN) had been entertained for decades for its initial development, but it was not until the 1960s that the major breakthrough occurred, when Dudrick and associates successfully administered a hypertonic glucose solution into a central vein.^{18,19} In the early years after the group's initial success, this approach to TPN began to be widely used in newborns with GI anomalies.^{20,21} Since then, the technique has been applied to the care of patients of all age groups, with dramatic results [see 8:23 Nutritional Support]. Less concentrated solutions are available for administration into peripheral veins.

Generally, TPN is reserved for infants and children who are threatened by catabolic or nutritional deficits because feeding via the GI tract is hazardous, inadequate, or impossible. Conditions that may necessitate TPN include intestinal obstruction from congenital disorders, prolonged postoperative ileus, peritonitis, intesti-

nal fistulas, chronic nonspecific diarrhea, necrotizing enterocolitis, short-bowel syndrome, extensive burns, and abdominal neoplasms treated with surgery, chemotherapy, and radiation. Besides being used for nutritional repletion of malnourished children, TPN may also be employed prophylactically when prolonged starvation is expected, as in cases of gastroschisis. In infants, TPN is indicated if nutrition is inadequate for longer than 3 days; however, in older children and adults, a longer period of inadequate nutrition may be tolerated, depending on patients' nutritional status before operation or at the onset of illness. The benefits of improved nutrition in terms of reducing mortality and morbidity must be weighed against the risks of serious complications, especially sepsis. TPN should not be employed when enteral nutrition is feasible. Every effort should be made to use the enteral route for feeding, including the use of transpyloric feeding tubes.

Infants receiving TPN must be carefully monitored. Essential clinical measurements include weight, length, and intake and output volumes. Blood tests must be employed judiciously and sparingly in infants and children because of their small total blood volume. At the start of therapy and once a week thereafter, a complete blood count should be done, blood urea nitrogen should be measured, and serum levels of electrolytes, glucose, calcium, phosphorus, magnesium, and albumin should be assessed. Serum levels of liver enzymes, bilirubin, and creatinine should be measured at the start of therapy and every 2 weeks thereafter.

On average, neonates gain 15 to 25 g/day with TPN, and older children gain 0.5% of TBW/day. Greater weight gains may signal excessive administration of fluids or intake of calories.

The main complications of parenteral nutrition include catheter-based problems (e.g., sepsis, malfunction, and venous thrombosis), electrolyte abnormalities, and (especially in infants receiving long-term TPN) hepatic cholestasis, which ultimately can result in cirrhosis and hepatic failure. Strategies to minimize liver damage include early and aggressive treatment of infection, avoidance of excessive caloric intake, limitation of protein intake, and supplemental trophic enteral nutrition.

HEMODYNAMIC IMBALANCE AND SHOCK

For proper assessment of shock in infants and children, it is necessary to be familiar with the normal vital signs in these age groups [see Table 3]. The two types of shock most frequently seen are hypovolemic shock and septic shock; in infants and children, septic shock is the most common form.²² The response of newborns and infants to hypovolemic or septic shock is significantly different from the response of older children and adults. For example, neonates affected by profound shock tend to become bradycardic, whereas adults are more likely to become tachycardic. Moreover, neonates, especially premature neonates, normally have a low blood pressure; consequently, shock often does not evoke any further significant reduction of blood pressure. The hypovolemia caused by the shock

results in decreased venous return, which lowers cardiac output; the reduced cardiac output leads to poor tissue perfusion and the development of lactic acidosis.

Gram-negative bacteria are the organisms most often responsible for septic shock. Peritonitis resulting from intestinal perforation is a common cause of septic shock in neonates and infants; other causes are urinary tract infections, respiratory tract infections, and contaminated intravascular catheters. The pathophysiology of septic shock differs substantially from that of hypovolemic shock; however, in both states, stasis and pooling of blood in the capillary bed lead to reduction of the circulating blood volume.²³

Treatment

The mainstay of therapy for hypovolemic shock is administration of fluid and blood. In neonates, the hematocrit should be maintained at 45% to ensure adequate oxygen delivery. In many infants, hypovolemic shock is caused not by hemorrhage but by dehydration (e.g., from severe gastroenteritis). This dehydration is usually hypertonic because of the significant loss of hypotonic fluid. As a rule, neonates and infants in hypovolemic shock lose much more water than electrolytes, and as a result, serum sodium levels may exceed 150 mEq/L. Emergency treatment involves infusion of isotonic solutions of sodium chloride with careful monitoring of serum electrolyte concentrations.

Because septic shock, like hypovolemic shock, is characterized by reduced circulating blood volume, initial therapy involves infusion of large volumes of colloid solutions. Most of the experimental and clinical data suggest that colloid solutions are preferable to crystalloid solutions in this setting, both for children and for adults. In addition, broad-spectrum antibiotics should always be administered.

If fluid infusion has been maximally effective (as evidenced by a normal to elevated central venous pressure) but hypotension persists, pharmacologic agents must be given to improve myocardial contractility. The most commonly used agents are the alpha and beta agonists dopamine and dobutamine, which primarily have inotropic and mild vasodilatory effects at lower doses. Infants and children in shock require continuous monitoring and close clinical observation and should therefore be managed in the ICU.

Common Surgical Problems of Newborns

Neonatal surgical problems often present as emergencies and necessitate rapid stabilization and transfer of the patient to a pediatric surgical center. Proper initial management is crucial and may have a pronounced effect on overall outcome. The organ systems most commonly affected are the respiratory tract and the GI tract.

EMERGENCY SURGICAL PROBLEMS

In many communities, the general surgeon is frequently called on to assist in the diagnosis and initial care of a neonate with an apparent surgical problem. After stabilization measures have been carried out and preliminary tests have been performed to establish a diagnosis, the baby may be transported to a pediatric center that is specially equipped and staffed to manage the specific surgical problem present.

The steps in the stabilization of a critically ill neonate before transport are similar to the ABCs of initial care in an adult (*Airway, Breathing, Circulation*). By the time the surgeon is consulted, the neonatologist or pediatrician may have accomplished initial stabilization and begun to prepare the baby for transfer. The surgeon's immediate responsibility may be to establish vascular

access. In some cases, a peripheral venous cannula may be appropriate; more often, a central catheter is inserted via an umbilical vein or artery. In babies with omphalocele or gastroschisis, the I.V. line ideally should be placed in the upper extremities or the neck. Appropriate fluids should be infused to prevent dehydration and to correct any fluid or electrolyte deficits. When required, a nasogastric or esophageal pouch suction tube should be placed and decompression initiated. This maneuver is extremely important if transport by air is considered: trapped gases change in volume with alterations in barometric pressure, and such changes may have particularly deleterious effects on infants who have intestinal gas, pneumothorax, or pneumomediastinum.

Vitamin K should be given in the form of phytonadione, 1 mg (0.5 mg for babies who weigh less than 1,500 g). Appropriate antibiotics should also be administered. Finally, the infant should be wrapped and placed in an incubator or a radiant warmer to stabilize body temperature and maintain it at normal levels.

The use of sophisticated transport teams with appropriate equipment and supplies is the safest method of moving these babies between hospitals. Early stabilization and close communication between the referring physician, the accepting physician, and the transport team are essential for minimizing the potential risks and morbidity associated with patient transfer.

The following seven emergency surgical problems are commonly encountered in neonates. Each involves special considerations in the preparation of the patient for interhospital transfer.

1. Congenital diaphragmatic hernia (CDH): insert a nasogastric or orogastric tube. Ventilation by face mask is contraindicated; if ventilation is required, intubate.
2. Esophageal atresia: insert a tube to aspirate secretions from pouch (use a Replogle tube, if available). If possible, avoid mechanical ventilation; if intubation is required, use high-frequency, low-pressure ventilation to prevent distention and possible perforation of the stomach.
3. Congenital lobar emphysema: support normal oxygenation. Minimize mean airway pressure.
4. Intestinal obstruction: use nasogastric or orogastric suction. Confirm placement and function of I.V. lines.
5. Omphalocele or gastroschisis: use nasogastric or orogastric suction. Cover the sac with nonadherent gauze, and take care not to rupture the membrane (if present); cover the intestine with saline-soaked gauze and a see-through bowel bag. Place the I.V. line in the upper extremity or the neck, if possible. Maintain hydration by increasing fluid administration to replace fluid lost from the exposed bowel. Support the bowel with dressings. Maintain body temperature.
6. Exstrophy of the bladder: cover the exposed bladder with a nonadherent dressing.
7. Meningomyelocele: cover the sac with a nonadherent dressing.

RESPIRATORY PROBLEMS

Cystic Disease of the Lung

Cystic lung disease, especially congenital cystic adenomatoid malformation (CCAM) of the left lower lobe, can mimic diaphragmatic hernia both clinically and radiographically [see Figure 2a].^{24,25} Unlike a newborn with diaphragmatic hernia, however, a newborn with CCAM will have an abdomen with the normal degree of protuberance. If an infant with CCAM experiences marked respiratory distress that necessitates intubation and mechanical ventilation, it is better to perform an emergency lobectomy than to subject the baby to a period of mechanical ventilation, with its

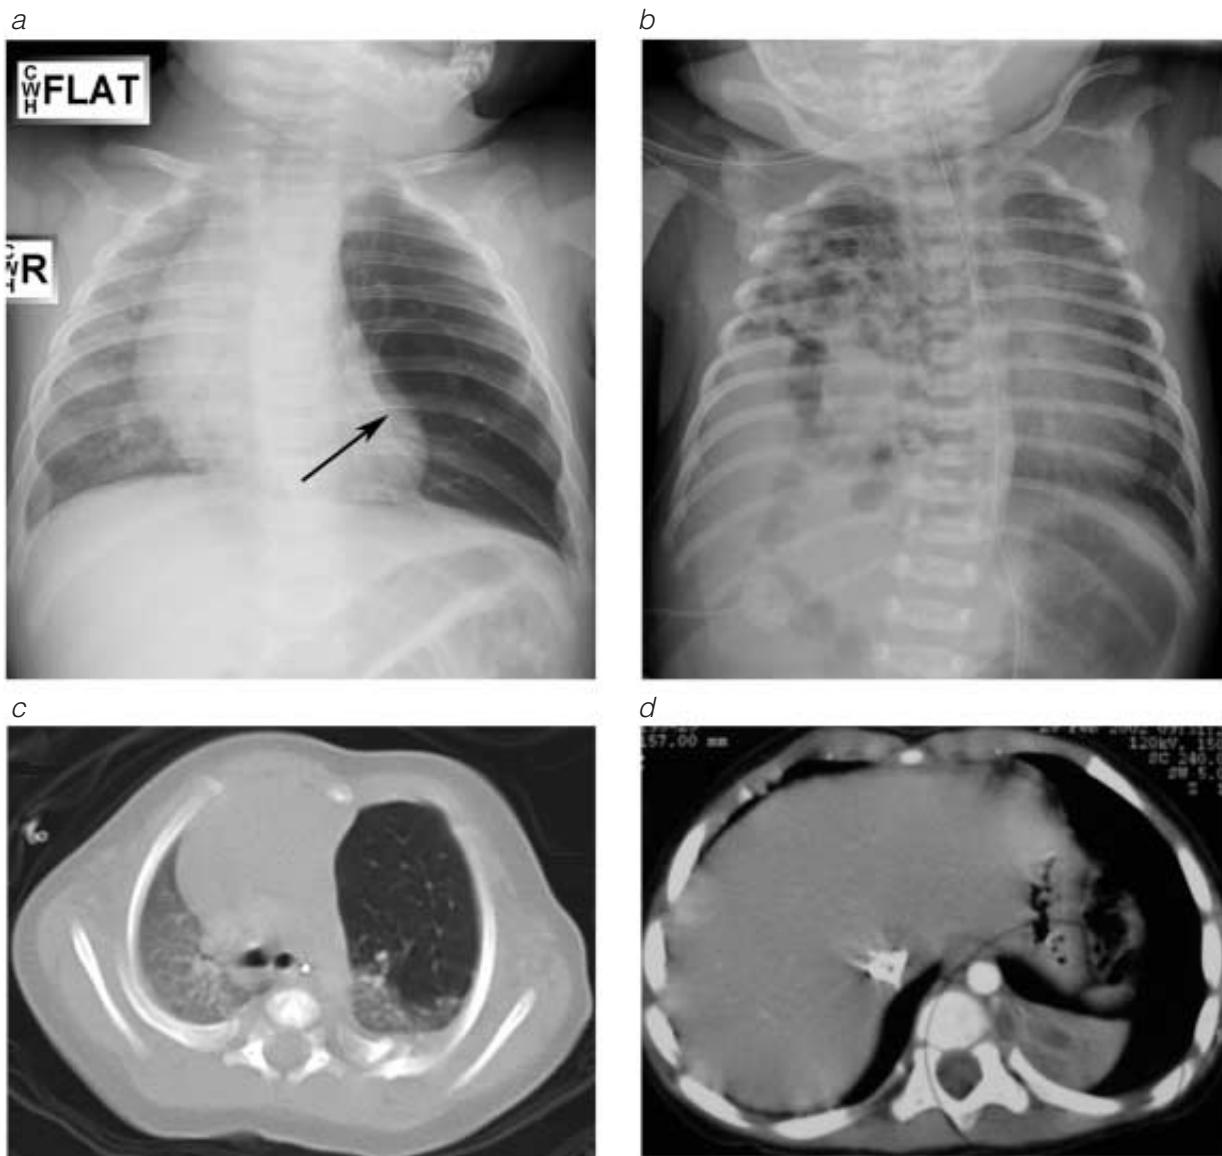

Figure 2 Shown are common neonatal chest abnormalities: (a) congenital cystic adenomatoid malformation (CCAM) with a large cyst in the left lung (arrow) and mediastinal shift; (b) congenital diaphragmatic hernia (CDH) on the right side, with the liver and intestines within the chest cavity; (c) hyperinflated left lung with mediastinal shift caused by lobar emphysema; and (d) pulmonary sequestration with consolidation caused by pneumonia.

attendant risks (i.e., barotrauma and oxygen toxicity). If the lesion is asymptomatic, it can be resected later in infancy to prevent infectious complications and possible (albeit rare) transformation into a malignancy.

Diaphragmatic Hernia

Infants with CDH may be quite ill at birth, often suffering from acute respiratory distress and hemodynamic instability. Because the intestines are located in the chest, an infant with CDH appears to have a scaphoid abdomen [see Figure 2b]. The entire stomach may be in the chest, and as a result, it may be difficult to pass a nasogastric tube into the stomach. A plain x-ray usually establishes the diagnosis.

CDH is an embryopathy that results from abnormal development of the diaphragm and the lungs. The defect in the diaphragm allows herniation of abdominal contents. On the affected side, as well

as on the contralateral side, the lung shows hypoplasia, which varies in severity. The small vessels (arterioles) are excessively muscularized and can easily constrict.²⁶ The main pathophysiologic consequence of CDH is not the presence of the hernia but, rather, severe pulmonary hypertension.²⁷ Accordingly, initial treatment is aimed at preventing or, if prevention is not possible, mitigating pulmonary hypertension and its sequelae.

Babies with CDH require immediate resuscitation, correction of acidosis, and, in most cases, endotracheal intubation. Placement of an orogastric tube can help decompress the GI tract. Once the baby is relatively stable, surgical intervention should be delayed to allow time for the pulmonary hypertension to decrease or disappear. There is evidence to suggest that gentle ventilation with permissive hypercapnia may decrease secondary barotrauma and long-term morbidity.²⁸ If the baby cannot be stabilized with conventional, jet, high-frequency, or oscillation ventilation and inhaled

nitrous oxide,²⁹ extracorporeal membrane oxygenation (ECMO) may be indicated; the hernia should be addressed after the ECMO run is completed.³⁰⁻³² During the procedure, the intestines are reduced into the abdominal cavity, and the diaphragmatic defect is repaired, either in the OR or in the NICU.³³ However, the operative procedure usually does not significantly alter the underlying pathophysiologic condition. In many cases, the newborn's condition improves at first after the operation but then begins to deteriorate. This response is seen less frequently with delayed surgical repair. If conventional treatment fails to control the pulmonary hypertension, ECMO may be instituted postoperatively. The precise impact of ECMO on overall outcome for CDH is still a matter of debate, though most pediatric surgeons agree that this technique has a role as a lifesaving measure if all other interventions fail.³⁴⁻³⁶

Lobar Emphysema

The term lobar emphysema refers to overexpansion of a segment of lung, which can compromise ventilation in a newborn if significant compression of a healthy lung or a mediastinal shift occurs [see *Figure 2c*.]³⁷ If the patient is exhibiting symptoms, urgent resection is usually required, though emergency bronchoscopic decompression has also been employed in this setting.³⁸ If the patient shows no significant symptoms, follow-up directed toward the affected areas of the lung is appropriate; occasionally, the condition resolves spontaneously.

Pulmonary Sequestration

The term pulmonary sequestration denotes a condition in which lung tissue is supplied with blood by the systemic circulation. Often, this condition is diagnosed prenatally by means of fetal ultrasonography.³⁹ Patients with pulmonary sequestration are often asymptomatic at birth, but if respiratory distress develops, urgent surgical intervention is required.⁴⁰ If the lesions remain asymptomatic, removal later in life is recommended so that they do not become a nidus for infection [see *Figure 2d*.]

INTESTINAL OBSTRUCTION

Not uncommonly, surgeons are asked to evaluate newborns for possible obstruction of the GI tract. These patients usually present with choking or vomiting. The list of possible causative conditions is fairly extensive, and most of these conditions must ultimately be managed by a pediatric surgeon. Nevertheless, it may be helpful in the initial stages to employ an algorithmic approach, which often serves to narrow the range of possible causes [see *Figure 3*.]⁴¹

The color of the emesis helps to establish the level of the obstruction. If the emesis is nonbilious, the obstruction is proximal to the ampulla of Vater. If an orogastric tube cannot be placed, the diagnosis is esophageal atresia, which can be confirmed by a chest x-ray that demonstrates a curled-up tube in the upper esophageal pouch. If the x-ray shows air below the diaphragm, the diagnosis is a distal tracheoesophageal fistula. If there is no mechanical obstruction of the esophagus, the diagnosis may simply be gastroesophageal reflux (GER). Other surgical causes of nonbilious emesis are preampullary duodenal atresia or web, neonatal pyloric stenosis (uncommon), and pyloric atresia (extremely rare).

Bilious emesis in a newborn is a potentially more serious problem. Except for medical ileus, the main causes are all related to underlying surgical problems. If the baby's abdomen is not distended, he or she may have a proximal obstruction. If an abdominal x-ray series shows a double-bubble sign without distal air, duodenal atresia is likely. If distal air is seen, the diagnosis is either

a duodenal web or malrotation with possible volvulus. The latter represents a much more worrisome situation and constitutes a true surgical emergency, which must be diagnosed quickly by means of an upper GI study. In a newborn with volvulus, prompt exploration is required to prevent extensive necrosis of the midgut.

If the abdomen is distended, the obstruction is more distal. Physical examination is warranted to rule out an incarcerated inguinal hernia. Inspection of the perineum is necessary to look for possible anorectal malformation. Stippled calcifications on an abdominal film are pathognomonic of meconium peritonitis, which usually necessitates surgical exploration. If the anus is patent, a contrast enema study helps establish a diagnosis. A microcolon represents an unused lower GI tract, which may be seen with jejunoleal atresia or meconium ileus. The latter condition is usually characterized by the presence of large amounts of meconium in the terminal ileum and can often be treated successfully by administering water-soluble contrast enemas. There are other meconium-related functional obstructions that occur without microcolon, such as meconium plug syndrome and small left colon syndrome, both of which usually respond to treatment with enemas. If the lower GI study shows a normal or slightly dilated colon with a narrowed or spastic-appearing rectosigmoid, the likely diagnosis is Hirschsprung disease, which can be confirmed by suction biopsy of the rectum.

ABDOMINAL WALL DEFECTS

The overall incidence of neonatal abdominal wall defects is approximately one in every 2,000 births; however, the incidence of gastroschisis appears to be rising slowly.⁴²⁻⁴⁴ Omphalocele represents an arrest in development, which may explain the increased frequency of chromosomal abnormalities and other structural birth defects in children with this condition.⁴⁵ The exact cause of gastroschisis is unclear, but it does not represent a normal stage of development; it appears to be more common with younger mothers, and environmental factors seem to play a role.^{43,46} The extra-abdominal intestine is prone to vascular compromise, which explains the higher incidence of bowel atresia in these patients.⁴⁷ Although debate continues, most authors believe that babies with gastroschisis can safely be delivered vaginally.⁴⁸⁻⁵²

Although omphalocele is associated with a higher overall mortality than gastroschisis is, the latter is more challenging to manage in the immediate postnatal period. The exposure of bowel results in greater insensible loss of fluid and heat. Kinking of the intestinal blood supply may lead to venous congestion and ischemia. It is crucial to place children with gastroschisis in a warm environment and to protect the bowel (which is easily accomplished with the help of a plastic bowel bag). Intravenous access should be established immediately, and resuscitation should be initiated, guided by the infant's heart rate. Transfer to a pediatric surgical center is mandatory. The surgical options are (1) primary repair of the defect, if the abdominal cavity accommodates the exposed organs easily, and (2) gradual reduction of the intestines by means of a silo technique.⁵³

Emergency surgical intervention is rarely required for management of omphalocele. Such defects may be either closed primarily or repaired with any of several staged approaches, depending on their size. Giant omphaloceles are best treated observantly, with the overlying membrane used as a temporary silo and definitive repair delayed until a reasonable intra-abdominal domain has developed.

CIRCUMCISION

Circumcision remains one of the most commonly performed procedures in male newborns. Approximately 1.2 million circum-

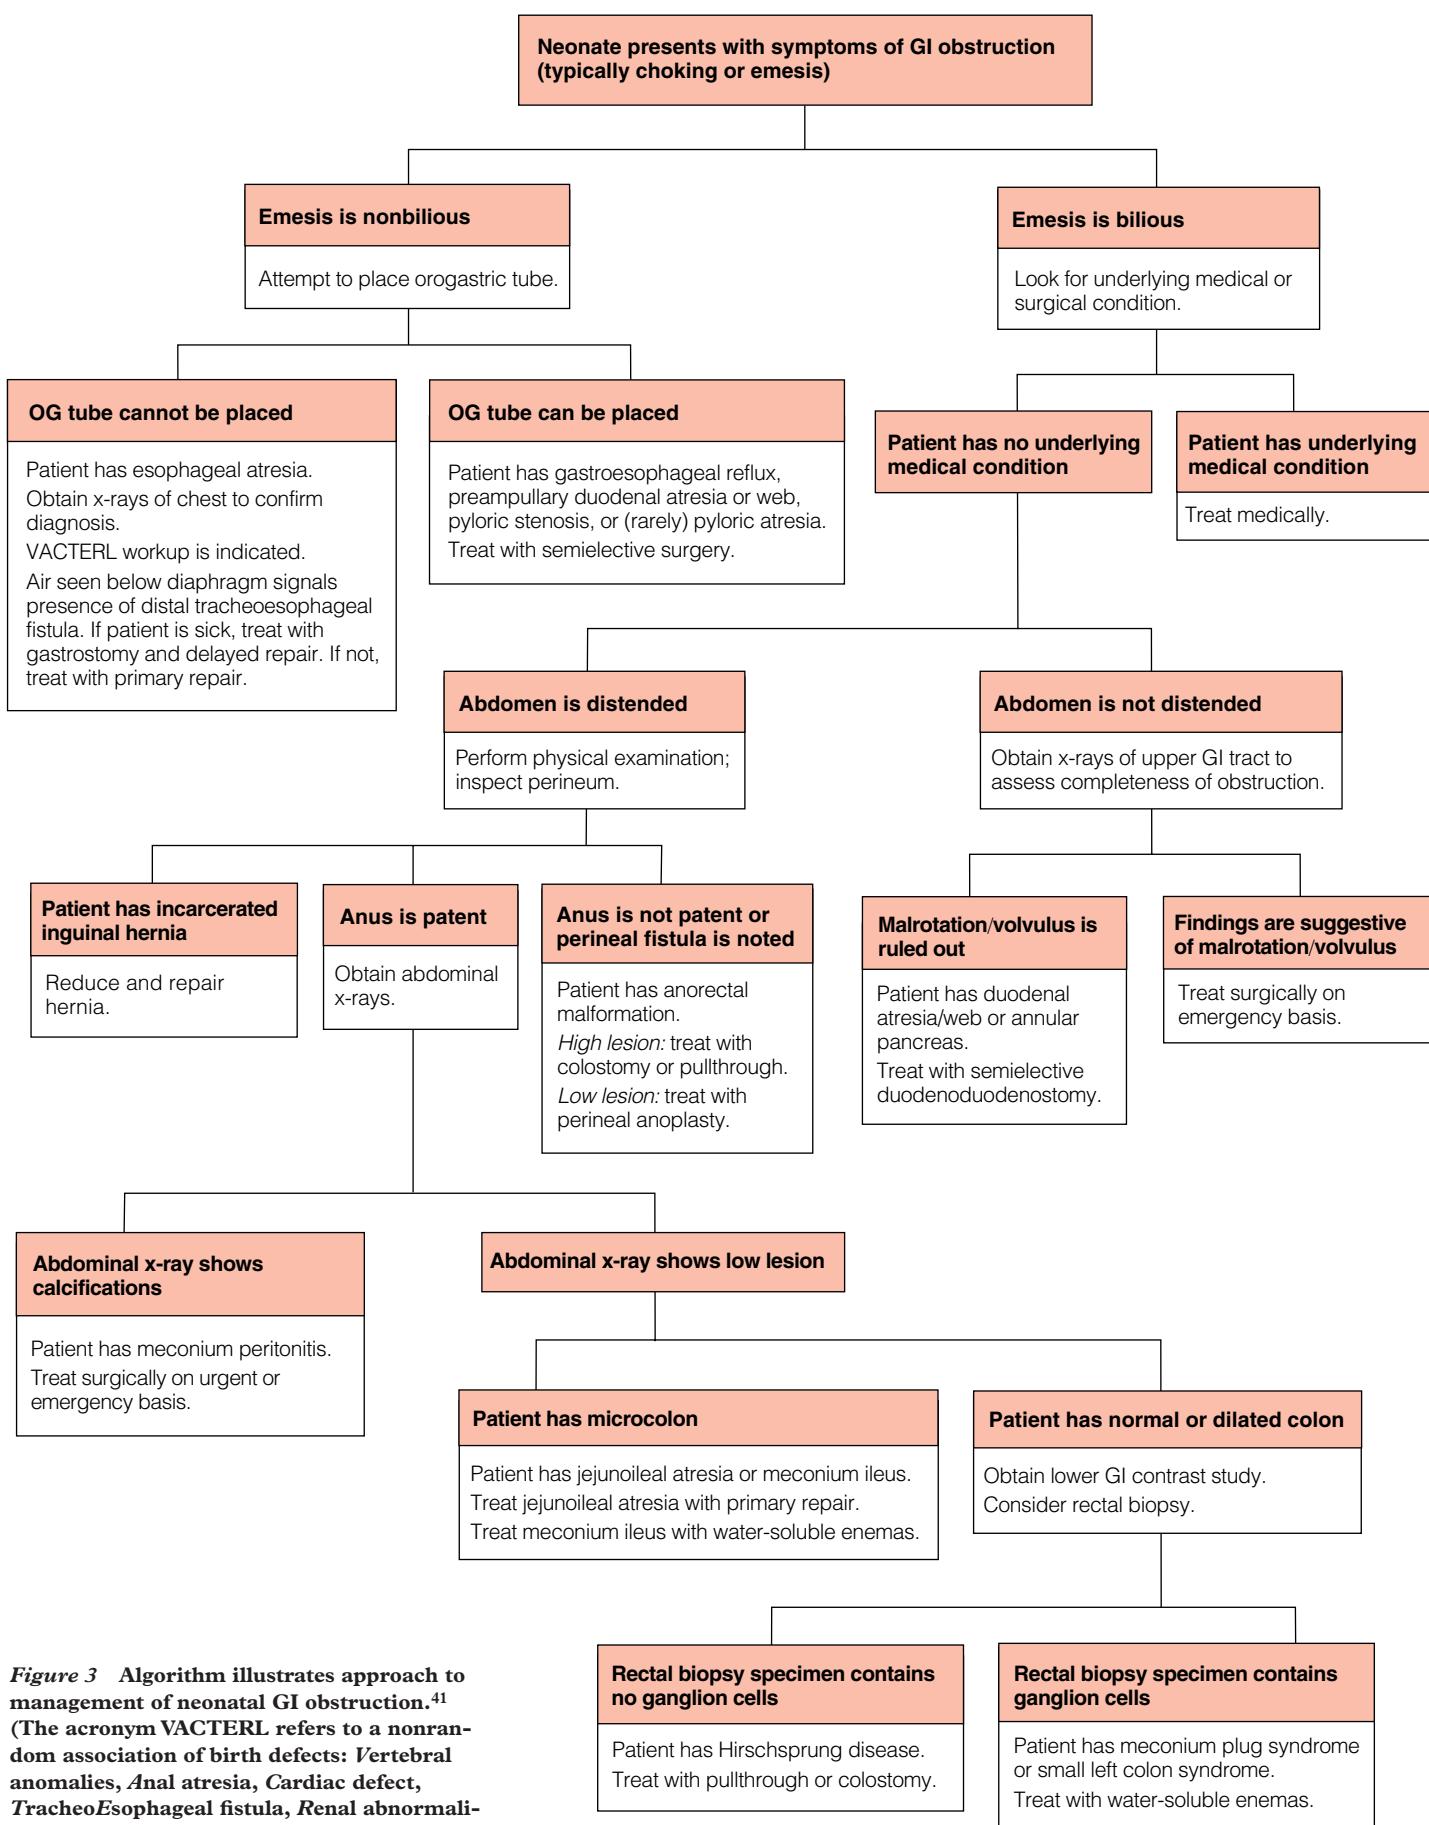

Figure 3 Algorithm illustrates approach to management of neonatal GI obstruction.⁴¹ (The acronym VACTERL refers to a nonrandom association of birth defects: *V*ertebral anomalies, *A*nal atresia, *C*ardiac defect, *T*racheo*E*sophageal fistula, *R*enal abnormalities, and *L*imb abnormalities.)

cisions are performed in the United States each year, at a total cost of at least \$150 million.⁵⁴ There continues to be a great deal of controversy regarding the medical benefits and risks of this procedure. Some authors argue that urinary tract infections, sexually transmitted diseases, and genital cancer occur less frequently in circumcised males; however, others dispute these findings.⁵⁵⁻⁵⁷ Circumcision can be performed either in an outpatient setting or in the nursery. The use of local anesthesia is recommended.⁵⁴ Complications are rare and usually minor, but mutilating injuries to the penis have been reported.^{58,59}

Common Surgical Problems in Infants and Children

PYLORIC STENOSIS

Hypertrophic pyloric stenosis affects between two and five of every 1,000 children; it is more common in white boys.⁶⁰ Patients typically present with progressive, projectile, nonbilious emesis 2 to 6 weeks after birth. They may show signs of severe dehydration with a hypochloremic, hypokalemic metabolic alkalosis (though the literature suggests that the incidence of this finding may be decreasing).⁶¹ Medical approaches to managing this problem have been described,^{62,63} but surgical correction after resuscitation is the treatment of choice. The classic open pyloromyotomy developed by Fredeet-Ramstedt is still widely performed, and advances in minimally invasive techniques have made it possible to perform laparoscopic pyloromyotomy with safety and efficacy.^{64,65}

GASTROESOPHAGEAL REFLUX

For appropriate treatment of GER in infants, it is important to distinguish between uncomplicated physiologic GER and symptomatic GER.⁶⁶ Symptoms that necessitate treatment include poor weight gain, esophagitis, apnea, apparent life-threatening events, and pulmonary complications. Upper GI contrast studies and 24-hour continuous pH monitoring are the gold standards for assessment. Endoscopy and esophageal biopsy may be useful for diagnosis and the evaluation of treatment. If GER does not resolve with simple feeding and positioning adjustments, acid suppressants, prokinetic therapy, or surface agents may prove effective. If GER is associated with anatomic abnormalities (e.g., hiatal hernia), apparent life-threatening events, or symptoms that persist despite optimal medical therapy, surgical intervention is usually indicated. In infants and younger children who require a feeding gastrostomy, a protective fundoplication is usually necessary if reflux is demonstrated on the upper GI study.

In the United States, the procedure most commonly performed to treat GER is a 360° Nissen fundoplication,⁶⁷ though partial posterior (Toupet) fundoplication appears to yield comparable results.^{68,69} Both procedures can also be performed laparoscopically. Initial success rates with surgical treatment are high, but long-term complications (especially recurrent reflux) are frequent, resulting in redo rates ranging from 7% to 26%.⁷⁰

NECK AND SOFT TISSUE MASSES

A neck mass [see 2:3 Neck Mass] is a common reason for a child to be seen by a surgeon. Even though the vast majority of these masses are benign, they often cause significant worries for parents. A detailed history and a thorough physical examination are crucial for narrowing down the otherwise extensive differential diagnosis [see Table 4].

The masses that are most commonly encountered in infants and children are enlarged lymph nodes caused by reactive postinfectious hyperplasia. Such masses feel soft, are often slightly tender on

palpation, are mobile, and tend to shrink over time. A higher degree of concern is appropriate with neck masses that are located suprACLAVICULARLY, grow rapidly, develop at multiple sites, are fixed to surrounding tissues, or feel hard. Swift diagnosis of the underlying process is crucial in this situation. Fine-needle aspiration (FNA) biopsy may render an initial diagnosis,^{71,72} but most treatment protocols require more tissue, which can be obtained through open surgical biopsy. Before the procedure, a chest x-ray should be obtained to determine whether the mass involves the mediastinum.

A mass in the anterior midline may be a remnant of the thyroglossal duct. Such masses should be excised at diagnosis to prevent any subsequent infectious complications. To minimize the risk of recurrence, the procedure includes the removal of the midportion of the hyoid bone.⁷³ A lateral neck mass, with or without a sinus tract to the skin, may be a remnant of the fetal branchial apparatus. Such masses should also be completely excised to reduce the risk of complications.

ABDOMINAL WALL HERNIA

Inguinal and umbilical hernia repairs are among the most commonly performed procedures in pediatric surgery. Umbilical hernias are commonly diagnosed at birth but tend to close spontaneously. The complication rate is very low, and thus, most pediatric surgeons postpone surgical repair until the patient is 2 to 4 years old. Inguinal hernias, on the other hand, pose a substantial risk of incarceration, especially during infancy, and should therefore be repaired as soon as they are diagnosed. High ligation of the sac is the treatment of choice. This operation is usually straightforward, but it can be challenging at times, particularly in premature infants with large hernias. Complications are rare; they tend to occur more frequently if the infant is premature or if the procedure was done on an emergency basis.⁷⁴ To minimize the risk of injury to the spermatic cord, a “no touch” technique should be employed. Whether the contralateral side should be explored remains controversial; some surgeons now use laparoscopy to assess the processus vaginalis of the opposite side.⁷⁵

UNDESCENDED TESTICLES

Approximately 4% of male neonates have an undescended testis at birth, but only about 1% still have this condition at the age of

Table 4 Differential Diagnosis of Pediatric Neck Mass

Location	Conditions to Be Considered
Anterior midline	Epidermoid inclusion (sebaceous) cyst Thyroglossal duct cyst Benign reactive hyperplasia of lymph node Thyroid nodule Ectopic thymus Thymic cyst Ectopic thyroid tissue Lipoma Dermoid
Lateral	Branchial cleft remnant Lymphangioma/hemangioma Benign reactive hyperplasia of lymph node Neoplasms (lymphoma, rhabdomyosarcoma, neuroblastoma) Lipoma Torticollis

1 year.⁷⁶ Accordingly, most pediatric surgeons recommend that neonates with an undescended testis be observed during the first year of life. If the testicle has not descended by the end of this period, inguinal orchiopexy may be performed; the success rate with this option is higher than 80%.⁷⁷ It is not unusual to find a structurally abnormal testicle during exploration. Potential complications include testicular atrophy and recurrent ascent of the gonad. Hormonal treatment (with human chorionic gonadotropin or luteinizing hormone-releasing hormone) is widely employed in Europe but has a success rate of only about 50%. Laparoscopy is a useful and cost-effective option for the evaluation of nonpalpable testes.^{78,79}

ABDOMINAL PAIN

Abdominal pain is a common finding in children and may arise from any of a wide variety of causes. Among surgical diseases, acute appendicitis is the most common cause of abdominal pain. In addition, however, the differential diagnosis must include perforated duodenal ulcer, Meckel's diverticulum, ulcerative colitis, Crohn disease, ruptured ovarian cyst, pelvic inflammatory disease, and, in younger children, intussusception. It is important to remember that medical problems (e.g., constipation, gastroenteritis, pancreatitis, and pneumonia) can also give rise to substantial abdominal discomfort.

Appendicitis

The diagnosis of appendicitis is based on the presence of localizing physical findings in the right lower quadrant of the abdomen. Even if the history and laboratory data are not typical, the presence of such findings should allow the surgeon to make the diagnosis and proceed with appropriate management.

If perforation of the appendix is suspected preoperatively, administration of broad-spectrum antibiotics should be started, and crystalloid should be infused. Intraoperative management of acutely perforated appendicitis varies widely among pediatric surgeons in the United States.⁸⁰ The evidence published to date on the benefits of intraoperative drain placement, peritoneal cultures, and laparoscopic techniques remains controversial.^{74,81-85}

In most cases of perforated appendicitis, the wound can be closed primarily.⁸⁶ Although there is some debate regarding the utility of imaging studies in patients with the classic findings of acute appendicitis, it appears that CT can be quite helpful in patients with delayed presentations or atypical symptoms.⁸⁷⁻⁸⁹ If perforated appendicitis with an abscess is identified, a safe and cost-effective treatment approach is to give antibiotics (first I.V., then oral), drain the collection percutaneously, and perform an interval appendectomy 6 weeks later.⁹⁰⁻⁹⁴

Crohn Disease

Occasionally, a teenager who exhibits the classic signs and symptoms of appendicitis turns out to have Crohn disease of the terminal ileum. This condition will be obvious at operation, when the mesenteric fat is seen to be creeping up along the sides of the inflamed ileum. If the base of the appendix is free of disease, appendectomy should be performed at the time of exploration.⁹⁵ When the child has fully recovered from the operation, a definitive workup, including a small bowel series and a colonoscopy with biopsy, should be performed to ascertain the extent of the Crohn disease. If an enterocutaneous fistula develops, TPN will be required for a prolonged period. If an intestinal stricture develops (typically, in the terminal ileum), resection may be required. Associated perianal Crohn disease can be very challenging to

treat. Medical therapy and surgical therapy should be carried out conjointly. Conservative surgical options (e.g., local drainage, fistulotomy, and setons) are preferred; if sepsis does not resolve or if severe incontinence persists, a stoma may be required.⁹⁶

Intussusception

Idiopathic intussusception usually develops between the ages of 6 months and 2 years. The invagination of small bowel into the cecum results in severe, crampy, intermittent abdominal pain, often associated with obstructive symptoms and bloody stools. Marked lethargy is also a frequent symptom. Air enemas and ultrasound-guided hydrostatic reduction have both been employed to treat this condition, with great success.⁹⁷⁻⁹⁹ Surgical exploration should be reserved for patients in whom reduction is unsuccessful and patients in whom there is reason to suspect an anatomic lead point that is causing the intussusception.

Meckel's Diverticulum and Lower GI Hemorrhage

Meckel's diverticulum represents a remnant of the omphalo-mesenteric duct. It occurs in approximately 2% of the pediatric population. If symptomatic, it can be associated with acute and substantial lower GI bleeding, obstruction, or diverticulitis.¹⁰⁰ The differential diagnosis of lower GI bleeding in children also includes GI infections, colonic polyps, duplication cysts, and inflammatory bowel disease. Meckel diverticulitis presents with symptoms very similar to those of acute appendicitis and should always be ruled out if the appendix appears normal on exploration. Management of an asymptomatic diverticulum discovered during an abdominal operation remains controversial, even though resection has been shown to carry a low risk of complications.^{101,102}

VENOUS ACCESS

To obtain venous access in an infant, a venous cutdown is performed, and a pediatric silicone (Broviac) catheter is passed through the common facial, external jugular, or internal jugular vein to the superior vena cava. This procedure is carried out in an OR or, if necessary, in the NICU. Adequate exposure must be obtained, proper instruments and fluoroscopy devices should be available, and strict aseptic conditions must be maintained. The venous catheter is tunneled from the point of entry into the vein to a skin exit site 5 to 10 cm away, with the aim of minimizing the likelihood of bloodstream contamination from dressing changes at the skin exit site. The catheter is brought out on the chest wall, where it is easily accessible and unlikely to be disrupted by an active patient. When no vein sites are available in the neck, the catheter may be advanced into the central venous circulation via a cutdown on the greater saphenous vein and tunneled to an exit site on the abdominal wall or the leg.¹⁰³ In older children and adults, percutaneous puncture of the subclavian vein is often performed in place of venous cutdown; this technique can also be used in infants.^{104,105} Regardless of the technique employed, manipulation of the catheters must be done with close attention to asepsis and antisepsis to minimize the risk of bacterial and fungal infection.

Pediatric Trauma

Whereas accidents are the third most common cause of death in the United States population as a whole, they are the single most common cause of death in children between the ages of 1 and 15 years.¹⁰⁶ Every year, about 20 million injuries occur in children, resulting in approximately 15,000 deaths and 100,000 cases of permanent disability. The first approach to be considered in

managing pediatric trauma is clearly prevention. In fact, preventive efforts have been gaining momentum, thanks in part to support from federal funds and from dedicated individual advocates. These efforts have included greater emphasis on the use of pediatric restraint devices in automobiles, improvements in the design of motor vehicles, the wearing of helmets by bicycle and motorcycle riders, improvements in the design of space heaters, the use of fire-retardant material for children's clothes (as dictated by the Flammable Fabrics Act), proper packing and labeling of poisons and medications, and the installation of appropriate fencing around swimming pools.

GENERAL PRINCIPLES

Although the general principles of trauma care are essentially the same for children as for adults, there are several significant differences that must be taken into account in the care of pediatric accident victims.¹⁰⁷ For example, children do not react to trauma in the same way as adults do. They often have difficulty in expressing pain and in articulating their complaints. They are often extremely frightened after an accident, and this fear may cause them to give misleading signals (e.g., by exhibiting signs of an acute abdomen even though no intra-abdominal injury has occurred). Children who experience stress often undergo developmental regression, typically accompanied by severe depression. All these psychological factors must be considered in the treatment of a pediatric accident victim.

Another key difference between children and adults is that children are still growing. Postoperative metabolic management after any form of stress, whether from a surgical procedure, from trauma, or from some other event, must take this difference into account. Children can compensate for hypovolemia effectively and keep their vital signs in the normal range, even in the presence of shock. However, a small blood loss that would be insignificant in an adult can result in marked hemodynamic changes in a small child. Moreover, water and heat loss can be far more extensive in small children than in older children and adults because smaller children have a greater surface area in relation to their weight and have a relative lack of insulating subcutaneous fat. Hypothermia aggravates acidosis and makes hemodynamic resuscitation much more difficult. Gastric dilatation, which can result in vomiting and pulmonary aspiration, is very common in young children after all forms of trauma. Finally, the nutritional requirements of injured children are greater than those of injured adults because children, as growing organisms, naturally have a high metabolic rate. Consequently, TPN often must be started earlier in the treatment of a child than it would be in the treatment of an adult in a comparable condition.

Not only are there significant physiologic and psychological differences between children and adults after trauma but there also are differences in accident patterns. Most childhood injuries result from blunt trauma. Head trauma is far more common in children than in adults: in fact, it accounts for most of the morbidity and mortality in the pediatric population. After motor vehicle accidents, which are the major cause of trauma in both children and adults, the next most frequent causes of trauma in children are events that are less important causes in adults: falls, bicycle accidents, drowning, poisoning, and burns from fires. Child abuse [see *Child Abuse, below*] is a unique and important cause of trauma in children.

Pediatric accident victims must be treated in centers that have experience in the care of traumatized children.^{108,109} Such centers must have an emergency department with a section that is specifically set aside for the care of children and is staffed by nurses and physicians who are familiar with the management of pediatric trauma. They must have a hospital with a pediatric ICU that is also

Table 5 Pediatric Trauma Score

Variable	Coded Value
Size	
> 20 kg	+2
10–20 kg	+1
< 10 kg	-1
Airway status	
Normal	+2
Maintainable	+1
Not maintainable	-1
Systolic BP	
> 90 mm Hg	+2
50–90 mm Hg	+1
< 50 mm Hg	-1
In the absence of proper size BP cuff, assess BP by assigning these values:	
Pulse palpable at wrist	+2
Pulse palpable at groin	+1
Pulse not palpable	-1
CNS status	
Awake	+2
Partially conscious or unconscious	+1
Comatosed or decerebrate	-1
Open wounds	
None	+2
Minor	+1
Major	-1
Skeletal injury	
None	+2
Closed fracture	+1
Open/multiple fractures	-1
Range of possible scores	-6 to +12
Scoring triage criterion for direct transport of patient to trauma center	< 9

staffed by experienced medical and paramedical personnel. Finally, they must have a transportation system that is capable of rapidly transporting critically ill pediatric trauma victims both by air and by land or water. The Pediatric Trauma Score [see Table 5] has been successfully used not only as a tool for grading severity of injury but also as a means of comparing trauma care across institutions.

AIRWAY MANAGEMENT, PAIN RELIEF, AND SEDATION

Establishing and maintaining a secure airway is of the utmost importance in treating any injured child. Most pediatric trauma programs have mechanisms in place that delegate this responsibility to the attending emergency physician or anesthesiologist so that the surgical team can continue assessing the patient. The airway team can also provide conscious sedation or elective intubation if a painful procedure (e.g., reduction of fractures or suturing of lacerations) proves necessary.

MANAGEMENT OF HEAD INJURY

Closed head injuries (CHIs) are the most common cause of death in children and account for close to 7,000 fatalities in the United States each year.¹¹⁰ Any child who had a witnessed loss of consciousness, is mentally altered, or has an abnormal Glasgow Coma Scale (GCS) score should undergo urgent CT scanning of the head. If the GCS score is lower than 8, intubation is necessary

to protect the airway. The main focus of therapy for severe CHI is on minimizing secondary insult to the brain by optimizing oxygen delivery. Management involves close monitoring of cerebral perfusion pressure and judicious use of sedatives, anticonvulsants, pressors, intraventricular drainage, or even surgical decompression to optimize cerebral perfusion. Evidence-based practice guidelines for the management of pediatric CHI patients are now available.¹¹¹

Because children with even minor structural injuries to the brain are at risk for hyponatremia, close monitoring of sodium levels is required.^{112,113} Patients who have postconcussive symptoms (e.g., vomiting, seizures, or headache) should be admitted, even if the head CT reveals no structural injury. It is our practice to follow these patients for 3 weeks after the injury to determine whether postconcussive symptoms are persisting. If these symptoms have not resolved, patients undergo a more detailed cognitive evaluation.

CERVICAL SPINE CLEARANCE

Cervical spine injuries in children are very rare but can have catastrophic consequences if missed. As with adult trauma patients, it is crucial to follow established protocols for systematically clearing the cervical spine. Early immobilization, clinical examination, plain x-rays, and advanced imaging studies can all be useful. Because of the anatomic differences between children and adults, certain modifications to adult protocols are necessary.^{114,115}

BLUNT SOLID-ORGAN INJURY

Abdominal trauma in children is usually blunt. Penetrating injuries occur in only about 20% of children who sustain trauma and are managed in essentially the same way as they are in adults [see *Section 7 Trauma and Thermal Injury*].

Children who sustain major trauma often have intra-abdominal injuries. Because gastric dilatation and reflex ileus are far more common in children than in adults after a major injury, the initial clinical evaluation of the child's abdomen may be highly misleading. Early insertion of a nasogastric tube decompresses the stomach and allows more accurate physical examination of the abdomen; in addition, it reduces the risk of aspiration pneumonitis. Once the child is stable with respect to hemodynamic and respi-

Figure 4 Shown is an abdominal CT scan from a patient who sustained multiple blunt injuries after being hit by an object through the windshield while driving. A deep central liver laceration is visible (black arrow), as is soft tissue emphysema (white arrow). The hepatic injury did not necessitate operative intervention.

Figure 5 Shown is an abdominal CT scan from a child who sustained blunt trauma. Several large cracks in the spleen are apparent (white arrow). A significant amount of intraperitoneal blood can be seen over the liver (black arrow).

Figure 6 Blunt abdominal trauma can result in injury to multiple solid organs. Abdominal CT scan shows partial devascularization of the left kidney (black arrow) and multiple splenic contusions (white arrows).

ratory status, the abdomen should be carefully examined for external evidence of trauma (e.g., ecchymoses, abrasions, and tire-tracks). The abdomen should then be carefully and gently palpated, with the awareness that a frightened child often tightens his or her rectus muscles in a way that gives a false impression of intra-abdominal injury. Serial abdominal examinations are essential.

CT has become the gold standard for evaluation of blunt abdominal injury in stable trauma patients.¹¹⁶ This modality is extremely accurate in evaluating solid-organ injuries and determining the amount of blood in the peritoneal cavity [see Figures 4 through 6]. It is also useful for detecting pneumoperitoneum resulting from intestinal perforation.¹¹⁷ To minimize exposure to radiation, the scan should be performed at the lowest radiation level feasible, and repeat scans should be avoided if possible.¹¹⁸ The usefulness of the focused assessment for the sonographic examination of the trauma patient (FAST) in children remains controversial at present.¹¹⁹⁻¹²¹

Because hollow viscus injury is uncommon in children who sustain blunt abdominal trauma, nonoperative treatment is the

accepted method of management for most hepatic and splenic injuries. Associated fractures of the lower ribs are rare in children with injuries to the liver or the spleen, though they are fairly common in adults with such injuries.¹²²

The initial plain film of the abdomen often demonstrates medial and inferior displacement of the gastric bubble caused by accumulation of blood under the left diaphragm. A CT scan will then accurately confirm the diagnosis of a splenic injury. A major reason why nonoperative treatment is recommended for pediatric splenic injuries is that the risk of overwhelming postsplenectomy infection (OPSI) is far higher in children than in adults; the younger the child, the higher the risk of OPSI. OPSI develops in 3.3% of pediatric patients who have undergone splenectomy and carries a mortality of 50%.¹²³

Once a hepatic or splenic injury has been diagnosed, management should follow the established guidelines for treatment of blunt solid-organ injuries in children.¹²⁴⁻¹²⁶

Ongoing hemodynamic instability despite aggressive resuscitation is the main indication for operative intervention; fortunately, it is a rare occurrence. The likelihood of successful nonoperative management of hepatic and splenic injuries continues to be higher in designated pediatric trauma centers.¹²⁷

The finding of intraperitoneal fluid on a CT scan without evidence of solid-organ injury remains a challenging clinical problem. Management of patients with this finding should be individualized; treatment options include observation with serial examinations, laparoscopy, and surgical exploration.^{117,128}

Among the less common injuries to intra-abdominal organs that occur in children are perforation of the stomach when an accident occurs shortly after eating (while the stomach is distended), perforation of the small intestine and large intestine at a point of fixation (e.g., the ligament of Treitz or the cecum), rupture of the left diaphragm, and damage to the duodenum or pancreas. The likelihood of visceral injury increases dramatically if bruising from a lap belt or a chance fracture is present.¹²⁹⁻¹³¹ Retroperitoneal perforation is suggested by the presence of air around the right kidney on a plain abdominal x-ray. Traumatic pancreatic injury is suggested by an elevation in serum amylase and lipase levels and by the presence of pancreatic edema on ultrasonography or CT. Obviously, perforations of the stomach, the intestine, or the duodenum call for exploratory laparotomy; in most cases, simple suture repair of the laceration is sufficient. Injury to the pancreas, on the other hand, can usually be managed nonoperatively with nasogastric decompression and I.V. fluids. Fracture of the pancreatic duct is quite rare in children and is usually secondary to compression of the pancreas against the vertebral column. In the past, this injury was usually treated with exploratory laparotomy and distal pancreatectomy, but current experience indicates that it can often be successfully treated by nonoperative means, though there is a risk that pseudocysts will subsequently develop.¹³²⁻¹³⁴ Intramural duodenal hematoma is relatively uncommon in children

and is usually well managed by providing nasogastric decompression for about 10 days and instituting TPN.¹³⁵

In any child who has sustained abdominal trauma, the diagnosis of a pelvic fracture should be seriously considered. Pelvic fractures can result in significant bleeding into the retroperitoneum, as well as injuries to the bladder and the urethra. The diagnosis can be confirmed by x-ray studies of the pelvis. In most cases, the fracture can be treated with bed rest, immobilization, and the replacement of lost blood.¹³⁶

Children with blunt multisystem trauma seldom die if they are alive when brought to an emergency department, unless they have sustained head injuries. Care of these patients requires aggressive, coordinated efforts on the part of a multispecialty team that is under the direction of a pediatric surgeon. The establishment of specifically designated pediatric trauma centers around the country was one of the most important developments in the care of children to occur in the 1980s; since then, multiple studies have demonstrated that this measure has substantially improved outcomes for injured children.¹³⁷

CHILD ABUSE

One of the unique varieties of pediatric trauma is child abuse, or the battered-child syndrome. It is a sad fact that intentional trauma is the most common cause of fatal injury in children younger than 1 year. The exact incidence of child abuse is not known, but it is believed that in the United States, about 160,000 children are seriously injured by deliberate abuse each year.¹³⁸ Risk factors include a low socioeconomic background, a single-parent family, low birth weight, and multiple siblings.^{139,140} The victims tend to be younger than 2 years, except when sexual abuse is involved, in which case the average age is about 10 years. The abuse can take many different forms, such as physical or mental injury, nutritional or hygienic neglect, delayed or inadequate treatment of disease, sexual abuse, and verbal abuse. Salient clues to the diagnosis include an unreasonable delay in seeking medical help for the child, inconsistencies between the trauma observed and the injury mechanism described, poor hygiene, and marked depression or lack of emotion in the child. The injuries most commonly seen are soft tissue injuries, burns, fractures, and head trauma. X-ray evidence of healing fractures of different ages (a finding described as long ago as 1946) and of rib fractures is highly correlated with abuse.^{122,141} Visceral injuries (e.g., hepatic fractures, splenic fractures, duodenal hematomas, and pancreatic fractures) are also associated with abuse, though less frequently.

Once a physician suspects child abuse, he or she is both legally and ethically obligated to report the situation to the appropriate hospital team and to the social services agency of the local jurisdiction. The typical hospital team usually includes a physician, a social worker, and a nurse. Prompt and full reporting often improves the chances that the parents will receive positive counseling, which may well reduce their subsequent abuse of the child.

3 THE PREGNANT SURGICAL PATIENT

David C. Brooks, M.D., and Cherie P. Parungo, M.D.

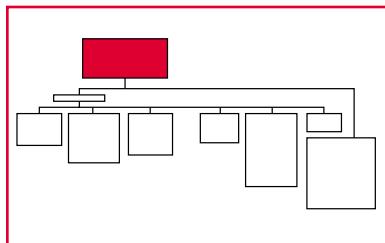

Approach to Abdominal Pain in Pregnant Patients

Since the early 1990s, the number of live births in the United States has ranged from 3.88 to 4.12 million per year.¹ Complications related to nonobstetric surgery are relatively uncommon, occurring in only 1% to 2% of pregnancies.² Management of the pregnant patient differs from that of other patients in several ways. First, pregnancy induces a variety of mechanical, hormonal, and chemical alterations that may confuse and mislead even the most experienced surgeon [see Discussion, Physiologic Changes in Pregnant Patients, below]. Second, a surgeon's natural inclination, when faced with a pregnant patient experiencing abdominal pain, is to temporize. This tendency, which generally arises from the misconception that surgical intervention may injure the fetus, is responsible for delays in diagnosis and ultimately for the unfavorable outcomes often associated with acute abdominal pathology in pregnant patients. Third, pregnant patients require a multidisciplinary approach to care that involves the surgeon, the obstetrician, the radiologist, and the anesthesiologist. Finally, and most important, a surgeon treating a pregnant woman is actually caring for two patients and has the same responsibility to both.

In what follows, we first review urgent surgical problems in the pregnant patient, then discuss the physiologic changes of pregnancy and how these changes help shape general surgical principles in this population. Finally, we address certain nonurgent surgical problems associated with pregnancy.

Initial Management

Initial management of any pregnant patient presenting with an acute abdomen or an acute surgical problem should include a thorough history and physical examination [see 5:1 Acute Abdominal Pain],

with particular consideration given to historical aspects of the pregnancy, the expected date of delivery, and the presence of any pregnancy-related complications. Whenever possible, an obstetrician should be consulted and included in the decision-making process. Initial maneuvers should include administration of supplemental oxygen, placement of an I.V. line with the capacity to deliver ample amounts of fluid or blood, insertion of a nasogastric tube if significant vomiting is present, and performance of routine laboratory evaluations, such as a complete blood count, assessment of serum electrolyte levels, and urinalysis. If the pregnancy has passed the 26th week, a fetal monitor should be employed. Radiographic investigations should be kept to a minimum, although abdominal and pelvic ultrasonography may be especially useful not only

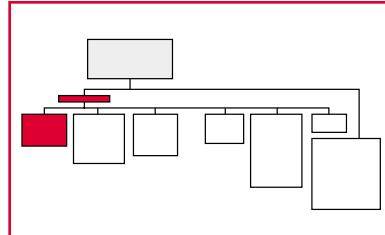

in assessing the maternal pathology but also in evaluating the fetus.

Acute abdominal surgical problems must be dealt with immediately. Management of less acute problems, however, must take into account the stage of the pregnancy. The risk of spontaneous abortion at operation is highest during the first trimester. The optimal time for elective surgery is during the second trimester because the uterus is smaller at that time than it is in the third trimester and because the fetus can be maintained in a relatively stable condition during the administration of general anesthesia.

Urgent Surgical Problems

TRAUMA

Trauma is estimated to occur in approximately 6% to 7% of gestations.³ It remains the leading cause of maternal death, accounting for 46.3% of deaths during pregnancy.⁴ Homicide is the most common cause of traumatic maternal death, followed by motor vehicle accidents, accidental injury, and suicide.⁵ Motor vehicle accidents account for 55% to 66% of all trauma during pregnancy, falls account for 22%, and domestic abuse and assaults account for 21%. The more severe the injury to the mother, the greater the risk of injury to the fetus. When the mother survives, fetal death is most commonly related to abruptio placentae. Major trauma causes placental abruption in 40% to 66% of cases; minor trauma causes placental abruption in 5% of cases.⁶ Fetal death may also result from complications of premature delivery or from direct penetrating injury to the fetus.

Blunt Injury

In the mother, blunt trauma (as in motor vehicle accidents) may cause multiple life-threatening injuries, including head trauma, intra-abdominal hemorrhage, pelvic fracture, and uteroplacental vascular injury. Pelvic fractures are a particular concern: because of the extensive vascular supply in this area, there is a significant risk of substantial hidden blood loss. Uterine blood flow at term is approximately 500 ml/min; thus, pregnant women are at significant risk for massive hemorrhage if the uterus is injured. Uterine expansion displaces the bladder into the abdomen, thereby increasing the risk of traumatic bladder injury. The upper urinary tract is generally spared from injury, however, because the gravid uterus shields the retroperitoneum from direct injury. It should be kept in mind that mild hydronephrosis is physiologic in pregnancy. Hepatic, splenic, and

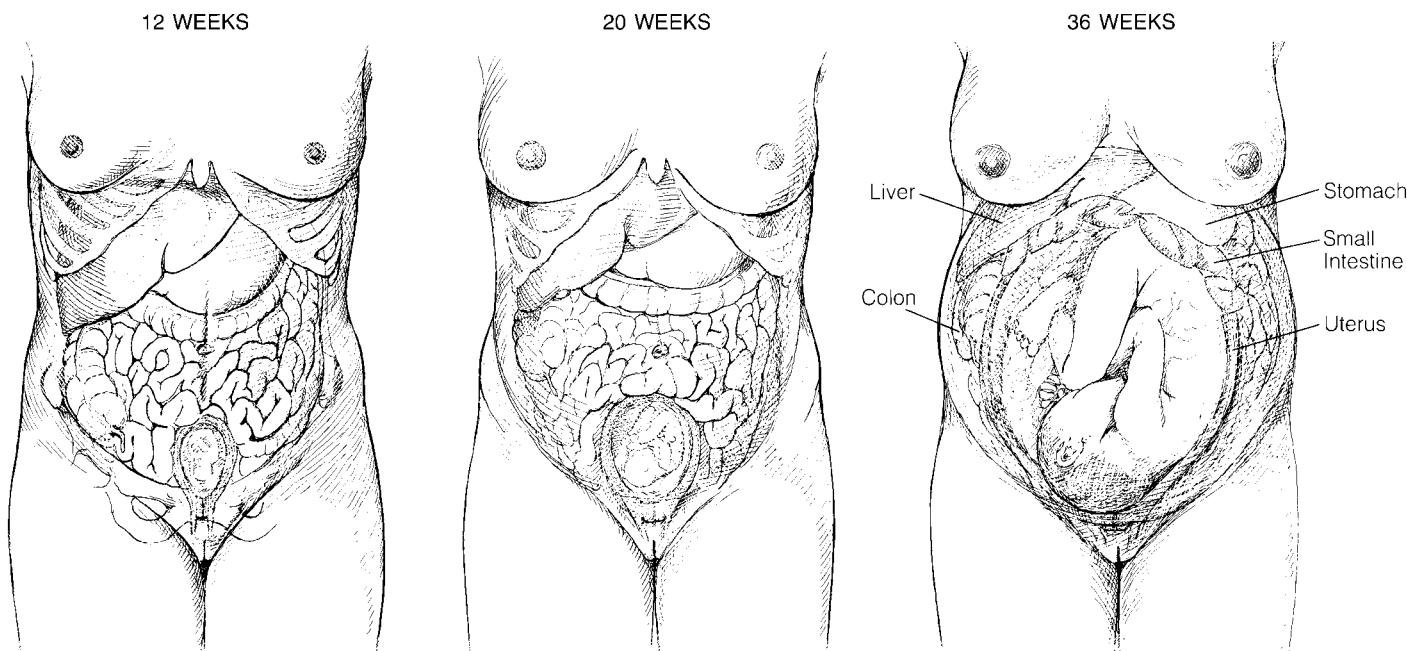

Figure 1 Enlargement of the uterus to accommodate the developing fetus shifts intra-abdominal contents superiorly and compresses retroperitoneal structures. These effects are particularly important during the second and third trimesters.

uterine injuries are common in high-speed motor vehicle accidents, but injuries to the GI tract, surprisingly, appear to be uncommon, largely because of the protective effects of the gravid uterus.⁷ Direct injury to the fetus as a result of blunt trauma is unusual because of the protection afforded by the maternal abdominal wall and the uterus. Blunt trauma may result in fetal skull fractures, fetal intracranial hemorrhage, or abruptio placentae; nevertheless, fetal demise is rare in this setting and usually is secondary to maternal demise.

Many women refrain from using seat belts during pregnancy because of discomfort or out of concern that the seat belt might injure the fetus; however, this practice has no effect on fetal death rates in automobile accidents. When unbelted women are ejected from an automobile, maternal mortality is 33% and fetal mortality is 47%.⁸ Three-point restraint is the safest choice for pregnant women in motor vehicles.

Penetrating Injury

Penetrating injury is usually more damaging to the fetus than to the mother. Mortality is actually lower for pregnant women with penetrating injuries than for nonpregnant women with similar injuries, presumably because of the shielding effect of the uterus and the fetus.⁹

Penetrating trauma, however, often results in direct fetal injury. Fetal mortality in this setting ranges from 40% to 70%, whereas maternal mortality ranges from 5% to 10%.¹⁰ In the first trimester, trauma generally poses little direct threat to fetal viability because the uterus is protected within the pelvis. In the second and third trimesters, however, when the uterus is located within the abdomen, penetrating trauma may result in direct fetal injury or rupture of the membranes. With penetrating abdominal trauma, the prognosis depends on which and how many organs are injured.

General principles of trauma management are applied when the need for laparotomy is under consideration. Visceral injury occurs 95% of the time if the peritoneum has been penetrat-

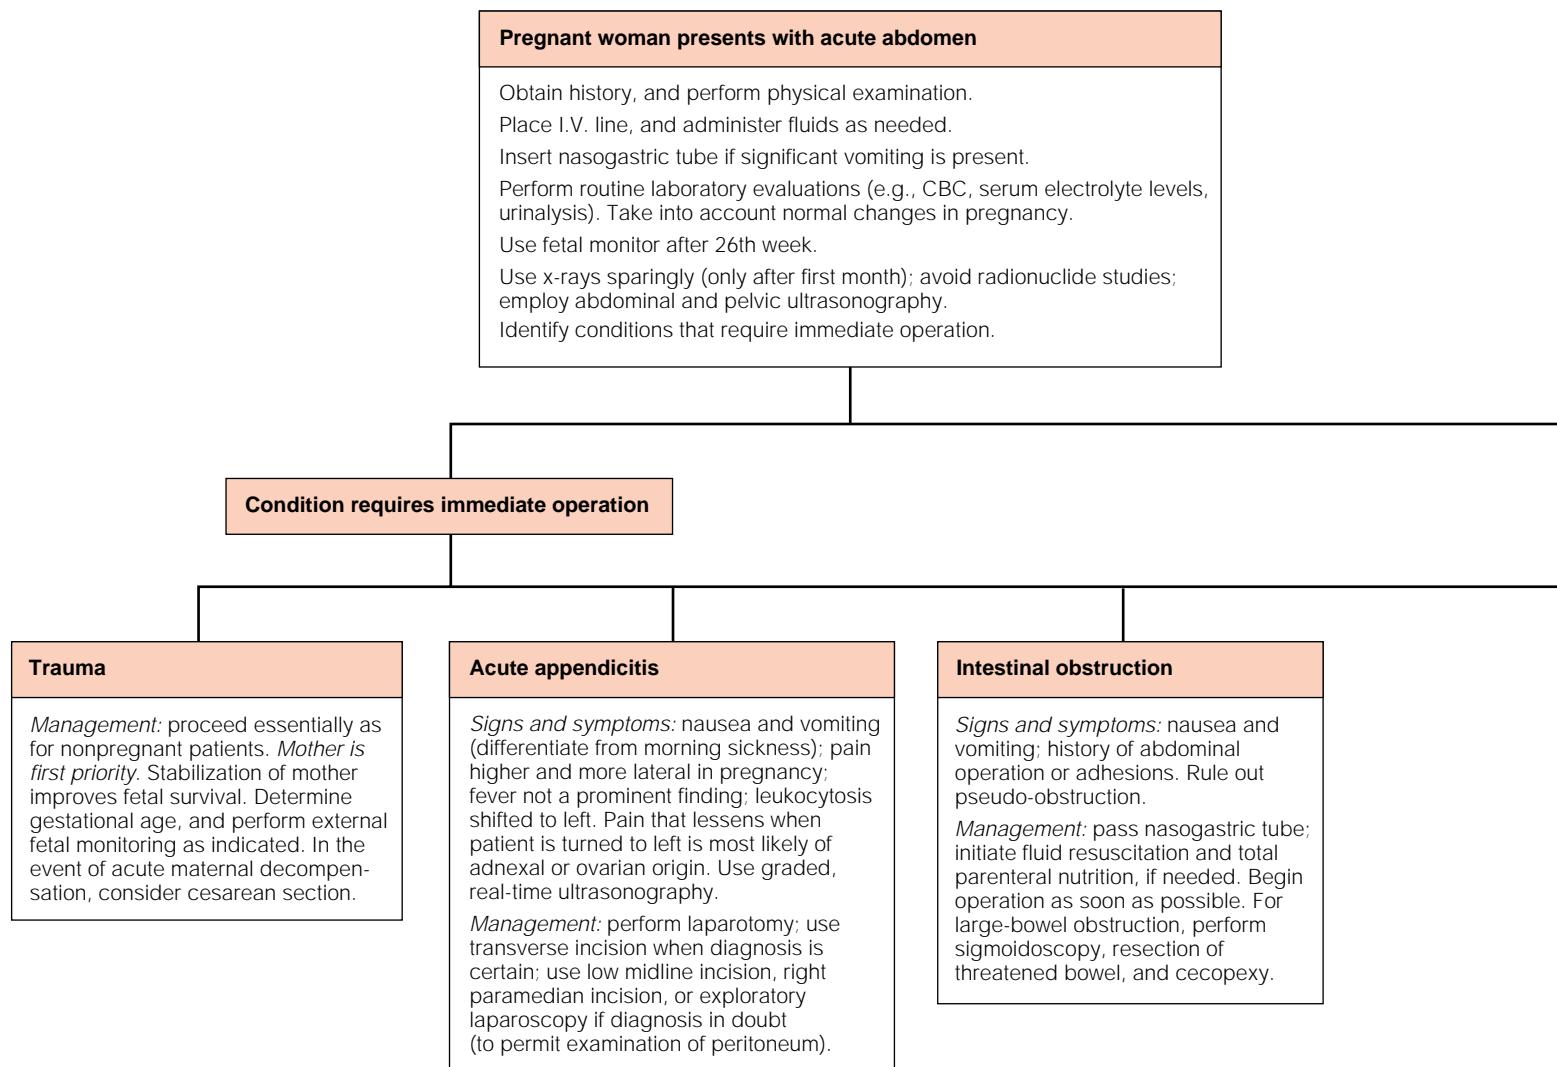

ed.¹¹ For this reason, many authorities advocate exploratory laparotomy for all high-velocity penetrating injury to the abdomen. How best to manage low-velocity penetrating injury remains somewhat controversial. Low-velocity injuries above the fundus of the uterus are almost always associated with visceral injury and thus call for exploratory laparotomy. Injuries below the fundus and anteriorly are seldom associated with visceral injury⁷ and thus can generally be managed nonoperatively. Subsequent laparotomy is indicated for worsening maternal symptoms. Subsequent cesarean section is indicated for a viable fetus in distress.

Domestic or partner violence during pregnancy occurs in 7% to 23% of all pregnancies.¹² If the patient is in an abusive relationship, the severity and frequency of assault typically increase during pregnancy.¹³ In addition, 20% of abused pregnant women attempt suicide¹⁴ or abuse alcohol or drugs. Abuse has many far-reaching consequences for the mother and the fetus that cannot be accurately measured. Unfortunately, partner violence often goes undiagnosed and hence untreated: as few as 12% of abused women are correctly identified in emergency room settings.¹⁵ Typical presentations of partner abuse include multiple injuries in various states of healing, inconsistent explanations of the injuries, minimization of the injuries, and delay in seeking medical attention.¹⁶ The face and the abdomen are struck more frequently during pregnancy. If a suspicion of partner violence arises, the physician should ask direct questions about threats and should provide appropriate contacts and support. A well-documented evaluation, unedited quotes, and careful drawings or pictures are also necessary in case the patient wishes to take legal action immediately or in the future. In all 50 states, domestic violence is a crime, and in some, failure to report suspected violence is a crime as well.

Management

Trauma is managed in essentially the same way in pregnant patients as in nonpregnant patients [see 7:1 Life-Threatening Trauma

Approach to Abdominal Pain in Pregnant Patients

Perforated duodenal ulcer	Spontaneous visceral rupture	Other conditions requiring urgent operation	Condition requires operation only if disease does not respond to medical management
<p>Management: plication of the perforation. Definitive ulcer operation should not be attempted. If patient is close to term, avoid cesarean section because of risk of uterine contamination.</p>	<p>General signs and symptoms: intra-abdominal hemorrhage, shock, acute abdomen.</p> <ul style="list-style-type: none">• Hepatic rupture: severe right upper quadrant pain; complication of preeclampsia• Renal rupture: probably secondary to hydronephrosis• Splenic rupture: occurs in conjunction with splenic artery aneurysm or capsular rupture, usually secondary to hypervolemia and splenomegaly• Esophageal rupture: may be associated with excessive vomiting during pregnancy (hyperemesis gravidarum)• Ruptured ectopic pregnancy <p>Note: in operation for hepatic rupture, cesarean section should be performed simultaneously.</p>	<p>Ectopic pregnancy. Ovarian torsion.</p>	<p>Acute cholecystitis: presents with epigastric or upper right quadrant pain, nausea and vomiting, occasional radiation of pain to right scapula; use ultrasonography to visualize. Do not use HIDA scan. Manage nonoperatively during first and third trimesters (fluid resuscitation and antibiotics); during second trimester, perform cholecystectomy. Use intraoperative cholangiography.</p> <p>Pancreatitis: presents with unremitting visceral pain that may radiate to the back and with raised amylase levels (2,000–3,000 IU). Operative intervention (preferably during second trimester) indicated by evidence of biliary obstruction but no evidence of stone passage or by failure of medical management.</p> <p>Peptic ulcer disease: treatment is based on symptomatic relief. Prompt operative intervention is indicated in the event of perforated duodenal ulcer.</p> <p>Inflammatory bowel disease: operative intervention is last resort if medical therapy ineffective. Indications for operation include abscess, fistula, or bowel obstruction (Crohn disease) or toxic megacolon (ulcerative colitis).</p>

and 6 Trauma and Thermal Injury]. The mother is the first priority: stabilization of the mother improves both maternal and fetal survival. Initial measures include efforts to support the airway, breathing, and circulation (the ABCs). The physiologic alterations characteristic of pregnancy affect maternal responses to injury [see Discussion, Physiologic Changes in Pregnancy, below].

The increased blood volume and enhanced cardiac output mask hypovolemia. Tachycardia and hypotension may not be accurate indicators of hypovolemia: as much as 2 L, or 30% of maternal blood volume, may be lost before hemodynamic instability is detected.¹⁷ The expansion of intravascular fluid volume that occurs in pregnancy affects the amount of replacement fluid needed. In the third trimester, patients should receive 1.5 times the amount of fluid that would ordinarily be given to compensate for this effect. Use of military antishock trousers (MAST) may decrease maternal venous return by compressing the uterus on the inferior vena cava; accordingly, their use is not recommended. Vasoconstrictive agents should never be used for hemodynamic stabilization until hypovolemia has first been treated. Epinephrine and norepinephrine lead to uteroplacental vasoconstriction and fetal compromise; ephedrine and phenylephrine may be used during pregnancy.

An important concern with advancing gestation is the possibility that the expansion of the gravid uterus [see Figure 1] can produce aortocaval compression, leading to supine hypotension. Left lateral displacement of the uterus is necessary to improve blood flow to both the mother and the fetus after the 20th week.

There are very few diagnostic procedures for which pregnancy is a contraindication. Radiographic investigation should be performed whenever necessary if the results are expected to affect management. It is usually possible to keep the total absorbed radiation dose below the level that is thought to increase teratogenic risk (i.e., 50 to 100 milliGrays [mGy]) [see Table 1].¹⁸ Plain films of the cervical spine provide useful information on head and neck injuries; computed tomographic scanning of the abdomen with contrast may offer the greatest amount of information on injuries to the retroperitoneum, the peritoneum, and the pelvis. Ultrasonography is now being used for acute trauma assessment in both pregnant and nonpregnant patients; the results to date have been good. Peritoneal lavage done in an open fashion through a supraumbilical incision may facilitate rapid assessment of intra-abdominal hemorrhage in cases of blunt trauma.¹⁹ A Kleihauer-Betke test for fetal red blood cells in the maternal circulation will reveal any fetomaternal hemorrhage present. (Fetomaternal hemorrhage is the passage of fetal blood into the maternal vascular system; it occurs more frequently in pregnant women who have suffered traumatic injury than in those who have not, and it can lead to fetal anemia, arrhythmias, and fetal exsanguination.²⁰) Rh_O (D) immune globulin and tetanus toxoid should be administered when indicated.

Early determination of gestational age by means of ultrasonography is a critical guide to further management decisions. Ultrasonography can also be used to monitor fetal heart tones, fetal activity, and amniotic volume. After the 20th week of gestation, cardiotocographic monitoring is an important adjunct for determining fetal status after trauma. Such monitoring should also be employed in the event of preterm contractions. As many as 40% of women experience preterm contractions, but only 3% progress to premature delivery.⁶ Preterm contractions in a pregnant trauma patient should initiate an evaluation

for abruptio placenta, uterine hemorrhage, and intra-abdominal hemorrhage. Given that placental abruption occurs in 66% of cases of major trauma and 5% of cases of minor trauma, the patient should be evaluated for ruptured membranes. Placental abruption usually occurs within 4 hours of injury. Ultrasonography is not sensitive enough to detect this condition²¹; therefore, cardiotocographic monitoring should be continued for 4 to 6 hours after stabilization and longer if any irregularity in the mother or fetus is noted.²² If the fetus has not yet reached the gestational age of 23 weeks or is not viable, the mother should receive supportive care. In these circumstances, cesarean section is reserved for cases of disseminated intravascular coagulation (DIC). If the fetus is viable and the mother stable, cesarean section can be carried out safely; if the fetus is viable and the mother unstable as a result of trauma, cesarean section should be carried out with the exploratory laparotomy.⁶ When the need for concurrent hysterotomy is under consideration, however, each case must be assessed individually. Patients undergoing an emergency cesarean section should receive a broad-spectrum antibiotic preoperatively.

In the event of acute maternal decompensation that does not respond to standard resuscitative measures, a cesarean section may be appropriate. In cases of particularly severe trauma, emergency operative resuscitation should be considered. If the patient is in cardiac arrest, thoracotomy and open chest massage, with concurrent cesarean section if the fetus is viable, have been recommended.⁵ Cesarean section may increase maternal circulating volume. Occasionally, cardiopulmonary resuscitation (CPR) is more effective after the gravid uterus is emptied. There is also less risk of supine hypotension after cesarean section, although the associated surgical blood loss may exacerbate maternal instability. Timing is critical: if anoxia is limited to 4 to 6 minutes, the fetus generally will not be harmed. Therefore, any attempt to deliver the fetus should begin within 4 to 6 minutes after maternal cardiac arrest. If the fetus appears to be still viable after this period has passed, cesarean section should be performed; isolated cases of fetal salvage after prolonged maternal anoxia have been reported. Fetal survival after delivery is dependent on its having reached a gestational age greater than 28 weeks. CPR of the mother

Table 1 Radiation Dose Absorbed by Unshielded Gravid Uterus from Radiographic Studies Often Performed in Trauma Patients

Radiographic Study	Unshielded Uterine Dose (mGy)
Cervical spine	No detectable contribution
Chest (AP)	0.003–0.043
Pelvis (AP)	1.42–4.86
Abdomen (AP)	1.33–4.51
IVP	2.02–8.15
Full spine (AP)	1.54–5.27
Femur (AP)	0.016–0.12
Humerus (AP)	< 0.00001
Cystography	1.35–4.41
CT scan	
Head	< 0.5
Thorax	< 10
Upper abdomen	< 30
Cumulative dose (without CT scan)	7.68–27.36
Cumulative dose (with CT scan)	> 7.68–67.86

AP—anteroposterior IVP—intravenous pyelography

should be continued during and after the delivery because it may improve maternal status and survival.

Two caveats should be kept in mind: (1) cesarean section should not be performed in an unstable patient because of an anticipated cardiac arrest, and (2) if CPR is successful before surgical delivery is attempted, cesarean section should not be performed, because in utero resuscitation is likely.²³

APPENDICITIS

Appendicitis is the most common surgical problem in pregnancy, occurring in 0.05% to 0.1% of pregnancies, but it occurs no more often in pregnant women than in nonpregnant women.^{24,25} The incidence is approximately the same in all three trimesters. The low maternal mortality—0.5% in 1977 and 0% in recent studies²⁶—notwithstanding, of all surgical problems during pregnancy, appendicitis causes the most fetal loss.²⁷ The particular dangers of appendicitis in pregnancy lie in the varied presentation of symptoms, the higher chance of delayed diagnosis, and the significant risk that surgery presents to the fetus.

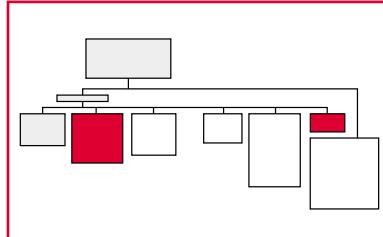

The symptoms of appendicitis mimic symptoms of normal pregnancy—namely, anorexia, nausea, vomiting, and abdominal discomfort. The most reliable symptom of appendicitis during pregnancy is periumbilical or diffuse abdominal pain that later localizes to the right lower quadrant.²⁸ Although as the gravid uterus grows, it pushes the appendix cephalad and posteriorly, right lower quadrant pain remains the most consistent symptom of appendicitis in any trimester.²⁸

On physical examination, appendicitis presents with tenderness in the right lower quadrant. It can be differentiated from adnexal or uterine pain with the help of the Adler sign: if the point of maximal tenderness shifts medially with repositioning on the left lateral side, the etiology is generally adnexal or uterine. Abdominal guarding, rebound tenderness, or referred tenderness is present in 60% to 70% of patients with appendicitis; however, these findings are less common during the third trimester because of the laxity of the abdominal wall muscles.²⁹ Elevated body temperature is not a consistent finding in pregnant patients with appendicitis.^{26,28}

Laboratory values can be misleading, in that pregnancy can cause a leukocytosis as high as 15,000 leukocytes/mm³ in the absence of any source of infection.³⁰ The white cell differential is more useful than the absolute count; increased levels of band cells or immature forms suggest that the leukocytosis may be secondary to an infectious process. A urinalysis is necessary to rule out a urinary tract infection, which occurs in 10% to 20% of pregnant women.

Diagnostic radiology should be employed deliberately and judiciously. Ultrasonography of the lower abdomen or transvaginal ultrasonography can often visualize an inflamed appendix without risk to the fetus. It can also distinguish other causes of abdominal pain, such as an ovarian cyst. The clinical presentation and an ultrasonogram are often sufficient to establish the diagnosis of appendicitis.^{31,32}

In very rare cases, a CT study of the pelvis should be done as well to elucidate a complicated presentation. A pelvic CT yields a total radiation dose of 25 mGy, and a directed helical, or spiral, CT study yields a total exposure of 30 mGy. Directed spiral CT has a sensitivity and specificity of 98%.³³ For both

pelvic CT and directed spiral CT, the total radiation doses are well below the threshold of safety established by the International Commission on Radiological Protection (ICRP), which is 100 mGy.³⁴ With plain films, the chance of obtaining valuable information is seldom worth the risk associated with the radiation. In certain cases, magnetic resonance imaging may be helpful for further delineation of the source of pain without the risk posed by ionizing radiation.

Differential Diagnosis

The condition most often confused with appendicitis is pyelonephritis, which occurs in 1% to 2% of pregnant women. The two diseases may present remarkably similar clinical pictures, especially when pyelonephritis occurs on the right side. Because of the mechanical effects of the gravid uterus on the ureter, pyelonephritis is more common in pregnant women than in nonpregnant ones. Furthermore, urinalysis yields abnormal results—either pyuria or hematuria—in as many as 20% of patients with appendicitis as a result of extraluminal irritation of the ureter by the inflamed appendix.³⁵ Nephrolithiasis can also be mistaken for appendicitis; it should be seriously considered whenever acute abdominal pain is present on the right side. Management of ureteral stones in pregnant patients presents a substantial challenge to both the surgeon and the urologist. Newer techniques, such as stents³⁶ and percutaneous nephrostomy tubes,³⁷ have been successful in obviating surgical intervention.

Right lower quadrant pain during early pregnancy may also be a presentation of ectopic implantation. Typically, a patient misses a period and then experiences some degree of vaginal bleeding or spotting. Abdominal or pelvic pain as well as cervical motion tenderness is present, and a mass is often appreciated on pelvic examination. When ectopic pregnancy is suspected, a serum human chorionic gonadotropin (hCG) assay should be performed along with transvaginal ultrasonography. If the serum hCG level is higher than 2,000 IU/L and an intrauterine gestational sac is not visualized by transvaginal ultrasonography, laparotomy or laparoscopy is indicated.

Torsion of an ovary or an ovarian cyst is also difficult to distinguish from appendicitis.³⁸ Although rare in pregnant patients, torsion of an ovarian cyst may occur in the early stages of the pregnancy. The physical examination is notable for pain in the right or left adnexa and the occasional presence of a tender mass. Transvaginal ultrasonography will frequently detect the cyst. Treatment requires laparotomy. The differential diagnosis of acute abdominal pain in pregnancy should also include ovarian cysts, mesenteric adenitis, degenerating fibroid tumors, salpingitis, inflammatory bowel disease, cholecystitis, ovarian vein thrombosis, ruptured corpus luteum, rectus hematoma, round ligament pain, abruptio placentae, chorioamnionitis, and adhesions.

Management

When there is evidence of appendicitis and no alternative diagnosis seems likely, operative intervention is warranted no matter what stage the pregnancy has reached.³⁹ The risk of the procedure to mother and child is minimal in comparison to the risks posed by delayed diagnosis, perforation, and abscess formation. Appendectomy in a pregnant patient does not increase the incidence of congenital malformation or stillbirth.²⁵ With routine surgical management, maternal mortality is negligible and fetal mortality is 2% to 8%.^{26,40} For a ruptured appendix, maternal mortality is 1% and fetal mortality is as high as 35%.^{38,41} Negative

laparotomy rates of 15% or lower are considered acceptable in the nonpregnant population, but negative laparotomy rates as high as 35% are considered acceptable in pregnant patients in the light of the grave consequences of delayed diagnosis.⁴¹

For appendectomy in the pregnant patient, a right lower quadrant muscle-splitting approach should be employed over the point of maximal tenderness. With late trimester pregnancies, this point of maximal tenderness may be higher than the traditional McBurney's point [see 5:31 Appendectomy]. The patient should also be turned 30° to the left to reduce pressure on the inferior vena cava and to facilitate exposure of the cecum. If there is doubt about the diagnosis, a low midline incision or a right paramedian incision should be made, especially if the patient has diffuse peritonitis. If appendicitis is found at the time of laparotomy, no further investigation for other intra-abdominal processes should be performed; such investigation may disseminate the infectious process and lead to late pelvic or abdominal abscesses. If, however, appendicitis is not found, the surgeon should thoroughly examine the peritoneal contents on the right side of the abdomen, taking care to avoid exerting traction on the uterus, which might lead to preterm labor. Appendectomy is advisable to avoid later confusion. If perforation occurs, the abdomen should be irrigated and drained. Skin closure should be avoided if abscess, advanced perforation, or gangrene is encountered.

Laparoscopic appendectomy, like all laparoscopic procedures, is controversial in the setting of pregnancy [see Discussion, Laparoscopic Surgery in Pregnancy, below]. When the diagnosis of appendicitis is uncertain, a laparoscopic approach can help rule out salpingitis, adnexal mass, or ectopic pregnancy.²⁹ When diffuse peritonitis is present, however, laparoscopy is associated with higher complication rates than laparotomy is.²⁹

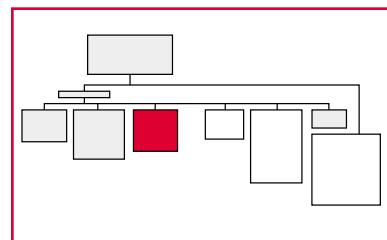

For a laparoscopic appendectomy in a pregnant patient, the first trocar (i.e., that for the camera) is placed in the sub-xiphoid area under direct vision via an open technique; this step allows visualization of all pelvic structures and the appendix. Once the appendix has been visualized, the right upper quadrant and right lower quadrant trocars should be placed under direct vision. If the size and position of the uterus make laparoscopic appendectomy difficult or impractical, the camera can be used to help locate the best available spot for an open incision.⁴²

Antibiotics should be given preoperatively. Postoperative wound infection can be minimized if adequate attention is paid to aseptic technique and handling of tissues. If perforation, peritonitis, or abscess formation is noted, I.V. antibiotics should be administered.

The premature delivery rate for pregnant women undergoing appendectomy ranges from 13% to 22%; this increased rate may contribute to the lower birth weights reported after maternal appendectomy.^{24,28} The risk of premature delivery is especially high during the first week after appendectomy. Given that tocolytics have never been shown to improve outcome in this setting, beta₂ receptor agonists are a better choice²⁹; they are indicated when advanced appendicitis is suspected or when active contractions have been documented.

INTESTINAL OBSTRUCTION

The incidence of bowel obstruction [see 5:4 Intestinal Obstruction] in pregnant patients ranges from one in 1,500 to one in 66,000.⁴³ The most

common cause of small-bowel obstruction during pregnancy is adhesions, which account for 55% of cases; volvulus accounts for 25% of cases, with hernia, cancer, and intussusception accounting for the remainder.^{44,45} As the incidence of operative procedures and the average age of the mother at gestation have risen, the likelihood of adhesive obstruction has risen as well. This problem may be further exacerbated by the hypomotility or dysmotility known to occur during pregnancy.⁴⁶ The need for laparotomy and lysis of adhesive bands during pregnancy is extremely low; however, when surgical management is necessary, fetal mortality is 26% and maternal mortality 5%. With intestinal obstruction, the main concern is to ensure that diagnosis is not delayed. Accordingly, any pregnant patient presenting with nausea, vomiting, and a history of abdominal surgery should be presumed to have a small-bowel obstruction until it is proved otherwise.

Large-bowel obstruction is less common than small-bowel obstruction but can be seen more often as pregnancy progresses. The most common cause of large-bowel obstruction is cecal or sigmoid volvulus. Volvulus during pregnancy is associated with a 21% to 43% mortality.⁴⁷ Colonic pseudo-obstruction, or Ogilvie syndrome, has also been reported late in pregnancy or in the early puerperium.⁴⁸ Striking colonic dilatation without anatomic obstruction is apparent, with gas filling the entire length of the colon from cecum to rectum. The danger of cecal perforation is high when the maximum diameter of the cecum exceeds 12 cm.

Management

Any sign of bowel ischemia or perforation in a pregnant patient with intestinal obstruction should prompt immediate operation. For small-bowel obstruction, a nasogastric tube should be inserted, fluid resuscitation should be initiated, a Foley catheter should be placed, and a full battery of blood tests should be performed, including assessment of blood gas levels and electrolyte levels and a complete blood count. Because of the leukocytosis known to occur in pregnancy, close attention should be paid to the differential blood count. Any sign of increasing acute-phase activity may suggest ischemia or perforation. Evaluation of acid-base status may also be useful in assessing bowel viability. A flat-plate and an upright abdominal film can confirm the diagnosis of small-bowel obstruction and rule out free air. The risk of radiation exposure to the fetus must be weighed against the potential morbidity and mortality of a missed diagnosis.

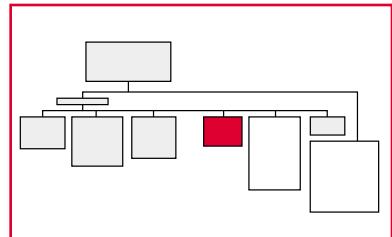

Once ischemia and perforation are ruled out, small-bowel obstruction should be treated with aggressive fluid resuscitation to ensure euvolemia and correction of electrolyte abnormalities. If long-term bowel rest is anticipated, total parenteral nutrition should be considered [see 8:23 Nutritional Support]. If conservative management does not lead to resolution, prompt operative intervention maximizes the chances of an excellent outcome for both fetus and mother.²⁹ A vertical incision allows the best exposure. The entire bowel must be examined for points of obstruction and assessed for viability. Segments of necrotic bowel should be resected, and an ostomy should be fashioned if necessary.

Large bowel obstruction is usually caused by volvulus. Sigmoid volvulus can usually be reduced by rigid or flexible sigmoidoscopy. If sigmoidoscopy fails, operative intervention with bowel resection and possible colostomy is indicated.²⁹ Treatment of a recognized cecal volvulus involves prompt operative intervention, resection of any threatened bowel, and cecopexy to prevent recurrence.

Pseudo-obstruction should be managed initially with bowel rest, electrolyte replacement, and the placement of a rectal tube. If these conservative measures fail to reestablish normal peristaltic activity, colonoscopy and intraluminal aspiration of the gas-filled colon should be tried. This approach is effective in as many as 85% of cases; however, it should be undertaken only by a skilled endoscopist because the potential for iatrogenic perforation of the bowel is extremely high. If there is no change in the size of the colon after 72 hours, a cecostomy is indicated.

PERFORATED DUODENAL ULCER

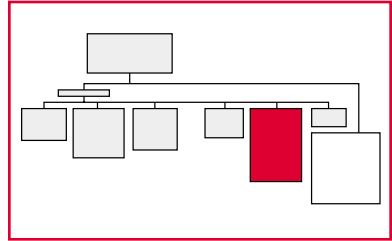

Although rare, perforated duodenal ulcer has been reported. When it occurs, it poses an extremely serious threat to both mother and fetus.

There is no place for expectant, nonoperative therapy: prompt operative intervention is crucial. Surgical therapy should be directed at plication of the perforation, and no attempt should be made to perform a definitive ulcer operation. If the woman is close to term, the child should be delivered vaginally rather than by cesarean section because of the prohibitive risk of uterine contamination.

SPONTANEOUS VISCERAL RUPTURE

Spontaneous rupture during pregnancy can involve the liver, the kidney, the spleen, or the esophagus. Spontaneous hepatic rupture during pregnancy is extremely uncommon, occurring no more frequently than one in 50,000 pregnancies and perhaps as infrequently as one in 250,000 pregnancies.⁴⁹ It is thought to be an advanced development in preeclampsia or eclampsia. Abdominal trauma and events that increase intra-abdominal pressure (e.g., sudden coughing, sneezing, or unusually strong contractions) have also been implicated as causes of spontaneous rupture. Rupture may occur during the second or third trimester, during delivery, or even in the early postpartum period. Typically, it develops in older, multiparous women in the third trimester.⁵⁰ Patients present with several days of severe right upper quadrant or substernal pain radiating to the back. The pain may precede the actual rupture by as much as a few days. Nausea, vomiting, hypertension, coagulopathy, and thrombocytopenia are frequently present. In some cases of rupture, the patient presents with hypovolemic shock. A right upper quadrant ultrasonogram often visualizes the rupture or the preceding subcapsular hematoma.²⁹

A limited number of renal ruptures have been described in conjunction with hydronephrotic kidneys; they are thought to be secondary to the physiologic hydronephrosis seen in pregnancy. Ultrasonography is the best imaging technique for diagnosis of renal rupture.⁵¹ Splenic rupture is the most common nonobstetric cause of intra-abdominal hemorrhage during gestation. It usually occurs in conjunction with splenic artery aneurysms or spontaneous capsular rupture. In most cases, it is probably secondary to the increased blood volume and splenic enlargement seen toward the later part of pregnancy.

Esophageal rupture has also been described, generally in association with heavy vomiting. Patients report sudden epigastric pain on vomiting that may radiate to the back and the chest. X-rays may reveal air in the mediastinum. An upper GI series with water-soluble contrast material will demonstrate the site of the rupture. Although esophageal rupture is not more common in pregnancy, it may be associated with the frequent nausea and vomiting seen with hyperemesis gravidarum. Ultrasonography, radionuclide scanning, and, ultimately, angiography may be helpful in diagnosing rupture of the liver, the kidney, or the spleen.

Management

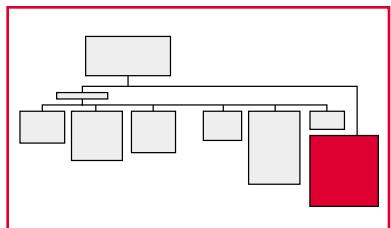

Prompt institution of volume support is essential, followed by emergency surgery and correction of any coagulopathy. Conservative management is reserved for stable patients with nonexpanding subcapsular hematomas. Serial ultrasonography is indicated. If adequate assessment of the hematoma, expanding hematoma, or rupture proves difficult or impossible, the patient should be taken to the OR for surgical treatment.⁵²

Operative management of hepatic rupture or expanding hematoma involves debridement of nonviable liver, hemostasis with electrocoagulation or packing, and adequate drainage. Cesarean section should be performed simultaneously, depending on the gestational age and the likelihood of fetal survival. This maneuver, when indicated, is curative. Maternal mortality as high as 50% to 75% has been reported, even with prompt surgical intervention. Fetal mortality can be even higher, reaching nearly 80% in some series.⁵³ Renal rupture necessitates urgent operative exploration. Every effort should be made to salvage the ruptured kidney. Suspected splenic rupture necessitates immediate laparotomy and splenectomy. Esophageal rupture is treated with immediate repair through the left chest, if the injury is to the lower portion of the esophagus, or through the right chest, if the injury is to the upper portion.

Conditions for Which Medical Management Should Be Attempted

BILIARY TRACT DISEASE

Acute cholecystitis is the second most common nonobstetric emergency in pregnant women. Symptomatic gallstone disease is far more common in women than in men because of the differential effects of the sex steroids on bile lipid composition and cholesterol saturation.⁵⁴ The difference in incidence begins at menarche, increases during the childbearing years, and decreases at menopause. By the age of 75 years, at least 35% of women and 20% of men have gallstones.⁵⁵

Gallstone disease is a result of cholesterol supersaturation and biliary stasis, both of which are promoted by pregnancy.⁵⁶ The elevated estrogen levels during pregnancy increase cholesterol secretion by the liver. Estrogen increases hepatic cholesterol uptake, increases cholesterol synthesis, and inhibits catabolism of cholesterol to bile acids. High concentrations of cholesterol in the bile overwhelm the solubilizing ability of bile salts, with the result that cholesterol stones form.⁵⁷ Elevated progesterone levels lead to bile stasis and decreased gallbladder contraction. Progesterone also causes incomplete emptying of

the gallbladder after stimulation by cholecystokinin (CCK).⁵⁸ The mechanisms are not understood, but it is thought that progesterone may decrease gallbladder reactivity to CCK.⁵⁹ The decrease in small-bowel motility that occurs secondary to progesterone elevation may alter enterohepatic circulation and decrease bile acid return to the liver.⁶⁰ The balance of bile salts and cholesterol is further altered in such a way as to favor cholesterol supersaturation and stone formation. Pregnancy also alters the pool of bile acids. The decreased percentage of chenodeoxycholic acid and the increased percentage of cholic acid during pregnancy also promote stone formation.

The incidence of gallstone disease in pregnant women ranges from 3.3% to 12.2%,⁶¹ and increases with gestational age; however, only 30% to 40% of patients with gallstones are symptomatic.⁶² The relative infrequency of symptomatic biliary disease is a function of the natural history of gallstones and of the time required to precipitate sufficient stones to generate symptoms.⁶³ Management of biliary colic consists of conservative therapy—namely, hydration, bowel rest if necessary, analgesia, and fetal monitoring. In pregnant patients, elective cholecystectomy for symptomatic gallstone disease should be delayed until after delivery. Fewer than 11% of symptomatic patients progress a more serious complication (e.g., cholecystitis, choledocholithiasis, or pancreatitis). Cholecystectomy during pregnancy is reserved for recurrent biliary colic or the aforementioned complications. It follows that cholecystectomy is rarely necessary in pregnant patients: it is undertaken once in every 10,000 live births.⁶⁴

Gallstone disease causes acute cholecystitis in only 0.05% to 0.08% of births.⁶⁴ The clinical symptoms of cholecystitis consist of epigastric or right upper quadrant pain, fever, nausea, vomiting, and occasional radiation of the pain into the right scapula. Physical findings include tenderness in the right upper quadrant and, occasionally, the Murphy sign. Elevated liver function test results indicate that complicated biliary tract disease or choledocholithiasis is likely; however, elevated alkaline phosphatase levels are seen in normal pregnancies and thus are diagnostically unhelpful.

Ultrasonography can diagnose gallstones and biliary ductal dilatation with an accuracy of 97%.⁵⁶ It can also detect pericholecystic fluid, reveal gallbladder wall thickening, and elicit a sonographic Murphy sign, all of which are characteristic of cholecystitis.⁶⁵ Radionuclide scans introduce the risk of fetal exposure to radiation. This risk almost always outweighs the potential value of any information to be gained from such a scan.

Differential Diagnosis

The differential diagnosis of cholecystitis includes appendicitis (see above), pyelonephritis, nephrolithiasis, acute pancreatitis (see below), myocardial infarction, gastroesophageal reflux disease, peptic ulcer disease (see below), hepatitis, and hepatic liver abscess. Significant hepatic syndromes can occur during pregnancy, such as intrahepatic cholestasis of pregnancy, acute fatty liver of pregnancy, infectious hepatitis, the hemolysis–elevated liver enzymes–low platelet count (HELLP) syndrome, and eclampsia.^{66–68} These syndromes should be considered if the clinical signs and symptoms observed in a pregnant patient do not conform to the typical picture of gallstone disease.

Management

Initial management of cholecystitis is conservative, comprising I.V. hydration, bowel rest, administration of meperidine

and antibiotics, fetal monitoring, and, if necessary, nasogastric decompression. This regimen is successful in 84% of patients.⁶⁹ Operative intervention is indicated in the presence of any of the following: failure of conservative management, recurrent disease, intractable nausea, maternal weight loss, fetal growth retardation, obstructive jaundice, gallstone pancreatitis, or peritonitis. Thus, serial monitoring of liver function test results and amylase levels is essential during conservative therapy. If cholecystectomy during pregnancy is necessary but not urgent, it is best to perform the operation in the second trimester: fetal mortality from a first-trimester cholecystectomy can be as high as 12%.⁷⁰ The rate of fetal loss decreases through gestation; however, beginning in the third trimester, the risk of preterm labor increases. Symptomatic gallstone disease is also a reasonable indication for surgical management.^{64,71} Half of patients with symptomatic gallstone disease require repeat hospitalizations; in addition, several investigators have found the incidence of spontaneous abortion, preterm labor, or premature delivery to be higher in patients treated nonoperatively than in those undergoing cholecystectomy.⁷² If cholecystectomy is performed in the second or third trimester, fetal mortality is lower than 5%.⁷³ There remains a degree of controversy regarding the relative merits of conservative management and aggressive surgical intervention for patients with symptomatic gallbladder disease.

Surgical treatment during pregnancy consists of either open cholecystectomy [see 5:22 Biliary Tract Disease] or laparoscopic cholecystectomy [see 5:21 Cholecystectomy and Bile Duct]. The advantages of laparoscopic over open cholecystectomy include earlier recovery, earlier mobility, reduced use of narcotics, smaller incisions, and fewer surgical site infections.⁷² When carried out with standard precautions, laparoscopic cholecystectomy does not increase the rate of fetal loss (5%) or of spontaneous abortion, nor does it have a greater adverse effect on birth weight, Apgar scores, or the rate of preterm delivery than open cholecystectomy does.⁷⁴ Laparoscopic cholecystectomy can be performed safely and effectively throughout pregnancy.^{74,75} Routine indications for conversion to open cholecystectomy apply, including uncontrolled bleeding and unclear anatomy. Additionally, conversion during pregnancy is indicated if the gravid uterus has expanded to the point where safe dissection of the gallbladder by laparoscopic means is impossible.^{75–79} If the fetus shows signs of distress, deflation of the pneumoperitoneum and conversion to an open cholecystectomy may be necessary. Laparoscopic cholecystectomy is contraindicated in pregnant patients with gallstone pancreatitis.

In patients with choledocholithiasis, intervention should be performed without delay. The common bile duct (CBD) should be explored by means of endoscopic retrograde cholangiopancreatography (ERCP) [see 5:18 Gastrointestinal Endoscopy], with fluoroscopy used economically and lead aprons worn to shield the fetus.²⁹ ERCP with sphincterotomy successfully addresses choledocholithiasis without increasing fetal mortality or the rate of preterm delivery.⁸⁰ Surgical management of choledocholithiasis with open or laparoscopic cholecystectomy and CBD exploration should be reserved for patients in whom ERCP fails. Choledocholithiasis with right upper quadrant tenderness, fever, and jaundice (Charcot's triad) suggests cholangitis. The only treatment options for cholangitis when ERCP fails are open cholecystectomy and percutaneous intubation of bile ducts.⁸¹ Intraoperative cholangiography can be used without problems after the second trimester,⁸² provided that the fetus is

shielded with lead during imaging to limit radiation exposure. Duct imaging should be reserved for patients who have risk factors for CBD stones (e.g., pancreatitis, a history of jaundice, or choledochal dilatation).²⁹

PANCREATITIS

Pancreatitis is rare during pregnancy, occurring in every 1,000 to 10,000 pregnancies.⁶⁴ Its incidence, like that of gallstone disease, increases with gestational age. Associated gallstone disease is present in 70% to 90% of pregnant women presenting with pancreatitis.^{64,80,83} Gallstone pancreatitis is associated with a maternal mortality of less than 37% and a fetal mortality of 10% to 60%.⁸² In the nonpregnant population, pancreatitis is associated with biliary tract disease in only 40% of cases, with alcohol-induced pancreatitis accounting for another 40%. In pregnant patients, pancreatitis can be secondary to hypertriglyceridemia⁸⁴ as well as to thiazide administration and hyperparathyroidism.⁸⁵ At present, there is little evidence to suggest that pregnancy itself is an etiologic mechanism in the development of pancreatitis.^{86,87}

The signs and symptoms of pancreatitis in pregnant women are indistinguishable from those seen in the general population. Patients report an unremitting, deep visceral pain that is usually midabdominal but may radiate into the back; nausea, vomiting, and anorexia are also typical symptoms. Findings in severe cases include hypotension, hypovolemia, and a rapid, thready pulse. Jaundice occurs in patients with CBD stones. The hallmark of the condition is diffuse abdominal pain combined with hyperamylasemia⁸⁸; amylase levels may approach 2,000 to 3,000 U/L and may be accompanied by lipase elevations.⁸⁹ Albumin, calcium, and bilirubin levels should be measured and liver function tests performed. The results should be interpreted with caution in the light of the alkaline phosphatase elevation known to occur in normal pregnancies. Ultrasonography should be undertaken with the aim of searching for evidence of cholelithiasis and choledocholithiasis. Visualization of the inflamed pancreatic head may be informative; however, this structure is often difficult to locate.

Management

Treatment should be aimed at correction of the hypovolemia that invariably accompanies pancreatitis.⁹⁰ Restriction of oral intake is necessary. A nasogastric tube should be placed in cases of intractable nausea. Intramuscular administration of meperidine at a dosage of 50 to 75 mg every 3 to 4 hours provides adequate analgesia. Antibiotics should be reserved for treatment of a specific infectious complication. Calcium levels should be kept within the normal range. Arterial blood gases should be monitored as indicated. Prolonged pancreatitis may necessitate lengthy periods of bowel rest. During extended periods without oral feeding, pregnant women should be maintained on total I.V. hyperalimentation.⁹¹

In patients with pancreatitis caused by extrahepatic biliary obstruction, endoscopic management has achieved excellent results. ERCP and sphincterotomy [see 5:18 Gastrointestinal Endoscopy] can both be performed safely during pregnancy. Definitive treatment with cholecystectomy and intraoperative cholangiography can safely be delayed until after delivery. Operative intervention should be reserved for patients with biliary obstruction in whom there is no evidence of stone passage. Efforts aimed at postponing operative intervention have been somewhat successful, though the recurrence rate approaches 50%. Early operative intervention has not been shown to

improve fetal survival.⁸³ During the first trimester, loss of the fetus is common⁹²; however, in the second trimester, operative intervention has a good chance of yielding excellent results for both mother and fetus.⁹³ Although unusual, pseudocyst formation has been reported in pregnant women. It is managed conservatively, without operative intervention. Laparotomy, debridement, drainage, and cholecystectomy are indicated for severe cases with pancreatic necrosis.

PEPTIC ULCER DISEASE

During pregnancy, symptoms of upper abdominal pain, nausea, and vomiting are not uncommon. Peptic ulcer disease usually begins with these same symptoms. Women with peptic ulcer disease usually experience symptomatic improvement during pregnancy. Elevated estrogen levels are believed to decrease gastric acidity during early pregnancy. Maternal gastrin production does not change during pregnancy, but histamine-stimulated acid output is lower. During the third trimester, however, maternal serum gastrin levels rise as a result of placental contribution, and symptomatic peptic ulcer disease may become more likely. During the late third trimester and the early postpartum period, basal and stimulated acid production returns to normal.

The diagnosis is made in much the same way in pregnant patients as in nonpregnant ones, except that physicians treating pregnant women should rely more on clinical information and less on radiologic intervention. Intractable pain that is not relieved by the usual therapeutic interventions should prompt endoscopic evaluation with a tissue biopsy for *Helicobacter pylori* culture.

Management

Safe symptomatic relief can be achieved with direct-acting agents (bismuth salicylate, sucralfate, aluminum hydroxide, and magnesium hydroxide). H₂ blockers and proton pump inhibitors are reserved for symptoms refractory to direct-acting agents. Most gastritis and ulcer disease is caused by infection by *H. pylori*. Treatment with the usual array of antibiotics (clarithromycin, amoxicillin, and metronidazole—but not tetracycline), direct-acting oral agents, and H₂ blockers is also safe in pregnancy.⁹⁴ Limitation of intake of nonsteroidal anti-inflammatory drugs (NSAIDs), tobacco, and caffeine also helps mitigate symptoms.

A perforated duodenal ulcer must be treated surgically [see Urgent Surgical Problems, Perforated Duodenal Ulcer, above]. Surgery is also indicated if significant hemorrhage—necessitating transfusion of more than six units over a 24-hour period—is observed. In this setting, maternal mortality is 14% after operation; however, it is 44% if surgical treatment is not provided.⁹⁵

INFLAMMATORY BOWEL DISEASE

Pregnancy does not affect either ulcerative colitis or Crohn disease to any great degree, nor do these diseases affect the welfare of the fetus appreciably.⁹⁶⁻⁹⁸ Active disease flare-ups are most common during the first trimester and during the early postpartum period.⁹⁹ In a review of pregnancies in patients with Crohn disease, the outcome of the pregnancy was not adversely affected by the disease. Although patients with active disease generally had poorer outcomes, neither pregnancy nor therapy affected the course of the disease.¹⁰⁰

In addition to these frank forms of inflammatory bowel disease (IBD), ulcerative or granular proctitis may also occur in

pregnancy. This poorly understood disorder is confined entirely to the distal 10 cm of the rectum. Endoscopically, the mucosa manifests multiple diffuse superficial ulcerations and friability. Above the distal 12 to 15 cm of the rectum, the mucosa assumes a normal appearance. Bleeding is observed, ranging from spotting with defecation to measurable loss. The disease is self-limited, almost never progressing to true IBD.

Management

Treatment of ulcerative colitis or Crohn disease involves administration of sulfadiazine, steroids, or both.¹⁰¹ Treatment with both of these agents is often recommended.¹⁰² Both steroids and sulfadiazine have been reported to cause congenital malformations in animal studies; however, because of the increased risk of fetal and maternal mortality in untreated cases of IBD, it is recommended that steroids and sulfadiazine be administered together as necessary to minimize the active effects of the disease.¹⁰³ If the disease does not respond to

medical management, operative intervention may be undertaken, but only as a last resort. In patients with ulcerative colitis, the most common indication for operation is toxic megacolon, which, if left untreated, can cause significant infant and maternal mortality. In patients with Crohn disease, the uncommon problems of abscess, fistula formation, and bowel obstruction may force operation; these conditions should be treated in the usual fashion. Greater reliance should be placed on fecal diversion in pregnant patients because of the increased risk of anastomotic dysfunction. Active Crohn disease may necessitate complete bowel rest and maintenance of nutrition by central I.V. feedings.^{104,105}

Patients with ulcerative or granular proctitis should not receive systemic treatment with steroids or sulfadiazine because of the potential toxicity to the fetus. Steroid enemas or enemas concocted from an elixir preparation of sulfasalazine may be administered. Low-residue diets may help control particularly bothersome symptoms.

Discussion

Physiologic Changes of Pregnancy

A variety of physiologic alterations occur during pregnancy. These include mechanical, hormonal, chemical, and hematologic changes [see Table 2] that are essential for maintenance of the pregnancy during the 40 weeks of gestation but that may also complicate the evaluation of abdominal problems in the pregnant patient.

RESPIRATORY CHANGES

The respiratory system undergoes several measurable changes as a result of the hormonal and physiologic influences of pregnancy. Elevated progesterone and estrogen levels cause blood volume and cardiac output to increase; as a result, pulmonary blood flow increases. With the added component of decreased blood albumin concentration and thus decreased oncotic pressure, mild lung edema may ensue.¹⁰⁶ Progesterone also acts as a direct respiratory stimulant, increasing the chemosensitivity of the respiratory center to CO₂.

In pregnant patients, both O₂ consumption and CO₂ production increase as gestation progresses. As the progesterone level rises, chemosensitivity to CO₂ and CO₂ production increase, and minute ventilation progressively rises by up to 30%.¹⁰⁷ Progesterone and increased CO₂ production are the main forces behind the condition known as hyperpnea of pregnancy. This condition results in a reduction in P_aCO₂ from 40 mm Hg to 34 mm Hg and an increase in arterial oxygen tension (P_aO₂) from 60 mm Hg to 100 mm Hg. This exaggerated gradient between the mother and the fetus facilitates efficient exchange of gases. With the decreased P_aCO₂, the pregnant patient also experiences respiratory alkalosis in relation to the fetus. The oxyhemoglobin dissociation curve is thus shifted to the right, again facilitating delivery of oxygen to the fetus. To prevent harmful pH increases, the kidneys respond appropriately by excreting bicarbonate.

As pregnancy progresses, tidal volume rises as a result of increases in chest circumference (usually about 5 cm). Although the growing uterus forces the diaphragm upward by as much as 4 cm, tidal volume is maintained, thanks to increased use of accessory muscles. Functional reserve capaci-

ty (FRC) decreases by 10% to 25% by week 12 of gestation because of decreased chest wall compliance. Relaxin, the hormone responsible for ligamentous relaxation of the pelvis, may also be responsible for laxity of the chest wall ligaments. As a consequence of this laxity, the subcostal angle increases from 68° to 103°.¹⁰⁸

As many as 75% of pregnant women are affected by dyspnea. Dyspnea of pregnancy comprises mild pulmonary edema, increased breathing load, increased drive, and greater use of accessory muscles.¹⁰⁶ It can complicate the assessment of any pregnant patient with an underlying surgical issue. In addition,

Table 2 Chemical and Hematologic Alterations in Pregnant Patients¹⁰³

Laboratory Test	Normal Values	
	Nonpregnant	Pregnant
Urinary acetone	Negative	Faint positive
Serum total protein (g/dl)	6.5–8.5	6.8
Serum albumin (g/dl)	3.5–5.0	2.5–4.5
Blood urea nitrogen (mg/dl)	10–25	5–15
Fasting blood glucose (mg/dl)	70–110	65–100
Two-hour postprandial blood glucose (mg/dl)	< 110	< 120 (plasma)
Serum calcium (mEq/L)	4.6–5.5	4.2–5.2
Serum phosphate (mg/dl)	2.5–4.8	2.3–4.6
Alkaline phosphatase (IU/L)	35–48	35–150
Cholesterol (mg/dl)	120–290	177–345
Triglycerides (mg/dl)	33–166	130–400
Serum folic acid (ng/ml)	5–21	4–14
Vitamin B ₁₂ (pg/ml)	430–1,025	Decreased
Hemoglobin (g/dl)	12	> 11
Hematocrit (%)	36	33
Serum iron (μg/dl)	> 50	> 60
TIBC (μg/dl)	250–400	300–600
% TIBC saturation	30	> 20
Serum zinc (μg/dl)	65–115	55–80
Urinary zinc (μg/dl)	200–450	200–450

TIBC—total iron-binding capacity

pregnant women typically have decreased oxygen reserve and thus are subject to rapid development of hypoxia and hypercapnia with hypoventilation or apnea. This vulnerability becomes especially important when such patients undergo intubation and anesthesia.

CARDIOVASCULAR CHANGES

During pregnancy, cardiac output rises by 30% to 50% [see Table 3]. This rise is attributable to an increased heart rate and, to a lesser extent, an increased stroke volume.¹⁰⁹ The HR increase may begin as early as 6 weeks after conception¹¹⁰; by the third trimester, HR is 15 to 20 beats/min faster than the baseline rate. The increase in the plasma volume may be as great as 50%. Despite the increases in cardiac output and blood volume, BP actually decreases because of the overwhelming effect of reduced systemic vascular resistance. BP reaches a nadir in the second trimester and returns to baseline levels by the time of delivery.¹¹¹

The gravid uterus may press on the inferior vena cava, decreasing venous return and causing cardiac output to decrease by as much as 30%. Pregnant women may even experience dizziness or syncope. To optimize cardiac output, the pregnant patient should be placed in the left lateral decubitus position.¹⁰⁷

Cardiovascular evaluation of the pregnant patient must take into account the altered cardiac output, blood volume, HR, and BP. Hypovolemia may not manifest itself as tachycardia or hypotension, as would normally be predicted; alternatively, tachycardia of pregnancy may be mistaken for hemorrhage. Careful analysis of the data is necessary whenever hypovolemia is under consideration. Additionally, pregnancy-associated signs and symptoms may complicate any evaluation of concurrent heart disease [see Cardiovascular Conditions during Pregnancy, below].¹¹²

GASTROINTESTINAL CHANGES

Appetite can vary greatly from one pregnant woman to another. The average increase in daily intake is 200 kcal/day during the first trimester. The recommended dietary allowance (RDA) is 300 kcal/day during pregnancy—more if the pregnant patient is an adolescent or especially physically active.¹¹³ As many as 70% of pregnant patients experience nausea and vomiting. Nausea of pregnancy, or morning sickness, frequently occurs between weeks 4 and 16 of gestation. Most patients respond to conservative treatment, including selective eating and avoidance of dehydration. Persistent nausea and vomiting, termed hyperemesis gravidarum, can lead to dehydration, electrolyte imbalance, and organ failure. It is important to exclude

other possible causes of nausea before attributing symptoms to nausea of pregnancy. This condition can complicate the diagnosis of appendicitis, gallbladder disease, pancreatitis, or bowel obstruction.

From 40% to 80% of pregnant women experience gastroesophageal reflux disease (GERD).⁹⁴ Esophagogastric junction tone decreases as intra-abdominal pressure increases, with reflux the result. In addition, under the influence of estrogen and progesterone, the stomach has decreased motility and an increased emptying time. Transit through the small bowel and the colon is also slowed.

Estrogens and progesterone are thought to influence cholestasis of pregnancy as well. The net effect of the two hormones is to increase the cholesterol concentration in bile. Estrogen also decreases bile flow. Progesterone promotes smooth muscle relaxation and stasis throughout the biliary system.¹¹⁴ In the evaluation of cholestasis or any liver disease, it is important to remember that placental alkaline phosphatase can increase measured alkaline phosphatase levels by a factor of three or four.

URINARY CHANGES

As cardiac output increases, the glomerular filtration rate increases by 30% to 50%. This increase reaches a peak at the end of the first trimester. Accordingly, creatinine clearance and blood urea nitrogen (BUN) levels fall by 25% over the first trimester. The kidneys themselves increase in size by 1.5 cm as a result of increased vascularity.¹¹⁵ The ureters become dilated as a consequence of the relaxing effects of progesterone on smooth muscle.¹¹⁶ Dextrorotation of the uterus causes further dilatation of the right ureter.

HEMATOLOGIC CHANGES

Normal pregnancy causes numerous changes in coagulation and fibrinolysis. Platelets become more reactive, and destruction is enhanced; to compensate, the pregnant patient increases production of platelets. Normal pregnancy increases hepatic and endothelial cell synthesis of many procoagulant factors. Pregnant women have normal anticoagulant factor levels except for a sharp decrease in protein S antigen and activity. In general, fibrinolytic activity is impaired during pregnancy; however, bleeding time and clotting time are unchanged. Overall, pregnancy is a hypercoagulable state.¹¹⁷ The risk of thromboembolism doubles during pregnancy.¹¹⁸ Accordingly, compression stockings should be used whenever surgical management is embarked on.

Leukocytosis is normally seen in pregnancy. What the net effect of a decrease in CD4⁺ cells, an increase in CD8⁺ cells, and

Table 3 Hemodynamic Values in Healthy Nonpregnant, Pregnant, and Postpartum Subjects^{109,164}

Parameter	Nonpregnant	36–38 Weeks' Gestation*	Postpartum
Heart rate (beats/min)	60–100	83 ± 10	71 ± 10
Central venous pressure (mm Hg)	5–10	3.6 ± 2.5	3.7 ± 2.6
Mean pulmonary arterial pressure (mm Hg)	15–20	—	—
Pulmonary arterial wedge pressure (mm Hg)	6–12	7.5 ± 1.8	6.3 ± 2.1
Mean arterial pressure (mm Hg)	90–110	90.3 ± 5.8	86.4 ± 7.5
Cardiac output (L/min)	4.3–6.0	6.2 ± 1.0	4.3 ± 0.9
Stroke volume (ml/beat)	57–71	74.7	60.6
Systemic vascular resistance (dyne · cm · sec ⁻⁵)	900–1,400	1,210 ± 266	1,530 ± 520
Pulmonary vascular resistance (dyne · cm · sec ⁻⁵)	< 250	78 ± 22	119 ± 47

*Values in pregnant patients were determined with patient in left lateral decubitus position.

an unchanged number of B cells may be the subject of some controversy at present.¹¹⁹ More important than the higher total number of cells is the altered activity exhibited by all leukocytes, a complicated picture that is still not fully understood.

Although pregnancy may appear to be an anemic state, it is not: blood volume actually increases (see above), and red cell mass rises by 30% [see Table 2].

General Perioperative Considerations in Pregnant Patients

The use of anesthesia in the course of an operation does not pose a teratogenic risk to the fetus.¹²⁰ Surgical treatment can be acceptably safe if appropriate attention is given to certain key perioperative considerations—namely, fetal monitoring, radiologic investigation, anesthesia, and the timing of the operation.

FETAL MONITORING

Monitoring consists of measuring uterine contractions with a tocometer, fetal HR with a Doppler transducer, and fetal movement and tone with ultrasonography. Together, these measurements yield a good indication of fetal health. Preoperative ultrasonography can also approximate gestational age when an accurate history cannot be obtained. Gestational age plays a pivotal role in all surgical decision making for a pregnant patient.

The fetal HR is routinely measured both preoperatively and postoperatively.¹²¹ Though the fetal HR can be heard 14 weeks after conception, it serves as an indicator of fetal oxygenation only after week 26. Specific fetal HR abnormalities—absence of variability, late or variable decelerations, and bradycardia—are predictive of impending fetal hypoxia, physical damage, or death. In the absence of these extreme (and hence obvious) fetal HR patterns, interpretation of fetal tracings can be complex.¹²² There are no conclusive data to suggest that any single monitoring technique reflects fetal outcome.¹²¹ Optimization of maternal physiologic status is more important than any mode of fetal monitoring.

RADIOLOGIC INVESTIGATION

X-rays and CT scans must be employed judiciously, given the risk that radiation poses to the pregnant patient. Depending on the exposure time and the total dose, radiation may cause failure to implant, malformation, growth retardation, CNS abnormalities, or fetal loss.

The standard units of measure for radiation are the Gray (Gy) and the rad; 1 Gy is equivalent to 100 rad, and 1 rad thus is equivalent to 1 cGy or 10 mGy. The ICRP has stated that radiation doses lower than 100 mGy do not increase the risk of fetal death, malformation, or developmental delay.³⁴ Doses between 200 to 500 mGy during weeks 8 to 15 of gestation, however, result in measurable IQ reductions, and doses higher than 600 mGy result in growth retardation and CNS damage. Most diagnostic procedures fall within the accepted safe range. The average radiation dose from an abdominal x-ray is 1.4 mGy, that from an abdominal CT scan is 8.0 mGy, that from a pelvic CT scan is 25 mGy, and that from a selective spiral CT scan of the abdomen and the pelvis is 30 mGy.

In many instances, alternate diagnostic modalities that do not employ ionizing radiation, such as ultrasonography and MRI, are sufficient to determine the proper treatment. If, however, diagnostic radiation does prove necessary, the fetus should be shielded, radiation exposure should be minimized,

and radiation doses should be carefully documented.¹²³ Careful cooperation with the radiologist will help limit radiation exposure. It is of particular importance that the patient be informed of the risks associated with radiation in comparison with the expected benefits of diagnostic radiation in her case.

ANESTHESIA

The physiologic changes associated with pregnancy have implications for anesthetic management. As noted (see above), oxygen reserve decreases with pregnancy. Upon intubation, hypoxia and hypercapnia with hypoventilation or apnea may develop rapidly. In one clinical study of obstetric anesthesia, airway difficulties occurred in 7.9% of intubated patients, compared with 2.5% of nonintubated patients¹²⁴; it is noteworthy that the primary reasons for difficult intubation were airway anatomy and technique, just as would be the case in nonpregnant patients. During intubation, pregnant women are also at increased risk for gastric aspiration owing to the decreased gastroesophageal sphincter tone. Because of this increased risk of aspiration, nasogastric suction should be freely employed. The stomach should be emptied before emergency procedures and continually decompressed throughout the operation and the early postoperative period.

Anesthesia can suppress the normal physiologic compensation for aortocaval compression, in which event hypotension can ensue. Positioning of the patient in a leftward tilt or the left lateral decubitus position can minimize hypotension.¹²¹ Liberal use of indwelling urinary catheters allows gross estimation of the adequacy of blood volume and splanchnic perfusion during general operative procedures. If intra-abdominal operation is necessary after weeks 12 to 16, the bladder must be decompressed to allow adequate exposure in the pelvis and the lower abdomen.

According to retrospective studies, all anesthetic, opioid, sedative-hypnotic, and anxiolytic agents pose some degree of risk to the fetus; none of them appears to be significantly more teratogenic or safer than any other.¹²¹ If vasopressors are necessary, ephedrine is the drug of choice, in that it causes less uterine vasoconstriction than epinephrine or norepinephrine does. Small doses of phenylephrine are also safe for use in pregnant women who are hypotensive [see Table 4].

TIMING OF SURGERY

If a surgical problem arises during pregnancy, the urgency of surgical treatment must be balanced against the risk such treatment poses to the mother and the fetus. Urgent procedures, such as appendectomy, should be carried out in the usual timely fashion [see *Urgent Surgical Problems*, above]: in such cases, the risks to both mother and fetus outweigh the risks of miscarriage and preterm labor. Semielective procedures are best done during the second trimester.⁷² In the first trimester, when organogenesis is ongoing, concerns arise about the teratogenic risks of medications and surgical interventions. During the first trimester, surgical procedures are associated with a miscarriage rate of 12%; during the second trimester, this rate falls to 0% to 5.6%. The incidence of preterm labor with surgical procedures is 5% in the second trimester but rises to 30% to 40% in the third trimester.¹²⁵ Elective procedures should be delayed until 6 weeks after delivery.

TOCOLYTICS

Even though surgical procedures have been associated with a higher incidence of preterm labor, especially in the third trimester, routine prophylactic use of tocolytics is not recom-

Table 4 Safety of Various Drugs Used during Pregnancy^{165,166}

Drug (FDA Pregnancy Category)	Toxicity	Comments
Analgesics/tranquilizers		
Ibuprofen (B)	Risk of postpartum hemorrhage; premature patent ductus arteriosus closure; no teratogenic effects	Use with caution toward end of pregnancy
Meperidine (B)	Decreased neonatal respiration; CNS depression	Greatest risk near term
Morphine (C)	Small size for gestational age; respiratory depression; fetal death	Greatest risk near term
Codeine (C)	Possible congenital anomalies	Avoid in first trimester
Acetaminophen (B)	None known	Analgesic of choice
Aspirin (C)	Anticoagulation effect; fetal bleeding; possible prolongation of pregnancy; no teratogenesis known	Use with caution, especially toward end of pregnancy not recommended for routine analgesia
Barbiturates (C)	Fetal addiction; neonatal bleeding; ?teratogenesis	Long-term administration not recommended
Diazepam (D)	?Cleft palate; ?heart defects; hypotonia; hypothermia; withdrawal symptoms	Long-term administration not recommended
Anesthetics		
Bupivacaine (C)	Bradycardia	Use with caution in late pregnancy
Lidocaine (B)	Bradycardia; CNS depression	Use with caution in late pregnancy
Halothane (C)	Uterine relaxation	Can cause abortion in early pregnancy
Nitrous oxide	?Teratogenesis in early pregnancy	Can be used in late pregnancy
Muscle relaxants (C)	Fetal curarization	Relatively safe; incidence of problems extremely low
Antibiotics		
Ampicillin (B)	None known	Safe
Aztreonam (B)	Not teratogenic in rodents	Safety in pregnancy unclear
Cephalosporins (B)	No embryocidal reports	Safe
Clindamycin (B)	None known	Safety in pregnancy unclear
Erythromycin, azithromycin (B)	Risk of cholestatic hepatitis; no reported congenital defects	Avoid in pregnancy
Fluoroquinolones (C)	Irreversible arthropathy in immature animals	Avoid in pregnancy
Gentamicin (C)	Possible 8 th nerve toxicity; no reported congenital defects, neonatal ototoxicity, or nephrotoxicity	Avoid in pregnancy
Imipenem (C)	None known	Safety in pregnancy unclear
Metronidazole (B)	Carcinogenic in rodents; possibly teratogenic	Contraindicated in first trimester; use with caution thereafter
Nitrofurantoin (C)	Hemolytic anemia in newborns; no known teratogenic effects	Contraindicated at term
Penicillin G (B)	None known	Safe
Streptomycin (D)	8 th cranial nerve abnormality	Contraindicated
Tetracycline (D)	Adverse effects on fetal teeth and bones; maternal hepatotoxicity; congenital defects	Contraindicated
Trimethoprim- sulfamethoxazole (C)	Hemolysis in G6PD-deficient patients; risk of kernicterus	Contraindicated at term
Vancomycin (C)	Potential fetal ototoxicity, nephrotoxicity	Avoid in pregnancy

mended. Tocolytics have a several side effects and have not been shown to improve outcome when used prophylactically. Tocolytics are best employed to treat active uterine irritability. Uterine irritability can also be reduced by controlling maternal pain and anxiety.¹²⁶

Laparoscopic Surgery in Pregnant Patients

The role of laparoscopic surgery in the management of pregnant patients remains to be established. Most current recommendations are based on retrospective and animal studies. Laparoscopy would appear to offer some significant benefits. For example, it leads to rapid postoperative recovery and mobilization and thus reduces the risk of thromboembolism associated with pregnancy. Hospital stays are shorter and hospital costs lower.¹²⁷ Often, less narcotic analgesia is required during recovery, and fetal depression from narcotic exposure is thereby minimized. Because laparoscopic surgery makes use of smaller incisions, incisional hernias are less common, and there is less incision-related discomfort as a result of the growing uterus and increasing intra-abdominal pressure.¹²⁵ Moreover, laparoscopic surgery involves less manipulation of the uterus and so may be less likely to induce uterine irritability, preterm

labor, premature delivery, or spontaneous abortion.⁴² Finally, when the diagnosis is uncertain, the surgeon can often use laparoscopy to identify appendicitis, ovarian masses, ovarian torsion, and ectopic pregnancy.

Pregnancy adds a level of risk to any laparoscopic procedure. Insufflation with CO₂ and increased intra-abdominal pressure lead to decreased uterine blood flow, decreased maternal vena cava return, and decreased maternal functional residual capacity.^{75,126} The combination of CO₂ pneumoperitoneum, the reverse Trendelenburg position, general anesthesia, and aorto-caval compression by the gravid uterus can decrease maternal cardiac output by 50%.¹²⁷ Animal studies suggest that CO₂ pneumoperitoneum may also cause an increase in maternal arterial CO₂ tension (P_aCO₂), resulting in maternal and fetal acidosis¹²⁸; however, there is active controversy as to whether these intraoperative alterations caused by CO₂ pneumoperitoneum actually affect fetal health.¹²⁹ Finally, when laparoscopic surgery is performed in a pregnant patient, the uterus is susceptible to direct damage, irritation, or penetration by a Veress needle or trocar.¹³⁰

Certain precautions can be taken to limit the risks associated with laparoscopic surgery during pregnancy.¹²⁵ Using the Trendelenburg position (or minimizing use of the reverse

Trendelenburg position) and left uterine displacement enhance venous return. Keeping intra-abdominal pressure below 15 mm Hg can minimize the decreases in uterine blood flow, maternal inferior vena cava return, and maternal functional residual capacity. Limiting the duration of insufflation minimizes the risks associated with CO₂ pneumoperitoneum. During laparoscopy, a transvaginal Doppler transducer should be used for fetal monitoring when possible; any signs of distress can be combated by decreasing intra-abdominal pressure and hyperventilating the mother. Standard noninvasive monitoring methods (e.g., capnography) are sufficient guides to P_aCO₂ values in routine cases.¹³¹ Ventilation should be adjusted in accordance with maternal P_aCO₂ levels. Finally, penetrating injury to the uterus can be minimized by entering the abdomen under direct vision and applying upward countertraction of the abdominal wall while placing a Hasson trocar.⁴²

Currently, the general tendency is to limit laparoscopic surgery in pregnant women to the first 28 weeks of gestation. Later in pregnancy, when the uterus is no longer confined within the pelvis and the lower abdomen, laparoscopic surgery becomes substantially more difficult. Although laparoscopic surgery, like laparotomy, increases the likelihood of preterm labor, tocolytics should be administered only in the event of documented or perceived contractions; given the side effects of tocolytics, their prophylactic use is more worrisome than the potential risk of preterm contractions.⁷⁴

When appropriate precautions are employed, laparoscopy poses no more risk to either the mother or the fetus than laparotomy does.^{72,130,132} Again, there are no significant differences between the two approaches with respect to preterm delivery rate, birth weight, Apgar score, growth restriction, infant mortality, or risk of fetal malformation.^{74,126}

Cardiovascular Conditions during Pregnancy

CARDIAC DISEASE

The incidence of heart disease during pregnancy is 1.5%, with rheumatic heart disease accounting for 60% to 75% of cases.¹³³ The current trend in the United States, however, is that fewer pregnant women are presenting with rheumatic heart disease and more are presenting with congenital heart disease.¹¹² Heart disease becomes an active issue during pregnancy because gestation places great stress on the cardiovascular system: cardiac output increases by 30% to 50%, HR by 15 to 20 beats/min, and plasma volume by 50%. Delivery places added stress on the heart as a result of physical exertion, pain, and drastic fluid shifts. There is some blood loss with delivery, but there is also an increase in venous return resulting from the release of the pressure imposed by the gravid uterus on the inferior vena cava. In addition, excess extracellular fluid is drawn into the vasculature after delivery. If the diseased heart has little reserve, pregnancy can push the patient into florid heart failure. Recognition of heart failure may be delayed because normal pregnant patients typically present with peripheral edema, dyspnea, and poor exercise tolerance.

The most common indication for cardiac surgery during pregnancy is native valve disease (36%),¹³⁴ of which mitral stenosis is the variety most commonly encountered. Progressive failure from mitral stenosis can cause arrhythmias that exacerbate symptoms. Pregnant women with aortic stenosis or hypertrophic cardiomyopathy may experience angina and syncope in addition to heart failure, and they tolerate arrhythmias

poorly. Aortic disease is the second most common indication for cardiac surgery during pregnancy (31%). Aortic dissection and aneurysm are associated with hypertension, atherosclerosis, and connective tissue disorders (e.g., Marfan syndrome and Ehlers-Danlos syndrome). Approximately 50% of all aortic dissections in women younger than 40 years occur during pregnancy. Other indications for cardiac surgery during pregnancy are prosthetic valve dysfunction (14%), congenital anomalies (e.g., atrial and ventricular septal defects) (7%), pulmonary embolism (6%), cardiac tumors (4%), and coronary artery disease (2%). Overall, cardiac surgery is associated with a maternal mortality of 0% to 3% and a fetal mortality of 12% to 20%.^{133,135} The outcome of a cardiovascular operation performed in a pregnant patient is affected by the indication for surgery, the condition of the mother, and the timing of the procedure in relation to the gestational age.¹³⁶

Management

Ideally, women of childbearing age who have heart disease should receive counseling before planned conception. Such counseling should address the risks of pregnancy, the issues related to anticoagulation, and the fetal mortality and morbidity associated with specific clinical situations. Any significant congenital heart condition should be corrected before pregnancy if possible. Vigilance for symptoms of heart failure should be an adjunct to routine prenatal care¹³⁷; if signs of failure develop, the patient should be hospitalized for treatment of volume overload, tachycardia, and possible arrhythmias.¹³⁸ If aortic dissection is noted, hypertension should be controlled.

The question of the optimal timing of cardiac surgery during pregnancy introduces a potential maternal-fetal conflict of interest. On one hand, maternal mortality from cardiac surgery is lowest in the first trimester; delaying operative treatment increases maternal mortality substantially.¹³⁴ On the other hand, fetal mortality and morbidity from cardiac surgery are highest in the first trimester and decrease as gestation progresses. Hence, the issue of how to time surgical management so as to safeguard both mother and fetus as well as possible is still the subject of some debate. In general, operative intervention should be delayed until the fetus is deliverable, at which time cesarean section can be performed, followed by cardiac surgery or aortic surgery.^{133,139} If it is necessary to perform a cardiac operation during the first or second trimester, precautions should be taken to minimize the effects of bypass on the fetus. High-flow, high-pressure bypass is favored by most surgeons, the rationale being that high rates are necessary during pregnancy to ensure perfusion to the fetus, especially in the context of a contracting uterus. Cardiotocographic monitoring should be instituted to measure the level of fetal stress during bypass. Bypass causes uterine contractions through dilution of progesterone, a natural inhibitor of uterine contractions. Patients with documented contractions should receive tocolytics.

Finally, any pregnant woman undergoing cardiac surgery should receive antibiotics as prophylaxis against endocarditis, the most lethal complication of such procedures.¹³⁴

SPLENIC ARTERY ANEURYSMS

Splenic artery aneurysms are rare, with an incidence of less than 1%. They are, however, four times more common in women than in men, and 25% of all splenic artery ruptures in women occur during pregnancy. Several factors contribute to the relatively high incidence of such rupture in pregnant women. Splenic arterial pressure is unusually high during preg-

nancy as a result of the increased cardiac output, the increased blood volume, and the pressure placed on the abdominal aorta and the iliac arteries by the gravid uterus. Pregnancy is also believed to break down the connective tissue component of the arterial wall. Multiparous women in the third trimester are at highest risk for a ruptured splenic artery aneurysm. In the non-pregnant population, splenic artery rupture is associated with a 25% mortality; however, in pregnant women, it is associated with maternal and fetal mortalities ranging from 75% to 95%,¹⁴⁰ mainly as a consequence of erroneous diagnosis. Upon diagnosis of rupture, immediate operative repair is necessary. If a splenic artery aneurysm larger than 2 cm is found in a woman of childbearing age, elective resection is indicated.¹⁴¹

RENAL ARTERY ANEURYSMS

Renal artery aneurysms are uncommon, appearing in 0.09% of the population; most are diagnosed incidentally in the course of CT scanning done for other indications. Renal artery aneurysms not only are associated with brittle hypertension but also carry a high mortality when they rupture. Because of the connective tissue laxity that develops during pregnancy, the risk of rupture is higher in pregnant than in nonpregnant women. When renal artery rupture occurs, immediate operative repair of the aneurysm is necessary. The most important indication for surgery in this situation is hypertension and female gender; the size of the aneurysm is a secondary concern.¹⁴²

Malignancies during Pregnancy

Cancer during pregnancy occurs in 0.07% to 0.1% of births.¹⁴³ The types most commonly encountered in this setting are breast cancer (19%), thyroid cancer (17%), cervical cancer (11%), Hodgkin disease (7%), and ovarian cancer (6%).¹⁴⁴ All cancers except for melanoma and hematologic tumors metastasize to the placenta but not to the fetus.^{145,146} The major risk factor for malignancy during pregnancy is age greater than 40 years. Pregnant women with malignancies are more likely to experience complicated hospitalizations, as are their babies. Malignancy during pregnancy also increases the chances of low birth weight and premature labor.¹⁴⁴

The measures commonly employed to treat cancer—surgery, irradiation, and chemotherapy—all pose significant risks to the fetus, especially in the first trimester. The degree of risk associated with operation depends not only on the gestational age but also on the disease, the stage of the cancer, and the nature of the procedure. Chemotherapy during the first trimester can cause fetal malformations, premature delivery, and restricted fetal growth in as many as 25% of cases; however, chemotherapy during the second and third trimester generally has a favorable long-term outcome.¹⁴⁷ Finally, any radiation therapy administered is likely to exceed the safety threshold for fetal radiation exposure.

Thus, treatment of cancer in a pregnant woman should involve close coordination between the oncology team, the obstetrician, and possibly a neonatologist. The patient must be well informed regarding the overall risks of treatment, the specific risks to herself if some components of therapy are delayed, and the specific risks to the fetus associated with each type of therapy.

BREAST CANCER

Pregnancy-associated breast cancer is defined as cancer diagnosed during pregnancy or up to 1 year after delivery.

Pregnancy-associated breast cancer is associated with a worse outcome than other types of breast cancer are. The poorer prognosis may be attributable to aggressive tumor growth in response to hormones of pregnancy. In addition, diagnosis of pregnancy-associated breast cancer is often delayed because of the normal hypertrophic thickening of the breast during pregnancy, the inability of mammography and ultrasonography to differentiate between normal breasts and breasts with malignancies in pregnant women, or the reluctance of surgeons to perform biopsies during pregnancy.¹⁴⁸

Management

Any suspicious breast mass should be aspirated to rule out the possibility that it is a cyst. If the mass disappears after aspiration, follow-up via physical examination is appropriate; mammography is not advisable, because it may damage the fetus. If the mass does not resolve, a core-needle biopsy or an open biopsy with local anesthesia should be performed [see 3:5 Breast Procedures], regardless of the stage of pregnancy. Strict attention to hemostasis and to ligation of obvious ductules is necessary to prevent postoperative hematoma or leakage of milk. Another common presentation is nipple discharge [see 3:1 Breast Complaints], which may signal a papilloma or duct ectasia and thus calls for biopsy. Inflammatory changes in breast skin are generally caused by staphylococcal or streptococcal infections; they occur most frequently in the postpartum period but also are occasionally seen during pregnancy. If inflammation does not resolve rapidly after antibiotics are administered, drainage is indicated and biopsy should be considered.

Management of breast cancer in pregnant patients does not vary greatly from that in nonpregnant patients.¹⁴⁹ Once the diagnosis of breast cancer is made, modified radical mastectomy [see 3:5 Breast Procedures] should be done expeditiously; it should not be delayed because of the pregnancy.¹⁴⁸ Given the high doses required, radiation therapy is contraindicated during pregnancy. Accordingly, lumpectomy with radiation therapy is an option only if radiation therapy can commence after delivery. As noted, chemotherapy is relatively safe during the second and third trimesters. For patients with stage III or IV breast cancer, termination of pregnancy may be considered to allow unrestricted treatment with chemotherapy and radiation. For all patients, treatment plans should be formulated on an individual basis, taking into account the risks facing both the fetus and the mother.

Burns during Pregnancy

Burns occurring during pregnancy should be evaluated in the same manner as burns occurring in the nonpregnant population [see 7 Trauma and Thermal Injury]. The total body surface (TBS) burned should be measured and documented (ideally with photographs). Adjustments must be made for the increased abdominal surface area seen in the later stages of gestation. Fetal outcome is dependent on the mother's condition: fetal mortality is 89% when the mother has burns over more than 50% of her TBS but falls to 21% when the mother has burns over less than 50% of her TBS.¹⁵⁰

Management

Generally, burns are treated in much the same way in pregnant patients as in nonpregnant patients; however, special attention should be paid to securing the airway and ensuring adequate breathing. Pregnant patients have a lower FRC and

are less able to compensate for hypoxia. Moreover, exposure to burns often puts the mother at risk for carbon monoxide inhalation. The fetus is especially susceptible to carbon monoxide poisoning because fetal hemoglobin has a higher affinity for carbon monoxide than maternal hemoglobin does; thus, carbon monoxide can easily lead to fetal hypoxia.¹⁵¹ Silver sulfadiazine cream should not be used near term because of its association with kernicterus in the infant. Finally, if the fetus is older than 24 weeks and the mother sustains burns over 50% or more of her TBS, cesarean section is indicated.

Electrical accidents are associated with a fetal mortality of 50%. Any woman who has experienced electric shock should undergo serial ultrasonography until delivery. Maternal mortality with such injuries is minimal.

Minor Surgical Problems of Pregnancy

HEARTBURN

Heartburn is a common complaint of pregnancy that results in part from decreased lower esophageal sphincter pressure and regurgitation of stomach contents.¹⁵² An alkaline reflux gastritis may in part be responsible because gastric acidity is decreased in pregnancy. Toward the later part of the pregnancy, 10% to 15% of pregnant women will also manifest severe reflux that is caused by a frank diaphragmatic hiatus hernia.

Management

Antacids containing aluminum hydroxide or magnesium hydroxide, such as Gelusil and Amphojel, should be taken 30 minutes to 1 hour after meals.¹⁰³ Positional changes, such as elevation of the head of the bed and maintenance of an upright posture for several hours after meals, should be encouraged. Chewing gum or sucking on hard candies tends to increase esophageal motility and decrease reflux. In severe cases, sucralfate may be given to soothe and possibly to heal active gastritis and esophagitis. Metoclopramide has also been found to be efficacious in cases of heartburn that is refractory to oral antacids.

CONSTIPATION

Increased levels of sex steroid hormones during pregnancy are thought to produce decreases in smooth muscle motility and subsequent functional decreases in bowel motility. Moreover, the pressure exerted on the bowel by the expanded and displaced uterus is thought to interfere with normal peristaltic activity.

Management

Stressing good bowel care and bowel training is helpful. Nonpharmacologic methods of increasing bowel activity, such as increasing the fiber and roughage in the diet to maximize stool bulk, are also useful. Foods with laxative properties, such as prunes, figs, apples, and citrus fruits, may facilitate stool passage. The patient should take at least eight to 10 extra glasses of fluid a day; water is preferable, but non-caffeine-containing liquids are also acceptable. Increased exercise may help in the passage of stool. A bulk laxative, such as Metamucil, or a stool softener, such as Colace, should be prescribed, regardless of whether the natural roughage foods are effective. Mild laxatives may be given when all other measures are inadequate. Small doses of milk of magnesia and similar osmotic reactive laxatives

are useful. Small amounts of mineral oil may be cautiously administered; prolonged use of mineral oil can cause liver degeneration and interferes with the absorption of fat-soluble vitamins.

HEMORRHOIDS

Nearly 10% of obstetric patients have hemorrhoids at some point during their pregnancy.¹⁵³ The development of hemorrhoids during pregnancy results from the decreased motility and the tendency toward constipation that occur in all pregnancies. These changes lead to straining at stool, during which the shearing force generated in the rectal canal can exacerbate and intensify preexisting hemorrhoid disease. Furthermore, the weight and pressure of the uterus itself tends to decrease venous return and increase the amount of pooling in vascular structures in the lower pelvis.¹⁵⁴ Hemorrhoids can present with itching, bleeding, or severe pain if the hemorrhoids thrombose.

Management

The best method of preventing hemorrhoids is to maintain adequate bowel function; when that is not feasible, the following general measures should be taken:

1. Warm sitz baths
2. A local astringent, such as a Tucks pad or witch hazel
3. Supine positioning with the legs elevated whenever that is possible
4. Manual replacement of the hemorrhoids after each bowel movement, regardless of the pain incurred
5. Astringent suppositories or creams, such as Anusol or Anusol HC
6. Minimization of constipation (see above)

Acutely thrombosed hemorrhoids should be incised with the patient under local anesthesia; the clot should be evacuated, astringent ointments applied, and bowel care resumed. Injection with sclerosing agents is not advisable. The potential for submucosal abscess formation and pelvic sepsis, though small, makes the procedure extremely dangerous.

Surgery is seldom indicated. In a study of 12,455 pregnant women, only 25 required surgical excision of the symptomatic tissue, which was done under local anesthesia. There were no maternal or fetal problems as a result of the procedure.¹⁵⁵ On rare occasions, hemorrhoid banding [see 5:37 Anal Procedures] may be indicated for excessive bleeding. It should be performed very carefully because of the potential for necrosis and infection.

VARICOSE VEINS

Varicosities become a problem with successive pregnancies. They are generally a minor nuisance in the primipara but become more bothersome the more children a woman has. Thrombophlebitis is not uncommon, but embolism is a rare complication. Varicose veins develop in women who are predisposed to this problem as a result of weakness in the valvular structures in the veins. The increased stasis and venous pressure created by the expansion of the uterus leads to progressive enlargement and engorgement of the veins. Besides cosmetic problems, varicosities can cause muscle aching, swelling, and, in severe cases, ulceration.

Management

Increased exercise that includes regular walking and activity is suggested. Elevation of the legs at rest is advised; prolonged

sitting is not. Support stockings and, in poor weather, support panty hose should be used. The stockings should be placed on the legs in the early morning, before substantial pooling has occurred. Injection therapy is contraindicated during pregnancy. Ligation of veins causing ulceration or phlebitis is recommended only in extreme cases. Administration of aspirin or other NSAIDs is also contraindicated. If anticoagulation is necessary, heparin should be given because it does not cause fetal damage and is fairly easily controlled.

DEEP VEIN THROMBOSIS

Pregnant women are more prone to deep vein thrombosis (DVT) [see 6:6 Venous Thromboembolism] during the later stages of pregnancy and the early postpartum period, largely because of alterations in the normal blood coagulation system, such as increased levels of clotting factors and decreased fibrinolytic activity. These intrinsic factors may be exacerbated by the venous stasis and increased blood viscosity that occur during pregnancy. Compression of the iliac veins by the growing uterus also predisposes pregnant women to thrombosis. Although venous thrombosis affects only 4.1% of women during pregnancy,¹⁵⁶ recognition and management of the disorder are important to prevent the potentially life-threatening sequelae of pulmonary embolism.

Leg swelling and prominent superficial veins are common in pregnancy and may delay the diagnosis of DVT. Phlebography is the most accurate, operator-independent study available for confirmation of DVT. Because the iliofemoral system is the most common site of DVT, it is crucial that it be well visualized; however, this may not be possible with the fetus shielded. Serial impedance plethysmography may be effective in diagnosing DVT while eliminating exposure of the fetus to radiation.¹⁵⁷ Doppler ultrasonography is relatively ineffective in predicting isolated pelvic thrombosis but may be attempted. Real-time B-mode ultrasonography is an extremely sensitive examination that is useful in detecting DVT. This technique achieves good visualization of venous thrombi within vessels; however, although it can readily visualize clots in leg veins, it is less specific above the inguinal ligament. Noninvasive screening is not useful during pregnancy because of the high false positive and false negative rates; it is not uncommon for DVT to occur immediately after a screening examination. Any signs or symptoms of DVT or pulmonary embolism are an indication for aggressive testing.¹⁵⁶ Radioactive fibrinogen should not be used near term, because of the potential hazard to the fetal thyroid.

Management

When the diagnosis is made, therapy with a low-molecular-weight heparin (LMWH) should be instituted for the duration of pregnancy, with postpartum anticoagulation, in the form of an LMWH or warfarin, continued for 6 weeks. LMWH doses should be adjusted according to weight and thus may increase throughout pregnancy and decrease after delivery. Unfractionated heparin can also be used during pregnancy. Current experience with LMWHs suggests that they are as efficacious and safe as unfractionated heparin.^{158,159} In addition, LMWHs have certain advantages over unfractionated heparin: once-daily or twice-daily subcutaneous administration, a predictable dose response, reduced passage across the placenta, and lower incidences of heparin-induced thrombocytopenia and heparin-induced osteoporosis. Warfarin should not ordinarily be given for maintenance anticoagulation: it has teratogenic potential during the first trimester and may induce bleeding during the later part of pregnancy.¹⁶⁰

Prophylaxis of DVT is recommended for subsequent pregnancies. For most women, 4 to 6 weeks of postpartum anticoagulation with an LMWH followed by warfarin is sufficient.^{161,162} For patients who are at high risk for DVT because of inherited thrombophilia, DVT outside of pregnancy, multiple episodes of DVT, morbid obesity, or prolonged bed rest, prophylactic anticoagulation may be necessary both ante partum and post partum. When surgery is planned during pregnancy, patients should be fitted with graded compression boots beforehand and should continue to wear them until they are ambulating regularly. Ambulation should commence on the night of the operation whenever possible.

ROUND LIGAMENT PAIN

The general surgeon is occasionally asked to evaluate the pregnant woman in the late stages of her pregnancy with a possible inguinal hernia. Groin hernia in the pregnant patient is extremely uncommon because the expanded uterus acts as a shield against the abdominal wall, preventing incarceration or strangulation of bowel contents. Groin pain is generally caused by excessive traction on the round ligament, usually on the left, during the later part of pregnancy. As the uterus rotates and the patient's position changes, this pain can become quite severe.

Treatment

Local heat and abdominal support are the mainstays of treatment. Positional changes are necessary, and the patient should rest in the supine position.

4 ORGAN PROCUREMENT

Sander S. Florman, M.D., Thomas E. Starzl, M.D., and Charles M. Miller, M.D.

Competent procurement of organs, both from cadaveric and living donors, is critical to the overall success of transplantation. This process includes not only the donor operation itself but also the evaluation of donors and potential recipients. Donors often have comorbid conditions, and not every organ is suitable for every recipient. Experience is probably the single most important factor for success. Organ procurement involves complex decision-making skills as well as a certain degree of technical expertise, particularly when multiple organs are to be utilized from a single donor. With the expansion of living donor options, judgment and skill are more vital than ever for achieving successful outcomes.

Many advances in organ donation have been made since the early 1990s. In particular, surgical techniques have been greatly refined. Not long ago, it was generally believed that a pancreas and a liver could not be procured for transplantation from the same donor. It is now even possible to take the heart, one or both lungs, the kidneys, the liver (whole or split), the pancreas, and the intestines from one donor and then to transplant them into as many as nine recipients at multiple transplant centers.¹ Currently, procuring multiple organs from a single donor is the rule rather than the exception. In addition, nonvascularized tissues (e.g., bones, corneas, blood vessels, valves, and skin) can be harvested and used to help many more patients. These advances in technique notwithstanding, arguably the most important advance in modern transplantation is the widespread use of University of Wisconsin (UW) preservation solution, which has improved the safety of organ preservation and relaxed the time constraints on the transplantation of all organs.

As outcomes after transplantation improve, the demand for transplantable organs continues to far exceed the supply. As of spring 2002, more than 79,000 people in the United States were on waiting lists for kidney, pancreas, heart, liver, or intestinal transplantation.² In response to this shortage, surgeons have sought to stretch the limits of the cadaveric donor pool by turning to extended-criteria donors. Use of older donors and donors with significant comorbidities (e.g., diabetes, hypertension, hepatitis B, hepatitis C, and steatosis) is now common.³ Many centers use hearts from 60-year-old donors⁴ and livers from donors in their 70s or even 80s,⁵ and some use organs from non-heart-beating donors.⁶ Kidneys from pediatric donors that previously would have gone unused now are often procured en bloc (i.e., together with a common patch of aorta and vena cava) for use in a single adult⁷; some centers even transplant two older adult kidneys into a single adult recipient.⁸ Transplant surgeons now routinely split livers for use in multiple recipients. In some cases, organs from marginal donors (e.g., those who are receiving significant amounts of vasopressors or who experienced prolonged anoxia before resuscitation) are given as a last resort to patients who would die without an immediate transplant. Occasionally, certain organs from donors who had renal failure or were themselves transplant recipients may even be usable.

Although, to some extent, the use of extended-criteria cadaveric organ donors has helped offset the disparity between the available cadaveric donors and the ever-growing list of candidates for transplantation, this measure clearly falls far short of meeting the demand. If the donor pool is to be maintained and expanded, greater awareness on the part of potential donors is crucial. The public should be encouraged not only to sign the backs of driver's licenses or to enroll in their state's donor registry but also, more important, to discuss individual wishes for organ donation with families and loved ones.

Efforts to increase donor awareness, though important, have not sufficed by themselves. As transplant waiting lists grow longer, transplant programs have also begun to alleviate the organ shortage by applying living donor transplantation more broadly. Kidneys have been taken from living donors for many years; however, technological advances—in particular, laparoscopic donor nephrectomy—have now made living donation even more appealing. Since the early 1990s, segmental livers from living donors have been used with great success in pediatric recipients, and more recently, good results have been reported from transplantation of right or left lobes into adult recipients.⁹ A few centers have even performed pancreas, intestinal, and lung transplants from living donors.¹⁰⁻¹² These procedures, though technically feasible, raise new ethical and philosophical issues and dilemmas.

In what follows, we outline the current state of organ procurement. With xenotransplantation still experimental and fraught with complex infectious and immunologic problems, procurement from cadaveric and live donors remains the cornerstone of transplantation at present. Cadaveric and live organ donors are discussed separately because donor evaluation, perioperative management, and the donor procedures themselves differ dramatically between the two groups.

Organ Procurement from Cadaveric Donors

POTENTIAL CADAVERIC DONORS

A patient does not become a potential organ donor until all attempts to save his or her life have failed. When a patient presents with a severe neurologic insult, all efforts should be directed at minimizing cerebral swelling and preventing brain herniation. This is often best accomplished by fluid restriction, hyperventilation, administration of diuretics as BP permits, and other therapies aimed at limiting cerebral edema. With advances in trauma management [see 7:2 *Injuries to the Central Nervous System*] and critical care, more patients survive their initial insults.

A neurologist, a neurosurgeon, or both should be involved in the management of any patient who has incurred a severe neurologic insult. Such consultation is important for any eventual

diagnosis of brain death, which can be made on clinical criteria alone but is often confirmed by means of electroencephalography (EEG), cerebral blood flow scanning, cerebral angiography, or some combination thereof. Irreversible coma as a criterion for death was defined by the Harvard criteria in 1968¹³ and then refined by the Uniform Determination of Death Act in 1981.¹⁴ The determination of death must include irreversible cessation of cardiopulmonary functions, neurologic functions, or both. Brain-dead patients have fixed, dilated pupils and lack protective corneal reflexes. Spinal reflexes, which do not involve the higher centers of the brain or the brain stem, may still be present. Spontaneous movements, known as Lazarus signs, occasionally occur as a consequence of primitive spinal reflex arcs. Donor surgeons should confirm that the clinical criteria of brain death have been documented appropriately. Individual hospitals and states may have different criteria for the declaration of brain death. Coma and brain death are discussed more fully elsewhere [see 8:11 *Coma, Cognitive Impairment, and Seizures*].

In 1998, the Department of Health and Human Services issued a rule that requires hospitals that participate in Medicare to report all hospital deaths and imminent deaths to their local organ procurement organization (OPO) in a timely manner.¹⁵ The OPO then evaluates the patient's potential for organ donation, assists in the administrative details necessary for the declaration of death, and acts as intermediary between the hospital (including the nurses and physicians) and the donor's family.

In general, health care workers involved in the care of the patient should not approach the family regarding donation, so as to avoid even the insinuation of complicity in the donation process. Thus, the medical care of the patient is kept separate from the process of organ donation. Furthermore, success at obtaining consent for donation from next-of-kin is considerably more likely when the person requesting consent has undergone specialized training.¹⁶

Once brain death has been declared and the decision has been made to proceed with organ donation, management of the donor is redirected toward optimizing potentially salvageable organs, a process that often necessitates aggressive fluid resuscitation.

It is imperative for health care providers to remember that whereas donors are not salvageable, dying patients are waiting for transplants, and their lives depend on the quality of the donated organs. Good donor management with careful attention to details (e.g., sterile technique, antibiosis, timely transfusion, and vasopressor management) is vital for achieving optimal outcomes from transplantation. In addition, it is important to demonstrate to health care workers, lay people, and donor families that donors are treated with respect and dignity. To transplant recipients and their medical caregivers, donors and their families are heroes.

Non-Heart-Beating Donors

The use of non-heart-beating donors is a relatively new concept in organ procurement. Historically, cadaveric organ donors were patients who had suffered an irreversible neurologic insult (e.g., head trauma, stroke, drug overdoses, or asphyxiation) and were declared brain-dead on life support. There are, however, many patients who do not meet the criteria for brain death but nevertheless have irreversible injuries. Faced with the severe shortage of organs for transplantation, many centers have established protocols by which such patients can be organ donors if their families consent. In the case of a "controlled" non-heart-beating donor, the patient is hospitalized and on life support.

Cannulas are placed, usually in the femoral vessels (so that the organs can be quickly flushed *in situ* with cold UW solution after death), life support is discontinued, the heart is allowed to stop, and the patient dies. In the case of an "uncontrolled" non-heart-beating donor, cardiac arrest has occurred before the cannulas are placed.⁶

COORDINATION OF DONOR AND RECIPIENT ACTIVITIES

After a potential donor has been identified, the donor coordinator from the local OPO obtains a detailed medical and social history. Potential organ recipients are categorized according to (1) ABO blood group, (2) degree of medical urgency, (3) length of time the patient has been on the transplant list (i.e., waiting time), (4) weight, (5) acceptable weight range of the donor, and (6) distance the recipient team is willing to travel for procurement. The donor's acute physiologic status is assessed on the basis of BP (an arterial line is placed if not already present), central venous pressure (CVP), urine output, arterial blood gas values, and blood chemistry. Serologic analysis must be done for syphilis (Venereal Disease Research Laboratory [VDRL]), hepatitis B surface antigen (HBsAg), hepatitis B core antibody (HBcAb), hepatitis C virus (HCV), cytomegalovirus (CMV), human immunodeficiency virus (HIV), and human T cell lymphotropic virus type I (HTLV-1). In certain cases (e.g., kidney, pancreas, and intestinal transplants), inguinal lymph nodes must be removed through a small groin incision at the bedside to facilitate tissue typing, which takes an average of 4 hours. For kidneys in particular, genetic matching of donor and recipient has been shown to improve outcome.¹⁷

After the potential organ donor has been studied and stabilized, the OPO coordinator contacts local and regional transplant programs about their needs for renal and extrarenal organs. The United Network for Organ Sharing (UNOS) maintains a national computer registry of potential recipients for all organs (<http://www.unos.org.org>).

Sharing of all organs is based on the principle that organs should be offered first to patients in the local area and then to patients within a larger geographic region. (The United States has been divided by UNOS into 11 geographic regions for distribution of organs.) If no suitable recipient can be found locally or within the UNOS region, the organ is offered to patients across the nation. An exception to this rule exists for kidneys. For kidneys, when there is a six-antigen match (i.e., a perfect histocompatibility match between a donor and a recipient on all six HLA-A, HLA-B, and HLA-DR antigens) or when there is at least phenotypic identity between a donor and a prospective recipient (i.e., no HLA mismatch), the kidney must be offered to the matched recipient regardless of geographic location.

Specific medical criteria for prioritizing patients on the waiting lists for various organs are described elsewhere.² The system for distributing livers changed in spring 2002 from one that gave significant weight to waiting time to one that stratified patients according to medical urgency.¹⁸ This new system has dramatically changed the way in which cadaveric livers are allocated and will undoubtedly have significant implications.

Once organs are matched to specific recipients, the local OPO procurement coordinator arranges an OR time for the donor procedure and organizes the arrivals of the participating surgical teams. Multiple-organ harvests require considerable coordination between the different institutions, surgeons, and coordinators. In the meantime, it is important that the donor be kept hemodynamically stable [see Cadaveric Donor Operation, *below*]. With the proliferation of experienced transplant centers, it has become

common for most organs to be procured by local procurement teams and shipped to the recipient institutions. This collaboration has improved the coordination of the retrieval process, reduced the transportation costs associated with long-distance procurements, and helped ease the burden on the recipient teams. Certain organs, such as hearts, intestines, and multivisceral grafts, are still generally procured by the recipient institution.

EVALUATION OF DONOR ORGANS

Donors are initially evaluated by the recipient surgeon on the basis of verbal reports of laboratory results and recent medical histories; however, the decision whether to use an organ ultimately depends on an experienced transplant surgeon's evaluation of the organ during the procurement procedure and on his or her knowledge of the potential recipient's medical status. Donor selection criteria vary for each organ and often vary by transplant center as well. Once-traditional limits are no longer absolute.

Liver

For livers, the results of liver function tests, including serum aspartate aminotransferase (AST), serum alanine aminotransferase (ALT), and bilirubin levels, should ideally be within normal ranges. Sometimes, depending on the donor's cause of death and degree of anoxia, test results are abnormal but improve with good resuscitation, in which case the liver may still be usable for transplantation. A history of hepatitis or alcoholism is a warning sign but not necessarily a contraindication to liver donation. Morbid obesity can pose problems for liver recovery: there is a high likelihood of macrovesicular steatosis, which increases the risk of primary nonfunction of the liver in the recipient. Microvesicular steatosis, on the other hand, is often the result of acute injury and is reversible; even significant degrees of microvesicular steatosis are generally not problematic.¹⁹ A percutaneous liver biopsy performed at the bedside may help prevent unnecessary donor laparotomies.

The relative sizes of the donor and the recipient must be taken into account. Advanced surgical techniques allow the liver to be split along anatomic divisions [see 5:23 *Hepatic Resection*] so that portions of a single organ can be used in multiple recipients or so that the liver can be cut down to fit into a smaller recipient. Size is a particular concern in pediatric liver transplantation. Because small baby donor organs are relatively scarce, most pediatric centers obtain appropriately sized livers for their patients by performing right hepatic lobectomies or trisegmentectomies on adult cadaver organs and implanting the left lobe or the left lateral segment, depending on the size-matching between donor and recipient. In most cases, the remaining portion of the liver should be used in another recipient.

Kidneys

Several clinical factors and laboratory test results may be useful for the evaluation of potential kidney donors. As with all transplantable organs, a prolonged donor down time with a significant degree of anoxia is undesirable. A history of diabetes, hypertension, or both in the donor may preclude the use of the kidneys for transplantation. The serum creatinine concentration and (perhaps more important) the creatinine clearance are vital markers of kidney function. Certain comorbid conditions (e.g., hypercholesterolemia and obesity) are less important determinants of utility with kidneys than they are with livers. Kidney biopsies can be very helpful and are frequently performed, particularly in older donors.

Heart and Lung

The criteria for heart and lung donors are generally more strict than those for liver and kidney donors. Donors are usually younger, with no history of cardiac disease and a reasonably normal chest x-ray and electrocardiogram (ECG). They are closely matched to recipients with respect to height, weight, and chest circumference. Echocardiography is useful for evaluating cardiac wall motion and can play a key role in the decision whether to use the heart for transplantation. For certain potential donors, coronary angiography is necessary. In general, the donor's heart should be slightly larger than the recipient's, because recipients often have cardiomegaly. The arterial oxygen tension (P_aO_2) of lung donors should be at least 350 mm Hg during ventilation, with a fraction of inspired oxygen (F_iO_2) of 1. In addition, bronchoscopy is frequently useful in evaluation of lungs for donation.

Pancreas

Pancreas donors are generally younger than kidney or liver donors. Because pancreas transplantation, like kidney transplantation, is not lifesaving, pancreas donors tend to be chosen more discriminately. Clearly, diabetes is an absolute contraindication to donation. Alcohol use and obesity are relative contraindications. Laboratory tests for amylase and lipase may be useful. The gross appearance of the pancreas in the donor is extremely important in determining its suitability for transplantation. In view of the increasing success of islet cell isolation techniques, pancreata that are not used for whole organ transplantation should be used for islet cell transplantation or research.²⁰

Intestine

Intestinal transplantation has been approved by the Health Care Financing Administration (HCFA) and is no longer considered experimental.²¹ Like pancreas and kidney transplantation, however, intestinal transplantation is not considered life-saving (because patients can be supported with parenteral nutrition). Accordingly, intestinal donors are chosen very selectively. The intestine is very sensitive to insult, particularly from hypotension; furthermore, many agents commonly used to support hypotensive donors cause mesenteric vasoconstriction, thereby limiting blood flow to the intestines. Size matching is extremely important in intestinal transplantation: results are very poor when the graft is too large and the abdomen cannot be closed primarily. Ideally, the donor should be 60% to 70% of the recipient's size. Because ischemia times must be kept short, HLA matching is rarely possible in this setting, and any potential benefit remains theoretical. Nevertheless, the crossmatch should be negative, particularly in isolated intestinal transplant cases. In addition, as in heart transplantation, it is often necessary to begin the recipient operation before the donor operation is completed so as to minimize ischemia times.

PERIOPERATIVE MANAGEMENT

Regardless of which organs are to be procured, the donor must be maintained in a stable physiologic state during the evaluation. Basic monitoring should include an arterial line for BP monitoring and blood gas surveillance, a central venous line for CVP monitoring, and an indwelling urinary catheter for measuring urine output. Because the basic physiologic situation rarely, if ever, improves in brain-dead patients, the interval between the pronouncement of death and the donor procedure should be kept as short as possible. Unstable donors should be managed aggressively, with treatment directed at maintaining

adequate circulation, ventilation, and diuresis. Donors are often dehydrated from earlier efforts to prevent or reduce cerebral edema, in which case rapid repletion of intravascular volume is required. Not infrequently, donors require blood transfusions.

Brain death is often associated with severe neurogenic shock and peripheral vasodilation. As a result, peripheral vascular resistance is often insufficient to support a normal BP, regardless of how well volume-loaded the patient may be. In such cases, vasoconstrictor support is required. Because many vasopressors produce severe visceral, renal, or mesenteric vasoconstriction, they should be used judiciously so as not to injure the transplantable organs. With severe brain trauma or anoxia, pituitary function often fails. The resulting absence of antidiuretic hormone (ADH) causes diabetes insipidus, and a large-volume diuresis ensues, which can lead to severe volume depletion and donor instability. Initial therapy for diabetes insipidus includes intravenous replacement of urine output with 0.5 N saline. Hypernatremia may develop (sometimes quite rapidly); electrolyte levels should be monitored frequently. If fluid replacement cannot keep up with the diuresis, I.V. vasopressin may be given.

Before the donor is brought to the OR, the procurement teams should review the donor's chart in the ICU. Both the declaration of brain death and the consent for organ donation should have been signed and included in the chart. In addition, blood type, serologies, and laboratory test results should be confirmed. Many donors are lost during transport to the OR, generally as a result of human error. It is important to ensure that vasoactive drips and the oxygen tank are full and running. In the OR, the anesthetic team begins to participate in donor management. As noted, spinal reflexes often persist in the donor; they can be controlled by administering a muscle relaxant (e.g., pancuronium bromide).

The surgeons performing the donor procedure should bear in mind that funeral personnel will need to work with the cadavers after the operation and that many donor families will want open-casket funeral services. Embalming requires cannulation of the femoral vessels; accordingly, it is important that these vessels, as well as the aortic arch vessels, be ligated during the donor procedure.

CADAVERIC DONOR OPERATION

The operation for multiple organ procurement must proceed in such a way that all of the transplantable organs can be removed without any of them being jeopardized. There are as many ways to perform donor operations as there are surgeons doing them. In general, however, regardless of which organs are to be procured, the operation includes a preliminary dissection of the great vessels of the abdomen and the chest. The aorta is isolated at preplanned levels to allow cross-clamping, so that the organs to be removed can be core-cooled *in situ* with cold intra-aortic and intraportal infusions, thereby avoiding warm ischemia. This technique has been adopted as an international standard.

The most refined version of *in situ* core cooling, commonly known as the rapid-flush technique, can be completed from beginning to end in less than 1 hour.²² The rapid-flush technique is the procedure of choice in unstable or non-heart-beating donors. With this approach, no dissection is done until after circulatory arrest and *in situ* core cooling of the organs, at which point all that is required is rapid dissection and subsequent cannulation of the infrarenal aorta. Some surgeons perform all of their organ procurements with this method. Its major drawbacks are (1) that most of the dissection is done in bloodless organs

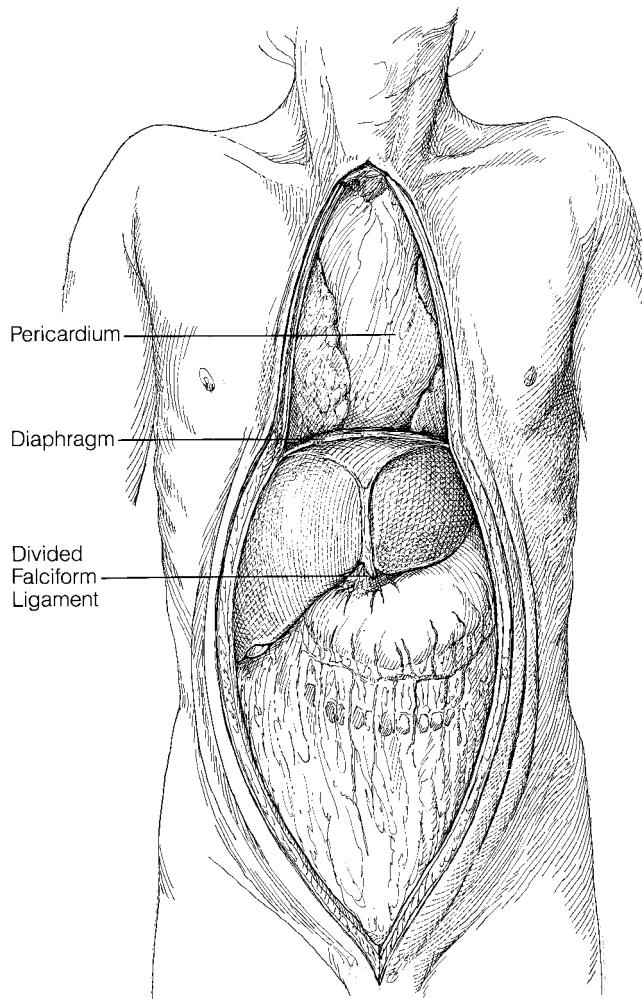

Figure 1 The incision used for multiple organ procurement is made from the suprasternal notch to the pubis. The falciform ligament is divided and the pericardium opened.

that have been infused with preservative and are uniformly discolored white and (2) that warm ischemia times are generally longer because no preliminary dissection was performed.

The operation begins with a complete midline incision extending from the suprasternal notch to the pubis [see Figure 1]. A sternotomy is performed, and if the heart is to be procured, the pericardium is opened and the heart inspected. A cursory examination of the abdominal and thoracic contents is made, and the organs are evaluated for their quality. It is critical that all occult pathologic conditions be fully investigated; biopsies should be obtained when indicated. The heart should be evaluated with respect to strength of contractions (i.e., snap), donor volume status, and possible cardiac injuries (e.g., contusions). The liver should be examined for contour, color, and consistency, which may provide clues to the degree of fibrosis or steatosis present. The pancreas can be visualized through the lesser sac and should be evaluated for color and fat content. The intestines should be examined for peristalsis and good arterial pulsations in the mesentery, which are reliable indicators of a healthy graft.

The traditional technique (which, as noted, is appropriate only in stable donors) involves significant dissection and is particularly helpful in multiple organ procurement, during which organs must be separated according to their blood supply. Minimal dissection is required to prepare the heart for removal.

The superior vena cava and the aorta are dissected to allow eventual occlusion of the inflow and outflow tracts. The heart team generally completes its preliminary work in roughly 15 minutes. The abdominal teams then proceed; their specific approach is based on the physiologic status of the donor. In hemodynamically stable donors, many surgeons, depending on their experience, prefer to perform varying amounts of dissection before *in situ* flushing, especially when multiple organ procurement is planned. Lengthy preliminary dissections should be avoided, particularly in unstable donors: ischemia during long dissections may cause poor graft function or even graft failure. Occasionally, when the donor has previously undergone a sternotomy and the heart is not being procured for transplant, it may be prudent to perform the sternotomy after the abdominal dissection is complete and the distal aorta has been isolated and cannulated. Although this approach provides more limited exposure at first, it helps ensure that the organs will not be lost should the heart be injured during the reopening of the sternum.

The left triangular ligament of the liver is then divided. In the majority (~67%) of cases, the common hepatic artery arises from the celiac axis. Often, there is aberrant hepatic arterial anatomy, including a left branch (accessory or replaced) that generally comes from the left gastric artery (~15% of cases) and traverses the gastrohepatic ligament; a right branch (accessory or replaced) that generally comes from the superior mesenteric artery (SMA) (~10% of cases) and courses behind the portal vein; or both.²² Identifying anatomic variations early in the pro-

cedure helps minimize the risk of accidental injury to vital structures. Once the gastrohepatic ligament is opened, the esophagus (with a nasogastric tube in place) is retracted to the left with a finger and a longitudinal incision made in the diaphragmatic crura between the retrohepatic inferior vena cava (IVC) and the esophagus [see Figure 2]. The supraceliac aorta is exposed at this level in preparation for later cross-clamping. Alternatively, the aorta can be clamped in the left chest (e.g., in a donor with an abdominal aortic aneurysm or severe abdominal aortic atherosclerosis). At this time, varying amounts of dissection can be completed, depending on which organs are to be procured, the surgeon's preference, and, in particular, the stability of the donor.

During the dissection, the distal abdominal aorta is encircled and the inferior mesenteric artery ligated and divided. Care should be taken in the dissection of the distal aorta to ensure that no accessory renal arteries originate from the proximal common iliac arteries. If such an artery is present or if the distal aorta cannot be cannulated, the distal common iliac artery can be encircled and cannulated. In addition, the inferior mesenteric vein is dissected free and cannulated for a portal flush. Generally, the catheter used for a portal flush is manually directed cephalad into the portal vein itself, unless the pancreas is being procured, in which case the cannula is left within the inferior mesenteric vein.

Once dissection is complete, the donor is systemically heparinized, and after 3 minutes or so, the distal aorta is ligated at the level of the bifurcation and the aortic perfusion cannula inserted and secured in place [see Figure 3]. The abdominal and thoracic teams should coordinate their efforts at this time. Effective circulation is terminated by cross-clamping the aorta at predetermined levels in the chest and in the abdomen [see Figure 4].

Cold UW solution is then instilled through the perfusion cannulas, and sterile ice is placed over all of the abdominal organs. With a pH of 7.4 and an osmolarity of 320 mOsm/L, UW solution maintains the organs' cellular integrity; in addition, it contains antibiotics, antioxidants, and heparin [see Table 1]. Cooling the organs to 4° C slows cellular metabolic functions dramatically; however, it does not arrest them completely, which means that a degree of ischemia occurs during cold storage. Once the aorta is cross-clamped, the clock starts, and all efforts are made to minimize cold ischemia times so as to maximize organ function in the recipient.

The various donor organs differ in their ability to tolerate cold ischemia, and general time limits have been established. Kidneys can be preserved for as long as 72 hours; thus, there is sufficient time for tissue typing and matching, and kidneys can be sent to recipients in distant cities. Nonetheless, when a kidney is stored for more than 24 hours, the chances that it will function immediately in the recipient diminish greatly. The pancreas and the liver may be safely preserved for as long as 20 hours; however, every effort should be made to limit the cold ischemia time to less than 12 hours. The intestine may be preserved for as long as 12 hours, but it should be implanted as soon as possible. For the heart and the lungs, time constraints are more rigid: they should be transplanted within 6 hours of removal from the donor. The accepted time limits, though generally correct, should not be considered absolute. For example, whereas organs from younger donors may tolerate ischemic times closer to the limits, organs from older donors typically will not.

Heart and Lung

After infusion of cold UW solution, the cardiac team proceeds first, removing the heart, the lungs, or both as expeditiously as

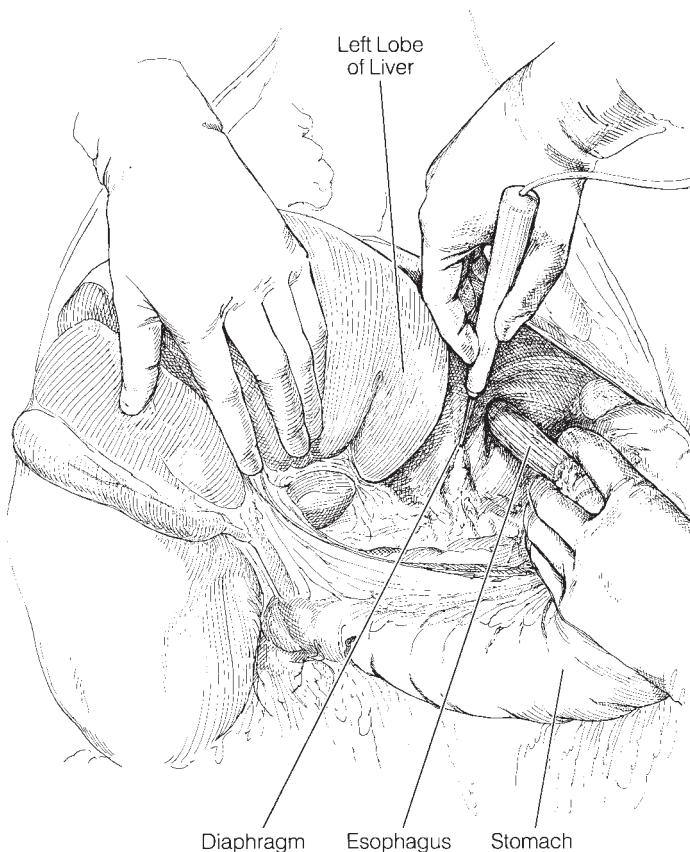

Figure 2 The left triangular and gastrohepatic ligaments are divided so that the left lobe of the liver can be retracted to the right. The diaphragmatic crura are divided between the esophagus and the vena cava to facilitate exposure and encirclement of the aorta at the level of the diaphragm.

Figure 3 The small intestine is reflected, the distal aorta is exposed, and the inferior mesenteric artery is ligated and divided. Catheters are inserted into the inferior mesenteric vein and into the distal aorta.

possible while the abdominal organs are covered with ice slush and perfused with the preservation solution. (As noted, the heart tolerates cold ischemia relatively poorly.) The heart is core-cooled with a potassium-rich cardioplegic solution infused via a cannula inserted into the ascending aorta. Blanching of the heart and cardiac arrest from the cardioplegic infusion occur within a few seconds. At the same time, systemic venous inflow is discontinued by bleeding the IVC into the chest. Care must be taken to leave enough suprahepatic IVC for both the liver and the heart [see Figure 5]. (In the event that the IVC within the pericardium is to be cross-clamped by the cardiothoracic team, the infrahepatic IVC must be vented into the lower abdomen to prevent venous hypertension.) The aorta is divided distal to the innominate artery, and the pulmonary artery is divided at its bifurcation. Most cardiac teams require approximately 10 minutes from the onset of cardioplegic infusion to complete the cardiotomy. The abdominal viscera are blanching and cooling while the cardiac team is completing its procurement.

The operative technique for lung procurement is generally similar to that for heart procurement [see Figure 6]. After mobilization and isolation of the aorta and the superior vena cava, the trachea is dissected as far above the level of the carina as possible. Prostaglandin E₁ (PGE₁) is given via a catheter in the main pulmonary artery, causing pulmonary vasodilation and thereby optimizing lung perfusion. After infusion of PGE₁ and systemic heparinization, the superior vena cava is ligated and divided. The distal ascending aorta is cross-clamped, the cardioplegic infusion is begun, and topical cold ice slurry is placed on the organs. The lungs are inflated, the endotracheal tube is withdrawn, and the trachea is stapled and divided. The posterior pleurae are incised, and the heart and the double-lung complex are removed from the thoracic cavity, taken to the back table, and separated.

Once the thoracic organs have been procured and the abdominal aortic flush completed, the ice is removed from the abdominal cavity—except for some left around the kidneys, which are routinely the last organs to be removed. A patch of diaphragm surrounding the suprahepatic IVC is removed with the liver, with care taken not to cut the esophagus or the aorta on the left side. Subsequent dissection is dictated largely by which organs are to be procured.

Liver, Pancreas, and Intestines

In liver procurement, the diaphragmatic patch is fashioned around the lumen of the suprahepatic IVC. The infrahepatic IVC

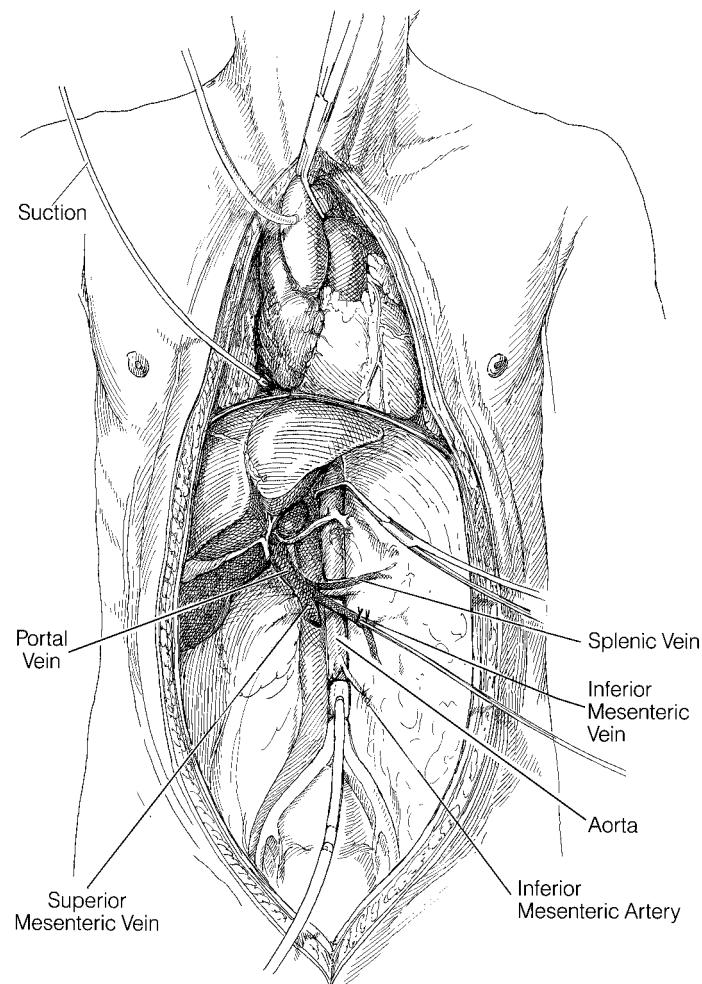

Figure 4 The aorta is cross-clamped at the diaphragmatic level and at the arch level in the chest at the time of rapid infusion.

is divided just above the level of the renal veins, the right adrenal gland is transected, and the liver is excised from any surrounding attachments. The hepatic hilar dissection is then completed. The lesser omentum is incised, and the gastroduodenal artery is identified, ligated, and divided. Care should be taken to ensure that the vessel ligated is truly the gastroduodenal artery and not a low-lying common hepatic artery. The common bile duct is divided close to the duodenum, either before cross-clamping or after the aortic flush, when the organs are cold. The gallbladder is incised and flushed with saline to remove bile from the bile ducts.

Once the gastroduodenal artery has been divided, the portal vein is uncovered posteriorly and followed inferiorly to the junction of the superior mesenteric vein (SMV) and the splenic vein, which are then transected [see Figure 7]. Alternatively, if the pancreas is to be procured, the portal vein is divided approximately 1 to 2 cm above the pancreas so as to leave both the liver and the pancreas with adequate lengths of portal vein. The area posterior to the portal vein must be inspected and divided carefully because it is here that an aberrant right hepatic artery originating from the SMA is most commonly found [see Figure 8]. The celiac axis is traced to its aortic origin and removed with a Carrel patch or a segment of the aorta.

Livers that are to be divided (e.g., into right lobe and left lobe or into right trisegment and left lateral segment) for transplantation into two recipients may be split either *in situ* during procurement or after removal from the donor during a back-table procedure [see Organ Procurement from Living Donors, Living Donor Operation, Liver, below].

The liver is placed in a sterile, empty bag immersed in a basin of ice-slush solution. A cannula may be placed in the SMV or the splenic vein and the liver perfused with additional UW solution. The hepatic artery and the common bile duct are also flushed on the back table. The organ is then packed in the effluent remaining in the bag, placed in an ice-filled cooler, and transported to the recipient hospital, where it is cleaned and prepared for implantation in a formal back-table procedure that takes approximately 30 minutes.

With this technique, removal of a cold and bloodless liver requires 15 to 30 minutes. If the pancreas, the intestines, or both are to be used for transplantation in addition to the liver, it is more efficient to remove the organs en bloc and then separate them on the back table. Simultaneous recovery of a whole pancreas and a whole liver was once considered impossible (because both procedures called for retention of the celiac axis and the portal vein), but safe techniques are now available for dividing the vasculature of these organs. Iliac artery and vein grafts are commonly used as extensions to allow transplantation of multiple abdominal organs from a single donor.

Table 1 Composition of University of Wisconsin (UW) Solution*

Raffinose, 30 mmol/L	Potassium, 125 mmol/L
Lactobionate, 100 mmol/L	Sodium, 125 mmol/L
Hydroxyethyl starch, 50 g/L	Magnesium, 5 mmol/L
Sulfate, 5 mmol/L	Adenosine, 5 mmol/L
Phosphate, 25 mmol/L	Glutathione, 3 mmol/L
Allopurinol, 1 mmol/L	

*Penicillin and heparin are added within 2 hours of use.

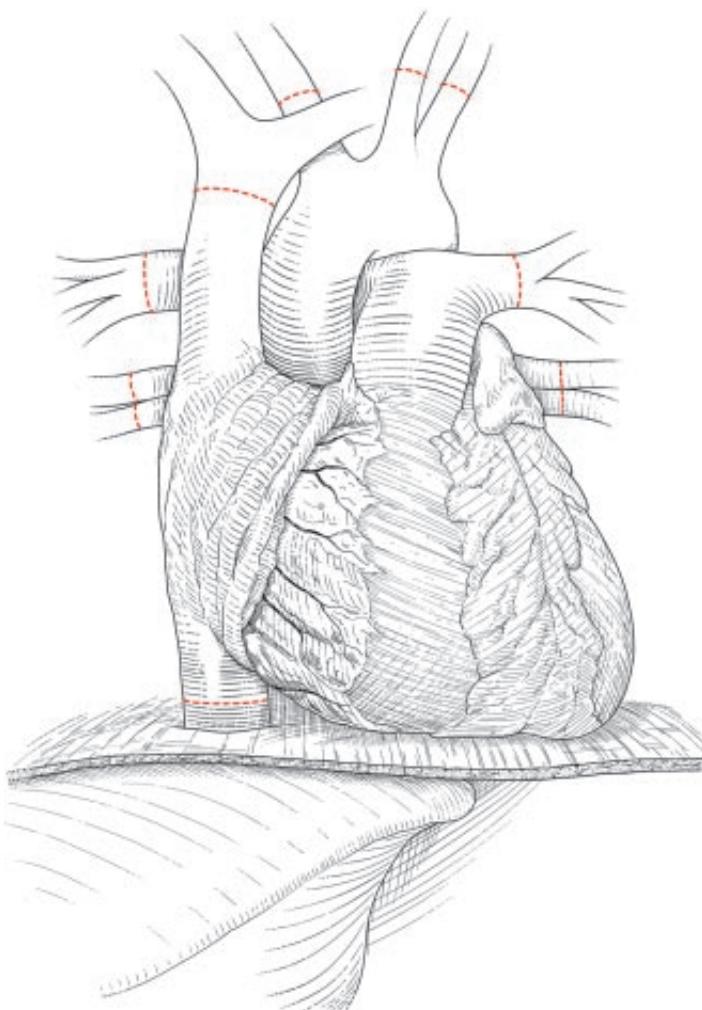

Figure 5 The heart is procured by dividing the aorta at the level of the arch and the suprahepatic vena cava with care taken to leave adequate caval length with both the heart and the liver.

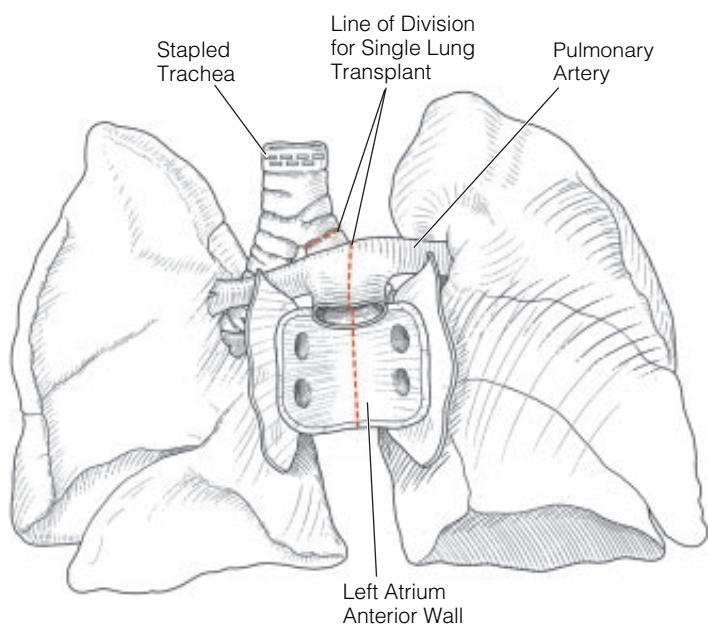

Figure 6 Shown is en bloc procurement of heart and lungs.

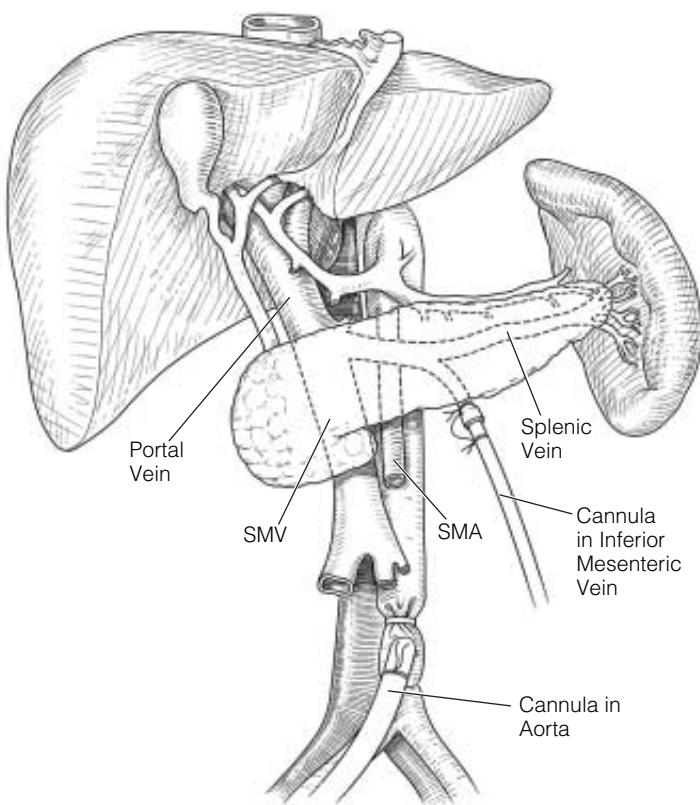

Figure 7 The junction of the superior mesenteric vein and the splenic vein is behind the pancreas, as depicted here. Cannulas are shown in the inferior mesenteric vein and the distal aorta.

En bloc removal of the liver and the pancreas, with or without the intestines, begins as described earlier (see above), with cannulation of the abdominal aorta. After in situ cooling with UW solution, the diaphragmatic attachments are divided, right medial visceral rotation is performed (Cattell-Braasch exposure), and a Kocher maneuver is carried out. The IVC is then divided above the level of the renal veins. The entire pancreaticosplenic complex can be reflected medially by dividing the lateral attachments [see Figure 9]. The aorta is exposed and opened anteriorly just below the origin of the SMA. The renal orifices are identified within the aorta, and a Carrel patch including the SMA and the celiac axis is fashioned, with care taken not to injure the orifices of the renal arteries [see Figure 9, inset]. With the improved techniques that allow use of the liver and the whole pancreas, the liver retains the majority of the portal vein. Once removed from the donor and placed in an ice-filled basin on the back table, the organs are kept immersed in chilled UW solution. The shorter portal vein segment remaining with the pancreas may be lengthened with an iliac vein graft from the donor. The donor celiac axis and hepatic artery stay with the liver. The splenic artery is divided at its origin from the celiac axis, and the SMA stays with the pancreas. In the case of a replaced right hepatic artery from the SMA, the SMA must be divided distal to the right branch. The pancreatic arterial supply is then reconstructed with a donor iliac artery Y-graft anastomosed to the splenic artery and the SMA [see Figure 10].

The organs are then separated along lines determined by their arterial and venous blood supplies. The intestines may be kept in continuity with the liver for use in a composite liver-intestine graft. If this is to be done, the continuity of the duodenum and the head of the pancreas must be kept intact as well. A compos-

ite liver-intestine graft requires considerable back-table preparation before implantation. In the case of an isolated small bowel procurement, the root of the small bowel mesentery is dissected at the level of the middle colic vessels, and the SMA and the SMV are identified and isolated. After cold flushing with UW solution, the SMA is divided just distal to the inferior pancreaticoduodenal artery (which supplies the head of the pancreas) and the SMV is divided at a similar level [see Figure 11].

The use of multiple organs from appropriate donors, including split liver grafts, should be encouraged. Care must be taken, however, to protect all of the organs, particularly when arterial hepatic anomalies exist. Because diabetics have the option of insulin administration, whereas patients with hepatic failure have no other options, if an anomaly in the donor precludes successful procurement of both the liver and the pancreas, liver recovery takes priority. Organs recovered from a single donor may end up at multiple recipient institutions; thus, cooperation between surgeons is essential before, during, and after the donor procedure.

Kidneys

After procurement of the liver, the pancreas, or the intestine, the kidneys (protected with ice to this point) are procured from their retroperitoneal positions. The ureters are divided at the level of the pelvic brim, with care taken not to strip the surrounding periureteral tissue. The kidneys are generally removed en bloc, with the lower abdominal aorta and the IVC kept in continuity [see Figure 12]. Once removed, the kidneys are immersed in a sterile bag in an ice-filled basin and are reperfused with cold UW solution, either individually or through the aorta. If the kidneys are to be separated, the left renal vein is transected flush at the point where it enters the IVC. The remaining IVC is kept with the right renal vein, which generally is considerably shorter than the left renal vein. The kidneys are then turned over

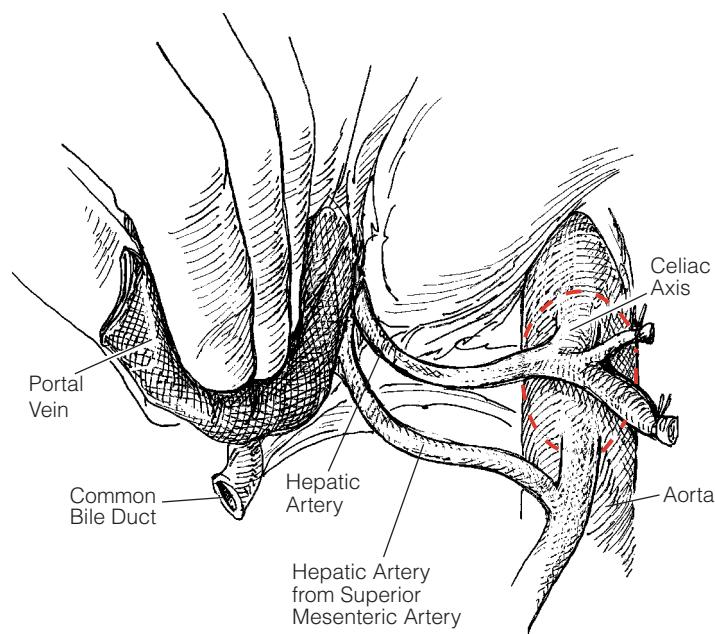

Figure 8 The typical replaced right hepatic artery originates from the first 2 cm of the superior mesenteric artery (SMA) near the aorta. It then runs posterior to the portal vein, as depicted here with the transected portal vein reflected. Also shown is the Carrel patch that will later be created to preserve the celiac axis and the SMA (dashed red line).

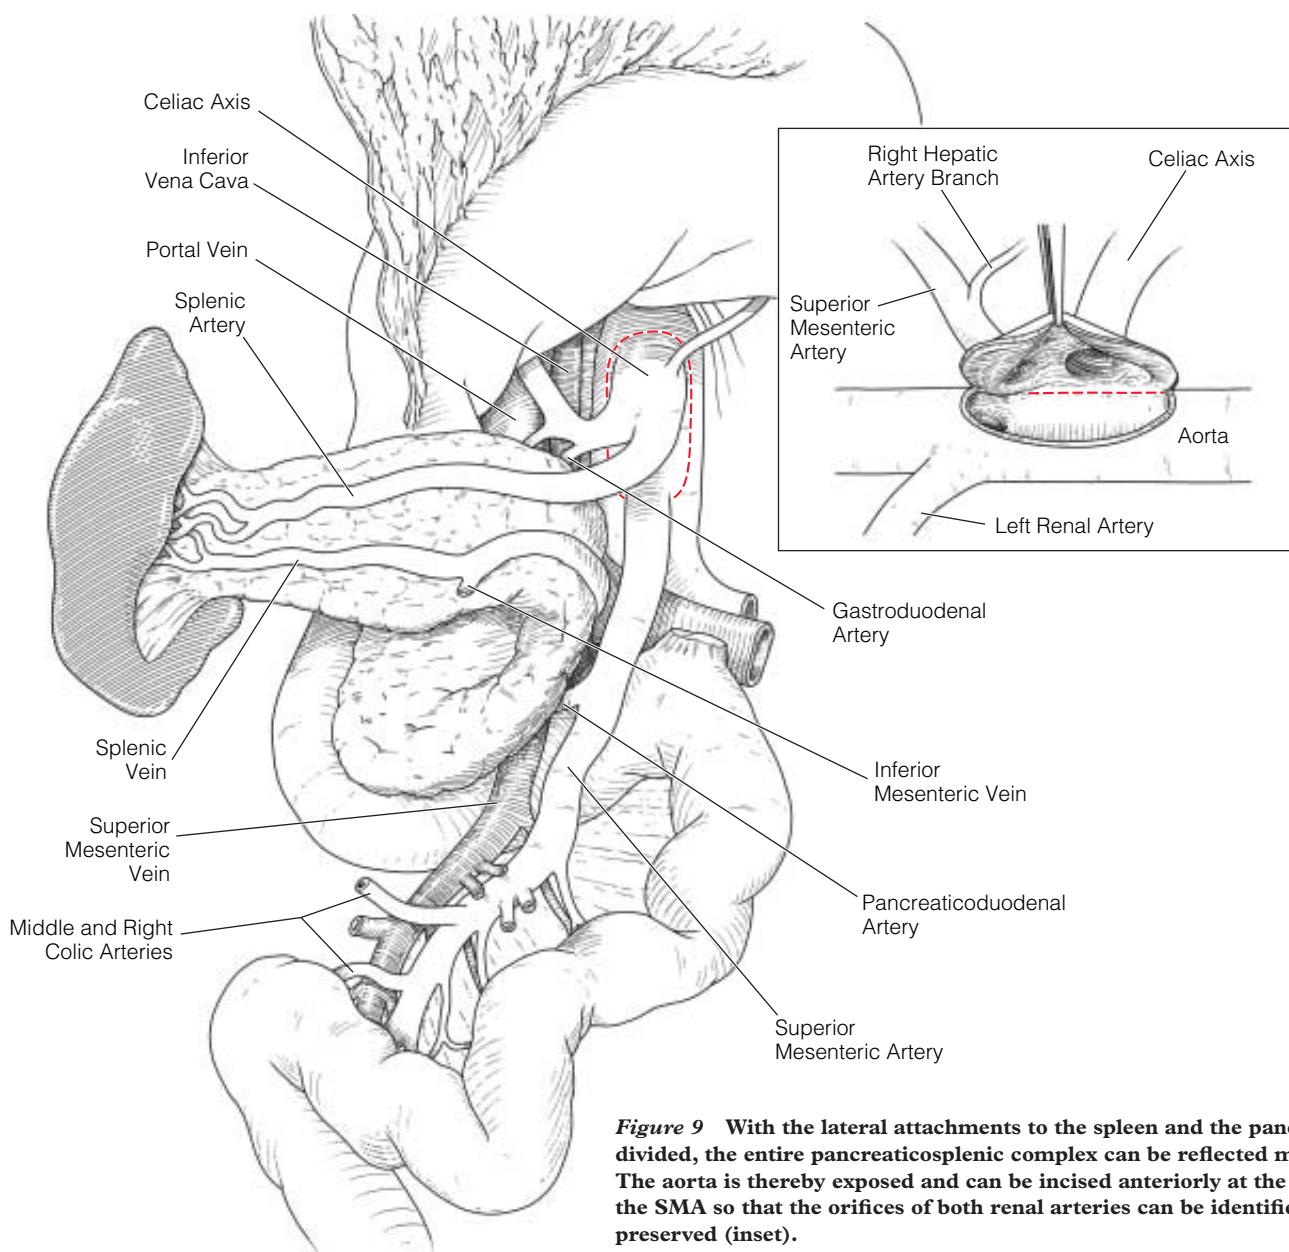

Figure 9 With the lateral attachments to the spleen and the pancreas divided, the entire pancreaticosplenic complex can be reflected medially. The aorta is thereby exposed and can be incised anteriorly at the level of the SMA so that the orifices of both renal arteries can be identified and preserved (inset).

so that the posterior wall of the aorta is accessible. The paired lumbar arteries arise posteriorly and are a perfect guide for directing the subsequent aortic incision. The posterior wall of the aorta is opened longitudinally in the midline (between the paired lumbars) in such a way as to expose the orifices of the renal arteries [see Figure 13]. The anterior wall of the aorta is then divided longitudinally to separate the kidneys. If continuous perfusion (i.e., pumping) is planned, aortic flaps can be fashioned and used to close the two kidneys, either together or separately, so that cannulas need not be placed directly into the renal arteries. Final preparation of the kidneys for implantation is performed at the recipient hospital on the back table.

The iliac arteries and veins, as well as the thoracic aorta, the carotid arteries, and the subclavian arteries, may be removed and placed in cold UW solution. Vascular grafts can be lifesaving in the event of an expected or unexpected technical problem in a recipient (e.g., portal vein thrombosis or celiac axis stenosis). These grafts are often invaluable in cases of living donation in which extension grafts are not readily available.

Organ Procurement from Living Donors

POTENTIAL LIVING DONORS

Living donor transplantation is not a new concept. In fact, the earliest successful kidney transplants were performed with living donors.²³ What began with kidneys has been extended to livers and, in a few centers, even to pancreata, intestines, and lungs. With living donors, even more than with cadaveric donors, good judgment and a high degree of technical skill are crucial for successful recipient and donor outcomes. Regardless of which organ is considered for donation, donor safety must be paramount. Informed, uncoerced consent is essential, and all efforts should be made to ensure that nothing less is obtained.

Evaluation of a living donor must be careful and comprehensive²⁴: it is a significantly more complex process than evaluation of a cadaveric donor. A multidisciplinary group of physicians, both medical and surgical, should be involved in the evaluation, along with social workers and mental health professionals. It is imperative that there be no financial arrangements between

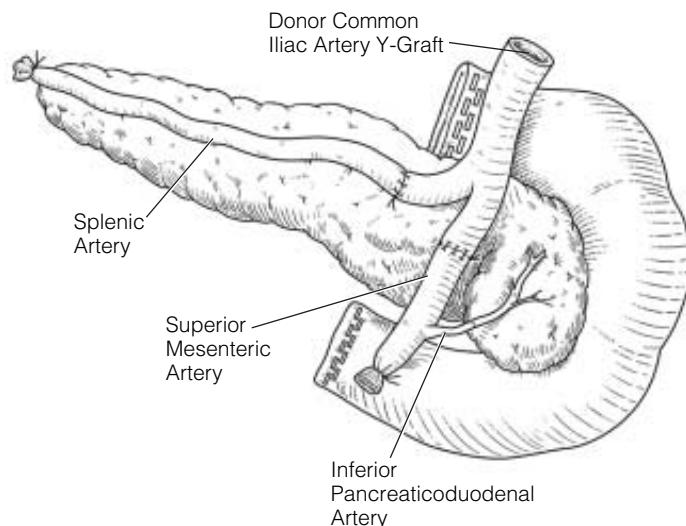

Figure 10 The pancreas is procured with a segment of duodenum. Shown is the posterior view of the pancreas and duodenum, with the spleen removed. The arterial reconstruction involves using a Y-shaped donor iliac artery graft and anastomosing it to the donor superior mesenteric and splenic arteries. Occasionally a vein graft (not shown) is needed for use as an extension graft for the portal vein.

recipients and donors. The National Organ Transplantation Act of 1984 makes the sale of organs illegal in the United States, and this practice should be universally condemned.²⁵

Evaluation for living donation begins with the identification of a willing donor. In general, subjecting a healthy volunteer to physical or emotional distress is antithetical to the basic principles to which all physicians subscribe. *Primum non nocere* ("first, do no harm") is the basis of the Hippocratic oath. If the supply of cadaveric organs were sufficient to meet the demand and if patients were not dying on the waiting list because of organ shortages, it would be difficult to justify living donation on ethical grounds. Living donation should be considered warranted when the donor procedure has been shown to be safe and technically feasible and when the donor has at least an emotional attachment to the recipient. Even this definition is difficult to fully realize on a daily basis as more and more Good Samaritan donors are volunteering their organs to complete strangers. Practice guideline recommendations regarding living donors have been outlined by the Live Organ Donor Consensus Group.²⁶

For kidney and liver donation, donors and recipients must be compatible with respect to major blood types. Recipients of any blood type may receive an organ from a type O donor. Type O liver recipients may successfully receive livers from type A donors in subgroup 2.²⁷ In rare circumstances (i.e., acute fulminant liver failure) and in very young infants, blood group barriers may successfully be crossed in liver transplantation, but such cases are exceptional. In other settings, blood type incompatibility leads to hyperacute rejection.

Any healthy adult (i.e., age >18 years) can be considered as a potential living liver donor. Many programs have upper age limits; virtually all would be reluctant to consider donors older than 60 years. The evaluation process should proceed in a logical and stepwise fashion, beginning with the confirmation of ABO compatibility. For most people, an evaluation for liver donation is the most intense physical and mental examination they have ever undergone. Not infrequently, subclinical maladies are diagnosed

in potential donors during the evaluation. Blood testing should be comprehensive and should include, at a minimum, a full set of blood chemistries; a complete blood count; a coagulation profile; thyroid function tests; serologic tests for hepatitis viruses (A, B, and C), HIV, cytomegalovirus, *Neisseria gonorrhoeae*, α_1 -antitrypsin, ferritin, ceruloplasmin, α -fetoprotein, antimuclear antibodies; a lipid profile; serum protein electrophoresis; urinalysis; and pregnancy testing. An ECG and a chest x-ray should also be obtained. Additional tests should be ordered as clinically indicated on an individual basis.

Imaging studies must include CT or MRI for estimating hepatic volumes and for determining details of the hepatic arterial, hepatic venous, and portal venous anatomy. With MRI scanning, cholangiography is also possible. Some centers may require endoscopic retrograde cholangiopancreatography (ERCP) for complete biliary tract evaluation, angiography for complete vascular evaluation, or both. Many centers require that potential donors undergo liver biopsy in specific circumstances (e.g., a history of alcohol abuse, obesity, or hypercholesterolemia), and some require this of all potential donors. Matching an appropriate donor with an appropriate recipient is complex and requires

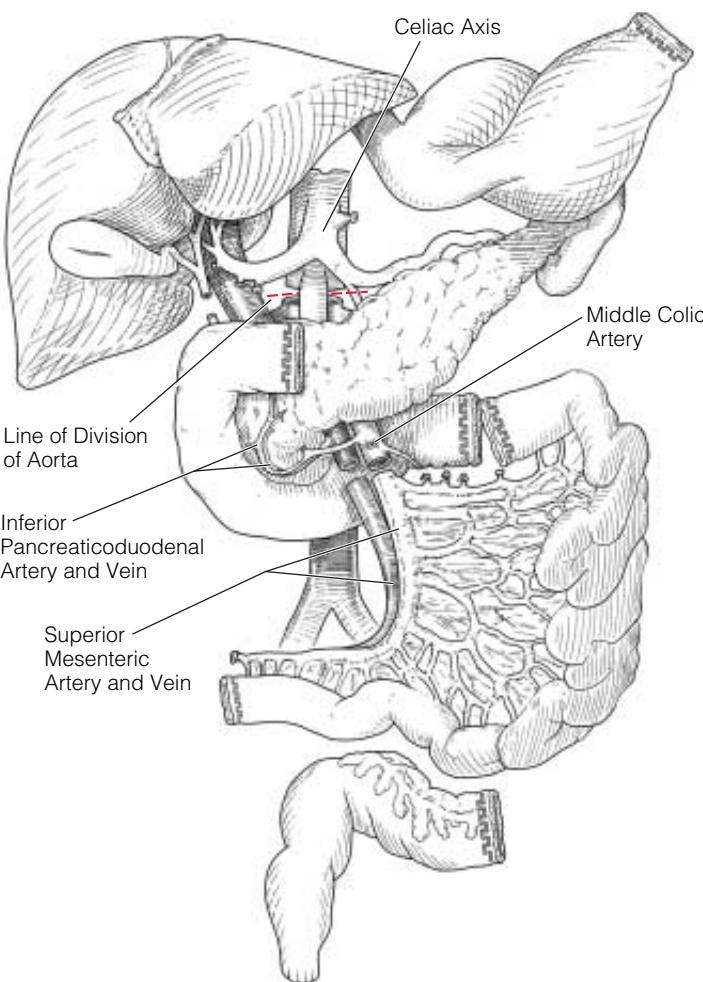

Figure 11 Shown is *in situ* separation of intestinal, pancreatic, and hepatic grafts. The mesenteric dissection is performed at the level of the middle colic vessels, with care taken to preserve the inferior pancreaticoduodenal artery and vein with the pancreatic graft. The aorta is divided just distal to the SMA and just proximal to the renal arteries.

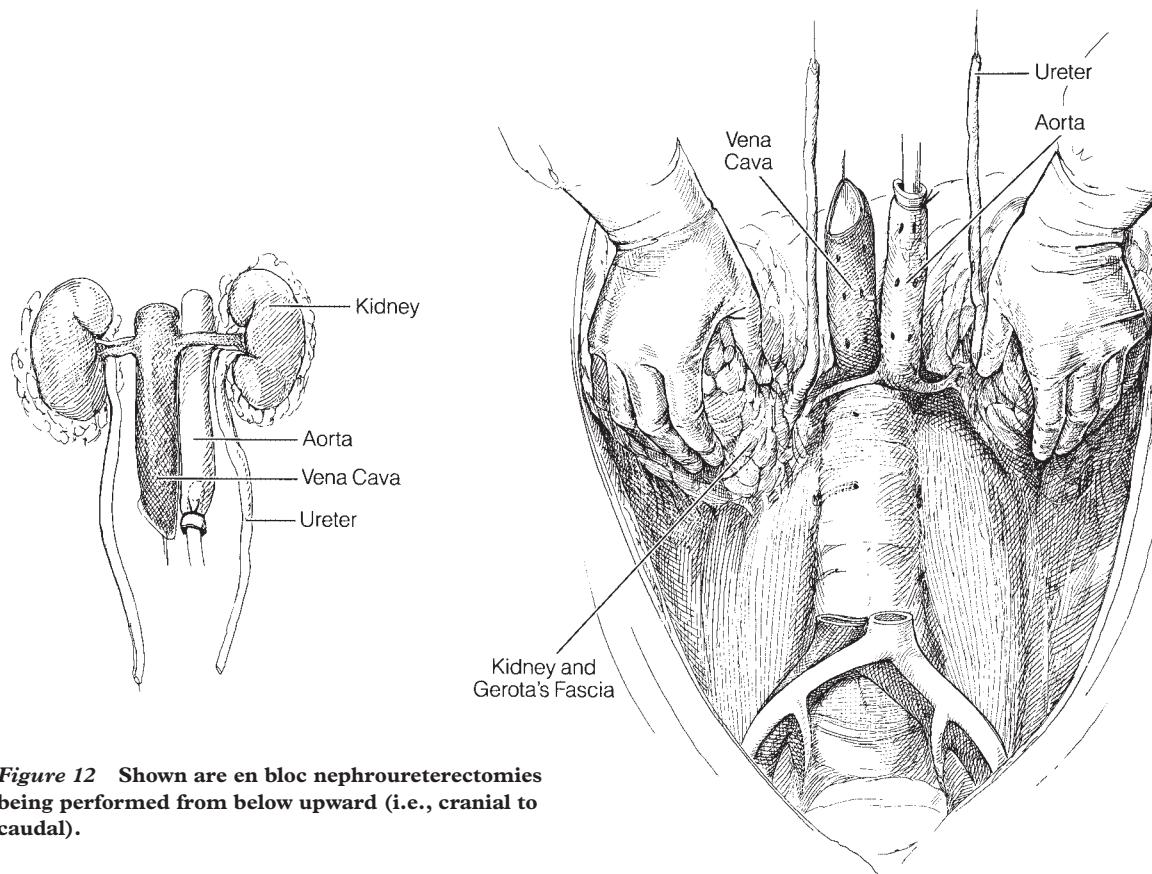

Figure 12 Shown are en bloc nephroureterectomies being performed from below upward (i.e., cranial to caudal).

an understanding of and an appreciation for multiple variables, including the severity of portal hypertension in the recipient, the volume of liver required by the recipient, the volume of liver remaining with the donor, and the anatomy of the donor (including the hepatic portal and venous anatomy as well as the biliary anatomy). Successful transplantation and donor outcome depend on appropriate matching.²⁸

LIVING DONOR OPERATION

Liver

Liver donation is generally riskier than kidney donation, and donation of larger portions of the liver (e.g., the left or right lobe) is riskier than donation of smaller portions (e.g., the left lateral segment). Only fully trained and experienced hepatobiliary surgeons with a good understanding of segmental liver anatomy [see Figure 14] should undertake liver procurement from living donors. At present, there is no official living donor liver registry; however, it is estimated that more than 2,500 such procedures have been performed worldwide, and several perioperative donor deaths have been reported.⁹ Clearly, even one donor death is too many.

The main anatomic liver resections are discussed in greater detail elsewhere [see 5:23 Hepatic Resection]. In hepatic resections done on living donors, the primary emphases are on limiting blood loss and preserving the anatomy of both the donated segment and the donor's remaining liver. Left lateral segmentectomy is performed according to well-established techniques by isolating the left hepatic artery, the left portal vein, and the left hepatic vein.²⁹ The left hepatic artery is dissected just distal to the branching of the right hepatic artery; the segment 4 branch is usually sacrificed. The portal branches to segments 1 and 4 are ligated, and the main branches of the left portal vein are thereby exposed. The left hepatic vein is isolated and controlled. A parenchymal transection plane is chosen just to the right of the falciform ligament and extended down to the hilar plate. The hilar plate and the left bile duct are sharply transected. Parenchymal transection is performed with the electrocautery, the ultrasonic aspirator, or both. The specimen is removed from the donor and immediately flushed with cold UW solution on the back table.

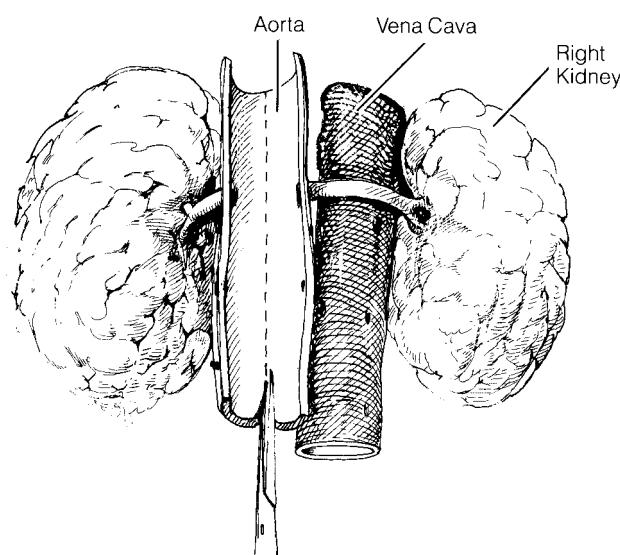

Figure 13 The aorta is opened posteriorly between the paired lumbar arteries.

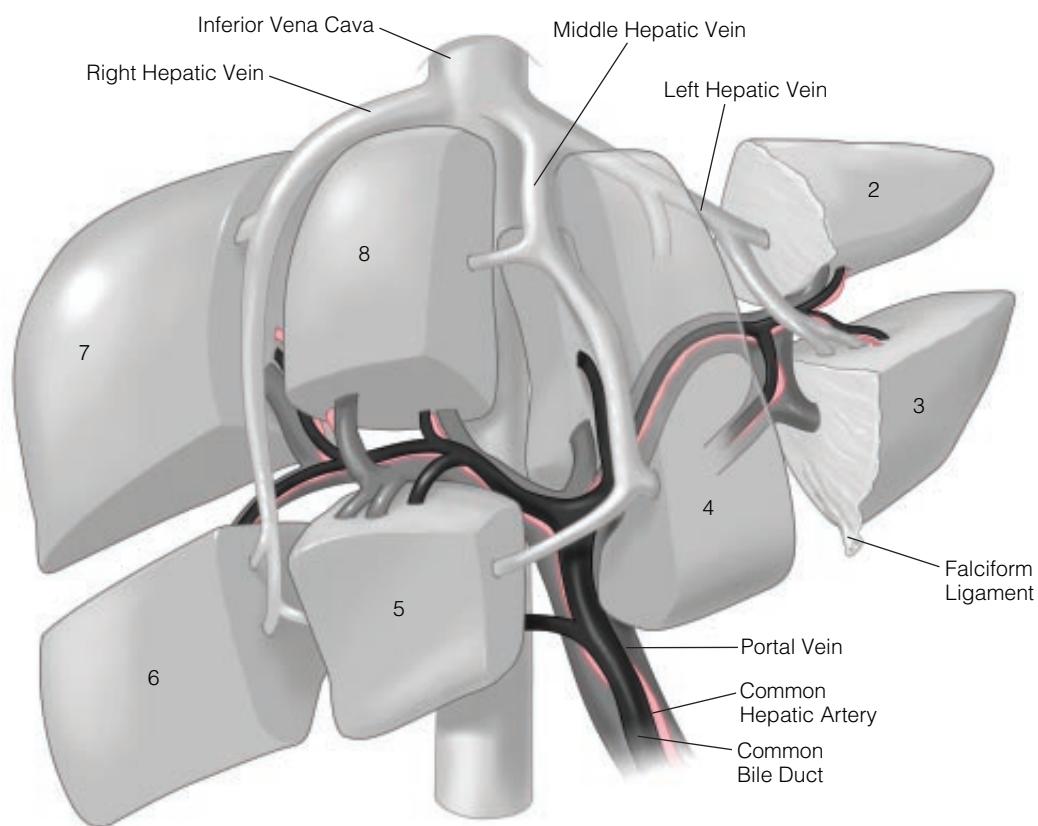

Figure 14 Depicted is segmental liver anatomy as originally described by Couinaud. The right lobe consists of segments 5 through 8, the left lobe of segments 2 through 4, and the left lateral segment of segments 2 and 3.

Right and left lobectomies are performed by isolating the inflow and outflow vessels in the hepatic hilum on the appropriate side, with care taken not to injure or devascularize the opposite side.^{29,30} The initial steps in a right lobectomy are cholecystectomy and fluoroscopic cholangiography to delineate the biliary anatomy. After mobilization of the right lobe, intraoperative ultrasonography may be performed to define the course of the major hepatic veins and to identify the presence of significant segment 5 and 8 veins that may have to be reimplanted; in addition, large short hepatic veins (i.e., diameter > 5 mm) are preserved for direct reimplantation into the recipient's IVC. Currently, with the improvements achieved in preoperative MRI and, more important, with the accumulation of extensive operative experience, intraoperative ultrasonography is becoming obsolete.

The hilar dissection is begun laterally, and the right hepatic artery is exposed to the right of the common bile duct, with attention paid to preserving, when possible, any significant segment 4 branches. The right portal vein is also identified and isolated. Extensive dissection around the donor's common bile duct should be avoided so as not to produce devascularization. The hilar plate is lowered and the right bile duct (or ducts) is divided sharply, with care taken not to compromise the remaining donor duct. The retrohepatic IVC is then dissected, and the right hepatic vein is isolated, with any large short hepatic veins preserved. A transection plane is chosen to the left of Cantlie's line, and dissection proceeds along the right border of the middle hepatic vein. Large short hepatic veins and significant anterior segment (i.e., segment 5 or 8) venous tributaries are preserved with right lobe grafts for subsequent reconstruction and re-

implantation in the recipient to prevent acute hepatic venous congestion.⁹

Kidney

Kidney donation from a live donor may be accomplished either via an open approach or laparoscopically. Open donor nephrectomy is performed through a right or left flank incision, depending on which kidney is to be removed. The flank muscles are divided, and the perinephric space is developed. The renal artery and vein are dissected free, and the ureter is identified and divided at the pelvic brim. The vessels on the right side, particularly the renal vein, are significantly shorter than those on the left; in addition, exposure is often more challenging on the right side as a consequence of the subhepatic location of the right kidney. Before the vessels are clamped and the kidney removed, donors are routinely given mannitol, both for its diuretic effects and for its antioxidant effects. Upon removal from the donor, the kidney is flushed with cold UW solution on the back table.

Although open donor nephrectomy has been the standard, the laparoscopic alternative is now regarded by many as the procedure of choice, particularly for left kidneys. Because of the relatively shorter vessels on the right side, some surgeons are reluctant to perform laparoscopic right nephrectomy, being concerned that the vessel shortening invariably caused by the stapler may make implantation more difficult. In addition, many donors have multiple renal arteries, an anomalous venous anatomy (e.g., a retroaortic left renal vein), or both, and these anatomic variations may preclude, or at least significantly complicate, laparoscopic donation. Laparoscopic donor nephrectomy is

described in more detail elsewhere.

Lung, Pancreas, and Intestines

Single-lung transplantation from a living donor has been per-

formed with some success.³¹ Procurement of the pancreas and the small intestine from living donors has been shown to be technically possible; however, serious concerns remain about the adequacy of partial grafts for correcting diabetes or short-gut syndrome. Such procedures are currently considered experimental.

5 UROLOGIC CONSIDERATIONS FOR THE GENERAL SURGEON

Ronald Rubenstein, M.D., and Robert B. Nadler, M.D., F.A.C.S.

An understanding of the urogenital system is a necessary component of general surgical education. Specifically, surgeons must be aware of the anatomic, physiologic, and pathologic features of urologic processes. Accordingly, in this chapter, we review the key features of genitourinary anatomy and discuss urologic problems that are commonly encountered by the general surgeon, including urologic trauma, iatrogenic injuries to the urogenital system, urologic malignancies, and benign prostatic hyperplasia (BPH).

Anatomic Considerations

KIDNEY AND URETER

The kidneys are obliquely placed on either side of the spine, deep within the retroperitoneum,¹ with the upper poles slightly more medial than the lower poles. On top of each kidney sits an adrenal gland, and these two structures are jointly surrounded by a perinephric fascial layer known as Gerota's fascia (an important anatomic structure that can act as a barrier to contain renal pathologic processes). The anterior and posterior leaves of Gerota's fascia, which extend anterior and posterior to the kidney, become fused around the kidney on three sides: laterally, medially, and superiorly. Inferiorly, however, Gerota's fascia remains an open potential space, containing the ureter and the gonadal vessels on either side. Gerota's fascia is surrounded by retroperitoneal fat.

A clear understanding of the position of the kidneys in the retroperitoneum is vital for surgical exploration. Generally, the right kidney is situated slightly lower than the left kidney, as a consequence of the mass effect of the liver; however, the positions of the kidneys vary somewhat with respiration. Posteriorly, the right kidney and the left have similar relations with adjacent structures. The diaphragm and the pleural reflections cover the upper posterior aspect of each kidney, and the 12th rib crosses the upper pole. On the left side, the 11th rib is directly posterior to the upper aspect of the kidney. The quadratus lumborum and the transversus abdominis aponeurosis cover the posterior surface, and the renal hilum lies against the psoas muscle. Anteriorly, the left kidney is in contact with the adrenal, the spleen, the stomach, the pancreas, the jejunum, and the splenic flexure of the colon [see Figure 1]. The anterior surface of the right kidney is covered to a large extent by the liver. The inferior portion of the right kidney is covered by the hepatic flexure, and the hilum is covered by the duodenum. It is important to recognize the planes between Gerota's fascia, the peritoneum, and the retroperitoneal organs.

Each kidney is supplied by a renal artery and drained by a renal vein. The renal arteries typically branch off the aorta just below the superior mesenteric artery at the level of the second lumbar vertebra, and the renal veins meet the vena cava at the same level. The left renal vein passes in front of the aorta and lies most anteriorly in the renal hilum. Behind the vein lies the renal artery, and the renal pelvis lies most posteriorly. Although, in general, there is one renal artery and one renal vein for each kidney, anatomic variations are common. The most common variation (occurring in 23% to 49% of persons)

is the presence of supernumerary renal arteries arising from the lateral portion of the aorta.²⁻⁷ Whereas there is extensive collateral circulation for the renal veins, the renal arteries are end arteries. Consequently, injury to the main renal artery or an accessory artery typically results in the loss of renal parenchyma. On the right side, the adrenal and gonadal vein drain directly into the vena cava; on the left side, these vessels drain into the renal vein [see Figure 2].

The renal collecting system includes the minor calices, the major calices, the renal pelvis, and the ureter. The ureter connects the renal pelvis to the bladder, and its role is to propel urine toward the bladder by means of peristalsis. The normal adult ureter is 22 to 30 cm long, and it exhibits three distinct narrowings as it travels through the abdomen and the pelvis: one at the ureteropelvic junction, one at the pelvic brim as it crosses over the iliac vessels, and one at the ureterovesical junction. For the purposes of surgical or radiographic description, the ureter is commonly divided into discrete segments. In surgical terms, the portion of the ureter that runs from the renal pelvis to the iliac vessels is the abdominal ureter, and the portion that runs from the iliac vessels down to the bladder is the pelvic ureter. In radiographic terms, the portion of the ureter that runs from the renal pelvis down to the upper border of the sacrum is the proximal ureter, the portion that runs from the upper border of the sacrum to the lower border is the medial ureter, and the portion that runs from the lower border of the sacrum down to the bladder is the distal ureter.

The ureter receives its blood supply from multiple branching vessels along its course. The proximal ureter is supplied medially by branches from the renal artery, the medial ureter is supplied medially by branches from the gonadal artery and the aorta, and the distal ureter is supplied laterally by branches from the common and internal iliac arteries. The arterial vessels then course longitudinally within the periureteral adventitia in an anastomosing plexus that can be extensively mobilized so long as it remains intact.

Posteriorly, the ureter runs along the psoas muscle to the point where the muscle crosses over the iliac vessels near the bifurcation of the common iliac arteries. Anteriorly, the right ureter is in contact with the ascending colon, the cecum, the appendix, the terminal ileum, and the corresponding mesenteries. The left ureter is in contact with the descending colon, the sigmoid colon, and the corresponding mesenteries. It is important to recognize that when these anterior structures are reflected during operation, the ureter tends to adhere to them rather than remain adherent to the psoas muscle. In women, specific attention must be paid to the status of the ureter at the pelvic brim, where it may be in contact with the fallopian tube and the ovary. Attention should also be paid to the uterine arteries, which cross anterior to the ureters near the cervix.

BLADDER

The bladder is a hollow organ that stores and expels urine. The normal adult bladder has a capacity of 400 to 500 ml. When empty, the bladder rests in the pelvis behind the pubic symphysis. As it fills, the bladder rises above the pubic bone, and if it is quite distended, it may be palpated in the lower abdomen.

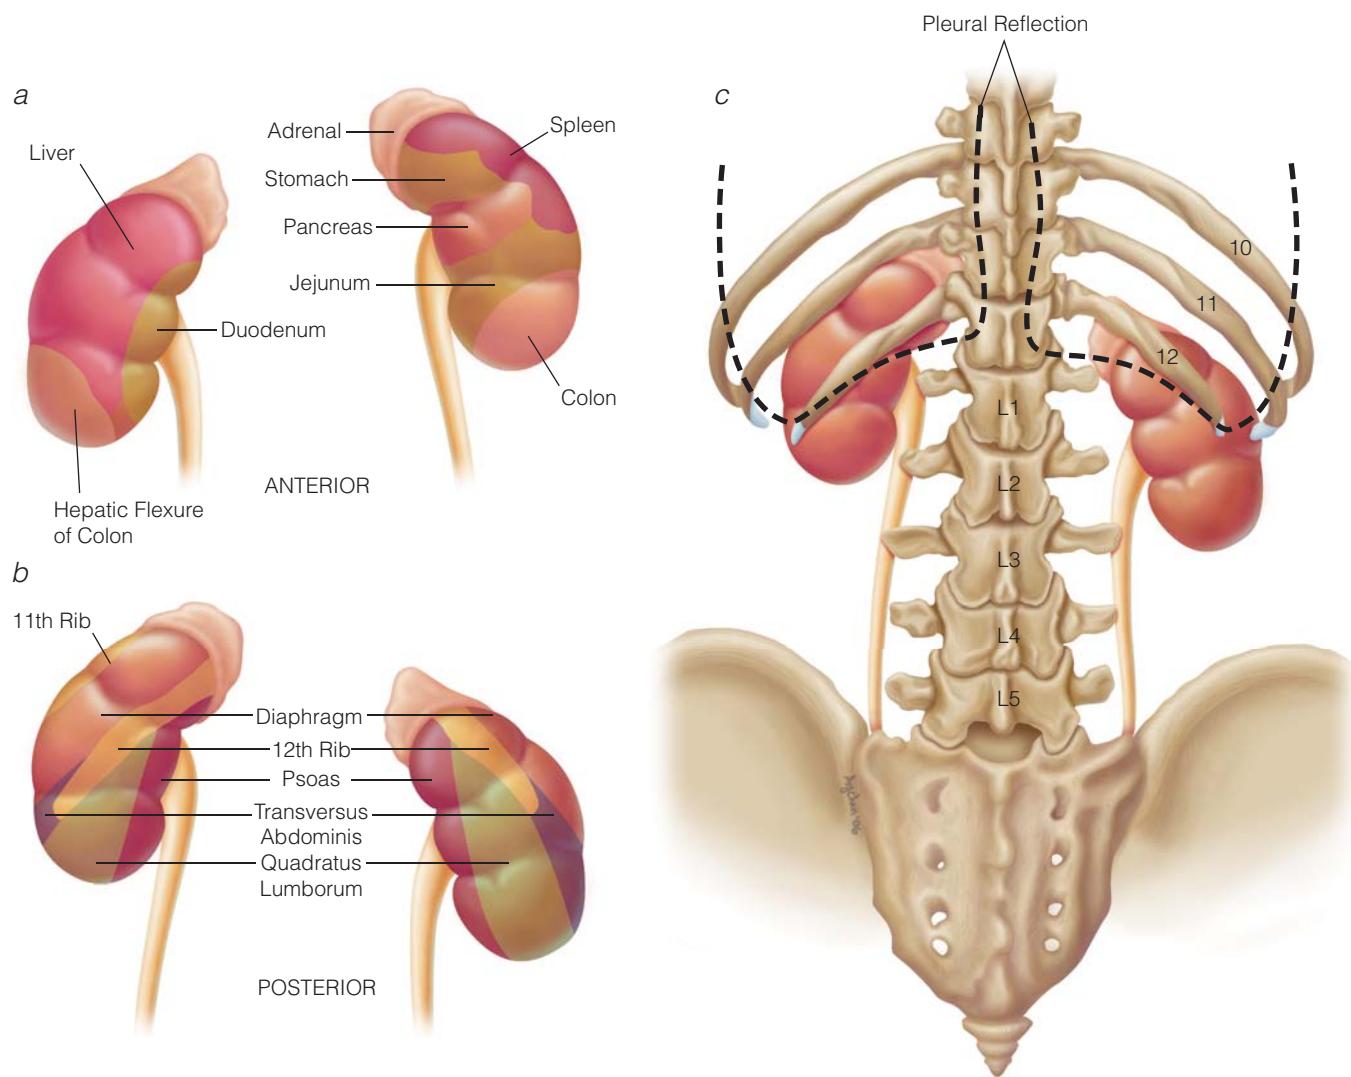

Figure 1 Shown are the anatomic relations of the kidneys (a) to the abdominal organs anteriorly, (b) to the body wall muscles and the ribs posteriorly, and (c) to the pleural reflections and the skeleton posteriorly.

The bladder is anatomically related to many other anatomic structures. Anteriorly, the bladder is tethered to the abdominal wall by the median umbilical ligament (i.e., the obliterated urachus). In rare cases, adenocarcinoma may develop in the urachal remnant; in other cases, the connection may remain patent and predispose to infection or drainage from the umbilicus. The superior aspect of the bladder is covered by a peritoneal layer that sweeps down from the anterior abdominal wall to meet the peritoneum covering either the anterior rectum (in males) or the uterus (in females). Laterally, the bladder is separated from the pelvic side walls by loose connective tissue and both retropubic and perivesical fat. In males, the base of the bladder is adjacent to the seminal vesicles, the ampullae of the vasa deferentia, the distal ureters, and the rectum. In females, the uterus and the vagina are interposed between the bladder and the rectum.

The bladder is very well vascularized and thus may be mobilized or partially resected without compromise of the blood supply. Most of the bladder's blood supply comes from the superior, middle, and inferior vesical arteries, which branch off from the anterior trunk of the internal iliac artery. In females, the bladder is further supplied by branches of the vaginal and uterine arteries.

The veins of the bladder come together to form several plexuses that drain into the internal iliac veins.

PROSTATE AND SEMINAL VESICLES

The prostate and the seminal vesicles produce constituents of the ejaculate. The normal prostate weighs between 18 and 20 g and is composed of glandular elements and fibromuscular stroma. Toward the apex, the prostate is tethered to the pubic bone by the puboprostatic ligaments. Laterally, the prostate is in direct contact with the pubococcygeal portion of the levator ani and is related to its overlying endopelvic fascia. Posteriorly, the prostate is separated from the rectum by the two layers of Denonvilliers' fascia. The prostate can be divided into transitional, central, and peripheral zones, and there is an anterior fibromuscular stroma that extends from the bladder neck to the striated urethral sphincter. The transitional zone is the area that gives rise to BPH, which can cause increased urinary resistance and voiding symptoms. The peripheral zone makes up the bulk of the prostate tissue and is the area where the majority of prostate cancers arise.

The seminal vesicles are about 6 cm long and lie in contact with the base of the bladder. Each seminal vesicle joins the ipsilateral

vas deferens to form the ejaculatory ducts, which exit the prostate at the verumontanum (i.e., the colliculus seminalis).

The prostate and seminal vesicles are supplied by the inferior vesical, internal pudendal, and middle rectal arteries; the seminal vesicles are also supplied by the vesiculoductal artery, a branch of the superior vesical artery.

PENIS AND URETHRA

The penis is composed of three bodies: the two corpora cavernosa, which are responsible for erectile function, and the corpus spongiosum, which contains the urethra and is contiguous with the glans. Individually, these bodies are covered by a dense fascial layer known as the tunica albuginea; together, they are covered by a thick layer of Buck's fascia. If one or more of the penile bodies is torn, the bleeding will be contained in Buck's fascia, and ecchymosis will be limited to the penile shaft.

The penis is supplied by the common penile artery, which is the terminal branch of the internal pudendal artery. This vessel travels through Alcock's canal and terminates in three branches: the bulbourethral artery, which supplies the urethra, the corpus spongiosum, and the glans; the deep artery, which travels within the corpus cavernosum and supplies the cavernous sinuses; and the dorsal artery, which runs in the neurovascular bundle beneath Buck's fascia and supplies the corpus spongiosum and the urethra.

The male urethra is approximately 20 cm long and can be divided into four anatomic sections: the prostatic urethra, the membranous urethra, the bulbous urethra, and the penile urethra. The

sphincteric mechanism is located in the membranous urethra. The female urethra is approximately 4 cm long and travels from the bladder neck below the pubic symphysis to open anterior to the vagina.

TESTES

The testes have two important functions: spermatogenesis and production of testosterone. Each testis is approximately 20 ml in size and is surrounded by tunica albuginea, which projects inward to form the mediastinum testis.

The testis is supplied by the gonadal or testicular artery, the vasal artery, and the cremasteric artery. The gonadal artery arises from the aorta, just below the renal artery, and courses through the spermatic cord to the testis; the vasal artery is a branch of the superior vesical artery; and the cremasteric artery branches off from the inferior epigastric artery. At the level of the internal ring, these three arteries are in close proximity, and particular care must be taken to keep from injuring them. Venous outflow is provided by the gonadal vein. The right gonadal vein empties into the inferior vena cava below the renal vein, and the left gonadal vein empties directly into the left renal vein.

Urologic Injuries

UROGENITAL TRAUMA IN PATIENTS WITH MULTIPLE INJURIES

Urologic injuries are common when multiple organ systems are damaged, occurring in about 10% of cases of major trauma.

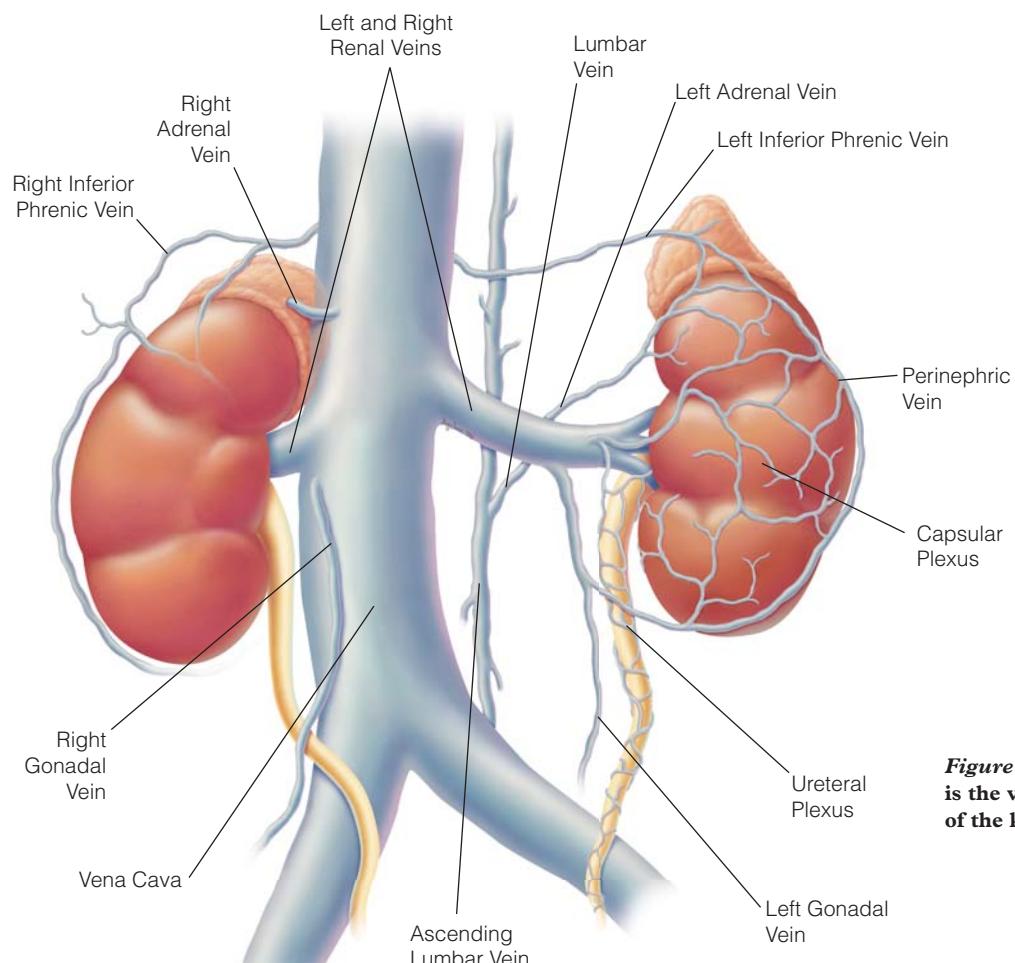

Figure 2 Illustrated is the venous drainage of the kidneys.

Although the majority of injuries to the urogenital tract are not life-threatening, they can result in substantial morbidity if they are not promptly diagnosed and treated. Accordingly, a surgical team treating a patient with multiple injuries must always keep in mind the possibility of concomitant urogenital trauma so that any urologic injuries found can be addressed in a timely manner.

Initial evaluation and resuscitation are generally carried out by an emergency department physician and a trauma surgeon; however, it is important that a urologist be involved as well. Assessment should proceed as outlined by advanced trauma life support (ATLS) protocol. The presence of gross hematuria, flank ecchymosis, rib fractures, pelvic fractures, or blood at the urethral meatus should raise the level of concern for urologic injury and serve as an indication for an expeditious urologic consultation.

Management of urologic trauma is addressed in more detail elsewhere [see 7:11 *Injuries to the Urogenital Tract*].

IATROGENIC INJURY TO UROGENITAL TRACT

Ureter

The majority of injuries to the ureter are iatrogenic. Iatrogenic ureteral injuries may be sustained during any open or laparoscopic procedure in the abdomen or the pelvis and may result from transection, ligation, laceration, resection, crushing, or ischemia. Such injuries are most likely to occur during gynecologic procedures; they also occur during general surgical and urologic procedures and, rarely, during orthopedic⁸ and vascular procedures.⁹ The ureter is most vulnerable to iatrogenic injury at several anatomic locations: at the pelvic brim, where gonadal and ovarian vessels cross; lateral to the uterus, where the ureter crosses under the uterine artery; over the iliac vessels, near the apex of the obturator fossa; and at the insertion of the trigone.

Although most ureteral injuries occur during routine, uncomplicated surgical procedures in which the pelvic anatomy appears normal,¹⁰ the likelihood of such injuries is increased by the presence of conditions that disrupt the architecture of the ureter, such as a large mass, a malignancy, inflammatory disease, endometriosis, a previous operation, irradiation, and congenital abnormalities. Increased blood loss, longer operating times, increased transfusion requirements, and longer hospitalizations are all associated with ureteral injury.^{11,12}

The best way of preventing iatrogenic ureteral injury is to clearly identify the ureter in the surgical field and in those regions where it is most susceptible to injury. Every attempt should be made to limit bleeding and to avoid placing sutures or using the electrocautery in areas where exposure is poor.

Placement of ureteral stents at the beginning of the procedure may facilitate identification of the course of the ureter. A 5-year review of prophylactic ureteral catheterization in patients undergoing colon surgery concluded that whereas stents did not prevent ureteral injuries, they could help surgeons recognize such injuries more quickly.¹³ Accordingly, the authors recommended stenting in patients at high risk for ureteral injury. A subsequent study from another group also recommended the use of stents in doubtful cases, on the grounds that prevention is better than treatment.¹⁴ Other authors, however, have argued that prophylactic ureteral stents are not without risk and have not affected the rate of ureteral injury.¹⁵ Prophylactic ureteral stenting continues to be a controversial practice.

Bladder

The bladder is the genitourinary organ that is most frequently injured during an operation.¹⁶ Fortunately, the bladder is very for-

giving of incidental injuries, and most such injuries are recognized intraoperatively, when they can easily be repaired with a two-layer closure using absorbable sutures. Bladder injury should be suspected when, during an operation, the Foley catheter is exposed, a laceration is noticed, urinary extravasation is present, urine in the Foley catheter becomes bloody, or (in the case of a laparoscopic procedure) gas begins to escape through the Foley catheter. Most patients have an identifiable predisposing factor that complicates the operation. Typically, this factor is previous surgery or inflammation, though bladder injuries resulting from surgery performed vaginally or laparoscopically do not seem to have a predisposing cause. The incidence of laparoscopic bladder injuries reportedly ranges from 0.02% to 0.3%.¹⁷ Foley catheter drainage is maintained for 1 to 2 weeks after repair, and the resulting success rates are quite high.

Urologic Malignancies

RENAL CELL CARCINOMA

It is currently estimated that deaths attributable to cancer of the kidney and the renal pelvis account for approximately 3% of all cancer deaths in the United States, and the annual incidence of renal cell carcinoma (RCC) continues to rise.¹⁸ Moreover, in 22% of patients, despite improvements in imaging and detection, the cancer will have already metastasized at the time of diagnosis.¹⁸ Approximately 85% of kidney cancers originate in the parenchyma; the remaining 15% are transitional cell carcinomas and develop in the collecting system.

In most instances, RCC is diagnosed incidentally during an imaging procedure that is performed to address some other problem. The classic triad of flank pain, hematuria, and a palpable abdominal mass is present in as many as 10% of cases.¹⁹ Because the range of possible presentations is quite wide, RCC is frequently referred to as the “internist’s tumor.” Patients may present with symptoms related to paraneoplastic manifestations, such as cachexia and fever (caused by cytokines), renin-mediated hypertension, nephropathy from immunoglobulin formation, hypercalcemia, cytokine-induced myelosuppression, polycythemia related to erythropoietin production, amyloidosis, or Stauffer syndrome (nonmetastatic hepatic dysfunction). Paraneoplastic symptoms tend to disappear once localized disease is treated.

All patients with hematuria or a renal mass should undergo further evaluation. The presence of gross or microscopic hematuria should prompt contrast evaluation of the kidneys and the ureters, as well as cystoscopy with urine cytology. The presence of a renal mass should prompt evaluation with either triple-phase computed tomography or magnetic resonance imaging with or without gadolinium (if the patient has a contrast allergy or renal insufficiency). No further assessment is required for simple cysts. Renal masses evaluated by means of CT are classified according to the Bosniak system, which correlates the appearance of the mass with the risk of malignancy [see Table 1].²⁰ Bosniak classes I, II, III, and IV roughly correspond to cancer risks of less than 2%, less than 12%, 52%, and greater than 90%, respectively.²¹⁻²⁷ The evaluation of a patient with a renal mass also includes a complete history, a careful physical examination, liver function tests, a comprehensive metabolic panel, and a chest x-ray.

If imaging identifies invasion into the renal vein or a tumor thrombus, further assessment (by means of venography, magnetic resonance angiography or venography, or CT reconstruction) aimed at determining the extent of vena cava involvement is necessary for successful removal of the mass. Renal masses that are

Table 1 Bosniak System for Classification of Renal Cysts²⁰

Category	Cyst Characteristics
I	Benign simple cyst with hairline-thin wall that has no septa, calcifications, or solid components; cyst has density of water and does not enhance
II	Benign cyst that may contain a few hairline-thin septa in which perceived (but not measurable) enhancement may be present; wall or septa may contain fine calcification or short segment of slightly thickened calcification; category includes uniformly high-attenuation lesions < 3 cm ("high-density cysts") that are well marginated and do not enhance; no further evaluation required
III*	Cyst that may contain multiple hairline-thin septa or minimal smooth thickening of wall or septa; wall or septa may show perceived enhancement; calcification may be present in wall or septa that may be thick and nodular, but without measurable enhancement; lesions are generally well marginated; category includes intrarenal nonenhancing high-attenuation lesions > 3 cm; follow-up studies required to confirm benign status
IV	Indeterminate cystic mass with thickened irregular or smooth walls or septa that show measurable enhancement; surgical management required, though some lesions will prove benign (e.g., hemorrhagic cysts, chronically infected cysts, multiloculated cystic nephromas) and others malignant (e.g., cystic and multiloculated cystic RCCs)

*F signifies follow-up.

suspected of harboring cancer on the basis of diagnostic imaging should not routinely undergo biopsy except (1) in cases where there is a possibility of metastasis from another primary cancer or (2) in accordance with the protocol for minimally invasive treatment alternatives (e.g., cryoablation and radiofrequency ablation). Routine biopsies of kidney masses have high false negative rates and tend to yield nondiagnostic results.

Staging is a well-established predictor of prognosis. The TNM staging system developed by the American Joint Committee on Cancer (AJCC) has been widely used for prognostic purposes in RCC patients. In a European study, the 5-year and 10-year disease-specific survival probabilities were 95.3% and 91.4% for TNM stage pT1a RCC, 91.4% and 93.4% for stage pT1b disease, and 81.6% and 75.2% for stage pT2 disease.²⁸ In another study, the 5-year disease-specific survival probabilities were found to be significantly worse for more advanced RCC: 67% for TNM stage III disease and 32% for stage IV disease.²⁹ In the past few years, various other prognostic factors have been validated that are not included in the TNM staging system, including tumor grade, histologic subtype, sarcomatoid features, histologic tumor necrosis, collecting system invasion, and performance status.³⁰ Accordingly, many institutions are now using a more comprehensive staging system for RCC.

For localized RCC, the standard treatment is radical nephrectomy, either open or laparoscopic (hand assisted, retroperitoneal, or transperitoneal). This procedure involves removal of the entire kidney and the fat within Gerota's fascia, which is accomplished with early identification and ligation of the renal artery and the renal vein. To preserve adrenocortical function, it is best to avoid performing unconditional ipsilateral adrenalectomy with radical nephrectomy for RCC: the benefit of routine adrenalectomy in this

setting is extremely limited, especially in patients with small lesions and low-stage disease.³¹ If the tumor is small (generally, < 4 cm) and occupies an anatomically favorable position, it may be removed by means of partial nephrectomy—again, either open or laparoscopic. To prevent bleeding and leakage of urine, care must be taken to ensure that vessels are controlled and the collecting system is closed.

Metastatic RCC responds poorly to standard chemotherapy and radiation therapy. In patients whose disease burden is suitable, whose performance status and general health are adequate, and who are about to undergo immunotherapy with interferon or interleukin-2 (or other trial regimens, as appropriate), cytoreductive nephrectomy should be considered. In selected patients with solitary or limited metastases (confirmed by careful staging investigations), aggressive surgical resection of all disease may prolong survival and should be considered, possibly in conjunction with immunotherapy.³²

BLADDER CANCER

Like RCC, cancer of the urinary bladder currently accounts for approximately 3% of cancer deaths in the United States. The median age at which bladder cancer is diagnosed is 73 years.¹⁸ In the United States, approximately 90% of bladder cancers are transitional cell carcinomas, about 5% are squamous cell carcinomas, and some 2% are adenocarcinomas. Cigarette smoking is the primary environmental risk factor, associated with 50% to 66% of bladder tumors in men and 25% in women.³³ Another risk factor is exposure to carcinogenic aromatic amines, especially benzidine and β-naphthylamine.³⁴ Bladder cancer has been linked to occupational exposure in aromatic amine manufacturing, dyestuff manufacturing, rubber manufacturing, painting, the leather industry, the aluminum industry, and truck driving.³⁵ In Africa and the Middle East, squamous cell carcinoma, associated with *Schistosoma haematobium* infection, is the most common form of bladder cancer.

In 80% to 90% of patients, bladder cancer presents as gross or microscopic hematuria, which commonly is painless and sporadic.³⁶ In some patients, the presenting complaint is a change in voiding habits, such as urgency, increased frequency, painful urination, or difficulty in voiding. Decreased bladder capacity (as a result of a mass effect) and ureteral obstruction are less common presenting symptoms and are suggestive of more advanced disease. Systemic complaints are suggestive of metastatic disease.

The presence of hematuria should prompt a full evaluation consisting of upper urinary tract contrast imaging, cystoscopy, and urine cytology. Cystoscopy is the current standard for detecting bladder masses. Urine cytology has a specificity that approaches 100% and is useful in helping to identify small lesions, lesions that are atypical in appearance, and lesions that are located in the upper urinary tract.³⁷ All suspicious bladder lesions should be resected and sent for pathologic diagnosis. Biopsy specimens should be obtained from the muscle layer to determine whether the tumor has invaded the muscle.

The stage and grade of the tumor are important for determining treatment and are independently correlated with prognosis. As with RCC, the AJCC's TNM system is commonly employed for staging. Bladder tumors that involve the mucosa (Ta) and the lamina propria (T1) are referred to as superficial disease, whereas tumors that extend beyond the lamina propria and invade muscle (T2a) are referred to as invasive disease. Three categories are used for grading, corresponding to well-differentiated disease (grade 1), moderately well differentiated disease (grade 2), and poorly differentiated disease (grade 3). As the stage and grade of the tumor

increase, the prognosis worsens. Carcinoma *in situ* is a separate disease entity whose presence is associated with a high risk of recurrence and a greater likelihood of disease progression.

Approximately 70% of bladder cancers initially present as superficial disease. Treatment consists of resection and cauterization. If pathologic examination confirms superficial disease, no further metastatic workup is necessary. Surveillance is mandatory, however, because of the high risk of recurrence and progression. Low-grade Ta lesions recur in 50% to 70% of cases and progress in approximately 5% of patients, whereas high-grade T1 lesions recur in more than 80% of cases and progress in 50% of patients within 3 years.³⁸ Patients with high-risk superficial disease—defined as carcinoma *in situ*; stage T1 lesions; or large, high-grade, recurrent, or multifocal Ta lesions—should receive further treatment with intravesical bacillus Calmette-Guérin (BCG).³⁹

Approximately 25% of bladder cancers are invasive at the time of initial diagnosis. The standard treatment for organ-confined invasive bladder cancer is radical cystectomy with extended lymph node dissection; urine is diverted into a conduit or neobladder created from the large or the small bowel. Disease that extends through the muscle into the fat (T3), node-positive disease, or metastatic disease requires further treatment with chemotherapy after the postoperative period. In older series, if bladder cancer was left untreated, fewer than 15% of patients would survive 2 years.⁴⁰ In a 2001 study of 1,054 patients treated at the University of Southern California, the 5-year survival was 60% to 75% for pT2 tumors, 36% to 58% for pT3 tumors, and 4% to 35% for pT4 or node-positive tumors.⁴¹

PROSTATE CANCER

Cancer of the prostate accounts for approximately 10% of cancer deaths in the United States. It is estimated that prostate cancer will be diagnosed in one of every six men,¹⁸ usually relatively late in life; between 1998 and 2002, the median age at which prostate cancer was diagnosed was 69 years. Over the past 2 decades, the incidence of prostate cancer has risen, partly because of the widespread use of the prostate-specific antigen (PSA) screening test. This rise, however, has not been uniform. Between 1989 and 1992, the incidence of prostate cancer increased by an average of 18% per year, but between 1992 and 1995, it declined by 14% per year; it may now have reached a plateau.⁴²

In the early stages, prostate cancer is generally asymptomatic. Currently, most cases of prostate cancer are detected by an abnormal digital rectal examination or an abnormal PSA test result that prompts prostate biopsy. Routine screening with a PSA test and a digital rectal examination should begin at the age of 40 in men whose life expectancy is greater than 10 years. African-American men and men who have a first-degree relative with prostate cancer are at higher risk for prostate cancer. The generally accepted threshold value for an abnormal PSA level has been 4.0 ng/ml; however, some investigators now question this value, on the grounds that a significant number of men have been found to have cancer with PSA values between 2.6 and 4.0 ng/ml.⁴³⁻⁴⁵ In addition, the rate at which the serum PSA level increases (i.e., PSA velocity) has become a very important factor in the diagnosis of prostate cancer.⁴⁶ For proper interpretation of PSA values, it is important to recognize that the serum PSA level can be influenced by multiple factors besides prostate cancer (including urinary retention, BPH, and prostatitis).

The stage and grade of the tumor play important roles in determining treatment and prognosis. As with RCC and bladder cancer, the most widely accepted staging system is the AJCC's TNM system. The most widely accepted grading system for prostate can-

cer is based on the Gleason score. In this system, the biopsy specimen is examined under low-power magnification, and the most prominent glandular pattern seen is graded on a scale of 1 to 5, with 1 representing the highest degree of differentiation and 5 the lowest. The next most prominent glandular pattern seen is then graded in the same fashion. The two grades are added to yield the Gleason score, which can range from a minimum of 2 (1 + 1) to a maximum of 10 (5 + 5). Cancers with scores of 6 (3 + 3) or lower are considered well differentiated; those with scores of 7 (3 + 4 or 4 + 3) are considered intermediate; and those with scores of 8 (4 + 4) or higher are considered poorly differentiated. The more poorly differentiated the cancer is, the more aggressive it will be and the worse the prognosis will be. In addition to the Gleason score, the clinical stage and the PSA level have important implications for treatment.

There are many options for treating prostate cancer, and there remains some controversy regarding what constitutes the most effective therapy. Typically, treatment is based on the stage and grade of the tumor, the PSA level, and patient characteristics such as general health status, comorbid conditions, age, body habitus, and personal bias. Clinically localized prostate cancer may be treated with curative intent by means of surgery or irradiation (i.e., external-beam radiation therapy or brachytherapy). When the disease is more advanced or the patient is unwilling to undergo operative treatment or radiation therapy, antiandrogen therapies or watchful waiting may be considered.

TESTICULAR CANCER

Testicular cancer accounts for only about 1% to 2% of all malignancies in men; however, it is the most common cancer in males between 15 and 34 years of age.⁴⁷ Moreover, since the middle of the 20th century, the incidence of testicular cancer has been increasing in the United States.⁴⁸ The exact cause of testicular cancer remains unknown. It has been hypothesized that testicular atrophy is a common pathway by which several etiologic factors may be involved in tumor development in the testis.^{49,50} Familial tendency, white race, and a history of cryptorchidism are established risk factors.⁵¹⁻⁵³

The classic presentation of testicular cancer is painless swelling or enlargement of the testis. A 1987 study of 5,172 patients with testicular cancer, however, found that the initial presenting complaints for this condition included a swollen or enlarged testis (58%), a mass in the testis (27%), a painful testis (33%), tender breasts (3%), and a history of trauma (4%).⁵⁴ Acute trauma is not a proven cause of testicular cancer, but it may lead to the awareness of a mass. Examination generally reveals an enlarged testis or a nodule on the testis; it may prove more difficult in a patient with a tender testis or a large hydrocele. Ultrasonography, which has been shown to be highly reliable in differentiating between intra-testicular and extratesticular lesions, may be performed to supplement the evaluation.^{55,56} In rare cases, testicular cancer may present with manifestations of systemic disease (e.g., pulmonary complaints or an abdominal mass).

Measurement of serum levels of tumor markers (i.e., human chorionic gonadotropin [hCG], α -fetoprotein [AFP], and lactic dehydrogenase [LDH]) is a well-established component of the management of testicular germ cell tumors and facilitates diagnosis, prognosis, monitoring of treatment, and prediction of relapse. Elevated serum concentrations of these markers are strongly suggestive of cancer, but the absence of such elevated concentrations in a patient with a testicular mass does not rule out cancer. hCG is secreted by the syncytiotrophoblasts present in certain germ cell tumors (i.e., embryonal tumors, teratomas, choriocarcinomas,

and fewer than 20% of seminomas). Its serum half-life is 16 to 24 hours. AFP is synthesized by yolk sac components of germ cell tumors. Its presence is diagnostic of nonseminomatous disease; it is never produced by pure seminomas or choriocarcinomas. AFP concentrations peak between gestational weeks 12 and 14 and start to decline after week 16, falling to undetectable levels after the first year of life. The serum half-life of AFP is 4.5 days. LDH, though not a highly sensitive tumor marker, has proved to be an independent prognostic variable in several large multivariate analyses of testicular germ cell tumors. Serum tumor marker concentrations are followed after radical orchectomy and should fall in proportion to their respective half-lives.

Treatment is determined by the pathology and stage of the tumor. Most testicular tumors are of germ cell origin and are classified as either seminomatous or nonseminomatous. Nonmetastatic disease can often be treated surgically by means of radical orchectomy, which is completed through an inguinal incision after vascular control of the spermatic cord has been achieved. Follow-up with diagnostic imaging and measurement of serum tumor marker levels is carried out to look for possible metastatic disease.

Seminomas account for nearly 48% of germ cell tumors and usually present during the fourth and fifth decades.⁵⁷ Initial metastasis is typically to either the periaortic lymph nodes near the renal hilum (for left-side lesions) or the pre caval lymph nodes between the aortic bifurcation and the renal pedicle (for right-side lesions). Crossover to the periaortic nodes is common with right-side lesions. Seminomas may also spread hematogenously to the lungs, the liver, the brain, bone, the kidneys, the adrenal glands, the gastrointestinal tract, or the spleen. These lesions are highly radiosensitive, and thus, irradiation is a key part of early-stage treatment. Low-stage disease is treated with radical orchectomy and radiation therapy, whereas advanced or bulky disease is treated with chemotherapy. Close follow-up is the rule.

Nonseminomatous germ cell tumors tend to be more locally aggressive than seminomas, and they have a high metastatic potential. Overall, the patterns of lymphatic and hematogenous spread are similar to those of seminomatous germ cell tumors; however, choriocarcinoma demonstrates a particularly aggressive natural history, with early hematogenous spread. Nonseminomatous germ cell tumors are treated with surgery, with platinum-based chemotherapy, or with both, depending on the disease stage. Low-stage disease is treated with radical orchectomy, followed by chemotherapy if tumor marker concentrations do not normalize. If the tumor marker concentrations normalize, subsequent options include surveillance and nerve-sparing retroperitoneal lymph node dissection (RPLND); without additional treatment, 30% of patients will experience relapses. The presence of lymphatic, vascular, scrotal, or spermatic cord invasion increases the likelihood of retroperitoneal lymph node involvement, and RPLND may therefore be preferred in these circumstances.⁵⁸ Disease with minor nodal involvement is treated with radical orchectomy and RPLND, followed by chemotherapy if RPLND demonstrates the presence of cancer. Disease with more extensive nodal involvement and metastatic disease are treated with chemotherapy. Close follow-up is the rule.

Benign Prostatic Hyperplasia

BPH becomes increasingly common in men as they age: histologic evidence from autopsy studies suggests that the incidence of BPH exceeds 50% in men older than 50 years and exceeds 75% in men older than 70 years.⁵⁹ The prostate is composed of stromal and epithelial components, and either stroma or epithelium (or

both) can give rise to hyperplastic nodules. Typically, nodules occur in the transition zone of the prostate. The etiology of BPH is multifactorial and is not yet completely understood. It is clear, however, that the endocrine system plays an important role and that the levels of testosterone and other hormones are significant factors. A positive family history and early onset of symptoms are associated with an increased risk of progression to more severe BPH. There may be an autosomal dominant or codominant pattern of inheritance.⁶⁰

Patients with BPH may present with obstructive or irritative symptoms, which are collectively referred to as lower urinary tract symptoms. Obstructive symptoms include incomplete emptying, intermittency, a weak stream, and straining; irritative symptoms include urgency, frequency, and nocturia. Although most patients present with one or more of these complaints, some patients may present with urinary tract infections, acute urinary retention, or renal failure. Because lower urinary tract symptoms are not disease specific, one must consider other urologic and medical conditions besides BPH, such as urinary tract infection, stones, prostatitis, strictures, cancer, and neurologic disease.

Patients should be evaluated with a careful history and a thorough physical examination. Symptoms should be quantified by using the International Prostate Symptom Score (I-PSS) questionnaire. This questionnaire consists of seven questions, the answers to which are scored on a scale of 0 to 5 to yield a total score ranging from 0 to 35. A total score of 0 to 7 indicates mild symptoms, a total score of 8 to 19 indicates moderate symptoms, and a total score of 20 to 35 indicates severe symptoms. I-PSS scores can be used to help determine treatment and assess its effectiveness, and their utility in this setting has been reliably validated. A complete urologic examination and a limited neurologic examination should be carried out. Routine PSA screening (for healthy persons of suitable age) and urinalysis should be performed. Whether further examination and testing are required is determined by the initial findings and the course of treatment. Additional evaluation may include measurement of serum creatinine concentrations, cultures, assessment of PSA levels, cystoscopy, biopsy, or urodynamic testing.

Treatment of BPH may involve observation, medical therapy, or surgical management. Symptoms tend to wax and wane, and many patients tolerate their symptoms reasonably well and prefer to avoid therapeutic interventions. Watchful waiting is a viable option for patients who have minimal symptoms and no evidence of renal or bladder dysfunction. Medical therapy focuses on relaxing the bladder neck and shrinking the prostate to facilitate more complete emptying of the bladder. Two classes of medications are used: alpha blockers and 5 α -reductase inhibitors. Alpha blockers are considered first-line treatment for all BPH patients. These medications act on the alpha-adrenergic receptors of the bladder neck and the prostate to help relax and open the channel. Their main side effects are related to their blood pressure-lowering effect. In 2003, the Medical Therapy of Prostatic Symptoms (MTOPS) Research Group published a study advocating combination therapy with an alpha blocker and a 5 α -reductase inhibitor to reduce the risk of overall clinical progression of BPH and the long-term risk of acute urinary retention and need for invasive therapy.⁶¹ Surgical intervention is generally reserved for patients who exhibit acute urinary retention and those who continue to experience significant symptoms despite medical treatment. Currently, surgical treatment is most often performed endoscopically. Prostatic tissue is resected with an electrocautery in the standard fashion, removed via transurethral resection of the prostate, or ablated with a laser. If the

prostate is extremely large (> 80 g), an open or laparoscopic^{62,63} simple prostatectomy may be performed.

Postoperative urinary retention, which occurs in 3.8% to 9% of cases,^{64,65} is a particularly troubling development. It has been associated with preexisting voiding issues, immobility, analgesics, administration of high fluid volumes during operation, and impaired mental status. Treatment is based on eliminating as many of these predisposing factors as possible. After an unsuccessful first voiding

attempt, a single catheterization is successful in resolving postoperative urinary retention in 39% of cases.⁶⁴ Generally, patients are given an alpha blocker first, and a voiding trial is administered once they have become ambulatory and are using less pain medication. Patients with a history of lower urinary tract symptoms should be started on an alpha blocker preoperatively, and administration of the medication should resume as soon as they are capable of tolerating liquids.

6 GYNECOLOGIC CONSIDERATIONS FOR THE GENERAL SURGEON

Edward S. Podczaski, M.D., F.A.C.S., and Paul R. Kramer, Jr., M.D.

For many general surgeons, gynecologic surgery is not a major component of practice. In a report published in 1995, surgical residents who graduated that year had handled, on average, only 1.6 gynecologic cases.¹ Nevertheless, it is clear that some surgeons devote a significant portion of their practice to treating gynecologic disorders. In a prospective registry of consecutive cases reported by seven rural general surgeons, 20% of the procedures were classified as gynecologic.² Furthermore, in a National Survey of Ovarian Carcinoma published in 1993, 21% of the primary surgical procedures for ovarian cancer were actually performed by general surgeons.³ At present, more than half of the general surgery residency programs in the United States offer no formal rotation in gynecology; accordingly, both residents and practicing surgeons may benefit from a discussion of basic gynecologic problems and their surgical management. In what follows, we consider the gynecologic conditions that are most commonly encountered by general surgeons. These conditions may be broadly classified as gynecologic emergencies, outpatient gynecologic problems (e.g., pelvic masses and abnormal uterine bleeding), or squamous dysplasias and gynecologic malignancies.

Gynecologic Emergencies

BLEEDING FROM OVARIAN CYSTS

Each month, the ovary of a premenopausal woman undergoes a cycle of hormonally driven changes characterized by follicular development, the emergence of a dominant follicle, ovulation, and the formation of a corpus luteum. Cystic enlargement of one of these physiologic structures is relatively common and is considered functional rather than neoplastic. Approximately 7% of asymptomatic women between the ages of 25 and 40 years have ovarian cysts larger than 2.5 cm.⁴ Functional ovarian cysts should not cause pain unless accompanied by bleeding, rupture, or torsion.

Follicular cysts are fluid-filled structures that arise from a normal follicle that fails to ovulate or does not undergo atresia. Rupture of follicular cysts may result in acute pain, which is usually of brief duration. Corpus luteum cysts arise from a mature, well-vascularized corpus luteum and may be associated with prolonged secretion of progesterone. They tend to be larger than follicular cysts and are more likely to cause clinical symptoms. Corpus luteum cysts range in severity from masses that cause no symptoms to ruptured cysts that cause catastrophic bleeding. Dull, unilateral lower abdominal and pelvic pain is the typical presenting complaint. Pelvic examination may show an enlarged, tender ovary. Unruptured corpus luteum cysts are followed conservatively. However, events such as coitus, exercise, or trauma may rupture the cyst, resulting in slight to significant intraperitoneal bleeding, in which case the patient usually experiences the sudden onset of severe lower abdominal or pelvic pain. The acute pain of a bleeding corpus luteum cyst is indistinguishable from that of a ruptured ectopic pregnancy.

A negative serum β -human chorionic gonadotropin (β -hCG) determination rules out an ectopic pregnancy. In hemodynamically stable patients, pelvic ultrasonography may establish a diagnosis and permit expectant management even if some intraperitoneal bleeding has occurred. The appearance of hemorrhagic cysts on computed tomography depends on the age of the clot: blood from an acute hemorrhage has a high attenuation value, whereas blood from a previous hemorrhage has an attenuation value approaching that of water. In an acute setting, CT typically demonstrates a cystic adnexal mass with areas of high attenuation at intramural and intracystic sites. A hemoperitoneum may also be present, with high-attenuation clot and blood accumulating in the dependent pelvis. Laparoscopy may be useful when the diagnosis is uncertain or when a stable patient has a moderate hemoperitoneum. In hemodynamically unstable patients, adequate volume and blood replacement are initiated and emergency laparotomy is performed. Once it is confirmed that the bleeding is from a ruptured cyst, conservative therapy, consisting of removing the cyst and achieving hemostasis, is initiated.

ADNEXAL TORSION

Abnormal enlargement of the adnexa, either by neoplasms or by cysts, may predispose to torsion of the tube and the ovary around the infundibulopelvic ligament, resulting in vascular compromise. Adnexal torsion is a gynecologic emergency: if untreated, it will result in infarction of the adnexa with eventual peritonitis. Although torsion can occur in postmenopausal women, it is most common in patients of reproductive age.

The presenting complaint is severe pelvic pain of abrupt onset, often accompanied by nausea and vomiting of sudden onset. The pain may be colicky or knifelike and is usually related to the degree of vascular compromise. There may be a history of waxing and waning pelvic pain corresponding to previous episodes of partial twisting and detorsion. Physical examination often demonstrates an acute abdomen with lower abdominal tenderness and guarding. Pelvic examination usually demonstrates a mass that may be difficult to assess because of tenderness. Low-grade temperature elevations may be noted, but significant fevers are unlikely. In most series, the accuracy with which adnexal torsion is diagnosed is approximately 70%.⁵ Ultrasonography demonstrates a mass in nearly all affected patients. However, the presence of arterial flow on Doppler ultrasonography does not exclude ovarian torsion: early in the development of ovarian torsion, lymphatic and venous flow may be obstructed while arterial perfusion is preserved.⁶ CT may demonstrate ovarian enlargement, smooth-wall thickening of the mass or tube, and uterine deviation towards the affected adnexa. On occasion, a twisted vascular pedicle (torsion knot or whirling sign) or lack of contrast enhancement within the twisted ovarian mass may be observed. Prompt surgical intervention is necessary to prevent adnexal infarction.

In the past, adnexal torsion was commonly treated aggressively, with salpingo-oophorectomy. This approach continues to be war-

ranted in perimenopausal and postmenopausal patients; however, a more conservative approach is now considered preferable for the treatment of women of reproductive age who desire future fertility. The traditional approach was based on two assumptions: first, that the twisted adnexum with vascular compromise was nonviable, and second, that detorsion was potentially dangerous because it might cause thrombus to be released from the clotted veins in the infundibulopelvic ligament. These assumptions proved to be unfounded. Accordingly, current management begins with untwisting the adnexum and assessing its viability. Once the torsion is unwound, the adnexum may demonstrate reperfusion or infarction without vascular recovery. Only a gangrenous adnexum must be completely removed.

Patients may be managed by means of either laparoscopy or laparotomy, depending on the clinical circumstances. In a series that included 40 young women with adnexal torsion, all of the patients were successfully managed conservatively, with unwinding of the torsion; laparotomy was performed in 26 of the 40 and operative laparoscopy in 14.⁷ Ideally, cystectomy, along with removal of the cause of the torsion, should be done at the time of detorsion. However, cystectomy on an edematous and fragile ovary may be technically difficult and may cause a further vascular insult to the remaining tissue. In such cases, it is advisable to evaluate the patient 6 to 8 weeks after the acute episode. If an ovarian mass is still found at that time, ovarian cystectomy may be performed via operative laparoscopy.

PELVIC INFLAMMATORY DISEASE

Pelvic inflammatory disease (PID) is an acute infection of the upper female genital tract that involves the uterus, the fallopian tubes, and the ovaries. It is a community-acquired disease and is initiated by a sexually transmitted agent that results in the ascent of vaginal flora into the upper genital tract. The resulting polymicrobial infection (caused by a mixture of anaerobes, facultative anaerobes, and aerobic organisms) can lead to a wide spectrum of disorders, including endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis.

Lower abdominal pain is the most frequent complaint. The pain usually is bilateral, rarely is of more than 2 weeks' duration, and often begins with or follows menses. Approximately half of the patients are febrile. Abdominal palpation demonstrates diffuse tenderness that is more pronounced in the two lower quadrants. Rebound tenderness and diminished bowel sounds are common. Pelvic examination reveals a purulent endocervical discharge with cervical motion and adnexal tenderness.

Empiric treatment of PID should be initiated in sexually active young women or women at risk in the clinical setting of lower abdominal tenderness, adnexal tenderness, and cervical motion tenderness. Additional criteria supporting the diagnosis include fever (oral temperature > 101° F), abnormal cervical or vaginal mucopurulent discharge, the presence of abundant white cells on saline microscopy of vaginal secretions, an elevated sedimentation rate, an elevated C-reactive protein level, and documentation of cervical infection with *Neisseria gonorrhoeae* or *Chlamydia trachomatis*.⁸ The differential diagnosis includes adnexal torsion, appendicitis, ectopic pregnancy, endometriosis, a hemorrhagic ovarian cyst, and urinary tract infection. Pertinent lab studies include determination of the serum β-hCG level (to rule out an ectopic pregnancy), microscopic examination of the vaginal discharge, a complete blood count, endocervical nucleic acid amplification tests for *N. gonorrhoeae* and *C. trachomatis*, sedimentation rate, and urinalysis. Clinical diagnosis of acute PID remains imprecise. Compared with laparoscopy (the gold standard for

Table 1 Recommended Outpatient and Inpatient Therapies for Pelvic Inflammatory Disease⁸

Type of Therapy	Regimen	Agents and Dosages
Outpatient	A	Ofloxacin, 400 mg p.o., once daily, for 14 days* <i>or</i> Levofloxacin, 500 mg p.o., once daily, for 14 days* <i>with or without</i> Metronidazole, 500 mg p.o., b.i.d., for 14 days
	B	Ceftriaxone, 250 mg I.M. in single dose <i>or</i> Cefoxitin, 2 g I.M. in single dose, and probenecid, 1 g p.o., administered concurrently <i>or</i> Another parenteral third-generation cephalosporin (e.g., cefotaxime or ceftizoxime) <i>plus</i> Doxycycline, 100 mg p.o., b.i.d., for 14 days <i>with or without</i> Metronidazole, 500 mg p.o., b.i.d., for 14 days
Inpatient	A	Cefotetan, 2 g I.V. q. 12 hr <i>or</i> Cefoxitin, 2 g I.V. q. 6 hr <i>plus</i> Doxycycline, 100 mg p.o. or I.V. q. 12 hr
	B	Clindamycin, 900 mg I.V. q. 8 hr <i>plus</i> Gentamicin, 2 mg/kg I.V. or I.M. loading dose, followed by maintenance dosage of 1.5 mg/kg q. 8 hr; once daily dosage may be substituted

*Should not be used in patients at increased risk for infection with quinolone-resistant *N. gonorrhoeae*.

diagnosis of PID), a presumptive diagnosis of PID has a positive predictive value of 65% to 90%.⁸ Unfortunately, many episodes of PID go unrecognized and subsequently give rise to infertility, ectopic pregnancy, chronic pelvic pain, or tubo-ovarian abscesses.

PID treatment regimens are designed to provide broad-spectrum empiric therapy of likely pathogens, including *N. gonorrhoeae*, *C. trachomatis*, anaerobes, and gram-negative facultative bacteria. Quinolone-resistant *N. gonorrhoeae*, prevalent in parts of Asia and the Pacific, is becoming increasingly common in California and Hawaii; this and other geographic variables associated with PID may affect the choice of antimicrobial agents. The Centers for Disease Control (CDC) has made specific recommendations for outpatient and inpatient (parenteral) antibiotic therapy [see Table 1].⁸ Criteria for inpatient therapy include inability to rule out a surgical emergency (e.g., appendicitis), severe symptoms, high fevers, failure to respond to oral antibiotics, and the presence of a tubo-ovarian abscess. Patients who are initially treated with parenteral antibiotics are usually switched to oral therapy within 24 hours after clinical improvement.

Tubo-ovarian abscess is the most serious manifestation of PID. There are no standardized diagnostic criteria for this condition, and a clinical diagnosis presents the same difficulties as a clinical diagnosis of PID itself. Most women with a tubo-ovarian abscess are young and desire future fertility. Fevers and pelvic pain are typical presenting complaints. Pelvic examination usually demonstrates a mass or extreme adnexal tenderness. Many

unruptured tubo-ovarian abscesses, unlike unruptured abscesses elsewhere in the body, can be successfully managed with antibiotics alone. Ultrasonography is useful for diagnosis and follow-up of cases that are managed conservatively. Medical management of an unruptured abscess consists of administration of appropriate antibiotics, close monitoring, and, possibly, drainage via colpotomy. Indications for surgical intervention include a questionable diagnosis, rupture of the tubo-ovarian abscess (a true surgical emergency), and failure of medical (i.e., antibiotic) therapy.

ECTOPIC PREGNANCY

Pelvic pain and vaginal bleeding in the first trimester are the complaints most commonly associated with ectopic pregnancy. Although hypotension, tachycardia, and guarding may be noted and alert the clinician to impending tubal rupture, most patients present with less alarming findings. Patients with a suspected ectopic pregnancy are initially assessed by means of transvaginal ultrasonography [see Figure 1]. Given the risk that an ectopic pregnancy may be coexisting with an intrauterine one (estimated to be between 1/4,000 and 1/15,000), the first task in the diagnostic evaluation is to exclude an intrauterine pregnancy.

Critical to the diagnosis of a suspected ectopic pregnancy is the concept of the so-called discriminatory cutoff,⁹ which is defined as the serum β -hCG level at which a normal intrauterine pregnancy can be ultrasonographically identified in nearly all patients. With a transvaginal approach, the discriminatory cutoff is usually between 1,500 and 2,500 mIU/ml; however, this value can be affected by the equipment used and by the experience (or inexperience) of the

sonographers. If the transvaginal ultrasonogram is nondiagnostic, a serum β -hCG test is performed to establish the serum level relative to the discriminatory cutoff. If an intrauterine pregnancy is not visualized above the discriminatory cutoff, the contents of the uterus are evacuated to distinguish an abnormal intrauterine gestation from an ectopic pregnancy. If the initial β -hCG is below the discriminatory cutoff, serial β -hCG measurements are required to document a viable or nonviable gestation. With a viable gestation, the β -hCG level should rise by at least 53% in 2 days.⁹ A precipitous decline in the β -hCG level suggests a spontaneous abortion; however, if the β -hCG level does not decline by at least 21% to 35% in 2 days (depending on the initial value), an ectopic pregnancy should be suspected [see Figure 1].⁹

The clinical scenario of hypovolemic shock, an acute abdomen, and a positive pregnancy test usually establishes the diagnosis of a ruptured ectopic pregnancy. The rupture of the ectopic gestation through the tube is followed by the abrupt onset of pelvic pain lateralized to the affected adnexa. The clinical manifestations of hemoperitoneum ensue, including abdominal pain, diaphragmatic irritation and syncope. If the site of tubal rupture is small or tamponades itself, the physical findings may be more subtle. The predominant symptom is pain, usually described as dull or cramping. A history of menstrual irregularity is usually present and may be accompanied by subjective symptoms of pregnancy. Current rapid urine β -hCG assays have a sensitivity of 20 to 25 mIU/ml and are readily available to confirm the diagnosis in a patient with an acute abdomen.

Once the diagnosis of a ruptured ectopic pregnancy is made,

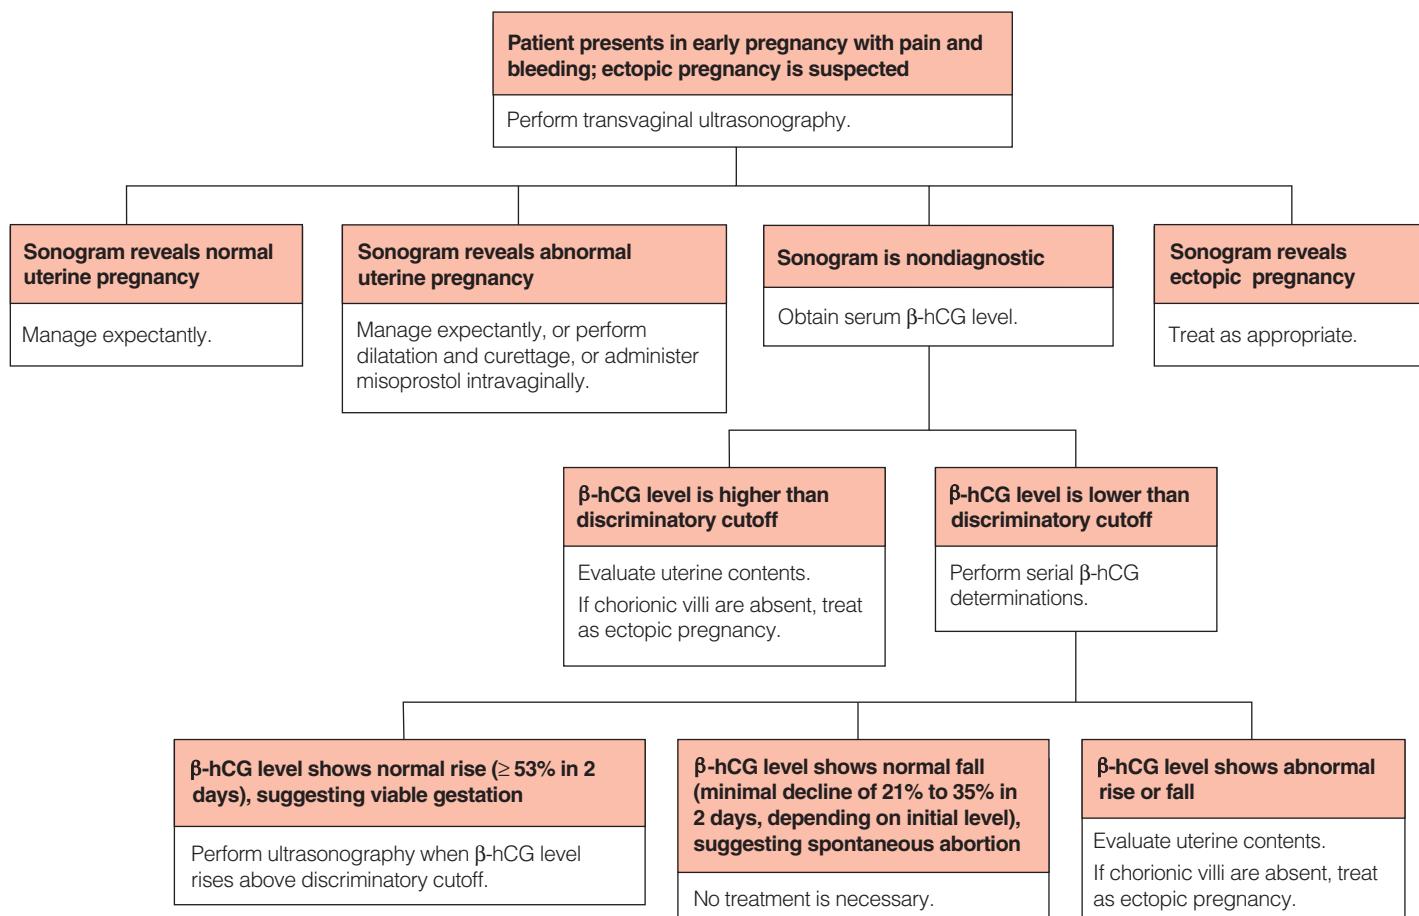

Figure 1 Algorithm illustrates evaluation of patients with suspected ectopic pregnancy.⁹

treatment consists of surgical removal of the ectopic gestation; there is no role for medical management (e.g., methotrexate) in the treatment of this condition. It should be kept in mind that not all ruptured ectopic gestations necessitate laparotomy. Hemodynamically stable patients can often be treated laparoscopically, depending on the clinical situation, the physical characteristics of the patient, and the equipment available. Diagnostic laparoscopy is an excellent tool for both diagnosis and treatment in such patients.

The patient's desire for future fertility must be considered before surgical intervention is initiated. For patients who wish to bear children in the future, conservative, tube-sparing surgery has been recommended. Linear salpingostomy is performed by making an incision in the antimesenteric aspect of the tube overlying the bulge of the ectopic gestation. The products of conception are removed, hemostasis is achieved through electrocautery, and the tubal defect is left open to heal by secondary intention. In cases of ectopic pregnancies at the distal or fimbrial portion of the fallopian tube, fimbrial expression with extrusion of the products of conception has also been performed. Patients undergoing conservative surgery should be followed with serial β -hCG determinations to ensure that there is no residual trophoblastic tissue. For patients who are hemodynamically unstable or who have no further desire of pregnancy, salpingectomy is the procedure of choice. Salpingectomy may also be necessary for adequate hemostasis after an unsuccessful attempt at salpingostomy.

VULVAR HEMATOMA

Vulvar hematomas are usually the result of blunt trauma (e.g., from straddle injuries, automobile accidents, or physical assault). The most important task in the management of a child with a vulvar hematoma is to determine the full extent of the problem. Management is usually conservative unless the hematoma is rapidly expanding. If the hematoma is not expanding after a minimum of 4 hours of observation, if the patient is able to void clear urine, and if the hematoma is not large enough to cause undue distress, nonsurgical treatment is indicated.¹⁰ Administration of analgesics and application of ice packs and pressure to the affected vulva for 8 to 12 hours after the event typically yield considerable symptomatic improvement. If the hematoma is expanding, is causing considerable pain, or is obstructing the urethra, it should be incised and evacuated with the patient under anesthesia. Any actively bleeding vessels should be ligated, and the cavity should be closed in layers. If the bed of the hematoma continues to ooze, a pack can be placed to tamponade any residual bleeding.

BARTHOLIN GLAND ABSCESS

Simple incision and drainage of a Bartholin gland abscess usually achieves prompt relief of symptoms, but it may increase the risk of later recurrence. The preferred approach has been to create a fistulous tract so as to marsupialize the gland cavity. To perform a marsupialization, a small elliptical incision is made in the vestibular mucosa overlying the wall of the abscess. The elliptical piece of mucosa is removed, exposing the wall of the Bartholin abscess. The wall of the abscess is then entered, and the contents of the abscess are evacuated. A portion of the wall underlying the elliptical mucosal defect is excised, and the wall of the cyst is approximated to the edge of the mucosa with a few 3-0 absorbable sutures. Alternatively, the Bartholin abscess may be stabilized manually and entered via a stab incision. The contents are evacuated, and a Word catheter is inserted into the cavity. The balloon is then inflated and left in place for drainage of the cyst. Marsupialization is accomplished by epithelializing the catheter tract.

Outpatient Gynecologic Problems

PELVIC MASS

The differential diagnosis of a pelvic mass is determined by the viscera occupying the pelvis and their potential pathologic alterations. The most common cause of an adnexal mass is an enlarged ovary. During the reproductive years, the majority of ovarian masses are functional cysts. Such cysts range in size from a few centimeters to 8 to 10 cm in diameter and usually disappear in 1 to 3 months. A premenopausal woman with a cystic adnexal mass less than 8 cm in diameter is usually followed for at least one menstrual cycle; the majority of such masses undergo spontaneous regression. Transvaginal ultrasonography may be particularly useful for establishing the size of the mass, as well as for distinguishing a simple cyst from a complex mass. A premenopausal patient with a large (> 8 –10 cm), predominantly solid, fixed, or irregular mass should be surgically evaluated. A postmenopausal patient with a simple unilocular cyst measuring less than 5 to 6 cm in diameter can be followed expectantly, provided that the CA 125 level is normal. In an autopsy study of 234 postmenopausal women who died of nongynecologic causes, 15% had ovarian cysts, and 3.8% had an ovarian cyst between 2 and 5 cm in diameter.¹¹ A postmenopausal patient with a large, suspicious (i.e., bilateral, irregular, fixed, solid, or accompanied by ascites), or complex mass requires surgical intervention.

Endometriosis is a benign, progressive disease defined as the presence of ectopic endometrial glands and stroma in aberrant locations in the pelvis. Hemorrhage may occur within the glandular tissue, followed by fibroblastic proliferation. The ovaries are the most common site of involvement, and ovarian involvement often results in obvious endometriotic cysts. Approximately 10% of cases may involve the rectosigmoid as well, and, depending on the degree of scarification, such involvement may be difficult to distinguish from a primary bowel neoplasm. Symptoms include pelvic pain and infertility. Medical therapy with nonsteroidal anti-inflammatory drugs (NSAIDs), combined oral contraceptives, progestins, or long-acting gonadotropin-releasing hormone (GnRH) agonists may be considered. The goals of conservative therapy are removal of gross endometriosis, lysis of adhesions, and restoration of normal anatomy. Definitive surgical treatment with hysterectomy and bilateral salpingo-oophorectomy is reserved for patients who experience intractable pain and who are no longer desirous of bearing children.

The majority of adnexal masses in women of childbearing age can be managed with cystectomy and ovarian preservation. Laparoscopic aspiration of an adnexal cyst as an isolated procedure is not recommended, because of the frequency of recurrence and the absence of any definitive pathology. Persistent cysts, cystadenomas, dermoids, and endometriomas may be managed with cystectomy, which removes the epithelial cyst lining and provides a tissue diagnosis. In a premenopausal patient with an adnexum that is not salvageable or is suspicious for malignancy, a salpingo-oophorectomy may be performed. In a postmenopausal patient with a mass, the entire ovary and tube should be removed for pathologic assessment. In carefully selected cases (e.g., patients with a negative CA 125 determination or a small, benign-appearing mass), removal of the ovary and tube can be done laparoscopically. Laparotomy is still considered the standard of care for the evaluation of potentially cancerous masses. A solid mass in a postmenopausal woman, the presence of ascites, and bilateral disease are all suggestive of malignancy. The two major concerns regarding the use of laparoscopy in the management of ovarian cancers remain the risk of tumor spillage and the delay in initiating definitive treatment.

In an open cystectomy, the ovary is immobilized, and the ovarian capsule is incised with a scalpel near the base of the cyst. Traction is placed on the incised ovarian capsule, and a Metzenbaum scissors is used to dissect the areolar tissue between the cyst wall and the capsule. After the cyst is removed, hemostasis is obtained in the bed of the cyst cavity. To reduce the risk of adhesions, the ovary usually is not sutured together. In a laparoscopic cystectomy, the utero-ovarian ligament is held so as to expose the antimesenteric aspect of the ovary. The ovarian capsule is incised with a monopolar scissors, and the cyst wall is exposed; the cyst wall is then bluntly separated from the ovarian capsule. The presence of an intact cyst wall facilitates the dissection. Eventually, the cyst is aspirated, and the remaining cyst wall is separated from the ovarian capsule by means of a 5 mm grasper. Repeated twisting of the cyst wall around the grasper (the so-called hair-curler technique) allows the cyst wall to be pulled away from the ovarian capsule. The collapsed cyst is then removed through one of the port sites and inspected for interior papillations or nodularities. The bed of the excision is inspected for hemostasis. To minimize adhesions, the edges of the ovary are not approximated with sutures.

In a postmenopausal patient with an ovarian mass, salpingo-oophorectomy is preferred, with the entire adnexum submitted for pathologic evaluation. In an open salpingo-oophorectomy, the broad ligament is entered by dividing the round ligament or by dividing the peritoneum lateral to the infundibulopelvic ligament. After the ureter is identified, the infundibulopelvic ligament is skeletonized, clamped, and ligated. The adnexum is mobilized toward the uterus, where the proximal fallopian tube and the utero-ovarian ligament are clamped, cut, and ligated. In selected postmenopausal patients with adnexal masses, salpingo-oophorectomy can be accomplished laparoscopically with bipolar electrodesiccation, suture ligation, or automatic staplers for control of the infundibulopelvic ligament.

LEIOMYOMAS

Leiomyomas, or myomas, arise as benign tumors from the myometrium and are the most common tumors of the uterus. Leiomyomas are often multiple and are grouped according to their location within the uterus; intramural, subserosal, and submucosal sites are the most common locations. Symptoms include pressure from an enlarging uterus, abnormal uterine bleeding, dysmenorrhea, and adverse pregnancy outcomes. The majority of women with myomas, however, are asymptomatic. In general, the severity of the symptoms is determined by the size and number of the fibroids, as well as by their location. The diagnosis of myomas is typically made through palpation of an irregular, enlarged uterus, though other causes of uterine enlargement or asymmetry must also be considered. Difficult cases may be resolved by employing ultrasonography or MRI to examine the uterus.

Small, asymptomatic leiomyomas may be managed with observation once a stable uterine size has been established. The need for intervention is determined on the basis of interval growth, lesion location, and patient symptoms. Rapid growth or enlargement of the uterus is another indication for surgical treatment because of the possibility of a uterine sarcoma, as well as an increased risk of operative complications. Women with symptomatic leiomyomas may be treated with myomectomy, hysterectomy, or, as is now becoming more common, uterine artery embolization. The choice between myomectomy and hysterectomy is usually determined by the patient's age, parity, and, most important, desire for future childbearing. The therapeutic effect of uterine artery embolization is thought to result from irreversible postembolic ischemia that

causes necrosis and shrinkage of the myomas.

Hysterectomy is the most commonly performed major nonobstetric operation in the United States, with approximately 600,000 done each year. Although hysterectomies can be performed via a vaginal or a laparoscopic approach, more than 60% are performed abdominally, especially for the treatment of leiomyomata.¹² An abdominal hysterectomy follows a clamp, cut, and tie approach and proceeds in a lateral-to-medial direction. The round ligaments are divided early in the procedure. Access to the broad ligament is gained by dividing the infundibulopelvic ligaments and performing salpingo-oophorectomy or by dividing the proximal tube at the utero-ovarian ligament and preserving the adnexa. The vesicouterine fold is transversely divided in an area where the bladder flap appears mobile. The bladder is reflected below the level of the uterine cervix, and the uterine arteries are skeletonized. Each uterine artery pedicle is clamped adjacent to the cervix, then cut and tied, and the cardinal ligaments are serially transected. Each pedicle is clamped, divided, and ligated medial to the previous purchase of tissue. Eventually, the vagina is entered, the specimen is amputated from the vaginal apex, and the open vaginal tube is closed. Potential urinary tract morbidity includes injury to the bladder (resulting in fistulas) and ureteral damage, most often occurring with clamping of the gonadal vessels (i.e., the infundibulopelvic ligament) or clamping of the uterine arteries.

ABNORMAL UTERINE BLEEDING

Abnormal uterine bleeding is one of the most frequent complaints expressed by patients seeking gynecologic care. Such bleeding is not in itself a diagnosis but, rather, a symptom that warrants evaluation. The term abnormal uterine bleeding includes excessive uterine bleeding (menorrhagia), bleeding between menses, and any combination of the two, as well as postmenopausal bleeding. Excessive uterine bleeding has been quantitatively defined as either menses persisting for longer than 7 days or a total menstrual blood loss that exceeds 80 ml. It is better, however, to define excessive bleeding in terms of the degree to which the abnormal bleeding deviates from a particular patient's established menstrual pattern—for example, an increase of two or more in the number of sanitary pads used daily or menses that persist for 3 or more days longer than normal. The differential diagnosis includes systemic disease (e.g., coagulopathies, hypothyroidism, and cirrhosis), reproductive tract disease (e.g., complications of pregnancy, benign disorders, and malignant lesions), iatrogenic causes (e.g., an intrauterine device [IUD]), and dysfunctional uterine bleeding. Dysfunctional uterine bleeding can only be established by excluding the other causes of abnormal uterine bleeding; it usually represents noncyclic bleeding resulting from disordered hormonal interaction.

The most important function of the history and the physical examination is to determine the source and the cause of the bleeding. A thorough examination is necessary to assess the lower genital tract, the cervix, the size of the uterus, and the status of the adnexal structures. If the patient is of reproductive age, determination of the urinary or serum β -hCG level should be considered at an early stage of evaluation. Serum β -hCG levels may remain elevated for as long as 38 days after a first-trimester abortion.¹³ Complications of pregnancy (e.g., threatened or incomplete abortions, ectopic pregnancies, retained placental tissue, or trophoblastic disease) are an important cause of abnormal uterine bleeding in women of childbearing age. An endometrial biopsy should be performed in women who have risk factors for endometrial cancer (e.g., obesity, chronic anovulation, or unopposed estrogen therapy), women with menorrhagia who are older than 35 to 40 years, and postmenopausal women who experience uterine bleeding. The

Table 2 Bethesda System for Reporting and Interpreting Results of Pap Smear

Section of Report	Explanation
Negative for intraepithelial lesion or malignancy	This section is where a "normal" result (the desired outcome) is reported. Abnormal findings not related to cancer risk are reported in two subcategories: (1) organisms (e.g., evidence of <i>Trichomonas</i> , fungal, herpesvirus, or some other infection) and (2) other nonneoplastic findings (e.g., evidence of injury and response to injury).
Endometrial cells present in woman 40 years of age or older	This section is to alert the physician that cells from the lining of the uterus are present when they normally should not be. It is a check on the status of the uterus and endometrium rather than the cervix.
Epithelial cell abnormalities*	<p>This section is where abnormalities associated with the risk of developing cancer are reported. These abnormalities occur over a spectrum ranging from slight changes to definite cancer. They are initially classified into squamous cell changes and glandular cell changes.</p> <p><i>Squamous cell abnormalities</i></p> <ul style="list-style-type: none"> Atypical squamous cells (ASC): cellular abnormalities that qualitatively or quantitatively fall short of definitive diagnosis of squamous epithelial lesion ASC of undetermined significance (ASC-US) ASC for which HSIL or high-grade changes cannot be excluded (ASC-H) Low-grade squamous intraepithelial lesion (LSIL): encompasses HPV infection, CIN I, and mild dysplasia High-grade squamous intraepithelial lesion (HSIL): encompasses CIN II and III, moderate dysplasia, severe dysplasia, and carcinoma in situ Squamous cell carcinoma (SCC): characterized by tumor diathesis (blood and necrotic debris), prominent macronuclei, and parachromatin clearing <p><i>Glandular cell abnormalities</i></p> <ul style="list-style-type: none"> Atypical glandular cells (AGC) (endocervical, endometrial, or not otherwise specified) AGC favoring neoplasia (endocervical or not otherwise specified) Endocervical adenocarcinoma in situ (AIS) Adenocarcinoma (endocervical, endometrial, extrauterine, or not otherwise specified)
Other malignancies	This section is where any malignant tumors other than primary SCC and glandular adenocarcinoma are reported.

* Patients with LSIL, HSIL, SCC, persistent ASC-US, ASC-US with high-risk HPV types, ASC-H, AGC, AIS, or adenocarcinoma undergo outpatient evaluation with colposcopy.

ectocervix is cleansed with antiseptic solution, and a flexible plastic catheter containing an obturator is advanced into the uterine cavity. The obturator is withdrawn, and tissue fragments are aspirated into the plastic catheter. Patients who are unable to tolerate this procedure may be evaluated by means of transvaginal ultrasonography. An endometrial stripe thinner than 5 mm is unlikely to represent an endometrial cancer.

Treatment of abnormal uterine bleeding depends on the underlying cause. Patients with demonstrated organic pathology are managed as appropriate for the specific condition present. Excessive uterine bleeding resulting from anovulation can be managed with cyclic progestins or an oral contraceptive. Acute severe menorrhagia (often accompanied by hemodynamic instability) can initially be managed with volume support and intravenous admin-

istration of estrogens to stabilize the endometrium and terminate bleeding; subsequently, after 24 hours of I.V. estrogen therapy, the patient is switched to an oral contraceptive. Excessive blood loss with ovulatory cycles can be managed with NSAIDs, an oral contraceptive, the levonorgestrel IUD, or surgical intervention (i.e., endometrial ablation). In one study, use of the levonorgestrel IUD resulted in an 87% reduction in menstrual blood loss after 3 months and a 95% reduction after 6 months, compared with blood loss recorded during pretreatment menses.¹⁴

SQUAMOUS DYSPLASIAS AND GYNECOLOGIC MALIGNANCIES

SQUAMOUS DYSPLASIAS OF LOWER GENITAL TRACT

Infection with low-risk human papillomavirus (HPV) types, such as HPV 6 and HPV 11, results in condylomas of the lower genital tract. Infection with high-risk types, such as HPV 16 and HPV 18, may result in dysplasias that have the potential to progress to invasive disease. The majority of sexually active women eventually become infected with high-risk HPV types. In most women, however, this infection proves transient: at 12 months' follow-up, 70% of HPV-infected women are HPV negative, and at 24 months' follow-up, 91% are HPV negative.¹⁵ Those women who experience persistent infections are at highest risk for the subsequent development of significant cervical dysplasias.

The Papanicolaou (Pap) smear is a screening test used to identify women who may have cervical dysplasia (also referred to as cervical intraepithelial neoplasia [CIN]) and early invasive disease. Patients with abnormal smears as determined by the Bethesda system [see Table 2] undergo outpatient triage with colposcopy. This technique uses a bright light source and magnification to examine the cervix after the application of dilute acetic acid, which acts as a mucolytic agent and accentuates epithelial and vascular changes suggestive of dysplasia. Small biopsies are obtained from abnormal-looking areas to allow mapping of potential areas of dysplasia. Expectant management is recommended for patients with mild squamous cell dysplasia (i.e., CIN I); treatment aimed at eliminating the dysplasia is usually recommended for patients with more significant lesions (i.e., CIN II or CIN III). In the past, many patients with cervical dysplasia were treated with ablative therapies, such as cryotherapy or laser vaporization. Currently, a loop electrocautery excision procedure (LEEP) is often employed to treat

Table 3 International Federation of Gynecology and Obstetrics Surgical Staging System for Endometrial Carcinoma

Stage	Description
I	IA Tumor is limited to endometrium
	IB Tumor invades ≤ 50% of myometrium
	IC Tumor invades > 50% of myometrium
II	IIA Tumor involves endocervical glands
	IIB Tumor invades cervical stroma
III	IIIA Tumor invades uterine serosa or adnexa, peritoneal cytology is positive, or both
	IIIB Tumor metastasizes to vagina
	IIIC Tumor metastasizes to pelvic or para-aortic lymph nodes
IV	IVA Tumor invades bladder or bowel mucosa
	IVB Tumor metastasizes to distant sites, including intra-abdominal or inguinal lymph nodes

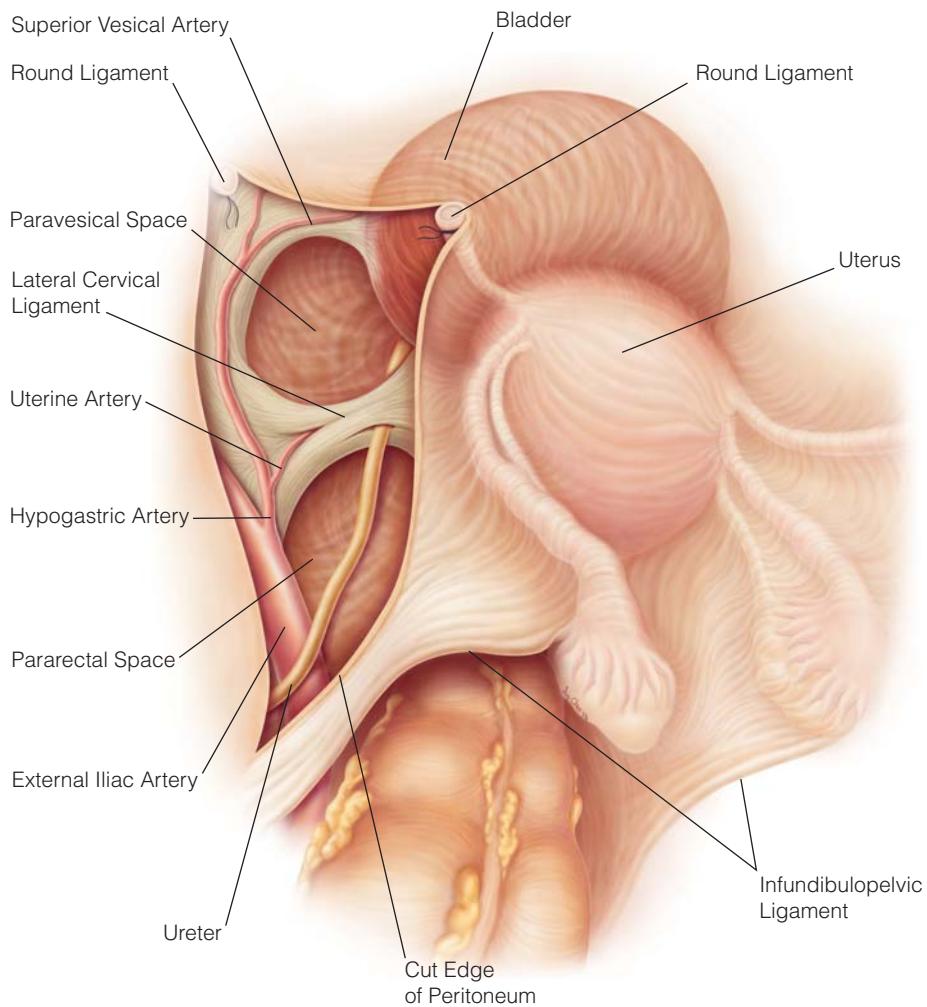

Figure 2 Depicted are the retroperitoneal spaces of the pelvis (i.e., the pararectal and paravesical spaces). Dissection of the pararectal and paravesical spaces demonstrates the base of the cardinal ligament separating the two spaces. In this representation, the superior vesical artery has been mobilized from the lateral wall of the bladder and relocated to a lateral position.²⁵

the dysplasia, as well as to submit tissue for pathologic analysis. Cold-knife cervical conization may be performed as an alternative to LEEP; it avoids creating thermal artifacts and may be more useful in patients who have glandular dysplasias or appear to be at risk for early invasive disease.

Women who have undergone a total hysterectomy for benign disease may discontinue Pap smear screening. Women who have undergone a hysterectomy and have a history of a significant cervical dysplasia (CIN II or CIN III) should continue annual Pap smear screening until three consecutive satisfactory negative cytology results have been obtained, at which point routine cytology screening can be discontinued. Women who have had high-grade squamous dysplasias of the cervix may also experience the development of vaginal dysplasia after hysterectomy.

Vaginal dysplasia is asymptomatic and typically is detected only after an abnormal Pap smear. Initial evaluation consists of colposcopy with directed biopsies of abnormal-appearing vaginal mucosa. Significant dysplasias may be either ablated with superficial laser vaporization or excised. Excision with partial vaginectomy is definitive treatment from a pathologic perspective, but it may be associated with a higher rate of complications.

Vulvar dysplasia may be visible in the form of discrete, slightly raised (papular), often pigmented lesions. Biopsy of the lesion establishes the diagnosis and rules out obvious invasive disease. Multifocal disease involving non-hair-bearing areas (often seen in young patients) can usually be treated with superficial laser vaporization or with topical application of imiquimod, an immune

response modifier in cream form that is currently used in the treatment of condyloma. Lesions in hair-bearing areas and confluent lesions (often seen in postmenopausal women) are best treated with wide local excision. Large unifocal confluent lesions may contain occult invasive foci that are identifiable only through excision and careful pathologic evaluation. The lesion, along with a 4 to 5 mm margin of normal tissue, is incised with a scalpel and dissected away from the underlying dermis with an electrocautery. The superficial defect is closed in one layer with interrupted sutures; a rhomboid flap may be required for more sizeable defects.

ENDOMETRIAL CANCER

Endometrial carcinoma is the most common gynecologic malignancy and accounts for more than 95% of uterine cancers. Although the majority of these carcinomas occur on a sporadic basis, an endometrial cancer can also be the initial manifestation of the Lynch syndrome (hereditary nonpolyposis colorectal cancer [HNPCC]) [see 5:14 *Hereditary Colorectal Cancer and Polyposis Syndromes*]. The lifetime risk of endometrial cancer for women with the Lynch syndrome is 40% to 60%, which equals or exceeds their risk of colorectal cancer.¹⁶ In the United States, approximately 40,000 new cases of endometrial cancer are diagnosed each year, of which 7,000 prove fatal. About 75% of these cases involve postmenopausal women, with the remaining 25% involving premenopausal women; only about 5% of cases involve women younger than 40 years. Endometrial cancers are adenocarcinomas and usually resemble the glands of the endometrial lining; howev-

er, approximately 10% have a nonendometrioid (i.e., papillary serous or clear cell) histology, a pattern associated with a biologically aggressive behavior. Abnormal vaginal bleeding or postmenopausal bleeding is the most common presenting complaint. Outpatient endometrial biopsy with aspiration of tissue from the uterine cavity often establishes the diagnosis. If the tissue obtained is insufficient or the patient cannot tolerate outpatient evaluation, dilatation and curettage (often with hysteroscopy) is performed with the patient under anesthesia.

Approximately 75% of patients with endometrial cancer have early disease. Therapy typically consists of hysterectomy, bilateral salpingo-oophorectomy, procurement of peritoneal specimens for cytologic examination, and staging. The regional lymph nodes are the most frequent site of occult metastatic disease. Accordingly, the surgical staging criteria [see Table 3] emphasize the pathologic status of the regional lymph nodes with selective pelvic and para-aortic lymphadenectomy. Although there are direct lymphatic channels from the uterus to the para-aortic area, it is uncommon to find positive para-aortic nodes in the absence of pelvic nodal involvement.

Selective pelvic lymphadenectomy removes the lymphatic tissue from the anterior and medial surfaces of the iliac vessels and from the obturator fossa superior to the obturator nerve. Sampling of the pelvic lymph nodes is facilitated by developing the pararectal and paravesical spaces in the retroperitoneum of the pelvis [see Figure 2]. The pararectal space is developed by means of blunt dissection between the ureter medially and the internal iliac (hypogastric) artery laterally. Dissection through the loose areolar tissue proceeds caudomedially toward the coccyx. The paravesical space is developed by sweeping the obliterated superior vesical artery and the bladder medially. The space is bordered by the pubic symphysis anteriorly and the obturator internus laterally. Development of the spaces provides the exposure necessary for skeletonizing the iliac vessels and the obturator nerve. Selective para-aortic lymphadenectomy consists of removing pre caval and aortic lymphatic tissue from the level of the inferior mesenteric artery to the middle of the common iliac artery bilaterally. Sampling of the para-aortic lymph nodes is then accomplished via either a direct or a lateral approach. With a direct approach, an incision is made into the peritoneum overlying the right common iliac artery and extended over the aorta. With a lateral approach, an incision is made in the lateral paracolic gutters, with the right or left colon reflected medially. In one study, a median of 11 pelvic and three para-aortic lymph nodes were obtained at selective lymphadenectomy.¹⁷

OVARIAN CANCER

Of all the reproductive tract malignancies, ovarian cancer poses the greatest clinical challenge. Although ovarian cancers can arise from germ cells, sex-cord cells, or stromal cells, approximately 85% arise from the coelomic epithelium and thus are termed epithelial cancers. The peak incidence of invasive ovarian epithelial cancers is between 56 and 60 years of age. Approximately 5% to 10% of these cancers have a hereditary component; women with *BRCA1/BRCA2* or Lynch syndrome (HNPCC) germline mutations are at increased risk. Prophylactic salpingo-oophorectomy in patients with *BRCA1/BRCA2* mutations virtually eliminates the risk of ovarian and tubal cancer and reduces the risk of breast and primary peritoneal cancer.^{18,19}

Ovarian cancer is the second most common gynecologic malignancy, but it has the highest fatality-to-case ratio of any reproductive tract cancer. Ovarian epithelial carcinomas spread primarily through exfoliation of cells, which places the entire peritoneal cavity at risk for metastases. Moreover, early recognition is difficult because the majority of patients have only vague and nonspecific

complaints. Not surprisingly, 60% to 70% of patients have advanced (stage III or IV) disease at diagnosis. Detection of ovarian cancer is further hindered by the fact that there is no effective screening test. The tumor-associated antigen CA 125 is expressed by more than 80% of ovarian epithelial cancers; however, though CA 125 levels are employed in following up patients with documented disease, they are not useful for screening purposes. In a group of 1,110 women at increased risk for ovarian cancer, annual surveillance with serum CA 125 determinations and additional transvaginal ultrasonography was unable to detect tumors at an early enough stage to influence the prognosis.²⁰

Surgical intervention serves three purposes in the setting of ovarian epithelial cancer: diagnosis, staging, and tumor debulking (cytoreduction). The staging of ovarian cancer is based on the pathologic findings at surgery [see Table 4]. Only a minority of women have stage I disease at diagnosis, and the decision whether to employ paclitaxel and carboplatin chemotherapy is predicated on the surgical extent of the disease. Unfortunately, thorough intraoperative staging is not always performed. In a series of 785 women found to have ovarian cancer in 1991, lymphadenectomy was not done in 66% of the patients with presumptive stage I or II disease.²¹

In patients who appear to have early rather than advanced dis-

Table 4 International Federation of Gynecology and Obstetrics Surgical Staging System for Ovarian Cancer

Stage	Characteristics
I	Tumor growth is limited to ovaries.
	IA Tumor is limited to one ovary; there is no ascitic fluid containing malignant cells; there is no tumor on external surface; capsule is intact
	IB Tumor is limited to the two ovaries; there is no ascitic fluid containing malignant cells; there is no tumor on external surface; capsules are intact
II	IC Tumor is either stage IA or IB, but (a) there is tumor on surface of one or both ovaries, (b) capsule is ruptured, or (c) ascitic fluid containing malignant cells is present or peritoneal washings are positive
	Tumor involves one or both ovaries, with pelvic extension.
	IIA Tumor extends or metastasizes to uterus or Fallopian tubes
III	IIB Tumor extends to other pelvic tissues
	IIC Tumor is either stage IIA or IIB, but (a) there is tumor on surface of one or both ovaries, (b) one or both capsules are ruptured, or (c) ascitic fluid containing malignant cells is present or peritoneal washings are positive
	Tumor involves one or both ovaries, with peritoneal implants outside pelvis, positive retroperitoneal or inguinal nodes, or both. Superficial liver metastasis equals stage III. Tumor is limited to true pelvis, but with histologically proven malignant extension to small bowel or omentum.
IV	IIIA Tumor is grossly limited to true pelvis, with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces
	IIIB Tumor involves one or both ovaries, with negative nodes but with histologically confirmed implants on abdominal peritoneal surfaces, none of which are > 2 cm in diameter
	IIIC Abdominal implants > 2 cm in diameter are present, retroperitoneal or inguinal nodes are positive, or both
IV	Tumor involves one or both ovaries, with distant metastasis. If pleural effusion is present, cytologic test results must be obtained to assign a case to stage IV.
	Parenchymal liver metastasis equals stage IV.

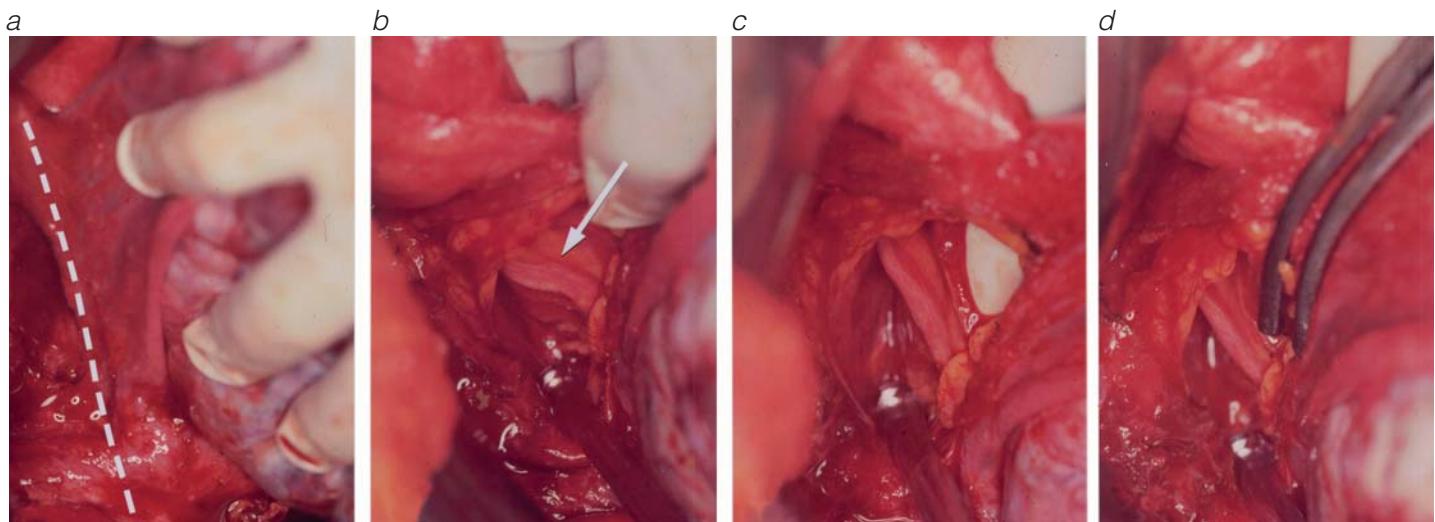

Figure 3 Shown is a retroperitoneal approach to a large, fixed ovarian mass that is adherent to adjacent structures. (a) The mass is drawn medially, and the peritoneum lateral to the infundibulopelvic ligament is divided (dotted line) to afford entry into the retroperitoneum of the pelvis. (b) The ureter (arrow) is identified on the medial leaf of the broad ligament in a location below the infundibulopelvic ligament. (c) An opening is made below the infundibulopelvic ligament and superior to the ureter, and the primary blood supply to the ovarian mass is thereby isolated. (d) The gonadal vessels are clamped, cut, and ligated. The mass is then dissected from the adjacent tissues in view of the ureter.

ease, the emphasis is on accurate staging. At least 30% of patients whose disease is seemingly confined to the pelvis show some evidence of upper abdominal or nodal spread. A midline incision is made, and upon entry into the peritoneal cavity, any free abdominal fluid is submitted for cytologic evaluation. If no abdominal fluid is present, pelvic washings are done with 50 to 100 ml of saline, and the saline is recovered and submitted for cytologic evaluation. The ovarian tumor should be removed intact (if possible) and submitted for frozen-section analysis. The intra-abdominal surfaces and the viscera are systematically inspected. Any suspicious areas or adhesions are subjected to biopsy. Random peritoneal biopsies are performed on the lateral upper and lower paracolic gutters, the bladder flap, the cul-de-sac, and the pelvic sidewalls. Sterile tongue depressors are used to obtain cytologic specimens from both infradiaphragmatic surfaces. An infracolic omentectomy is performed. The regional nodes are palpated, and any enlarged lymph nodes are removed. Finally, the pelvic and para-aortic nodes are sampled to allow detection of any occult spread.

Because the majority of patients with ovarian epithelial cancers present with advanced disease, the main goal of surgical intervention is often tumor debulking. The purpose of cytoreduction is to remove the primary cancer, as well as any metastases. If complete resection of metastases is not feasible, the aim is to reduce the bulk of the residual disease to, ideally, a diameter of 1 cm or less (so-called optimal debulking). Optimal cytoreduction enhances the response to I.V. paclitaxel and carboplatin chemotherapy, and patients with minimal residual disease have a distinct survival advantage over those with more substantial residual disease. Furthermore, current data indicate that patients who have undergone optimal debulking may be candidates for intraperitoneal, as opposed to I.V., chemotherapy. There is evidence to suggest that the use of intraperitoneal chemotherapy may improve survival rates.²²

The removal of pelvic disease is accomplished via a retroperitoneal approach [see Figure 3]. Although ovarian cancers commonly involve and distort peritoneal surfaces, they usually do not have a significant effect on the retroperitoneal anatomy. The retroperi-

toneum is entered laterally along the surface of the psoas muscle. The procedure is initiated by either dividing the round ligament or entering the peritoneum lateral to the infundibulopelvic ligament. Upon entry into the retroperitoneal space, the infundibulopelvic ligament, the ureter, and the great vessels are identified. The pararectal and paravesical spaces may be developed to facilitate the removal of locally advanced pelvic disease [see Figure 2]. If the disease involves the bowel, its mesentery, or both, resection and reanastomosis may be necessary, either to remove an obstruction or to achieve optimal tumor debulking. Small bowel resection may be required to achieve optimal cytoreduction in as many as 10% of patients.^{23,24}

Primary peritoneal and tubal cancers are relatively rare malignancies whose presentation may include a mass, malignant ascites, or pain. These tumors are more frequent in patients with *BRCA1/BRCA2* mutations, and they bear a histologic resemblance to, as well as behave as, ovarian epithelial carcinomas. Treatment is identical to that of ovarian cancer, with initial surgical intervention establishing the diagnosis and the disease stage. After tumor debulking, paclitaxel and carboplatin chemotherapy is administered. Patients with tubal cancers should undergo hysterectomy and bilateral salpingo-oophorectomy. If there is no evidence of gross tumor spread, a staging procedure is performed that includes sampling of the pelvic and para-aortic lymph nodes, infracolic omentectomy, and procurement of peritoneal specimens for cytologic examination through multiple peritoneal biopsies.

CERVICAL CANCER

Although cervical cancer is only the third most common gynecologic malignancy in the United States, it is the most common genital tract cancer in the world. Patients with early invasive carcinomas may present with nothing more than an abnormal Pap smear, but most complain of postcoital bleeding or a bloody vaginal discharge. With early disease, colposcopy or conization may be required to establish the diagnosis; however, the majority of patients have a gross cervical lesion, and punch biopsy is usually

Table 5 International Federation of Gynecology and Obstetrics Surgical Staging System for Cervical Cancer

Stage	Characteristics
I	IA Tumor is invasive carcinoma that can be diagnosed only by microscopy IA1: Tumor has measured stromal invasion of ≤ 3 mm and extension of ≤ 7 mm IA2: Tumor has measured stromal invasion of > 3 but < 5 mm and extension of ≤ 7 mm
	IB Tumor is clinically visible lesion limited to cervix or microscopic lesion more extensive than stage IA IB1: Tumor is clinically visible lesion with maximum diameter of ≤ 4 cm IB2: Tumor is clinically visible lesion with maximum diameter of > 4 cm
II	Tumor invades beyond uterus but does not reach pelvic wall or lower third of vagina. IIA Tumor does not obviously involve parametrium IIB Tumor obviously involves parametrium
III	Tumor extends to pelvic wall. On rectal examination, there is no cancer-free space between tumor and pelvic wall. Tumor involves lower third of vagina. All cases with hydronephrosis or a nonfunctioning kidney are included unless known to be attributable to another cause. IIIA Tumor involves lower third of vagina, with no extension to pelvic wall IIIB Tumor extends to pelvic wall, hydronephrosis is present, or kidney is nonfunctioning
IV	Tumor extends beyond true pelvis or involves mucosa of bladder or rectum (as proved by biopsy). Bullous edema per se does not permit case to be allotted to stage IV. IVA Tumor spreads to adjacent organs IVB Tumor spreads to distant organs

performed to establish the diagnosis. As a result of the necrotic debris and blood, cytology yields false negative results in as many as 50% of invasive cervical carcinomas. When a gross cervical lesion is present, biopsy and histologic evaluation are mandatory.

The staging of cervical cancer is based on the clinical findings and takes into account the results of pelvic examination, chest radiography, and intravenous pyelography (IVP) [see Table 5]. Stage I cervical cancer denotes disease that is limited to the cervix itself. It may be subdivided into stages IA (microscopic disease) and IB (more advanced or grossly visible disease). The assignment of a cervical cancer to stage IA requires that cervical conization be done to assess the depth and lateral extent of stromal invasion. Microinvasive carcinoma is a tumor that invades the cervical stroma to a depth of 3 mm or less, without lymphovascular space involvement. Stage II cancer denotes disease that involves the upper two thirds of the vagina or parametrial disease that has not reached the pelvic sidewall. Stage IIIB cancer denotes parametrial disease that has reached the pelvic sidewall or results in ureteral obstruction.

Treatment of cervical cancer is predicated on the patient's suitability for surgery and on the stage and bulk of the tumor. Young patients with early, genuine microinvasive carcinomas and a desire for future childbearing may be followed conservatively after conization with negative margins. For the majority of patients with microinvasive cancers, definitive treatment consists of simple abdominal or vaginal hysterectomy; the risk of pelvic nodal metastasis is lower than 1%. Patients with stage IA2, IB, and IIA disease may be treated with radical hysterectomy. This surgical procedure differs from simple abdominal hysterectomy in several respects. In

a simple hysterectomy for benign disease, the vascular pedicles are placed close to the uterus and the cervix. A radical hysterectomy dissects out the lower aspect of the ureters, allowing wider clearance of the central specimen and the adjacent adventitial tissues (e.g., cardinal ligaments and parametria). At an early point in the procedure, the pararectal and paravesical spaces are developed [see Figure 2]. If the disease appears to be limited to the central specimen, the uterine artery is divided at its point of origin from the superior vesical artery and mobilized over the ureter. The parametria, lying between the pararectal and paravesical spaces, are divided. The ureters are separated from the medial peritoneum of the posterior leaf of the broad ligament, then dissected out to the point where they insert into the bladder. Once the distal ureters have been mobilized, clamps are placed into the paravaginal tissues, and an extra margin of lateral tissue is removed. The rectovaginal septum is also developed to allow division of the uterosacral ligaments closer to their point of origin at the sacrum. The upper 2 cm of the vagina is removed in continuity with the rest of the specimen. A systematic pelvic lymph node dissection is then performed, with skeletonization of the common iliac artery, the external iliac artery, the external iliac vein, and the obturator nerve.

Patients who have more advanced disease (stage IIB or higher) or are unable to undergo surgery are treated with radiotherapy and chemotherapy as a radiation sensitizer. Initially, protracted, fractionated external beam radiotherapy is administered. By using a number of fields, external beam treatment distributes radiation to the central tumor and the pelvic lymph nodes in a relatively homogeneous fashion. External radiotherapy is followed by intracavitary radiotherapy, in which a radioisotope is placed into the uterus, the cervix, and the upper vagina. The radiation delivered by intracavitary radiotherapy is distributed according to the inverse square law: a substantial amount is delivered to the central tumor, but the dose falls off rapidly in adjacent tissues as the distance from the central lesion increases.

VULVAR CANCER

Vulvar cancers arise from the epidermis of the vulva and are usually of squamous histology. Approximately 30% to 40% of vulvar cancers are related to exposure to HPV, usually in younger patients and those with preexisting vulvar dysplasia. In the majority of patients, however, no clear cause can be identified. Vulvar carcinomas spread by embolization along lymphatic channels, which ter-

Table 6 Characteristics of Complete and Partial Moles

Parameter	Complete Mole	Partial Mole
Anatomy	No fetus or fetal parts present	Fetus or fetal parts present
Histology	Generalized villous swelling; diffuse trophoblastic proliferation	Focal trophoblastic proliferation and villous swelling; villous scalloping and prominent trophoblastic inclusions
Karyotype	Diploid, usually 46 XX (all genetic material is paternal)	Diandric triploidy
Presentation	Uterus large for dates; pre-eclampsia; hyperthyroidism; theca-lutein cysts	Missed or incomplete abortion
Natural history	20% chance of requiring chemotherapy	3% to 4% chance of requiring chemotherapy

minate at the inguinofemoral lymph nodes. Superficial and medial lymph nodes are the ones most commonly involved. The pelvic lymph nodes are rarely involved unless the ipsilateral inguinal nodes contain metastatic disease.

Treatment must take into account both the primary vulvar lesion and the possibility of inguinal node metastasis. Historically, radical vulvectomy with bilateral groin dissection was the standard of care for the treatment of vulvar cancers. Currently, the emphasis is on performing the most conservative surgical procedure that is consistent with cure of the disease. Radical local excision with surgical evaluation of the inguinal nodes has become the modern standard of care for most patients. The vulvar lesion is excised with margins of at least 1 cm. The incision is carried to the inferior fascia of the urogenital diaphragm, which is coplanar with the fascia lata of the thigh and the fascia over the pubic symphysis. If more than 1 mm of stromal invasion is noted, surgical evaluation of the inguinofemoral lymph nodes is required. Bilateral groin dissections are not necessary unless the lesion is on the clitoris, the anterior labia minora, or the perineum or lies within 1 cm of the midline. If the extent of stromal invasion is 1 mm or less, node dissection is not necessary, because the risk of groin metastasis is low.

Surgical evaluation of the inguinal nodes has also evolved over time. The current surgical options are (1) a superficial inguinal node dissection that removes the lymphatic tissue above the fascia lata and the cribriform fascia and (2) a complete inguinofemoral node dissection that removes both the superficial nodes and the deep nodes lying below the cribriform fascia and medial to the femoral vein. Advocates of the first option view the superficial inguinal nodes as the sentinel lymph nodes of the groin and consequently maintain that a more extensive dissection is generally not required.

Patients found to have positive inguinal nodes at groin dissection receive adjuvant radiotherapy. Patients with advanced, unresectable primary disease, who in the past were treated with exenteration, now are treated with radiation and chemotherapy as a radiation sensitizer. Local (perineal) recurrences are treated with wide local resection. Unfortunately, recurrences in the inguinal nodes after primary therapy usually are refractory to further therapy and often prove fatal.

GESTATIONAL TROPHOBLASTIC DISEASE

Gestational trophoblastic disease is a blanket term for a range of placenta-derived neoplasias that include hydatidiform mole, invasive mole, gestational choriocarcinoma, and placental site tumor. Of these conditions, the one most frequently encountered is hydatidiform mole, or molar gestation. In the United States, moles occur in approximately one of every 1,000 to 1,200 pregnancies. Patients present with vaginal bleeding, passage of mole tissue through the vagina, a uterus that is large for the gestational age (as determined on the basis of the last menstrual period), or medical complications deriving from the mole. The diagnosis is established through ultrasonographic examination of the uterus. Therapy consists of evacuation of the uterine contents (ideally by suction curettage) and subsequent serial serum β -hCG determinations, with adequate contraception during the follow-up period. Moles usually are complete but sometimes are partial (i.e., occur with fetal tissue or even a fetus). The distinction between complete and partial moles, though initially regarded as little more than a medical curiosity, actually reflects identifiable differences in anatomy, histology, presentation, and natural history [see Table 6].

If β -hCG levels rise or plateau or there is evidence of metastatic disease, further therapy for postmolar malignant gestational trophoblastic neoplasia is required. Before effective chemotherapy became available, it was common practice to perform hysterectomy, allowing pathologic assessment of the uterine contents (persistent mole, invasive mole, or choriocarcinoma).

Currently, most women with gestational trophoblastic disease can be successfully managed by means of chemotherapy, without risk to the reproductive organs. Patients are evaluated for metastases with various radiologic studies and are stratified according to prognostic risk factors (as assessed by criteria developed by the National Institutes of Health, the International Federation of Gynecology and Obstetrics, or the World Health Organization). Sites of metastatic disease are documented; however, to avoid the risk of a major hemorrhage, they are not subjected to biopsy. Therapy is governed by the level of risk present. Single-agent therapy (with methotrexate or actinomycin D) is given to patients with low-risk disease, and aggressive multiagent therapy is given to patients with high-risk disease.

NORMAL LABORATORY VALUES

Clinical Chemistry

Analyte	Specimen	Units Used at MGH*	SI Units
Acetoacetate	P	< 1 mg/dl	< 100 µmol/L
Albumin	S	3.5–5.5 g/dl	35–55 g/L
Aldolase	S	0–6 U/L	0–100 nkat/L
Alpha ₁ -antitrypsin	S	85–213 mg/dl	0.8–2.1 g/L
Alpha-fetoprotein	S	< 15 ng/ml	< 15 µg/L
Aminotransferases	S		
Aspartate (AST, SGOT)		0–35 U/L	0–0.58 µkat/L
Alanine (ALT, SGPT)		0–35 U/L	0–0.58 µkat/L
Ammonia, as NH ₃	P	10–80 µg/dl	6–47 µmol/L
Amylase	S	60–180 U/L	0.8–3.2 µkat/L
Angiotensin-converting enzyme (ACE)	S	< 40 U/L	< 670 nkat/L
Anion gap	S	7–16 mmol/L	7–16 mmol/L
Apolipoprotein	S		
Apolipoprotein A1		119–240 mg/dl	1.2–2.4 g/L
Apolipoprotein B		52–163 mg/dl	0.52–1.63 g/L
Apolipoprotein B-to-apolipoprotein A1 ratio		0.35–0.98	0.35–0.98
Arterial blood gases, sea level	WB, arterial		
Bicarbonate (HCO ₃ ⁻)		21–30 mEq/L	21–28 mmol/L
Partial pressure of carbon dioxide (PCO ₂)		35–45 mm Hg	4.7–5.9 kPa
pH		7.38–7.44	7.38–7.44
Partial pressure of oxygen (PO ₂)		80–100 mm Hg	11–13 kPa
β-Hydroxybutyrate	P	< 3 mg/dl	< 300 µmol/L
β ₂ -Microglobulin	S	1.2–2.8 mg/L	1.2–2.8 mg/L
Bilirubin	U	≤ 200 µg/L	≤ 200 µg/L
Total	S		
Direct		0.3–1.0 mg/dl	5.1–17.0 µmol/L
Indirect		0.1–0.3 mg/dl	1.7–5.1 µmol/L
Indirect		0.2–0.7 mg/dl	3.4–12.0 µmol/L
Brain natriuretic peptide (BNP)	P	< 167 pg/ml (age- and sex-dependent)	< 167 ng/L (age- and sex-dependent)
Calcium	S	9.0–10.5 mg/dl	2.2–2.6 mmol/L
Calcium, ionized	WB	4.5–5.6 mg/dl	1.1–1.4 mmol/L
CA15–3	S	0–30 U/ml	0–30 kU/L
CA19–9	S	0–37 U/ml	0–37 kU/L
CA27–29	S	0–32 U/ml	0–32 kU/L
CA125	S	0–35 U/ml	0–35 kU/L
Calcitonin	S		
Male		3–26 pg/ml	3–26 ng/L
Female		2–17 pg/ml	2–17 ng/L
Carbon dioxide			
Content, sea level	P	21–30 mEq/L	21–30 mmol/L
Partial pressure (PCO ₂), sea level	WB, arterial	35–45 mm Hg	4.7–5.9 kPa
Carbon monoxide content	WB		Symptoms with 20% saturation of hemoglobin
Carcinoembryonic antigen (CEA)	S	0–3.4 ng/ml	0–3.4 µg/L
Ceruloplasmin	S	27–37 mg/dl	270–370 mg/L
Cholinesterase	S	5–12 U/ml	5–12 kU/L
Chloride	S	98–106 mEq/L	98–106 mmol/L

Note: This table contains reference values for adults for laboratory tests commonly ordered at the Massachusetts General Hospital (MGH) and recorded in the Case Records. The table revises the most recently published data (Normal Reference Laboratory Values. N Engl J Med 339:1063–72, 1998). Laboratory values are expressed in the units used at the MGH and the units of the Système International d'Unités (SI units). The table is not intended to provide a comprehensive review of reference values, since this information is widely available in standard textbooks. To avoid suggesting an endorsement of commercial products by the hospital or the *Journal*, information on specific methods and instruments is not provided. Reference values are affected by many variables, including the patient population and the laboratory methods used. The ranges used at the MGH, as well as in chapters of *ACP Medicine*, may therefore not be appropriate for other institutions and may not be optimal in some situations.

†The creatine kinase relative index is calculated as [MB isoenzyme (in nanograms per milliliter) ÷ total creatine kinase (in units per liter)] × 100.

JF—joint fluid P—plasma PRP—platelet-rich plasma RBC—red blood cell S—serum U—urine WB—whole blood

Clinical Chemistry (continued)

Analyte	Specimen	Units Used at MGH*	SI Units
Cholesterol	P		
Low-density lipoprotein (LDL) cholesterol		< 100 mg/dl	< 2.59 mmol/L
Optimal		100–129 mg/dl	2.59–3.34 mmol/L
Near or above normal		130–159 mg/dl	3.36–4.11 mmol/L
Borderline high		160–189 mg/dl	4.13–4.88 mmol/L
High		≥ 190 mg/dl	≥ 4.91 mmol/L
Very high			
High-density lipoprotein (HDL) cholesterol			
Low		< 40 mg/dl	< 1.03 mmol/L
High		≥ 60 mg/dl	≥ 1.55 mmol/L
Total cholesterol			
Desirable		< 200 mg/dl	< 5.17 mmol/L
Borderline high		200–239 mg/dl	5.17–6.18 mmol/L
High		≥ 240 mg/dl	≥ 6.18 mmol/L
Copper	S	70–140 µg/dl	11–22 µmol/L
	U	3–35 µg/24 hr	0.047–0.55 µmol/24 hr
Coproporphyrins, types I and III	U	100–300 µg/24 hr	150–460 µmol/24 hr
C-peptide	S	0.5–2.0 ng/ml	0.17–0.66 nmol/L
Creatine kinase	S		
Total			
Female		40–150 U/L	0.67–2.50 µkat/L
Male		60–400 U/L	1.00–6.67 µkat/L
MB isoenzyme	S	0–7 ng/ml	0–7 µg/L
Relative index [†]	S	Method-dependent	Method-dependent
Creatinine	S	< 1.5 mg/dl	< 133 µmol/L
Erythropoietin	S	5–36 IU/L	5–36 IU/L
Fatty acids, free (nonesterified)	P	< 8–25 mg/dl	0.28–0.89 mmol/L
Fibrinogen and fibrinogen-degradation products [see under Hematology and Coagulation]			
Folic acid	RBC	150–450 ng/ml/cells	340–1,020 nmol/L/cells
γ-Glutamyltransferase	S	1–94 U/L	1–94 U/L
Glucose	P		
Fasting			
Normal		75–115 mg/dl	4.2–6.4 mmol/L
Diabetes mellitus		> 125 mg/dl	> 7.0 mmol/L
2-hr postprandial	P	120 mg/dl	< 6.7 mmol/L
Hemoglobin A _{1c}	WB	3.8%–6.4%	0.038–0.064 hemoglobin fraction
Homocysteine	P	4–12 µmol/L	4–12 µmol/L
Hydroxyproline	U	0–1.3 mg/24 hr	0–10 µmol/24 hr
Iron	S	50–150 µg/dl	9–27 µmol/L
Iron-binding capacity	S	250–370 µg/dl	45–66 µmol/L
Iron-binding capacity, saturation	S	20%–45%	0.2–0.45
Ketone (acetone)	S, U	Negative	Negative
Lactate	P, venous	5–15 mg/dl	0.6–1.7 mmol/L
Lactate dehydrogenase	S	100–190 U/L	1.7–3.2 µkat/L
Lactate dehydrogenase isoenzymes	S		
Fraction 1 (of total)		14%–26%	0.14–0.25
Fraction 2		29%–39%	0.29–0.39
Fraction 3		20%–26%	0.20–0.25
Fraction 4		8%–16%	0.08–0.16
Fraction 5		6%–16%	0.06–0.16
Lead (adult)	S	< 10–20 µg/dl	< 0.5–1 µmol/L
Lipase	S	0–160 U/L	0–2.66 µkat/L
Lipids, triglyceride [see Triglycerides]			
Lipoprotein(a)	S	0–30 mg/dl	0–300 mg/L
Magnesium	S	1.8–3.0 mg/dl	0.8–1.2 mmol/L
Mercury	WB	0.6–59 µg/L	3.0–294 nmol/L
	U, 24 hr	< 20 µg/L	< 99.8 nmol/L

Clinical Chemistry (continued)

Analyte	Specimen	Units Used at MGH*	SI Units
Microalbumin 24-hr	U	< 20 mg/L or < 31 mg/ 24 hr	< 0.02 g/L or < 0.031 g/ 24 hr
Spot, morning		< 0.03 mg albumin/mg creatinine	< 0.03 g albumin/ g creatinine
Myoglobin	S		
Male			19–92 µg/L
Female			12–76 µg/L
5'-Nucleotidase	S	0–11 U/L	0.02–0.18 µkat/L
Osmolality	P	285–295 mOsm/kg serum water	285–295 mmol/kg serum water
	U	300–900 mOsm/kg	300–900 mmol/kg
Oxygen Content, sea level	WB, arterial	17–21 vol%	
	WB, venous (arm)	10–16 vol%	
Saturation, sea level	WB, arterial	97%	0.97 mol/mol
	WB, venous (arm)	60%–85%	0.60–0.85 mol/mol
Partial pressure (PO ₂)	WB	80–100 mm Hg	11–13 kPa
pH	WB	7.38–7.44	
Parathyroid hormone-related peptide	S	< 1.3 pmol/L	< 1.3 pmol/L
Phosphatase			
Acid	S	0–5.5 U/L	0.90 nkat/L
Alkaline	S	30–120 U/L	0.5–2.0 nkat/L
Phosphorus, inorganic	S	3–4.5 mg/dl	1.0–1.4 mmol/L
Porphobilinogen	U	None	None
Potassium	S	3.5–5.0 mEq/L	3.5–5.0 mmol/L
Prealbumin	S	19.5–35.8 mg/dl	195–358 mg/L
Prostate-specific antigen (PSA)	S		
Female		< 0.5 ng/ml	< 0.5 µg/L
Male			
≤ 40 yr		0–2.0 ng/ml	0–2.0 µg/L
> 40 yr		0–4.0 ng/ml	0–4.0 µg/L
PSA, free (men 45–75 yr with PSA values between 4 and 20 ng/ml)		> 25% associated with benign prostatic hyperplasia	> 0.25 associated with benign prostatic hyperplasia
Protein			
Total	S	5.5–8.0 g/dl	55–80 g/L
Fractions	S		
Albumin		3.5–5.5 g/dl (50%–60%)	35–55 g/L
Alpha ₁		0.2–0.4 g/dl (4.2%–7.2%)	2–4 g/L
Alpha ₂		0.5–0.9 g/dl (6.8%–12%)	5–9 g/L
Beta		0.6–1.1 g/dl (9.3%–15%)	6–11 g/L
Gamma		0.7–1.7 g/dl (13%–23%)	7–17 g/L
Globulin		2.0–3.5 g/dl (40%–50%)	20–35 g/L
Pyruvate	P, venous	0.5–1.5 mg/dl	60–170 µmol/L
Sodium	S	136–145 mEq/L	136–145 mmol/L
Transferrin	S	230–390 mg/dl	2.3–3.9 g/L
Triglycerides	S	< 160 mg/dl	< 1.8 mmol/L
Troponin			
I	S	0–0.4 ng/ml	0–0.4 µg/L
T	S	0–0.1 ng/ml	0–0.1 µg/L
Urea nitrogen	S	10–20 mg/dl	3.6–7.1 mmol/L
Uric acid	S		
Male		2.5–8.0 mg/dl	150–480 µmol/L
Female		1.5–6.0 mg/dl	90–360 µmol/L
Urobilinogen	U	1.0–3.5 mg/24 hr	1.7–5.9 µmol/24 hr
Vitamin A	S	20–100 µg/dl	0.7–3.5 µmol/L
Vitamin B ₁ (thiamine)	S	0–2 µg/dl	0–75 nmol/L

Clinical Chemistry (*continued*)

<i>Analyte</i>	<i>Specimen</i>	<i>Units Used at MGH*</i>	<i>SI Units</i>
Vitamin B ₂ (riboflavin)	S	4–24 µg/dl	106–638 nmol/L
Vitamin B ₆	P	5–30 ng/ml	20–121 nmol/L
Vitamin C (ascorbic acid)	S	0.4–1.0 mg/dl	23–57 µmol/L
Vitamin D ₃ (1,25-dihydroxyvitamin D)	S	25–45 pg/ml	60–108 pmol/L
Vitamin D ₃ (25-hydroxyvitamin D)	P	10–68 ng/ml	24.9–169.5 nmol/L

Vitamin K	S	0.13–1.19 ng/ml	0.29–2.64 nmol/L

Therapeutic-Drug Monitoring and Toxicology

Drug	Therapeutic Level		Toxic Level	
	Units Used at MGH*	SI Units	Units Used at MGH*	SI Units
Acetaminophen	10–30 µg/ml	66–199 µmol/L	> 200 µg/ml	> 1,324 µmol/L
Amikacin				
Peak	25–35 µg/ml	43–60 µmol/L	> 35 µg/ml	> 60 µmol/L
Trough	4–8 µg/ml	6.8–13.7 µmol/L	> 10 µg/ml	> 17 µmol/L
Amitriptyline	120–250 ng/ml	433–903 nmol/L	> 500 ng/ml	> 1,805 nmol/L
Amphetamine	20–30 ng/ml	148–222 nmol/L	> 200 ng/ml	> 1,480 nmol/L
Barbiturates, most short-acting			> 20 mg/L	> 88 µmol/L
Bromide			> 1,250 µg/ml	> 15.6 mmol/L
Carbamazepine	6–12 µg/ml	26–51 µmol/L	> 15 µg/ml	> 63 µmol/L
Chlordiazepoxide	700–1,000 ng/ml	2.34–3.34 µmol/L	> 5,000 ng/ml	> 16.7 µmol/L
Clonazepam	15–60 ng/ml	48–190 nmol/L	> 80 ng/ml	> 254 nmol/L
Clozapine	200–350 ng/ml	0.6–1.0 µmol/L		
Cocaine			> 1,000 ng/ml	> 3,300 nmol/L
Cyclosporine	Varies with time after dose and type of transplantation, with ranges of 100–400 ng/ml	Varies with time after dose and type of transplantation, with ranges of 83–333 nmol/L	Varies with time after dose and type of transplantation	Varies with time after dose and type of transplantation
Desipramine	75–300 ng/ml	281–1,125 nmol/L	> 400 ng/ml	> 1,500 nmol/L
Diazepam	100–1,000 ng/ml	0.35–3.51 µmol/L	> 5,000 ng/ml	> 17.55 µmol/L
Digoxin	0.8–2.0 ng/ml	1.0–2.6 nmol/L	> 2.5 ng/ml	> 3.2 nmol/L
Doxepin	30–150 ng/ml	107–537 nmol/L	> 500 ng/ml	> 1,790 nmol/L
Ethanol			> 300 mg/dl	> 65 mmol/L
Behavioral changes			> 20 mg/dl	> 4.3 mmol/L
Clinical intoxication			> 100 mg/dl	> 1 g/L
Ethosuximide	40–100 µg/ml	283–708 µmol/L	> 150 µg/ml	> 1,062 µmol/L
Flecainide	0.2–1.0 µg/ml	0.5–2.4 µmol/L	> 1.0 µg/ml	> 2.4 µmol/L
Gentamicin				
Peak	8–10 µg/ml	16.7–20.9 µmol/L	> 10 µg/ml	> 21.0 µmol/L
Trough	< 2–4 µg/ml	< 4.2–8.4 µmol/L	> 4 µg/ml	> 8.4 µmol/L
Ibuprofen	10–50 µg/ml	49–243 µmol/L	100–700 µg/ml	485–3,395 µmol/L
Imipramine	125–250 ng/ml	446–893 nmol/L	> 500 ng/ml	> 1,784 nmol/L
Lidocaine	1.5–6.0 µg/ml	6.4–26 µmol/L		
Central nervous system or cardiovascular depression			6–8 µg/ml	26–34.2 µmol/L
Seizures, obtundation, decreased cardiac output				
Lithium	0.6–1.2 mEq/L	0.6–1.2 nmol/L	> 8 µg/ml	> 34.2 µmol/L
Methadone	100–400 ng/ml	0.32–1.29 µmol/L	> 2 mEq/L	> 2 mmol/L
Methotrexate	Variable	Variable	> 2,000 ng/ml	> 6.46 µmol/L
1–2 wk after low dose			> 9.1 ng/ml	> 20 nmol/L
48 hr after high dose			> 227 ng/ml	> 0.5 µmol/L
Morphine	10–80 ng/ml	35–280 nmol/L	> 200 ng/ml	> 700 nmol/L
Nortriptyline	50–170 ng/ml	190–646 nmol/L	> 500 ng/ml	> 1.9 µmol/L
Phenobarbital	10–40 µg/ml	43–170 µmol/L		
Slowness, ataxia, nystagmus			35–80 µg/ml	151–345 µmol/L
Coma with reflexes			65–117 µg/ml	280–504 µmol/L
Coma without reflexes			> 100 µg/ml	> 430 µmol/L
Phenytoin	10–20 µg/ml	40–79 µmol/L	> 20 µg/ml	> 79 µmol/L
Procainamide	4–10 µg/ml	17–42 µmol/L	> 10–12 µg/ml	> 42–51 µmol/L
Quinidine	2–5 µg/ml	6–15 µmol/L	> 6 µg/ml	> 18 µmol/L
Salicylates	150–300 µg/ml	1,086–2,172 µmol/L	> 300 µg/ml	> 2,172 µmol/L
Theophylline	8–20 µg/ml	44–111 µmol/L	> 20 µg/ml	> 110 µmol/L
Thiocyanate				
After nitroprusside infusion	6–29 µg/ml	103–499 µmol/L	> 120 µg/ml	> 2,064 µmol/L
Nonsmoker	1–4 µg/ml	17–69 µmol/L		
Smoker	3–12 µg/ml	52–206 µmol/L		
Tobramycin				
Peak	8–10 µg/ml	17–21 µmol/L	> 10 µg/ml	> 21 µmol/L
Trough	< 4 µg/ml	< 9 µmol/L	> 4 µg/ml	> 9 µmol/L
Valproic acid	50–150 µg/ml	347–1,040 µmol/L	> 150 µg/ml	> 1,040 µmol/L
Vancomycin				
Peak	18–26 µg/ml	12–18 µmol/L	> 80–100 µg/ml	> 55–69 µmol/L
Trough	5–10 µg/ml	3–7 µmol/L

Quantitative (antibody to proteinase 3)		<2.8 U/ml	<2.8 kU/L
Antineutrophil cytoplasmic autoantibody, perinuclear (p-ANCA)	S		
Qualitative		Negative	Negative
Quantitative (antibody to myeloperoxidase)		<1.4 U/ml	<1.4 kU/L
Antinuclear antibody	S	Negative at 1:40 dilution	Not applicable
Anti-parietal cell antibody	S	Negative at 1:20 dilution	Not applicable
Anti-Ro antibody	S	Negative	Not applicable
Antiplatelet antibody	S	Negative	Not applicable
Anti-RNP antibody	S	Negative	Not applicable
Anti-Scl-70 antibody	S	Negative	Not applicable
Anti-Smith antibody	S	Negative	Not applicable
Anti-smooth muscle antibody	S	Negative at 1:20 dilution	Not applicable
Antithyroglobulin	S	Negative	Not applicable
Antithyroid antibody	S	<0.3 IU/ml	<0.3 kIU/L
Bence-Jones protein	S	None detected	Not applicable
Qualitative	U	None detected in 50-fold concentrated specimen	Not applicable
Quantitative	U		
Kappa		<2.5 mg/dl	<0.03 g/L
Lambda		<5.0 mg/dl	<0.05 g/L
β ₂ -Microglobulin	S	<0.27 mg/dl	<2.7 mg/L
	U	<120 µg/day	<120 µg/day
C1 esterase inhibitor protein	S		
Antigenic		12.4–24.5 mg/dl	0.12–0.25 g/L
Functional		Present	Present
C-reactive protein	S		
Routine		0.08–3.10 mg/L	0.08–3.10 mg/L
High sensitivity		0.02–8.00 mg/L	0.02–8.00 mg/L
Complement			
C3	S	86–184 mg/dl	0.86–1.84 g/L
C4	S	20–58 mg/dl	0.20–0.58 g/L
Total complement, enzyme immunoassay	S	63–145 U/ml	63–145 kU/L
Factor B	S	17–42 mg/dl	0.17–0.42 g/L
Cryoproteins	S	Negative	Not applicable
Immunofixation	S	Negative	Not applicable
Immunoglobulin			
IgA	S	60–309 mg/dl	0.60–3.09 g/L
IgD	S	0–14 mg/dl	0–140 mg/L
IgE	S	10–179 IU/ml	24–430 µg/L
IgG	S	614–1,295 mg/dl	6.14–12.95 g/L
IgG1	S	270–1,740 mg/dl	2.7–17.4 g/L
IgG2	S	30–630 mg/dl	0.3–6.3 g/L
IgG3	S	13–320 mg/dl	0.13–3.20 g/L

White blood cells (WBCs) [see Leukocyte count]			

Microbiology

<i>Specimen</i>	<i>Organisms Routinely Cultured</i>	<i>Organisms Also Reported</i>	<i>Normal Flora</i>
Throat	Group A β -hemolytic streptococci, pyogenic groups C and G β -hemolytic streptococci, <i>Arcanobacterium haemolyticum</i>	If complete throat culture is requested: <i>Haemophilus influenzae</i> , <i>Staphylococcus aureus</i> , <i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i> , and yeast	α -Hemolytic streptococci, nonhemolytic streptococci, diphtheroids, coagulase-negative staphylococci, saprophytic <i>Neisseria</i>
Sputum	Pneumococci, <i>H. influenzae</i> , β -hemolytic streptococci, <i>S. aureus</i> , <i>Moraxella (Branhamella) catarrhalis</i> , gram-negative bacilli	Presence or absence of normal throat flora	Little or no normal throat flora, if specimen carefully collected
Urine	Aerobic bacteria and yeast: "abundant" if $> 10^5$ colony-forming units/ml, "moderate" if 10^4 – 10^5 colony-forming units/ml	"Few" if 10^3 – 10^4 colony-forming units/ml, "rare" if 10^2 – 10^3 colony-forming units/ml (either may indicate clinically significant bacteruria if accompanied by pyuria, clinical symptoms, or both)	No mixed bacterial species (i.e., not more than one of the following: lactobacilli, non- β -hemolytic streptococci, diphtheroids, coagulase-negative staphylococci, or <i>Gardnerella vaginalis</i>) if specimen carefully collected
Blood	Aerobic and anaerobic bacteria, yeasts		None; common contaminants: aerobic diphtheroids, anaerobic diphtheroids, coagulase-negative staphylococci
Cerebrospinal and other fluids	Aerobic and anaerobic bacteria; yeasts (including <i>Cryptococcus</i>)	Any organism isolated	None
Stool	Enteric pathogens: <i>Salmonella</i> , <i>Shigella</i> , <i>Campylobacter</i> , <i>Plesiomonas</i> , and <i>Aeromonas</i> when predominant	Moderate or abundant yeast or <i>S. aureus</i> ; presence or absence of normal gram-negative enteric flora; if special cultures requested, <i>Yersinia</i> , <i>Vibrio cholerae</i> , <i>V. parahaemolyticus</i> , or hemorrhagic strains of <i>Escherichia coli</i> (O157)	Enterobacteriaceae, streptococci, <i>Pseudomonas</i> , small numbers of staphylococci and yeast (and anaerobes that are not routinely cultured)
Wounds	Aerobic and anaerobic bacteria, yeasts		
Cervical or vaginal	Gonococci, group A β -hemolytic streptococci, pyogenic groups C and G β -hemolytic streptococci, <i>S. aureus</i> (Gram stain for diagnosis of bacterial vaginosis according to Nugent score)	Yeasts and enteric gram-negative rods if present in large numbers	

Metabolic and Endocrine Tests

<i>Analyte</i>	<i>Specimen</i>	<i>Units Used at MGH*</i>	<i>SI Units</i>
Adrenocorticotropin (ACTH)	P	6.0–76.0 pg/ml	1.3–16.7 pmol/L
Aldosterone	S, P	2–9 ng/dl	55–250 pmol/L
Supine, normal-sodium diet	S, P	2–5 times supine value with normal-sodium diet	
Upright, normal-sodium diet	S, P	2–5 times supine value with normal-sodium diet	
Supine, low-sodium diet	S, P	2–5 times supine value with normal-sodium diet	
Random, low-sodium diet	U	2.3–21.0 µg/24 hr	6.38–58.25 nmol/24 hr
Androstenedione	S	50–250 ng/dl	1.75–8.73 nmol/L
Cortisol	S		
Fasting, 8 A.M.–noon		5–25 µg/dl	138–690 nmol/L
Noon–8 P.M.		5–15 µg/dl	138–414 nmol/L
8 P.M.–8 A.M.		0–10 µg/dl	0–276 nmol/L
Cortisol, free	U	20–70 µg/24 hr	55–193 nmol/24 hr
Dehydroepiandrosterone (DHEA)	S		
Male		180–1,250 ng/dl	6.24–41.6 nmol/L
Female		130–980 ng/dl	4.5–34.0 nmol/L
Dehydroepiandrosterone (DHEA) sulfate	S		
Male		10–619 µg/dl	100–6,190 µg/L
Female (premenopausal)		12–535 µg/dl	120–5,350 µg/L
Female (postmenopausal)		30–260 µg/dl	300–2,600 µg/L
Deoxycorticosterone (DOC)	S	2–19 ng/dl	61–576 nmol/L
11-Deoxycortisol (8 A.M.)	S	12–158 ng/dl	0.34–4.56 nmol/L
Dopamine	P	<87 pg/ml	<475 pmol/L
	U	65–400 µg/day	425–2,610 nmol/day
Epinephrine			
Supine (30 min)	P	<50 pg/ml	<273 pmol/L
Sitting	P	<60 pg/ml	<328 pmol/L
Standing (30 min)	P	<900 pg/ml	<4,914 pmol/L
	U	0–20 µg/day	0–109 nmol/day
Estradiol	S, P		
Female			
Menstruating		<20–145 pg/ml	184–532 pmol/L
Follicular phase		112–443 pg/ml	411–1,626 pmol/L
Midcycle peak		<20–241 pg/ml	184–885 pmol/L
Luteal phase		<59 pg/ml	217 pmol/L
Postmenopausal		<20 pg/ml	184 pmol/L
Male			
Estrone	S, P		
Female			
Menstruating		1.5–15.0 pg/ml	55–555 pmol/L
Follicular phase		1.5–20.0 pg/ml	55–740 pmol/L
Luteal phase		1.5–5.5 pg/ml	55–204 pmol/L
Postmenopausal		1.5–6.5 pg/ml	55–240 pmol/L
Male			
Follicle-stimulating hormone (FSH)	S, P		
Female			
Menstruating		3.0–20.0 mIU/ml	3.0–20.0 IU/L
Follicular phase		9.0–26.0 mIU/ml	9.0–26.0 IU/L
Ovulatory phase		1.0–12.0 mIU/ml	1.0–12.0 IU/L
Luteal phase		18.0–153.0 mIU/ml	18.0–153.0 IU/L
Postmenopausal		1.0–12.0 mIU/ml	1.0–12.0 IU/L
Male			
Fructosamine	S	1.61–2.68 mmol/L	1.61–2.68 mmol/L
Gastrin	S	<100 pg/ml	<100 ng/L
Glucagon	P	20–100 pg/ml	20–100 ng/L
Growth hormone (resting)	S	0.5–17.0 ng/ml	0.5–17.0 µg/L
Human chorionic gonadotropin (hCG) (nonpregnant women)	S	<5 mIU/ml	<5 IU/L
17-Hydroxyprogesterone	S	5–250 ng/dl	0.15 nmol/L
Male			
Female

Urine Analysis

<i>Analyte</i>	<i>Units Used at MGH*</i>	<i>SI Units</i>
Acidity, titratable	20–40 mEq/24 hr	20–40 mmol/24 hr
Ammonia	30–50 mEq/24 hr	30–50 mmol/24 hr
Amylase	4–400 U/L	0.07–7.67 nkat/L
Amylase-to-creatinine clearance ratio [†]	1–5	1–5
Calcium (with dietary calcium of 10 mEq/24 hr or 200 mg/24 hr)	< 300 mg/24 hr	< 7.5 mmol/24 hr
Creatine, as creatinine		
Female	< 100 mg/24 hr	< 760 µmol/24 hr
Male	< 50 mg/24 hr	< 380 µmol/24 hr
Creatinine	1.0–1.6 g/24 hr	8.8–14 mmol/24 hr
Eosinophils	< 100 eosinophils/ml	< 100 eosinophils/ml
Glucose, true (oxidase method)	50–300 mg/24 hr	0.3–1.7 mmol/24 hr
Microalbumin	0–2.0 mg/dl	0–0.02 g/L
Oxalate	2–60 mg/24 hr	228–684 µmol/24 hr
pH	5.0–9.0	5.0–9.0
Phosphate (phosphorus)	400–1,300 mg/24 hr (varies with intake)	12.9–42.0 mmol/24 hr (varies with intake)
Potassium	25–100 mEq/24 hr (varies with intake)	25–100 mmol/24 hr (varies with intake)
Protein	< 150 mg/24 hr	< 0.15 g/24 hr
Sediment		
Bacteria	Negative	Negative
Bladder cells	Negative	Negative
Broad casts	Negative	Negative
Crystals	Negative	Negative
Epithelial cell casts	Negative	Negative
Granular casts	Negative	Negative
Hyaline casts	0–5/low-power field	0–5/low-power field
RBC casts	Negative	Negative
RBCs	0–2/high-power field	0–2/high-power field
Squamous cells	Negative	Negative
Tubular cells	Negative	Negative
Waxy casts	Negative	Negative
WBCs	0–2/high-power field	0–2/high-power field
WBC casts	Negative	Negative
Sodium	100–260 mEq/24 hr (varies with intake)	100–260 mmol/24 hr (varies with intake)
Specific gravity	1.001–1.035	1.001–1.035
Urea nitrogen	6–17 g/24 hr	214–607 mmol/24 hr
Uric acid (with normal diet)	250–800 mg/24 hr	1.49–4.76 mmol/24 hr

*Massachusetts General Hospital.

[†]The amylase-to-creatinine clearance ratio is calculated as [amylase clearance ÷ creatinine clearance] × 100.
